Figure 5 presents the sodium concentrations in leachate. The data were used from April 2001 to April 2006. The data fit fairly well except for the data collected in 2002 September. When the data were examined, it was seen that April 2002 and September 2002 data were exactly the same indicating that maybe September 2002 data were not actually obtained from a field sample. Based on the graph, sodium concentration would be below the MCL by the year 2011. Sodium is probably derived from the dissolution of salts in the waste (Statom et al., 2004)

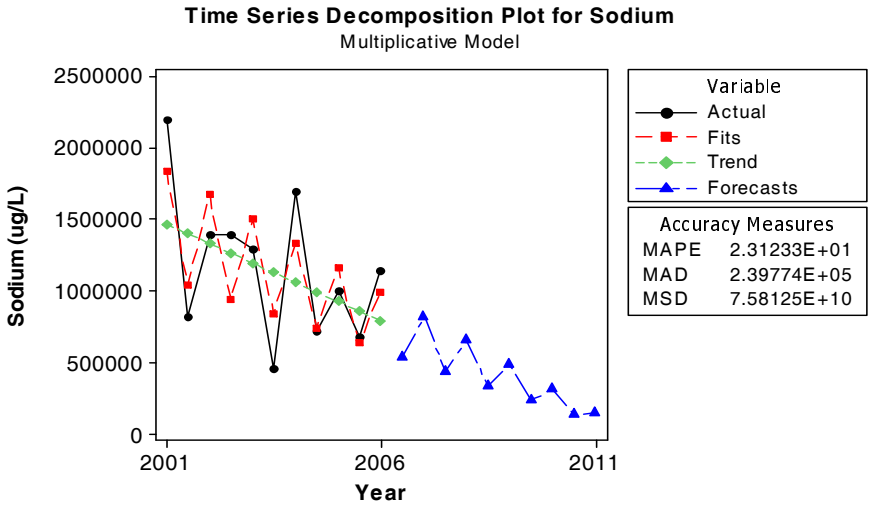

Figure 5. Time series projections of sodium generation

Figure 6 shows the bicarbonate generation in leachate. The data were used from September 2001 to September 2005. Due to the data in April 2006 has enormous value, this period was counted as an outlier. The figure shows that bicarbonate has an increasing trend. When organic content of the waste is decomposes due to the high moisture content, great amount of bicarbonate formed as a by product of bacterial respiration. The other source for bicarbonate could be cap system of landfill. Cover system consists of a two-foot thick limerock cover. As rain falls through the atmosphere, it absorbs carbon dioxide and forms a weak carbonic acid the acidic water slowly dissolve limestone.

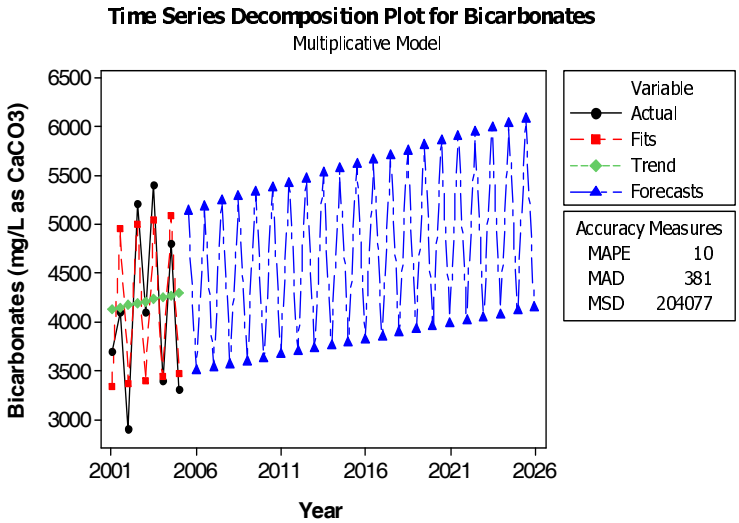

Figure 6. Time series projections of bicorbanate generation

After plotting all common parameters detected in leachate, trends of these parameters were identified. Based on trend analysis result, future level of each parameter was predicted shown in Table 3. The data from case study landfill showed

significant seasonal trends for most of the landfill parameters. The parameters showed seasonal trend better fitted to timer series decomposition method. Decreasing trends were seen for leachate quantity, landfill gas and methane , chloride, sodium , total dissolved solids, vinyl chloride,1,4-Dichlorobenzene, Chlorobenzene,Xylenes, Ethylbenzene, Toluene, Total BTEX, cis-1,2-Dichloroethylene. Increasing trends were seen for iron and bicarbonate. Steady trends were seen for pH, ammonia and benzene.

Table 3. Trends of parameters of interests landfill (Tansel et al., 2008).

Time Series Parameters	Trend	High Value	Low Value	Mean	Comment
Leachate quantity (m^3/month)	Decreasing	1847	54	630	Projections and observations indicate decreasing trend
Landfill gas generation rate m^3/month	Decreasing	54900	7251	22099	Projections and observations indicate decreasing trend
Sodium (mg/L)	Decreasing	2200	460	1150.5	MCL will be reached in 2011
Chloride (mg/L)	Decreasing	1400	600	984.3	MCL will be reached in 2023
Total Dissolved Solid (mg/L)	Decreasing	5800	1300	4030	MCL will be reached in 2031
Iron (µg/L)	Increasing	4400	1400	2935.4	Projections indicates iron has increasing trend
Ammonia as N (mg/L)	Decreasing	3100	16	836.5	Projections indicate decreasing trend, observations indicate steady trend. Projections indicate that level will be close to zero in 2014.
Bicarbonate (mg/L)	Increasing	13300	590	4584.6	Projections indicates bicarbonate has increasing trend
pH	Steady	8	7	7.48	
Vinyl chloride (µg/L)	Decreasing	3	1	1.7	MCL will be reached in 2010
1,4-Dichlorobenzene (µg/L)	Decreasing	12	1	6.98	Already below MCL
Chlorobenzene (µg/L)	Increasing	15	7.3	11.1	Already below MCL. Projections indicate increasing trend, observations indicate steady trend.
Benzene (µg/L)	Decreasing	4	0.18	3.13	Projections show a decreasing trend, observations show a steady trend. Projections show that MCL will be reached in 2030.
Toluene(µg/L)	Decreasing	7.6	1	3.39	Already below MCL
Ethylbenzene(µg/L)	Decreasing	19	3.9	8.98	Already below MCL
Xylenes (µg/L)	Decreasing	28	5.8	13.26	Already below MCL
Total BTEX(µg/L)	Decreasing	51.3	18.6	30.45	Already below MCL

Conclusions

In this study landfill leachate quality and quantity data, landfill gas quantity data, were evaluated to forecast the functional stability of the landfill. For the leachate, the leachate quality and quantity data were analyzed to identify trends. Time series multiplicative decomposition model in general provided an adequate forecast for future planning purposes for the parameters monitored in leachate. Analyses showed that leachate quantity has been decreasing overtime. Plotted leachate parameters data showed significant seasonal variations. A total of 46 parameters have been monitored in case study landfill. Among these parameters, 28 parameters are non-detected parameters (always below detection limit), eight parameters are always above Maximum Concentration Limit (MCL, Chloride, bicarbonate, sodium, ammonium as N, iron, benzene, vinyl chloride and total dissolved solids), and ten parameters are below the MCL (1,4 dichlorobenzene, chlorobenzene, cis-1,2 dichloroethylene, ethylbenzene, dichlorodifluoromethane, methyl-tert-butyl ether, tetrachloroethene, toluene, xylene and total BTEX). Except for iron and bicarbonate, the contaminants in leachate have decreasing trend. The purpose of the evaluation of leachate is to determine whether the leachate management practices may be optimized, reduced or discontinued. As a result of the leachate analysis, the following suggestions were made:

- Significantly reduce or stop the monitoring frequency for non detected parameters,
- Reduce monitoring frequency for parameters consistently below MCL,
- Continue monitoring for parameters above MCL, and
- Refine projections of parameters above MCL as more data become available.

For the landfill gas (LFG) module, generated LFG trend was analyzed overtime. Total landfill gas quantity has been decreasing overtime. Outcomes of landfill gas analysis showed that remaining LFG generation potential is so small. Therefore eliminating active LFG management and converting to a passive venting system is acceptable.

ABSTRACT

In June 2008, catastrophic flooding of the Cedar River inundated a large portion of downtown Cedar Rapids, Iowa. As a result, floodwaters deposited a large amount of sediment throughout the city. The sediment origin is of intense scientific and public interest due to the quantity of deposited sediment and the potential presence of persistent organic pollutants (PCBs, chlordanes, and synthetic fragrances) attached to the sediment. The primary objective of this study is to determine the temporal and spatial patterns of deposited sediment. Two potential sediment sources have been identified: the bed of the Cedar River and the channel banks. We hypothesize that sediment from the two sources was distributed heterogeneously throughout the city. Therefore, samples were gathered from the two source areas, as well as from terrestrial areas within and adjacent to the flooded region. We will compare the deposited sediment gathered from the terrestrial areas with the sediment obtained from the source areas using natural biogeochemical tracing techniques. The tracing techniques will include an analysis of radionuclides (e.g., ^{7}Be, ^{210}Pb, ^{137}Cs), stable isotopes ratios (e.g., δ^{15}N and δ^{13}C), and elemental ratios (C/N). This comparison will allow us to determine the provenance of the sediment particles, which will assist us in developing a sediment budget for the segment of the Cedar River that flows through downtown Cedar Rapids. Further, we will identify the key processes affecting sediment delivery and redistribution that occurred during the flood. Sediment dynamics during floods is poorly described in the existing scientific literature. The methods established in this study will provide for engineers and researchers the ability to track the transport of sediments in similar floods.

Keywords: sediment transport, radionuclide, stable isotope ratio, floods

1. INTRODUCTION

Recent investigations into episodic sediment transport processes have utilized biogeochemical tracing techniques as a means to determine erosional and depositional patterns. Primary biogeochemical tracing techniques used in these investigations

have included radionuclides (Blake, Walling, & He, 2002; Palinkas, Nittrouer, Wheatcroft, & Langone, 2005), stable isotope ratios (Fox & Papanicolaou, 2007; Olley, 2002), and elemental ratios (Leithold & Blair, 2001; Middelburg & Nieuwenhuize, 1998). Specifically, the aforementioned biogeochemical tracing techniques can be used to identify sediment transport processes affecting sediment delivery and redistribution during floods.

Radionuclide analysis is a key technique used to trace sediment transport patterns during floods. Some radionuclides are naturally occurring (^{7}Be, ^{210}Pb), while others are anthropogenically produced (^{137}Cs). ^{7}Be ($t_{1/2}$ 53.3 d) is produced as solar radiation interacts with Earth's atmosphere. Resulting atmospheric ^{7}Be is delivered to the surface of the Earth via fallout. ^{210}Pb ($t_{1/2}$ 22.3 y) is produced as a result of decaying ^{226}Ra. As ^{226}Ra, which is found in most soils and rocks, decays, a series of processes eventually lead to the production of excess ^{210}Pb in the atmosphere (Mabit, Benmansour, & Walling, 2008). Excess atmospheric ^{210}Pb is deposited as fallout on the surface of the Earth. ^{137}Cs ($t_{1/2}$ 30.2 y) in the soil is the result of atmospheric nuclear testing that took place from the 1950s to the 1970s. Currently, fallout of ^{137}Cs has fallen below detectible levels, excluding regions near nuclear accidents such as Chernobyl (Ritchie, 2001). The difference between the naturally occurring radionuclides and anthropogenically produced radionuclides is important. Naturally occurring radionuclides are produced and delivered to soil over time regardless of anthropogenic activities, whereas anthropogenically produced radionuclides may or may not be delivered to soil over time as anthropogenic patterns change.

After fallout, the radionuclides are quickly and strongly fixed to surface particles. Redistribution of surface particles (and consequently, radionuclides) throughout a watershed typically occur as a result of physical processes (Mabit, et al., 2008). The attached radionuclides allow researchers to trace sediment transport patterns.

To determine sediment transport patterns, numerous samples must be obtained from regions that were as well as were not affected by floodwater. Samples must be collected from both the inundated regions and the non-flooded (heretofore referred to as reference) regions in order to allow researchers to compare radionuclide activities within each region. This comparison is necessary because radionuclides can be delivered to floodplains via two distinct methods: direct input from atmospheric fallout and accumulation of sediment during depositional periods. Assuming a homogeneous distribution of fallout-delivered radionuclides across the study area, higher radionuclide activity in the inundated floodplain areas relative to reference areas can be assumed to have resulted from depositional processes (Blake, et al., 2002).

Two other key techniques used to trace sediment transport patterns require a determination of stable isotope ratios and an elemental ratio. Stable isotope ratios (δ^{15}N and δ^{13}C) and a C/N elemental ratio have been used to trace sediment throughout a watershed (Fox & Papanicolaou, 2007). The use of these ratios holds strong promise in tracing temporal and spatial patterns of sediment over the course of

a flood. Investigation into the ability of these ratios to trace the patterns of sediment in floodwater, however, is preliminary at this point.

The primary objective of this study is to determine the temporal and spatial patterns of deposited sediment. Specifically, this study will establish methods that will allow engineers and researchers to track the transport of sediment in floods similar to the June 2008 flood of Cedar Rapids. Methods established will incorporate biogeochemical tracing techniques, including an analysis of radionuclides, stable isotopes ratios, and elemental ratios.

2. STUDY AREA DESCRIPTION

Cedar Rapids is divided by the north-south flowing Cedar River (Figure 1, aerial image courtesy of maps.live.com). The western portion of the city is dominated by residential areas. Bordering the eastern bank of the Cedar River is the downtown business district. North of the business district and east of the Cedar River is Cedar Lake. Numerous automobile bridges connect the two sides of the city, with the largest, most upstream being the Interstate-380 bridge.

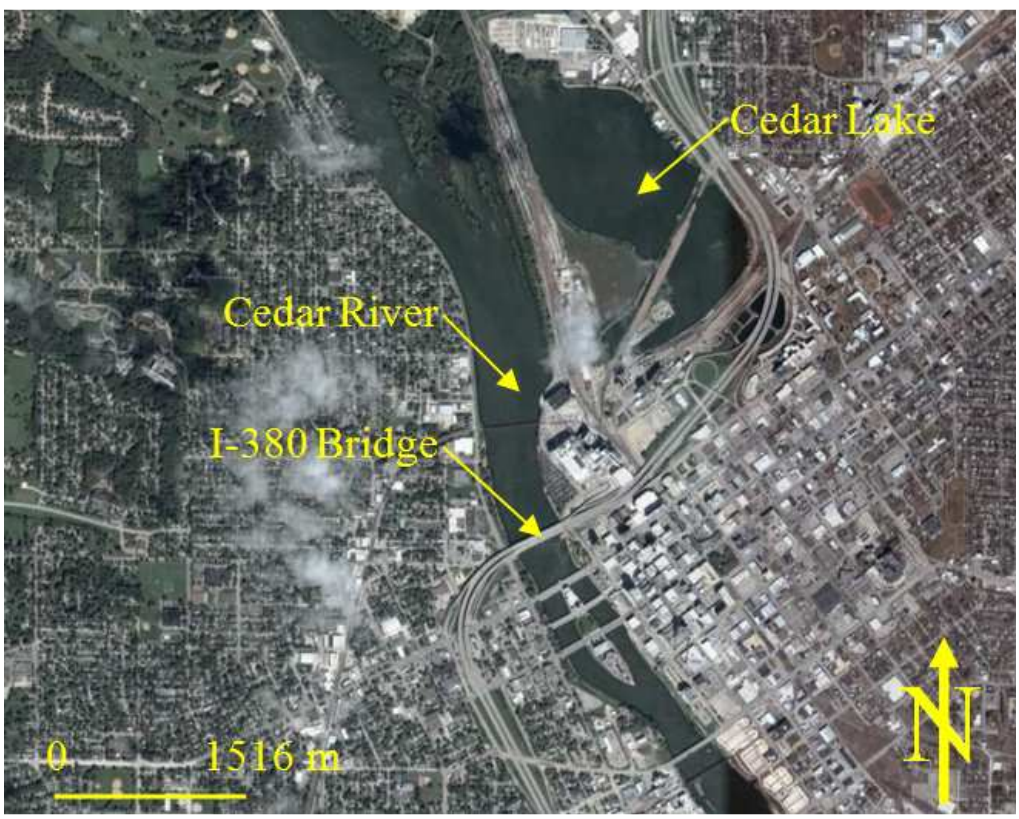

Figure 1: Aerial view of Cedar Rapids during normal flow conditions.

The I-380 bridge is significant to this study due to a gated weir system that was installed beneath the bridge. An aerial view of the bridge and the nine gates is

displayed in Figure 2 (aerial image courtesy of maps.live.com). During the flood, gates 7, 8, and 9 were left closed. As the floodwater reached this obstruction, floodwater velocity was reduced, allowing suspended matter to settle upstream of the gates.

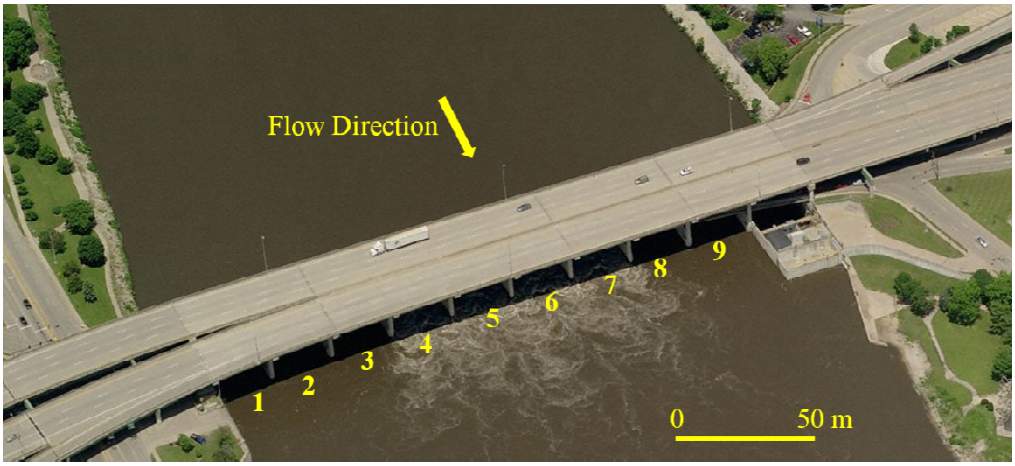

Figure 2: I-380 bridge with gated weir system during normal flow conditions.

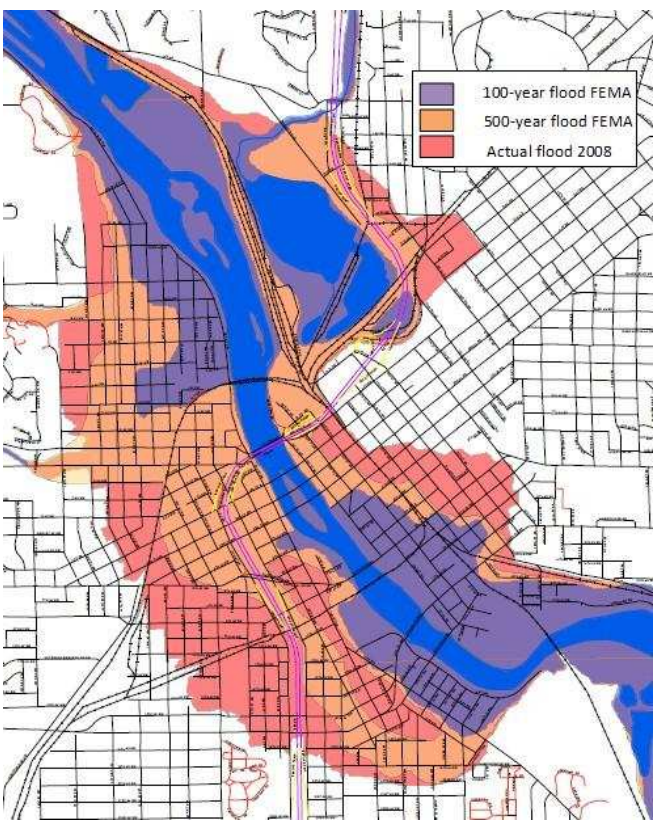

Figure 3: Flood extents.

Figure 3 displays the 100- and 500-year flood boundaries according to the Federal Emergency Management Agency (FEMA) and the recorded flood extents (Corridor Recovery, 2008). In some locations, the recorded flood boundaries are far outside of the 500-year flood border. During the flood, approximately 10 square miles were affected by the floodwaters (Corridor Recovery, 2008). Both residential and commercial areas were within the inundated areas.

3. METHODOLOGY

Source, depositional, and reference samples were gathered to determine the provenance of the sediment particles. Using a systematic procedure, the clay-sized fraction of each sample was isolated. After isolation of the clay-sized fraction, samples were analyzed for biogeochemical tracers.

3.1 SAMPLING

Samples were collected from source and depositional areas after the flooding of Cedar Rapids. Two potential sediment sources were identified: the bed of Cedar Lake and the channel banks. Both 30-cm cores and 5-cm surface samples were collected from the stream banks. On the west bank of the Cedar River, 11 surface samples were obtained and 7 cores were taken. On the east bank, six surface samples were collected and four cores were taken. Upstream of the I-380 bridge (shown in Figure 2), five samples were gathered.

Two depositional areas were identified: the bed of the Cedar River immediately upstream of the I-380 bridge and inundated terrestrial areas. The bed of the Cedar River where the five source samples were obtained can be assumed either a sediment source or a depositional area depending on the location from which the flood is being viewed. If observing the flood upstream of the I-380 bridge, the aforementioned sampling area immediately upstream of the bridge can be assumed a depositional area due to the decreased floodwater velocity at this location relative to the incoming floodwater velocity. However, if viewing the flood downstream of the I-380 bridge, the sampling area can be assumed a sediment source because some sediment was likely suspended at this point as the floodwater passed over the bed sampling location. Therefore, the same five source samples gathered upstream of the I-380 bridge were also used as depositional samples.

Terrestrial samples were collected from the inundated region and reference locations. Outside of the inundated areas, 21 reference samples were collected. Within the inundated terrestrial regions, 235 samples were gathered. These 235 samples are heretofore referred to as ‘terrestrial’ samples.

3.2 LABORATORY PREPARATION OF SEDIMENT SAMPLES

The bulk of the surface area of each sample is contained within the clay-sized fraction (Leithold & Blair, 2001); therefore, the majority of the tracers is also contained

within it. As a result, isolation of the clay-sized fraction of each sample was completed to maximize the radionuclide activity per gram. A systematic process was used to isolate the clay-sized fraction of each sample. First, samples were oven-dried at 60°C. Samples were then lightly crushed with a rolling pin to <2 mm. Sub-samples (approximately 90 g each) were next removed from each sample and disaggregated using a 30.22 g L^{-1} solution of deionized water and sodium hexametaphosphate in a 1 mL to 1 g ratio. The sand-sized fraction of the disaggregated samples was then removed through sieving. The remaining clay- and silt-sized particles were suspended in deionized water after thorough mixing. A settling procedure was then completed utilizing Stokes' Law. The settling time for silt-sized particles (>0.002 mm) to settle 10 cm was determined to be 7 hr, 40 min. After 7 hr, 40 min only clay-sized particles were contained within the top 10 cm of the water column. A slow siphoning of the top 10 cm of the water column allowed for isolation of the clay-sized fraction while minimizing remixing. Two additional repetitions of the mixing, settling, and siphoning processes were completed to ensure removal of the majority of the clay-sized particles. Finally, the siphoned clay-sized fraction solution was oven-dried at 60°C until only solids remained.

3.3 LABORATORY BIOGEOCHEMICAL ANALYSIS

Analysis of the clay-sized fraction was completed for the ^{210}Pb, ^{7}Be, ^{137}Cs, and ^{40}K radionuclides. Gamma ray emissions were detected by a high purity germanium detector that was continuously cooled in a liquid nitrogen bath. Each sample was analyzed for 82800 s. This sample time was chosen because a high counting time (20000 to 80000 s) is required to obtain an acceptable analytical precision of less than ±10% at the 95% confidence level (Mabit, et al., 2008). The gamma ray emissions were converted to a digital signal using a DSPEC jr 2.0 integrated gamma spectrometer. The accuracy of the gamma spectrometer is listed as a change of <±3% of the reference peak from 0 to 50000 counts per s (Ametek, 2008). Using a MAESTRO-32 MCA Emulator, the digital signals were converted to and recorded as radionuclide activity. The radionuclide activity of each sample was standardized by dividing the activity (gamma ray emission counts) of each sample by both the amount of time the sample was analyzed (s) and the mass of the sample (g), yielding units of cts/s/g. Then, the standardized radionuclide activity was corrected back to the date of the flood. From this, the relative radionuclide activity of each sample was determined.

4. RESULTS

Preliminary results indicate that ^{137}Cs and ^{7}Be are the most promising radionuclides to use to trace the temporal and spatial patterns of the sediment. Currently, analysis of the radionuclide activity of 26 terrestrial, 16 reference, and 5 river samples has been completed.

4.1 RELATIVE ACTIVITIES

Relative activities for ^{7}Be and ^{137}Cs were determined for terrestrial, reference, and river samples. The means (μ) and standard deviations (σ) for each of the sample groups are displayed in Table 1.

Table 1: Radionuclide activity means and standard deviations.

	^{7}Be		**^{137}Cs**	
Sample Location	μ	σ	μ	σ
Terrestrial	5.50E-04	3.20E-04	1.46E-02	1.16E-02
Reference	9.40E-04	4.83E-04	1.16E-02	9.08E-03
River	2.46E-03	1.11E-03	4.05E-03	4.76E-04

Analysis of the radionuclide activity means and standard deviations is currently in the preliminary stages. However, a statistical analysis (Student's t-test) was completed on the sample groups to determine the distinctness of each sample group. Assumptions used in the Student's t-test included: 1) normal distribution of the sample sets, 2) independent sample sets, and 3) equal variances within the sample sets. A zero mean difference between the sample sets was specified as the null hypothesis. The p-value was then calculated using two-tailed statistical analyses. A low p-value (<0.10) indicated that the means of the sample sets were distinct with 90 percent confidence. Table 2 displays the results of the Student's t-test.

Table 2: Student's t-test results.

^{7}Be		**^{137}Cs**	
Sample Set Comparison	*p-value*	*Sample Set Comparison*	*p-value*
Reference vs. Terrestrial	0.014	Reference vs. Terrestrial	0.39
Reference vs. River	0.0015	Reference vs. River	0.083
River vs. Terrestrial	0.0000012	River vs. Terrestrial	0.055

As exhibited in Table 2, five of the six sample set comparisons can be considered statistically distinct with 90 percent confidence. The reference versus terrestrial sample set comparison for ^{137}Cs cannot be considered distinct with 90 percent confidence. The five sample set comparisons can be assumed statistically distinct because the low p-values allow for a rejection of the null hypothesis. Because the null hypothesis assumed a zero mean difference between the samples, and because the null hypothesis was rejected for the five sample set comparisons, those five comparisons can be considered statistically distinct.

The radionuclide activities of ^{7}Be and ^{137}Cs were plotted spatially. Figure 4 displays contours of ^{7}Be activities across the sampling area, while Figure 5 exhibits contours of ^{137}Cs activities.

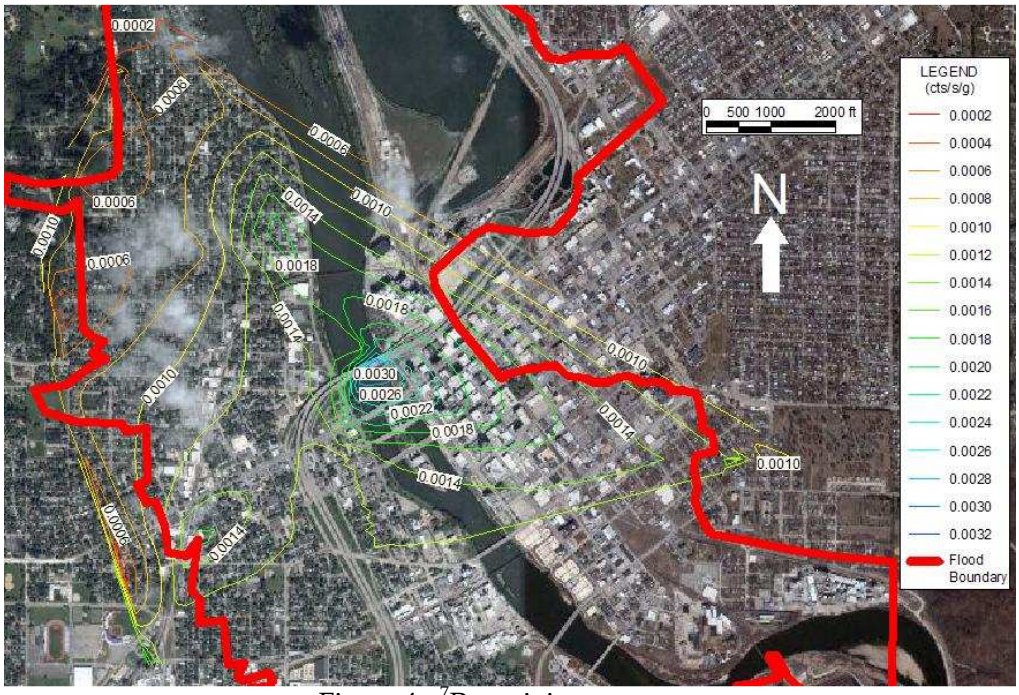

Figure 4: ^{7}Be activity contours.

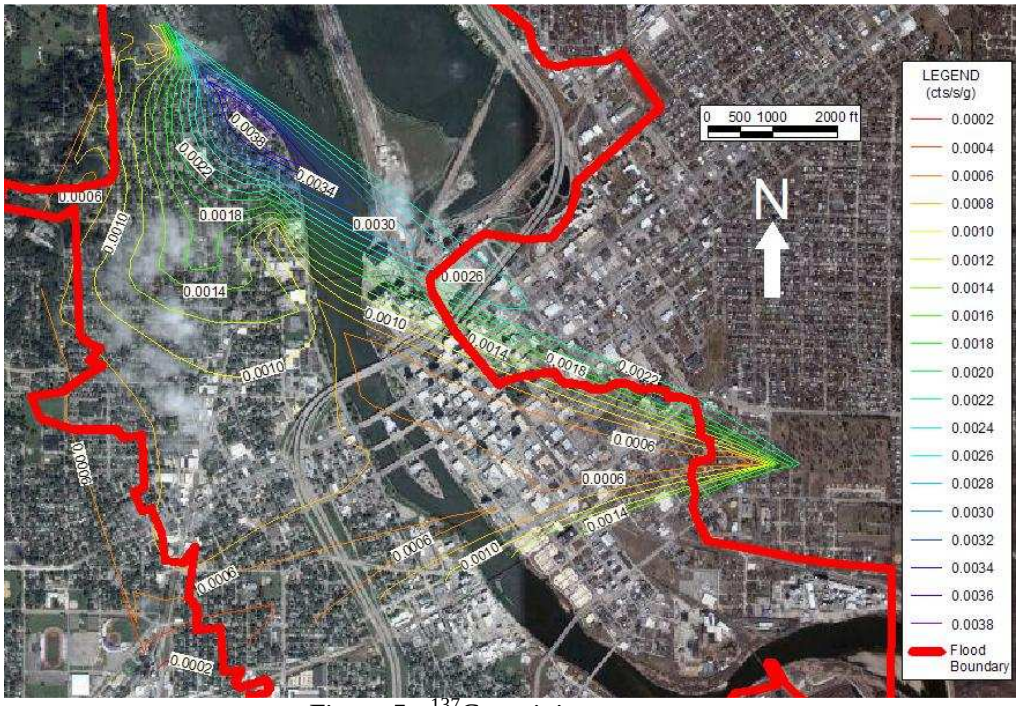

Figure 5: ^{137}Cs activity contours.

As exhibited in Figure 4, the highest activities of ^{7}Be are in the immediate vicinity of the I-380 bridge. Figure 5 displays high activities of ^{137}Cs at the northeastern edge of

the sampling region. In fact, Figure 4 and Figure 5 exhibit opposing trends. Where the activities of ^{7}Be are high, ^{137}Cs activities are low, and vice versa.

Two different conclusions can be drawn from this observation. The first conclusion is that more sediment was deposited in areas enriched in ^{137}Cs. Because ^{137}Cs is no longer being delivered to the soil through atmospheric processes in measurable quantities (Ritchie, 2001), exposure of the source area to the atmosphere is irrelevant. Determination of the ^{137}Cs activities allows for the quantification of erosional and depositional amounts (Mabit, et al., 2008). Therefore, ^{137}Cs can indicate where the majority of the sediment was deposited. Higher activities of ^{137}Cs indicate that more sediment was deposited in areas along the northeastern border of the sampling region.

The second conclusion is that sediment deposited in areas with high activities of ^{7}Be was of surficial origin. Because ^{7}Be is delivered to soil via atmospheric processes, a general source area can be determined. Sampling areas with high activities of ^{7}Be were enriched with deposited material having relatively high ^{7}Be contents. The only source areas with high ^{7}Be contents were surficial areas. Therefore, the sediment deposited near the I-380 bridge was likely of surficial origin. Further analysis of these results complemented with sediment modeling will likely provide further reasoning about the provenance of the deposited sediment.

5. CONCLUSIONS

Biogeochemical tracers have been widely used to trace sediment through watersheds. However, sediment transport processes during floods have been poorly documented in existing scientific literature. The current focus of this study has been to begin to map these processes using radionuclide tracers. ^{137}Cs and ^{7}Be have insofar shown to be the most promising radionuclides based on sample means, standard deviations, statistical analyses, and relative activity contours. Because ^{137}Cs production and fallout has been minimal in recent years, quantification of erosional and depositional amounts can be determined using this radionuclide. ^{7}Be, on the other hand, can provide clues as to the general source area of deposited material. After further analysis of the results, conclusions may be drawn regarding the specific provenance of the deposited material. These conclusions will likely provide to engineers and researchers tools with which to track the transport of sediments in similar floods.

ABSTRACT

We measured the toxicity of TiO_2 nanoparticles to nitrifying bacteria under ultraviolet conditions. Nitrifying bacteria play an important role of nitrification in wastewater treatment plants. Although there was no inhibitory effect of TiO_2 nanoparticles under ambient light or dark conditions, nitrification inhibition was significantly increased when TiO_2 nanoparticles were exposed to ultraviolet (UV) for 30 minutes. Under UV exposure, both TiO_2 nanoparticles and bulk TiO_2 generated the same amount of reactive oxygen species (ROS) in the cells although TiO_2 nanoparticles were more toxic than the bulk counterpart. While the inhibition was well correlated to intracellular ROS concentration, the ROS correlations were different for the different forms of TiO_2 or for the different nanoparticles (e.g., Ag vs. TiO_2), indicating that ROS is not a good chemical marker of the toxicity of nanoparticles.

INTRODUCTION

TiO_2 nanoparticles are one of the most used nano-materials in nanotechnology enhanced products such as cosmetics, sunscreen, and paint, because they have photocatalytic property to generate reactive oxygen species after light exposure (365 nm, UVA). But little is known on how the exposure of TiO_2 nanoparticles affects wastewater treatment. TiO_2 is semiconductor with bandgap energy 3.2 eV (365nm). Whena shortwave light less than 365nm shines on TiO_2, reactive oxygen species (ROS) are generated by photoelectrochemical mechanisms. The main objective of this work was to evaluate the role of ROS in determining nanotoxicity. Nitrifying bacteria are sensitive to a number of environmental factors such as pH, dissolved oxygen concentration, and temperature, and are therefore susceptible to inhibition in wastewater treatment (Hu et al. 2002). We cultured nitrifying bacteria and measured oxygen uptake rates of nitrifying bacteria treated with commercially available TiO_2 (Anatase). Also we compared the toxicity of nano-Ag and nano-TiO_2 and bulk TiO_2 to better understand the mode of action of nanoparticles.

METHODS AND MATERIALS

TiO_2 nanoparticles (TiO_2 NPs) were purchased in anatase form (Nanostructured & Amorphous Materials Inc, Los Alamos, NM) because of its high efficiency as a photocatalyst. Silver nanoparticles (Ag NPs) were prepared in the laboratory following a previous report (Choi et al. 2008). Transmission Electron Microscopy (TEM, JEOL 1400) was applied under an acceleration voltage of 100 keV for size valication. The toxicity of nanoparticles was evaluated by the oxygen uptake rate changes after adding nanoparticles suspension into a nitrifying culture. The nitrifying bacteria were enriched for more than two years under a continuous system (1day HRT, 20 days SRT, at 25 ± 2 ^oC) and an aliquot of nitrifying culture was used in a batch system for each toxicity test. The rate of dissolved oxygen (DO) decrease was measured during the nitrification process in closed respirometric bottles. Ammonium nitrate was used as the only nitrogen source because the ammonia monooxygenase (AMO, $NH_3 \rightarrow NH_2OH$) was the most sensitive to nanoparticles. A UVA lamp (Blak-Ray Lamp Model UVL-56, 365 nm, 750 μW/cm^2 at 15cm) was used to activate the TiO_2 NPs for 30 mins before each toxicity test. Intracelluar ROS accumulation was measured using fluorescent dyes (dichlorodihydrofluorescein diacetate, Invitrogen, OR, USA). Nanoparticle-treated cultures were distributed 200 μL in each 96-well microplate and the fluorescence was measured using a microreader (VICTOR^3, PerkinElmer, CT, USA) with a 485 nm excitation and a 535 nm emission filter. Increased fluorescence was measured after 30 mins exposure of TiO_2 only or TiO_2 + UVA and normalized as H_2O_2 concentration using standard calibration of H_2O_2 and fluorescence increase.

RESULTS AND DISCUSSION

We found 100 mg/L TiO_2 inhibited only 24.4 (±5.4) % to ammonia oxidation. However, after 30mins UVA exposure, the toxicity of TiO_2 was increased dramatically and it inhibited nitrification by 65.8 (±7.7) % at 1 mg/L TiO_2. We found the toxicity of TiO_2 under UVA was synergistically increased because the toxicity was more than the sum of individual toxicity of UVA (Figure 1) and TiO_2. The toxicity of TiO_2 was linearly increased as increasing UVA exposure time (Figure 1) and TiO_2 concentration (Figure 2). Furthermore, TiO_2 nanoparticles were more toxic to nitrifying bacteria than the bulk TiO_2 (ANOVA, $P< 0.05$) (Figure 2).

However, at the same TiO_2 concentrations, there was no statistical difference of intercellular ROS concentration between the bulk and the commercial nano-TiO_2 (ANOVA, $P< 0.05$, Figure 3). Figure 3 shows the toxicity of TiO_2 was strongly related to intracellular ROS. Without UV exposure, no reactive oxygen species were detected in the nitrifying culture treated with nano-TiO_2 (Figure. 3).

The ROS concentrations corresponded to 100 ~ 310 μM H_2O_2 at 0 ~ 2 mg/L nano-TiO_2 under UVA exposure. These values were ten times larger than the ROS concentrations measured in similar nitrifying culture treated with nano-Ag (1 ~ 20 μM H_2O_2) (Figure 4) (Choi and Hu 2008). Silver nanoparticles generated much less ROS in the cells but show higher degree of inhibition than nano-TiO_2. The relationship of ROS with nano-Ag inhibition could be explained with the saturate model (Choi and Hu 2008). In contrast, a linear relationship (R^2 =0.98) with nano-TiO_2 inhibition was observed (Figure 3). These results suggest that other cytotoxicity mechanisms of nanoparticles are present in addition to intercellular ROS accumulation. It appeared that TiO_2 may inhibit nitrification in wastewater plants when the nitrifiers are exposed to UV light from sunlight.

CONCLUSION

- TiO_2 nanoparticles were activated under UV exposure to generate reactive oxygen species (ROS) that were correlated with nitrification inhibition. There was no inhibition by TiO_2 nanoparticles in the absence of UVA. Compared to nano-TiO_2, bulk TiO_2 generated the same amount of ROS but with lower toxicity.
- Based on the comparison of ROS concentrations from different nanoparticles (e.g., Ag and TiO_2) and different chemical forms (nano-TiO_2 vs. bulk TiO_2), the reactive oxygen species are not a good chemical marker to indicate the toxicity of nanoparticles.

ABSTRACT

Throughout the United States, nonpoint source pollution from stormwater runoff, failing septic tanks and other diverse sources is a significant, often dominant, cause of noncompliance with water quality standards in large watersheds. Even with this knowledge, considerable economic resources are spent on reduction of conventional point source pollution (e.g., wastewater discharges and combined sewer overflows) with little more than a casual understanding of the nonpoint source pollution sources within a large watershed, or of the potential value of dollars spent, as measured by improvements in receiving water quality or designated use attainability. This work shows that quantification of nonpoint sources and their influence on regulatory compliance should be at the forefront of watershed management efforts, not as a replacement for point source abatement, but as a factor worthy of equivalent scientific and economic attention. With this guiding principle, this work illustrates how abatement costs and resulting environmental improvements for both point and nonpoint source controls must be clearly understood and managed together if the fundamental precepts and objectives of the Clean Water Act are to be addressed decisively.

In 2002, the U.S. Army Corps of Engineers initiated the Merrimack River Watershed Assessment Study to address water quality impairments on the Merrimack River. As a result of combined sewer overflows (CSOs) and other point and nonpoint sources, many reaches of the river have been placed on the New Hampshire and Massachusetts 303(d) lists for violations of bacteria water quality standards. The goal of the study was to quantify the relative impacts of point sources and nonpoint sources on water quality, and to compare the economic and environmental value of alternative management strategies. The study blended comprehensive field monitoring with detailed simulation modeling that compared alternative management strategies for watershed-wide pollution abatement. The management strategy which resulted in the greatest value of abatement dollars was a combination of modest treatment upgrades and partial combined sewer separation with modest nonpoint source reduction throughout the watershed. This balanced approach showed more value than scenarios focusing only on long-term CSO control plans and full combined sewer separation, emphasizing the need for a more comprehensive approach to managing sources of pollution as well as the need for more attention on the economic value of nonpoint source abatement alternatives for large watersheds.

STUDY OVERVIEW

A watershed assessment study was conducted for the Merrimack River watershed in southern New Hampshire and northeastern Massachusetts (USACE, 2006). The study included a comprehensive monitoring program, a continuous flow and water quality model, and an analysis of stakeholder-developed alternative pollution management options. Many reaches of the river are listed on NH and MA 303(d) lists for violations of bacterial water quality standards. The sources of these impairments are not readily apparent, as most of the upper watershed consists of forested land and rural communities, with the most downstream reaches flowing through five urban communities before emptying into the Atlantic Ocean: Manchester NH, Nashua NH, Lowell MA, Lawrence MA (Greater Lawrence Sanitary District, GLSD), and Haverhill MA. The five communities, each of which are serviced by aging combined sewer systems, have signed individual consent agreements with the United States Environmental Protection Agency to commit large sums of money to the abatement of combined sewer overflows (CSOs) in accordance with the federal Clean Water Act. Each community is in various stages of development and implementation of CSO Long-Term Control Plans (LTCPs). Since enforcement protocols are specific to individual communities, these plans are being developed in isolation from the rest of the watershed, and even from the other CSO communities along the mainstem. Collectively, these communities may need to spend up to $500 million on CSO control alone to comply with EPA mandates. While there are credible estimates of the bulk bacterial loads discharged from these CSOs each year, the plans were mandated with incomplete understanding of the relative magnitude of these loads with respect to other loads throughout the basin, and more importantly, with no attempts to quantify the expected improvements in river compliance or use attainability.

The CSO communities recognized the need for a comprehensive look at the issue and formed the Merrimack River Basin Community Coalition. The Coalition approached the New England District of the United States Army Corps of Engineers (USACE) for assistance in conducting the multi-jurisdictional watershed assessment. The USACE was able to assist through study authorization provided in Section 729 of WRDA 1986, as amended and entered into a 50-50 cost sharing agreement with the Coalition to perform the Merrimack River Watershed Assessment Study. The study was structured around the following three basic tenets:

1. Pollution abatement should not be limited to local enforcement, as this results in only partial accounting of pollution sources and can ignore the prevailing causal mechanisms within a watershed.
2. Pollution abatement investments should only be made when expected environmental benefits can be well defined, measured, and prioritized.
3. Pollution abatement should be a cooperative process, with local, state, and federal authorities working to ensure the productive allocation of financial resources to restore and protect the nation's natural resources.

This watershed assessment, therefore, has placed the implementation of LTCPs in proper context by asking the question: "What are the *relative* instream impacts

attributable to CSOs and to other sources, and how can watershed restoration be balanced such that investments in LTCPs, wastewater treatment technology, septic system rehabilitation, illicit connection detection and abatement, etc. are commensurate with expected improvements?" In other words, the USACE study helped quantify how much of the documented impairment is attributable to each major identifiable source type (CSOs, wastewater treatment plants, nonpoint sources), and therefore the extent to which alternative abatement strategies are actually likely to help restore the river.

MERRIMACK RIVER WATERSHED

The Merrimack River is formed by the confluence of the Pemigewasset and Winnipesaukee Rivers in Franklin, New Hampshire. The River flows southward for approximately 125 kilometers in New Hampshire; it turns abruptly across the New Hampshire - Massachusetts border and flows in a northeasterly direction for approximately another 80 kilometers before discharging to the Atlantic Ocean at Newburyport, Massachusetts. The final 35 kilometers of the River, downstream of Haverhill, Massachusetts, are tidally influenced. A map of the Merrimack River watershed is shown in Figure 1.

The Merrimack River watershed covers an area of approximately 13,000 square kilometers in New Hampshire (76 percent of the drainage area) and the northeastern portion of Massachusetts (24 percent of the drainage area), making it the fourth largest watershed in New England. It encompasses a variety of terrain and climate conditions, from the mountainous White Mountain region in northern New Hampshire to the estuarine coastal basin of northeastern Massachusetts. Precipitation in the watershed is fairly evenly distributed throughout the year; however temperatures in the basin generally vary widely on an annual basis. A mix of deciduous and evergreen forest, covering approximately 77 percent of the watershed area, dominates the land use in the basin. Urban areas, including residential, industrial, and commercial land uses, make up the second largest land use category, covering approximately 10 percent of the total watershed area.

CONTINUOUS SIMULATION MODELING

A suite of three modeling software packages were used in conjunction with existing CSO models for the five urban centers to create a continuous flow and water quality model for the Merrimack River from Hooksett, NH to Newburyport, MA. The watershed hydrology and nonpoint source loads were modeled using HSPF[1], except for the land areas covered by the individual CSO models for the five major communities, which were developed prior to this study in SWMM[2] and MOUSE[3]. The flows and loads from the watershed model and CSO models were input to the more detailed instream hydraulic and water quality models at the upstream boundary, the confluences of major tributaries, and at diffuse points along the mainstem to account for direct runoff to the channel. SWMM was chosen as the model code for the hydraulics, and WASP[4] was used to simulate water quality in the mainstem

4 Water Quality Simulation Program, developed by the U.S. Environmental Protection Agency

Merrimack River. The models were calibrated to data collected as part of the comprehensive monitoring aspect of the study, which included wet- and dry-weather surveys of flow, mainstem and tributary water quality, and CSO outfalls. Examples of the calibration results from the continuous flow and water quality model are shown in Figure 2.

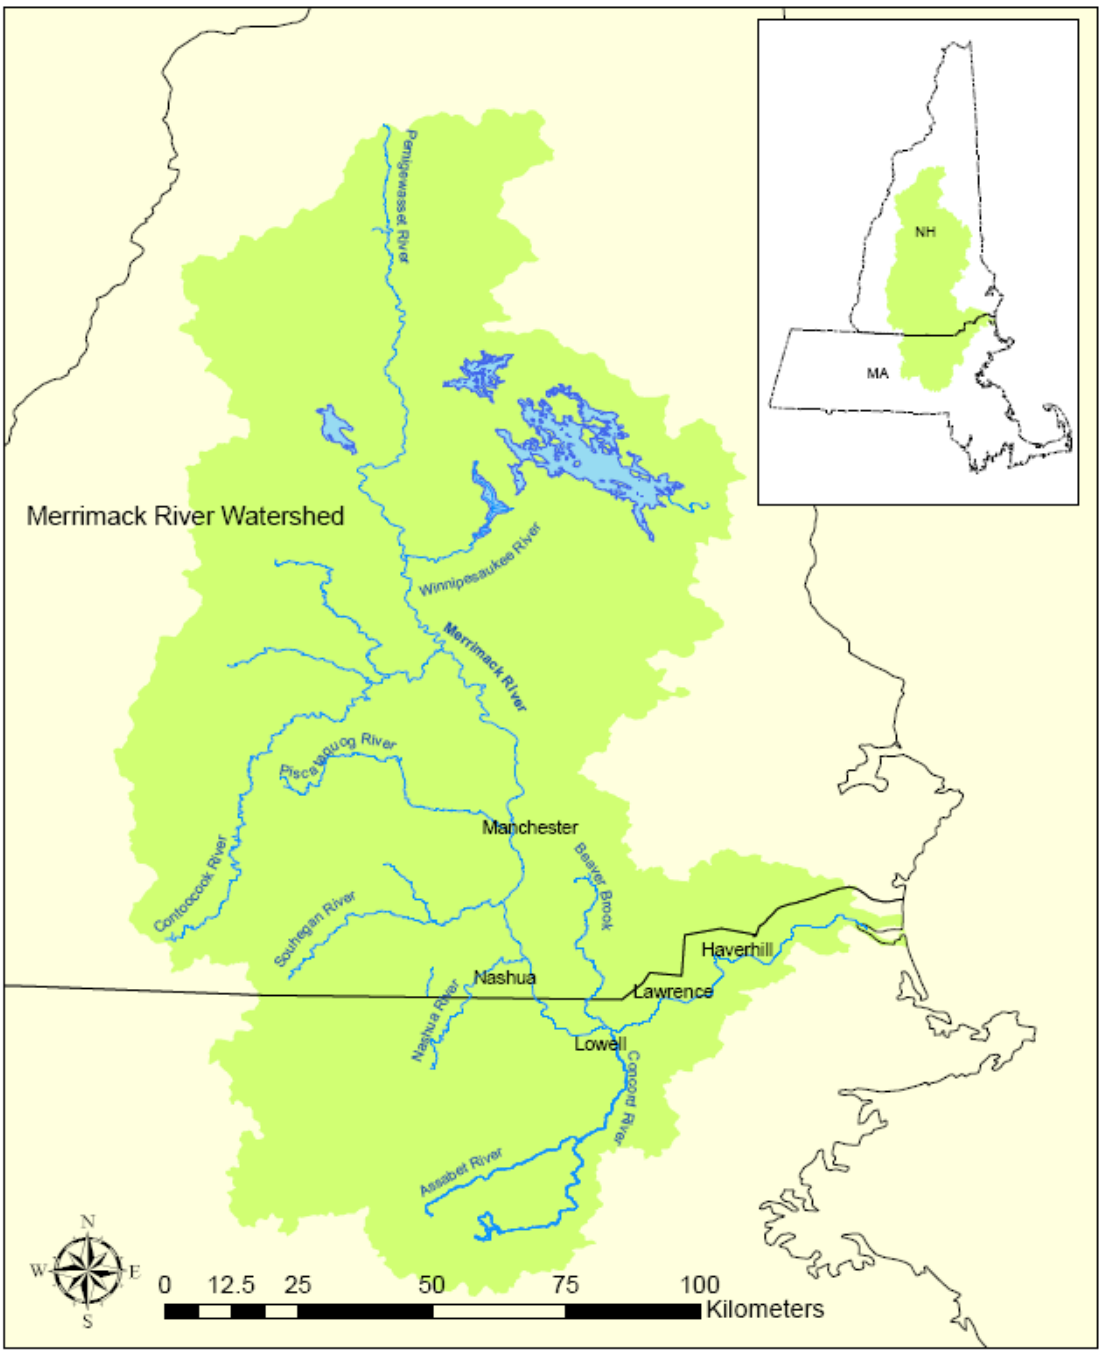

Figure 1: Merrimack River Watershed

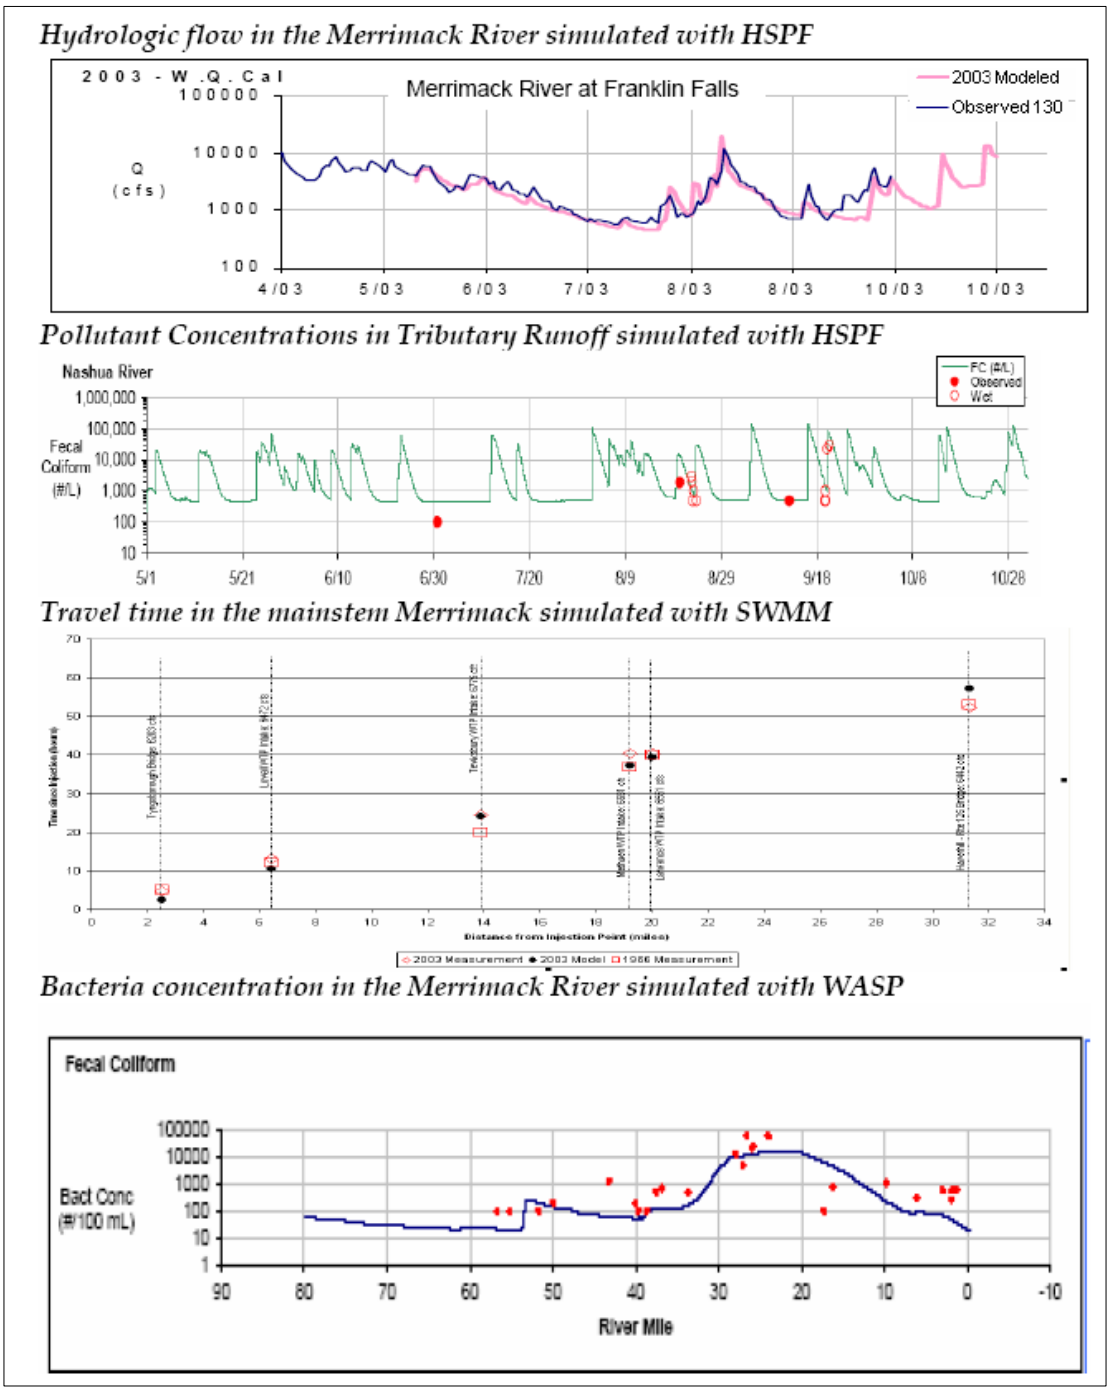

Figure 2: Representative Calibration Results (USACE, 2006)

ANALYSIS OF ALTERNATIVE MANAGEMENT STRATEGIES

Comprehensive water quality monitoring, flow measurement, and dynamic simulation modeling of the watershed were employed to develop qualitative and quantitative understanding of the relative impacts of contributing bacteria sources, the impacts of reducing specific load categories, and the costs associated with abatement. What resulted was a clear indication of the leading causes of non-compliance in this

watershed, and the most cost-effective abatement strategies. Interestingly, since bacteria compliance in Massachusetts and New Hampshire is a time-averaged standard, the leading contributor to noncompliance with standards was *not* the source that contributed the most pollutant load. Details of the monitoring study and the modeling are available through project reports posted on the Army Corps of Engineers Website (www.nae.usace.army.mil/projects). Specific reports include:

- Field Monitoring Report
- Model Development Report
- Phase I Final Report

The field data and models were first employed to test the fundamental hypothesis for this large watershed; that nonpoint sources (NPS) are a significant contributing source of bacteria even though the basin contains five communities with CSO outfalls. The analysis suggested that while the total annual load from combined sewers could be expected to exceed the total load from all other sources, the timing of the loads was critical in assessing compliance with standards and use attainability. Combined sewer overflows, while depositing enormous quantities of untreated bacteria into the river, occur infrequently, only during severe rainstorms. They are usually short in duration (measured in minutes or hours), and unacceptably high concentrations of the bacteria generally disperse and decay within hours or days. Conversely, nonpoint source loads from failing septic systems, wash-off from even modest rain events, illicit sewer connections, etc. occur on a more continuous basis, and while the cumulative contribution may be less than that of CSOs, the constancy of the load renders these sources the leading cause of time-averaged non-compliance and failure to support recreational uses and shellfish harvesting in the river.

Prior to simulating alternative abatement scenarios, stakeholders from local, state, and federal agencies convened to identify the most appropriate ways to measure progress toward compliance with bacteria water quality standards. The group, which included regulatory agencies, non-profit organizations, project sponsors, and research organizations, reached consensus on the most important metric for the river; the number of river miles that could be brought into compliance with each alternative abatement strategy. This metric formed the basis of a fundamental comparison of plans with different focal points, each of which could be associated with economic costs, and through simulation modeling, expected environmental benefits in the form of river miles brought into compliance with state standards for bacteria levels.

To determine expected environmental benefits, alternative abatement plans that focused on specific load types were simulated. CSO abatement, in the form of established short-term and long-term control plans were modeled by linking pre-existing collection system models of the five cities to the watershed and riverine models. The effects of full sewer separation were also modeled, even though this is not part of established control plans (and would have a countering side-effect of increasing urban stormwater loads during all rainstorms). Nonpoint source abatement plans on the scale of a 13,000 square kilometer watershed are more difficult to formulate and simulate, and indeed there is very little precedent for such activity at this scale. Following the intent of EPA's Phase II Stormwater program, though, it was

assumed that the Best Management Practices (BMP's) commonly promoted could, on average, reduce bacteria levels in runoff and baseflow by approximately 20%. This, then, was the benchmark associated with the management strategy for nonpoint source bacteria; a target of 20% reduction throughout the basin. This exercise in no way implies that diffuse loads are so evenly distributed, or that each community or county would require the same level of controls. It simply represented an idealized method of developing a planning-level costs and benefits for a very large and diverse watershed.

Following this assumption, then, was an attempt to estimate order-of-magnitude costs for achieving 20% reductions. It follows that if Phase II BMPs are suggestive of approximately 20% reduction in bacteria (granted, a very heuristic value), that costs associated with Phase II compliance could be related to this reduction, though full compliance generally yields additional improvement in nutrients and other contaminants in addition to bacteria. Again, using heuristic knowledge from representative communities already embarking on Phase II compliance programs in New England, a cost scale was developed and applied, and which will be subsequently examined and tested later in this study. The smallest communities in the Merrimack watershed, with dispersed populations of just a few hundred people, were assigned a theoretical cost of $1 million to comply with Phase II stormwater requirements, while the largest communities, with dense populations of approximately 100,000 were assigned a cost of $5 million. In a watershed with 13,000 square kilometers and nearly 2 million people, this averaged out to roughly $250 per capita, or 37,000 per square kilometer. Spread over ten years, which is a reasonable equivalent planning time for CSO control plan implementation, the analysis predicted a cost of $25 per capita per year to reduce basin-wide NPS bacteria by 20%. Again, these assumptions will be explored further in subsequent sections.

The costs of alternative management programs were then plotted against the number of river miles that the models predicted could revert into compliance as an environmental return on investment. The results are shown in Figure 3, and illustrate the rapidly diminishing returns of exclusive focus on CSO abatement.

The analysis suggests that environmental returns on investment for prioritizing NPS abatement above CSO control at this regulatory juncture would be 4 times higher than continuing purely with CSO abatement and no basin-wide NPS program. Furthermore, it is clear that there is an obvious limit to the improvements that can be attributed to CSO abatement, (in this case, only 16 to 19 of the 130 river kilometers studied, even though the CSO cities and their impacts span the entire 130 kilometers). When municipal budgets are scrutinized more and more heavily due to uncertain economic conditions at all levels of the public and private sectors, it becomes increasingly difficult to justify expenditures with such poor returns. A far more sensible approach would be to shift regulatory focus to NPS reduction on a regional basis, while de-emphasizing continued CSO abatement and phasing it in much more gradually over time (since it does have undeniable benefits using the scale presented herein, as well as other epidemiological benefits which are not considered directly due to the prioritization of stakeholder interests).

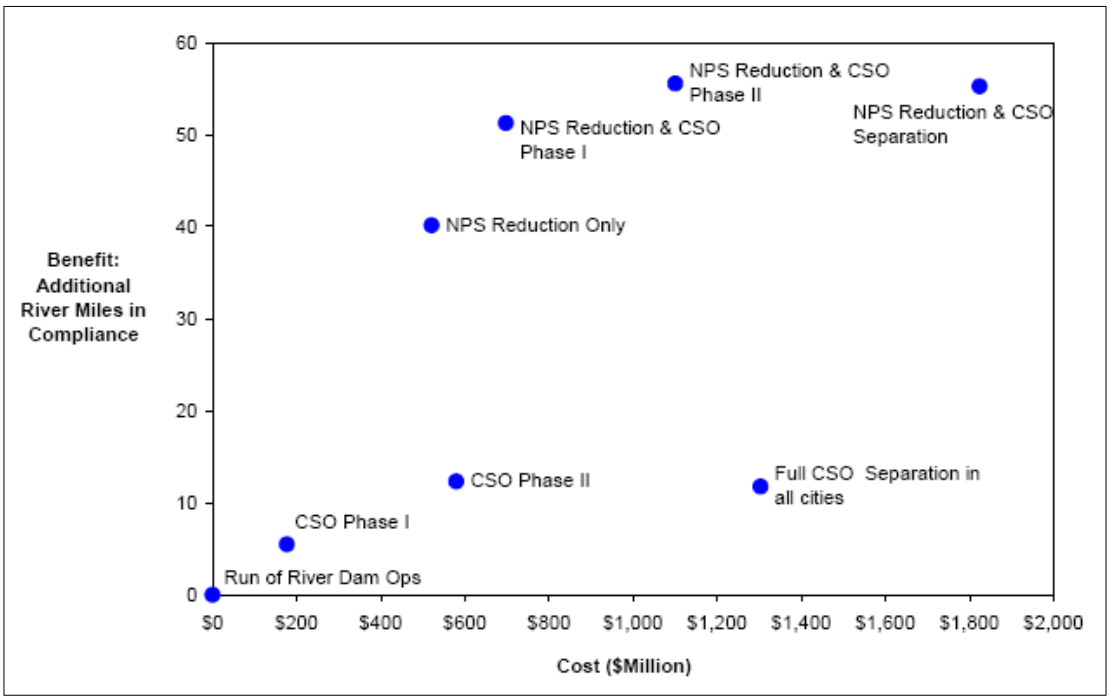

Figure 3: Comparative Value of Alternatives

COMPARISON OF NONPOINT SOURCE ABATEMENT COSTS

There is limited information available on the success, in economic terms, of NPS bacteria pollution abatement programs in large watersheds. The well documented Long Island Sound programs have focused mostly on point source reductions and beach closures rather than the in-stream impacts of NPS bacteria loads. Nonpoint source reductions are a large aspect of the Chesapeake Bay programs, but the major concern in the watershed are nutrients. Despite the lack of documented cases of large scale NPS pollution abatement programs, it is still possible to draw on the successes of small scale programs and apply the same logic to larger watersheds.

Of the many successful NPS abatement programs documented for small watersheds, the majority involve largely agricultural watersheds. However, several have focused on other sources including wildlife and failing private septic systems. In many cases, there are few or no point sources entering these small rivers, so the impairments have necessarily been attributed to NPS. While this is not the case in the Merrimack River watershed, it may be true for the many smaller communities and subbasins. The principle of the value of dollars spent on NPS abatement in small watersheds should also be applicable to large watersheds. A comparison of the balanced watershed management alternative realized by the Merrimack River Watershed Assessment Study and the small scale NPS successes in other watersheds across the country supports the concept that NPS abatement as part of a balanced program for large river basins is most cost effective.

The Coneross Creek watershed is an example of a successful NPS abatement program in a small watershed that had a combination of a few point sources as well as NPS problems resulting in fecal coliform impairments. After a three year program funded

by EPA Section 319 funds, monitoring showed significant improvement in the fecal coliform counts in the creek, to the point of de-listing the waters as impaired (EPA, 2007). The Coneross Creek watershed (200 square kilometers) is part of the larger Savannah River basin which forms the border of South Carolina and Georgia. The watershed encompasses several rural suburban communities, with land uses including forested, agricultural/grassland, and urban (SC DHEC, 2000). Based on county population densities, the Coneross Creek watershed is significantly more rural than the southern portions of the Merrimack River watershed (SOURCE:2000 census). The NPS abatement program, however, focused largely on individual land owners, making a scaling up approach based on population possible.

The NPS abatement program in the Coneross Creek watershed cost a total of $1.1 million over the course of 3 years (EPA, 2007). The program components included public outreach and education, implementation of agricultural best management practices, and reparation of failing septic systems. Based on population estimates of the watershed (U.S. Census, 2000), the project cost was approximately $37 per capita per year. That figure, scaled up based on population, yields an estimate of $74 million per year (or $5,700 per square kilometer) for the entire Merrimack River Watershed, which has a total population of about 2 million people (USACE, 2006).

More generally, the estimated cost of EPA Phase II stormwater programs is $3.75 to $6.00 per capita per year (Reese, 2003). There are significant differences in the watershed characteristics of the Coneross Creek and Merrimack River basins, and the NPS abatement program for the Merrimack would necessarily be much different than that of the Coneross Creek. However, this scaling up exercise gives another model for estimating the potential cost and benefit of including a significant NPS abatement program as part of a balanced watershed management strategy. Figure 4 shows a summary of the various NPS abatement program costs and estimates.

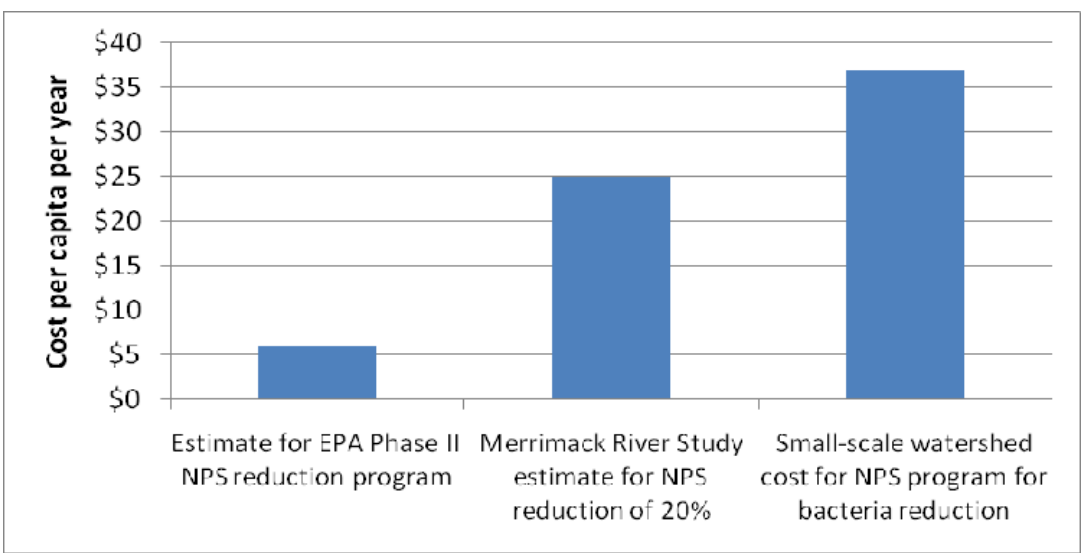

Figure 4: Cost Comparisons for Nonpoint Source Abatement

CONCLUSIONS

The results of the Merrimack River Watershed Assessment Study reveal the importance of a thorough understanding of the impact of nonpoint source pollution in large watersheds with multiple potential causes of noncompliance. Particularly, quantifying the contributions from nonpoint sources and directly comparing alternative management strategies – a spectrum of approaches from point source elimination only (LTCPs), nonpoint source reduction only, and balanced abatement strategies – will lead to a better understanding of the most economical and effective way of bringing a river into compliance. The lack of research and documentation of nonpoint source abatement programs in large watersheds forced an estimation of the cost of such a program for the Merrimack River. Comparisons made with the available information, including the cost of a small-scale successful nonpoint source abatement program and EPA Phase II stormwater program cost estimates, demonstrate that the approximation of $25 per capita per year for 20% reduction in nonpoint source pollution is reasonable. An economical analysis of the management alternatives associated with point and nonpoint source abatement on a watershed scale must include a logical metric for comparison, such as bringing river miles into compliance, to effectively evaluate the options that exist for communities within a large watershed. The Merrimack River study can be used as a benchmark for future pollution management planning in large watersheds throughout the country. Similar studies are highly recommended to build support for the hypothesis that the Merrimack River case is an example of a common situation where the focus of pollution abatement strategies (and funding) in large watersheds lean heavily toward point source reduction, to the exclusion of potentially dominant nonpoint source pollution.

ABSTRACT

The nitrogen (N) budget is studied to evaluate N inputs and outputs of DHF Reservoir Watershed (DRW), where it is cold semiarid climate in northeastern China. Using the data of 2003 as a typical calculation year, the input of N is quantified from the aspects of atmospheric deposition, fertilizer use, biological fixation, net food and feed input, output of N from ammonia volatilization, denitrification and runoff export, respectively. It is addressed that the atmosphere deposition, fertilizer use and food and feed input dominates more than 90% of the total input. In the output side of N, the ammonia volatilization and denitrification are the main items, which account for 55% of the total N input and 95.1% of the total N output. However runoff N export is 6.49% of the total N input. This is owing to the more water retention time in reservoir for N settling and more sites for denitrification. Over the whole watershed, the budget of N is positive (13.52 kg ha^{-1} yr^{-1}), which results in the N accumulation in landscape and the TN concentration increase in DHF Reservoir.

KEYWORDS*: Nitrogen, Budget, Water quality, Northeastern China*

1. Introduction

Research finds that the input of reactive nitrogen (N) to global cycles have increased dramatically as a result of anthropogenic activities, which would accelerate the N accumulation in landscapes and the N delivery into water bodies (Galloway et al. 2004; Galloway et al. 1995). Total reactive N inputs into the global system have increased from 15.6 Tg yr^{-1} to 139 Tg yr^{-1} between 1890 and 1990 (Galloway and Cowling 2002). As N is a major determinant of water quality, the big increasing of reactive N load will likely cause severe damage to environmental services at local, regional, and global scale.

In order to understand the nitrogen dynamics in the watershed scale, recent studies have constructed N budget, which include N inputs and N outputs. The budget has been well documented at the scale of watershed, which aim at the identification of the fate of N surpluses or in long-term assessment of N fluxes and their respective impact on the environment. Boyer et al. constructed budget describing N inputs and outputs for 16 catchments in the northeastern U.S.A (Boyer et al. 2002). At the same time, Xing and Zhu addressed N budget in the three major rivers in China (Xing and Zhu 2002). N temporal and spatial trends have been investigated by budget (Schaefer and Alber 2007). On the other hand, N budget is used in the environment management, which is developed to evaluation the decreased effect of impoundments on N fluxes(Bosch and

Allan 2008).

In China, there is the largest population in the world. To meet the food and fiber demands of 1.3 billion people, application of N fertilizers has been increasing drastically to 22.20 Tg N in 1995, which is one fourth of the world's total (Liu et al. 2006). There surplus N inputs far exceed N outputs in products shipped out of agricultural ecosystems (Chen et al. 2008). However, There is little knowledge about N budgets in China. Chen et al. developed N budgets in an agricultural watersheds in a warm and humid area of southeast China (Chen et al. 2008). Liu et al. investigate both temporal and spatial changes in the N budgets of Yangtze River basin (Liu et al. 2008). These researches are focused on south or middle of China. Because climate change can result in marked changes in N cycles, these researches are not enough. Now the region of northeastern China , the main foodstuff producing region, has been suffered potential N risk (Sun et al. 2008). For example, The TN concentration of DHF Reservoir Watershed (DRW) , which provides drinking water for the 20 million people in Liaoning province, is increased from 0.98 mg $L^{-1}$to 2.23 mg L^{-1}. However, the sources and the fate of N in the cold semiarid region of the northeastern China are hardly studied.

The objective of this study is to quantify N inputs and outputs for the DRW, a watershed in northeastern China. It mainly focuses on providing a further understanding of the relation between N budget and water quality trend in the cold semiarid catchment. Generally, for a river watershed, 20-26% of the total N inputs in average is exported through runoff (Boyer et al. 2002; Howarth et al. 2006). Due to the decreased effect of reservoir, there will be different relation in the large-scale reservoir. This research on nitrogen-water quality linkages should be broadened to address the issues of N losses and N balance in a watershed-scale.

2. Materials and methods

2.1 Study area

The DRW (518 910 ha) is a mixed land use watershed located in northeastern China. It has three tributaries, which includes Hun River (52.7%), Suzi River (37.1%) and She River (10.2%)(Figure 1.). The annual precipitation varies from 650 mm ~ 800 mm, and 50% of precipitation occurs in July and August. The catchment includes Qinyuan Country, Xinbin Country and Fushun Country. DRW comprises arable land (15.47%), forest (80.26%), wetland (0.82%), water body (2.25%), and residential land (1.20%). The cultivated land and population are shown in Table 1. And the distribution of the land use is shown in Table 2.

Table 1 Cultivated land area and population in DRW

Cultivated land area (ha)			Population (10^3 persons)		
Upland	Paddy field	Total	Rural	Urban	Total
75 586	12 671	87 757	251.2	156.0	407.2

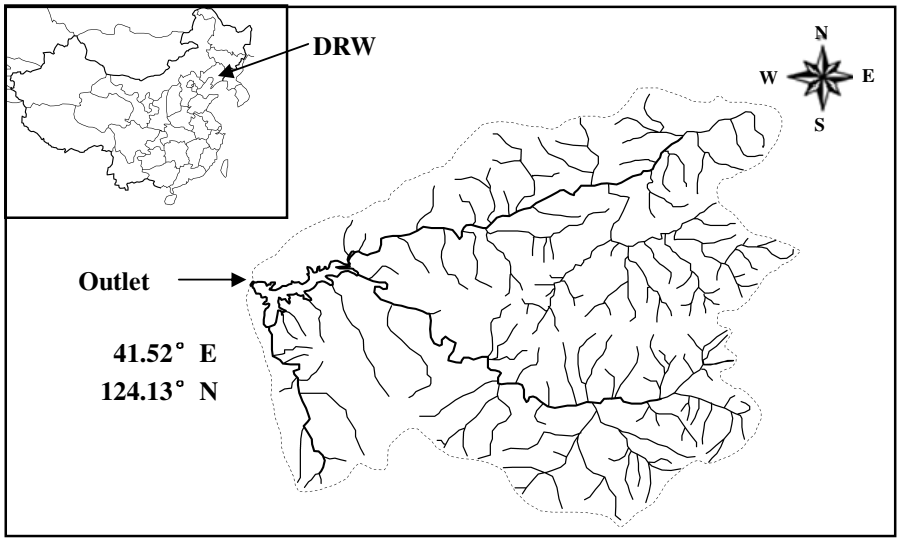

Figure 1 The map of DHF reservoir watershed

In this study, fluxes of N input and output is individually quantified using various approaches and available data: local and national statistical data, digital land cover map, local meteorological and hydrological data, as shown in Table 3. All fluxes are conducted for 2003 to investigate the increasing N concentration in DRW between 2000 and 2005.

Table 3 Basic data used in this study

	Item	Source
Agricultural data	Maize, rice, soybeans, vegetables, N fertilizer	Fushun yearbook Fushun statistical yearbook
Population	Total population, rural population	Fushun yearbook Fushun statistical yearbook
Livestock population	Pigs, cattle, sheep, poultry	Fushun yearbook Fushun statistical yearbook
Land use/cover data	Digital land cover map of China	www.geodata.cn
Hydrological data	Water quantity and quality	Annals of DHF

2.2 Nutrogen budget

The N budget of DRW is studied by the approach described in Boyer's study (Boyer et al. 2002). Mass conservation of N in watershed system can be described as:

$$\triangle S = M_{\text{total}} - X_{\text{total}} \quad (1)$$

Where M_{total} is the mass of total N inputs within the system during a year, X_{total} is the annual mass of total N outputs of the system, $\triangle S$ is the change in the mass of N in the representative year. According to field survey, we constructed the N budget model for DRW that lists the fluxes (inputs and outputs) across the whole watershed, as presented in Figure 2

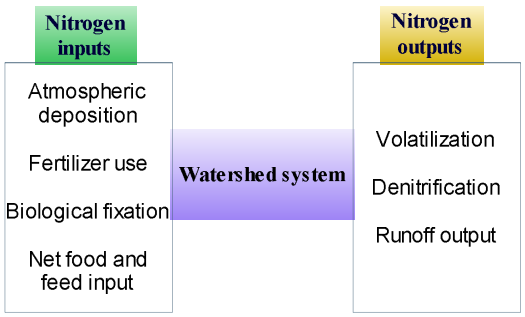

Figure 2 Conceptual diagrams of nitrogen budget

N budget inputs include atmospheric deposition (M_{ad}, which is composed of wet deposition (M_{wd}) and dry deposition (M_{dd})), fertilizer use (M_f), biological fixation (M_{bf}), net food and feed input (M_{ff}). Watershed system consists of soil stock, pool stock, and atmospheric stock. N outputs are composed of volatilization (X_v), denitrification (X_d), runoff export (X_{re}). Due to the large area of DRW, the leaching N loss is assumed to be equal to the return flow to stream flow and reservoir.

2.3 Total N inputs

2.3.1 Fertilizer

The Industrial fixation of nitrogen for the use as fertilizer currently totals approximately 80 Tg a year and represents the largest human contribution of nitrogen to the global cycle. The statistical data of N fertilizer is obtained from the Fushun yearbook and Fushun statistical yearbook. It is assumed that N fertilizers are used equivalently in the arable land. There are about 8 614T N used into DRW in 2003.

2.3.2 Atmospheric deposition

Atmospheric deposition is another main source of N inputs. The N deposition to ecosystems in the absence and presence of human influence increases from 0.5 kg N $ha^{-1}yr^{-1}$ to 10 kg N $ha^{-1}yr^{-1}$ (Galloway et al. 2008). In the DRW, historic data on wet deposition is not available. We used information in the Sanjiang Plain, which is similar in climate and geography with DRW (Sun et al. 2007). Wet TN deposition in the forms of nitrate (NO_y), ammonium (NH_4^+) and organic nitrogen is 7.57 kg ha^{-1} yr^{-1}. In order to estimate the value of dry atmospheric deposition, we employed a proportion of wet deposition N cited from the previous studies. The total N deposition could be quantified by method of Lovett and Lindberg(Johnson and WLindberg 1991)

$$M_{ad} = -0.72+2.07 \cdot M_{wd} \quad (2)$$

2.3.3 Biological fixation

N fixation is estimated by multiplying the area of N-fixing species with literature-derived N fixing rates. Soybeans are the major N fixing crop in DRW, which is accounting for 19% of the N in total crop production. According to the Boyer et al., the fixation rate for soybeans is 96 kg ha^{-1} yr^{-1} (Boyer et al. 2002). In addition, rice land and forest land also could fix N. The fixation rates are 15 kg N ha^{-1} yr^{-1} and 1 kg N ha^{-1} yr^{-1} respectively (Bashkin et al. 2002). Summarized result is shown in Table 4.

Table4. Biological fixation rate in DRW

	Soybeans land	Rice land	Forested land
Fixing rating (kg ha^{-1} yr^{-1})	96[a]	15[b]	1[b]
Area (ha)	5670	6631	416487

Sources: a. Boyer et al 2002; b. Bashkin et al 2002.

2.3.4 Net food and feed input

Both human and animals require food and feed, and these demands are met both by local agriculture and by imports from other regions. Transfer of agricultural products could be important source of N to a watershed. For example, Howarth et al. estimated that the net input of N in food and feed is 28% of total N inputs to the NE U.S. region.

In DRW, human population and livestock populations are obtained from Fushun yearbook and Fushun statistical yearbook. The production and average consumption (urban, rural) of cereal, meat and vegetable are obtained from Fushun statistical yearbook. Animal consumption is estimated by multiplying populations by published annual per capita N consumption rates (Van Horn 1998). The animal consumption rates used in this study are shown in Table 5. According to the Fushun statistical yearbook, the cereal, meat, and vegetable for human food consumption are 95 kg, 29.5 kg 158.2 kg for urban people, 170.94 kg, 27.7 kg and 225.66 kg for rural people.

Table5. Animal N consumption rates (kg animal-1 yr-1)

Animal	Pigs & hogs	Beef cattle	Dairy cattle	Sheep	Poultry
N consumption rates	8.51	66.75	156	5.97	0.13

Source: Van Horn (1998)

2.4 Total N outputs

2.4.1 Ammonium volatilization

Volatilization is a major N loss fluxes. Fertilizer use, confined animal feeding operations, and manure application on fields contribute most to ammonia emission (Goebes et al. 2003). Gaseous N loss rate through fertilizer primarily varies with fertilizer types and application method. Ammonium bicarbonate, urea, and mixed fertilizer are the main N fertilizers applied in the DHF. According to Chen et al, the volatilization losses as a percentage of fertilizers applied: 25% for urea and ammonium nitrate, 18%for other combined fertilizers (Chen 2002).

Human and animal wastes are another source of NH_3 volatilization. A number of emission factors have been proposed for developing ammonia emissions inventories. The emission factor includes the process of animal breed, manure management and application (Battye et al. 2003; Faulkner and Shaw 2008; Xing and Zhu 2002). The emission factors for different animals are listed in Table 6.

Table 6 Emission factors for animals in DHF (kg N hd^{-1} yr^{-1})

Beef cattle[a]	Dairy cattle[a]	Pigs&hogs[a]	Sheep[b]	Poultry[a]	Human[c]
10.71	19.68	4.78	1.34	0.15	0.2

Sources: a. Faulkner and Shaw 2008; b. Battye et al. 2003; c. Xing and Zhu 2002

Forest and wetland also could generate ammonia emission. The ammonia emission factors are selected as 1.2 kg N ha^{-1} $yr^{-1}$and 0.3 kg N ha^{-1} yr^{-1}, which is equal to the factor given by Buowman et al.(Bouwman et al. 1997)

2.4.2 Denitrification

Denitrification is another important N output from natural and human altered systems (Schlesinger 2009). Previous researchers suggest that continental shelf sediments account for the largest portion (44%) of total global denitrification, followed by terrestrial soils (22%) and oceanic oxygen minimum zones (14%). Within watersheds, the amount of land-based denitrified N is generally highest in terrestrial soils, with progressively smaller amounts denitrified in groundwater, rivers, lakes and reservoirs. Seitzinger et al. suggested that denitrification in soil, groundwater, lakes and rives are 10-15 kg N ha^{-1} yr^{-1}, 2.5-5 kg N ha^{-1} yr^{-1} and 0-0.5 kg N ha^{-1} yr^{-1} in northeast of China (Seitzinger et al. 2006). We choose the mean values in the DRW.

2.4.3 Runoff export

In the DRW, The reservoir outlet is the pass of watershed output. Therefore the TN concentration of runoff is relative stable. The average TN concentration at the outlet is 1.54 mgL^{-1} in 2003. The amount of N export in runoff is flow-weighted, and estimated by multiplying measured concentration of TN.

3. Results and discussion

3.1 DHF nitrogen budget

Table 7 shows the values of all variables used for calculating the N budget in DRW in 2003. On the inputs side, atmosphere deposition and N fertilizer application constitute major contributing factors at 14.95 kg N ha^{-1} yr^{-1} and 15.26 kg N ha^{-1} yr^{-1}, or approximately 31.59% and 32.25% of the total N input into the watershed, respectively. The left parts are biological fixation and net food and feed input, which are contribute at 2.4 kg N ha^{-1} yr^{-1} and 9.55 kg N ha^{-1} yr^{-1}. In total, 47.32 kg N ha^{-1} yr^{-1} is imported into the watershed. On the output side, N outputs through ammonium volatilization and denitrification are found to be 9.60 kg N ha^{-1} yr^{-1}, 15.97 kg N ha^{-1} yr^{-1} or 20.29%, 33.75% of total N inputs, respectively. N output from runoff is relatively small at 3.07 or 6.49% of the total N input.

Table 4 N budget of the DRW

	$\triangle S$	M_{total}	M_{ad}	M_f	M_{bf}	M_{ff}	X_{total}	X_v	X_d	X_{re}
DRW (kg N ha^{-1} yr^{-1})	13.52	47.32	14.95	15.26	2.40	9.55	33.80	9.60	15.97	3.07
Percent of N inputs	28.57	100.00	31.59	32.25	5.07	20.18	71.43	20.29	33.75	6.49

The N budget of the DRW is positive, which indicates that there is 13.52 kg N ha^{-1} yr^{-1} entering into DRW. The accumulation of N is due to the input rates of atmospheric deposition, fertilization, and net food and feed input are not matched by output rates in Ammonia volatilization, denitrification and runoff output. N accumulation in the watershed results in TN concentration increasing from 0.98 mg L^{-1} to 2.03 mg L^{-1} in the period from 2000 to 2005.

3.2 Water quality of DHF reservoir

Soil is the major source of N to reservoirs. It plays the most important role in determining N concentration in the reservoir. For the DHF reservoir, the concentration of TN has increased from 0.98 mg L^{-1} to 2.03 mg L^{-1} in the period of 2000-2005. The nitrogen increases are highly correlated with the human generated inputs of nitrogen. These inputs are dominated by fertilizers, atmospheric deposition and net food and feed input. The N budget for the DHF catchment indicates that a lot of N input enters into the DHF Reservoir every year.

As to the relation of N input and water quality, previous research found that the flux of N in large rivers is well explained as a function of the catchment N budget. Boyer et al. and Howarth et al. reported that the runoff typically export about 26% of their total inputs (Boyer et al. 2002; Howarth et al. 2006). The estimated N runoff outputs are not directly comparable to these values (3.07<10.38, which is used in net food and feed input).

Reservoir TN concentration depends on the balance of N inputs into and outputs out of balance as well as the consumption and production by biological processes in the reservoir. Inputs of N for DRW are mainly from watershed soils and atmospheric deposition. Outputs of N include nitrogen lost by outflow from outlets, to the sediment and by denitrification. Research demonstrate that the impoundments could remove N from environment. There are more water retention time in lake for N settling and more sites for effective denitrification (Hillbricht-Ilkowska 1999). N denitrification has been shown to be the primary mechanisms to removing N for reservoir (Stanley and Doyle 2002). Due to the influence of impoundment, the river runoff export only account for 11.4% of total N input (Bosch and Allan 2008). In addition, there are a lot of BMP (vegetation) installation in DRW, which could reduced the N delivery from soil to water (Zhu et al. 2008) .

3.3 Budget uncertainty analysis

Budget approaches differ in how the system is defined, in what fluxes are considered to be internal to the system versus inputs or outputs from the system, and in which fluxes are excluded because they are considered insignificant or highly uncertain. There is also variation in how some fluxes are combined to form net fluxes. Although the budget is constructed with systemic considering and best data available in DRW, there could be unavoidable uncertainty in the N budget associated with N inputs and outputs. Most farmers in the watershed burn rice straw to

ease tillage and control rice stem rot following the harvest of rice. Another component of N loss due to incineration is domestic incineration of wood fuel. In the rural area in the DHF catchment, people still use wood fuel for cooking, which is collected from the nearby fields. Due to the lack of relative data, the N wet deposition obtained from the Sanjiang Plain data will increase the uncertainty in N budget.

4. Conclusions

The major result of this study is that the N budget of DHF reservoir watershed is constructed, where is located in the northeast of China. Taking 2003 as a typical calculation year, the N budget is positive (13.52 kg N ha^{-1} yr^{-1}). It results in the N accumulation in landscape and TN concentration increasing in DHF Reservoir. Furthermore, the research indicates that the atmosphere deposition, fertilizer use and food and feed input dominate more than 90% of the total N input. In the N output side, the ammonia volatilization and denitrification are the main factors, which account for 55% of the total N inputs and 95.1% of the total N outputs. However, the N export in the runoff is only 6.49% of the total N input; this is owing to the more water retention time in reservoir for N settling and the more sites for denitrification. The result of N budget can be used to understand the ecosystem processes and evaluate the N risk in the catchment.

ABSTRACT

In 2004, the EPA mandated all states to develop Action Plans and nutrient water quality criteria to rehabilitate impaired waters. In accordance with this mandate, the Kansas Department of Health and Environment (KDHE) has developed a nutrient removal policy whereby wastewater treatment plants (WWTP) with capacity greater than 1 mgd must meet technology based biological nutrient removal (BNR) goals to concentrations of 8 mg/L total nitrogen (TN) and 1.5 mg/L total phosphorus (TP). These guidelines were set to achieve the recommended overall nitrogen and phosphorus reduction of 30% for the State's lakes and streams (KDHE Water Bureau, 2004). This total reduction will involve best management practices for non-point sources as well as the previously stated goals for the point source contributors. This paper will discuss the key issues of BNR upgrades in Kansas: (1) capital costs, (2) data collection, (3) staff requirements, (4) operating costs, and (5) sustainability. While other states have established enhanced nutrient removal (ENR) or limit-of-technology (LOT) standards for severely impaired waters, the state of water quality in Kansas enables most utilities to upgrade their systems for BNR goals. This provides essential time for planning, training, and funding, while improving the overall water quality in Kansas.

INTRODUCTION

The Gulf of Mexico contains a hypoxic zone, or area of low dissolved oxygen concentration (< 2 mg/L), also known as the dead zone, that extends up to 125 km offshore and to a depth of 60 m depending on the season (EPA Science Advisory Board, 2007). Both nitrogen and phosphorus are nutrients in wastewater effluents that have been linked to hypoxic conditions in the Gulf of Mexico. The US Environmental Protection Agency (EPA) has been closely monitoring the Dead Zone, and established the Mississippi River/Gulf of Mexico Watershed Nutrient Task Force (or Task Force) in 1997. In 2001, the Task Force, in coordination with the White House Office of Science and Technology Policy, issued the Action Plan for Reducing, Mitigating, and Controlling Hypoxia in the Northern Gulf of Mexico (EPA, 2001). The plan implemented ten management actions, with progress to be assessed every five years.

In response to the Federal Action Plan, KDHE identified 224 impaired stream segments and 187 impaired reservoirs in the river basin and issued a Surface Water Nutrient Reduction Plan in December 2004 as a guide for the State's approach to reducing nutrients (KDHE Bureau of Water, 2004). This plan outlines the regulations for nutrient reduction at Kansas wastewater treatment plants over 1 mgd, since these facilities generate approximately 85 percent of the point-source nitrogen and phosphorus discharges in Kansas. Point sources generate approximately 18 percent of the 51,000 pounds of nitrogen, and 25 percent of the 7,000 pounds of phosphorus leaving the State annually, but are the easiest to monitor and regulate (KDHE Bureau of Water, 2004).

Currently, 18 WWTP throughout the State have nutrient monitoring requirements and goals written into their NPDES permit Schedule of Compliance (Tate, 2008). The goals for each of these plants are the previously stated technology-based BNR limits for nitrogen and phosphorus on an annual average basis. The monitoring of nitrogen and phosphorus is required on a monthly basis for most of the plants in Kansas subject to this requirement. At this time, no limits have been incorporated into any permits, but the limits could be added in the coming years as part permit requirements. Additionally, as part of the permit Schedule of Compliance, the State has required several utilities to conduct feasibility and cost studies for adding BNR treatment to their existing plants.

It is the State's plan that plants larger than 1 mgd be in compliance with the BNR limits within the next 15 years. The WWTP have been placed into five categories based on size, transportation rates, and location, to determine the priority of implementing nutrient reduction plans (KDHE Water Bureau, 2004).

CAPITAL COSTS

Nitrogen and phosphorus can be removed from wastewater to the limits proposed by the State by biological treatment. BNR is a combination of treatment processes that manipulate the treatment environment to allow microbes to remove nitrogen species and phosphorus. To accomplish this, the new or modified treatment trains must be divided into several zones where the operating conditions are controlled to be aerobic, anoxic, or anaerobic.

Biological nitrogen removal occurs in two stages. First, ammonia within the raw wastewater is converted to nitrite and then to nitrate in the oxic portion of the basin, provided that the system is operating at an adequate solids retention time (SRT). Upgrading for nitrification typically involves construction of additional aeration basins and secondary clarifiers. To remove nitrates, mixed liquor recycling pumps must be installed to convey nitrified wastewater to new anoxic zones, where denitrification can take place. Figure 1 is a traditional BNR plant layout.

The biological phosphorus removal process requires the addition of two reaction zones to the traditional BOD removal treatment train. The first is a pre-anoxic zone where RAS is held to remove any remaining dissolved oxygen and nitrate from the RAS stream before it enters the anaerobic zone. The second is an anaerobic zone where RAS and raw wastewater are combined and mixed. The biological phosphorus removal system does not need any special consideration in the aerated oxic portion of the basin other than to ensure that the MLSS is not over-aerated before entering the final clarifier. This oxygen control in the final part of the aeration basin is needed to minimize carryover of oxygen into the RAS stream.

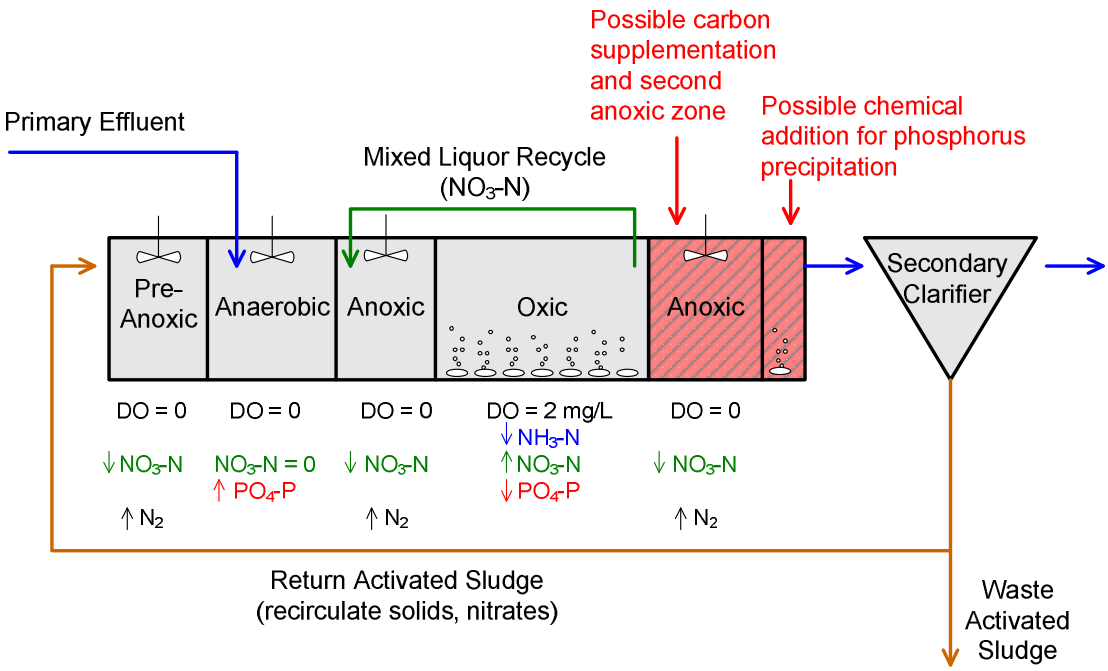

Figure 1: Typical BNR Schematic and Nutrient Transformations

With the volatile costs of steel and concrete, the most cost-effective expansion plans include reuse of existing facilities. To whatever extent possible, utilities should rehabilitate concrete structures as part of their BNR upgrades. Simple upgrades, such as adding baffle walls to create anoxic zones, or replacing clarifier sludge removal mechanisms, offer significant cost advantages over demolition and new construction. Gravity thickeners or sludge storage tanks can be converted into fermenters in some cases, and depending on the plant effluent phosphorus limits, enough volatile fatty acids (VFA) could be fermented onsite to offset the need for purchasing chemicals.

If existing facilities are reused, it is important to consider that most existing liquid trains will need to be derated from their original capacity. To maintain the capacity of the plant and to add biological nutrient removal capabilities, additional trains or facilities may need to be added in conjunction with reuse of existing facilities. This approach is still a more cost-effective than building all new facilities.

Table 1 summarizes recent projects designed and constructed in Kansas to upgrade existing plants to include biological phosphorus removal. For comparison, all of the construction costs are listed in Year 2009 dollars based on the ENR indices. The BNR expansion average cost per mgd is $2,840,000. The variance in this range is due partly to the scope of the expansion, the treatment processes selected, and the condition of the existing facilities.

Table 1. Kansas Wastewater Treatment Plant Expansions

NUTRIENT REMOVAL – WASTEWATER TREATMENT PLANTS												
		Type of Project							Phosphorus Removal		Nitrogen Removal	
Project Location	Year Constructed	Study	Design	Design-Build	Size (mgd)	WWTP Upgrade / Expansion	Construction Cost (millions in 2009 $)	Construction Cost Per MGD (millions in 2009 $)	Biological	Chemical	Nitrification	Denitrification (anoxic zones)
Independence, KS	2001	•		•	3	•	8	2.7	•		•	•
Johnson County, KS (Blue River)	2005	•	•		10.5	•	34.6	3.3	•	•	•	•
Johnson County, KS (ICMB)	2007	•	•		12	•	32.7	2.7	•		•	•
Johnson County (Millcreek)	2006	•	•		14	•	12.2	0.9			•	
Lawrence, KS (Kaw River)	2000	•	•		12.5	•	50.4	4.0			•	
Topeka, KS (North Topeka)	1994	•	•		12	•	43.8	3.6	•		•	

As new and modified treatment facilities are designed and constructed, it is prudent to consider additional facilities that may be required in the future to meet potentially more stringent nutrient removal limits and to reserve sufficient space on the site and within the hydraulic profile of the facility.

DATA COLLECTION

While most plants currently monitor influent and effluent BOD, TSS and possibly ammonia, few plants in the Midwest have sufficient records on nitrate or phosphorus concentrations. Very few plants have records of influent soluble carbon or volatile fatty acids, constituents that drive biological nutrient removal. It is important for facilities to implement additional sampling programs during studies and facility planning efforts, so that the necessary data will be available when plant expansions enter detailed design. Standards have been developed for wastewater characterization (Melcer, 2003), and Figure 2 summarizes the general types of wastewater chemical oxygen demand (COD) and their role in biological nutrient removal.

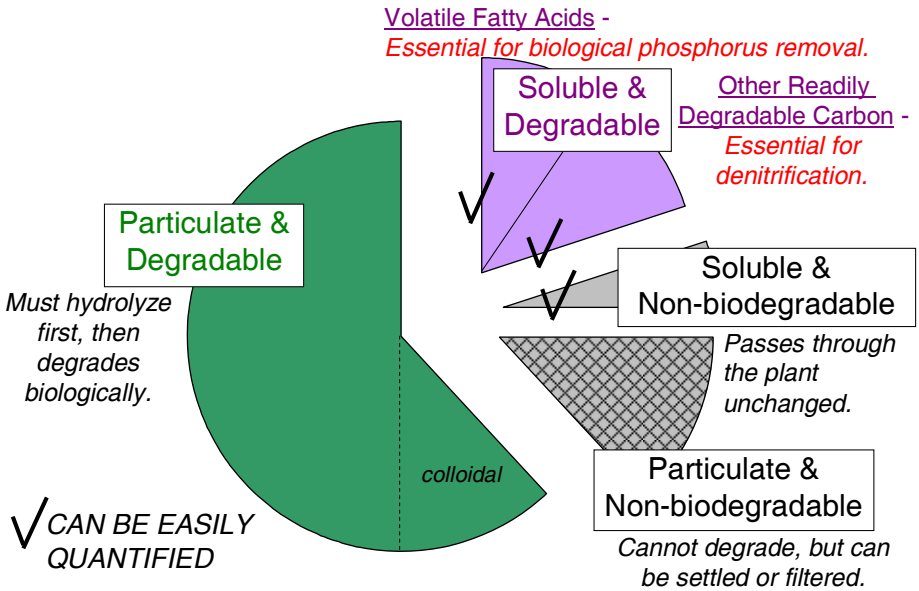

Figure 2: Typical Proportions of Wastewater Chemical Oxygen Demand

It is important to quantify the influent readily biodegradable COD for all BNR facilities. If the influent wastewater characteristics are not susceptible to biological denitrification, the facility may have to be upgraded to provide larger anoxic zones or carbon supplementation. Wastewater denitrification occurs at three well-known rates (Barnard, 1975), and complete denitrification is highly dependent on the available carbon and detention time as shown on Figure 3. If the facility is subject to a total nitrogen (TN) or total inorganic nitrogen (TIN) limit, sampling must also be conducted to quantify the recalcitrant dissolved organic nitrogen, or rDON (Bratby, 2008).

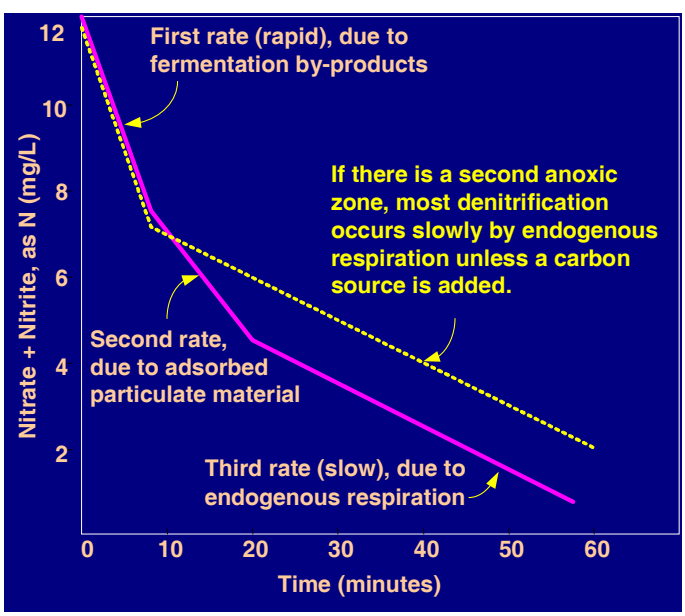

Figure 3 – Three Rates of Denitrification in Wastewater

If the influent wastewater is not amenable to biological phosphorus removal, the facility may require chemical feed facilities for phosphorus precipitation or VFA supplementation. A cost-effective solution may be to construct an on-site fermenter which generates VFA from primary sludge. Johnson County Wastewater is constructing two fermenters as part of its BNR upgrades at the Douglas L. Smith Middle Basin Plant in Overland Park, Kansas. The facility is unique in that it will process sludge from another plant in addition to its own, and the hauled sludge is a source of "imported" nutrients that had to be taken into account the design (Phillips et al, 2006).

STAFF REQUIREMENTS

Biological nutrient removal facilities require careful monitoring of dissolved oxygen; recycle rates; and ammonia, nitrate and phosphorus concentrations. Not only must operators understand the equipment that they work with, but they must also understand the microbiology fundamentals. Utilities must plan for additional training and certification of their current operators as well as for adding new operators, maintenance workers, and laboratory staff. Equipment that requires operation and maintenance at a typical BNR facility is shown on Figure 4. A plant that removes only BOD and TSS would include the oxic zone, clarifier, and RAS and WAS pumps only, with much less sampling and monitoring. In general, when a plant is upgraded for nutrient removal, the utility should plan for at least one additional operator and one additional laboratory technician, and possibly several more positions for larger expansions.

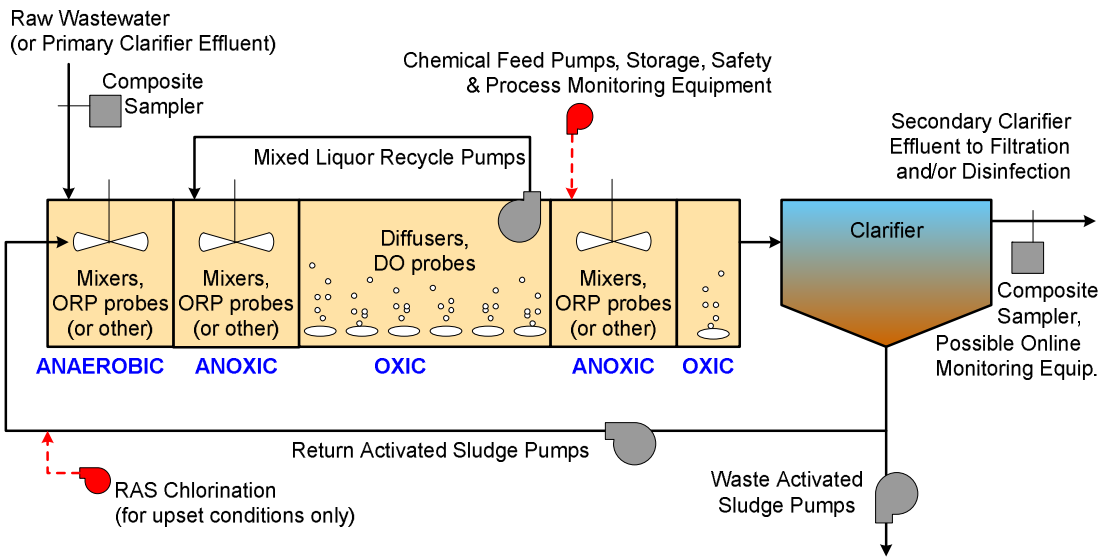

Figure 4: Equipment at a Biological Nutrient Removal Facility

OPERATING COSTS

Upgrading to nitrification can double the amount oxygen needed from that used for an activated sludge process that removes BOD only, which can double the costs of electricity. Anoxic zone mixers and mixed liquor recycle pumps, which must convey two to four times the plant influent flowrate, also add to electricity use. Depending on the level of treatment required, expensive chemicals may be needed to enhance denitrification or phosphorus removal, and utilities must plan for increases in operating costs accordingly.

Biosolids treatment and disposal must also be considered. In general, a plant that nitrifies will produce less biosolids than a plant that removes BOD and TSS only; however, if chemicals are added for phosphorus removal, sludge quantities can increase substantially. Also, when plant expansions reach a certain size (generally 10 mgd) it may be cost-effective to add primary clarification to reduce the number of new aeration tanks to be constructed. This generates new sludge that must be processed, which is typically accomplished by anaerobic digestion. In addition to producing Class A biosolids that can be land-applied, a second benefit of anaerobic digestion is that the methane generated can be harvested to generate electricity and thus reduce electrical costs.

For most households in Kansas, the monthly wastewater bill has traditionally been the lowest utility bill, compared to the gas or electric bills which can be ten or twenty times the monthly cost of a wastewater bill. As utilities expand and upgrade for nutrient removal, and operating costs increase, rate payers can expect a significant increase in monthly bills. Smaller communities will suffer the greatest increases, since there are fewer households in the service area to contribute to the overall operating costs. These increases could range from approximately $200 per month in smaller communities (4,000 or fewer) to $28 dollars per month in communities with 100,000 citizens (KDHE Water Bureau, 2004).

SUSTAINABILITY

In the past, environmental issues have focused on a “cradle to grave” approach by which chemicals, for example, are tracked from their production point to the end user. Today, utilities can benefit from a “cradle to cradle” approach by which energy optimization studies and carbon footprint analyses accompany traditional engineering studies to develop solutions that meet the triple bottom line: economic, environmental and social responsibilities. By looking at the entire picture, utilities can plan responsibly for the future.

A sustainability study must include three components: economic, social, and environmental impacts. Economic impacts can be quantified by determining capital and operating costs through a present worth evaluation. Social impacts can be evaluated with public participation hearings, surveys, and maintaining good communications with regulators, neighboring communities, and invested

stakeholders. The third component of a sustainability study, environmental impacts, is more difficult to evaluate. While there are models that can accurately predict plant effluent quality, there are currently no standard approaches to quantifying or predicting wastewater plant greenhouse gas (GHG) emissions. Extensive carbon footprint studies have been conducted in Australia (Bridle et al., 2008; de Haas et al., 2008) and many expect GHGs to become regulated in the United States in the coming years, so many utilities are changing the way they approach projects.

CONCLUSIONS

Kansas is a small part of the Mississippi/Atchafalaya River Basin (MARB), which covers 31 states and includes 41 percent of the US population; however, KDHE is a leading agency in addressing nutrient control. Point sources are not the largest contributors to the Gulf of Mexico hypoxia, but they are the easiest to monitor and regulate. Many WWTPs in Kansas have already implemented facility improvements to achieve BNR goals of 8 mg/L TN and 1.5 mg/L TP. A sampling of recent projects concluded that capital expenditures ranged from $0.90 to $4.00 per gallon of treated wastewater (based on 2009 dollars). By comparison, "limit of technology" (3 mg/L TN, 0.3 mg/L TP) projects in the Chesapeake Bay area averaged $8.20/GPD based on 2006/2007 dollars (Harper et al., 2008).

Improving water quality through BNR projects will come at a cost to rate-payers, who could expect utility bills to increase by $50 per month, or much more for smaller communities. BNR facilities require much more sampling, monitoring and maintenance and therefore their operating costs are higher than the costs associated with BOD and TSS removal. As a result, states such as Kansas will experience a demand for skilled laboratory technicians and wastewater treatment plant operators who are certified for biological nutrient removal. A disadvantage is that utilities may have trouble filling these open positions, especially with retirements on the rise. Training budgets will have to be expanded in order to keep up with changing nutrient policies and facility upgrades. Adapting to nutrient control policies will not be easy, but with careful planning, Kansas utilities have the opportunity to lead the region in finding sustainable solutions for its communities.

ABSTRACT

The objective of this study was to assess the potential of applying enhanced bioremediation on the treatment of petroleum-hydrocarbon contaminated soils. Microcosm experiments were conducted to determine the optimal biodegradation conditions. The control factors included oxygen content, nutrient addition, addition of commercially available mixed microbial inocula, addition of wood chips and rice husks (volume ratio = 1:1) as bulking agents, and addition of organic amendments (chicken manures). Results indicate that the supplement of microbial inocula or chicken manures could significantly increase the microbial populations in soils, and thus, enhance the efficiency of total petroleum hydrocarbon (TPH) removal (initial TPH = 5,500 mg/kg). The highest first-order TPH decay rate and removal ratio were approximately 0.015 day^{-1} and 85%, respectively, observed in microcosms containing microbial inocula (mass ratio of soil to inocula = 50:1), nutrient, and bulking agent (volume ratio of soil to bulking agent = 10 to 1) during 155 days of incubation. Results indicate that the first-order TPH decay rates of 0.015 and 0.0142 day^{-1} can be obtained with the addition of microbial inocula and chicken manures, respectively, compared with the decay rate of 0.0069 day^{-1} under intrinsic conditions. Thus, chicken manures have the potential to be used as substitutes of commercial microbial inocula. The decay rate and removal ratio can be further enhanced to 0.0196 day^{-1} and 87%, respectively, with frequent soil shaking and air replacement. Results will be useful in designing an ex-situ soil bioremediation systems (e.g., biopile, landfarming) for practical application.

INTRODUCTION

Accidental releases of petroleum products from above-ground or underground storage tanks (USTs) are one of the most common causes of soils contamination. Among those petroleum products, diesel oil is one of the most widely used fuel oils in society today. Although diesel oil is largely comprised of simple unbranched n-alkanes in the range of C10-C22, it also contains more recalcitrant and less biodegradable petroleum hydrocarbons. Thus, diesel-oil contaminated soils are more difficult to treat compared to more volatile petroleum products (e.g., gasoline). Currently, with the increasing attention towards the environment preservation, biological decontamination has become a valuable alternative to chemical treatments. Bioremediation is an ecologically acceptable technology that uses microorganisms to efficiently degrade pollutants in the environment. Biopile and landfarming systems have been listed as feasible ex situ remedial technologies for the treatment of petroleum-hydrocarbon contaminated soils, especially for soils polluted with less biodegradable and less volatile petroleum product (e.g., diesel oil). Biopiles, also known as biocells and compost piles, are used to reduce concentrations of petroleum products in excavated soils through the processes of biodegradation (US EPA, 2004; Sarkar et al., 2005).

Biopiles are constructed by forming excavated contaminated soils into piles above ground with the aim of enhancing conditions for biodegradation. Landfarming, also known as land treatment or land application, is an above-ground soil remediation technology. Landfarming usually involves spreading excavated contaminated soils in a thin layer on the ground surface and stimulating aerobic microbial activity within the soils through aeration and/or the addition of minerals, nutrients, and moisture. The enhanced microbial activities in both biopile and landfarming systems result in degradation of adsorbed petroleum constituents through microbial degradation. Addition of organic material to the contaminated soils can be beneficial, as it is a source of co-substrates, microorganisms, and nutrients, and ameliorates the structure and water-retaining capacity of the soils. For optimum biopile and landfarming conditions, it is important to know the characteristics of the contaminated soils before the beginning of treatments. Although there are many biopile and landfarming systems for the treatment of petroleum-hydrocarbon contaminated soils, there is a lack of information on the addition of organic materials, bulking agents, microbial inocula on optimizing bioremedial conditions of biopile and landfarming systems for the treatment of diesel-oil contaminated soils. Thus, the primary objective of this study was to assess the potential of enhancing the bioremediation efficiency on the clean up of diesel-oil polluted soils. In this study, microcosm experiment was performed for efficiency evaluation by the nutrient supplementation, addition of commercially available mixed microbial inocula, addition of wood chips and rice husks as bulking agents, and addition of organic materials (chicken manures). Optimal conditions obtained from the study could be used to improve the treatment efficiency of the ex situ soil bioremediation systems (e.g., biopile, landfarming) for the treatment of diesel-oil contaminated soils.

MATERIALS AND METHODS

Construction of microcosms. Microcosms were constructed to evaluate the effectiveness of enhanced bioremediation of diesel oil-contaminated soils under different biodegradation conditions. The six major groups applied in this study included control group (A), nutrient addition group (B), bulking agent addition group (C), commercially available mixed microbial inocula addition group (D), organic material addition group (E), and soil shaking and air replacement group (F). Each microcosm was constructed with 50 mL nutrient medium or deionized (DI) water, certain amount of amendments (bulking agent, mixed microbial inocula, or organic materials), and 150 g of fuel oil-contaminated soils in a 300-mL bottle sealed with Teflon-lined rubber septa. The headspace in each microcosm was approximately 150 mL, and was filled with air. The final mineral medium in each microcosm consisted of (milligram per liter of H_2O) $(NH_4)_2SO_4$, 100; K_2HPO_4, 174; KH_2PO_4, 136; $CaCl_2$, 0.4; $FeCl_3 \cdot 6H_2O$, 0.3; H_3BO4, 0.03; concentrated HCl, 0.25, $MgSO_4 \cdot 7H_2O$, 3; $MnSO_4 \cdot H_2O$, 0.09; and $NaMoO_4 \cdot 2H_2O$, 0.01. The medium solution was autoclaved before use. The initial soil TPH concentrations in microcosm bottles were approximately 5,500 mg/kg. The pH of each microcosm solution was approximately 7.5, and was relatively stable throughout the experiment (varied from 7 to 7.5) (data not shown). In Group A, both live and dead control microcosms were prepared. The live control microcosms only contained diesel-oil contaminated soils and DI water. Dead control bottles contained 250 mg/L $HgCl_2$ and 500 mg/L NaN_3, and soils used for this control group were autoclaved before use. In Group B, nutrient solution instead of DI water was used to evaluate the feasibility of TPH biodegradation enhancement by nutrient addition. In Group C, bulking agents of wood chips and rice husks (volume ratio = 1:1) were mixed with soils to increase the soil permeability. In Group D, commercially available mixed microbial (Oil Gator^{TM}) was added into the microcosms to increase the population TPH degraders. In Group E, organic material (chicken

manure) was added to increase the bacterial populations and organic carbon. In Group F, microcosm shaking (and rotation) and air replacement was provided to simulate the soil tilling and air supplement of landfarming system. Thus, in Group F, the microcosms were opened and shaken (and rotated) for 30 min once a week. After shaking, the microcosm was then sealed for further incubation.

Chemicals and sample analyses. The diesel oil was purchased from Chinese Petroleum Corp. (Taiwan) and used as received. Microcosms were incubated in the dark at 25°C. The microbial inocula used in this study were dry powders consisting of mixed cultures of oil-degrading bacteria, trade name "Oil Gator^{TM}," (Product Service Company, Jackson, Mississippi, USA), which has been approved by US Environmental Protection Agency (US EPA) for field application. Wood chips, rice husks, and chicken manures were collected from a rice mill, a lumber mill, and a chicken farm in southern Taiwan, respectively. Duplicate microcosms were sacrificed at each time point and analyzed for TPH concentrations. The TPH was characterized by the presence of hydrocarbons ranging from C_6 to C_{40} (APHA, 2001; TEPA, 2003). Five grams of soil sample collected from each microcosm was added in a 40-mL vial containing 10 mL of mixture of n-hexane/acetone (v/v, 1:1). The 40-mL vial was shaken for 24 h then spun on a Hettich-Zentrifugen EBA 21 Centrifuge for 30 min at 10,000 rpm. The supernatant was collected and stored until analysis at 4°C in the dark. Analysis of TPH extract was performed using a Hewlett-Packard 6890 gas chromatography (GC) equipped with a flame ionization detector and a DB-1 (HT) capillary column (0.32 mm x 30 m). The injector temperature was 300ºC and the detector temperature was 350ºC. The oven temperature was programmed to increase from 50ºC (5 min) to 350ºC (10 min) at 10ºC/min. Headspace gas sample was collected from each microcosm and analyzed for carbon dioxide and oxygen contents. To account for the bulking agent addition on the determination of soil TPH, the final TPH concentrations in soils were calculated by multiplying the reciprocal of soil percentage in media (soils and bulking agents). Hnu gas analyzer (Model 108) (MA, USA) was used for carbon dioxide and oxygen measurements in the headspace of microcosms.

Microbial enumeration and decay rate calculation. Microbial enumeration was performed for each group of microcosms on selected day to determine the number of total heterotrophs and total anaerobes. Total plate counts were conducted using plate count agar (Difco) to assess the approximate size of the total cultivable heterotrophic bacterial in soil samples using the spread plate method [27]. Prepared plates were incubated at 30ºC for 48 h, then counted for colony forming unit (CFU). The total anaerobes are enumerated using five-tube MPN assay [8]. The total anaerobe tubes contained media and were scored positive based on optical density. The following first-order decay model for soil TPH concentration evaluation was used to determine the first-order decay rates for TPH in the microcosms:

$$C_e = C_0 \exp(-kt) \qquad (1)$$

where C_0 is the initial TPH concentration in soil sample before treatment (mg/kg), C_e is the TPH concentration in soil sample after treatment (mg/kg), k is the temperature-dependent decay rate constant (day^{-1}), and t is the operation period (day). In this study, the treatment efficiency (percentage of TPH removal) was determined using the difference between the initial (day 0) and final (day 155) soil TPH concentrations in microcosms.

RESULTS AND DISCUSSION

Control and nutrient addition groups. Figure 1 shows the variations in soil TPH concentrations in Groups A (A1: live control; A2: dead control) and B (with nutrient

addition). TPH concentrations on Day 0 and Day 155 (the last day of incubation) in each group of microcosm were used to calculate the percentage of TPH removal. Approximately 7.2% of TPH removal was observed in A2 microcosms during the 155-day investigation period. This indicates that physical and chemical reactions had only little contributions on TPH removal in this system. TPH concentrations in A1 dropped from 5,415 to 2,953 mg/L after 155 days of incubation. Results reveal that naturally occurring microorganisms in A1 microcosms were able to degrade 45% of TPH, and caused the decrease in TPH concentrations. The trend of TPH degradation levelled off after approximately 74 to 93 days of operation. Results show that the TPH removal had a good match with the first-order decay model during the first half of the operational period from 0 to 74 days. Because the level off of TPH removal trend was observed after 74 days of operation, the first-order decay rate was calculated from day 0 to day 74. The calculated first-order decay rate for A1 was 0.0069 d^{-1}. The calculated decay rate was close to the decay rates reported in other studies (Wilson and Kolhatkar; Chen et al., 2005; Kao et al., 2005). Results from Group B microcosms show that slight higher TPH removal ratio was observed with nutrient addition. TPH concentrations in Group B microcosms dropped from 5,318 to 2,276 mg/L (Figure 1). This indicates that approximately 57% of TPH was removed after 155 days of operation. Results show that the TPH removal curve matched with the first-order decay model during the first half of the operational period, and the calculated first order decay rate was 0.0111 d^{-1} (calculated from day 0 to day 74). Results reveal that TPH bioremediation rate could be enhanced with nutrient addition. Because site soils contained intrinsic nutrient and bacteria, addition of extra nutrients only caused slight increase in TPH removal rate (Figure 1). Results from Group B microcosms also show that the TPH removal curve levelled off after 74 days of operation. This indicates that nutrient was not a limiting factor of the TPH biodegradation during the later part of incubation. Figure 2 shows the variations in measured oxygen and carbon dioxide contents in the headspace of representative groups of microcosms. Results indicate that the oxygen content dropped from approximately 20.3% on day 0 to 0.2% on day 35, and carbon dioxide content increased from approximately 0.1% on day 0 to 12% on day 35 in A1 microcosms. Similar trends of oxygen and carbon dioxide variations were observed in Group B (data not shown). This reveals that the redox conditions had been changed from aerobic to anaerobic conditions after approximately 35 days of incubation in both A1 and B microcosms. No significant changes of the oxygen and carbon dioxide contents were observed in A2 microcosms, and the observed oxygen and carbon dioxide contents remained at approximately 20 and 0.1%, respectively during the 155 days of incubation (data not shown). This indicates that biodegradation processes did not occur in the kill control group (A2). Results indicate that the total heterotrophs in A1 microcosms increased from 3.2×10^5 CFU/g of soil on day 0 to 8.1×10^5 CFU/g of soil after 30 days of incubation. Slight decrease in the populations of total heterotrophs was observed on days 70 and 155 in A1. This might be due to the fact that more biodegradable organics and oxygen were depleted during the later part of the incubation period. However, the total anaerobes in A1 increased from 5.88×10^2 cell/g of soil on day 0 to 2.8×10^4 cell/g of soil after 30 days of incubation. The populations of total anaerobes increased to 3.3×10^4 and 6.1×10^4 cell/g of soil on days 70 and 155, respectively. This indicates that the oxidation-reduction (redox) conditions in A1 microcosm became more appropriate for the growth of anaerobic microorganisms, and total anaerobes became the dominant microorganisms. The observed variation in microbial population in Group B was similar to Group A1 microcosms. This also indicates that the anaerobic degradation was the dominant biodegradation pattern after the complete consumption of oxygen.

Bulking agent addition groups. Figure 3 shows the variations in soil TPH concentrations in Groups C1 to C4 microcosms (with bulking agent addition). Approximately 74, 69, and 64% of TPH removal were observed in Groups C1, C2, and C3 microcosms, respectively. Thus, TPH removal ratio in Group C1 (volume ratio of soil to bulking agent = 3 to 1) was higher than the TPH removal rates observed from Groups C2 (volume ratio of soil to bulking agent = 5 to 1) and C3 (volume ratio of soil to bulking agent = 10 to 1). This indicates that higher volume ratio of soil to bulking agent caused higher TPH degradation rates. The addition of bulking agents in microcosm would cause the increase in soil permeability, and thus, increase the bioavailability of petroleum hydrocarbons to bacteria under both aerobic and anaerobic conditions. Although the total oxygen amount in microcosm would be the same, more efficient oxygen consumption rate and higher TPH degradation rate would occur in microcosms with bulking agents addition. After the depletion of oxygen, anaerobic biodegradation dominated the degradation processes. Again, bulking agents would increase the bioavailability of petroleum hydrocarbons to anaerobic bacteria in microcosms. Thus, higher percentage of TPH removal was observed in C1 with higher soil to bulking agent ratio after 155 days of operation. Compared with the TPH removal ratio in Group C3, results show that a slight increase in the percentage of TPH removal was observed (67% of TPH removal) in Group C4 (soil to bulking agent ratio = 10 to 1) with nutrient addition (Figure 2). Results reveal that bulking agent addition had more significant effect on TPH degradation than the effect caused by nutrient addition. Results of Groups A, B, and C also indicate that appropriate bulking agent and nutrient addition would enhance the removal of TPH. However, results from the microcosm study also indicate that TPH removal trends in Groups B and C levelled off after approximately 93 days of operation. Most petroleum hydrocarbons are biodegradable under both aerobic and anaerobic conditions. Nevertheless, rates of BTEX biodegradation under aerobic conditions are higher than those under anaerobic conditions. Aerobic bioremediation generally proceeds more quickly than anaerobic bioremediation. Organic compounds are removed more completely under aerobic biodegradation. Petroleum hydrocarbons with less molecular weights, less aromatic rings, and less branched structures are usually more biodegradable and can be biodegraded in the early stage of the biodegradation processes. Thus, more biodegradable hydrocarbons were degraded during the early part of the operational period under aerobic conditions. The less degradable components, which could not be easily degraded by intrinsic bacteria, remained in the soils for a longer period of time before removal. Thus, no significant TPH removal can be observed during the latter operational period (from day 93 to day 155). Results show that TPH decay curve followed a typical first-order degradation pattern. The first-order decay rates for Group C microcosms were calculated from day 0 to the day that the TPH removal was insignificant (day 93). The calculated first-order decay rates for Groups C1, C2, C3, and C4 were 0.0123, 0.0105, 0.0099, 0.01 d^{-1}, respectively. Although the calculated decay rates for all four groups of microcosms were close, results indicate that Group C1 with soil to bulking agent ratio of 3 to 1 had higher decay rate. The variations in oxygen and carbon dioxide contents in the headspace of C1 microcosms are shown in Figure 2. Results show that oxygen content dropped significantly after the start of the incubation (Figure 2), and it dropped to 1% after approximately 30 days of incubation. Thus, the redox conditions of the microcosms shifted from aerobic to anoxic/anaerobic conditions after 30 days. Similar variations in oxygen and carbon dioxide contents in C2 to C4 microcosms were observed (data not shown). The variation of the redox conditions also caused the decrease in TPH removal rate in the latter part of the operation. Results indicate that the total heterotrophs in C1 microcosms increased from 3.2×10^5 CFU/g of soil on day 0 to 4.4×10^6 CFU/g of soil after 30 days of incubation. Slight decrease in the populations of total heterotrophs was observed on days 70 and 155 in C1. This might be due to the fact of oxygen consumption, which inhibited the

growth of total heterotrophs. However, the total anaerobes in D1 increased from 5.88×10^2 cell/g of soils on day 0 to 7.1×10^4 cell/g of soil after 30 days of incubation. This indicates that the redox conditions in Group C1 microcosms became more appropriate for the growth of anaerobic microorganisms, and total anaerobes became the dominant microorganisms after 30 days of operation. Similar trends of microbial growth were observed in Groups C2 to C4 (data not shown). This also indicates that the anaerobic degradation was the dominant biodegradation pattern after the oxygen consumption.

Inocula addition groups. Figure 4 shows the variations in soil TPH concentrations with and without the addition of inocula (Oil Gator™), bulking agent (soil to bulking agent ratio = 10 to 1), and nutrients. Approximately 80, 83, and 85% of TPH removal were observed in Groups D1, D2, and D3 microcosms, respectively. A slight increase in TPH concentration was observed on day 35 due to the effects that some high molecular weight petroleum hydrocarbons were biodegraded and produced byproducts with lower molecular weights, which appeared within the C_6 to C_{40} range. This would also cause the regulation compliance problem at the early stage of soil remediation due to the increase in TPH concentration in soil samples. Although a slight increase in TPH concentrations was also observed in Groups A1, B, and C during the incubation period from days 40 to 50, the increment was not significant (Figure 1). This might be due to the effects that the TPH decay rates in those microcosm groups were only moderate, and thus, the accumulation of degradation byproducts would not cause a significant increase in TPH concentrations. Among Groups D1 to D3 microcosms, results show that the highest TPH degradation rate was observed in Microcosms D3 with nutrient, bulking agent (soil to bulking agent ratio = 10:1), and Oil Gator™ addition. The TPH degradation rate in Group D2 was slightly higher than the rate observed in D1. This indicates that nutrient addition was not an important factor on TPH removal. Oxygen contents in the headspace of D3 microcosms dropped from 21% to 0.1% after approximately 23 days of operation, and thus, the redox conditions of the microcosms shifted from aerobic to anoxic/anaerobic conditions after 23 days. Similar variations in oxygen and carbon dioxide contents in Groups D1 and D2 microcosms were observed (data not shown). The abrupt consumption of oxygen content could be due to the increase in microbial populations caused by the addition of oil Gator™. The variation of the redox conditions also caused the decreased in TPH removal rate in the latter part of the operation. Results indicate that the total heterotrophs in Group D1 microcosms increased from 3.2×10^5 CFU/g of soil on day 0 to 6.2×10^7 CFU/g of soil after 30 days of incubation. Slight decrease in the populations of total heterotrophs was observed on days 70 and 155 in D1. However, the total anaerobes in D3 increased from 5.88×10^2 cell/g of soils on day 0 to 3.2×10^5 cell/g of soil after 30 days of incubation. The populations of total anaerobes increased to 5.7×10^5 and 2.9×10^5 cell/g of soils on days 70 and 155, respectively. This indicates that the redox conditions in D3 microcosm became more appropriate for the growth of anaerobic microorganisms, and total anaerobes became the dominant microorganisms. Similar trends of microbial growth were observed in Groups D1 and D2 (data not shown). This also indicates that the anaerobic degradation was the dominant biodegradation pattern after oxygen consumption. Compared with the results from Groups A, B, and C, addition of Oil Gator™ in Group D could further enhance the TPH removal. Because the applied inocula, Oil Gator™, contained mixed petroleum hydrocarbon degraders, the increased microbial species and populations could increase the TPH degradation rates. Moreover, the inocula also caused the continuous removal of TPH during the later operational period although the decay rates were much lower (Figure 4). Results also show that TPH concentrations in D3 microcosms met the target level of 1,000 mg/kg after 155 days of operation (dropped to 842 mg/kg on day 155). The calculated first-order decay rates for Groups D1, D2, and D3 microcosms were 0.0143,

0.0147, and 0.015 d^{-1}, respectively, from days 0 to 74. The observed oxygen content was less than 0.1% after 23 days of operation in D3 microcosms, which shifted of redox potential from aerobic to anoxic/anaerobic conditions. This also indicates that the anaerobic biodegradation processes were the dominant biodegradation patterns after 23 days.

Organic material addition groups. Figure 5 shows the variations in soil TPH concentrations in Group E microcosms with the addition of organic material (chicken manure) and with or without the bulking agent (soil to bulking agent ratio = 10 to 1) addition. Oxygen contents in the headspace of E2 microcosms dropped from 20.7% to below 0.1% after approximately 23 days, and thus, the redox conditions of the microcosms shifted from aerobic to anoxic/anaerobic conditions after 23 days. Similar variations in oxygen and carbon dioxide contents in E1 microcosms were observed (data not shown). The abrupt consumption of oxygen content could be due to the increase in microbial population caused by the addition of chicken manure. Results show that the total heterotrophs were increased in the early stage of the incubation and decreased after 30 days of operation. This could be due to the addition of chicken manure in the microcosms. The observed total anaerobes in E2 microcosms were increased to 9.2×10^5 cell/g of soil after 30 days of incubation. This might be due to the complete oxygen consumption after 23 days, which caused the decrease in total heterotrophs and increase in total anaerobes. Again, microbial populations in E1 microcosms were similar to the observed populations in E2 microcosms (data not shown). Results also indicate that a slight increase in TPH concentration was observed in the early stage of the operational period from days 15 to 23 (Fig. 4). This might be due to the effects that chicken manure contained some organic carbons, which fell into the diesel oil range (C_6 to C_{40}), and thus, caused the increase in TPH concentrations. Similar to the degradation trends of Group E microcosms, a slight increase in TPH concentration was observed after 35 days of operation. This could be also due to the production of byproducts with low molecular weights, which appeared within the C_6 to C_{40} range. The increase in TPH concentrations in soil samples might cause the regulation compliance problem at the early stage of future field operation. Because most of the organics in chicken manure are biodegradable, TPH concentrations in both E1 and E2 microcosms dropped to below 1,000 mg/kg and met the target level of 1,000 mg/kg after 155 days of operation. Approximately 80% and 82% of TPH removal were observed in Groups E1 and E2 microcosms, respectively. The calculated first-order decay rates for E1 and E2 microcosms were 0.014 and 0.0142 d^{-1}, respectively, from day 0 to day 74. Slightly higher TPH removal rate was observed in Microcosms E2 than the rate observed in E1. This indicates that bulking agent addition in E2 also enhanced the TPH degradation through the effect of increased soil permeability. Results from five groups (A to E) of microcosm study show that chicken manure and Oil Gator™ addition had significant contributions on the improvement of TPH biodegradation. This could be due to the effect that both chicken manure and Oil Gator™ addition increased the microbial species and population in soils. Contaminated soils are often poor in organic matters, and have general low microbial activities. Bioremediation can be enhanced by introducing nutrients and organic matters, and through inoculation of enriched microbial consortia into soil. Chicken manure would serve as the source of co-substrates and nutrients to microorganisms. It might also improve the structure and water-retaining capacity of the soils. Thus, the microbial population and microbial activity would increase after the addition of chicken manure. The diversified microbial species in both chicken manure and Oil Gator™ were able to degrade most of the petroleum hydrocarbons varied from C_6 to C_{40}. Although an increase in TPH concentrations was observed in the early stage of operation, subsequent TPH removal was significant. Results indicate that addition of chicken manure was an appropriate alternative for the addition of commercial available inocula.

Microcosm shaking and air replacement group. Group F was conducted to simulate the soil tilling and air replacement caused by land farming or biopile processes with the addition of organic material (chicken manure) and bulking agent (soil to bulking agent ratio = 10 to 1). Figure 5 shows the variations in soil TPH concentrations in Group F microcosms. Results from the headspace gas analysis show that oxygen content remained high due to the air replacement process (Figure 2). Thus, the redox condition in Group F remained aerobic throughout the experiment. Results from the microbial enumeration also corresponded with the observed oxygen contents in microcosms. Results show that the populations of total heterotrophs remained high and total anaerobes remained low in F microcosms. This could be due to the addition of chicken manure and frequent air replacement of the microcosms. Results show that significant TPH decrease was observed since the beginning of the operation. This indicates that shaking and air replacement could enhance the TPH biodegradation and maintain a high TPH removal efficiency. TPH concentrations in F microcosms dropped from 5,415 to 720 mg/L after 155 days of incubation (approximately 87% of TPH removal), and the calculated first-order decay rate was 0.0196 d^{-1}. Although the final TPH concentration in F was only slightly lower than the observed final TPH concentrations in Groups D2, D3, and E2 microcosms, the calculated decay rate for Group F microcosms was higher. Thus, the incubation time or remediation time can be significantly reduced. Because the microcosms in Group F were opened for air supplement, the mechanism of volatilization might be also the cause of increased degradation efficiency. Results also reveal that air quality monitoring should be performed if landfarming or biopile systems are applied for the remediation of petroleum-hydrocarbon contaminated soils due to the occurrence of volatilization mechanism. Results from the microcosm study indicate that the residual compounds are not easily biodegraded under both aerobic and anaerobic conditions. Thus, more aggressive remedial measures (e.g., chemical oxidation, soil washing) are required if the soil remediation goals are more stringent than the action level (1,000 mg/kg) applied in this study.

CONCLUSIONS

In this study, batch microcosm experiments were conducted to assess the potential of application of enhanced bioremediation processes to clean up diesel-oil contaminated soils. The laboratory microcosm experiments were conducted to determine the optimal biodegradation conditions of diesel-oil hydrocarbons. Conclusions obtained from this study include the following:

(1) Addition of nutrient, commercially available mixed microbial inocula (Oil Gator™), bulking agents, and organic materials (chicken manure) would enhance the efficiency of TPH biodegradation. Higher first-order TPH decay rates were observed in microcosms with the addition of chicken manure (decay rate = 0.0142 day^{-1}) or mixed microbial inocula (decay rate = 0.015 day^{-1}). Thus, chicken manures have the potential to be used as substitutes of commercial microbial inocula. TPH decay rate was only 0.0069 day^{-1} in microcosms under intrinsic conditions.

(2) The TPH decay rate and removal ratio can be further enhanced to 0.0196 day^{-1} and 87%, respectively, with frequent soil shaking and air replacement.

(3) Less TPH removal efficiency was observed in the later stage of the incubation in microcosms without air supplement. This might be due to the following two effects (a) complete oxygen consumption, and (b) the remaining compounds or byproducts might be less biodegradable, which caused the decreased TPH removal rates.

(4) The decreased oxygen and increased carbon dioxide contents in the headspace of microcosms indicate the occurrence of aerobic biodegradation. Moreover, the increased total heterotrophs in the early stage and increased total anaerobes in the later stage of the microcosm study also confirmed the shift of aerobic biodegradation to anaerobic biodegradation pattern when complete oxygen consumption was observed.
(5) Addition of organic materials (chicken manure) would increase the microbial population, and thus, caused the increased TPH removal rate. However, addition of chicken manure would also cause the increase in TPH concentration and regulation compliance problem in the early stage of the operation.

This performance study provides us insight into the characteristics and kinetics of diesel-oil contaminated soils remediation by enhanced bioremediation. These findings would be helpful in designing an ex-situ field-scale bioremediation system (e.g., landfarming or biopile) for practical application.

Abstract

Enhanced polymerization of phenolic contaminants induced by the application of the enzyme horseradish peroxidase (HRP) has drawn attention of many researchers due to its potential for remediation of contaminated soils. This study utilized 2,4-dichlorophenol (DCP) as a probe solute to evaluate the ability of HRP to stabilize pesticide derivatives in a model humin-mineral geomaterial. The model soil was derived from a natural surface soil treated with alkali to remove humic and fulvic acids. The resulting humin-mineral material had SOM content and chemical characteristics that were different from the parent soil. Sorption of DCP was complete within 24 hrs and most of the sorbed DCP was removed from the geomaterial by water and methanol suggesting weak solute-sorbent interactions. Phase distribution of DCP polymerization products (DPP) also appeared to be complete within 24 hrs, but a significantly higher amount of the solute was stabilized in the presence of HRP. The total extractable solute decreased, and DPP bound residues increased with contact time and initial solute concentration. These results illustrate the potential of utilizing HRP-mediated oxidation for in situ stabilization of pesticide derivatives, such as DCP, in humin-mineral geomaterials representative of soils found below the root zone.

Background

Enhanced polymerization of phenolic contaminants induced by the application of the enzyme horseradish peroxidase (HRP) has drawn attention of many researchers due to its potential for remediation of contaminated soils. Sorption and binding of phenolic contaminants to the humin component of SOM is of interest due to the latter's abundance

in soil, representing up to 50% of soil organic carbon (Kononova, 1966), and due to humin's strong interactions with organic pollutants in the subsurface (Kohl and Rice, 1998). This study utilized 2,4-dichlorophenol (DCP) as a probe solute to evaluate the ability of HRP to stabilize pesticide derivatives in a model humin-mineral geomaterial.

Methodology

The model soil was derived from a natural surface soil (3.2% SOM) treated with alkali to remove humic acid (HA) and fulvic acid (FA). Detailed information about the parent surface soil is provided elsewhere (Lesan and Bhandari, 2003). HA and FA removal required a total of 42 sequential fill-and-withdraw extraction cycles with alkali. The alkali-extracted soil was thereafter conditioned by 10 washes with distilled-deionized water, 10 washes with pH 7 phosphate buffer to neutralize pH, and finally 10 washes with $CaCl_2$. Dried soil material was homogenized and stored in the refrigerator at 1 °C until further use. The alkali extracted soil or humin-mineral (HM) soil contained a total of 1.1 % SOM as humin.

Solute sorption and extraction procedures have been described by Palomo and Bhandari (2005). Water and methanol extractable solute was defined as the "solvent extractable" fraction, which represented the fraction of solute slowly released from soil. Sorption was conducted at five different initial DCP concentrations (ranging from 0.5 to 500 μM) and three contact times (1, 7 and 28 days). Experimental procedures were carried out in absence (DCP only) and presence of HRP. Addition of HRP to the systems induced the formation of dichlorophenol polynmerization products (DPP).

Results and Discussion

The phase distribution of solute between water and the humin-mineral soil was complete within 24 hrs for both DCP and DPP; no significant increase in the levels of sorbed solute was observed beyond 1 day. At all initial solute concentrations, DPP sorption was significantly higher than that observed for DCP only (Figure 1). The solute removed by solvent extraction was reduced upon addition of HRP. Thus, the total solute stabilized was significantly increased when the phenolic polymerization was induced

(Figure 1). At 500 μM, the sorbed mass of DCP and DPP was 602 and 2234 μmole/kg, respectively. While the stabilized mass of DCP and DPP was 11 and 512 μmole/kg, respectively, respectively.

Most of the sorbed DCP was removed from the geomaterial through solvent extractions, suggesting weak solute-sorbent interactions. The total extractable solute decreased, and DPP stabilized residues increased with contact time and initial solute concentration (Figure 2).

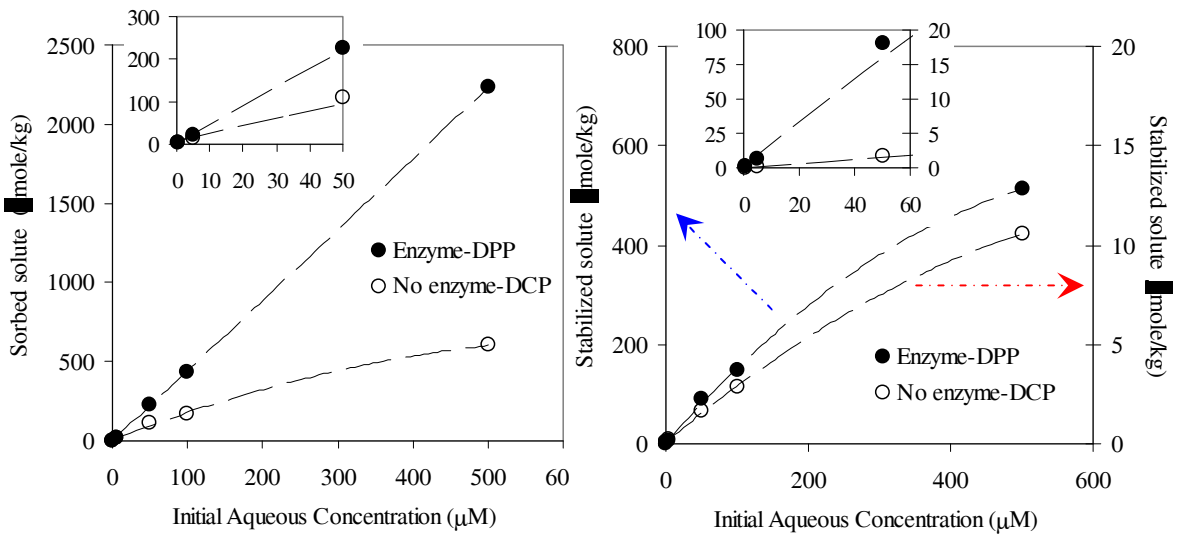

Figure 1- Sorbed (left) and stabilized (right) solute in the absence or presence of enzyme, 7 days of contact time, humin-mineral fraction of agricultural soil.

The utilization of HRP to induce polymerization of DCP was successful and it increased the quantity of mass initially sorbed to the soil. Dichlorophenol polymerization products included precipitated oligomers of DCP, oligomers formed by cross coupling of SOM and DCP, soluble oligomers and sorbed DCP trapped in the soil structure. Solute distribution results showed that, for both DCP and DPP, the extractable fraction decreased and the stabilized residue increased as a function of contact time.

A comparison of the HM sorption results to those obtained for the parent soil (AG) is shown in Figure 2. In the absence of enzyme, significantly more DCP was sorbed to AG (~1089 μmole/kg,) than to HM (~601 μ mole/kg). However, the masses of stabilized residues at the end of the 28 days of contact were comparable (25 and 18 μmole/kg, for AG and HM, respectively). When HRP was added, sorption to AG and HM was 1959 and 2211 μmole/kg, respectively. While the mass of DPP sorbed to HM was higher than the mass sorbed to AG, the amount of DPP stabilized in the soil was slightly higher for AG soil (795 and 636 μmole/kg, for AG and HM, respectively). However, the amount of stabilized chemical was not proportional to the SOM content. Results show high affinity of HM toward DPP, indicating that the chemical characteristics of humin compensate for the reduction of SOM content. These results illustrate the potential of utilizing HRP-mediated oxidation for in situ stabilization of pesticide derivatives, such as DCP, in humin-mineral geomaterials representative of soils found below the root zone.

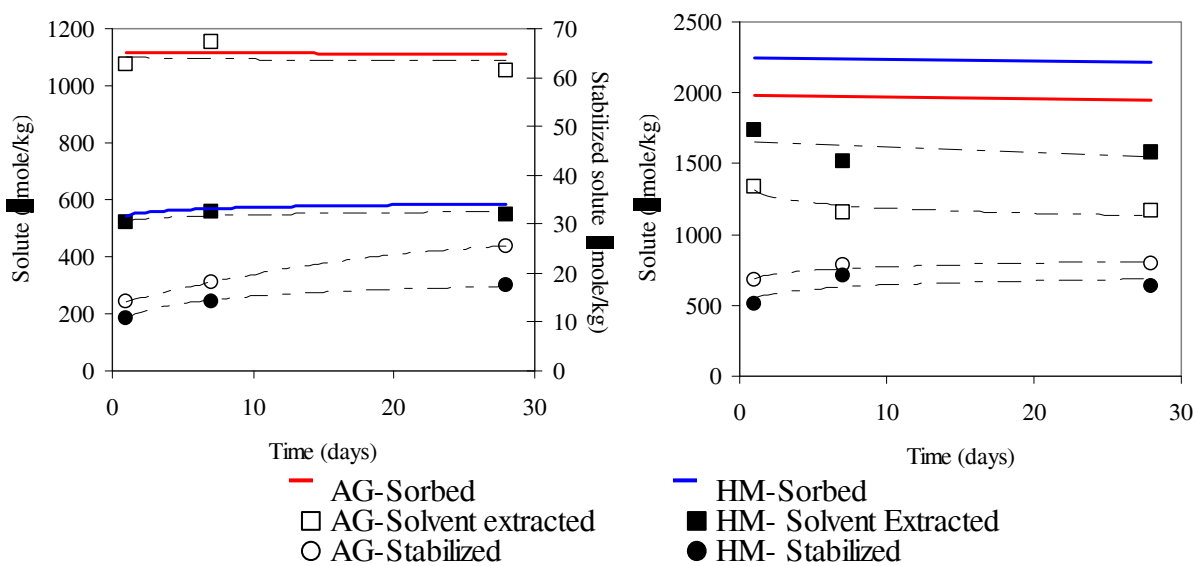

Figure 2- Solute distribution as function of contact time. On the left DCP only (no enzyme added), on the right DPP (enzyme added), C_o=500 μM. Humin-mineral results are in solid symbols, surface soil data in hollow symbols. Solid lines represent the total solute sorbed.

pH variation and its effect on metal concentration during electrokinetics

Ming Xiao[1] PhD, PE, M. ASCE, and Ashleigh D. Love[2], Zheng Teng[3], PhD, PE

Extended Abstract for

the ASCE-EWRI World Environmental & Water Resources Congress 2009 (EWRI09)
Topic: Environmental
Sub-Topic: Soil and Subsurface Remediation

Extended Abstract

Heavy metal contaminated soils pose significant threat to the environment and human health. Electrokinetic remediation is an emerging remedial technology that removes the contaminants from silty or clayey soils by applying an electric potential across contaminated and saturated soils using a pair of electrodes. The anode attracts negatively charged contaminants, and the cathode attracts positively charged contaminants, such as heavy metal ions. When the cationic contaminants reach the cathode, they can be pumped out with the contaminated water and disposed or treated safely. However, the electrokinetics is complicated by the metal precipitation before the metal ions can reach the cathode. This is caused by electrolysis that occurs at both electrodes. At the anode, water is oxidized, releasing oxygen and creating H^+ that results in an acid front moving towards the cathode. At the cathode, hydrogen is evolved and a base front of hydroxyl ions (OH^-) is generated and moves to the anode. The metal ions migrating toward the cathode tend to react with OH^- when they reach the base front to form metal hydroxides, which precipitate from the pore fluid as solid form.

The pH of the pore solution is a dominant variable that appears to control electroosmosis and contaminant migration in clays (Eykholt and Daniel, 1994; Acar and Alshawabkeh, 1996; Reddy et al., 1997). The reactions that are directly regulated by pH include adsorption and desorption, dissolution and precipitation, complexation and speciation (Hicks and Tondorf, 1994). The effectiveness of electrokinetics depends on achieving an acidic pH in the soil such that the metal ions are not adsorbed to soil surface and remain mobile in pore fluid. The experiments by Eykholt (1992) indicated the sharp pH front developed within several days and persisted within the cathode region of the soil throughout the testing period. Since ionic mobility of the hydrogen ion is about 1.8 times that of the hydroxyl ion (Acar and Alshawabkeh, 1993), the acid and base fronts usually

meet at regions close to the cathode. For example, Probstein and Hicks (1993) found that the pH jump, which is the sharp increase of pH where the acid and base fronts meet, occurs at 2/3 of the total distance from the anode; and Al-Hamdan and Reddy (2008) observed the pH jump occurred at 0.74 of the total distance from anode. A test by Yu and Neretnieks (1996), however, showed that the pH jump moved to anode in sand, possibly caused by the adsorption of hydrogen ions in the sand.

pH was usually measured longitudinally in laboratory and field tests. Whether and how pH varies with depth is unknown. Meanwhile, variation of metal ion concentrations with depth was reported in the literature. Alshawabhek et al. (2005) observed transverse upward migration of metal ions and an increase in concentrations in the upper few centimeters of the soil; they attributed this phenomenon to the evaporation and upward pore fluid flow. Pilot tests by USAEC (2000) showed a significant increase in metal concentrations of cadmium and chromium as the soil depth decreased from 10ft to 5ft.

This paper reports the experimental work that aims to identify the possible causes of vertical variation of metal ion concentration, such as pH and water content. A sandy clay is spiked with lead chloride ($PbCl_2$). The soil is uniformly compacted and then saturated in a Plexiglas soil box (30cm long, 12.7cm wide, 20cm tall). Electrokinetic geosynthetics (EKG) is used as electrode. EKG is an electrically conductive geosynthetic material and was recently explored in the UK (Jones et al., 2005, 1996; Kalumba and Glendinning, 2006). EKG materials are formed by incorporating conductive elements with the traditional geosynthetics, or the geosynthetics is made of or coated with conductive polymer. Use of EKG has not been reported in the US, and commercial manufacturing of EKG is not available. In this research, graphite rods (2.7mm in diameter) are tired together and bonded to geogrid to serve as electrodes. Graphite is electrically conductive and does not introduce new ions into the soil. The electrodes are connected to a DC power supply, which can supply adjustable voltage from 0 to 100V. Constant-voltage method is used, and the voltage gradient is maintained at 1V/cm. Five perforated tubes are pre-installed in the soil, so that pH probes can be inserted into the tubes to measure the pH in the pore water at different depths, longitudinal locations, and time. A small solid-stem flight auger (0.5inch in diameter) is used to retrieve soil samples during the process of the test, and lead concentrations at different depths, longitudinal locations, and time are measured using the inductively coupled plasma spectroscopy (ICP). The retrieved soil samples are also tested for water content. The results are analyzed to identify possible effects of pH and water content on metal concentration during electrokinetics.

Pore-scale Characterization of Residual Non-aqueous Phase Liquids (NAPLs) in Fractional Wettability Porous Media

Riyadh I. Al-Raoush

Department of Civil and Environmental Engineering, Southern University and A&M College, Baton Rouge, LA 70813, Tel: (225) 933-7780, Fax: (225) 771-4320, Email: riyadh@engr.subr.edu

Abstract

The objective of this research was to investigate the impact of wettability of porous media on pore-scale characteristics of residual non-aqueous phase liquids (NAPLs). Synchrotron X-ray microtomography was used to obtain high-resolution 3D images of fractional wettability sand systems. Pore-scale characteristics of NAPL blobs such as volumes, lengths, interfacial areas and shape factors were computed from the 3D images. Four systems of different NAPL-wet mass fractions containing the residual NAPL were imaged and analyzed. In systems comprised of 100%, 50%, 25%, and 0% NAPL-wet mass fractions, residual NAPL saturations were 0.125, 0.067, 0.083, and 0.121; mean blob volumes normalized by the volume of a sphere with mean grain diameter were 0.97, 1.23, 1.93, and 2.39; normalized mean blob interfacial areas were 43.75, 35.86, 34.25, and 30.88 mm^{-1}; and mean sphericity index values were 0.216, 0.262, 0.455, and 0.569, respectively. Findings revealed that spatial variation in the wettability of porous media surfaces has a significant impact on pore-scale characteristics of residual NAPL blobs in saturated porous media systems.

1.0 Introduction

The release of non-aqueous phase liquids (NAPLs), such as gasoline and chlorinated solvents, into the subsurface can lead to groundwater contamination. As NAPLs migrate downward through a porous medium, residual portions are entrapped in the complex void space due to capillary forces and serve as a long-term source of groundwater pollution. Pore-scale characterization of the residual NAPL phase is required for the assessment, design and implementation of an efficient cleanup and remediation strategy.

Different methods have been used for pore-scale characterization of NAPLs in porous media. Main techniques include direct observation of NAPLs in the pore space (Chatzis and Morrow, 1983; Conrad et. al., 1992; Mayer and Miller, 1992; Wardlaw and McKellar, 1985; Powers et. al., 1992), 2D micromodels (Sahloul et. al., 2002; Chomsurin and Werth, 2003) and 3D imaging techniques (Johns and Gladden, 1999; Al-Raoush and Willson, 2005; Culligan et. al., 2006; Goldstein, et. al., 2007).

While these investigations provide valuable insights on the characteristics of NAPLs, they all assume uniform wettability of the porous media (i.e., either water-wet or NAPL-wet systems). In water-wet systems where the solid surfaces are preferentially wetted by water, residual NAPL is entrapped in larger pore bodies as disconnected volumes which range in complexity from simple singlets which occupy single pore bodies to complex ganglia that extend in length to occupy multiple pore bodies.

Spatial variation in wettability is common in natural subsurface systems where a combination of water-wet and NAPL-wet solid surfaces can be found. This type of porous media is called fractional wettability porous media. Variations in wettability of natural subsurface systems occur due to variations of porous media properties such as mineral composition, organic matter distribution, surface roughness and sorption of active agents to the surface of the porous media (Anderson, 1986; Powers and Tamblin, 1995). Spatial variation of wettability has a significant impact on pore-scale distribution and configuration of residual NAPL in subsurface systems, which in turn influences pore-scale displacement mechanisms (McDougall and Sorbie, 1995; Harrold et. al., 2001; Peri and Blunt, 2007) flow (Hui and Blunt, 2000; Jackson et. al., 2003; Karabakal and Bagci, 2004), NAPL-water interfacial area (Bradford and Leij, 1997; Jain, 2003), NAPL dissolution (Bradford and Abriola, 2001; Zhao et. al., 2007), capillary pressure and relative permeability (Masalmeh, 2003; Gladkikh and Bryant, 2006), residual phase saturation (Lackner and Torsaeter, 2006), and infiltration of fluids into porous media (Munehide and Tomokasu, 2008).

The objective of this research was to investigate the impact of fractional wettability of porous media on the characteristics of residual NAPLs. High-resolution 3D mages of different fractional wettability sand systems were obtained using synchrotron X-ray microtomography. Quantification of the morphology and entrapment patterns of residual NAPL was obtained using 3D image processing algorithms.

2.0 Materials and Methods

2.1 Materials

A uniform fine sand of median size (D_{50}=250 μm) was used as the porous medium. A uniform size of grains was selected to eliminate the impact of heterogeneity of the grains while investigating the impact of wettability on the morphology of residual NAPL phase. Immiscible fluids used in the experiment were de-aired water (represents the aqueous phase) and Soltrol 220 (Chevron Philips Chemical Company). Soltrol 220, a mixture of C_{13}-C_{17} hydrocarbons, was used to model organic contaminates since it has properties similar to common hydrocarbon contaminants. Soltrol was doped with Iodononane (10% by mass) to enhance its contrast in the images. After preliminary imaging of the system, it was observed that the contrast of the images was sufficient to extract (i.e., segment) the organic fluid (i.e., Soltrol) in the image without the need to dope the aqueous phase. The density and viscosity of the aqueous solution are 0.97 gm/cm^3 and 1.02 cP, respectively; and for the doped soltrol, 0.78 gm/cm^3 and 4.79 cP, respectively.

Octadecyltrichlorosilane (OTS) (Acros Organics) was used to create NAPL-wet sand system following the procedure presented in (Bradford and Leij, 1996). The procedure is summarized as follows: a solution was created by adding 5% by volume of OTS to ethanol. The solution was then added to untreated sand (i.e., water-wet) until it became completely saturated; the mixture was stirred for several hours. The mixture was rinsed off with ethanol that removed most of the OTS, and then evenly placed in a pan in a vented area to air dry overnight. The remaining mixture was cured in an oven at 100°C for an hour to allow the remaining ethanol to be evaporated. Fractional wettability systems were obtained by combining various mass fractions of untreated and OTS-treated sands. Systems will be designated herein by their percentage of OTS-treated sand (i.e., equivalent NAPL-wet mass fraction). Four different systems containing the residual NAPL were imaged; 100%, 75%, 50%, and 0% OTS-treated mass fraction (i.e., NAPL-wet mass fractions, respectively).

2.2 Creation of residual NAPL saturation

A special cell was fabricated to establish the residual NAPL in the saturated fractional wettability systems and to be mounted in the tomography station for imaging. The cell consisted of a column of polycarbonate connected to aluminum end fittings to allow insertion of tubes to perform drainage and imbibition of fluids. The height of the column was 83.5 mm and the inside diameter was 6.0 mm. Porous polypropylene frits (10 μm) were placed at both aluminum ends of the columns to retain the porous media and to ensure homogenous injection and displacement of the immiscible fluids.

Fractional wettability sand systems were packed under dry conditions to ensure homogenous distribution of sand grains in the column. Approximately 2.0 pore-volumes of de-aired water were injected vertically upward through the column at a constant rate of 2.5 ml/hr using a syringe connected to a Cole-Parmer Series 74900 syringe pump. The doped Soltrol was then injected vertically upward at the same constant flow rate used for the de-aired water. Water was finally flushed through the column to displace the NAPL and create the residual NAPL saturation.

2.3 Microtomography imaging

The systems were imaged using synchrotron X-ray microtomography at the GeoSoilEnviroCARS 13-BM-C beamline at the Advanced Photon Source, Argonne National Laboratory, IL. Image resolution is 7.47 μm/pixel in all 3D directions. To avoid boundary effects on the spatial distribution and configurations of immiscible fluids, scans were obtained approximately at mid portions of the columns. Multiple scans were obtained at different locations of each column to obtain large volumetric images. Image reconstruction was performed using algorithms developed by GSECARS to convert CT attenuation data to 3D volumetric data. Each microtomography scan allowed obtaining an image of 600x600x520 voxels (i.e., cubic domain inside the column to avoid boundary effects), where the third dimension is the vertical dimension. For each system, three different scans were obtained at different vertical locations and then stacked to obtain larger images of size 600x600x1200 which were used in the analysis of residual NAPL characterization.

2.4 Characterization of residual NAPL from 3D images

Volume, interfacial area, lengths and shape factors of NAPL blobs were computed using the algorithms developed in (Al-Raoush and Willson, 2005; Lorensen and Cline, 1987). More details can be found in these references.

3.0 Results and Discussion

Fig. 1 shows an example of NAPL residual blobs obtained from 3D imaging of the 0% OTS system, only a portion of the entire image used in analysis is shown in the figure. The color scheme in the image reflects blob identification where blobs are labelled by distinct numbers (shown as different colors in the image). Porosities obtained from images are 0.331, 0.327, 0.334, and 0.325 for the 100%, 50%, 25%, and 0% OTS-treated systems, respectively. Residual NAPL saturations are 0.125, 0.067, 0.083, and 0.121 for the 100%, 50%, 25%, and 0% OTS-treated systems, respectively. The trend of residual NAPL saturations is similar to the ones reported for fractional wettability systems given in (Morrow, 1975; Powers et. al., 1995) where residual NAPL saturations are less in fractionally wet systems (i.e., 50% and 25% OTS-treated systems in this work) and increase as the systems become more NAPL-wet or water-wet.

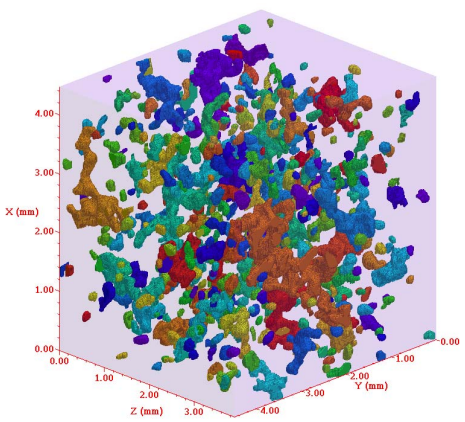

Figure 1: 3D image of residual NAPL extracted from the 0% OTS system.

Fig. 2 shows frequency distributions of blob volumes normalized by the volume of a sphere that has a diameter equivalent to the median grain diameter, D_{50}. In all systems, NAPL blobs vary greatly in size and complexity by orders of magnitude. As can be seen in figure, wettability of the porous medium has a significant impact on sizes of residual NAPL blobs and their distributions in the void space. In the 100%OTS-treated system, blobs have preference for entrapment in small pores, corners, and at contacts of solid surfaces through continuous thin NAPL films. Note that NAPL films are not resolved at the resolution of images in this paper. Therefore, NAPL blobs are distributed in the void space by large numbers with small volumes which makes the total magnitude of residual saturation high. Mean blob volumes normalized by the volume of a sphere with median grain diameter, D_{50}, are 0.97, 1.23, 1.93, and 2.39; and the maximum normalized volumes are 8.81, 13.66, 16.79, and

21.74, for the 100%, 50%, 25%, and 0% OTS-treated systems, respectively. Note that maximum normalized volumes are not shown in the figure to enhance the visualization. A trend of decrease in mean blob volume (i.e., individual blobs) is observed as more fractions of the porous media rendered NAPL-wet indicating that spatial distribution of wettability controls locations and entrapment patterns of residual NAPL blobs. This in turn influences processes such as relative permeability and pressure saturation relations. In a complete NAPL-wet system, the effective permeability to NAPL is much lower than in water-wet systems (at any given saturation) because water in the larger pores hinders the flow of NAPL. This becomes more pronounced as the water saturation increases until the residual NAPL saturation is obtained at higher levels than it would be in a water-wet system. On the other hand, the effective permeability to water is high because residual NAPL is located in the small pores and is coating the larger pores with a thin film which does not affect the flow of water. The relative permeabilities are controlled by the distribution of the fluids in the pores of the void space. The relative permeability of a fluid at any saturation is a function of its mobility, which in turn is a function of capillary size and wettability. The wetting phase has a lower mobility if it is located in the smaller pores and is adhering to the surface of the porous media. However, in a water-wet system, where NAPL occupies the large pores and most of them are coated with a thin water film, NAPL flow occurs through the larger pores where the NAPL is located, water does not exist to impede the flow of NAPL, the NAPL effective permeability, relative to water, is very high. On the other hand, the water effective relative permeability is very low, even when the NAPL saturation are reduced to the residual level**,** because residual NAPL in the large pores remains to effectively block the flow of water.

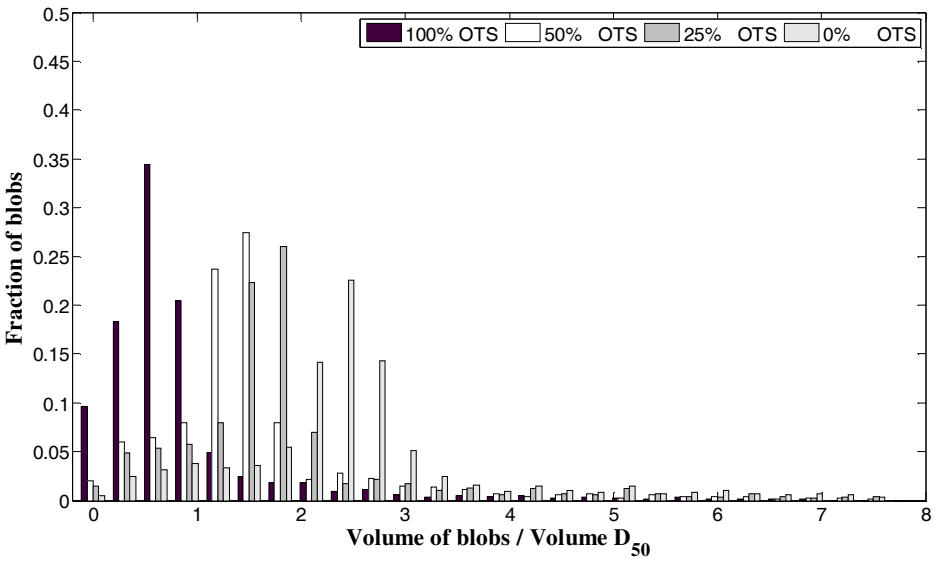

Figure 2: Frequency distributions of blob volumes normalized by the volume of a sphere that has a diameter equivalent to the D_{50} of grains

Fig. 3 shows frequency distributions of blob maximum lengths normalized by the D_{50}. Normalized mean blob lengths are 1.10, 1.45, 1.67, and 1.96; and the maximum normalized lengths are 6.27, 11.31, 10.13, and 15.21, for the 100%, 50%, 25%, and 0% OTS-treated systems, respectively. Note that maximum normalized lengths are not shown in the figure to enhance the visualization These data indicate that as the porous medium comprises more water-wet surfaces, residual NAPL blobs increase in size and length due to the entrapment preferences discussed previously.

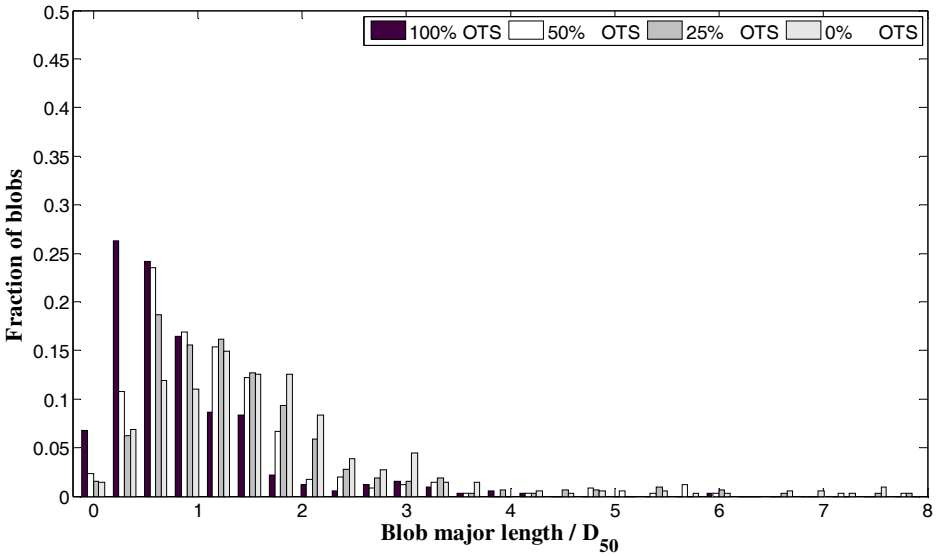

Figure 3: Frequency distributions of blob major lengths normalized by the D_{50} of grains

Fig. 4 shows frequency distributions of NAPL-water interfacial areas normalized by the volume of each blob. Normalized mean blob interfacial areas are 43.75, 35.86, 34.25, and 30.88 mm^{-1}; and the maximum normalized interfacial areas are 112.43, 81.2, 94.78, and 71.90 mm^{-1}, for the 100%, 50%, 25%, and 0% OTS-treated systems, respectively. Note that some maximum values are not shown in the figure to enhance the visualization. Normalized interfacial areas reach the highest mean value in the completely NAPL-wet system (i.e., 100% OTS-treated) and the lowest mean value in the completely water-wet system. The trend of the normalized interfacial areas obtained in this work is similar to the one observed experimentally in (Bradford and Abriola, 2001). This is mainly because blobs tend to decrease in size and assume more spherical shapes as NAPL-wet surfaces increase in the system. This observation becomes apparent as the normalized interfacial area of each individual blob is compared to that of a perfect sphere of equivalent volume; small blobs tend to assume spherical shapes compared to large blobs which usually assume more irregular and branched shapes. This can be seen clearly in Fig. 5 which shows frequency distributions of sphericity index (shape factor) for all systems. Mean sphericity index values are 0.216, 0.262, 0.455, and 0.569; and maximum values are 0.857, 1.507, 1.507, and 1.990, for the 100%, 50%, 25%, and 0% OTS-treated systems,

respectively. Distributions of sphericity index for all systems are consistent with distributions of volumes and lengths provided in Fig.2 and Fig. 3, respectively.

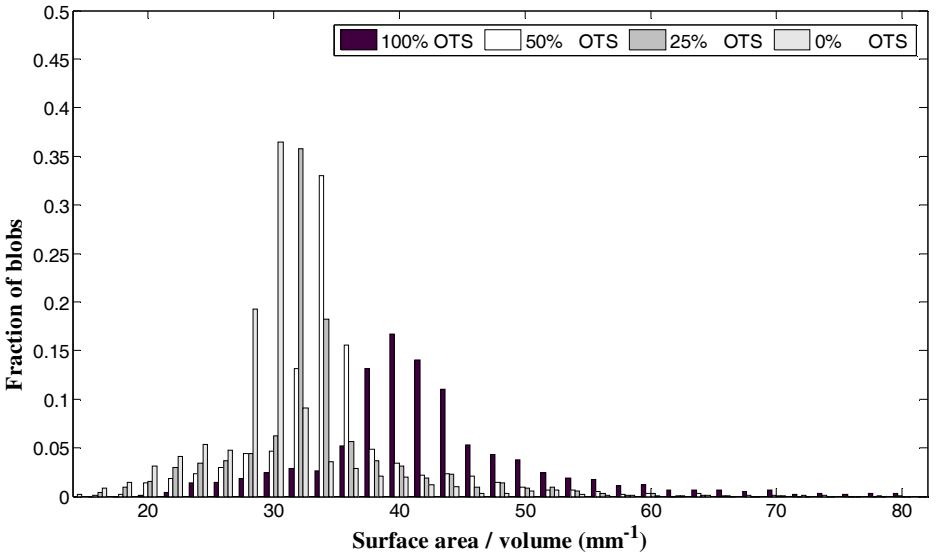

Figure 4: Frequency distributions of NAPL-water interfacial areas normalized by the volume of each blob

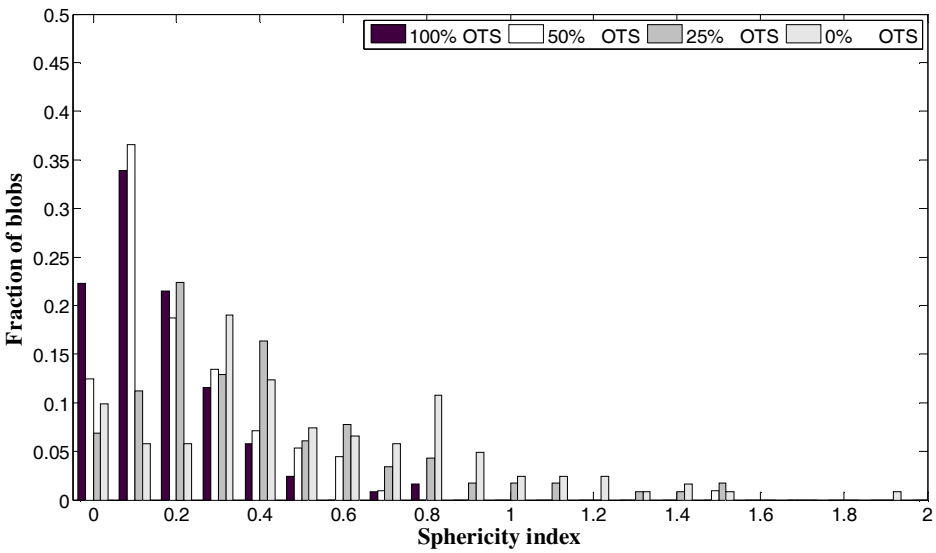

Figure 5: Frequency distributions of sphericity index (shape factor) for all systems

4.0 Conclusions

Findings indicate that spatial variation in wettability of porous media has a significant impact on pore-scale characteristics of residual NAPL blobs in saturated porous media systems. As the porous medium comprises more water-wet surfaces, residual NAPL blobs increase in size and length due to the entrapment at large pore bodies.

Therefore, NAPL-water interfacial areas are smaller in NAPL-wet systems where blobs tend to be more spherical and less branched. Overall residual NAPL saturations are less in fractional wettability systems and increase as the systems become more NAPL-wet or water-wet.

Acknowledgments
This research was performed, in part, at Argonne National Laboratory as a research participant in the FaST Program. The program is administered by Argonne's Division of Educational Programs with funding provided by the U.S. Department of Energy and the National Science Foundation (Contract No. HRD-0310426). The experiment was performed at the GeoSoilEnviroCARS beamline (13-BM-C) at the Advanced Photon Source. GeoSoilEnviroCARS is supported by the National Science Foundation Earth Sciences (EAR-0217473), Department of Energy Geosciences (DE-FG01-94ER14466), and the state of Illinois. Use of the APS was supported by the U.S. Department of Energy, Basic Energy Sciences, Office of Energy Research, under contract No. W-31-109-Eng-38. I would particularly like to thank Maude Johnson, Meagan Pinkney and Lindsey Thomas (Southern University and A&M College), Dr. Mark Rivers and Dr. Peter Eng (GeoSoilEnviroCARS) for their assistance with the imaging portion of this work.

ABSTRACT

The City of Wichita, Kansas faced a significant environmental challenge when volatile organic compounds impacted a large volume of groundwater extending south of the downtown area to the Arkansas River. This contaminated groundwater posed a threat to human health and the environment and threatened to stagnate economic development as a result of the environmental liability concerns across the project area that encompasses about 3,850 acres and 8,000 parcels of residential, commercial, and industrial properties.

The City, with CDM's assistance, investigated the contaminated groundwater, designed and built a groundwater treatment system to protect human health and the environment, and designed and built the Wichita Area Treatment, Education, and Remediation Center (WATER Center) to provide environmental education resources for the entire Wichita community. The City has turned an environmental liability that threatened human health into an environmental education resource for current and future generations.

1.0 INTRODUCTION

In the early 1990's, the City of Wichita, Kansas (City) faced a significant groundwater contamination issue that consisted primarily of tetrachloroethene (PCE), trichloroethene (TCE), *cis*-1-2-dichloroethene (*cis*-1,2-DCE), and vinyl chloride (VC). Investigative efforts resulted in the delineation of a groundwater plume more than four miles long and a mile-and-a-half wide. This plume of contaminated groundwater extended beneath some 8,000 parcels of land, including more than 550 businesses and hundreds of residential properties. The area was named the Gilbert-Mosley Site (Site) after two streets that intersect near the location at which the contamination was first detected.

The contaminated groundwater threatened human health and the environment, and it also threatened to create significant economic problems. Faced with their own questions of liability, banks immediately stopped lending to business and home buyers in the area.

Unless a solution was developed quickly, the federal government would have most likely classified the Site as a Superfund site, aggravating what already promised to be a long and costly problem. The potential costs quickly added up when projections indicated that if the Site would have entered the Superfund program the property values for the area would decrease by 40% or more, thus creating a financial burden on the taxing entities (city, county, and school district).

The City decided to take the initiative and develop a plan to clean up the Site. A unique partnership between the public and private sectors was established, involving intergovernmental partnerships with local, state, and federal government support, along with participation from the private sector — banks, responsible parties (industry), and the real estate community. The plan's fundamental premise would be the City's acceptance of responsibility for the cleanup of the Gilbert-Mosley Site in exchange for funding commitments from public and private sector partners.

The public funding was established through a new type of tax increment financing (TIF) district in which a decremental type of tax was used to fund the cleanup. This decremental TIF required Kansas State laws to be modified by the legislature. This system allowed the City to maintain property values and use 20% of the 1991 tax value for the Site cleanup. The taxing partners had to agree in order for the funding to be secured. Both the Sedgwick County and USD 259 school district agreed to the decremental TIF in order to prevent a much more significant loss (estimated at 40% or more) of property tax values and tax income.

2.0 SITE HYDROLOGY

Figure 1 shows the location of the Site, the Site boundaries, and the various contamination plumes. The Site is approximately 3,850 acres in size, covers an area approximately 4.4 miles long from north to south, and varies in width from 1.1 to 2.1 miles from west to east. The Site is situated within the Arkansas River floodplain, and the topography of the Site has little relief. The Arkansas River is the most prominent surface water feature and flows towards the south near the western border of the Site and then turns east, south of the Site.

The geology of the Site consists primarily of Arkansas River Valley alluvium and associated terrace deposits overlying the Wellington Formation bedrock. The Wellington Formation is primarily a gray and blue shale of Permian Age. The alluvial sediments consist of interbedded gravels, sands, silts, and clays. The alluvial sediments have a thickness of between 24 and 54 feet and average 30 feet in depth across the Site.

The depth to groundwater across the Site is shallow and in the alluvial aquifer - ranging from 16 to 20 feet across the Site and averaging 18 feet below ground surface. Groundwater levels in the alluvial aquifer fluctuate seasonally and may vary as much as 3 feet, depending on the proximity to the Arkansas River, their flow levels, and the amount of precipitation received. General groundwater flow is to the south, with a gradient

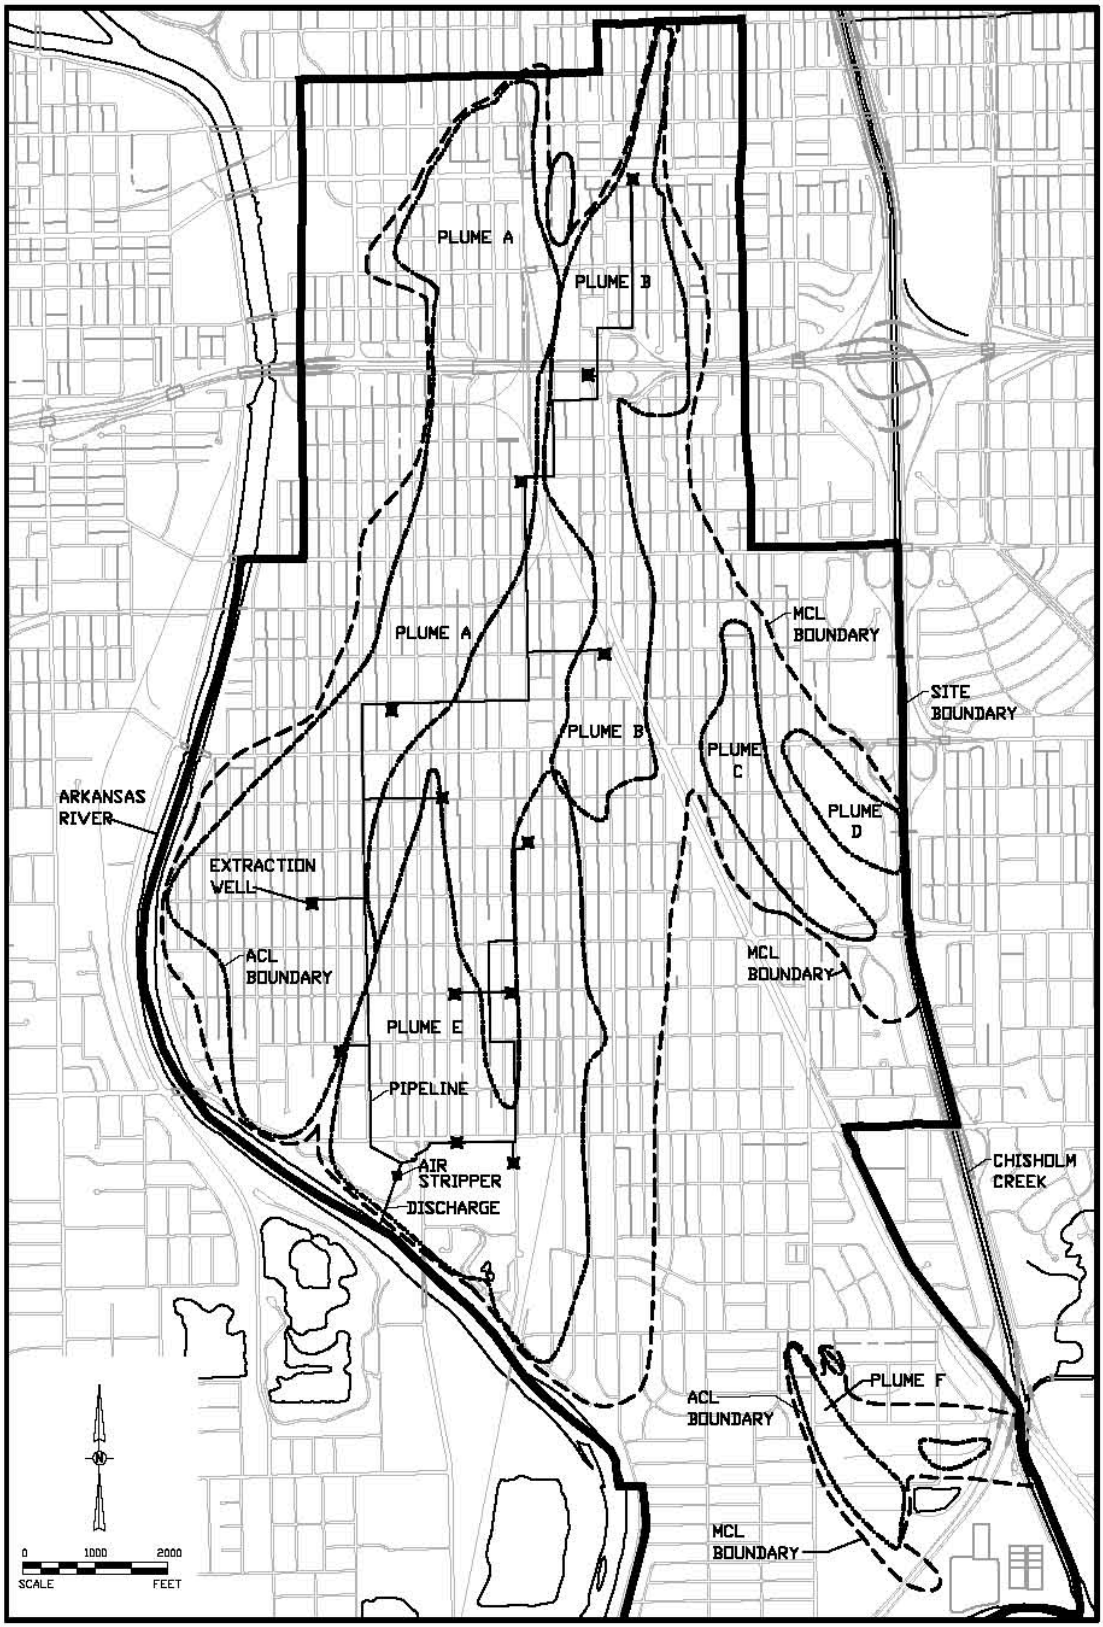

Figure 1: Gilbert-Mosley Site

between 0.0007 and 0.0014 feet/foot across the Site, and the hydraulic conductivity ranges between 380 and 707 feet per day. An average groundwater velocity for the Site, as determined from the calibrated flow model, ranges from 1.2 to 1.7 feet per day.

3.0 INVESTIGATION OF CONTAMINATION

The present boundaries of the Site and the contaminated groundwater plume extents were developed as a result of a series of site investigations that have been conducted privately and by KDHE since 1986. Groundwater contaminated in excess of the maximum contaminant levels (MCLs) covers approximately 2,220 acres, and over 20 sources have been identified. As indicated in Figure 1, six different contaminated groundwater plumes have been identified (Plumes A through F). The City is addressing Plumes A, B, C, and E, and KDHE is addressing Plumes D and F.

Over 5,000 samples of soil, surface water, and groundwater were collected to determine the extent of contamination and to identify source areas. Most of the samples were groundwater collected using direct push (hydraulic) techniques. Throughout most of the plume areas, concentrations of PCE, TCE, and *cis*-1,2-DCE range from 100 to 500 µg/L, and concentrations as high as 19,000 µg/L of PCE and 17,000 µg/L of TCE exist in the groundwater near source areas.

4.0 CORRECTIVE ACTION DECISION

After a public meeting, the Final Corrective Action Decision (CAD), similar to a United States Environmental Protection Agency (USEPA) Record of Decision (ROD) was signed on September 30, 1994. This CAD established the framework for addressing the environmental contamination at the Site.

Among other items, the CAD included the following elements: institutional controls, public education, hydraulic containment, monitoring, source control, and the establishment of alternate cleanup levels. All of these items have been either fully or partially completed by the City, and additional project efforts will continue into the future as appropriate.

4.1 Institutional Controls / Public Education

The City established institutional controls within the defined boundaries of the Site to prohibit the connection of newly-constructed private water wells for private or public drinking water uses. In addition, a public educational program was initiated to discourage the use of groundwater contaminated above the MCLs within the Site.

4.2 Hydraulic Containment

The City installed the Plumes ABE groundwater treatment system to establish hydraulic containment to prevent further migration of the Plumes A, B, and E groundwater. Groundwater contaminated above KDHE's alternate cleanup levels (ACLs – as further

discussed in Section 4.5) is targeted for containment, and any pumped groundwater is treated to below MCLs for the contaminants of concern. The hydraulic containment is anticipated to be terminated once the monitoring efforts indicate that the ACLs have been achieved and sustained over a one-year period. No active remediation is currently being performed at Plume C, and KDHE is responsible for the remediation of the contamination at Plumes D and F.

4.3 Monitoring

The City installed compliance monitoring wells at the zero line (i.e., the area where groundwater contamination was below MCLs) to monitor for the chemicals of concern on a quarterly basis until 2005 and then semi-annual, and the City is currently conducting semi-annual monitoring efforts. Long-term monitoring is anticipated to be required at the compliance and selected monitoring wells for a minimum period of 10 years of annual monitoring following the termination of the hydraulic containment efforts.

4.4 Source Control

The City has initiated investigations and source control activities at certain source areas to investigate and eliminate and/or reduce the toxicity, mobility, and volume of waste/contaminants at the Site. The appropriate future source area control efforts will be determined on an individual basis following source investigations, and source controls have already been implemented at several locations. To date, the City has implemented:

- Two contaminated soil removal projects
- Three air sparging and soil vapor extraction projects
- Three vapor intrusion mitigation systems, and
- The initial design of one electrical resistive heating project for DNAPL

The primary remedial process that the City has utilized for source area controls consists of air sparging and soil vapor extraction. (AS/SVE). The air sparging (AS) process blows compressed air into the groundwater and allows the air to migrate up through the volatile contaminants - thereby allowing the contaminants to enter into the gaseous state.

The soil vapor extraction (SVE) uses a vacuum blower to pull soil gases from the vadose zone above the groundwater out of the ground. The soil gas movement captures the air and volatile contaminants from the AS system and removes volatile contaminants from the soil zone. Typically, the volatile contaminants are below the air-permitting requirements of KDHE and require no off-gas treatment.

4.5 Establishment of Alternate Cleanup Levels

The City proposed ACLs that KDHE approved in the CAD. The ACLs include chemical-specific 10^{-5} excess carcinogenic risk concentrations, or federal MCLs, whichever were greater, to address the uncertainties associated with cumulative risk factors. The federal MCLs, 10^{-5} chemical-specific risk levels, and KDHE's ACLs are summarized in Table 1.

Table 1: Comparison of MCLs and KDHE's ACLs

Contaminant	MCLs (µg/L)	10^{-5} Chemical-Specific Risk Levels (µg/L)	KDHE's ACLs (µg/L)
Tetrachloroethene (PCE)	5	14	14
Trichloroethene (TCE)	5	21	21
1,2-Dichloroethene* (*cis*-1,2-DCE)	70	36.5	70
Vinyl Chloride (VC)	2	0.25	2

* Not a carcinogen (based on a Hazard Index of 1.0).

The plume boundaries based on the MCL and ACL values are shown in Figure 1, and the Plumes ABE groundwater treatment system has been installed to provide hydraulic containment of Plumes A, B, and E. The pumped groundwater is treated to below the MCLs, and the treated effluent is discharged to the nearby Arkansas River under the terms of a National Pollutant Discharge Elimination System (NPDES) permit that was issued by KDHE. The use of the ACLs reduced the total groundwater volume to be treated by an estimated 40 percent and helped to reduce the estimated project cost by approximately $8 million when compared to the initial cost projections.

5.0 DESIGN AND CONSTRUCTION EFFORTS

The CAD established the need for the City to design, construct, and operate a groundwater treatment system to provide hydraulic containment of the contaminated groundwater plumes. The City made the decision to expand the scope of the project to include the construction of extensive environmental education resources to supplement the groundwater treatment system, and these project enhancements resulted in the construction of the Wichita Area Treatment, Education, and Remediation Center (WATER Center). The extensive environmental education components of the project were included to teach current and future generations of schoolchildren and other site visitors about the importance of pollution prevention and environmental stewardship.

In order to expedite the design and construction efforts, three different project phases were established, and a design-build construction approach was selected to accelerate the schedule, allow for greater flexibility and efficiency, and provide the ability to incorporate value-engineering and cost-effectiveness improvements throughout the design and construction efforts. CDM (Wichita, Kansas) was retained as the designer-builder for the project, and Gossen Livingston Associates (Wichita, Kansas) was hired by CDM to provide the architectural design.

The WATER Center is pictured in Figure 2, and the three project phases included the center treatment building (Phase I), the surrounding education building and plaza (Phase II), and numerous site enhancements across the park (Phase III).

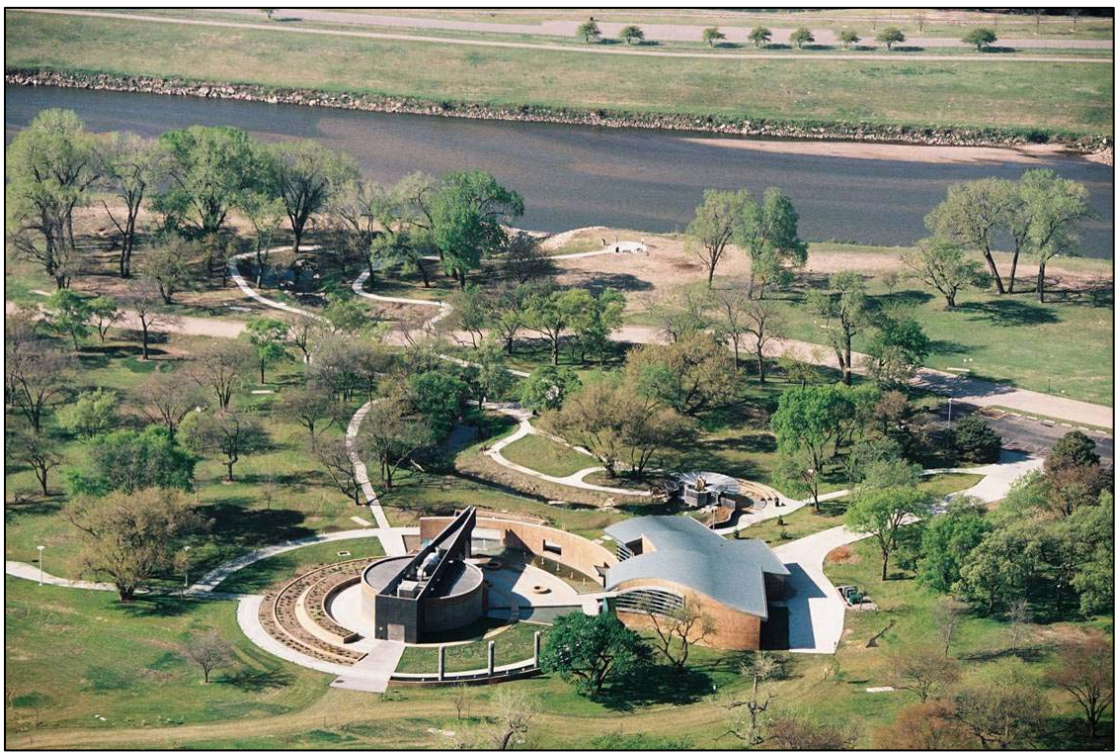

Figure 2. Aerial View of the WATER Center

5.1 Phase I – Groundwater Treatment System and Treatment Building

The Plumes ABE Groundwater Treatment System (Treatment System) consists of 13 extraction wells, 5.3 miles of influent piping, and a hydraulic-venturi air stripper groundwater treatment system. The Treatment System is designed to pump and treat a design flow rate of 860 gallons per minute (1.2 million gallons per day) and a maximum flow rate of 1,095 gpm (1.6 mgd). The approximate locations of the extraction wells, influent piping network, and air stripper are shown on Figure 1.

The 13 extraction wells are 10 inches in diameter and were constructed using stainless steel screens and Schedule 80 PVC casing pipes. The wells were completed with a flush-mount cap, and the total well depths ranged from 28 to 37.5 feet below ground surface. The wells were installed using a reverse-circulation drilling method, and each well was developed to remove sediment from inside the well. Step testing of each well was performed to evaluate the well performance and to determine the local hydrologic characteristics of the aquifer in the immediate vicinity of each well.

To convey the groundwater pumped from the extraction wells to the groundwater treatment building, approximately 28,000 feet of SDR-11 high density polyethylene

(HDPE) piping sections were installed using a horizontal directional drilling technique that minimized disruption and property damage in the residential and commercial areas.

The groundwater treatment building (pictured in Figure 3) is approximately 3,000 sq. ft. in size, and the interior of the treatment building includes a large circular area that contains the groundwater treatment system pumps, hydraulic-venturi treatment heads, control panels, and discharge stacks (pictured in Figure 4). The groundwater treatment system consists of a subsurface concrete tank that is divided into six modules and a clearwell section. Each module includes a transfer pump, two hydraulic-venturi treatment heads, a manifold piping section, transfer hoses, a pressure gauge, and a sample port. These items and other treatment system components were supplied by Hazleton Environmental (Hazleton, Pennsylvania).

Figure 3. Treatment Building

Figure 4. Treatment System

The groundwater flows through each module in series, and the water is progressively treated by the hydraulic-venturi treatment heads through which the water is pumped through spray rings to generate a large amount of surface area for the contaminants to volatilize. The contaminated air flows through the two interior discharge stacks to the discharge fan installed on the roof of the treatment building.

The hydraulic-venturi air stripper treatment system was selected for its compact size, ease of operation and maintenance, and quiet operation—a key consideration given the location of the treatment system in a public park across the street from a residential area. The water flows through the hydraulic-venturi treatment heads aspirate air flows that eliminate the need for large blowers that would create significant noise levels.

The contaminated air is discharged through a discharge fan and stack on the roof of the treatment building, and the contaminant levels contained in the exhaust air are significantly below the threshold level for regulatory permitting. The treated effluent water from the treatment system is discharged to the Arkansas River through either a gravity drain pipe or by the clearwell pump that uses the treated water to supply the fountains, aquarium, fish observatory, meandering creek, and other water feature items.

5.2 Phase II – Environmental Education Building and Plaza Area

The Phase II environmental education building and plaza area are located adjacent to the Phase I treatment building in Herman Hill Park. The 6,300-sq. ft. environmental education building includes an exhibit area with an aquarium (the aquarium uses a single-pass flow of treated water from the treatment system), several offices, public restrooms, a classroom, and a mechanical area. The education building is constructed with concrete walls and a standing-seam metal roof, and the walls and roof are curved to create an architecturally-unique design.

The environmental education building currently includes basic exhibits that are used to teach WATER Center visitors about subjects such as the importance of wetlands, "healthy" versus "unhealthy" aquatic environments, characteristics of native fish species, and other pollution prevention and environmental stewardship topics.

The circular plaza area includes a large number of fountains, terraced landscaped areas, sidewalks, seating elements, specialized lighting features, and a circular concrete arc wall. The plaza area fountains use the treated water from the groundwater treatment system, and this water is also used to supply the overhead discharge from the aqueduct and the water flow that cascades down the poetry water wall on the education building.

6.0 GROUNDWATER TREATMENT SYSTEM OPERATIONS

As of early 2009, the groundwater treatment system had been in nearly continuous operations for over six years and over 2.5 billion gallons of groundwater had been treated. The performance monitoring efforts have indicated that the treated groundwater met the discharge criteria established by the project-specific NPDES discharge permit, and Table 2 provides a sample of the influent and effluent contaminant concentrations during the first six years of operations.

Table 2: Treatment System Influent and Effluent Contaminant Concentrations

Date	Influent (Inflow)				Effluent (Outfall)			
	PCE (µg/L)	TCE (µg/L)	*cis*-1,2-DCE (µg/L)	VC (µg/L)	PCE (µg/L)	TCE (µg/L)	*cis*-1,2-DCE (µg/L)	VC (µg/L)
NPDES	**- - -**	**- - -**	**- - -**	**- - -**	**5**	**5**	**70**	***2***
1/3/2003	110	17	30	1.0	1.8	<1	1.9	<1
3/19/2004	70	13	25	<1	1.2	<1	2.4	<1
3/10/2005	42	9.5	19	<1	<1	<1	1.7	<1
6/28/2006	42	8.9	17	<0.8	<1.1	<0.6	1.1	<0.8
9/20/2007	26	8.4	15	<0.8	<1.1	<0.6	0.7	<0.8
9/24/2008	17	5.5	11	<0.8	<1.1	<0.6	<0.5	<0.8

In addition to the influent and effluent water samples, the sampling efforts for the exhaust air discharge have indicated that the discharge levels have been significantly below the level of regulatory interest and confirmed that an air permit was not required.

7.0 WATER CENTER EDUCATIONAL EFFORTS

City staff have conducted a wide range of on-site and off-site environmental education programming efforts, and the WATER Center has also functioned as a community resource for a wide range of other events.

The on-site programs have included Herman Hill Park site visits by school groups, community organizations of all types (i.e., Big Brothers and Big Sisters, Boy Scouts of America, various nonprofit groups, etc.), and a wide variety of internal City and State of Kansas meetings and events. The off-site programs have included City staff visits to schools, community facilities, and other organizations to present various environmental education programs.

A large number of park visitors have also visited the exterior of the WATER Center and the Herman Hill Park site improvements (plaza area, fish observatory, creek, park shelter, etc.) outside of the open hours of the facility.

In addition to the environmental education programs, the WATER Center has also served as a resource for the entire Wichita community, and the Herman Hill Park facilities have been used for events ranging from the Park Board summer programs to wedding receptions.

8.0 CONCLUSION

The contaminated groundwater in the Gilbert and Mosley Project area posed a significant risk to human health and the environment, and the City faced possible USEPA Superfund intervention in the early 1990s. As a result, real estate development in many areas of the Site ceased due to the contamination and potential environmental liability concerns. The values of thousands of properties were in jeopardy and were projected to decrease 40 percent in value – thus significantly eroding the City's tax base. Through a series of innovative project approaches by the City, many positive benefits have been achieved - including the construction of the WATER Center, restoration of property values throughout the project area, and redevelopment of portions of the Site. In one area of the Site (the Old Town area and warehouse district), over $300 million of commercial development has occurred.

The WATER Center's treatment building, environmental education building, and various site improvements (plaza, fish observatory, creek, rehabilitated park shelter, etc.) will provide environmental education opportunities for current and future generations and will instruct schoolchildren and other site visitors about the importance of pollution prevention and environmental stewardship. The dramatic architecture, water features, and environmental education components combine to make the WATER Center a landmark project and a resource for the entire Wichita community.

Use of In-planta Solid Phase Sampling Devices to Delineate VOC Plumes

Joel Burken, Kendra Waltermire and Emily Sheehan

ABSTRACT

Plants directly interact with surrounding water, air, and soil, collecting and storing chemicals and elements from the surrounding environment. Two new and innovative sampling methods in which this valuable data can be accessed to replace as well as supplement contaminated-site investigations have been developed. When determining the extent of the plume on a contaminated site, groundwater sampling may be limited due to time, site access, and expense. By using new techniques that place sampling devices inside the trees on site, we can sample trees naturally occurring on a contaminated site or those planted in phytoremediation or redevelopment efforts, evaluate the plume size, and even monitor changes in concentration. These methods will have a minimal footprint and can be accomplished with little materials cost, time, or labor demands. These quick sampling techniques can provide an array of data within a short amount of time to help the efficiency in placement of groundwater monitoring wells, saving time and money as well as undue impact to the ecosystems at hand or personal property.

INTRODUCTION

Tree cores collected from contaminated sites have shown concentrations of VOCs that correlate with the groundwater concentration of VOCs. Previous research has proven that cores can be taken from the tree and analyzed using gas chromatography to determine contamination within the subsurface, particularly for chlorinated solvents (Vroblesky et al. 1999; Larson et al. 2008). The cores are a good qualitative analysis, but the heterogeneity of the cores leaves a range of unpredictability and error. In order to reduce these variables, new methods have been designed. One of the new methods is using a Solid Phase Micro Extraction (SPME) sampler to directly sample the VOC concentration qualitatively in cores. SPME samplers consist of fibers of varying matrixes that have highly absorptive characteristics. SPME samplers passively extract the VOCs through absorption and then the concentration of the sample can be determined by using gas chromatography for analysis (Skaates et al., 2005; Legind et al., 2007). Fibers can also decrease the mobilization costs, site impacts, permanent capital costs and repeat sampling costs. As well, the sensitivity was increased from coring analysis by 20-100 times.

In this research, sampling methods were brought into the trees, rather than taking a small portion of the tree to the laboratory. SPME samplers and a new sampling device called Solid Phase Samplers (SPSs) were placed into trees to show

that they have potential for rapid, improved sampling of trees for groundwater delineations. The following results show there clearly is great potential for this application and the patent-pending technology may greatly increase the accuracy of Phase I site investigations and concurrently decrease costs and damage to property and the environment.

MATERIALS AND METHODS

Field Sampling Using SPME In New Haven, MO, PCE contaminated groundwater has impacted the city water supply and tree-core sampling was critical in delineating the sources on the contamination (Struckhoff et al 2005, Schumacher et al. 2004). On the Kellwood Site (OU2) five trees were cored and then tested using *in-planta* SPME analysis. Cores were collected as previously described (Struckhoff et al 2005, Schumacher et al. 2004) and in the borehole remaining, SPME analysis was conducted using time weighted average (TWA) methods (Koziel and Pawliszyn, 2001), using 100 μm Carboxene SPME fibers supplied by Supelco Analytical (Sigma-Aldrich Co., Bellafonte, Pennsylvania). In TWA analysis, a SPME fiber with a high contaminant affinity is exposed to a sample media with the fiber retracted into the SPME needle for a given period of time. For TWA analysis, the contaminant concentration in the fiber must not be near the equilibrium concentration or the TWA rules of sampling are violated. The fibers were exposed in the trees at the New Haven Kellwood Site (OU2) site for 70 – 75 minutes, capped and transported to the Missouri S&T environmental engineering laboratory for analysis using an Agilent 6890 GC with detection via ECD. Details are presented elsewhere (Sheehan 2009).

SPS development and Testing SPSs were constructed and exposed to a steady concentration of PCE to evaluate absorption rates. SPSs were constructed using polydimethyl silicone (PDMS) tubing cut into sections with mass ~0.5g. Mass was accurately determined and recorded, and each section was placed on a threaded stainless steel screw and secured with a nut, Figure 1. SPSs were placed in methanol for two days and allowed to dry under a hood to remove any contamination from production, shipping and storage. The SPSs were then placed in an incubator for 2 days at 100°C. The tubes were then cooled off and placed into a 100 mL beaker within a 300 mL screw top jar also containing a layer of PDMS oil dosed with PCE/TCE, Figure 2. This controlled the chemical activity (i.e. concentration) in the gas phase at low levels, without depleting the mass via absorption into the SPSs. There was no direct contact of SPSs with PDMS oil containing PCE/TCE. The tubes were placed within the PCE/TCE environment at the same time. To determine the uptake rates, the tubes were removed at varying times: 1 hour, 2 hour, 12 hour, 24 hr/1 day, 2 days, 3 days, 4.25 days, 7 days, 11 days, and 14 days. When a tube was removed from the vial with tweezers, the tube was placed within a 20 mL headspace sampling vial and immediately capped then stored at 4 ˚C. Once all SPSs were removed, they were run at once in a headspace autosampler at 35 ˚C with direct injection to an HP 5890 GC with ECD for detection. The data was plotted over time.

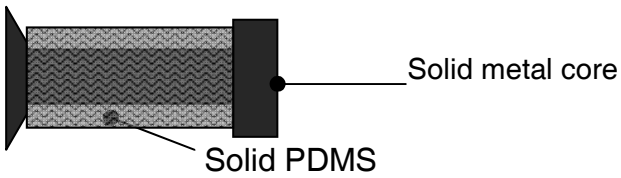

Figure 1: Solid Phase Sampler (SPS) assembly

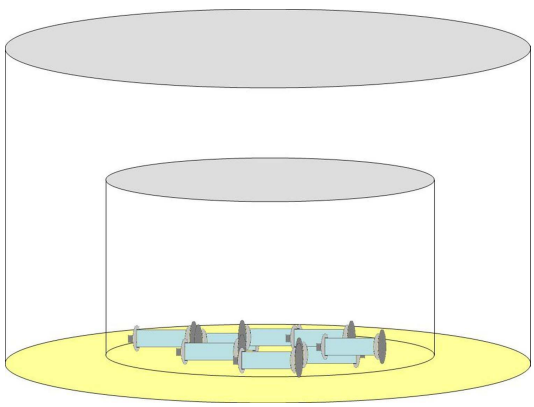

Figure 2: Solid Phase Samplers were placed in an open beaker inside a closed beaker containing PCE and TCE dosed PDMS oil.

Comparison of SPSs Versus Cores

As tree cores are highly variable in their collection and initial evaluation was set to evaluate tree xylem tissue versus the SPSs as a material, surrogate cores were used and constructed by cutting dowel rods at a mass of ~0.5g, diameter 0.4 cm, and the mass of each was recorded. The SPSs and cores were placed in a 100 mL beaker, as noted above, with an added aluminum foil divider placed in the center to separate the cores from the SPSs. The SPSs and cores were exposed for 3 weeks allowing them both to come to equilibrium with the surrounding environment. SPSs and cores were removed using tweezers and placed into separate vials and capped for analysis as noted above.

RESULTS

Field Comparison of *In-planta* SPME Methods and Tree Core Analysis Sampling of trees at the New Haven Kellwood Site (OU2) was conducted on 4 trees known to be in a polluted area that had been previously analyzed and one tree that had been sampled and never shown to contain contaminants (Schumacher et al, 2004). Results of tree core analysis using accepted methods revealed contamination of both TCE and PCE in the trees. Based on peak areas using the same GC methods, the *in-planta*

SPME methods had peak areas from 4 to 230 times higher, with an average increase of 13 times for TCE and 62 times greater for PCE, Table 1. For the one duplicate analysis, the SPME also had a similar variation between the two analyses, 85% vs 91% for TCE and 55% vs 53% for PCE. This analysis shows that SPME *in-planta* analysis has definite potential for providing improved method detection limits with similar variability in analysis. The SPME analysis also has the benefit of potentially rapid analysis. The headspace methods for tree core analysis generally have a 24 hour equilibration period, although recent method development has shown that heating samples can reduce the equilibration period required (Vroblesky, 2008).

Table 1 Comparison of standard tree core analysis and *in-planta* SPME analysis with TWA methods.

Tree #	Cores-TCE	Cores-PCE	SPME-TCE	SPME-PCE
Tree 1	3.8×10^2	2.1×10^4	5.8×10^3	1.2×10^6
Tree 2	6.1×10^2	1.9×10^4	1.7×10^4	4.4×10^6
Tree 3	9.4×10^1	5.2×10^2	5.8×10^2	2.5×10^3
Tree 4a	5.3×10^1	2.8×10^3	3.7×10^2	3.3×10^4
Tree 4b	3.6×10^2	6.2×10^3	4.3×10^3	7.1×10^4
Tree 5	ND	1.4×10^2	ND	7.2×10^3

Sorption Rates for SPSs Results for the absorption rates showed a clear relationship for both PCE and TCE absorption, Figure 3. Absorption as measure by the mass transferred to the SPSs increased rapidly over the first 96 hours and then reached apparent equilibrium at approximately 240 hours, 10 days. Equilibrium was reached if the change was less than 1 % over 72 hours. A simple first order uptake model was applied to each, Equation 1, with a first order uptake coefficient of 0.017 hr^{-1} and 0.024 hr^{-1} for PCE and TCE respectively. The importance of this methodology is to show that the SPS is more sensitive and predictable in the uptake (i.e. absorption). While the sensitivity is beneficial for getting the lowest possible method detection limits, the predictability of the uptake lets short term sampling (24 hours) be extrapolated to actual equilibrium concentrations.

$$A = A_{max} (1\text{-}e^{-kt}) \qquad \text{(Equation 1)}$$

Where A = peak area, A_{max} = peak area at equilibrium, k = 1^{st} order rate coefficient (hr^{-1}), t = time (hours).

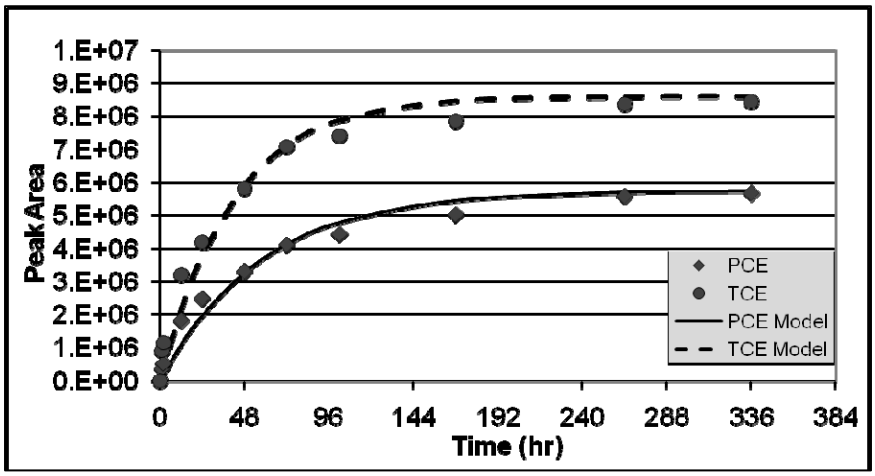

Figure 3: SPS-controlled absorption rate of PCE and TCE, showing equilibrium in approximately 10 days. The absorption followed a 1st order kinetic model.

Comparison of SPS and Core Equilibrium Concentration The equilibrium comparison of cores and SPSs exposed to the same headspace concentration revealed that the SPSs were more sensitive for PCE and had lower variability for both PCE and TCE; while core and headspace analysis was slightly more sensitive for TCE, Figure 4. The SPS peak area response was 98% higher than the core analysis for PCE, whereas the SPS response was 35% lower than the core analysis. The SPSs were more reproducible. The 95% confidence interval was only 0.9% and 0.8% of the mean for SPS analysis of PCE and TCE respectively, where as these values were 2.7% and 2.4 % for the cores analyzed.

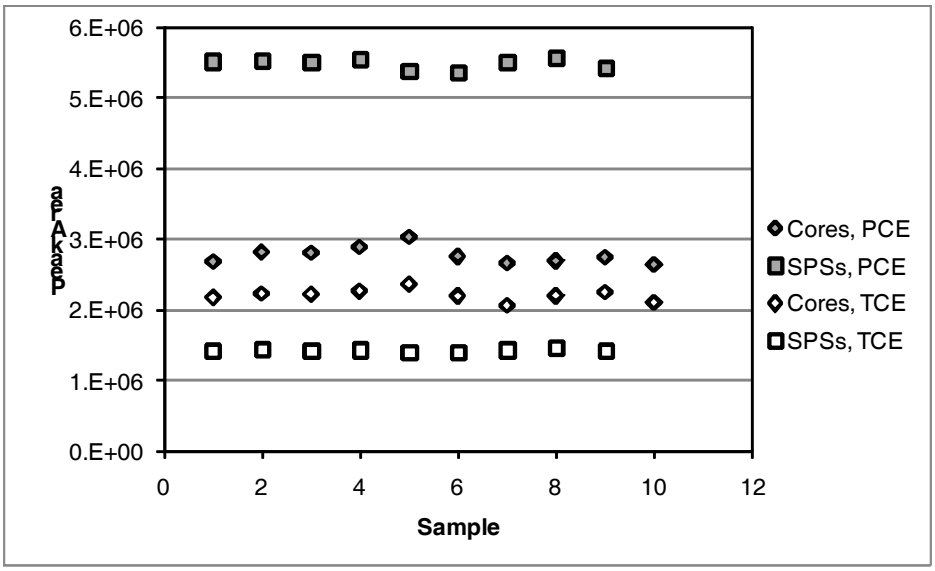

Figure 4: The SPSs and Cores were dosed and analyzed on the GC-ECD headspace autosampler.

CONCLUSION

Using the SPME fibers and SPSs to sample trees in the field appears to have benefits relative to traditional tree coring analyses. These methods may improve the vegetation-sampling approaches that have great benefits for Phase I site assessments and also for monitoring groundwater concentrations at phytoremediation sites. Plant sampling overall has benefits of minimal environmental or property disturbance. Sampling is accomplished with very little materials cost, energy use, or labor demands. As well, with the reproducibility of the SPME fiber and SPSs, groundwater monitoring can be replaced or become more efficient through these methods that are at the very infancy of development. This new approach is patent-pending and appears to have a bright future if optimized further.

ACKNOWLEDGEMENTS

The authors would like to thank Drs. Philipp Mayer and Ulrich Karlson – Goswinkle for their assistance in developing the application of SPME analysis in plants. We also thank Supelco for their support in providing demonstration and discount SPME fibers to test these methods. This work was supported in-part by the OECD Research Fellowship program and the Ministry of the Environment, Ontario, Canada.

Abstract

The definition of contaminant source release is a necessary element of contaminant mass transport simulation in the saturated zone. At many sites the release history is unknown, and there has been a significant body of research to develop inverse models to define finite release histories. Instead of rigorously defining the source history, a mass balance-based approach is tested to explicitly account for uncertainty in equal length rectangular pulse release variables. The approach has been incorporated into a spreadsheet model which uses a one-dimensional solution to the advection dispersion equation. A concentration dataset collected at a Superfund site was used for model calibration and verification. Several synthetic datasets with known input parameters were also used for model calibration and verification. The model provided reasonable results when the source time parameters were assumed to be random, and the results improved when the mass of contaminant in the aquifer was also assumed to be random. However, the improvements came at the cost of degraded calibration parameter values.

Introduction

The classic approach for modeling mass transport in a groundwater system requires initiating the simulation with the release of the contaminant to the system. Thus the conceptual model and subsequent analytical and numerical transport models require characterization of the source location and the source release function. There is a significant body of literature that addresses the identification of groundwater contamination sources as summarized by Michalak and Kitanidis (2004), Sonnenborg, et al. (1996), and Hill and Tiedeman (2007). Some representative works include Domenico and Robins (1985) which developed the extended pulse model to identify unknowns including the source concentration, source dimensions, the time of when the contaminant first entered the groundwater, the position of the center of mass, and the groundwater dispersivities. The authors acknowledged that unique solutions were not likely using field data although the model was useful for placing

reasonable bounds on the unknowns. Ala and Domenico (1992) developed a two-dimensional analytical method called the two-well solution to find the unknowns associated with a finite plane source. Skaggs and Kabala (1994) evaluated complex contaminant release histories (that is, releases other than continuous or rectangular pulses) using Tikhonov regularization. One of the conclusions of their work was that plume history could be adequately recovered if dispersion was relatively minor compared to advection even if the concentration measurements contained moderate random errors. A similar conclusion was developed by Alapati and Kabala (2000) who used a non-linear least-squares method without regularization to recover the release history of a source with a known location. Skaggs and Kabala (1998) also provide limitations when developing the release history of a source with observed data. These include the time since the release, which can be better estimated as the actual time since the release decreases. They show that deconvoluting solute transport systems is an ill-posed problem with solutions that improve as the quality of observed data improves. This sensitivity poses a significant issue to pragmatic application of contaminant release history characterization with field datasets.

Elmore (2007) used a concentration data collected using a direct push drill rig to estimate a subset of the source parameters including the time since the source release t_r, the duration of the release t_s, and the concentration of the source C_0, for a rectangular pulse. That work introduced a one dimensional (1D) spreadsheet model that could be used to estimate t_r, and t_s, by manual iteration with C_0 as a dependent variable assuming that the source location was known.

Much of the previous work focused on developing finite definitions of source history. The focus of this paper is to implement an automated deterministic model that provides reasonable solutions to source parameters by verifying the calibration mechanism with synthetic datasets. The approach initially developed in Elmore (2007) will be expanded to develop a mass-balance basis to estimate t_r, t_s, and C_0 using both synthetic and actual site concentration data.

Model Development

The governing equation for mass advection, dispersion, degradation, and sorption in a one-dimensional flow field is

$$R\left(\frac{\partial}{\partial t}C\right) = -v_x \cdot \left(\frac{\partial}{\partial t}C\right) + D_x \cdot \left(\frac{\partial^2}{\partial t^2}C\right) - k \cdot R \cdot C \qquad (1)$$

where C is the solute concentration, t is time, v_x is the average pore water velocity in longitudinal direction of flow, x is longitudinal distance from source, D_x is the longitudinal dispersion coefficient, k is the net degradation rate constant, and R is the retardation factor for linear, equilibrium sorption defined by Spitz and Moreno (1996).

The Van Genuchten and Alves (1982) solution to Equation 1 given a rectangular source release of magnitude C_0 for t_s is based on the assumptions that advection and dispersion occur in a uniform regional flow field with constant ground water velocity and homogeneous, isotropic aquifer properties.

A dependent relationship between the mass release variables C_0 and t_s may be developed using a mass balance approach by assuming that the groundwater plume has constant rectangular dimensions with width W, thickness b, and length, L. Given a constant concentration C_j for each band, which is the arithmetic average of predicted concentrations in band j, the total mass in solution in the aquifer is given by

$$M = n \cdot W \cdot b \left[\sum_{j=1}^{m} \left(C_j \cdot L_j \right) \right] \tag{2}$$

The normalized total mass in the aquifer is defined as

$$M' = \sum_{j=1}^{m} \left(C_j \cdot L_j \right) \tag{3}$$

where

$$M' = \frac{M}{n \cdot W \cdot b}$$

Spitz and Moreno (1996) provide the following equation for the total contaminant mass per unit aquifer volume

$$\Delta M = C \cdot n + C_a \cdot (1 - n) \cdot \rho_s \tag{4}$$

where C_a is the adsorbed concentration measured as mass of contaminant per mass of dry aquifer matrix material and ρ_s is the density of solids in the aquifer. The adsorbed fraction is also related to the dissolved concentration according to the linear adsorption isotherm equation which may be expressed as

$$C_a = C \cdot foc \cdot K_{oc} \tag{5}$$

where foc is the fraction of organic carbon and K_{oc} is the organic carbon adsorption coefficient. Substituting Equation 5 into Equation 4 and incorporating the contaminant retardation factor, R, gives

$$\Delta M = C \cdot n \cdot R \tag{6}$$

The total mass M_T in the aquifer is the product of the rectangular aquifer volume and ΔM which results in

$$M_T = n \cdot R \cdot W \cdot b \cdot \sum_{j=1}^{m} \left(C_j \cdot L_j \right) \tag{7}$$

Thus the normalized total mass in the aquifer at the time that the dissolved concentrations are measured is defined as

$$M'_T = R \cdot \sum_{j=1}^{m} \left(C_j \cdot L_j\right) \quad (8)$$

where

$$M' = \frac{M_T}{n \cdot W \cdot b}$$

The total mass released to the aquifer by a rectangular pulse through a finite plane with a height b and a width W is given by

$$M_T = v_x \cdot n \cdot W \cdot b \cdot t_s \cdot C_0 \quad (9)$$

which can be normalized as

$$M'_T = v_x \cdot t_s \cdot C_0 \quad (10)$$

If there is no mass decay, the total mass in the aquifer estimated at the time that the band concentrations are measured is equal to the total mass released to the aquifer, and Equation 8 can be substituted into Equation 10 and solved for the initial concentration

$$C_0 = \frac{R}{v_x \cdot t_s} \cdot \sum_{j=1}^{m} \left(C_j \cdot L_j\right) \quad (11)$$

Solutions to the 1D form of the governing equations are readily available in spreadsheet form, and several spreadsheet models are available for free download at the U.S. Environmental Protection Agency (USEPA) website. The use of a spreadsheet makes the manipulation of site concentration data to calculate the C_j values relatively trivial, and the model developed by Dawson (1995) incorporating the Van Genuchten and Alves solution was modified to incorporate Equation 11. Following the mass balance approach used to derive Equation 11, two calibration variables are defined as O, the normalized observed mass, and P, the normalized predicted mass, by the following equations

$$O_j = C_j \cdot L_j \quad (12)$$

$$P_j = \Delta x_j \cdot \sum_{i=1}^{m} C_P(x_i, t_r) \quad (13)$$

where C_P is the model predicted concentration at the points $x_1, x_2, \ldots, x_n$ that land within band j, and the points are separated by the distance

$$\Delta x_j = \frac{L_j}{n} \quad (14)$$

where n denotes the total number of predicted concentration points along the entire plume length.
The use of O and P allow the calculation of paired-data calibration parameters such as the Root Square Mean Error ($RMSE$) defined by Spitz and Moreno (1996). When the minimum range of $RMSE$ values varies per simulation in a given domain of t_r and t_s, the $RRMSE$ is useful to facilitate simulation comparison where

$$RRMSE(t_s, t_r) = \frac{RMSE(t_s,t_r)}{\min [RMSE(t_s,t_r)]} \quad (15)$$

where

$RMSE(t_s, t_r)$ = the $RMSE$ of an iteration defined by a coordinate set of t_r and t_s
$\min [RMSE(t_s, t_r)]$ = the smallest $RMSE$ of all t_r and t_s combinations within a simulation's region boundaries of t_r and t_s

Best estimates of t_r and t_s are determined by identifying regions of low $RRMSE$ values through rigorous calibration iterations along set ranges of t_r and t_s. The coordinates of t_r and t_s at which the corresponding $RRMSE$ error is reduced indicate likely estimates of the actual t_r and t_s. The coefficient of determination, the modeling efficiency, the relative percent difference, and the coefficient of residual mass defined by Spitz and Moreno (1996) were also incorporated into model calibration.

Application

The spreadsheet model was applied to a trichloroethylene (TCE) dataset collected at a Nebraska Superfund site which has been the subject of prior groundwater modeling studies including Elmore (2007), Miller and Elmore (2005), and Elmore and DeAngelis (2004). The unconfined aquifer at the site consists of glacio-fluvial sands and gravels where flow occurs through primary porosity and it is reasonable to assume that the Dupuit theory of vertical equipotential lines is valid for the aquifer. The plume area of the aquifer has not historically been subject to large stresses such as irrigation pumping, and the plume is relatively far from flow and head boundaries. Thus the assumption of steady uniform flow necessary to apply the Van Genuchten and Alves solution is reasonable for the subject plume. A direct push groundwater investigation was conducted in 2002 and 2003 to characterize the extent of the TCE contamination. TCE concentrations above the site action level of 5 μg/l were detected in fifty-nine locations which defined an approximately rectangular plume shape with dimensions of 5,000 m by 550 m. One to six samples were collected at different depth intervals at each location, and no data other than TCE concentrations were collected during the investigation. When multiple depth intervals were sampled at a single location, the arithmetic average of the results was assigned to the location to compress the three dimensional transport system into two dimensions. The plume was then divided into equal length bands for analysis. A remedial action well was installed in the approximate center of the plume 2,930 m from the source. The well was sampled several times contemporaneously with the direct push investigation to

provide treatment design data, but the remedial action well data were not used to calculate the statistics of any simulation. Site aquifer testing data were used to characterize the aquifer K as 39 m/d, Elmore and Vandeberg (1997) gave the hydraulic gradient in the area of the subject plume as 0.0023, the site foc average as 0.00028, and the saturated thickness, b, as $24.7\ m$. Mehran et al. (1987) estimated K_{oc} value for TCE as 120 mg/l, and Piskin (1971) estimated the site n_e as 0.145 and n was assumed to be equal to that value. The density of the solids was assumed to be 2.65 g/cm^3 based on the typical value given by Freeze and Cherry (1979). Elmore (2007) found that dispersion was relatively minor compared to advection. The model was best calibrated using $RRMSE$ as the primary calibration parameter by varying t_s and t_r to generate Figures 1a and 3a. As shown on the figures, areas were mapped at values of $RRMSE = 1.1$, and the coordinates of the centroid of the greatest calibration contour overlap area was selected as the best approximations of t_r and t_s.

Results and Discussion

To reiterate the objective, the contaminant transport model discussed in this paper develops estimates of the initial concentration of the contaminant release (C_0), the time since the contaminant was released (t_r), and the time of contaminant source release (t_s). A synthetic transport system provides given contaminant source release history parameters. The synthetic observed datasets in this experiment were expected to accommodate development of the most appropriate model calibration mechanism by producing the highest quality field data without measurement error. Six synthetic datasets with given analytical solutions of $C_0,\ t_r,\ t_s$ were developed by creating a random number generation selector. The selector randomly chose observed data points from a predicted dataset produced by the Van Genuchten and Alves (1982) solution to Equation 1. The sample size of each synthesized observed dataset represented 5-10% of the predicted dataset.

Equal length bands of analysis were superimposed over each synthetic transport system and tested to determine the most appropriate number of analysis bands to achieve the greatest accuracy. Several model calibration simulations with unique numbers of analysis bands were performed for each synthetic dataset. The number of bands overlaid on each synthetic dataset ranged from three to twelve. Several calibration parameters were tested in each simulation and the normalized mass observed and predicted values were best calibrated with $RRMSE$. Figure 1a graphically represents the accuracy of several different band number calibration simulations when using the $RRMSE$ as the calibration parameter. The plume characterizations of simulations with three or less bands resulted in degraded accuracy. The maximum number of bands was determined by ensuring that each band contained at least one synthetic observed datapoint, which typically required a maximum of twelve bands.

Figure 1: a) Synthetic dataset calibration parameter $RRMSE = 1.1$ contours shown with ±5% accuracy region (left). b) Contours are enlarged showing number of bands per simulation with the synthetic dataset (right). Synthetic solution coordinates: $t_s = 16.5\ yr,\ t_r = 20.0\ yr$

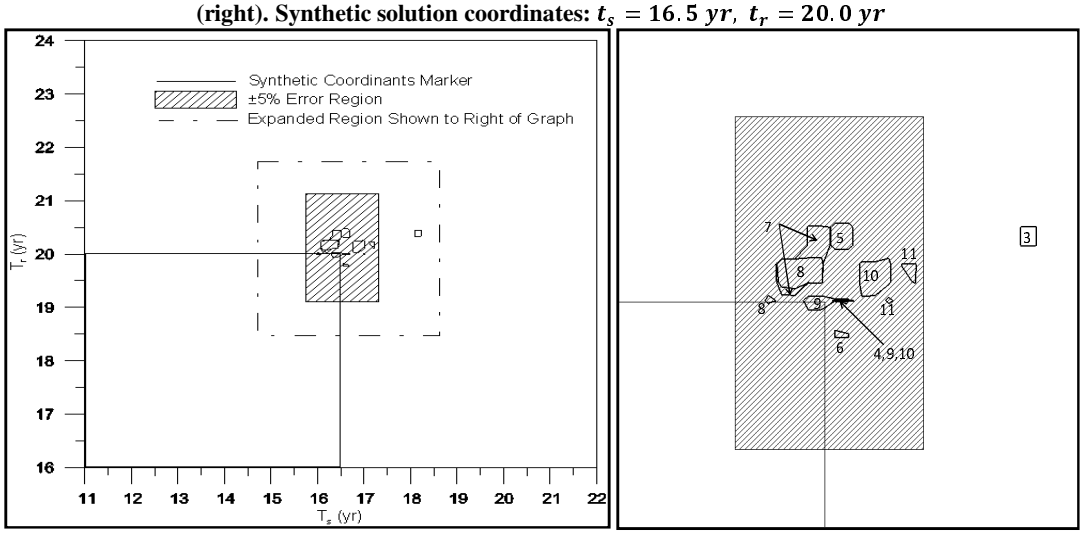

Figure 2: C_0 predictions at synthetic calibration results presented in Figure 2. Synthetic C_0 solution: 4000µg/l

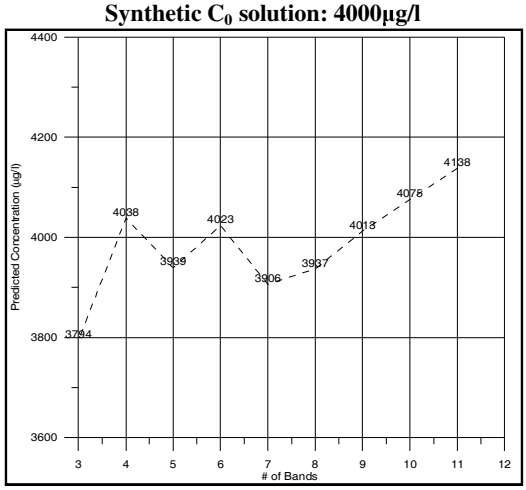

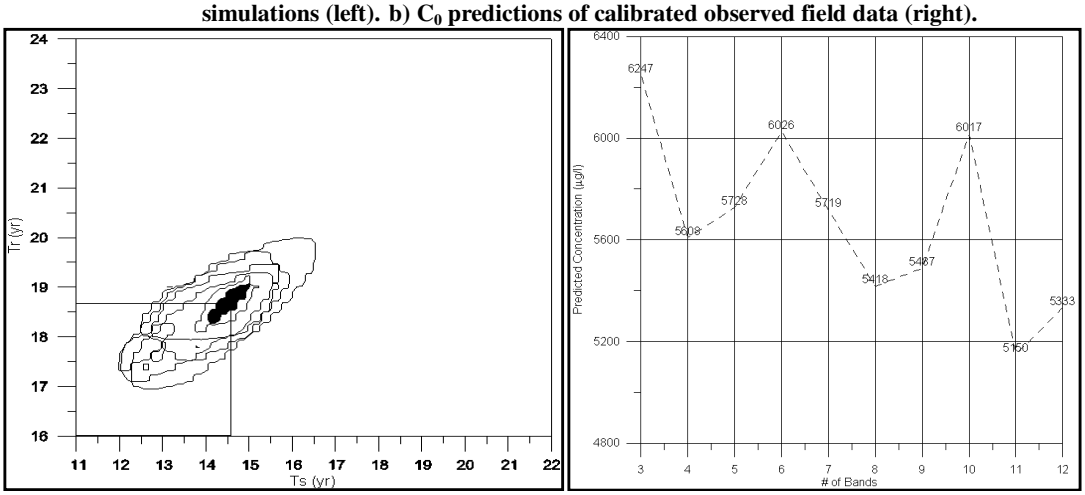

Figure 3: a) Observed field data calibration parameter $RRMSE = 1.1$. The shaded area (with centroid coordinates $t_s = 14.6,\ t_r = 18.7$) marks the contour overlap of equal length band number 3-12 simulations (left). b) C_0 predictions of calibrated observed field data (right).

The literature review indicated that it is uncommon for a source history investigation to be applied to field data. For example, a table in Michalak and Kitanidis (2004) lists 14 of 19 inverse modeling applications as having been applied at hypothetical sites. The use of field data creates additional challenges due to the variability of the data compared to hypothetical cases. The sources of the variability may include an unsteady release function, the spatial variability of the aquifer hydrogeology, and concentration measurement error. It is assumed that both the direct push dataset and the well dataset include measurement error and release variability. Furthermore, it would seem reasonable to state that the direct push dataset addresses spatial variability while the well dataset addresses temporal variability. Yet there are inaccuracies associated with these assumptions. While it is convenient to assume that the direct push data represent the TCE concentrations at a single point in time, the data were collected over an approximately 2 year period. Likewise, it is convenient to assume that each time that the well was sampled over the 2 year period; it was pumped so that the resulting capture zone was equally developed to remove an element of spatial variability from the data. However, there were no data collected characterizing the actual extent of capture zone developed during any of the 11 well sampling events. Therefore, both concentration datasets include elements of all of the sources of variability but there is insufficient information available to systematically evaluate the comparability of the concentration datasets. The two concentration datasets are not atypical of those available to practitioners so model verifications have been performed with the explicit acknowledgement that the data may not be perfect in terms of theoretical comparability.

Conclusions

A constant band length likely best represents observed values because the band length is directly proportional to the normalized mass observed. When equal length bands were tested with actual observed values, the $RRMSE = 1.1$ contours became contiguous and consistently overlapped a critical point of interest and were used as an estimates of t_s and t_r. If the adjacent band width, L_j, significantly varies, the normalized mass observed will proportionally vary, which can mask the influence of the observed concentration, C_j, from the calibration parameter $RRMSE$. The synthetic data calibration shown in Figure 2 supports the model's accuracy in estimating the initial concentration, C_0, by ≤5% of the solution, 4000µg/l. Figure 3b shows greater variation of predicted C_0, but the percent variation of the solution suggests reasonable results because no solution varies more than ±10% of the average predicted initial concentration after exclusion of the simulation with three bands of analysis.
The model may appeal to modelers and designers who can rapidly modify the spreadsheets to evaluate concentration time series at various points as well as calculating the potential mass to be treated and the associated treatment costs. The apparent utility of the spreadsheet model should not overshadow the limitations of the underlying 1D model. The 1D model will have limited application based on site-specific hydrogeologic conditions where there is a low potential for multiple or complex contaminant sources. At many sites, the spreadsheet model may provide

preliminary results that may be useful in designing additional data collection efforts or provide the point of departure for more sophisticated multi-dimensional numerical models.

ABSTRACT

Sediment samples were collected from three different locations and analyzed for selected parameters to study the effects of selected sediment characteristics and contributing source areas on sediment PAHs concentration,. For all cases, the particles in the size range of 180 to 355 µm were most dominant in the sediments. Sediment COD, percent of material weight loss on ignition (material composition analysis) and sediment PAH concentrations showed similar trends of smaller and larger particles associations with higher values than with the intermediate sizes. However, most of the mass of the PAHs were associated with the smaller and intermediate sized particles. Sediments affected by commercial area runoff were found to have higher concentration of PAHs than the sediments affected by non-commercial area runoff.

INTRODUCTION

PAHs are ubiquitous environnemental contaminants and are an example of persistent organic pollutants of environmental concern (Cheung et al. 2006). Prior to the 1800s, the bulk of PAH discharges to the environment were of natural origin, with limited contributions from anthropogenic sources (Metre et al. 2000). There was a shift in the sources of PAH contamination from uncombusted to combusted fossil fuels. The increase in PAH sediment concentrations was coincident with the increase in automobile use and power production, both major consumers of fossil fuels. The magnitude of PAH pollution in runoff depends on the type of contributing source area. Pitt et al. (1999) found the highest runoff PAH concentrations in sheetflow samples from vehicle servicing and parking areas among samples collected from different source areas, with higher concentrations associated with longer interevent periods between rains. Kuklick et al. (1997) observed extreme variability in PAH concentrations, ranging from 33 µg kg^{-1} dry weight in the Edisto River estuary to 9600 µg kg^{-1} dry weight in some areas of urbanized Charleston Harbor showing large effects of urbanization on sediment PAH contamination. The spatial distribution of

PAHs observed by McCready et al. (2000) indicated increased concentrations of PAHs nearer to areas where stormwater enters the Sydney Harbor, Australia.

PAHs in urban runoff can occur in both particulate and soluble forms, although studies have identified the particulate forms as being the most predominant (Hwang and Foster 2006; Pitt et al. 1999). Due to their extremely low solubility and hydrophobic nature, most PAHs are associated primarily with particulate matter. According to Hwang and Foster (2006), particulate-associated PAHs in urban runoff accounts for 68 to 97% of total PAHs in the runoff. The particulate-bound PAHs tended to settle and accumulate in receiving water sediments. Factors that affect the PAH associations with the particulate matter in the aquatic environment include the physical and chemical properties of the specific PAH contaminant, the physical and chemical properties of the aquatic medium, and the physical and chemical properties of the particulate matter. Zhou et al. (1998) observed no correlation between particulate bound PAH concentrations with salinity of samples, while suspended solids concentrations had negative correlations and particulate organic carbon concentrations had positive correlations with particulate bound PAH concentrations They also observed higher concentrations of PAHs with finer particles (generally classified as clay materials, which have large surface areas per unit weight) than with the coarser particles (generally classified as sand particles, which have comparatively less of the organic matter needed for greater PAH sorption). A similar pattern was observed by Aryal et al. (2005), who monitored suspended solids and solid-associated PAHs in Swiss highway runoff for four rain events (samples were only collected during the initial 3 mm of runoff). The concentrations of PAHs in fine fractions (<45μm) were higher than their concentrations in coarse fractions (>45μm). Contributing source areas may also effect the PAHs distribution pattern by solid particle sizes. For example, Guggenberger et al., (1996) noticed homogenous distributions of PAHs by particle sizes in rural soils whereas Muller et al., (2000) observed non-homogeneous distributions of PAHs in urban soils. Recent investigations have also found high PAH concentrations associated with large organic material trapped in stormwater floatable material controls (Rushton 2006), indicating material composition of sediments effects the PAH associations.

This paper describes the measured PAH concentrations on size fractionated sediment particles analyzed using Thermal Desorption analytical methods, PAH trends with respect to selected sediment parameters, and possible major source area effects on sediment PAH pollution. Selected parameters examined for analyzing the trends of PAHs on size fractionated particulate matter included material composition (such as paper debris, organic matter, rubber, or asphalt) and Chemical Oxygen Demand (COD). The sediments affected by residential runoff, commercial area runoff and runoff from residential area with a known history of separate sewer overflows (SSOs) were studied during this research.

MATERIALS AND METHODS

Study Area and Sampling Sediment samples were collected from three different creeks in and around Tuscaloosa and Northport, AL. One sampling area along each of the three creeks was chosen in such a way that the sediment analysis scheme for PAHs represented the sediments affected by different known urban conditions.

One of the sampling areas was along Cribbs Mill Creek, which is an urban creek in Tuscaloosa, AL. The sampling area along the creek was chosen at the downstream end of a few hundred foot long concrete-lined channel in a residential neighborhood. The sediment (bed load) on the concrete channel was therefore mainly affected by the runoff from the surrounding residential areas, with minimal bank erosion material. Another sampling area was along Hunter Creek, which is an urban creek originating in Tuscaloosa County and passes through Northport before joining the Black Warrior River. The sediment at the sampling location was mostly affected by runoff from heavy traffic along McFarland Blvd., commercial areas, and runoff from a trailer park residential area. Physical observations at the site indicated that an outfall from an automobile maintenance shop on the side of the creek directly affected the sediment at the sampling location. The third sampling area was along Carroll's Creek, which starts in Fayette County and joins Lake Tuscaloosa in Tuscaloosa County. The sediment at the sampling location was directly affected by runoff from a high-density residential area on one side of the creek and forested lands on the other side of the creek. The sediment at the sampling point has a history of contamination from sanitary sewage overflows from a separate sewer system (SSOs) in the adjacent residential area (Consent Order NO. 07-139-CWP from the Alabama Department of Environmental Management (ADEM) to the City of Northport, issued in July 2007, there were three SSO incidents during 2006).

All samples were collected in pre-cleaned and autoclaved glass sample bottles using a manual dipper sampler made from polypropylene. The collected sediment samples were dried in aluminum trays at 104°C to remove moisture and then were sieved using a set of stainless-steel sieves with openings of 45, 90, 180, 355, 710, 1400, and 2,800 μm and a mechanical shaker. In addition, large organic material (leaves and other debris) were manually separated from the largest particle fraction and analyzed separately.

Analyses for Material Composition and COD: The material composition of sediments was determined using "Thermal Chromatography" (an expansion of the volatile solids analyses) techniques (Ray 1997). A known amount of sediment sample was placed in a crucible that was heated to higher temperatures, progressively, at set intervals, from 104 to 550^{o}C. After each heating interval, the crucible (with sample) was cooled and weighed in order to determine the percent mass burned off since the last temperature. A heating time of 1 hour at each temperature was maintained to ensure stable weights. Table 1 shows the corresponding temperatures where different material would be combusted. COD analysis of size fractionated sediments was conducted by reactor digestion HACH method 8000.

Analyses for PAHs Concentration: The thermal desorption (TD) sample preparation method uses elevated temperatures as a means to transfer the analytes from solid sample matrices to the gaseous analytical system. This unit was directly attached to the inlet of a gas chromatograph / mass spectrometry (GC/MS) for quantification of PAHs on the size fractionated sediment samples. This TD/GC/MS method was developed and tested for urban creek sediments for PAHs as part of the research activities. The instruments used during this procedure were an

AutoDesorb™ unit (Scientific Instrument Services, Inc. Ringoes, NJ, USA) coupled to a gas chromatograph (Agilent 6890) and a mass spectrograph (Agilent 5973N).

Table 1. Thermal Chromatography Method Parameters

Temperature (°C)	Material lost at these temperatures
Up to 104	Moisture
104 – 240	Paper debris
240 – 365	Leaves and grass
365 – 470	Rubber
470 – 550	Asphalt
Above 550	Remaining material are non-combustible

RESULTS AND DISCUSSION

Sediment Particle Size Distribution: Five samples from each of three creeks were collected and analyzed for particle size distributions (psd). Figure 1 shows the observed psd and box-whisker plots of the particle size ranges observed in the samples. For all cases, the particles in the size range of 180 to 355 µm were dominant. Overall, most of the particles were distributed in the size range of 90 to 710 µm.

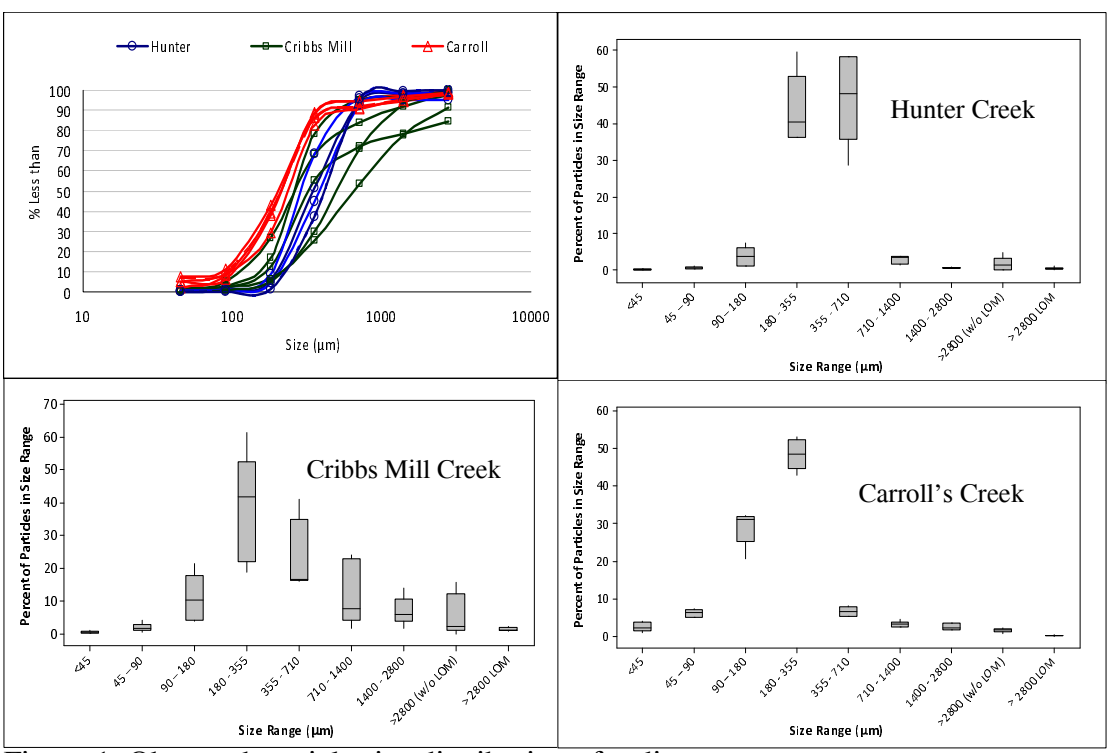

Figure 1. Observed particle size distribution of sediments

Sediment Material Composition and CODs: A composite sediment sample created from the five samples collected at each sampling location was prepared and analyzed for major material composition using thermal chromatography. Table 2 shows the

percentage weight losses observed. Material lost between 240 and 365^{o}C indicates the amount of leaves and grass associated with each particle size that may preferentially sorb PAHs, while material lost between 365 and 550^{o}C indicates rubber and asphalt material that likely have substantial PAH concentrations as part of the component material. Other than for the case of the largest size fraction (> 2800 µm) large organic material (LOM), all other fractions were mostly non-combustible (or non volatile). For the > 2800 µm LOM fraction, most of the material was found to be volatile, and mostly consisted of leaves, grass clippings, etc. The thermal chromatography analyses of sediments indicated that the smaller and larger sediment fractions were associated with a larger volatile content compared to intermediate-sized fractions (Figure 2). The high volatile contents of the large size sediments are caused by presence of relatively large portions of leaf and grass clippings in these sample components.

All sediment fractions of the individual samples were analyzed for COD, as shown in Figure 3. For the >2800µm (LOM only) fraction, the observed CODs for Hunter Creek, Cribbs Mill Creek and Carroll's Creek are 1.6 x 10^{9}, 1.5 x 10^{9} and 1.3 x10^{9} mg/kg respectively. Similar to the total volatile content of sediments, smaller (< 90µm) and larger (> 710µm) size fractions had higher COD concentrations when compared to the intermediate-sized particles. The median COD was found to be associated with particles of about 355µm in size. Log-transformed volatile solids concentrations and associated COD concentrations were strongly linearly related. The regression ANOVA p value was below 0.05 and the response factor (slope term) of the regression was also significant ($p < 0.05$) at 95% C.I.

PAH Content of Size Fractionated Sediment Fractions: Thirteen PAH compounds which were considered to be of most interest due to their potential harmful effects, and which were most abundantly found in earlier stormwater research (Pitt, et. al., 1999), were quantified, with the concentration results shown in Table 4. As shown during the ANOVA analyses, the variations in the PAH concentrations within each size fraction group were smaller than the variations in the concentrations between the size fraction groups. The analytical results showed that, generally, smaller sized and larger sized particles (especially LOMs) were associated with higher concentrations of selected PAHs compared to the medium sized particles (Table 4). This trend is similar to previously reported PAH data (Rushton, 2006). The bimodal distribution of the PAH concentrations was similar to the bimodal distributions observed for volatile content. Prior fugacity modeling by Bathi, et al (2007) showed that PAHs are strongly associated with the organic content of the particulates in aquatic systems. The leaf fractions are therefore found to have the highest concentrations of some of the PAHs because of their higher organic content. Higher concentration of PAHs in the smaller size fractions was also likely associated with their higher organic content

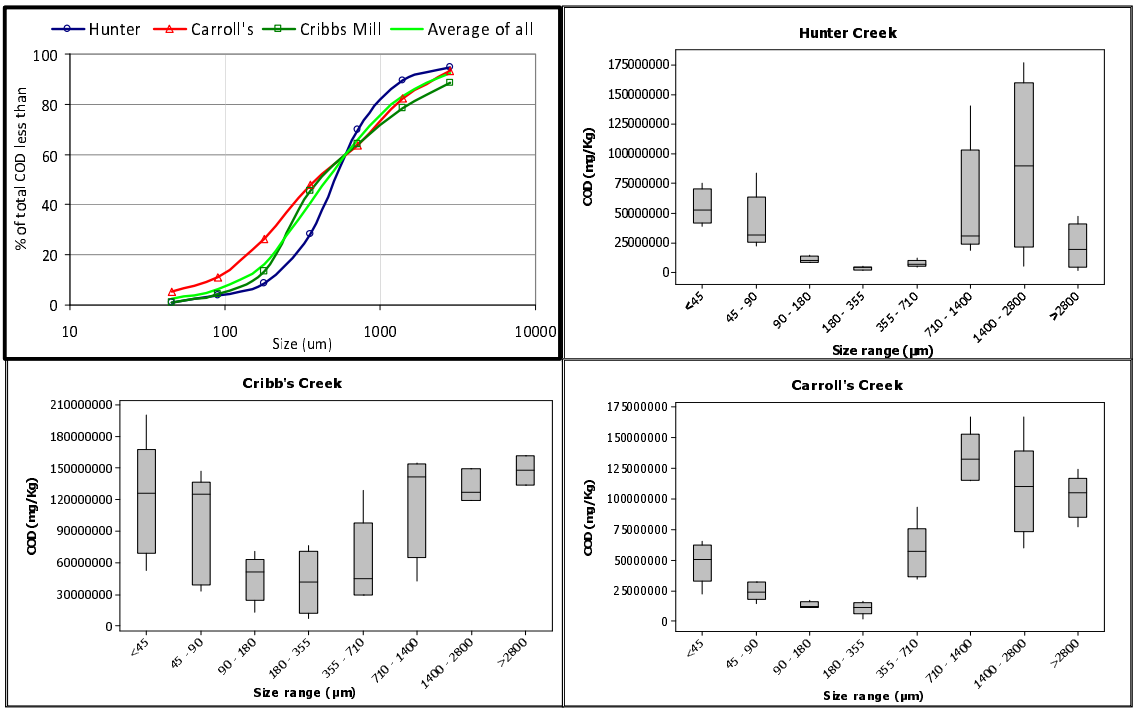

Figure 3. Observed COD of urban creek sediments

and large surface areas of these small particles. Earlier studies by Boehm and Farrington (1984) also found a direct positive relationship between PAH content and the silt/clay fraction of sediments. One-way ANOVA analysis showed significant difference in the analyte concentrations for the different particle sizes ($p < 0.05$). Cluster analyses of the PAH data by particle sizes indicated that for most of the analytes, the >2800µm LOM fraction was a separate group compared to all the other sizes combined (Analyses results are not shown in this paper). Although the smaller (< 90 µm) and larger (> 710 µm) size fractions of the creek sediments were found to contain the highest levels of PAHs, these fractions only represented <1% of the total sediment mass. Therefore, the greatest mass load of the the PAHs was associated with the intermediate sized sediment fractions.

Linear regressions of COD to PAH concentrations on each particle size for each creek showed a significant response factor (slope term) for slightly more than half of the cases tested. When the large-sized LOM samples alone were considered, about 90% of the conditions had significant slope terms, indicating strong linear relations between COD and PAH concentrations. Two-way ANOVA analyses of the PAH concentrations were conducted to investigate the particle size and location as variables. These tests indicated that, except for naphthalene, fluorene, phenanthrene, and indeno(1,2,3-cd)pyrene, all the other PAH analytes were affected by the sediment locations. One-way ANOVA analyses of the concentrations for different particle size ranges comparing the locations showed that for most of the analytes, there were a larger number of significant differences between the creek locations for the smaller particle sizes (<45 and 45 – 90 µm) than for the other sizes (Analyses results are not showed in this paper). Using probability plots and other graphical analyses, Hunter Creek was found to have significantly higher concentrations than the other creeks, especially for the small particle sizes. Hunter Creek sediment had a history of

contamination of hydrocarbons from creek-side businesses that caused the increased PAH concentrations. Cribbs Mill Creek generally had higher PAH concentrations than the sewage-contaminated Carroll's Creek sediments. This might be due to the long lapse in time since the Carroll's Creek sediments were affected by the SSOs (more than a year). The contaminated sediment at Carroll's Creek was either flushed from the contamination site or buried below the surface sampling depth. The Cribbs Mill Creek sampling location was in a long concrete channel with no bank erosion material affecting the sediment concentrations. The concrete lining also had obvious algae growths that may have preferentially sorbed PAHs.

Table 2. Two-Way ANOVA P Values for Analyte Concentrations

PAH	P Value

Conclusions

Selected characteristics were analyzed for fifteen sediment samples from urban creeks. Sediments were found to be mostly composed of particles in the size range of 90 – 710 μm. The volatile content, COD and PAH content of the sediment particle size fractions had a bimodal distribution, with smaller and larger particles containing relatively higher values then the intermediate particles. The highest concentrations were associated with the LOM fractions. The volatile content and COD of the size fractionated sediments showed strong first order polynomial relationships. The presence of fragmentary plant material in the larger size fractions and the high clay/silt content in the smaller size fractions caused higher PAH concentrations. Positive linear relationships was also seen between PAH and COD content, but was most obvious in the sediment fractions with higher volatile (or COD) content. Sediment samples affected by commercial area runoff were found to have higher PAHs concentration than the samples affected by runoff from non-commercial areas.

ABSTRACT

Several studies regarding sorption and dissipation of testosterone in soils have been conducted recently; these studies concluded that the transport of testosterone is limited in the soil/water system. However, this may not explain wide occurrences of testosterone in ground and surface water. In this study, soils from two agricultural fields located in Nebraska, with 3 depths in each location, were utilized to study sorption and desorption of testosterone. The sorption results of batch tests indicated that the Freundlich sorption capacity of the soils ranged from 8.53–38.82 $\mu g^{1-n} mL^n g^{-1}$. The results of desorption experiments indicated that after 3 washes by hormone free distilled water, about 35.14– 102.35 % of the testosterone adsorbed onto the soil in the adsorption tests were desorbed from the soil. Correlations between sorption and soil properties such as cation exchange capacity, surface area, and soil organic matter were investigated. Also, the behavior of sorption and desorption of soils at different depths was compared.

INTRODUCTION

Testosterone is a representative androgenic hormone that can occur artificially or naturally. At a very low concentration level, its wide existence and adverse effects on human and animals have drawn more recent attentions. Agricultural application of manure is an important source of testosterone and other steroid hormones. Hence it is important to understand fate and transport of testosterone in the soil/water system because the presence of testosterone in the environment may pose great impacts on surface and ground water quality.

Recently, several studies have been conducted on sorption, degradation and transport of testosterone in soils. Sorption of testosterone in the soil is believed to be strong. Lee et al. (2003) reported testosterone sorption in sediment and four soils. Sorption of testosterone was believed to reach equilibrium in 24–31 hours. The nonlinear Freundlich sorption coefficient (K_f) in Drummer soil is 59.1 μg^{1-n} mL^n g^{-1} while in other solids sorption was liner with K_d ranging from 4.57 to 27.3 L/kg. Casey et al. (2004) reported maximum K_d values occurred within 5 hours and ranged from 0.5 to 1200 L/kg. Sangsupan et al. (2006) reported that average testosterone K_f values were 26.7 μg^{1-n} mL^n g^{-1} for the 0–10 cm soil depth and 14.0 μg^{1-n} mL^n g^{-1} for the 20–30 cm soil depth. Kim et al. (2007) studied testosterone sorption independent of its

metabolites androstenedione; the K_f values ranged from 228.56 to 3890.45 (μg/kg) $(\mu g/L)^n$. Dissipation of testosterone is rapid according to previous studies. The reported half lives of testosterone are between 8.5 to 21 hours under anaerobic conditions (Lorenzen et al., 2005). These studies have indicated testosterone has a high affinity to the soil and is rapidly degraded to other less potent metabolites. Therefore, researchers have concluded that transport of testosterone is limited in the soil/water system. However, it is difficult to use this conclusion to explain the frequent detections of testosterone in ground and surface water. For example, testosterone has been detected in sediments below a dairy-farm wastewater lagoon to the depth of 45 m reported by Shai A et al. 2008. This observation may be explained by different characteristics in different soils, reversibility of sorption, or other unknown mechanisms that may be related to fate and transport of testosterone.

To fully understand the fate and transport of testosterone in subsurface soils, it is imperative to conduct adsorption and desorption tests with soils at different depths and different properties. The objectives of this study were to conduct: (1) batch sorption tests of testosterone using two agricultural soils, each with 3 different depths and testosterone transformation being inhibited; and (2) desorption tests of testosterone from the same soils after the sorption equilibrium being achieved. This paper presents the results of adsorption isotherms and desorption characteristics that are related to soil properties and soil depth.

MATERIALS AND METHODS

Chemicals and reagents. Testosterone at the highest possible purity (> 98%), methanol and sodium azide were obtained from Sigma-Aldrich (St. Louis, MO). ^{14}C-labeled testosterone was obtained from American Radiolabeled Chemicals (St. Louis, MO). Unlabeled testosterone stock solutions (100 mg/L) was prepared with HPLC grade methanol and was stored in a –20 °C freezer before use; ^{14}C-labeled testosterone series of stock solutions with different activities levels were prepared in solutions of methanol and ultra pure water and were stored in a –4 °C refrigerator.

Soil samples. Soils of 3 depths (0–15.24, 15.24–30.48 and 30.48–60.96 cm) were taken using a steel soil sampling kit (7.6-cm i.d., 80-cm length) driven by a hydro driven probe from an agricultural field in North Platte, NE (NP soil) and Haskell Agricultural Lab in Concord, NE (HAL soil). For each type of the soils, 10 replicates (parallel sub-samples) were taken from locations > 50 cm apart from each other. Once soils arrived at the lab, they were air dried at room temperature and gently passed through a 2-mm sieve. Each soil used in this study was a composite of the ten replicates. Soil properties, such as soil organic matter, cation exchange capacity (CEC), humic matter, metals and soil texture were tested in the Midwest Laboratories (Omaha, NE). The surface area of each soil was tested in the Department of Civil and Environmental Engineering at the University of Virginia.

Sorption and desorption tests. Sorption isotherms were tested in a 10 mL glass centrifuge tube batch reactor (15-415, Kimble, USA). Each batch reactor was loaded with 1 g of the dry soil and 10 mL of ultra pure water containing 0.01 M

$CaCl_2$ and 200 mg/L NaN_3 and then spiked with a combination of unlabeled and ^{14}C-labeled testosterone to form a desired initial testosterone concentration. The glass centrifuge tube batch reactors were sealed with Teflon-lined caps and rotated top to bottom (360°/5 s) for certain time intervals. At the end of the time interval, triplicate reactors were removed and centrifuged. For each reactor an aliquot of 500 μL was taken to test for radioactivity by scintillation counting using a 2500 TR Liquid Scintillation Counter (Packard, Downers Grove, IL). The difference between the initial and final radioactivity in the liquid phase was attributed to sorption of the hormone. Then total testosterone sorbed was calculated by extrapolating the sorption of the labeled testosterone.

Sorption isotherms were tested under 24°C. Six initial testosterone concentrations from 0.003–2 μg/mL were obtained by spiking with both labeled and non labeled testosterone. These concentrations were chosen because they spanned 4 orders of magnitude and represented concentrations of testosterone in manure used for land application. The reactors (triplicates) were then agitated by rotation for 18 hours and then centrifuged at 2000 g for 40 minutes to separate the soil and water. Testosterone adsorbed on the soil was calculated based on mass balance. The Freundlich (eq. 1) and/or Langmuir model were used to fit sorption data:

$$S = K_f C^n \quad (1)$$

where S is the concentration of the hormone adsorbed on the soil (mg g^{-1}); C is the hormone aqueous concentration (mg L^{-1}); n is a measure of sorption isotherm linearity (unitless); and K_f is the Freundlich sorption coefficient (μg^{1-n} mL^n g^{-1}).

After each sorption isotherm test, the liquid phase in the centrifuge tube was poured out from the tube, and then 10 mL hormone free water with 0.01 M $CaCl_2$ and 200 mg/L NaN_3 was introduced into the tube. The tubes were capped and rotated under the same condition as in the sorption isotherm test for 24 hours. After centrifugation, an aliquot of 500 μL was taken to test for radioactivity, and the desorbed testosterone was calculated on the basis of mass balance. The liquid phase in the centrifuge tube was poured out from the tube, and the centrifuge tube was used for the second and then the third desorption test (thus, total 3 cycles were conducted after each adsorption test).

Statistic analysis. Data were tested for significant difference against each other using a Student's T-test for two sample means with unequal variances. For soils sampled at different depths, data were analyzed for significance using a Type 3 Test of Fixed Effects, which is an analysis of variance (F-test) assuming normal populations with different means. Two-tail P values less than 0.05 were considered significant. The statistical test is nominally only testing whether the samples were less than the controls, using a two-tailed test (instead of a one tailed) would effectively double the strength of the test (William P et al., 1992). All statistic analysis is done by EXCEL.

RESULTS AND DISCUSSION

Soil properties. As shown in Table 1, the organic matter content of both the soils decreases with an increase in soil depth. While NP soils contain more sand (30–35%), HAL soils have more clay (20–25%). According to the USDA soil triangle figure, the HAL and NP soils belong to sand silt loam. The CEC ranges from 12.3 to 17.5 meq/100g. Soil metals such as Fe, Cu, Ca and Mg were tested; generally the HAL soil has higher metal content than the NP soil.

Table 1. Selected Soil Properties, Freundlich Parameter K_f and Desorption Percentage (%) as a Function of Soil Depth and Locations.

Properties/ parameters	Depths of HAL Soil (cm)			Depths of NP Soil (cm)		
	0–15.2	15–30.5	30.5–61.0	0–15.2	15–30.5	30.5–61.0
OM[a] (%)	2.2	2	1.3	1.8	1.3	0.7
Clay[b] (%)	20	20	25	12	10	10
Silt (%)	62	65	62	55	60	55
Sand (%)	18	15	13	33	30	35
Total Fe[c]	21	18	11	9	6	4
Total Cu[c]	4.7	4.7	4.5	3.6	3.4	0.9
Total Ca[c]	2131	2733	2826	1856	2115	2290
Total Mg[c]	318	339	358	247	227	221
S_a (m^2/g)[d]	12.61	13.52	17.40	13.37	14.12	13.22
TPV[e] (mL/g)	0.0135	0.0145	0.0183	0.0134	0.0143	0.0133
CEC[f]	13.9	16.9	17.5	12.3	13.2	15.8
K_f[g]	38.82	33.67	32.22	16.47	11.89	9.98
ADP[h] (%)	35.14	39.21	44.34	99.98	90.98	102.35

[a]OM: organic matter. [b]CEC: cation exchange capacity. [c]units = mg/kg. [d]S_a = surface area. [e]TPV = total pore volume. [f]units = meq/100g. [g]units = μg^{1-n} mL^n g^{-1}. [h]ADP = accumulated desorption percentage after three cycles of desorption tests.

Correlations between soil properties and sorption and desorption. The Freundlich sorption coefficient K_f ranges from 8.5293 to 38.8192 μg^{1-n} mL^n g^{-1}. This range is consistent with Lee's results using similar silt loam soil (Drummer soil). Sorption decreases with an increase in soil depth for both the HAL and NP soils. As shown in Table 2, selected soil properties have been correlated with sorption (K_f) and desorption (%). The strength of correlation (R^2) was used to characterize impacts of different properties. Since testosterone has no charge in water during normal pH ranges, the CEC is believed not to relate with sorption. This is verified by $R^2 = 0.1649$ when CEC and K_f are correlated with liner regression with interceptions. However,

the clay, sand, OM (organic matter) content and soil metals are believed to relate with sorption. In a descending order of strength, sorption (K_f) is related to total Fe (R^2 = 0.8647), Mg (R^2 = 0.8592), sand (R^2 = 0.8472, inverse correlation), clay (R^2 = 0.8222), total Cu (R^2 = 0.6765), and organic matter (R^2 = 0.5214). Therefore, these parameters are of utmost importance in determining sorption of testosterone in the soils used in this study. This is consistent with previous studies.

Table 2. Correlation Strength R^2 between Sorption Parameters K_f, Desorption Percentage (%) and Selected Soil Properties.

Soil Properties	Correlation Strength, R^2	
	With K^f (μg^{1-n} mL^n g^{-1})	With Desorption (%)
OM (%)	0.5214	0.384 (inverse)
Clay (%)	0.8222	0.8325 (inverse)
Silt (%)	0.6313	0.8032 (inverse)
Sand (%)	0.8472 (inverse)	0.9341
Surface area (m^2/g)	0.0244	0.0548 (inverse)
Total pore volume (mL/g)	0.1369	0.203 (inverse)
CEC (meq/100g)	0.1649	0.2735 (inverse)
Total Fe (mg/kg)	0.8647	0.7725 (inverse)
Total Cu (mg/kg)	0.6765	0.6348 (inverse)
Total Ca (mg/kg)	0.2457	0.3909 (inverse)
Total Mg (mg/kg)	0.8592	0.8762 (inverse)

Sand is a weak sorptive content for steroid hormone. Partitioning into organic carbon domains of the soil may be the major sorption mechanism as concluded by Casey et al. (2004). The clay content correlates with sorption, presumably due to the testosterone partition onto clay mineral surfaces through hydrophobic interaction with siloxane (–Si–O–Si–) bonds as reported by Van Emmerik et al. (2003). This can also explain why multivalent cations (Mg, Fe) have strong correlation with sorption. Because these cations normally associate with certain clay (Brannon et al. 1997) which may interact with testosterone.

In a descending order of strength, desorption (%) is related to sand content (R^2 = 0.9341), total Mg (R^2 = 0.8762), clay content (R^2 = 0.8325), total Fe (R^2 = 0.7725). Desorption mainly relates with sand content. Sand is a weak sorptive content, the greater the sand content is the larger percentage of sorbed testosterone might come off the soil. Table 2 also shows the inverse relationship between the clay content and organic matter. The interaction between testosterone and soil metals in the sorption step prevents further testosterone desorption, which explains soil metals generally have strong correlation with desorption inversely.

Effects of soil depth on sorption and desorption. As shown in Figure 1, sorption of testosterone decreased with increased depth. The top 15.24-cm soil has the greatest sorption capacity. For the HAL soil, p = 0.0122 for comparison between 0–15.24 cm and 15.24–30.48 cm; p = 0.0187 for between 0–15.24 cm and 30.48–60.96 cm; and p = 0.416 between 15.24–30.48 cm and 30.48–60.96 cm soil. For the NP soil, p = 0.0185 for comparison between 0–15.24 cm and 15.24–30.48 cm; p = 0.00249 for between 0–15.24 cm and 30.48–60.96 cm; and p = 0.105 between 15.24–30.48 cm and 30.48–60.96 cm. All depths are significantly different from each other ($p < 0.05$) regarding sorption. More importantly, topsoils are different from subsurface soils.

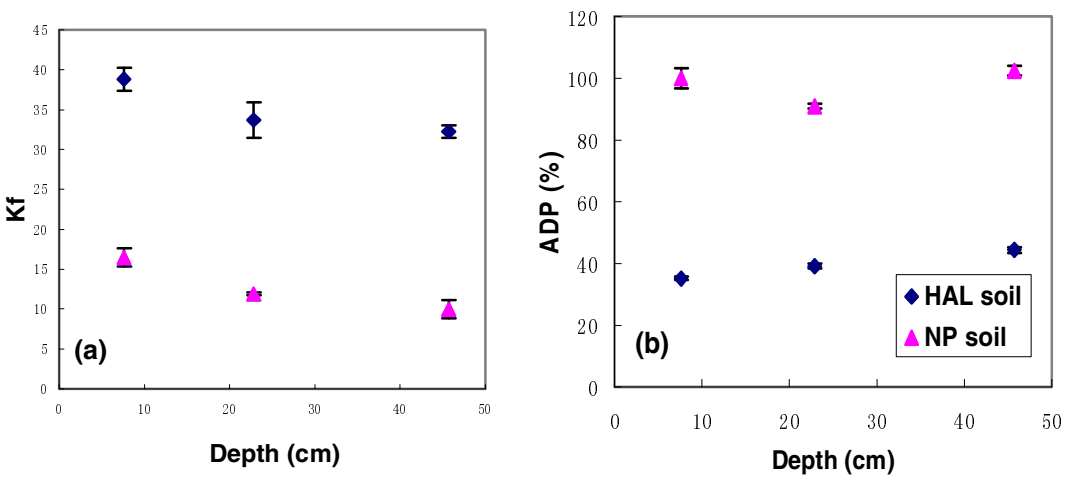

Figure 1. (a) Freundlich sorption parameters K_f of different depths (7.62, 22.86, 45.72 cm) for HAL and NP soils at 24 °C; and (b) accumulated desorption percentage (%) of different depth for HAL and NP soils at 24 °C. Error bars stand for standard deviations (n = 3). ADP stands for accumulated desorption percentage after three cycles of desorption tests.

Desorption percentages significantly increased with the soil depth ($p < 0.05$). For HAL soil, p is 0.0212 for comparison between 0–15.24 cm and 15.24–30.48 cm; p is 0.0087 for between 0–15.24 cm and 30.48–60.96 cm; and p is 0.316 between 15.24–30.48 cm and 30.48–60.96 cm. For NP soil, p is 0.0124 for between 0–15.24 cm and 30.48–60.96 cm; p is 0.127 between 15.24–30.48 cm and 30.48–60.96 cm; and p is 0.221 between 15.24–30.48 cm and 30.48–60.96 cm. This may be because the OM content decreases with increasing depth. A greater OM content is believed to cause stronger binding of testosterone, which leads to less desorption as reported by Hildebrand et al (2006). One exception is between the NP 0–7.62 and 15.24–30.48 cm soil. While the NP 0–15.24 cm soil has a greater OM content than the NP 15.24–

30.48 cm soil, the NP 15.24–30.48 cm soil has a less sand content. Comparison of NP 0–15.24 cm and NP 15.24–30.48 cm desorption data indicates no significant differences (p = 0. 134).

SUMMARY

The sorption of testosterone in this study is comparable with previous studies. However, the desorption experiments that followed adsorption tests indicates a greater potential for sorbed testosterone to come from soils. Also, the organic matter, clay content, sand content and soil metals are important in determining sorption while desorption is mostly related with the sand content, clay content and soil metals. Soil depth posed a remarkable impact on sorption and desorption. Generally, sorption decreases while desorption increases with an increase in soil depth. The findings of this study suggest that it is important to consider soil properties and soil depth when we evaluate fate and transport of testosterone in soil/water systems.

A Study on Spatial Distribution of Water Quality And The Behavior of Do Concentration in Tidal Area of Urban Rivers

M. Okabe[1], M. Kawamura[1], T. Kato[2], T. Yamada[2]
[1] *Graduate School of Science and Engineering, Chuo University, Japan;*
[2] *Dept. of Civil Engineering, Chuo University, Japan*
masato_okabe@civil.chuo-u.ac.jp

The aims of these observations are to clarify the urban river water quality in tidal area. This paper explains the spatial distribution of water quality in the tidal area during normal water discharge and the time series of the dissolved oxygen content before and after the flood. This is the basic research to improve water quality.

From the results of the observation, following results are obtained; 1) BOD concentration meets the environmental criteria in Japan. 2) T-N and T-P concentrations rise at the observation points below the discharge points from the water reclamation centers. 3) In the observation during rainfall, the dissolved oxygen saturation decreases from 20% to below 5% at observation point in two hours, and the value recovered after 6 days to recover up. Moreover other observation, dissolved oxygen rises to around 100% in all layers.

Key Words: *Spatial distribution of water quality, Urban river, Tidal area Dissolved oxygen, Field observation,*

1. Introduction

Urban developing around the river has been performed conventionally as not only water resources but also the place of recreation and relaxation for people and space of healing in the world. However in Japan, river development which has very high safety-level for flood disaster has been carried out to secure measures of the flood and storm surge disaster in the high economic growth period As a result, there is great achievement for river improvement but people lost chance to play and luxuriate in the urban river. In recent years, the time comes when we discuss the city and basin that coexist with nature in various plans related to the formation of the country in Japan. Under such situation, it is recognized as a very important problem to improve the water quality and environment in the urban river.

The authors have conventionally conducted many field observation and theoretical development, numerical analysis to ascertain to clarify the state of water quality. For example, the authors[1),2),3)] clarify formation process of the water quality hydrograph that describes water quality change for flooding. We show that the water quality hydrograph is classified into three types and suggest theory of deriving its prediction method from only the law of conservation. Therefore it is possible to track water quality change for flooding in theory. Moreover the authors[4,)] carried out field observations. These observations were about longitudinal distribution and temporal and spatial characteristics of water quality in tidal area of Arakawa River. In conclusion, it is reported that saltwater intrusion in Arakawa River is well-mixed type during spring tide and weakly-mixed type during neap tide and saltwater during neap tide is oxygen depletion. Whereas quantitative estimation that responds to each river because state of water quality shows different circumstances under the basin characteristics and in ordinary water discharge or for flooding. In addition, it is difficult to clarify water quality environment in the river because hydrological and water quality data in the urban river is insufficient.

This paper reports result of three field observations (1. the spatial distribution of water quality in the tidal area in ordinary water discharge, 2. the time series of salinity, the dissolved oxygen and other water qualities before and after the flood, 3. the observation of the salinity intrusion) in the tidal area of Kanda River, Nihombashi River, Sumida River and Arakawa River. Herewith, we clarify the state of water quality in tidal area of urban rivers and this paper is basic research to practice action to clean up water quality.

2. Overview of intended rivers and method of field observation

2.1 Overview of intended rivers

Overview of observation points is shown in Figure 1. Arakawa River has 173km mainstream length and 2940km^2 basin area and we research 21km from river mouse in tidal area of Arakawa River. Sumida River is tributary stream of Arakawa River and the urban river that reaches 100% penetration of sewer system and 80% of its quantity is municipal discharge. Sumida River meets Kanda River and Nihombashi River downstream. Kanda River has 24.6km mainstream length and 105 km^2 basin area and urban river that. Nihombashi River has tributary stream of Kanda river and 4.8km length. Reference point for length of Kanda River and Nihombashi River is reference point of Sumida River in this paper.

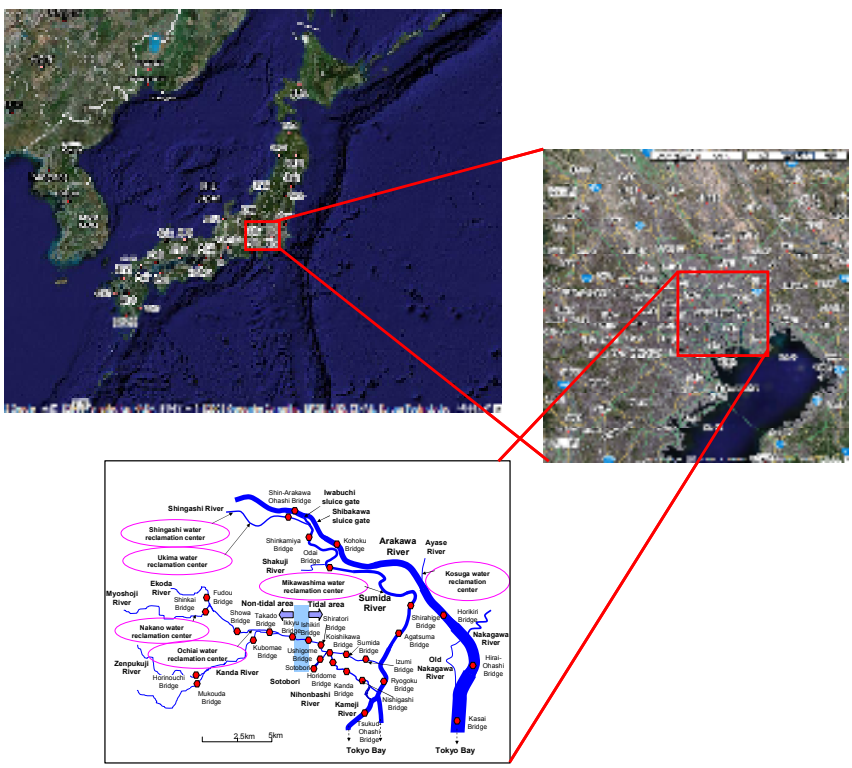

Fig.1 The Overview of Kanda River, Nihombashi River, Sumida River and Arakawa River

2.2. Method of observation

The time series of a tidal level, the rainfall and temperature for three weeks from observation day in normal water discharge are shown in Figure 2. When we obtain water samples, state of water flow is following flow and observation is finished every point before water flow changes reverse. In Sumida River, we moved and obtained water samples by boat and in other rivers; we do it from the bridges. We measure water temperature and salinity and dissolved oxygen(DO) by Multi-Parameter Water Quality Meters(HydroLab) and analysis BOD, total nitrogen(T-N), total phosphorus(T-P), ammonia nitrogen(NH_4 –N) chlorophyl-a and total coliform. BOD and T-P is obtained at three points on vertical direction (surface layer: 30cm from water surface, middle layer: middle depth and bottom layer: 30cm from river bed). Furthermore we practiced continuous measurement (for 107 hours) from 2007 August 28th to September 2nd. We measured the vertical distribution of velocity, dissolved oxygen and salinity to research saltwater intrusion and water environmental quality at Nishigashi point (5.5km from river mouse) in Nihombashi River as shown in Figure 1. We practiced time series measurement at the same point from 2008 May 12th to May 23rd and measured BOD concentration and total coliform obtaining water sample in surface layer and the vertical distribution of flow velocity and dissolved oxygen in a similar way. Workhorse ADCP (Teledyne RD

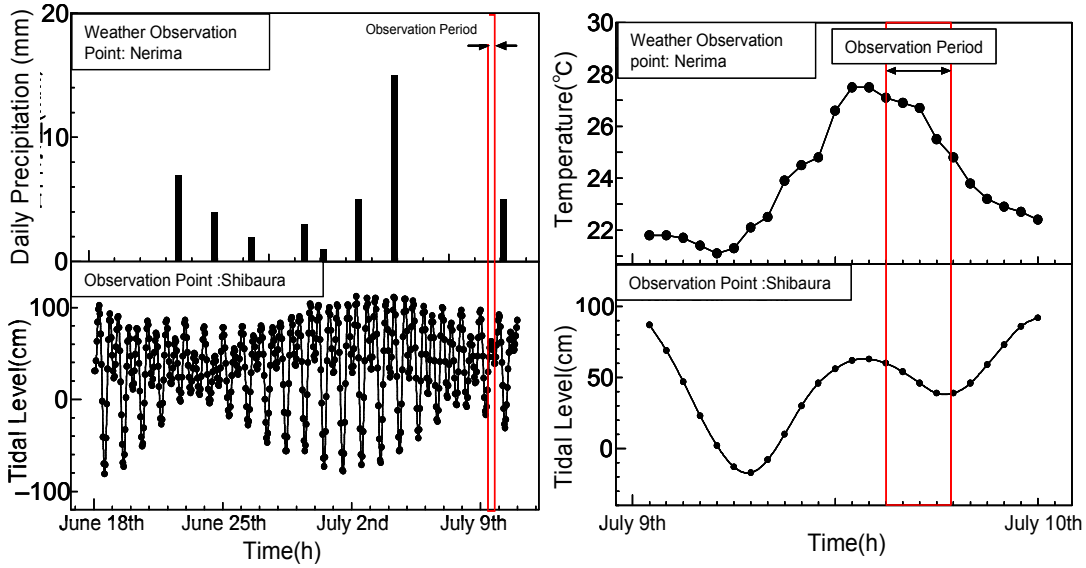

Fig.2 Observing period and time series of Tidal Level , Rainfall and Temperature

Instruments, Inc) was used to measure the vertical distribution of velocity. Dissolved oxygen and salinity were continuously measured at 5 points in the vertical direction (10, 30, 50, 70 and 90 percent of water depth) once every hour.

3. Result of observation of water quality in ordinary water discharge in Nihombashi River, Kanda River, Arakawa River and Sumida River

3.1 Spatial distribution of various water qualities

Obaservation of water quality in ordinary water discharge is practiced in summer and autumn. Result of observation of BOD, T-P, T-N NH_4 –N, total coliform, salinity and dissolved oxygen in Nihombashi River, Kanda River, Arakawa River and Sumida River in autumn is shown in Figure 3. Concentration (except salinity, total coliform and NH_4 –N) which shows red mark in Figure 3 is nonqualified for the environmental criteria of Ministry of the Environment in Japan. Maximum BOD concentration of surface layer is 6.1mg/l at Ushigome Bridge point in Sotobori canal. BOD concentration indicates the value below the environmental criteria (3mg/l) at 80% of the observation points. BOD concentration of bottom layer in Kanda River indicates high value around Sotobori canal point. Max value is 17.0mg/l at 2km upper point from Sotobori Canal and the value decreases in the direction of flowing. Sotobori canal converge 9.5km point from river mouse in Kanda River and Sotobori canal water flow in Kanda River a little bit.

Total phosphorus indicates more than 0.1mg/l at 90% of all observation points and is nonqualified for the environmental criteria. The value of Kanda River and Nihombashi River is higher than Arakawa River and Sumida River and increase on the lower side of flow point from Ochiai water reclamation center (sewage treatment plant). The result of total nitrogen is same result that total phosphorus has but increase on the lower side of flow point from Nakano water reclamation center (above the Nakano water reclamation center). Water volume discharged by Ochiai water reclamation center is almost $2.5m^3/s$ and ordinary flow volume at Ikkyu Bridge in Kanda River is almost $3.2m^3/l$.So almost of flow volume in Kanda River and Nihombashi River is water volume discharged by Ochiai water reclamation center. Ochiai water reclamation center use advanced treatment for BOD and SS though it is important to treat Nitrogen and Phosphorus hereafter.

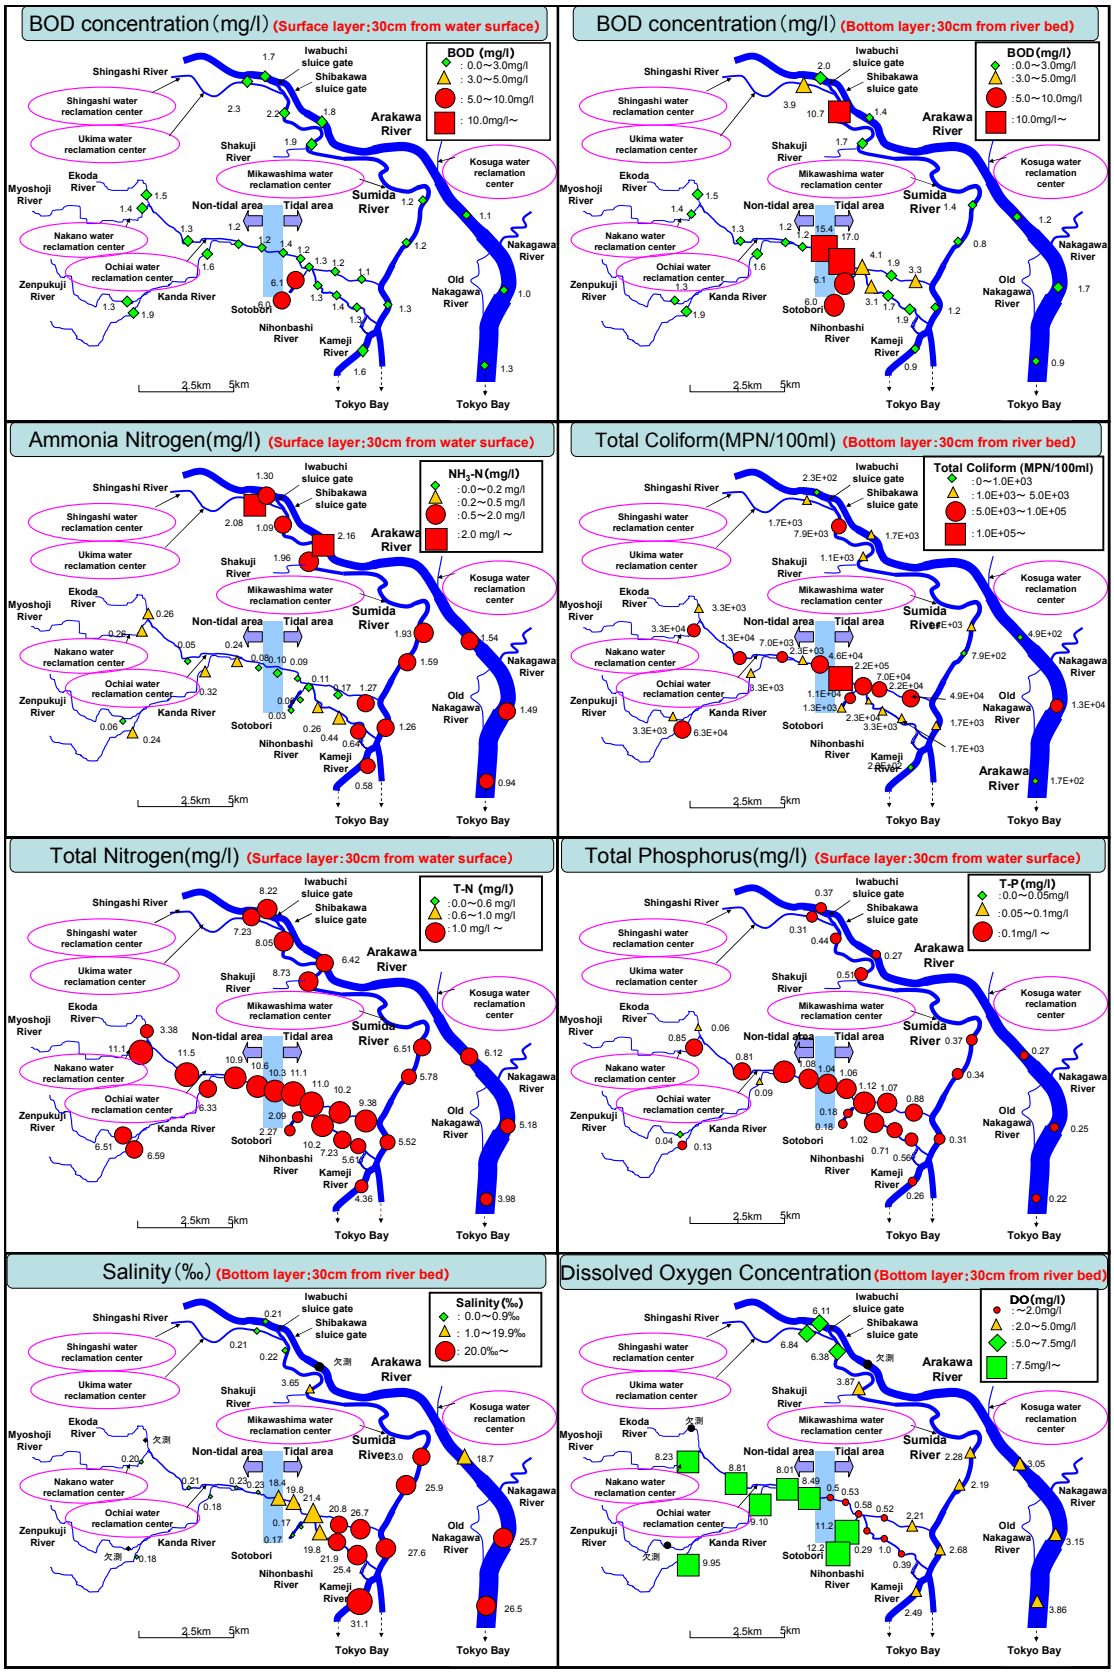

Fig.3 Spatial distribution of water Quality in the tidal area of Kanda River, Nihombashi River, Sumida River and Arakawa River [Date: 16/11/2007]

Ammonia nitrogen in Arakawa River and Sumida River is higher than Kanda River and Nihombashi River and in the following current influence from downstream may remain upper reaches because Maximum value is at end point in Kanda River and Nihombashi River. Total coliform is high in upstream of Kanda River, Sumida River and Arakawa River and decreases in the direction of Tokyo Bay. Total coliform that is used environmental indicator for swimming in river is nonqualified for the environmental criteria and it suggests low of water amenity in the urban river. Salinity (30cm from river bed) intrude to uppermost stream in Kanda River. Dissolved oxygen concentration (30cm from river bed) in Nihombashi River and Kanda River is below 1mg/l and oxygen deficit layer exists in Nihombashi River and Kanda River.

3.2 Longitudinal distribution of various water qualities

Longitudinal distribution of result of water quality observation in autumn is shown in Nihombashi River and Kanda River in Figure 4, Sumidagawa River in Figure 5, Arakawa River in Figure 6. As shown in

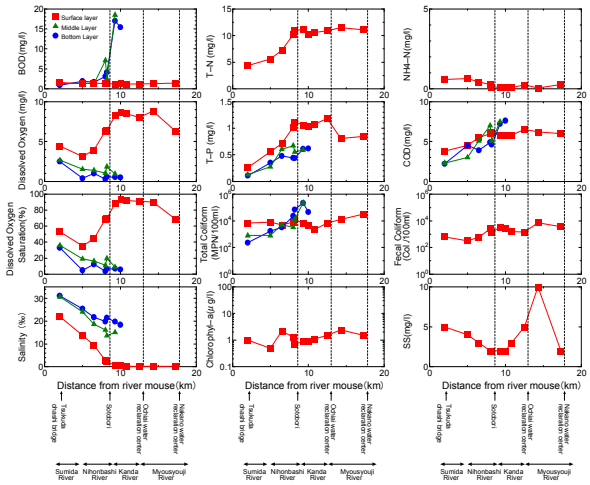

Fig.4 Longitudinal distribution of water Quality in the tidal area of Kanda River and Nihombashi River [Date: 16/11/2007]

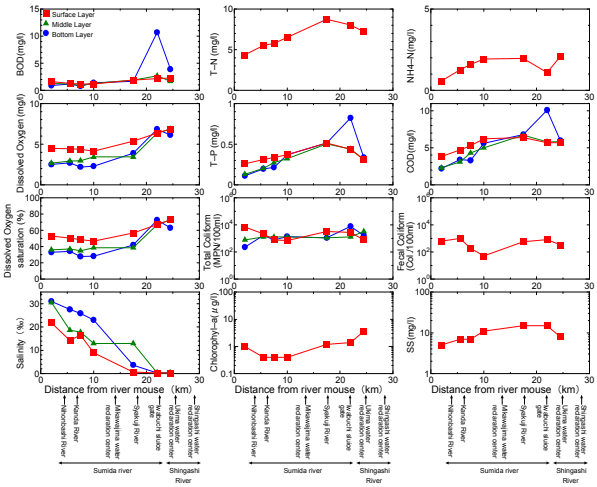

Fig.5 Longitudinal distribution of water Quality in the tidal area of Sumida River [Date: 16/11/2007]

Figure 4, total phosphorus is higher value in surface layer than bottom layer and BOD concentration is higher in bottom layer than surface layer. Total coliform in surface layer hardly changes in vertical direction and in bottom layer indicates high value 2km uppers point from Sotobori canal and decreases in the direction of flowing. Dissolved oxygen in Nihombashi River indicates exceptionally low value and oxygen deficit layer exists in middle and bottom layer in Nihombashi River and Kanda River. As shown in Figure 5, BOD and total phosphorus indicate uniform distribution in vertical direction at many points in Sumida River. While BOD and total phosphorus in Sumida River indicate uniform distribution in vertical direction in Figure 5, total phosphorus in surface layer increases around river mouse. Salinity intrudes to 17km point from river mouse. As shown in Figure 6 BOD and total phosphorus in Arakawa River indicate uniform distribution in vertical direction. The following are shown from the

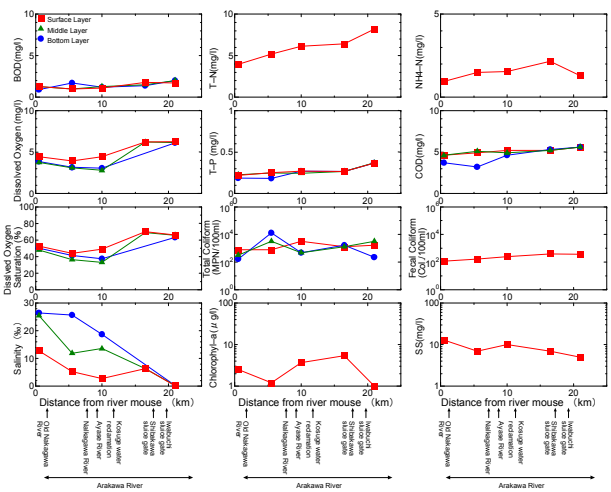

Fig.6 Longitudinal distribution of water Quality in the tidal area of Arakawa River [Date: 16/11/2007]

observation result of spatial distribution of various water quality of showing above. Factors of formation of water quality in Nihombashi River and Kanda River are attributed to influence of treated water from water reclamation center and water from Sotobori canal. We clarify that BOD concentration is high in bottom layer and total phosphorus is high in surface layer. In Sumida River and Arakawa River water quality measured in this observation except Chlorophyl-a around downstream of Shingashi River is high value and decrease in the following. BOD concentration indicates high value in Arakawa River and total phosphorus in Arakawa and BOD concentration in Sumida River show uniform distribution in vertical direction at many points.

4. Characteristic of saltwater intrusion in Nihonbahsi River

Dissolved oxygen showing above in Nihombashi River and Kanda River is exceptionally low value and hypoxic layer on the river bed. To comprehend factors of influx of hypoxic water from Tokyo Bay and formation of river flow on the river bed, we execute observation of characteristic of saltwater intrusion in Nihombashi River.

Continuous change of dissolved oxygen, Salinity and velocity is measured in vertical distribution at Nishigashi Bridge point (5.5km from river mouse) in Nihombashi River between 2007 August 28th and 2007 September 2nd (including spring tide) The authors also measure vertical distribution of dissolved oxygen and salinity in Nihombashi River and Kanda River. Therefore formation of distribution of dissolved oxygen and salinity is difficult around upstream of tidal area in Kanda River and so result of observation at 5.5km point in Nihombashi River is representative result of saltwater intrusion from Tokyo Bay in this paper. Time-series of vertical distribution of dissolved oxygen, salinity, velocity and tidal level is shown in Figure 7. Dissolved oxygen is high value in surface layer and law value on the river bed during falling tide. Salinity is law value in

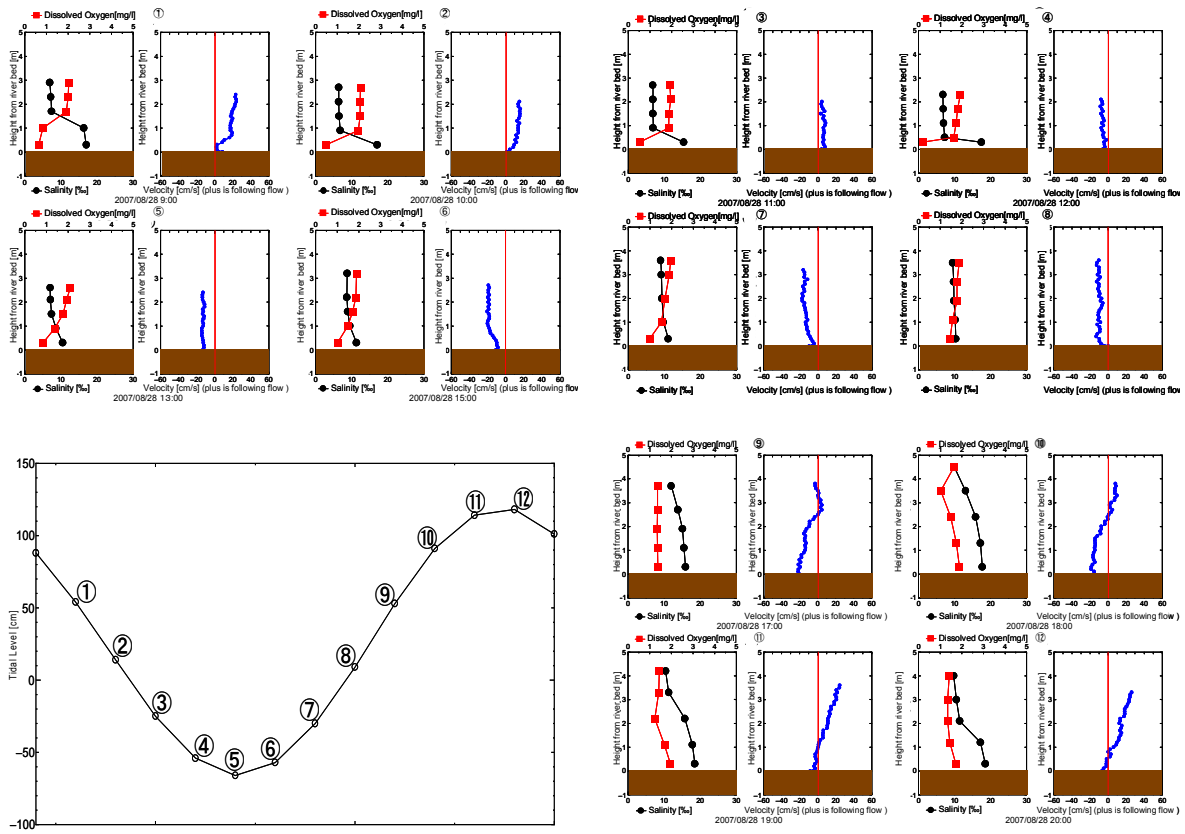

Fig.7 Vertical profile of Dissolved Oxygen Concentration, Salinity, and Velocity and time series of tidal level [Date:28/08-04/09/2007]

surface layer and high value on the river bed. Therefore formation of salinity is weekly-mixed type with double layer. However dissolved oxygen and salinity of surface layer and on the river bed is almost uniform distribution from fall of the tide to flowing tide and saltwater intrude in well-mixed type. Furthermore vertical distribution of velocity, flow on the river bed is little in following flow but it occurs in reverse flow. As mentioned above saltwater intrude in well-mixed type. As shown No.7, 8 and 9 in Figure 7, dissolved oxygen is uniform distribution in vertical direction in reverse flow and higher than in ordinary water discharge. In conclusion, in the phenomenon of hypoxic water on the river bed in Nihombashi River, the flow of the hypoxic water from Tokyo Bay is not a cause. The cause of hypoxic water in Nihombashi River is attributed to continual consumption of oxygen by bottom sediment under formation of flow on the river bed that does not mostly occurs However, it is need to research consumption of oxygen by bottom sediment and verify above consideration

5. Dissolved oxygen saturation and salinity changes during rainfall

Developing sewer system, water environmental quality has been dramatically improved in Nihombashi River and Kanda River while the problem of combined sewer system is that overflow waste water flow to river during rainfall.

It rains in observation in 2007.Total rainfall is 20mm in a couple of hours and maximum hourly rainfall intensity is 10mm/h (AMeDAS Nerima). Figure 8 shows time-series of salinity, dissolved oxygen saturation, tidal level, flow velocity and hourly rainfall intensity . During rainfall, dissolved oxygen saturation rapidly decrease. The cause of dissolved oxygen decrease includes two cases. One case includes that first treatment water from Nakano and Ochiai water reclamation center (sewage treatment plant) or overflow water from sewer system exceed quantity of ordinary discharge (1.6m^3/s in Nihombashi River) to a large degree. It is possible that overflow water from combined sewer system is anaerobic and high concentration of BOD and quantity of flow in Nihombashi River during observation is 42m^3/s (observation value of ADCP)

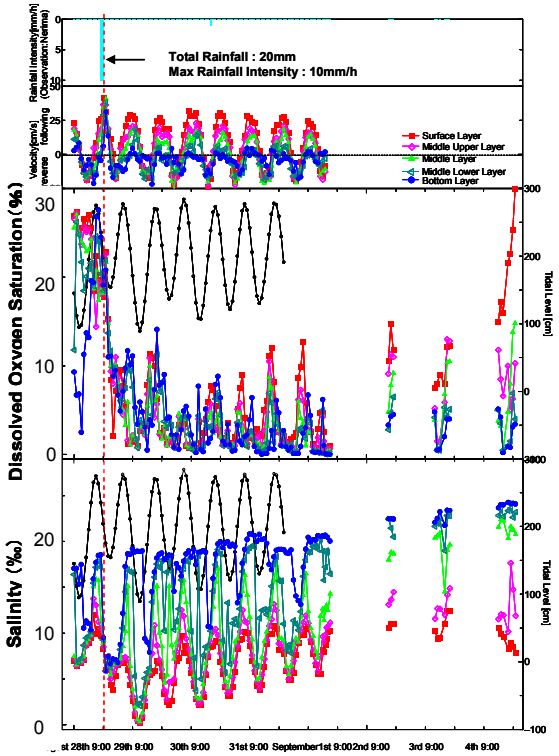

Fig.8 Time series of Velocity, Rainfall, Dissolved Oxygen Saturation and Salinity [Date:28/08-04/09/2007]

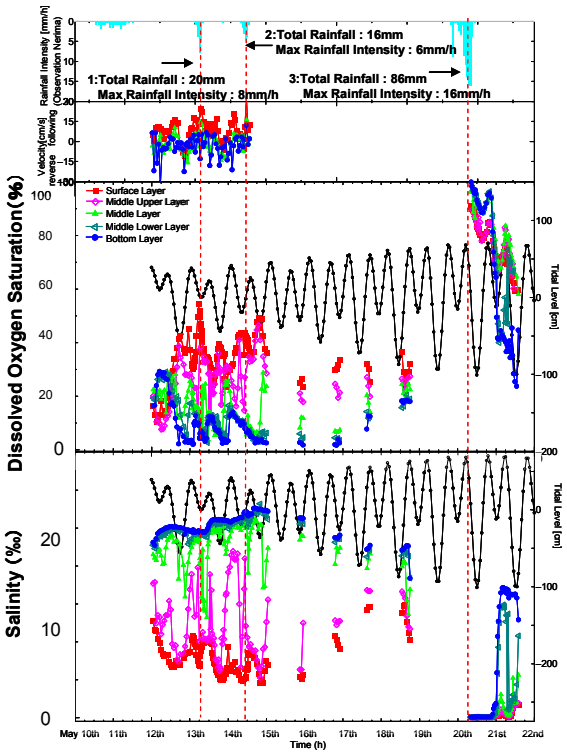

Fig.9 Time series of Velocity, Rainfall, Dissolved Oxygen Saturation and Salinity [Date:12-23/05/2008]

that exceed to a large degree. Therefore it is possible to strongly influence state of water quality. The other cause is attributed to the assumption that particulate matter is kicked up from bottom sediment by rising velocity (nearly 40cm/s) in rainfall and chemical reaction like oxidation or reduction reaction occurs. In addition salinity decreases in all layers for six hours after rainfall. After rainfall, it takes 2days for appearance and odor of river to become normal again before rainfall and 6 hours for salinity to become normal again while 6 days for dissolved oxygen to become normal again. Recovery time of dissolved oxygen is later than salinity. From the observation result, we clarify that it is 6 days that dissolved oxygen becomes normal again from spring tide to neap tide after rainfall.

The Result of observation in 2008 is shown in Figure 9. Its observation conducts from neap tide to spring tide. It rains early in the observation. Total rainfall is 19mm in six hours and maximum hourly rainfall intensity is 8mm/h. Scale of rainfall in observation in 2008 is almost same scale as observation in 2007, but dissolved reduction of oxygen and salinity does not happen in all layers after rainfall. The cause of no reduction in all layers is attributed to no kicking up particulate matter from bottom sediment because of little rising of velocity (10cm/s) on the river bed.

Heavy rain occurred later in the observation. Total rainfall was 86mm in 14 hours and maximum hourly rainfall intensity was 16mm/h. The observation result shows that 5 hours after end of rainfall dissolved oxygen saturation rises 100% and salinity dropped below 1‰. This phenomenon is attributed to the assumption that rainwater flowing in river washed away hypoxic water that existed before heavy rainfall to the downstream. Dissolved oxygen is falling as time goes on and value on the river bed decrease before rain, and value in surface layer also decrease but is higher than before rainfall.

From the observation result, we clarify that below 3 cases occur as variation of dissolved oxygen and salinity after rainfall. 1) When total rainfall is 20mm in a couple of hours and maximum hourly rainfall intensity is 10mm/h, velocity on the river bed rise and dissolved oxygen and salinity fall in all layers. 2) When total rainfall is 19mm in six hours and maximum hourly rainfall intensity is 8mm/h, velocity on the river bed dose not rise and dissolved oxygen and salinity does not change value in all layers. 3) When total rainfall is 86mm in 16 hours and maximum hourly rainfall intensity is 16mm/h, dissolved oxygen rises to around 100% and salinity fall to nearly 0 ‰ in all layers.

6. BOD, total coliform and turbidity during rainfall

The problem in urban river is that overflow waste water from combined sewer system and primary effluent water from sewage treatment plant flow to river during rainfall. To research changing of water quality by the influences, we practice fixed-point observation from 2008 May 12th to 15th. The observation points where BOD, total coliform and turbidity is measured in Kanda River and Nihombashi River during rainfall is shown in Figure 10. As shown in figure, point **A** is 2km below point of flowing from Ochiai water reclamation center, point **B** is 100m below a large exit of storm outfall uppermost stream in tidal area in Kanda River and point **C** is in Nihombashi River, and surface water is obtained at every point. The time-series of BDO, total coliform and rainfall is shown in Figure 11.

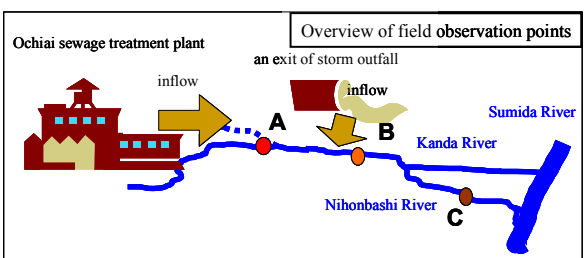

Fig.10 The Overview of observation in Kanda River and Nihombashi River

At point **A** BOD begins to rise three hours later after rainfall and maximum value is 96.0mg/l.But total coliform does not almost change during rainfall. Due to the combined sewer system, discharge in sewer

system flows into Ochiai water reclamation center during heavy rain.When quantity of flow into water reclamation center increase, it changes normal treatment into primary treatment. At this time, water reclamation center does not use advanced treatment for BOD, but treatment for salinity is used as usual. Cause of observation result at point **A** is attributed to discharge of primary treatment.

BOD and total coliform increase during rainfall at point **B**, and maximum value of BOD is 64mg/l and maximum value of total coliform is 1.3×10^8 MPN/100ml. At this time, overflow from the large exit of storm outfall is checked. When the rain grew heavier and the rain water flowed into the combined sewer system, early swollen water in the sewer system flows into water reclamation center. Then the quantity of the flow increases further diluted foul water overflows from the exit of storm outfall to the river. The observation result at point **B** is attributed to this obtaining overflow water in surface layer.

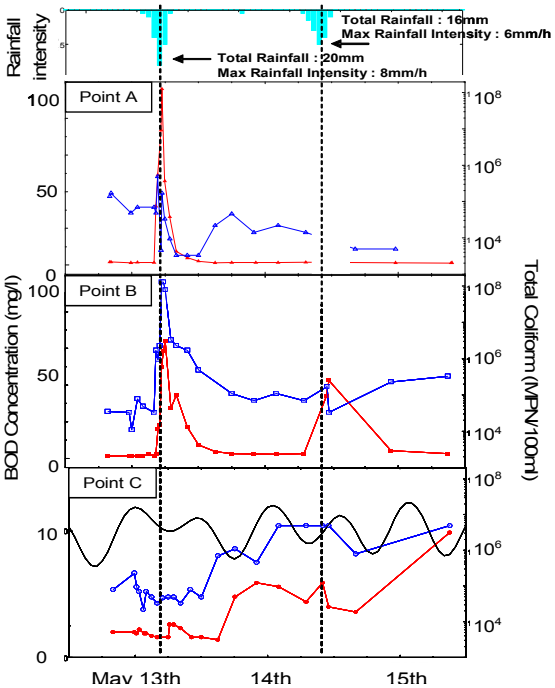

Fig.11 Time series of rainfall, BOD and Total Coliform [Date:12-23/05/2008]

BOD concentration and total coliform at point **C** slowly rise after rainfall. It takes 2 days to rise to maximum value of BOD (10mg/l) after rainfall. This result is attributed to slowly flowing from upstream and retaining water in Niohnbashi River as a tidal river.

Correlation diagram of BOD and turbidity is shown in Figure 12. There strong correlation between BOD and turbidity. If facilities of removing turbidity are set, it is possible to mitigate water pollution in

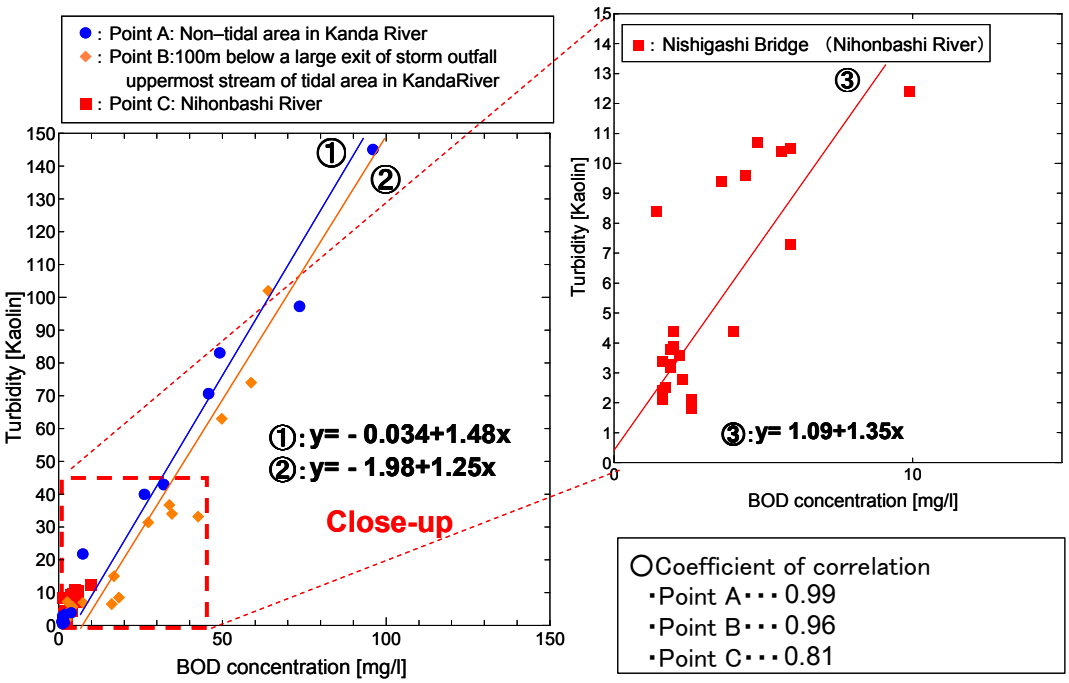

Fig.12 Correlation chart between BOD and Turbidity [Date:12-23/05/2008]

Nihombashi River and Kanda River.

7. Summary of observation result

In this paper, the result of observation of temporal and spatial characteristics of water quality in Nihombashi River, Kanda River, Arakawa River and Sumida River were discussed. Obtained knowledge is shown below.

1) From result of observation in ordinary water discharge. BOD concentration of surface layer indicates the value below the environmental criteria (3mg/l) at 80% of the observation points, but the value of bottom layer in Kanda River indicates high value around Sotobori canal point. Max value is 17.0mg/l at 2km upper point from Sotobori canal and the value decreases in the direction of flowing.
2) Total nitrogen and total phosphorus is nonqualified for the environmental criteria at almost observation points. The value of Kanda River and Nihombashi River is high value on the lower side of flow point from the water reclamation center and the value decreases in the direction of flowing.
3)From result of saltwater intrusion, In Nihombashi River, it is well-mixed type in reverse flow and weekly-mixed type with double layer that dissolved oxygen is high value in surface layer and law value on the river bed in following flow.
4) From the result of time series of water quality, we clarify 3 cases that dissolved oxygen and salinity rapidly fall in all layers and dissolved oxygen and salinity does not change value before rainfall in all layers and dissolved oxygen rises to around 100% and salinity fall to nearly 0‰ in all layers. In addition, it takes 6 days for dissolved oxygen to become normal again from spring tide to neap tide after rainfall.
5) BOD concentration rapidly rises during rainfall and fall after that uppermost stream in tidal area of Kanda River. Total coliform rapidly rises during rainfall and fall after that below the exit of storm outfall. In Nihombashi River, BOD concentration and total coliform slowly rise after rainfall. It takes 2 days to rise to maximum value of BOD (10mg/l).
6) The bed load of Nihombashi River move over regardless of rainfall.

ABSTRACT

Most amphibians require suitable wetlands for breeding, oviposition, and juvenile development. Newly metamorphosed juveniles disperse into terrestrial habitat where they spend the majority of their adult lives in undisturbed forest or grassland adjacent to the wetland. Development of new infrastructure can result in wetland draining and habitat fragmentation thereby disrupting necessary life history functions. To ensure the long-term survival of amphibians, it is imperative that developers take into account their conservation needs during project planning and construction of replacement wetlands. In order to assist planners and managers in this effort, we present an index that quantifies the biotic integrity of amphibian populations within constructed wetlands throughout northern Missouri. The index is modeled after Ohio's Amphibian Quality Assessment Index (AQAI) and it incorporates ecological and abundance information for each species inhabiting a wetland. Although refinements will continue, current results indicate this tool can help assess the biological integrity of constructed and natural wetlands. The index can be modified to accommodate regional differences in species' ecology.

INTRODUCTION

The decline of many amphibian species throughout the world is well documented and has received much public attention (Stuart et al. 2004). There are multiple reasons for these declines but habitat loss and alteration is widely perceived as the primary cause (Gardner et al., 2007). Most amphibian species require suitable wetland habitat for breeding and juvenile development. Impaired wetland function at natural sites through alterations in hydrology or the inadequate construction and placement of restored and created wetlands can result in a net loss of habitat necessary for reproduction. Due to their biphasic life cycle, many species also require suitable terrestrial habitat adjacent to the wetland for foraging, hibernation,

aestivation, and shelter. The required amount of land surrounding the wetland is known as "core terrestrial habitat" and it varies in width for each species. However, a distance of 300m from the wetland's edge likely incorporates the needs of most species (Semlitsch and Bodie, 2003; Rittenhouse and Semlitsch, 2007). Additional wetlands in the area, and suitable habitat between them, provide individuals with opportunities for gene exchange and allow for re-colonization of wetlands when local populations crash due to stochastic events. Therefore, destruction, alteration, or fragmentation of the terrestrial core zone can result in habitat loss, disruption of essential life history functions, and population decline even when the aquatic environment is undisturbed.

The goal of federal wetland regulations, and those of some states, is "no-net-loss" of wetlands. However, despite the U.S. Clean Water Act mandating the protection of the physical, chemical, and biological integrity of wetlands, net gains in acreage do not necessarily translate to net gains in ecological function (Semlitsch, 2008). Therefore, replacement wetlands may not adequately compensate ecologically for those lost. For example, although Dahl (2006) found that overall acreage of wetlands in the U.S. increased between 1998 and 2004, most gains were attributed to construction of freshwater ponds that offset the loss of freshwater vegetated wetlands. As the author points out, this trend represents a shift in class and wetland function. Freshwater ponds are not an equivalent replacement for vegetated wetlands. Because many species of wetland plants and animals are dependent upon specific wetland types, replacement wetlands that do not meet their requirements equate to habitat loss regardless of acreage gained.

In order to evaluate the effectiveness of constructed and restored wetlands, it is imperative to examine how they function ecologically. To do this, wetland managers and regulatory authorities need clear performance criteria that are based upon the ecology of wetland inhabitants. While some functional-based wetland assessments rely upon indicators such as energy flow facilitation, nutrient cycling support, and plant or animal community maintenance (Brinson and Rheinhardt, 1996), these assessments often do not contain metrics that incorporate information about the biological components of wetlands (King et al., 2000). Therefore, indexes of biological integrity (IBI's) have been developed that rely upon information about the relative abundance of key indicator species to assess the biotic components of habitats. The first IBI was developed to assess fish communities in small streams in Indiana and Illinois (Karr, 1981). Since its introduction, the original IBI for fish has been modified for use in other regions, ecosystems, and other taxa (Kerans and Karr, 1994; King et al., 2000).

The Ohio Amphibian Index of Biological Integrity (AmphIBI) was developed by the Ohio EPA to create amphibian-based wetland bio-criteria that assesses the extent of wetland disturbance in conjunction with the Ohio Rapid Assessment Method (ORAM version 5.0), an index that categorizes wetlands by type and level of human disturbance (Micacchion, 2002, 2004). Like other IBI's, the AmphIBI uses a set of metrics which are ranked measurements of variables that represent expectations of biological integrity. When the metrics from a wetland are summed, the index provides a "score" that represents the amphibian biotic integrity of the wetland relative to others of the same type. The Ohio AmphIBI is composed of five metrics,

each containing 1 – 10 points, for a total of 50 possible points (see below). The cumulative rating results in better representation of disturbance-based amphibian biotic integrity than the individual metrics separately.

In this paper we introduce a prototype biotic index to assess amphibian assemblages in northern Missouri wetlands. The index is similar to the AQAI in that it is weighted and includes information about each species' sensitivity to disturbance and the number of individuals of each species captured at a site. The index also includes information about each species' range and its abundance throughout Missouri. Our objective is to develop a regionally modifiable, multi-metric amphibian-based biotic index, using the AmphIBI as a template, for Missouri wetlands.

METHODS

We selected 49 constructed wetlands within 26 northern Missouri counties for assessment of amphibian community biotic integrity. Most (37) were within the Central Dissected Till Plains Ecoregion. Eleven were located within the Ozark Highlands Ecoregion and one was slightly within the Osage Plains Ecoregion (Fig. 1). Twenty-nine were "wildlife" or "herp" ponds on Missouri Department of Conservation wildlife areas and 20 were Missouri Department of Transportation compensatory mitigation wetlands. We selected wetlands on public-owned lands that we had permission to access and conduct surveys. For logistical purposes, wetlands were grouped geographically into seven sampling zones, each containing 5 – 9 wetlands. Zone sampling order within each survey period was randomly determined.

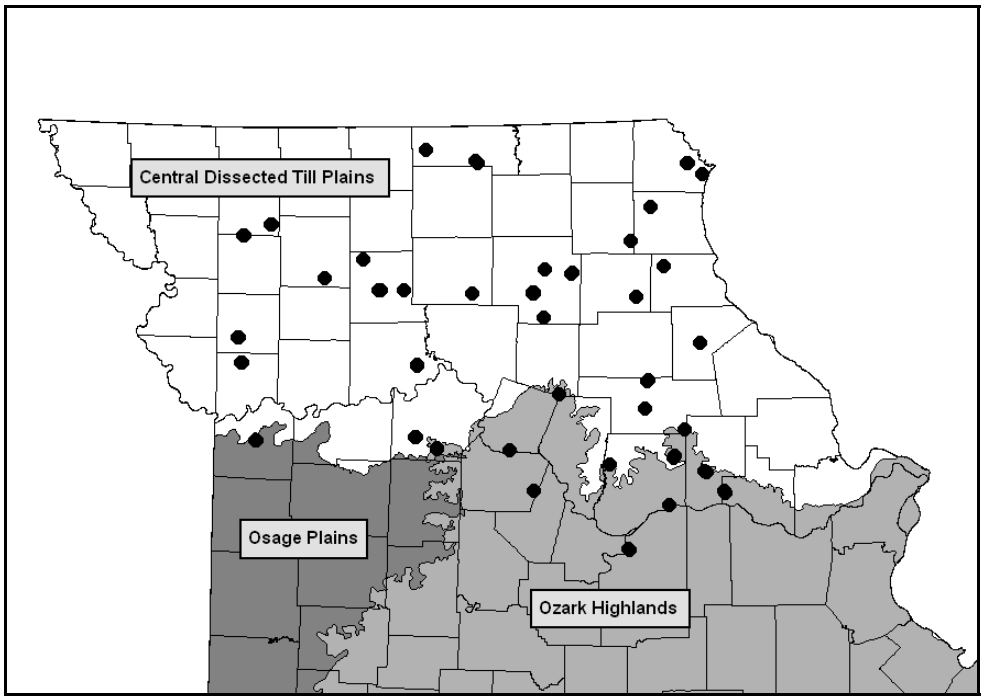

Figure 1. Locations of sampled wetlands. Some dots represent multiple wetlands due to proximity

Amphibian sampling. To increase the probability of detecting breeding adults, eggs, and larvae of most species, amphibian surveys were conducted at each wetland during three time periods in 2006 (March/April, May/June, and July/August). Data from all three periods were pooled. All surveys were conducted during daylight hours. Sampling occurred only if wetlands contained water. Some wetlands contained no standing water during one or more of the sampling periods and therefore data from these sites are based upon one or two surveys.

We used area-constrained dip-netting and commercial minnow traps to capture amphibians and fish. Dip-netting resulted in greater capture frequency of most amphibian species than minnow traps (Shulse and Semlitsch, *unpublished data*) so we used only the dip-net captures in our analyses. Dip-net sweeps were scaled to the size of the wetland (1 sweep/25m² of wetland surface area, 15 sweeps minimum, 200 maximum). Sweeps were ~1.5m long with the net pressed to the bottom of the wetland and dragged toward the sampler. All sweeps were distributed proportionately throughout the different habitats within each wetland. All amphibians and fish were identified in the field and released unharmed at the point of capture. Some amphibians could not be identified reliably to species in the field (leopard frogs, treefrogs, and toads) so individuals within these groups were assigned to three generalized categories (Table 1).

Each amphibian species was assigned a numerical conservation coefficient (CC - Table 1). To obtain these coefficients, amphibian biologists at the University of Missouri discussed the ecology of each species and assigned a score between 1 and 10 for three ecological criteria – sensitivity to disturbance, rarity of the species within Missouri, and range of the species within Missouri. The three scores for each category were averaged to obtain the CC. Higher scores indicate higher conservation priority. The CC's were used to calculate the amphibian conservation index score (ACI) for each wetland. This involves multiplying the number of individuals of each species captured by their respective CC. The result is a subtotal for each species. Subtotals are summed and the total divided by the number of all individuals. This provides the ACI score (range 0 – 9) for the wetland (see example in Table 2).

Table 1. Conservation coefficients for amphibian species captured in Missouri.

Species	Disturbance	Rarity	Range	CC
Acris crepitans	3	1	1	2
Ambystoma opacum	8	10	8	9
Ambystoma maculatum	8	9	8	8
Ambystoma texanum	5	7	6	6
Ambystoma tigrinum	6	10	8	8
***Anaxyrus* – Toad group**	1	3	1	2
***Hyla* – Treefrog group**	5	3	2	3
Leopard frog group	4	4	2	3
Lithobates catesbeianus	1	1	1	1
Lithobates clamitans	2	2	5	3
Nothophthalmus viridescens	8	8	7	8
Pseudacris crucifer	6	7	5	6
Pseudacris triseriata	2	5	5	4

Table 2. Example of amphibian conservation index calculation for a wetland in the Ozark Highlands of Missouri. Adapted from Micacchion, 2002; 2004.

Species	Number of Individuals	CC	Subtotals
Ambystoma opacum	**2**	**8**	**16**
Ambystoma maculatum	**41**	**9**	**369**
Hyla versicolor	**30**	**3**	**90**
Leopard frog complex	**4**	**3**	**12**
Nothophthalmus viridescens	**1**	**8**	**8**
Totals	**78**	**---**	**495**
Biotic Index Score	**6.35**		

Wetland features. To assess the utility of the Ohio AQAI Micacchion (2002) used their values as independent variables in linear regressions with ORAM 5.0 scores as the dependent variable. The Missouri Department of Transportation does not currently employ a metric-based wetland rating system (B. Brooks *pers comm.*). Therefore, we created a trial wetland features index made up of multiple metrics in order to examine the utility of our ACI scores. Although the AQAI, AmphIBI, and ORAM 5.0 are disturbance focused, we were interested in how features relating to the design, placement, and water quality affected amphibian biotic integrity. We measured several features both within the aquatic environment of the wetland and within the 300m terrestrial core zone surrounding each wetland. Features selected are those that have been found to affect amphibian communities from previous investigations. The metrics are: 1) Littoral zone; 2) Fish presence; 3) pH; 4) Depth; 5) Percent undisturbed area with the core zone. The metrics, their scores, and scoring breakpoints are shown in Table 3. Amphibian species richness has been found to be greater in wetlands with shallows (15:1 within-water slopes or less) and that lack predatory fish (Porej and Hetherington, 2005). Steeper slopes (2:1 or 3:1) are commonly observed at farm ponds (Shulse, *pers. obs.*). We therefore used these two extremes in assigning breakpoints and scores. While studies have found that highly acidic conditions can negatively affect amphibians (Dunson and Wyman, 1992; Freda and Dunson, 1985), high pH has also been shown to be detrimental to amphibians (Semlitsch, *unpublished data*). Wetlands in our study were not highly acidic and ranged from 6.2 – 9.79 with median 7.48. We assigned scoring breakpoints so that approximately half of the wetland scores fell on each side of the median. Wetlands with long hydroperiods (>2 yrs) may accumulate large numbers of aquatic macroinvertebrate and fish predators (Semlitsch, 2002). Many amphibian species rely upon temporary wetlands to breed and thus avoid predators associated with permanent water. However, wetlands that are too shallow can dry rapidly resulting in larval death. We found that wetlands we surveyed less than 0.20 meters deep dried in early summer 2006. However, wetlands that were greater than 1 meter deep had stable hydrology. We assigned 0 points to wetlands at both extremes and 10 points to wetlands with intermediate depths. Wetlands between 0.2 and 1m deep tended to dry completely by late summer. The scores for % Undisturbed area of the core zone were chosen to reflect what we perceived to be biologically necessary for amphibian community integrity.

Littoral zone slope and pH were measured at each cardinal direction in the wetlands we sampled. For large wetlands (>0.6 ha) two additional locations were evaluated and all six were spaced evenly around the perimeter. Slopes were calculated by measuring water depth along transects perpendicular to the water's edge at 1m and 3m from the shore. Slope at each location was calculated from the depths and then averaged for each wetland. Measurements of pH were recorded using a Hanna Low-Range Combo Waterproof Tester, and averaged across location and sampling period at each wetland.

Terrestrial core zone analysis. Analyses of land use within the core zone were performed using ArcMap 9.2 GIS software (Environmental Systems Research Institute, 2006). Surveyed wetlands were located on 2006 National Agricultural Imagery Program (NAIP) orthorectified digital aerial photography (2m resolution) and their boundaries were delineated to create a polygon representing each wetland within the GIS. Wetland polygons were overlaid on Missouri Resource Assessment Partnership (MoRAP) Land use and Land cover data (LULC 2005). We performed a buffer analysis of the first 300m radius of terrestrial habitat surrounding each wetland to obtain percentages of each land-use and land-cover type within the area. We summed the percentages of all undisturbed land-use types (grasslands, forest, and deciduous woody/herbaceous mixed, and all wetland types) to obtain a cumulative percentage for this category. The remaining land-use types that represented disturbance were cropland, urban, and impervious surfaces. We did not include a disturbance metric because lower % Undisturbed scores reflected greater disturbance.

Statistical analysis. All analyses were performed in SPSS version 16.0 (SPSS Incorporated, Chicago, Illinois). To examine the relationship between the prototype amphibian biotic index and the wetland features index, we used linear regression with the wetland features index as the dependent variable and the amphibian biotic index values as the independent variable. We also examined the significance of individual metrics within the wetland features index by performing a multiple regression analysis using the generalized linear model feature specifying a normal distribution and log link function in SPSS. In this model, the amphibian biotic index scores were used as the dependent variable and each metric in the wetland features index were independent variables.

Table3. Metric scores and breakpoints for wetland features index.

Metric	Score 0	Score 3	Score 7	Score 10
Littoral Zone Slope	3:1 or steeper	4:1 – 9:1	10:1 – 14:1	15:1 or shallower
Fish Presence	Present	----------	----------	Absent
pH	> 8.00	7.50 – 7.99	7.01 – 7.49	6 – 7
Depth (meters)	0 – 0.19 or > 1	----------	----------	0.2 - 1.0
% Undisturbed	< 45	45 – 59	60 – 84	85 – 100

RESULTS AND DISCUSSION

Figure 2 illustrates the relationship between the ACI values and the trial wetland features index. There is a significant positive relationship between the two variables although the variance explained by the ACI was somewhat moderate (adjusted $R^2 = 32.7\%$). This is very similar to the results presented in Micacchion (2004) (df = 52, F = 26.21, $R^2 = 33.5\%$, p =<0.001). Micacchion's results showed that as disturbance of the wetlands increased, AQAI scores decreased indicating that the amphibian community biotic integrity in their wetlands was negatively associated with the level of human disturbance. While our wetland features index had a metric representing the lack of disturbance in the core zone, and pH and fish presence could be related to disturbance, littoral zone slope and depth represent wetland design features. The results of the multiple regression analysis are shown in Table 4. All five of the metrics had a positive β estimate but only three - Littoral Zone Slope, pH, and % Undisturbed - had 95% confidence intervals that did not include zero, although Depth was close. Therefore, these metrics were most significant in the model examining the relationship between ACI scores and wetland features. The pH metric had a particularly significant effect in the model. This may reflect slightly acidic conditions of the forested wetlands utilized by many species with high CC values. These results underscore the importance of wetland design, aquatic conditions, and wetland placement on the composition of amphibian communities. However, it is important to mention that other metrics based upon other variables (e.g. dissolved oxygen, salinity, distance to nearest wetland, etc.) or higher resolution of our chosen variables (e.g. separating % Undisturbed into its different components) could provide different results and shed light on the details of the relationship. Nevertheless, our intent was solely to create a trial features index with which we could test the utility of our amphibian conservation index.

As previously mentioned, the ACI is similar to Ohio's AQAI. The AQAI is one of five metrics that make up the AmphIBI. The four additional metrics are: 1) disturbance-sensitive species relative abundance; 2) disturbance-tolerant species relative abundance; 3) number of pond breeding salamanders present; 4) presence of the indicator species - spotted salamanders (*Ambystoma maculatum*) or wood frogs (*Lithobates sylvaticus*). When total AmphIBI scores are plotted against ORAM 5.0 scores, the variance explained in the model is improved over the results presented above using only AQAI scores (df = 52, F = 52.61, $R^2 = 50.3\%$, p<0.001, from Michacchion, 2004). The additional four metrics significantly improved model fit. In order to develop a more robust index explaining the relationship between amphibian biotic integrity and wetland quality, we are currently exploring additional metrics to create a multi-metric index similar to the AmphIBI. Preliminary results from a metric representing the relative abundance of species with CC's above 6 have been promising. However, another metric scoring the relative abundance of species with CC's less than 4 has been less clear. This metric worked well in the AmphIBI and there was a clear positive correlation between low ORAM 5.0 scores and the relative abundance of disturbance-tolerant species. The inclusion of non-disturbance based metrics in our rating system may explain why this pattern has not been

observed in our analyses. Amphibians with low CC ratings (leopard frogs, treefrogs, and toads) have been observed to prefer wetlands with shallow littoral zones that lack predatory fish (Porej and Hetherington, 2005; Shulse and Semlitsch, *in prep.*). Their relative abundance in wetlands with high index scores based on these factors could explain this trend.

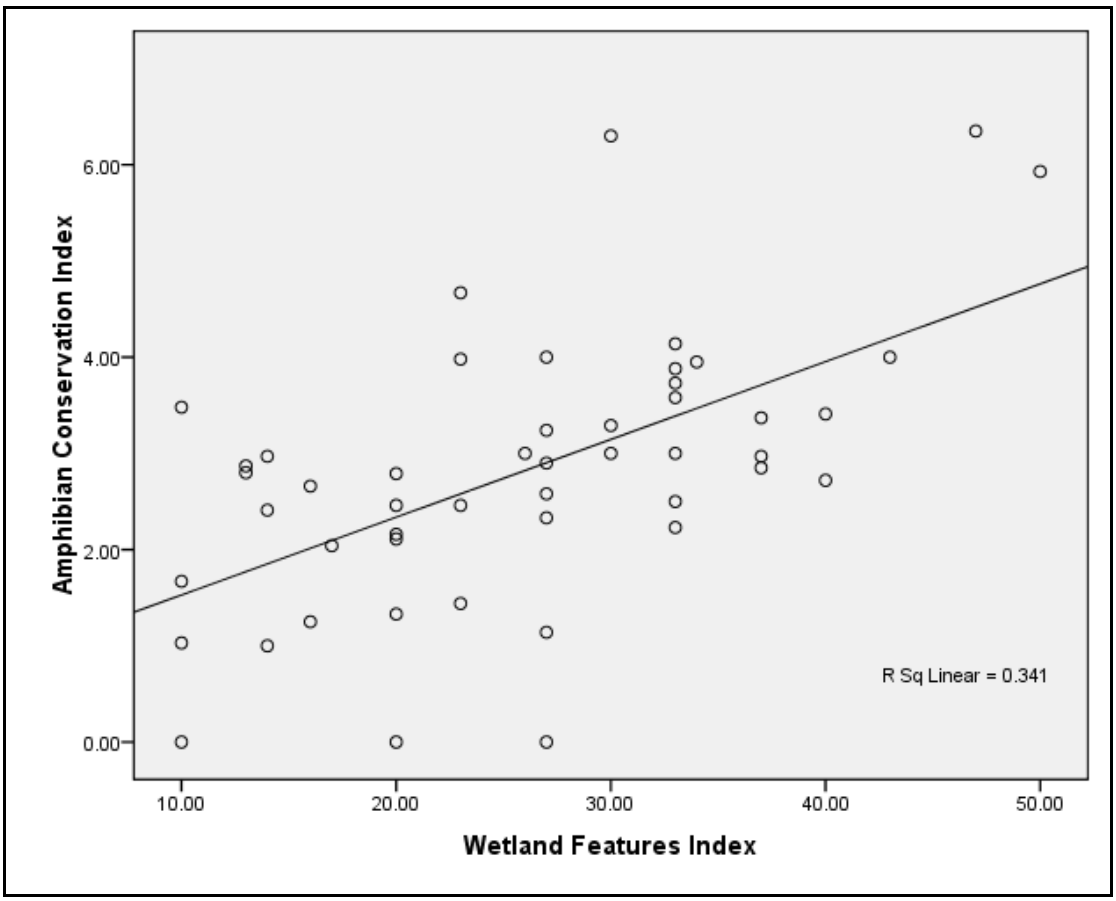

Figure 2. Regression plot of prototype amphibian biotic index vs. trial wetland features index for Missouri. Adjusted $R^2 = 0.327$, df = 47, F = 24.36, p<0.001.

Table 4. β estimates and 95% confidence intervals for metrics in the Missouri wetland features index. ($\chi^2 = 38.17$, df = 5, p<0.001, n = 49).

Metric Score	β	Lower 95% C.I.	Upper 95% C.I.	Sig.
Intercept	0.057	-0.343	0.457	0.779
Littoral Zone Slope	0.044	0.011	0.078	0.010
Fish Presence	0.018	-0.006	0.043	0.138
pH	0.049	0.021	0.077	<0.005
Depth	0.018	-0.001	0.038	0.068
% Undisturbed	0.042	0.009	0.076	0.013

We are also testing a metric that scores the percentage of pond-breeding salamanders based on county records found at each site (Porej et al., 2004). The AmphIBI uses a similar metric; however scores are based upon the absolute number of salamanders recorded at each site. This method would not work well for our index because our wetlands were located in multiple ecoregions within the state and some salamander species did not occur throughout the entire study area. Preliminary results with our percentage-based metric appear promising. The AmphIBI metric using presence of spotted salamanders and wood frogs would not work for a statewide or northern Missouri index because these species have limited distribution north of the Missouri River. As Miccachion (2002, 2004) points out, these species are excellent indicator species for vernal pools in upland forests. We are currently exploring the ecology of northern Missouri amphibian species to determine an appropriate indicator species to use as a metric in the final biotic index.

The AmphIBI is recommended for use only in forest and shrub temporary wetlands (vernal pools) and not for emergent depressional systems (Maccachion, 2002; 2004). This is because amphibian communities of emergent sites show little variation in response to disturbance both within and surrounding the wetlands and therefore these wetlands consistently score low. We saw a similar pattern with many of the mitigation wetlands that were relatively new (< 10 years old) and had high percentages of disturbed land surrounding them. These sites also tended to have higher pH values, probably due to a lack of surrounding forest and leaf litter accumulations. Therefore, these sites are probably inappropriate for many species because they have hostile aquatic and core terrestrial zone environments. Over time, if these sites are allowed to develop a forested canopy, they may provide more suitable habitat. However, this would be most likely only in sites with suitable habitat corridors connecting them to neighboring source populations and with low amounts of disturbance in their terrestrial core zones.

A few additional differences between the ACI and the AQAI merit mention. First, several of the individual coefficient scores differ. This is due primarily to our inclusion of range and rarity information. While treefrogs are somewhat intolerant to disturbance in the terrestrial habitat surrounding their breeding sites (Johnson et al., 2007), they are common and range statewide in Missouri (Johnson, 2000). Therefore, we assigned them a CC of 3 as opposed to the AQAI rating of 5. Conversely, we found spring peepers (*Pseudacris crucifer*) and smallmouth salamanders (*Ambystoma texanum*) to be uncommon and somewhat sensitive to disturbance surrounding their breeding sites. They were therefore rated higher in our index (CC's of 6 as opposed to 2 and 4 respectively in the AQAI). Another difference is sampling methodology. We advocate the use of standardized dip-netting rather than aquatic funnel trapping for amphibian collection. As mentioned, we found that dip-netting resulted in captures of most amphibian species at more sites than funnel trapping. Some species of amphibians with relatively sessile larvae may not be captured effectively in funnel traps that require animal movement. Additionally, 24 hour periods are required to set and collect funnel traps whereas dip-netting can be completed in several hours or less. This eliminates multiple trips to remote wetlands thereby reducing travel and personnel time. Therefore, if standardized techniques and training protocol are followed, dip-netting methods can result in rapid, effective, and economical results.

The results from our study indicate that our prototype biotic index can be used to examine the relationship between amphibian community biotic integrity and features of constructed wetlands in northern Missouri. The index should also be tested at reference natural wetlands; however, we feel that it should perform suitably based on its similarity to the Ohio index. It is probable that multiple indexes will have to be employed, each created for a different region of the state. We will continue to investigate additional parameters for the Amphibian Conservation Index and test its utility with other wetland rating systems.

ABSTRACT

Infrastructure decisions for transportation include where to locate rights-of-way (ROWs) for new transportation routes. These new routes can impact wetlands by replacing them with roadways and by impacting the landscape that supports biodiversity within the wetland. State departments of transportation (DOTs) need guidance for how to evaluate alternative ROWs in light of the potential impact on wetlands. Because a wetland and the surrounding landscape are spatial in nature, they are well-suited to analysis via a geographic information system (GIS). Many landscape parameters can be devised and information layers developed. Meaningful information layers are those that describe the impact that the landscape has on the amphibian life cycle. An interdisciplinary research team from the University of Missouri and the Missouri Department of Transportation (MoDOT) brings the unique perspectives of civil engineering, geography and biological sciences to bear on this problem. At the "micro" scale, amphibian species and abundance have been sampled within 49 constructed wetlands in northern Missouri. These data has been analyzed from the biological perspective to create a habitat quality rating for each wetland, considering that some species are more sensitive to wetland changes, with their presence indicating a higher quality environment. This rating provides the dependent variable, y, for the creation of a regression equation relating landscape parameters to amphibian health, and thus wetland quality, at a "macro" scale. As a first step in developing a regression equation, appropriate GIS variables must be developed. Factors such as land cover, and the presence or absence of roads and streams have been identified as being important to amphibian health. However, one cannot simply utilize layers of land cover, because the important factor is how the amphibians interact with the landscape. This paper focuses on the effort to devise a set of GIS parameters that accurately represent amphibian interactions with the landscape. There

are a number of important requirements for this amphibian-based GIS analysis. . In addition, amphibians first encounter those landscape conditions that are closer to the wetland, so greater importance is associated with nearer features. Because migrating adult or dispersing juvenile amphibians may travel from a wetland in any direction, the analysis must be performed on landscape parameters that occur within discrete "quadrants" or portions of quadrants radiating out from a wetland. In addition, earlier encounters can impact how other features are evaluated, so the context and location of conditions is important, and features must be evaluated from inner to outer locations in a sequential fashion. For example, if an amphibian encounters an interstate highway that constitutes an absolute barrier, then a forested area on the other side of the road has no value because it cannot be used to benefit the amphibians. Lastly, a parameter such as access to water can induce both positive and negative impacts, and the GIS parameter must represent this duality. With appropriate GIS parameters, the regression equation can be developed and used to inform the selection of ROWs to avoid locations that provide important habitat for amphibians.

INTRODUCTION

Wetlands are areas of seasonally, intermittently or permanently waterlogged soil or inundated land. Wetlands are complex, diverse ecosystems which are linked to the landscape surrounding them. The health of wetland is dependent upon the biological, chemical and hydrological processes and the activities occurring within their surroundings.

The amount of wetlands had decreased in the past centuries due to belief that they were worthless lands and because of the increase in the demand for agricultural lands. Approximately 50% of wetlands in the conterminous United States have been drained since European settlement, usually for agricultural usage (Tiner, 1984). The terrestrial habitats surrounding and adjacent to wetlands are critical for the management of natural resources and biodiversity conservation (Semlitsch and Jensen, 2003).

Wetlands are important systems that shelter and sustain a diversity of fauna including invertebrates, water birds, fish and amphibians. Wetlands are places where sediments accumulate, soils and landforms are created, nutrients are recycled and water is purified. Part of the reason that terrestrial habitat adjacent to wetlands are not protected is due to the lack of a clear understanding of the distances from shorelines that are biologically relevant to the wetlands (Semlitsch, 1998).

AMPHIBIANS

Amphibians in the Midwest United States have suffered major loss of habitat due to the conversion of nearly 90% of pre-settlement wetlands to agricultural uses (Dahl 1990). Pond-breeding amphibians require aquatic and terrestrial habitats to complete their lifecycles, and preservation of both habitats is necessary for maintaining local populations. Current wetland regulations focus primarily on aquatic habitats, and criteria to define critical upland habitats and regulations to protect them are often ambiguous or lacking (Porej et al., 2004). Pond-breeding amphibians are an

integral part of wetland ecosystems; however, the replacement or creation of quality amphibian habitat is usually not one of the goals of wetland replacement (Porej et al., 2004).

Semlitsch and Rothermel (2003) proposed the use of stratified criteria that would include three terrestrial zones adjacent to core aquatic and wetlands habitats (Figure 1):

- Aquatic Buffer, the first terrestrial zone (starting from wetland edge), would buffer the core aquatic habitat and protect water resources.
- Core Habitat, the second terrestrial zone (starting from wetland edge), would comprise the core terrestrial habitat defined by semi-aquatic species or species-group use.
- Terrestrial Buffer, the third terrestrial zone (starting from outward edge of second zone), would buffer the core terrestrial habitat from edge effects and surrounding land use practices.

Many species require both aquatic and terrestrial habitats and are limited to areas where there is sufficient moisture for reproduction and survival and access to adjacent terrestrial habitat (Jameson, 1957; Wilbur, 1987; John-Alder and Morrin, 1990; Vos and Stumpel, 1995). Few attempts have been made to model amphibian population dynamics (Halley et al., 1996; Gibbs, 1993) and fewer have been spatially explicit to considered landscape complementation (Vos and Stumpel, 1995). Zanini et al. (2008) stated that increasing urbanization and habitat alteration make it particularly important to find ways to assess the impact of land cover changes on the distribution of natural population.

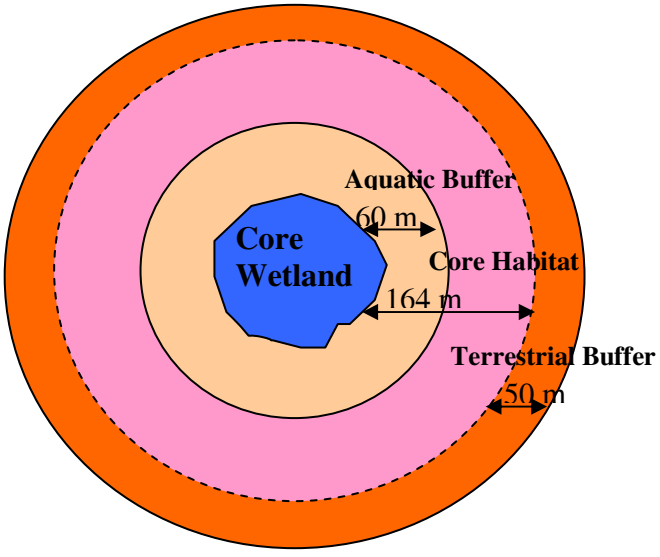

Figure 1. Zones for protection for wetlands (modified from Semlitsch & Rothermel, 2003)

AMPHIBIAN IMPACT AND ANALYSIS

Roads have a huge impact on the environment, with high amphibian mortality caused by traffic being reported in the literature (Ashley and Robinson, 1996; Lodé, 2000; Smith and Dodd, 2003). The researchers stated that the roads represent the most important source of variation in species richness. Similar results were reported in a study of North American salamanders (Porej et al., 2004). Findlay et al. (2000) found that road construction and the associated increase in human presence represents one of the major ways humans transform landscapes. Forman and Deblinger (2000) showed that the significant ecological effects of roads on plants and animals, including amphibians, average 600 m outward from a road.

Relatively few landscape-level studies of amphibian density and movement have been conducted (Houlahan et al., 2000; McGarigal and Cushman, 2002). The majority of the studies have focused on relationships between forest cover and species occurrence, showing positive relationship between amphibian population and area of forest in the surrounding landscape (Dupois and Stevenson, 1999; Trenham and Shaffer, 2005). Knowledge is still quite rudimentary about the population-level implication of habitat area, edge, isolation and road mortality relationship; effective conservation of amphibian population is limited by the lack of specific ecological knowledge and lack of landscape level studies of the effect of habitat loss and fragmentation or movement, survival rate and population dynamics (Cushman, 2006). Law et al. (1991) stated that determining the most relevant physical parameters on a landscape can be used as a basis for decision making and the design of response to specific environmental management challenge.

It is important to develop and implement new methodologies which address broader landscape areas surrounding the wetlands and to analyze the habitat interaction within it. Also, it is important to consider how multiple factors interact across different wetland buffer zones that could affect amphibian population. The present research is an attempt to analyze the interaction between amphibians and landscape conditions in the northern Missouri wetlands.

Roise et al. (2004) stated that the requirements to regulate wetlands (minimize impacts and implement compensatory mitigation) can be quantified and therefore infer that wetland management can be made more efficient through a combination of mathematical programming techniques, a wetlands functional evaluation methodology and information contained within a geographic information system (GIS) model of a landscape.

DATA ACQUISITION/ RESOURCES

A total of 49 wetlands will be analyzed during this study. The locations of the wetlands are shown in Figure 2. ArcGIS 9.2 software will be used to analyze all the wetlands spatially.

- The spatial and GIS wetland location data layer (shapefile) was collected as part of the overall project (Shulse, 2006) which contains information about all the constructed wetlands involved in the research.

- Spatial and GIS data layers necessary (land use/ land cover, streams, roads and topography) are readily accessible through the Center for Applied Research and Environmental Systems (CARES) and the Missouri Spatial Data Information Service (MSDIS) websites. The scales of the GIS data layers obtained are:
  - Land use/ land cover
    - Digital version in raster format obtained from MSDIS (2006) at a scale of 1:24,000.
  - Streams
    - Digital version includes rivers and streams at a scale of 1:24,000.
  - Roads
    - Digital version includes the roads and highways for which MoDOT is responsible.
  - Topography
    - 60 meter digital elevation model (DEM) in raster format from MSDIS.

METHODOLOGY

Missouri amphibian data from forty-nine constructed wetlands in northern Missouri (Figure 2) will be used to develop a regression equation (Eq. 1) which will describe wetland health in terms of the surrounding landscape characteristics. Amphibian data (number of each species in the various lifecycle stages) have been collected and analyzed from the biological perspective to create a habitat quality rating for each wetland (Shulse, 2008). This rating provides the dependent variable, Y, for the development of the regression equation relating landscape parameters to amphibian health. Landscape characteristics that will constitute the independent variables are: roads, streams, forest, landscape position and age of wetland. This model will be expected to increase the effectiveness of constructed wetlands and will decrease the probability of negative effects on the habitat of the wetland due to road constructions.

Once developed, equation 1 can be used to predict or estimate amphibian health under different landscape/ ROW scenarios for decision making. While the independent variables are shown as being represented as X_n, the actual terms may include powers and coefficients, or other functions, applied to the landscape parameters, as shown below:

$$\mathbf{Y=aX_1^b+cX_2^d+eX_3^f+gX_4^h\ldots.} \quad \text{(Eq. 1)}$$

Y=amphibian health, habitat quality rating

X_n=landscape parameters (e.g., roads, streams, forest area, landscape position and age)

a, c, e, g,…= coefficients applied to landscape parameters

b, d, f, h,…= powers to which landscape parameters are raised

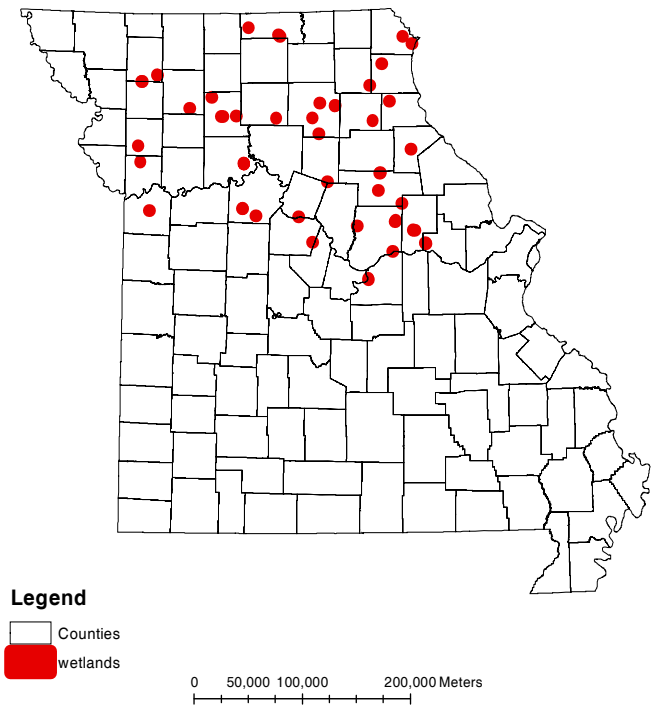

Figure 2. Point locations of compensatory wetlands in the study

SPECIFICATION OF LANDSCAPE PARAMETERS

The specification of features around each wetland will be determined using ArcGIS 9.2. The landscape analysis will consist of circular buffers up to 2.1 kilometers. Rings of 300, 600, 900, 1500 and 2100 meters from the edge of the wetlands will be analyzed. Each wetland will also be divided into quadrants and each wetland will be analyzed independently. Distance from the landscape feature to the wetlands will be an important factor for the prediction of the health of the wetlands. For example, if there is a highway closer to the wetlands area, this may be expected to cause more negative impact to wetlands health than a road that is far away from the wetland area.

The following points summarized the methodology to be used:

I. Landscape parameters

Landscape characteristics that will be used are: road, forest area, streams, landscape position and age. For the features of roads, streams and forest area each ring area will be checked to determine the contribution of each feature to wetlands health. A proximity analysis will be performed by dividing the parameter by the distance of the midpoint of the ring from the centroid of the wetland.

a. Roads
    i. Length of roads in each ring in each quadrant will be measured.
    ii. Both the eastbound and westbound directions of a highway will be measured in order to account for the increase width of such roads.
    iii. The length of road will be divided by the distance from each wetland centroid to the distance of each ring mid-point.
    iv. Independent variable unit will be (length of roads)/ (distance of the wetland centroid to mid-point of the ring).
b. Streams
    i. Length of the streams in each ring in each quadrant will be measured separately for perennial and intermittent streams.
    ii. The length of stream will be divided by the distance from each wetland centroid to the distance of each ring mid-point.
    iii. Perennial streams will be used as a surrogate for the potential presence of fish (possible flood case scenario) and will be expected to have a negative correlation with amphibian health.
    iv. Intermittent streams will be used as a surrogate for amphibian habitat and will be expected to have a positive impact in amphibian's health.
    v. Independent variable unit will be (length of streams)/(distance of the wetland centroid to mid-point of the ring).
c. Forest area
    i. Forest area data will be extracted from land use/land cover data layers.
    ii. Forest area will be determined for each quadrant within each ring for each wetland.
    iii. Independent variable unit will be (area of forest) /(distance of the wetland centroid to mid-point of the ring).
d. Landscape position
    i. DEM, forest area and stream data layers, as well as the digitized wetlands layer will be used determine the landscape position of each wetland.
    ii. A wetland located in an upland position in the landscape would be expected to have less contributing water to support the wetland, but a smaller probability of predatory fish.
    iii. A wetland located in a downslope position in the landscape would be expected to have a greater water contribution from runoff, but a greater probability of predatory fish, which can cause a decrease in the amphibian population.
    iv. The watershed of each wetland will be delineated using ArcGIS 9.2 to define the upland position and the downward position of each wetland.
    v. Independent variable unit will be a normalized value of landscape position.

e. Age of wetland
   i. Age of wetland is an important parameter due to the interactions of amphibians with landscape and the time available for amphibians to colonize the wetlands.
   ii. Independent variable unit will be a normalized value of age of the wetland.

II. Data standardization

a. Data standardization allows the transformation of parameters with various dimensions into dimensionless parameters with values between 0 and 1. This formula can convert numerical data into a standardized scale from 0 to 1.

$S = (X_i - X_{min}) / (X_{max} - X_{min})$, where S is the standardization value for the original value, X_i is the original value, X_{min} is the lowest value and X_{max} is the highest value.

b. Once the parameters are represented in a dimensionless format they can be used in Equation 1.

III. Analysis

a. The initial analysis, to determine the specific forms of the independent variables terms and coefficients will be conducted with the quadrant data summed for each ring. The analysis will consist of examining relations among the standardized landscape characteristic to amphibian abundance. The statistics package, STATA will be used to determine the correlation.

b. Quadrants
   i. Quadrants are important (Figure 3) to check the connectivity between wetlands. If two or more wetlands are near each other, the two wetlands may function as an ecosystem instead of individual wetlands.

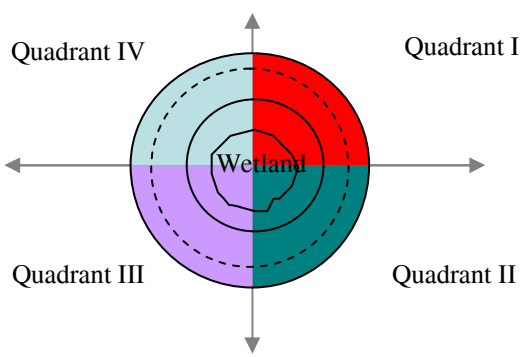

Figure 3. Wetland area divided in 4 different quadrants

   ii. Quadrants are useful to perform directional analysis along a ROW where multiple wetlands could be impacted by ROW selection. They can help in the determination of the intersection of the right-of-way with the functional portions of a wetland.

iii. For individual wetlands located near one another, the amphibian health values will be calculated for each quadrant. In this way, if a wetland will be impacted by road construction, one can determine which quadrant contribute most to amphibian health and thus should be protected and which ones will have less negative impact from future road construction activities.

c. Barriers
   i. A subsequent analysis will evaluate the potential impact of roadways as barriers on the previously determined correlations.
   ii. The analysis will test if roadways eliminate the benefits of forested areas and/or intermittent streams.
   iii. The correlation analysis will be performed as before, except that roads, streams and forest area in quadrants rings and beyond the location of a highway will not be included.

CONCLUSIONS

The goal of this research is to identify landscape characteristics that estimate wetland health in northern Missouri. The model will aid in the development of a rapid wetland assessment tool that could help in the decision making process of a right-of-way, useful for government agencies such as MoDOT and the Missouri Department of Conservation.

Amphibian data will provide the quantitative data to relate to wetland landscape characteristics. The amphibian data will provide the framework for the development of a landscape characteristic model that will predict health of wetlands (based on amphibian data). This methodology will help in the decision making process of the optimum location of a proposed the right-of-way to determine the location that would have the least negative impact on the wetland health.

ABSTRACT

Weatherby Lake is one of the cleanest lakes in the State of Missouri. According to test samples of TMDL, phosphorous, heavy metals, and other pollutants, the water quality of Weatherby Lake is comparable to many pristine lakes in Canada. Development upstream of Weatherby Lake in the Platte County area in recent years has threatened the water quality of Weatherby Lake and has prompted action by the Weatherby Lake Improvement Company (WLIC) to take a positive pro-active role in the protection of this natural resource.

INTRODUCTION

Weatherby Lake (Figure 1) is a Class Four City located in Platte County, Missouri. The City was incorporated in 1936 and covers approximately 836 Acres (338.3 Hectares). Weatherby Lake itself is has a total drainage area of 2750 Acres (1112.9 Hectares) and a surface area of approximately 274 Acres (110.9 Hectares) at normal pool level or 33% of the City's land area. The top of the dam is approximately at elevation 890 Feet (271.3 Meters), with a height of 84 Feet (25.6 Meters), a length of 1100 Feet (335.3 Meters), and a maximum pool depth at the dam of approximately 80 Feet (24.4 Meters).(1)

WLIC is responsible for the maintenance of the Lake and its facilities. WLIC and the Missouri Volunteer Lake Program have formed a partnership with a group of 30 local volunteers, also known as the "Stream Team" (Figure 2); which samples influent into the lake and submits those samples to monitor total suspended solids (TSS), Nitrogen, Phosphorous, PH and Chloride. The Stream Team also takes Secchi Disc readings of Weatherby Lake.

In addition to these duties the Stream Team also monitors influent during rain events to determine water quality into Weatherby Lake from the surrounding upstream watershed.

Figure 1; Aerial of Weatherby Lake

In addition to work performed by the Stream Team, monitoring of the facility's inlets and coves is conducted by underwater surveys to determine when dredging may be required. Dredging operations can be extremely costly, time consuming, and disruptive of the use of Weatherby Lake by its residence.

The following is from the Mid-America Association of Conservation District's (MAACD), Missouri Department of Natural Resource's (MDNR) and the Environmental Protection Agency's (EPA) *Urban Conservation Policy Handbook (1998).*

Landowners located downstream of construction sites incur the expense of cleaning up sediment deposits. Accelerated sediment loads reduce the capacity of streams, ponds, and lakes. Direct expenses are incurred when excessive sediment loads must be dredged to restore the capacity of the lake. For example, WLIC, Platte County, Missouri, incurred the expense of dredging the lake to remove sediment. Within five years the same areas had to be dredged again due to construction activities upstream. WLIC spends an average of more than $100,000* annually to maintain the capacity of the lake. This expense includes the dredging operations plus the cost of additional land necessary for sediment disposal. The cost of removing the sediment, transporting it off site and disposing of it averaged over $8 per cubic yard (2).

*According to WLIC officials, approximately 40% of the annual fees collected annually go into a dredging and siltation fund for the maintenance of Weatherby Lake.

According to the Missouri Water Quality Report (Section 305b) dated 2006, Weatherby Lake monitoring data taken by the University of Missouri through 2005 was recorded as shown in Table 1.(3)

Table 1; Trophic Status of Weatherby Lake

Years of Record	SECCHI DEPTH (M)	TOT. PHOS. (µg/L)	TOT. NIT. (µg/L)	CHL-A (µg/L)	Trophic State
3	2-3**	20	403	5	M***

** The Missouri Water Quality Report indicates that the Secchi Depth reading was 2-3 meters. WLIC personnel indicate that this value is actually greater than recorded in Table 1

*** Trophic State: O=Oligotrophic, M=Mesotrophic, E=Eutrophic, HE=Hypereutrophic Unclassified Lake Trophic

Trophic state is an important way to characterize lakes because it relates directly to such factors as lake clarity. Lake clarity is greater in oligotrophic and mesotrophic lakes. Fish production tends to be greater in eutrophic lakes. Very clear water lakes are classified as oligotrophic with little nutrients, sediment, plants, and small populations of fish. Eutrophic lakes are the other end of the spectrum with nutrient rich waters that support larger, more diverse fish and plant populations with poor secchi dish readings.

Weatherby Lake is classified as a mesotrophic lake which lies between oligotrophic and eutrophic lakes; with clear water, submerged plant growth, and medium levels of nutrients. It should be noted that some nutrients in a lake are beneficial; however overproduction of algae that may be caused by overproduction of nutrients into a lake from the watershed may be harmful to the overall health of the facility.

Samples collected by the Stream Team from watercourses upstream of Weatherby Lake have helped determine when increased levels of suspended solids, settleable solids, phosphates, nutrients, and other contaminants in stormwater runoff from the watershed have occurred. (4)

Figure 2; Stream Team Volunteers taking samples at Weatherby Lake

STATEMENT OF THE PROBLEM AND PLAN OF ACTION

Non-source point pollutant loading from commercial development upstream of Weatherby Lake on Rush Creek prompted action by WLIC which was the construction of a regional water quality basin on the tributary downstream of the development activity to help protect Weatherby Lake.

This water regional water quality basin, known as The Rush Creek Detention Facility, presented many technical, non-technical, and permitting problems including;

- Planning
- Ownership
- Operation and Maintenance
- Safety
- Regulatory and legal issues
- Coordination between private and governmental agencies

The most challenging issue was related to permitting the Rush Creek Facility, which was the first of its kind for the Development Services Branch of Kansas City, Missouri. A major hurdle that had to be overcome was how to permit a privately owned Regional Permanent Best Management Practice (BMP) on a public stream. The Rush Creek project set a precedent for future BMP projects.

RUSH CREEK RETENTION AND WATER QUALITY BASIN

The tributary area to the Rush Creek retention facility is approximately 542 Acres (219.3 Hectares). The facility is composed of a fore bay, a 24 foot (7.3 Hectares) high dam, 3.6 Acre-Feet of permanent pool area with a principal spillway that consists of a 12 Feet by 6 Feet Reinforced Concrete Box (RCB) with an inlet equipped with anti-vortex walls, an 18 Inch (0.45 Meters) drawdown pipe and gate valve. The facility also has two 30 foot (9.1 Meters) emergency spillways that were designed for concurrent one-hundred year storm events to meet current APWA and Kansas City criteria. Approximately 1500 Feet (457.2 Meters) of 18 Inch (0.45 Meters) sanitary sewer relocation and a specially designed access road for emergency and maintenance access, to the dam and primary spillways were required for the project (Exhibit A).

PRIVATE OWNERSHIP ON A PUBLIC STREAM

Even though the Rush Creek facility is privately owned, it lies on a public stream, which presented a unique set of challenges for WLIC and Kansas City to overcome. In addition to being permitted through Kansas City, the U.S. Army Corps of Engineers, and the Missouri Department of Natural Resources permits were obtained for its development.

City permitting included the following City departments:

- KCMO Planning and Zoning Department
- KCMO Legal Department
- KCMO Development Services Branch
- KCMO Water Services Division
- KCMO Emergency Services
- KCMO Parks and Recreation Department

Other permits included the following agencies:

- United States Corps of Engineers (USACOE) Kansas City District
- Missouri Department of Natural Resources

The permitting and approval process for the Rush Creek facility took over two years to complete.

A Preliminary Development Plan had to be drafted for the project and submitted to planning and zoning department to gain approval of the City Counsel. Easement dedications for a public street associated with the property on which the facility is located and other easements pertaining to the BMP had to be drafted and executed. These easements ensure ongoing access for the City, protection of the facility, and protection of Rush Creek, if the property were sold.

A "Covenant to Maintain" agreement had to be developed between Kansas City and WLIC to ensure proper ongoing maintenance of the Rush Creek facility. WLIC's attorney and the City's attorney worked on the legal language of the agreement while Wilson & Company worked on the technical issues in the agreement including language for ongoing maintenance and operation of the Rush Creek Facility.

Initially, the 18 Inch (0.45 Meters) interceptor sewer was going to be maintained in place and lined under the facility. During final design, it became clear that moving approximately 1500 Feet (457.2 Meters), of the existing 18 Inch (0.45 Meters) sanitary sewer line around the dam structure was in the best interest of both WLIC and the City for protection of the permanent pool, dam and the sanitary sewer. Plans for this relocation were developed and submitted to Kansas City Water Services Department for approval as part of the Rush Creek project.

The outlet structure for the Rush Creek facility was revised to meet KCMO and APWA requirements. This included adding a second emergency spillway to the dam and re-sizing the primary outlet structure. Wilson & Company worked with Kansas City Water Services Department to include the Rush Creek Facility in the hydraulic basin planning activities on Rush Creek. This facility is designed to accommodate dual 100-year storm events through the emergency spillways with 1 Foot (0.3 Meters) of freeboard. Excavation of a permanent pool area upstream of the primary outlet is sized to accumulate 5 years worth of sediment before dredging is necessary. An 18 Inch (0.45 Meters) drawdown valve is capable of completely draining the facility in approximately 2

hours. A beach analysis was conducted for the facility and an emergency action plan was drafted in conjunction with KCMO Emergency Services and submitted to KCMO and WLIC in case there is ever a breach of the dam. All of the hydraulic data was returned to KCMO Water Services Department to incorporate into their Rush Creek Master Watershed Plan.

Initiation of construction took place on September 8, 2008 which was 6 years after the inception of the plan, which included the following:

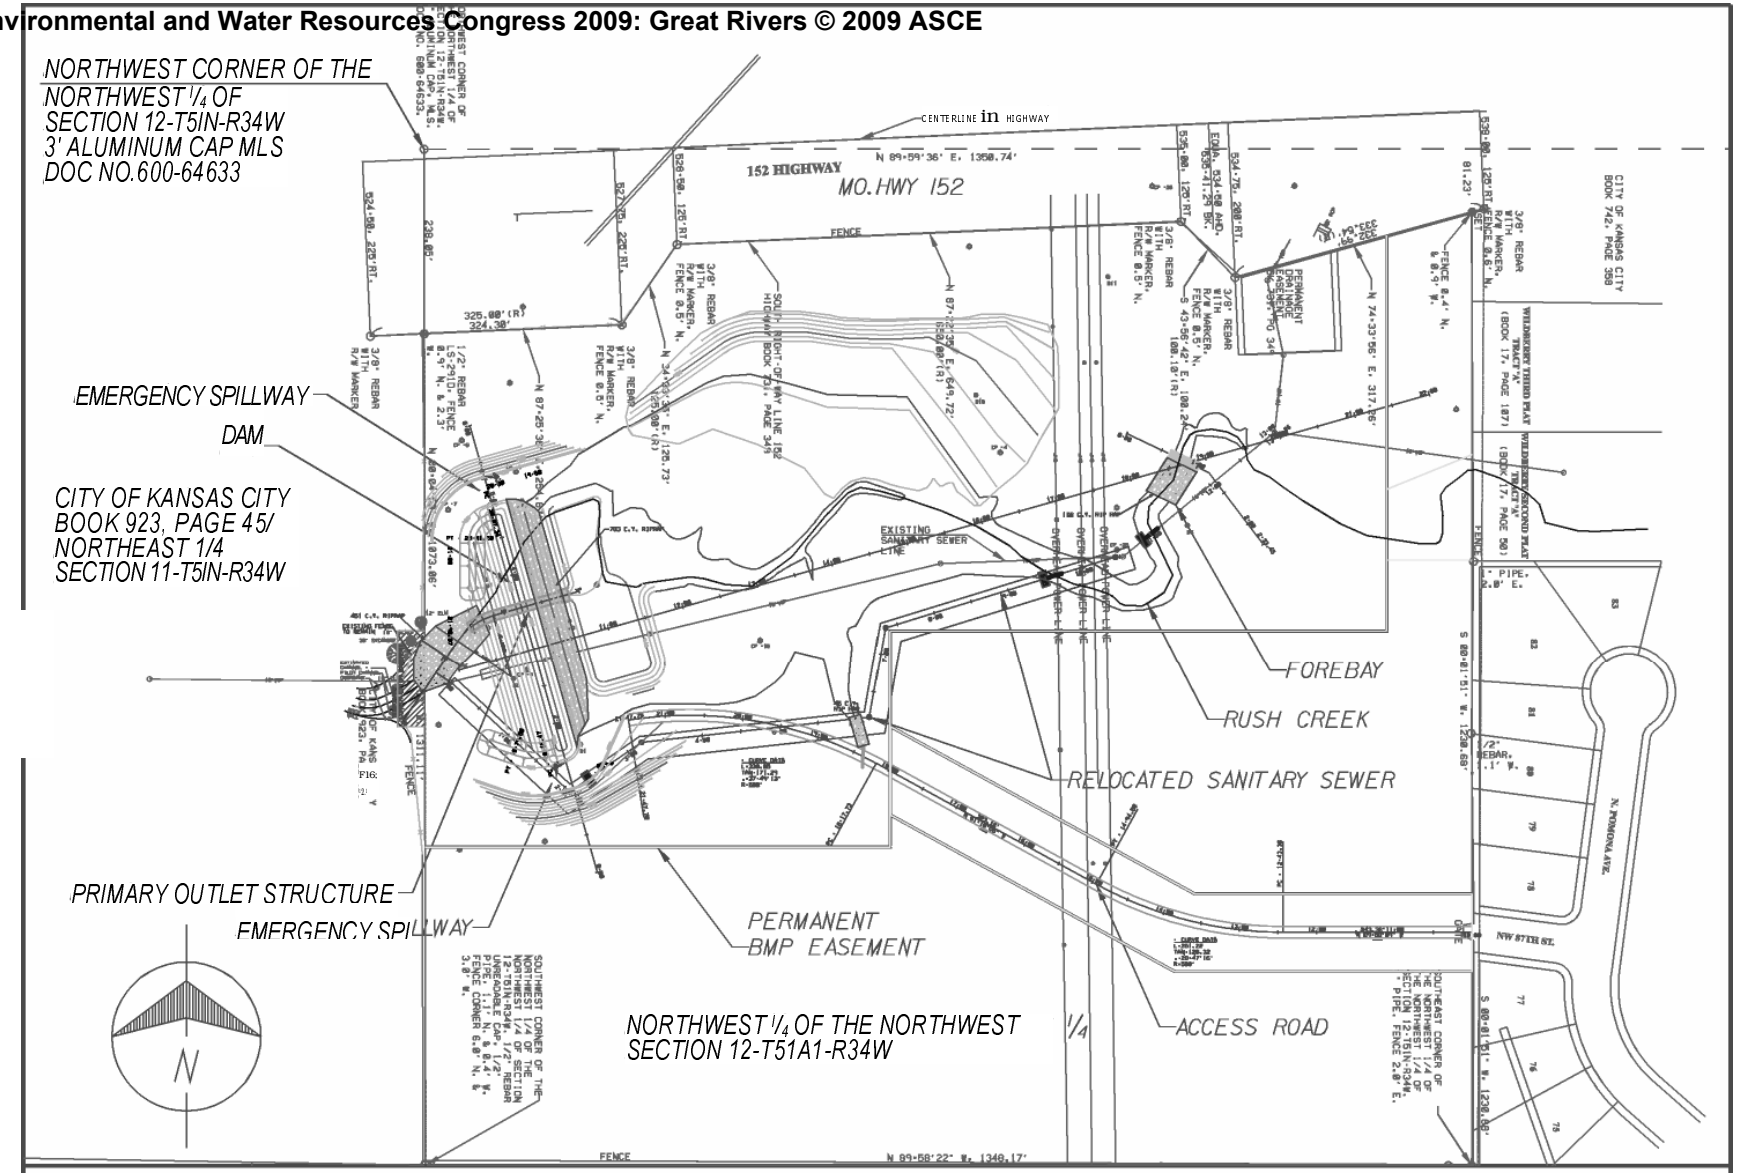
- Drafting and acceptance of the Preliminary Development Plan by planning and zoning and the City Counsel
- Drafting the drainage report
- Drafting an emergency management plan
- Plans, specifications and estimates
- Drafting and executing the "Covenant to Maintain" agreement
- Drafting and recording all other easements

CONCLUSONS

Weatherby Lake's citizens continue to be very proactive in maintaining a water quality monitoring program for their facility. A partnership with the Missouri Volunteer Lake Program and this proactive stance provided a baseline for the development of the Rush Creek project and will serve as a guide to help fine tune the operation of the facility as conditions change on Rush Creek.

Even though all parties entered into the Rush Creek Project with best intentions, there were still conflicting technical, legal and political issues that had to be resolved, which included:

- Planning
- Ownership
- Operation and Maintenance
- Safety
- Regulatory and legal issues
- Coordination between private and governmental agencies



The bulk of the work for the Rush Creek Basin was not technical in nature, but legal and political. Since the Rush Creek Detention facility was one of the first regional water quality basins permitted by Development Services, it helped Kansas City start to set a precedent for others to follow for planning and permitting this kind of facility.

The Rush Creek Facility was much larger than most permanent BMPs that will be installed on private property in the coming years. Because of this there was more intense involvement of City staff and departments than there would be for smaller facilities; however, the experiences of the Rush Creek Basin will be multiplied many times over as Kansas City prepares to incorporate these "Green Solutions" into the Combined Sewer Overflow (CSO) program in the coming years.

These Green Solutions in Kansas City will necessitate the use of private property to help mitigate peak discharges associated with wet weather events that contribute to combined sewer overflows. The City is planning on spending five-hundred million dollars out of the two-billion dollar program to install these facilities which amounts to approximately 25% of the CSO infrastructure.

Many of these facilities will end up on private property and will be maintained by private property owners or homeowner associations with their own "Covenant to Maintain" agreements with the City, which may include permanent easements for these facilities.

This will take a private/public partnership not with only one property owner, but many. The City will need to establish a system to efficiently permit, monitor, and possibly maintain this infrastructure in order to make the CSO program effective and viable. The Rush Creek Detention Facility helped set a precedent for others to follow in the future.

ABSTRACT

This study uses laboratory and theoretical experiments considering upstream, narrow and downstream sections of the channel in its normal and inundated state conditions. In a normal state condition, results proved that as the cross-section of a channel decreases, the higher the velocity and maximum water depth occurs. Asymmetry of flow was caused by the occurrence of different velocities and pressures at the exit right and left sides section of a narrow path and was dependent on the initial boundary conditions applied at upstream section of the channel. On the other hand, bank overflow starts to inundate where maximum water depth occurs during the normal state condition then goes to the floodplain upstream side direction. Moreover, Ishikawa's theoretical overflow equation correlates with the laboratory and theoretical results. Understanding the flow characteristics of a channel will allow us to predict and identify the direction and extent of damage in case of flood.

INTRODUCTION

Narrow path form, also known as sudden contraction is one of the natural shapes of a channel. It is known that the form of a channel affects the flow of water in it. At the same time, through erosion and deposition, the flow can also modify the channel shape. Correct measurement of flow characteristics is very essential in the study of the existing states of fluid motion. It is obviously necessary to understand the essential principles of such motion in order to predict with fair certainty what the characteristics of flow, will be under any given conditions (Rouse, 1946).

Previous study says that asymmetrical flow or the so called, Coanda Effect is the fact that the flow becomes asymmetric in spite of symmetric test sections and symmetric inlet and outlet conditions. An increase of velocity near one wall is accompanied with a decrease in pressure, and once a pressure difference is established across the duct, it will maintain the asymmetry of the flow. The choice of one side or the other is dependent on subtle details of the initialization and transient history of the flow.

Appropriate examples of a narrow channel can be found in Fukawa, Tone River and Kitagami River in Japan (**Figs. 1 and 2**). These areas are abundantly populated and are highly susceptible to flooding as it lies in lowlands that are below the flood water level of the river. Although through many years of flood control efforts, the

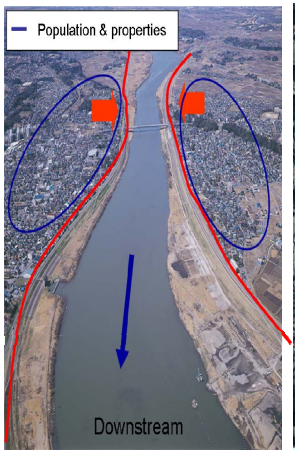

Fig. 1 Tone River

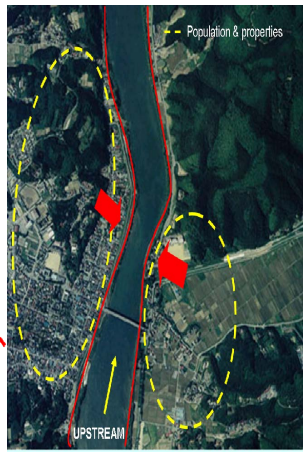

Fig. 2 Kitagami River

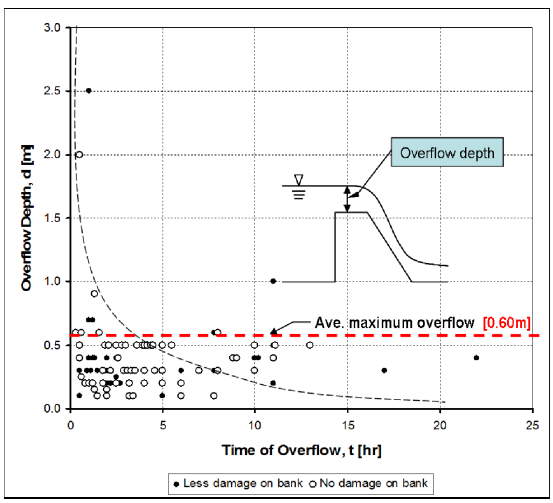

Fig. 4 Maximum Overflow Depth Survey (K.Suga, et. al 1981)

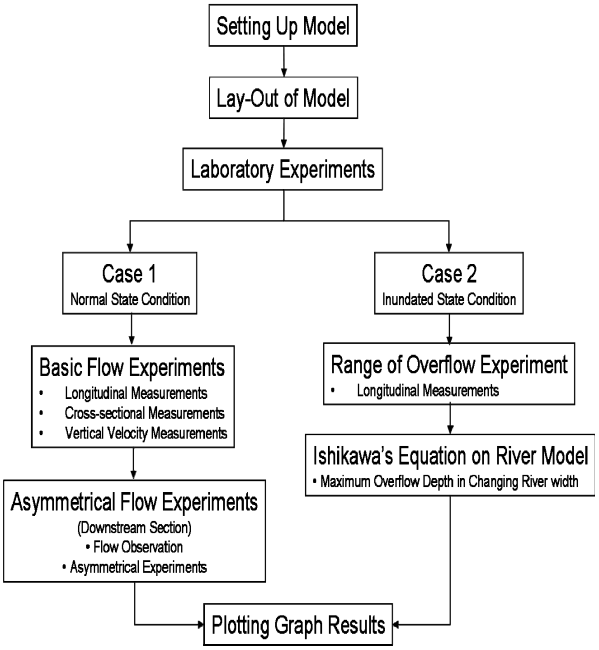
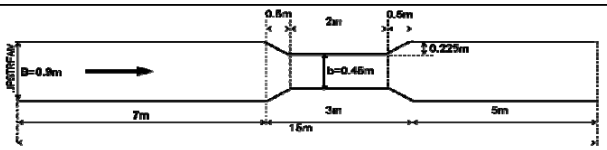
total inundated areas have been reduced, the flood damaged has hardly decreased because population and properties continues to increase in the said area Due to the existence of the same along the narrow channel, widening of the river as flood countermeasure will not be possible.

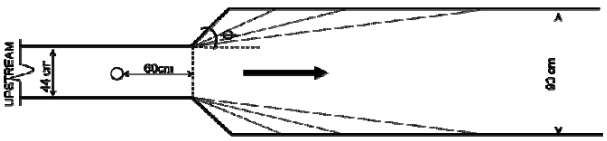
A survey on the occurrence of maximum overflow depth was conducted to the residents living near the real rivers in Japan and was found that the average maximum overflow depth occurred was approximately 0.60 m. as shown in **Fig. 4.** River banks with less damage and no damage data were considered in the survey (K. Suga et. Al, 1981).

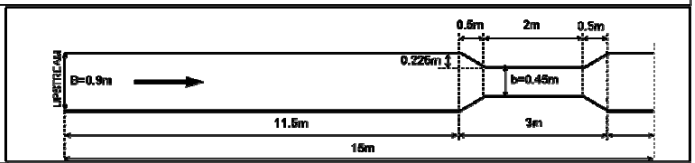
Also, a related theoretical study on overflow was published in determining the maximum overflow depth (Ishikawa, 1982). Its objective was to obtain the overflow water depth profile using the maximum overflow depth equation derived from the continuity and energy conservation momentum equations. Results from this study shows that the maximum overflow depth reach up to 1.35m using the theoretical analysis conducted on real rivers of Japan in 1982. It was based from the ratio of river width, B against height of the bank, H (B/H) parameters and was found applicable if there is a sudden change in river width. However, if there is no significant difference between the channel width and narrow width, it is not clear whether this equation will still be applicable. This theory was found to accurately calculate the maximum height of the overflow from riverbank. Hence, it served as a good working equation to calculate the highest overflow depth.

There are existing structural flood mitigating measures being implemented by Japan's government river administrators. Theories are also in place to determine the maximum overflow depth. This study aims to determine the flow behavior in a narrow open-channel through laboratory experiments using small-scale river model and a theoretical calculation using Ishikawa's theory on bank overflow.









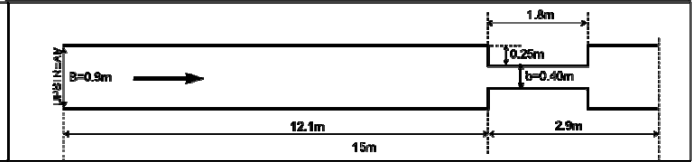


Fig. 5 Methodology Chart

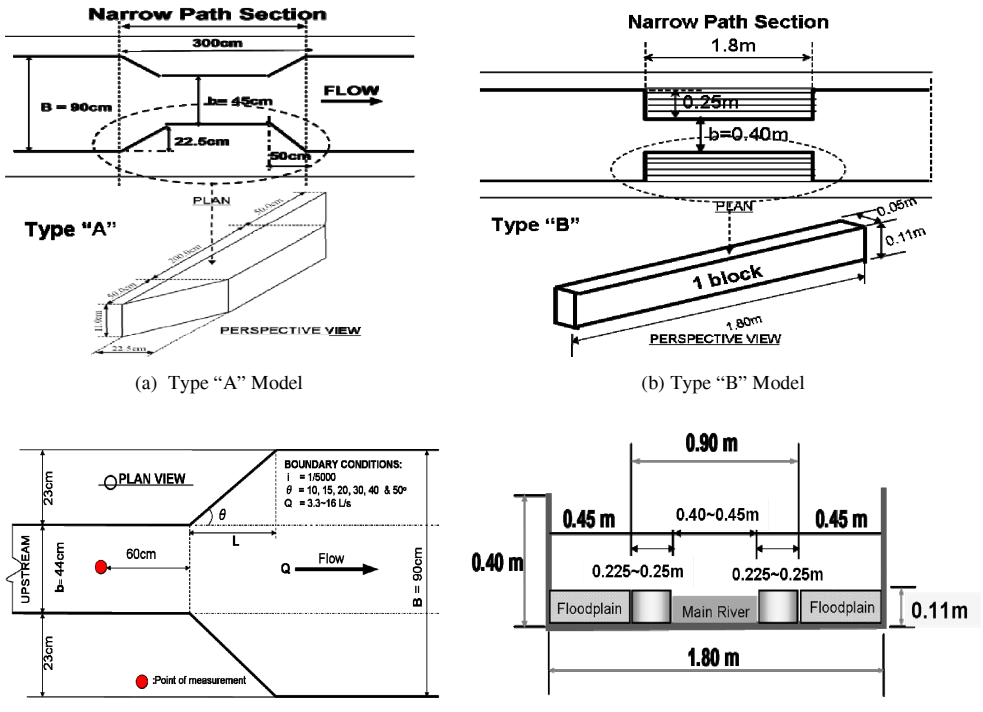
METHODOLOGY

Research procedure

There were two cases conducted in this research: 1) normal state condition and 2) inundated river condition. Case 1 aims to determine the basic flow characteristics of a narrow channel model and investigate occurrence of asymmetrical flow at downstream section through laboratory experiments. On the other hand, case 2 seeks to examine the extent of overflow and behavior of flow using laboratory experiment and theoretical calculation analysis. See methodology chart in **Fig. 5**. River model dimensions and narrow channel model locations were stipulated in **Table 1**.

Table 1: Narrow Path Location

Experiment	Narrow Location (from Upstream)	Diagram
Case 1: Normal State Condition		
I. Basic Flow	7.0 m	
II. Asymmetrical Flow	9.0 m	
Case 2: Inundated State Condition		
III. Range of Overflow	11.5 m	
IV. Ishikawa's Overflow Equation	12.1 m	



Laboratory experiments on two cases were both performed in a one-sided glass rectangular flume 15 m long, 1.80 m wide and 0.40m deep. It has an adjustable slope of up to a maximum of 1/50 or 30 cm height difference between upstream and downstream sides of the flume. The downstream tailgate was fixed at a certain angle to maintain a steady flow at upstream side of the channel. A 15 kW - 4 pole three phase induction motor pump (HITACHI, Silent Power) is attached to it that supplies discharge of up to 123~124 L/s maximum. Water depth measurements were taken using a point gauge with a reading accuracy of $\pm$1mm. Alternatively, velocities were measured using a 2D-electronic magnetic current meter (KENEK, VM-801H) for case 1-I, which has an adjustable range of 0~200 cm/s and a movable time constant from 0.05~1 sec. On the other hand, for case 1-II, velocities were measured using 3D-electronic magnetic current meter (KENEK, VM-1001RS). With an adjustable range of 0~200 cm/s and a time constant of 0.5~10 secs.

To verify Ishikawa's overflow theory (1982), the third method applied in this research is using his theoretical equation equal to:

$$\delta_2 h_2^{\,2} + \left\{\gamma_2 - \frac{3}{2}(1-b)\right\} h_2 + \frac{3}{2}(1-b)\Delta h + b = 0$$

where: h_2: the maximum overflow water depth; δ_2, γ_2: dimensionless coefficient channel change at the upstream side boundary; b: channel width; and Δh: height difference at upstream and downstream side boundaries as derived in Ishikawa (1982).

River Model Lay-out

(a) Type "A" Model

(b) Type "B" Model

(c) Type "C" Asymmetrical Model

(d) Cross-Section

Fig. 6 Narrow Path Models Detail

In a rectangular flume, a compound river small scale-model was first constructed that produces a main river that measures 15m long, 0.90m wide and 0.11m deep and floodplains at both sides that measures 15m long, 0.45m wide and 0.11m deep. Then a narrow channel model was laid at each side of the main river. Three different narrow path models were used (**Fig. 6**): (a) Type "A" model for basic flow and range of flow experiments which measures 3m long, 0.225m wide and a depth of 0.11m; (b) Type "B" model for Ishikawa's overflow experiment, composed of blocks which measures 1.8m long, 0.05m wide and 0.11m depth each; and (c) Type "C" model for asymmetrical flow experiments, changing the angle of the narrow exit section as model were used.

Laboratory Experiments

Case 1 - Normal State River

1. Basic Flow Experiment

First, a normal state river condition was conducted. In this case, narrow section was installed 7 m from upstream side of the 15 m flume as stipulated in Table 1-I. River conditions and boundaries were: length equal to 15.0m; flume total width of 1.8m; model width of 0.9m; narrow path width of 0.45m; height of the model equal to 0.11m; and a river slope was set to 1/1000. Also, Manning's number used for the main river was equal to 0.025 $s/m^{1/3}$ and 0.017 $s/m^{1/3}$ for the river bank. Discharge applied at the upper stream boundary, Q was equal to 15L/s constant. Longitudinal, cross-sectional and vertical measurements were conducted in order to acquire velocity distribution and water depth results at each point of measurement. Longitudinal measurements were taken at the middle of the river model. Water depth and velocity were measured at 32 points and 27 points, respectively. On the other hand, cross-sectional velocity measurements were conducted at five (5) cross-sections spaced at an interval of 0.25 m to 0.50 m. Measurements were conducted with 5 points at section 1 to 3; 11 points at section 4; and 9 points at section 5. Widths at each section also vary: sections 1 and 4 equal to 90cm; sections 2 and 4 equal to 67.5cm and section 3 equal to 45cm. While, vertical velocity distribution measurements were conducted at seven (7) sections of the narrow channel with five (5) points of measurements from the bottom of the channel going up to the water surface.

2. Asymmetrical Flow Experiment

This research conducted two (2) experiments. First experiment was merely flow observation experiment. Second experiment on the other hand was conducted to thoroughly identify the asymmetry and symmetry of the flow.

First, an experimental observation was conducted at the downstream section of a narrow channel. River and boundary conditions were : length equal to 15.0m; flume total width of 1.8m; model width of 0.9m; narrow path width of 0.45m; height of the model equal to 0.11m; and a river slope was set to 1/1000. Also, Manning's number used for the main river was equal to 0.025 $s/m^{1/3}$. Discharge applied at the upper stream boundary, Q was equal to 18L/s constant. Blue dye was used to identify the direction and pattern of the flow. First, it was sprayed at the middle section of the channel, and then sprayed randomly without spreading at a specific point. To further

understand the occurrence of this phenomenon, asymmetry laboratory experiments were conducted. The exit section of the narrow model was then changed and adjusted to 10^{o}-50^{o} angles. Furthermore, bed slope was set to 1/5000 and upstream boundary conditions were set to a minimum of 3.3L/s to a maximum of 16L/s.

Case 2 - Inundated River

1. Range of Overflow Experiment (Longitudinal Measurement)

An experiment on an inundated narrow river model measuring the length of inundation was then next conducted. Narrow model section was then transferred near the downstream side, 11.5 m from upstream. River conditions and boundaries for this case were the same as experiment on basic flow characteristics, except for the discharged supplied which was equal to 10 L/s as upstream boundary condition and positioning of the narrow model previously stated.

2. Inundation Width Reduction Experiment (Ishikawa's Overflow Equation)

Different model and method of experiment was conducted for Ishikawa's overflow equation. Ten (10) pcs. - 5cm x 11cm x 180cm wooden blocks were used as narrow path model. They were equally placed (5 blocks) at each bank side to create a narrow path model with an angle of 90^{o}. The narrow blocks were positioned 12.1 m away from upstream section. River conditions and boundaries for this experiment were the same as the aforementioned experiments previously discussed, from model total length, flume total width, model width, narrow width, height, slope to Manning's number. It differs only with the discharged supplied which was equal to 30 L/s as upstream boundary condition, positioning and shape/angle of the narrow model. Each block (from inner) was taken out every after measurement. Measurements were taken 10 times at 7 different narrow widths, measured and then results were averaged. This experiment was conducted to determine the relationship between the width reduction ratios against non-dimensional overflow depth.

RESULTS AND DISCUSSIONS

1. Normal State River

1.1 Longitudinal Measurement

Results in **Fig. 7** shows that water depth fluctuates as it approaches the narrow

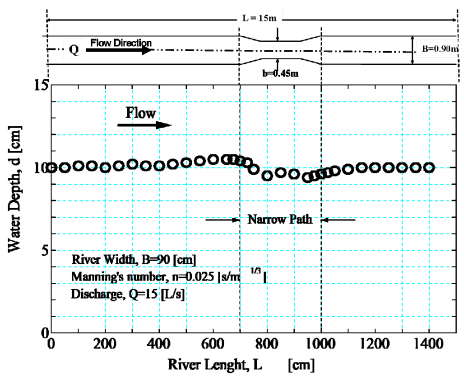


Fig. 7 Water Depth Profile

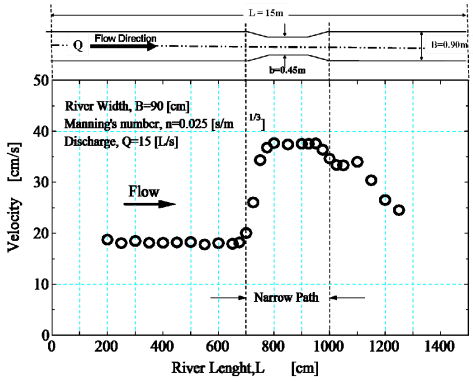

Fig. 8 Velocity Profile

path section of the channel. Then water depth level gradually goes back to its normal depth as it exits the narrow path section.

So with the velocity profile result in **Fig. 8**, velocity abruptly increases as it enters the narrow path section of the channel and gradually decreases as it exits the same. It was also observed that the velocity doubles its value at the narrow path section as compared to its velocity value at upstream section of the channel.

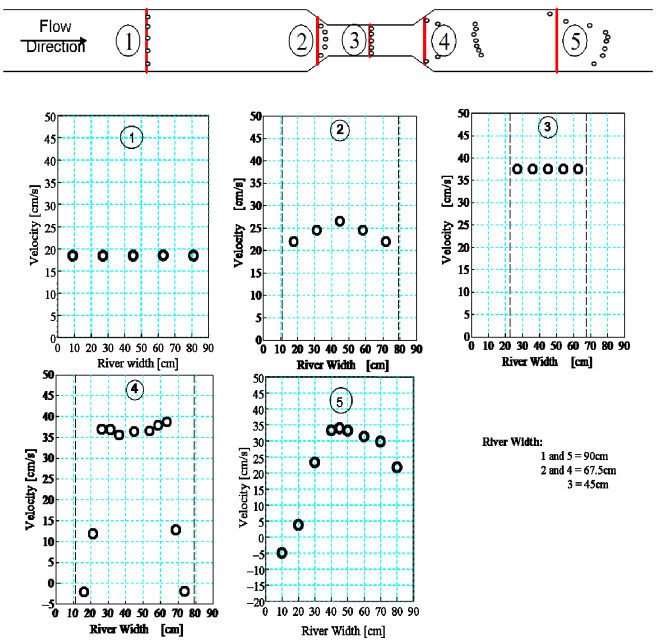

Fig. 9 Cross-Sectional Velocity Profile

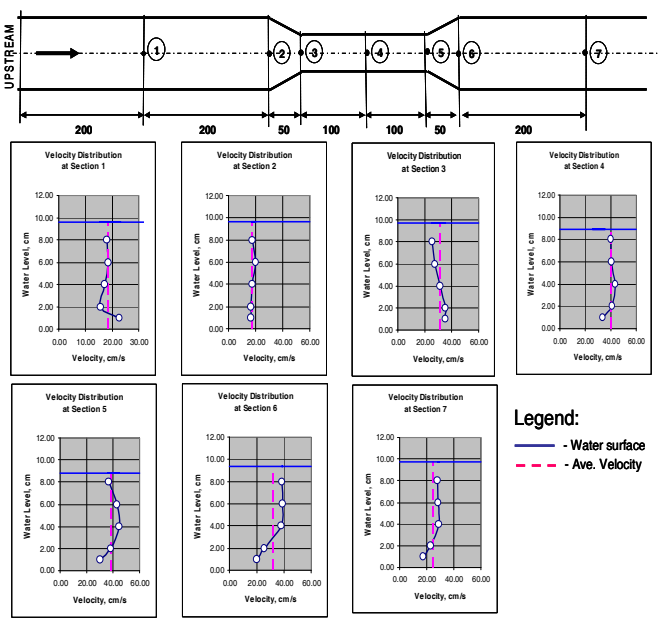

Fig. 10 Vertical Velocity Distribution

1.2 Cross-sectional Measurements

Results are shown in **Fig. 9**. Results show that velocity distributions at sections 1-3 had symmetrical velocity distributions. As observed, as the flow exits a narrow section, velocity distributions becomes asymmetrical as shown in sections 4 and 5.

1.3 Vertical Velocity Distribution

Vertical velocity distribution was conducted to determine how the flow behaves from bottom to the water surface of a narrow channel at the mid-section of the channel (**Fig. 10).** Result shows that at the upstream section of a narrow channel, velocity is not gradually increasing and it only shows almost the same value. Like the cross-sectional experiments results,

maximum velocity occurs at the narrow section of the channel. Velocity distributions at downstream side show that velocity gradually increases as it goes up to the water surface.

1.4 Asymmetrical Flow Experiments

Fig. 11 results show that an asymmetrical flow pattern occurs as the flow exits the narrow path. It was observed that it is when an adverse pressure gradient occurs along the sidewall of the channel.

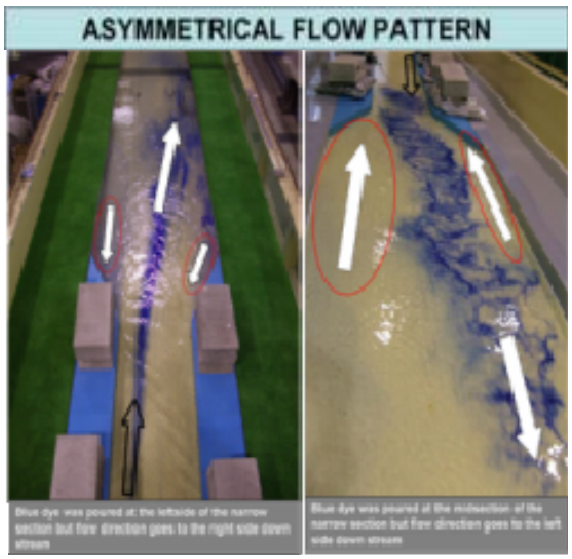

Fig. 11 Asymmetrical Flow Observation

This experiment aims to determine the asymmetry direction of the flow at the exit section of a narrow channel. **Fig. 12** shows the symmetry and asymmetry flow boundaries. Result shows that asymmetry flow to the right mostly occurs at cot θ equal to 5.68. Also, at Froude number, Fr value greater than 1.0 at cot θ value 0.84 and from Fr 1.05 at cot θ value 1.19. On the contrary, asymmetry to the left mostly happens in between Fr value 0.80~1.05 at cot θ value equal to 1.73, 2.75 and 3.73 respectively. Furthermore, symmetry occurs at Fr greater than 0.95.

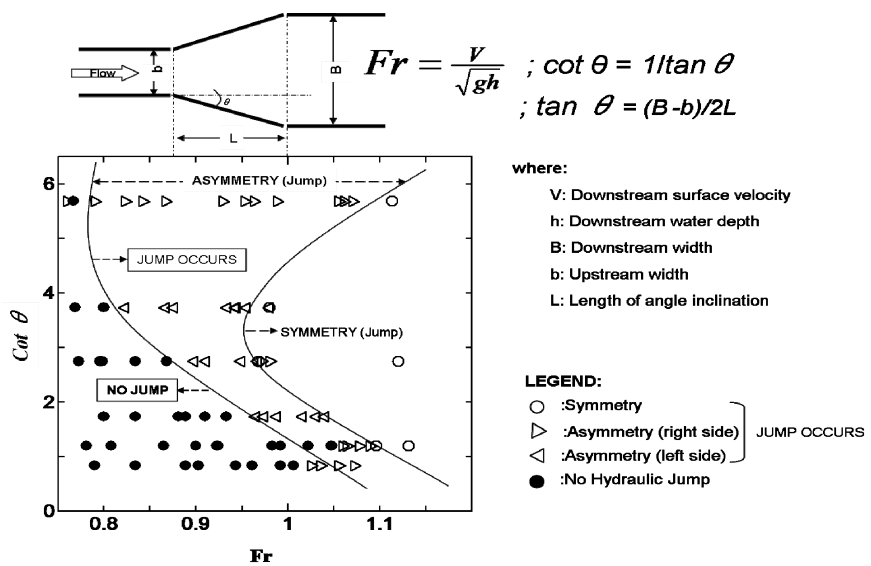

Fig.12 Symmetry and Asymmetry Boundaries

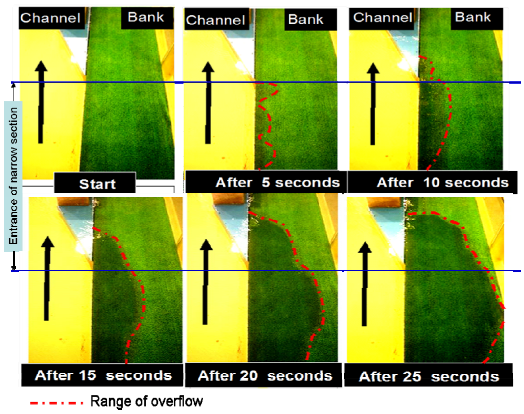

Fig. 13 Longitudinal Range of Bank Overflow

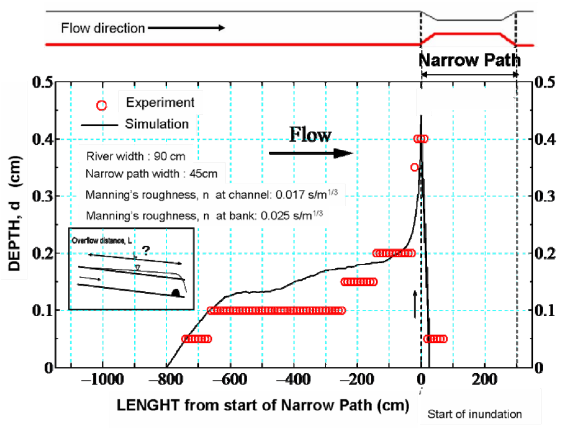

Fig. 14 Cross-Sectional Overflow Distance

2. Inundated River

2.1 Range of Overflow Experiment

Fig. 13 shows Inundation results in longitudinal measurement. Result shows that inundation starts at the upstream approach of the narrow path during the 25 seconds observation. Water starts to inundate from approach section back to upstream side direction.

On the other hand, **Fig. 14** shows that inundation flows back to up to 740cm long from the top of the river bank flowing to upstream direction.

2.2 Comparison to Ishikawas' overflow coefficient

Fig. 15 shows the relationship between the overflow depth and the width reduction ratio. Result shows that the laboratory experiment matches the theoretical line (overflow coefficient, c) equal to 1.0. It also shows that the narrower the width of a channel, the higher the overflow depth.

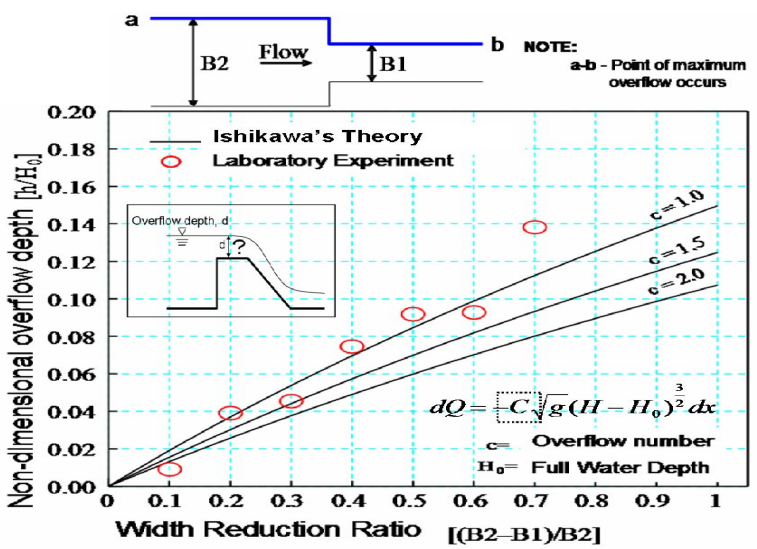

Fig. 15 Overflow Discharge Coefficient Graph

CONCLUSIONS

Case 1

This case shows that as the flow approaches a narrow section of the channel, water depth abruptly increases and as it enters the narrow path, velocity gradually speeds up. Longitudinal and vertical distribution profiles show that the maximum velocity occurs along a narrow section of a channel model. Regardless of the position of the initial pouring of blue dye, flow direction randomly goes to the right or left side of the downstream section of a narrow channel. The observation experiment proves Bernoulli's theorem: "that as the speed of a moving fluid increases, the pressure within that fluid decreases."

Symmetry occurs at Fr greater than 0.95. On the other hand, asymmetry of flow to the right or to the left direction is dependent on the angle inclination of the downstream section of the channel.

Case 2

Inundation starts at the upstream approach section of the narrow path and flows back horizontally to upstream side direction. Based on the results showed with the comparison to Ishikawa's theoretical line in this case, a narrow path falls under overflow coefficient, c equal to 1.0. This study proves that in a sudden contraction/narrow section, Ishikawa's theory was found effective for a sudden contraction channel. Furthermore, it was concluded that using Ishikawa's theoretical calculation can predict a bank overflow depth.

ABSTRACT

River bridges are very important elements of transportation systems, failures of which may not only lead to loss of several lives and excessive damages but also various deficiencies including socio-economic factors. Several aspects of bridge failures should be investigated jointly to gather information for scour-resistant design practices. This study specifically focuses on the effect of clear water scouring at vertical-wall abutments on bridge stability. Determination of the time-dependent volume and surface area of scour hole around a vertical-wall abutment would yield relevant information to assess the safety level of the bridge foundation. To this end, temporal variation of geometric features of scour holes around vertical abutments under clear water conditions are examined with reference to an experimental study. Findings of this study would yield some information concerning loss of structural resistance, safe design of footing and sizing and placement details of armoring countermeasures against scouring.

INTRODUCTION

Bridges are subject to various external impacts, such as development of adverse hydraulic conditions during severe floods, disastrous earthquakes, etc., most of which lead to complete failure. Statistical analysis of bridge failures indicate that most frequent cause of bridge failures are attributable to excessive scouring during floods (Shirhole and Holt 1991; Lagasse et al. 1998; and Wardhana and Hadiprioni 2003). Other reasons of failure include overloading, collision and deficiencies in design, construction, material, lack of repair and maintenance, etc (Yanmaz et al. 2007). Bridge failures can lead to loss of several lives and properties, traffic disruption, and deficiencies in various socio-economic conditions. If the reason of bridge failure is not concerned with the structural design and materials, it may originate from lack of hydraulic evaluations, which may also result in pronounced uncertainty in view of bridge stability. New bridges need to be designed to withstand extreme conditions that are likely to occur in the light of lessons learned from past events. On the other hand, existing structures should be monitored periodically on behalf of decision-making for the degree of necessary protective works to be implemented to increase the safety (Yanmaz et al. 2007).

Depending upon the severity of flow conditions, considerable quantities of bed material may be removed from the surrounding of piers and abutments, which leads to loss of structural resistance. Safety margin of the abutment foundation against scouring, which is the difference between the depth of footing and the maximum depth of scour, would decrease during the passage of a severe flood. Hence the resistance, which is the ability of a bridge to withstand external effects would reduce greatly. Assessment of the current safety level of the footing is based on the value of the safety margin as well as geometric characteristics of the bed topography in and around the scour hole. That is why determination of the volume and the surface area of the scour hole around bridge elements is of importance. This study is focused only on the investigation of these aspects around bridge abutments.

The close upstream of a bridge abutment is subject to a strong pressure field. This leads to a three dimensional separation of flow. The primary vortices, which migrate downstream past the abutment, carry significant amount of bed material from the scour hole. Hence the whole vortex structure (primary vortices and wake vortices) scour the loose bed yielding the development of a scour hole around the abutment. Since equilibrium scouring situations are achieved in relatively long durations under clear water conditions, i.e. of the order of several days in a laboratory medium (Melville and Coleman 2000), the corresponding prototype durations may yield relatively long flow durations. That is why the design of bridge foundations on the basis of equilibrium clear water scour depths may give considerably greater values than may occur if the flow is of short duration (Yanmaz and Altinbilek 1991). Therefore, investigation of temporal variation of clear water scour at bridge elements is of importance to estimate the possible extension of the scour hole, which would provide information for safe design of footing and the scour countermeasure to be implemented. The objective of this study is to investigate the geometric characteristics of the instantaneous scour holes around vertical-wall bridge abutments under clear water conditions. To this end, expressions are developed for intantaneous values of volume and surface area of scour holes around vertical-wall abutments.

EXPERIMENTS

Sets of experiments were carried out to investigate the time-dependent variation of scour hole characteristics around vertical-wall abutment models under clear water conditions in a flume 30 m long, 1.25 m wide, and 1.0 m deep with a bed slope of 0.001. Side walls of the flume are made of glass for visual observations. The channel bed material is uniform quartz sand with a median size of D_{50}=1.8 mm. To investigate the effect of abutment size, abutment models made of plexiglas having lengths of L=12.5 cm and 10 cm were tested. Experiments were performed under a constant densimetric particle Froude number of F_d=2.38, which is defined as $u/(\Delta g D_{50})^{0.5}$, where u is the mean approach flow velocity, Δ is the relative density, and g is the gravitational acceleration. Since similar scouring characteristics are expected under different F_d values because of fundamental similarity of all types of local scouring situations, tests performed under a constant value of F_d are found to be representative for the implication of the general scouring trend. In the experiments,

maximum scour depths around the vertical-wall abutments, d_s, are measured against time, t, relative to the initial bed level using a vertical scale attached to the interior of hollow plexiglas abutment with a stick having a small inclined mirror at its end. In the course of experiments, it was observed that the rate of scour development was high in the early stages of the tests. The rate of change of scouring decreased slowly with respect to time. That is why investigation of temporal variation of scour hole characteristics during the principal phase may be of practical interest. Hence, the test duration of an experiment was limited by six hours according to the physical limitations of the laboratory. During this test period, the final equilibrium scour depths were not achieved although the rate of scour reduced to smaller values for all experiments.

Throughout the conduction of the experiments, it was observed that the maximum scour depths occurred around the upstream corner of the abutment. For the determination of time-dependent shapes of scour holes around bridge abutments, experiments were stopped at the end of different test durations; namely 5, 20, 60, 100, and 150 min to determine the contours of the scour holes around abutment models using point gages. Measurements were carried out with respect to the coordinate system given in Figures 1 through 5, which show contours of the bed topography around the abutment with L=12.5 cm obtained at the end of the aforementioned test durations After each run, the bed was flattened to run the experiment with the next duration. An inspection to these figures implies that the upstream side of the abutment is subject to severe scouring where primary vortices dominate scouring action. Contrary to the case of a bridge pier around which symmetrical flow takes place, the rear face of the abutment is subject to considerable accretion in the wake region, which is bounded by the side wall of the channel.

ANALYSIS OF TEST RESULTS

Kose (2007) developed a semi-empirical model for temporal variation of scour hole around vertical-wall abutments using the results of the aforementioned tests. This model was based on the application of the sediment continuity equation to the scour hole around the abutment. The expression developed for instantaneous volume of the scour hole, V, around a vertical-wall abutment is as follows:

$$\frac{V}{d_s(t)L^2} = \frac{A\alpha}{6}\left(1+S\cot\phi\right)+\frac{B}{3}\left(1+2S\cot\phi+3S^2\cot^2\phi\right)+\frac{C}{3}\left(1+S\cot\phi\right)+ \frac{D}{3}\left(1+2S\cot\phi+S^2\cot^2\phi\right)+\frac{E}{3}-\frac{5\alpha}{6} \quad (1)$$

where $d_s(t)$=instantaneous maximum depth of scour, α=W/L, W=width of abutment, $S=d_s(t)/L$, ϕ=angle of repose of the sediment, $A=\ln\left|\sec(\arctan(2/\alpha))+2/\alpha\right|$, $B=\arctan(2/\alpha)$, $C=\ln\left|\sec(\arctan(E))+E\right|$, $D=\arctan(E)$, and $E=\alpha/2$.

The results of the analysis indicated that the shape of the scour hole remained almost unchanged with respect to time and the side angles of the scour hole, except the rear face of the abutment, was approximately equal to the angle of repose, ϕ, of the sediment. Dey and Barbhuiya (2005) also observed that the upstream scour holes around abutment models of different shapes had a similarity at different times. They concluded that this implied a layer-by-layer scouring process until an equilibrium state was achieved. As a result of this analysis, the volume of the scour hole can be approximated by an inverted semi-cone with a rectangular base having a width, W, and a length, L (Kose 2007). The predictive ability of Equation (1) is checked by the application of a software, which can evaluate the area and volume elements bounded by irregular contours. The volumes obtained from Equation (1) and the software were found to be in relatively good agreement (Kose 2007). The geometric characteristics of the scour holes around vertical-wall abutments can also be expressed with reference to the contours drawn around the abutment models. Using the computed values of instantaneous scour hole volumes obtained from the aforementioned software, the following regression equation with a coefficient of determination of 0.98, is obtained:

$$\frac{V}{d_s(t)L^2} = 1.142T_s^{0.142} \quad (2)$$

where T_s is a dimensionless time parameter, $tD_{50}(\Delta gD_{50})^{0.5}/L^2$, as also previously used by Yanmaz and Altinbilek (1991) and Yanmaz (2006) and t is the time. In a similar way, the temporal variation of the surface area of the scour hole can be expressed by the following equation having a coefficient of determination of 0.960:

$$\frac{A}{WL} = 3.722T_s^{0.182} \quad (3)$$

where A*=A/(WL) with A being the instantaneous surface area of the scour hole. Since Equations (1) and (2) express the dimensionless scour hole volumes, both of them can be used for the practical prototype applications. However, it is obvious that use of Equation (2) is easier. These equations require selection of appropriate design parameters. The length of an abutment is normally dictated by structural and geotechnical requirements. Bed material characteristics in close vicinity to the bridge site are obtained from the collected soil samples, whereas the design time is to be selected according to the hydrological regime of the basin concerned. It should be emphasized herein that the most crucial term is the duration of the design flood. For a conservative design, sufficiently long flow durations, compatible to the local hydrologic conditions of the bridge site concerned, can be taken. Use of Equations (2) and (3) require determination of the scour depth at a vertical-wall abutment corresponding to the design time, which can be obtained using an appropriate equation, such as the one proposed by Oliveto and Hager (2002). They derived the following equation for time-dependent clear water scour depth at vertical-wall abutments

$$\frac{d_s}{L_R} = 0.085\sigma^{-0.5} F_d^{1.5} \log T_d \tag{4}$$

where $L_R=L^{2/3}y^{1/3}$, y=depth of approach flow, σ=geometric standard deviation of particle size distribution, $T_d=t/t_R$, and $t_R=L_R/(\Delta g D_{50})^{0.5}$.

Information obtained from the scouring characteristics at vertical-wall abutments would yield some relevant information for the assessment of the stability of the structure. With the progression of the scour hole, the resistance of the structure to withstand external forces, such as earthquake and flood induced inertia forces, reduces. Assessment of the loss of reduction in the system resistance induced by excessive scouring may dictate the degree of foundation strengthening measures to be implemented. Information concerning the depth, surface area, and volume of the scour hole can also give some clues about the depth and areal extension of the protection zone around the abutment. Within this context, the size of ripraps and the number of armoring layers in the protection area can be found. However, additional experiments need to be conducted to generalize the design details of this armoring countermeasure, which would be the subject of a different future research.

CONCLUSIONS

Topographic characteristics of scour holes around vertical-wall abutments under clear water conditions have been investigated under a densimetric particle Froude number of 2.38. The experiments were carried using abutment lengths of 10 and 12.5 cm in a flume having a quartz sand as the bed material with a median size of 1.8 mm over a bed slope of 0.001. Experiments were stopped at various test durations and the corresponding scour contours around the vertical-wall abutment model were measured. Experimental results implied that the volume of the scour hole around a vertical-wall abutment could be approximated by an inverted semi-cone with a

rectangular base having a width, W, and length, L, which is given by Equation (1). Another volume expression was also obtained based on empirical approach as given in Equation (2). Dimensionless surface area of the scour hole is expressed by Equation (3). Use of Equations (2) and (3) requires determination of the depth of scour, which corresponds to the design duration of the flood. To this end, the equation proposed by Oliveto and Hager (2002) can be used. Findings of this study would provide relevant information to assess the time-dependent loss of resistance of a bridge against excessive scouring. Furthermore, interpretation of the scour hole characteristics would also give information concerning the determination of the areal extension of armoring countermeasures to be implemented around vertical-wall abutments. Additional experiments need to be conducted to generalize the design details of armoring countermeasures at vertical-wall abutments.

ABSTRACT

Taiwan rivers generally have steep slopes, are subject to high flows, have frequent earthquake activity, and have relatively weak bedrock. Bedrock is often exposed and rock scour is an important river process. For example, the river channel downstream of the Shih-Gang on the Tachia River experienced severe rock scour since the Chi-Chi earthquake of 1999 uplifted a portion of the river approximately 10 m. The occurrence of deep rock scour has been a major threat to river infrastructure at many other locations in Taiwan.

In this study, a rock scour model is implemented into a one-dimensional (1D) hydraulic and sediment transport model. The rock scour model has components to predict the potential scour due to direct flow hydraulic forces and scour due to sediment abrasion. The resultant 1D model is capable of simulating the combined effects of rock erosion and alluvial river erosion and deposition. The new model is applied to the Tachia River in the reach affected by the Chi-Chi earthquake in 1999. Findings related to the applicability and limitations of the current rock scour models are reported.

INTRODUCTION

In Taiwan, many alluvial rivers are characterized by the presence and exposure of soft bedrock. The bedrock consists of mainly mudstone and sandstone which are relatively weak (shear strength between 0.5 ~ 25.0 MPa) and subject to substantial erosion during high flows. Once the sediment overlying the bedrock is eroded by the river, the river can begin to erode the bedrock. The scour can damage infrastructure such as bridge piers or diversions founded on the bed rock. To address this significant concern, an extensive research and development program has been set up by the Water Resources Agency of Taiwan. One of the aims is to understand and document the rock scour characteristics such that a predictive model may be formulated.

Rock erosion occurs when water is flowing over bedrock in a fluvial environment. A number of mechanisms are responsible for the erosion of rock. They include hydraulic scour or plucking (plucking of rock fragments by fluid shear stresses), abrasive scour (interaction between rock and moving sediment particles), dissolution, and cavitation. In addition, weathering (chemical or physical) contributes

to the weakening of rock. Dissolution is not a factor within the time scales of interest in this study and velocities are not high enough to cause cavitation.

It is theoretically advantageous to treat different mechanisms separately; however, it is difficult to distinguish the mechanisms in the field. Hydraulic scour can occur without the assistance of sediment particles but many times the flows that can scour bedrock can also carry significant amounts of sediment. Similarly, abrasive scour is strongly dependent on the hydraulic flow characteristics such as shear and turbulence. It is possible that one reach of the river is dominated by hydraulic scour while another by abrasive scour. Or, both mechanisms may operate to erode the rock for some rivers.

In a companion paper "Predicting Rock Scour in an Alluvial River with a Two-Dimensional Model" by Lai et al. a review of rock scour model is presented. In that paper, a two-dimensional (2D) application of the rock scour model is presented. Greimann and Vandeberg (2008) also detailed the development and application of SRH-1D to predict bedrock scour. Here we present a 1D application of the rock scour model. The 2D model can be used for reaches on the order of several kilometers in length and can simulate several years of flow data, but due to computational limitations, cannot be applied to entire rivers or for long term simulations. It is necessary to use a 1D model to calculate large time and spatial scales.

A PROPOSED ROCK EROSION MODEL

We propose that the hydraulic scour and abrasive scour should be modeled separately. Field reconnaissance is recommended to determine whether the study site is hydraulic scour dominant, abrasive scour dominant, or if both play important roles. The proposed combined rock scour rate model takes the following form:

$$E = k_P U \left(\frac{\tau}{\tau_{cri}} - 1 \right)^n + E_a \tag{6}$$

where E is total rock erosion rate; k_P is hydraulic erodibility; U is depth averaged flow velocity; τ is bed shear stress; τ_{cri} is critical shear stress for hydraulic rock scour; n is an empirical exponent; and E_a is abrasive scour rate. In this paper, we are only considering the hydraulic scour of rock. Abrasive scour will be considered in future 1D analysis, and is considered in the companion paper on 2D scour.

The first term on the right hand side of (6) represents the hydraulic scour rate and it is set to be a function of the stream power (τU). The above form has the advantage of being dimensionally consistent as opposed to the dimensional equations used in many existing models such as that of Tomkin et al. (2003). It is also consistent in form to the cohesive sediment transport relationships used in the mobile-bed models. The exponent, n, is assumed to equal 1 as existing data is insufficient to support the use of nonlinear relations. Therefore, two empirical parameters are needed for the hydraulic scour: k_P and τ_{cri}.

Numerical Model Description

The proposed rock erosion model is incorporated into the existing SRH-1D version 2.1, which is a 1D cross section averaged hydraulic and sediment transport mobile bed model for river systems developed at the Bureau of Reclamation (Huang and Greimann, 2008). The model is available for download at: http://www.usbr.gov/pmts/sediment/. The model can simulate steady and unsteady flow, sediment transport, and erosion and deposition. Version 2.1 can now also simulate the effects of bedrock.

Governing equations and numerical methods of SRH-1D are omitted; and only the implementation of the rock erosion model is described here. The bed material beneath the bed surface is divided into a number of sub-layers in the original SRH-1D and they may be spatially distributed. At each cross section, every sub-layer has its own thickness and sediment gradation. A new sub-layer type is added, designated as the "erodible rock", to apply the rock erosion model. If there are granular materials on top of the erodible rock, they are eroded first; if the bedrock is exposed, rock erosion is initiated. The user enters the cross sectional station and elevation points of the bedrock. The bedrock and cross section representation used in SRH-1D is given in Figure 1.

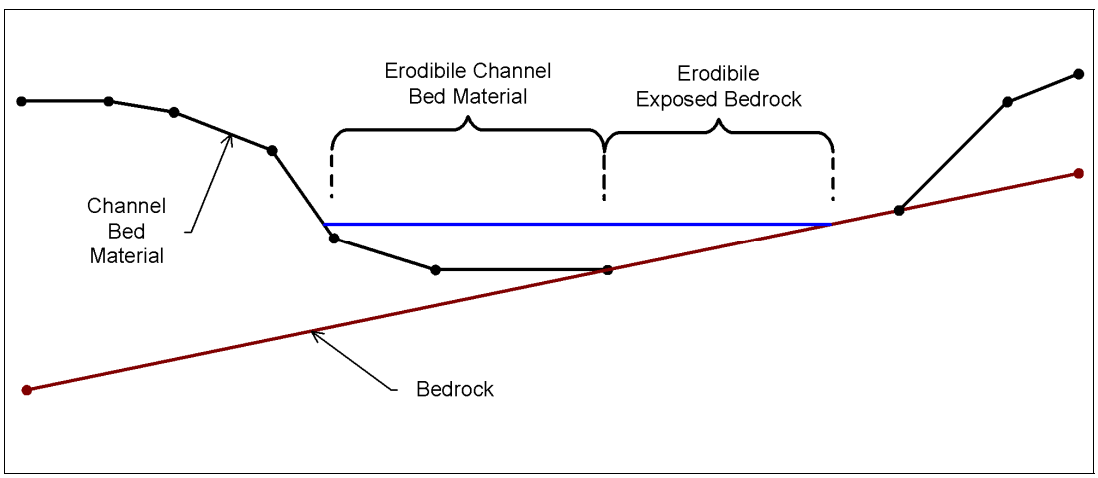

Figure 1. Cross sectional representation of bed rock and alluvial material.

Test and Application of the Rock Erosion Model

The rock erosion model is applied to Tachia River in the reach extending from 10 km upstream of Shih-Gang Dam to the ocean. The Chi-Chi earthquake of 1999 cause approximately 10 m of uplift in the vicinity of the dam. The fault actually passed through the middle of the dam and the North portion of the dam is now 10 m lower than the South portion. The uplift caused by the earthquake and the presence of the dam created a deposition zone upstream of the dam and an erosion zone downstream of the dam. The area near Shih-Gang Dam and the fault line is given in Figure 2. The dam is now repaired but because of the reduction in river slope upstream of the fault, sediment is depositing upstream of the fault line and severe erosion is induced downstream of the fault line. The river profile before and after the earthquake is shown in Figure 3. The displacement caused by the 1999 earthquake,

and the subsequent deposition upstream of the fault line and erosion downstream of the fault line is shown in the figure.

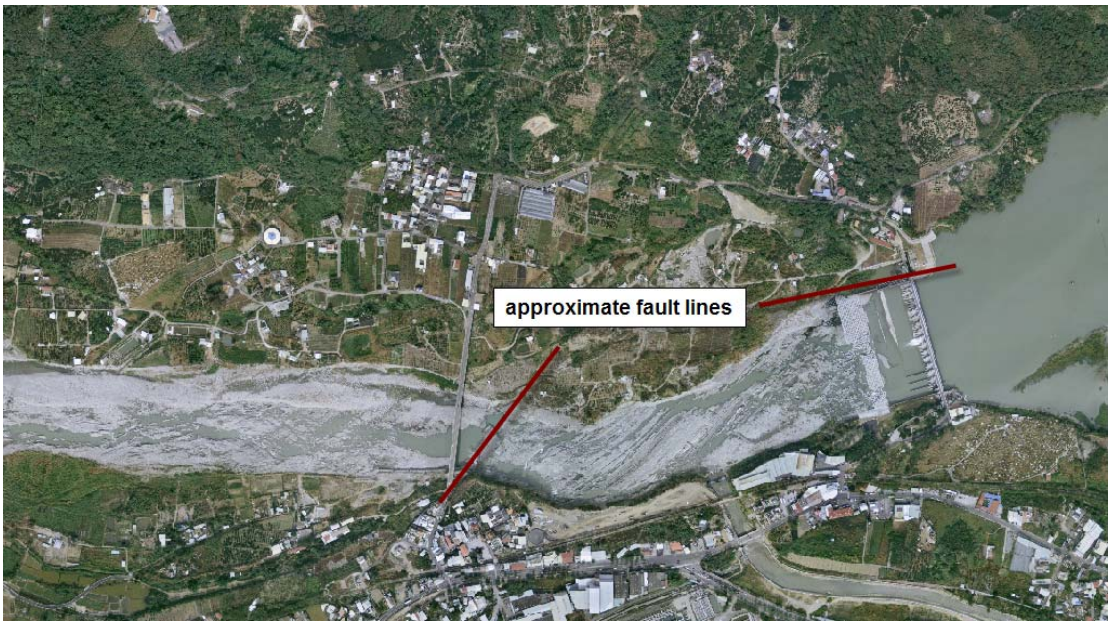

Figure 2. Aerial view of the Tachia River in the vicinity of the Shih-Gang Dam. The fault lines are noted on the figure.

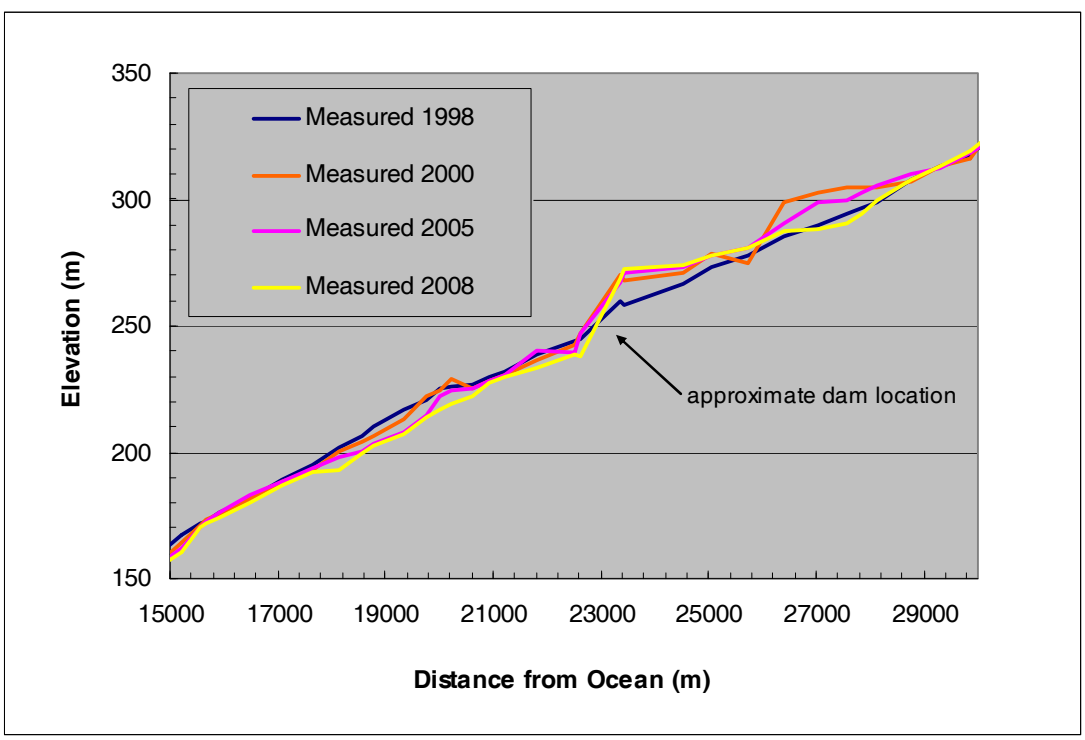

Figure 3. River profile measured at various times. The earthquake occurred in 1999.

The SRH-1D model requires several inputs. They can be divided into hydraulic, sediment and bedrock inputs. The hydraulic inputs include the flow discharge, the cross sectional geometry, and hydraulic roughness parameters. The flow discharge was recorded at Shih-Gang dam and is shown in Figure 4. We simulated the period from 2000 through 2004. There were several large storms during that period and extension erosion downstream of Shih-Gang dam. The flows during that period are given in Figure 4. The flow in the river is extremely variable and the sediment transport and scour are dominated by typhoon events that occur during the summer months. Flows less than 50 cms were ignored. The cross sectional geometry was surveyed by the Taiwan Water Resources Agency in 2000 and 2005. Therefore, it was possible to compare the simulated geometry changes results against measured geometry changes during that period. The hydraulic roughness assumed in the main channel was 0.04. Because of the steep slopes the flow is near critical conditions throughout almost the entire river.

The sediment inputs to the model include the incoming sediment load and the initial bed material gradations. The incoming sediment load was calculated by assuming that the river is at transport capacity at the upstream cross section. This is probably a good assumption because of the tremendous sediment volumes introduced into the upper river as the result of the 1999 earthquake. The initial bed material gradations were taken from several test pits throughout the simulated reach. One interesting feature of the river is that the bed material actually gets coarser in the downstream direction, which is opposite of most rivers. It is likely due to the severe aggradation occurring in the upper watershed due to multiple landslides and also due to the severe erosion occurring in the lower river below Shih-Gang Dam.

Several sediment transport parameters also need to be input, the most important being the formula used to compute the sediment transport capacity. For the simulations shown here, the Parker bedload formula (Parker, 1990) is used in conjunction with the Engelund-Hansen total load formula (Engelund and Hansen, 1972). The Parker equation is used for the gravel sized and larger sediment and the Engelund-Hansen formula is used for the sand sized sediment.

The bedrock geometry input parameters include the bedrock geometry and the erosion rate coefficients. For this paper, we consider only hydraulic scour. The bedrock was assumed to be fully exposed in the reach immediately downstream of the dam for a distance of approximately 3 km. The bedrock erosion coefficients are discussed in the following section.

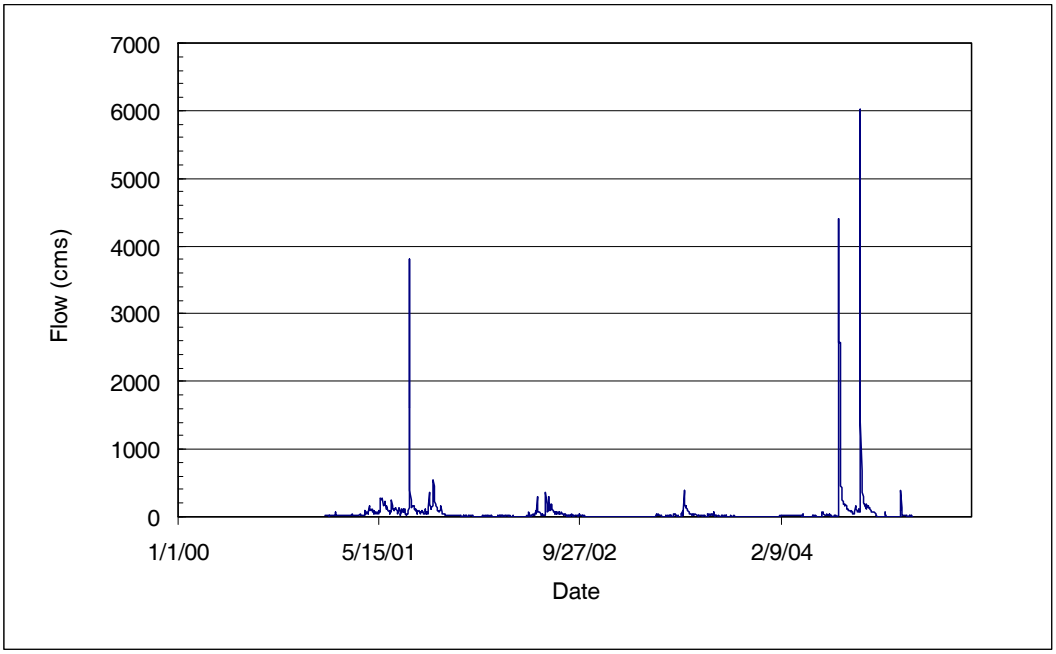

Figure 4. Flow during period of simulation beginning in January 2000 and ending in Dec 2004.

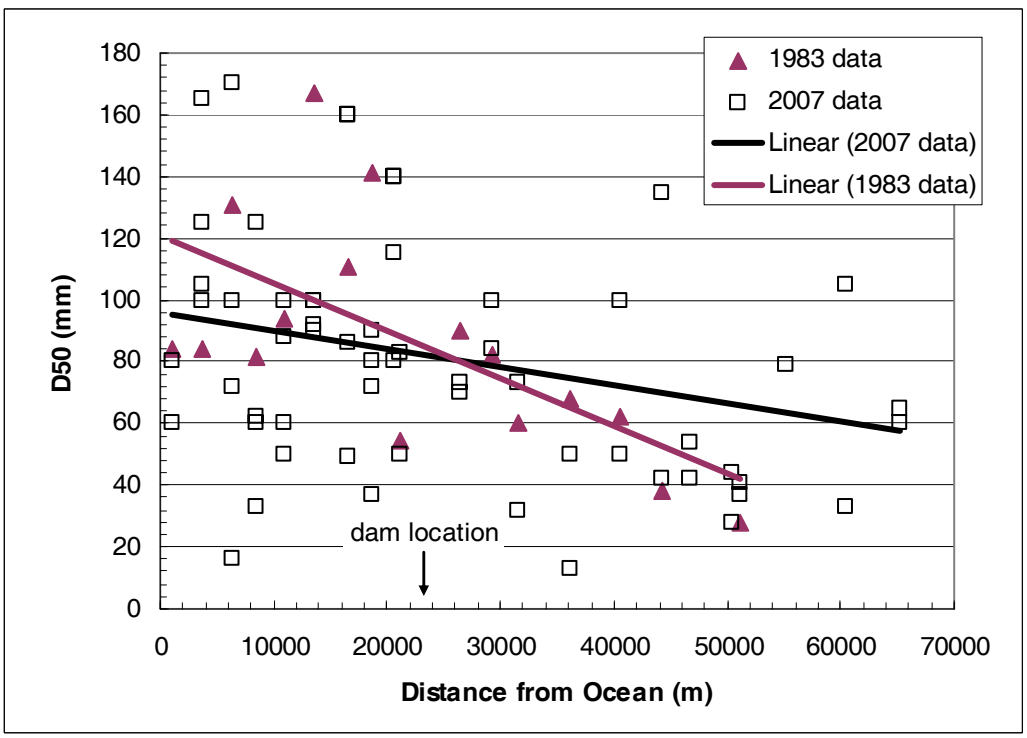

Figure 5. Measured D50 (median diameter) as a function of distance from the ocean. Linear fits to the data are also shown.

RESULTS AND DISCUSSION

We calculated the cases with and without hydraulic rock scour. For the case without hydraulic rock scour, the bedrock was assumed to be not erodible and only the sediment in the river was allowed to erode. For the case of hydraulic rock scour we calibrated the critical scour shear stress, τ_{cri}, and the erosion rate coefficient, k_p. Based upon fits to the erosion data from 2000 to 2005, the calibrated values were τ_{cri} = 200 Pa and k_p = 6E-6. The observed bedrock erosion is within 1 km of the dam and the 1D model including bedrock erosion reproduced the average bed elevation change (Figure 6). The average bed decreased 2m in the location downstream of the dam. The model was not able to reproduce the location and magnitude of local scour, but this is considered beyond the capability of a 1D model. A 2D model would be required to compute the magnitude and location of local scour. The average erosion and deposition patterns of sediment were also reproduced by the model with a few exceptions. Overall, the agreement is considered satisfactory and it was able to reproduce the reaches that were aggrading and degrading. The simulated average bed elevation changes assuming no rock erosion is also shown in Figure 6. The only difference, as expected, is in the area immediately downstream of Shih-Gang dam where the bedrock is exposed.

The measured and computed volume of erosion and deposition is given in Figure 7 for the case of bed rock erosion. There is some bedrock erosion in the reach immediately downstream of the dam. Beyond that bedrock erosion is not significant because it is not exposed or it is considered more resistant to erosion. The computed volumes of total erosion and deposition are in general agreement with the measurements. The volume of bedrock erosion is considerably smaller than the erosion of sediment, but it is significant to the infrastructure located in that reach. As mentioned previously, only hydraulic scour is currently considered. Further tests on the important of abrasive scour will also be considered in future simulations.

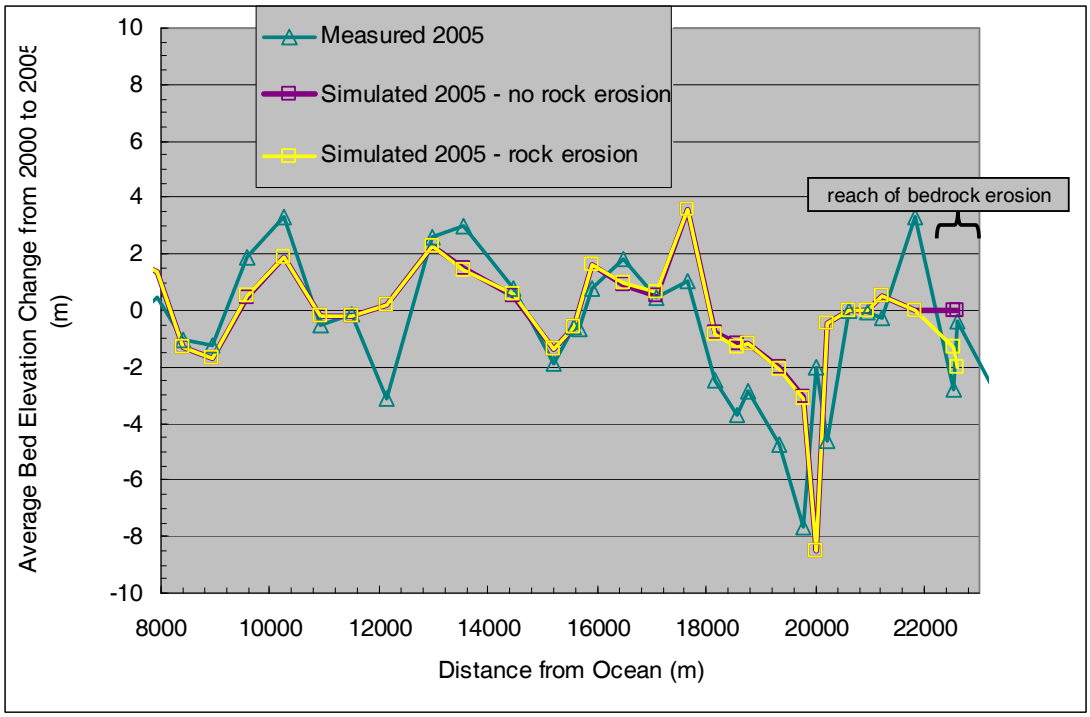

Figure 6. Measured and simulated average bed elevations changes from 2000 to 2005. The model was run with and without rock erosion.

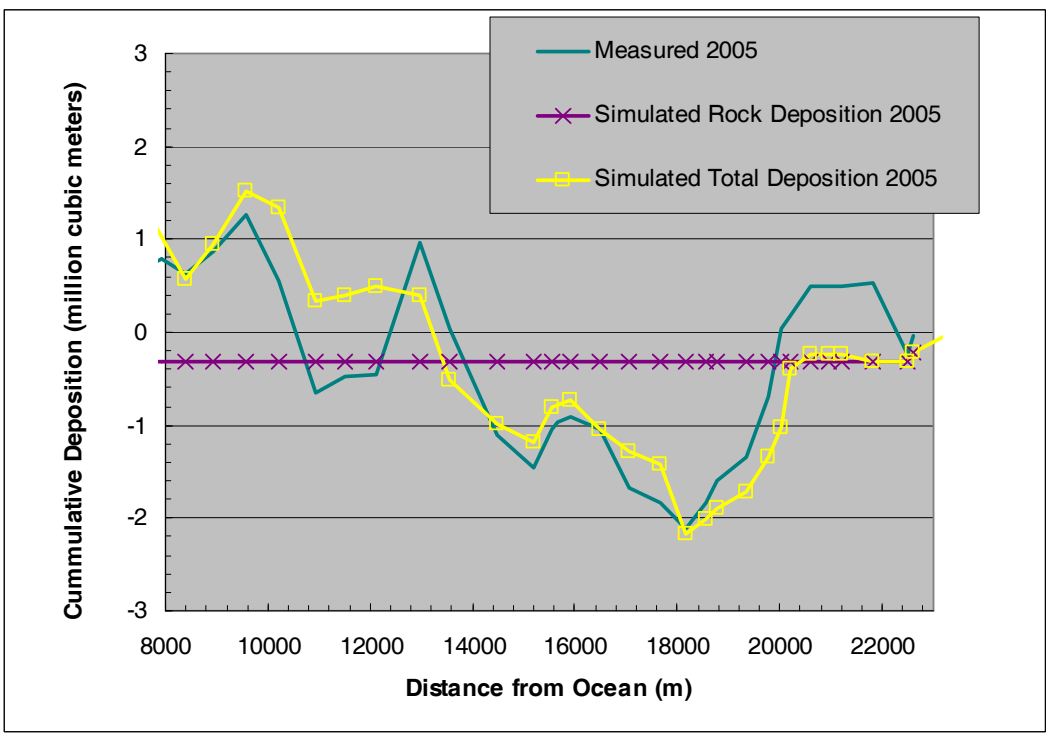

Figure 7. Measured and simulated average bed elevations changes from 2000 to 2005. The model was run with rock erosion.

CONCLUDING REMARKS

A review was conducted for the rock erosion models and a specific rock erosion model is proposed and implemented into an existing 1D model: SRH-1D. The model is then applied to study the erosion downstream of the Shih-Gang Dam on the Tachia River. The following conclusions may be drawn: (1) The presence of rock in the river channel can exert important influences on the erosion and deposition in the river channel, (2) Scour of bedrock can occur under relatively short time scales given the particular conditions in Taiwan, (3) The 1D model can reproduce the average bed elevations changes and the erosion and deposition volumes in the reach, but cannot reproduce the magnitude and location of local scour.

ACKNOWLEDGEMENT

The author would like to acknowledge that the Water Resources Agency of Taiwan has sponsored this study. The project Liaison Officer, Director Chen, Hung-Kwai, and the review committee in Taiwan have provided valuable technical comments. Peer review provided by Jianchun Huang at Reclamation is greatly appreciated.

Abstract

Most rivers in Taiwan have a steep slope, subject to high flows, and have relatively weak bedrock. Bedrock is often exposed and rock scour is an important river process. For example, the river channel downstream of the Chi-Chi Weir on the Choshui River experienced up to 10 meters of rock scour since the construction of the weir in 2001. The occurrence of deep rock scour has been a major threat to river infrastructure at many other locations in Taiwan.

In this study, rock scour models are reviewed and a specific rock scour model is proposed. Among rock scour mechanisms, those due to flow hydraulic force and sediment abrasion are considered to be important. The rock scour model is incorporated into an existing two-dimensional (2D) mobile bed model, SRH-2D version 3. The resultant 2D model is capable of simulating the combined effects of rock erosion and alluvial river erosion and deposition. The new model is applied to the river reach at the Chi-Chi Weir in an attempt to test and verify the applicability of the rock scour model. Findings related to the applicability and limitations of the current rock scour models are reported.

Introduction

In Taiwan, many alluvial rivers are characterized by the presence and exposure of soft rocks on the river bed. The bedrock consists of mainly mudstone and sandstone which are relatively weak (shear strength between 0.5 ~ 25.0 MPa) and subject to substantial erosion during high flows. Therefore, soft rock erosion is an important river process in Taiwan. For example, the river channel downstream of the Chi-Chi Weir on the Choshui River experienced up to 10 meters of rock scour since weir construction in 2001.

Rock scour is important to locations where the overlying cobble and gravel river bed has been removed and the relatively weak mudstone or sandstone has been exposed. The large floods that occur in Taiwan wear away the rock, resulting in the erosion of bridge pier foundations, diversion structures, and other infrastructure. To address this significant concern, an extensive research and development program has been set up by the Water Resources Agency of Taiwan. One of the aims is to understand and document the rock scour characteristics such that a predictive model may be formulated.

Tomkin et al. (2003) compared various empirical models for bedrock incision and concluded that they generally cannot explain observed behavior because the current simple empirical approaches do not account for the varying channel capacity in different parts of the river, nor do they account for the distribution of discharge with time. By building a bedrock erosion module into numerical hydraulic and sediment transport models, the variations in channel capacity and specific discharge time series can be explicitly simulated. Therefore, we are

seeking to develop a numerical model which incorporates a rock erosion model and to test and assess the applicability of such models. Such an effort was initiated in 2007 by modifying the one-dimensional (1D) mobile bed sediment model SRH-1D to include the rock erosion model (Greimann and Vandeberg 2008). It was successfully applied to the reach downstream of the Chi-Chi Weir. The new 1D model can now be used to estimate reach averaged rock erosion.

In the current study, a two-dimensional (2D) rock erosion model is developed and tested. The need for a 2D model was recognized during the SRH-1D study, as some erosion areas were observed to be local and exhibit lateral variations. 2D modeling is usually needed for cases where 2D effects are important. Examples include near-field flow zones with in-stream structures such as weirs, diversion dams, release gates, coffer dams, etc.; bends and point bars; perched rivers; and multi-channel systems. 2D models may also be needed if certain hydraulic characteristics are deemed important which include flow recirculation and eddy patterns, lateral variations, overtopped banks and levees, differential flow shears on river banks, and interaction between the main channel, vegetation, and the floodplain.

In the following, a specific rock scour model is developed based on an extensive review, the model is then incorporated into the existing 2D mobile-bed model, SRH-2D version 3, and the model is finally applied to the reach at the Chi-Chi weir.

A Review of Rock Scour Models

Rock erosion occurs when water is flowing over bedrock in a fluvial environment. A number of mechanisms are responsible for the erosion of rock. They include hydraulic scour or plucking (plucking of rock fragments by fluid shear stresses), abrasive scour (interaction between rock and moving sediment particles), dissolution, and cavitation. In addition, weathering (chemical or physical) contributes to the weakening of rock. Only the first two processes are reviewed here since solution is of no interest to this study and cavitation requires extremely high velocity which is probably relevant mainly on spillways and plunge pools.

It is theoretically advantageous to treat different mechanisms separately; but a practically it is difficult to distinguish the mechanisms in the field. Hydraulic scour can occur without the assistance of sediment particles but is influenced by the presence of sediments through particle-rock collision. Similarly, abrasive scour is strongly dependent on the hydraulic flow characteristics such as shear and turbulence. It is possible that one reach of the river is dominated by hydraulic scour while another by abrasive scour. Or, both mechanisms may operate to erode the rock for some rivers.

Clear water alone can cause bedrock scour by instantaneous or progressive failure of closed-end rock joints or by dynamic ejection of single rock blocks (Bollaert and Schleiss 2005). Hydraulic scour is used to refer to this mechanism in this study (plucking is another term used by some researchers). The hydraulic scour erosion rate is normally made a function of flow force; but the selection of the force variable is no easy task. In theory, the instantaneous pressure differentials and shear stresses applied to rocks are the cause of failure rather than a steady applied force (Annandale 2006). This means the instantaneous shear stress or turbulent fluctuations should be used. However, the use of instantaneous quantities is not practical for modeling purposes and average quantities have to be adopted. Therefore, equations relating hydraulic forces to bedrock scour are often empirical in nature.

Several empirical models have been used to estimate reach scale bedrock erosion. Typical methods to compute rock scour rate use the following general equation (Sklar and Deitrich, 2006):

$$E = C\psi^n \tag{1}$$

where E is erosion rate; C is empirical constant representing rock properties; ψ is a flow parameter, e.g. stream power (P) or shear stress (τ); and n is an empirical exponent. The coefficients C and n must be calibrated to each field site and C is a dimensional constant. For example, stream power is used by Seidl and Dietrich (1992), Anderson (1994), and Willett (1999); and average shear stress is used by Howard (1994) and Tucker and Slingerland (1996).

Models based on the excess shear stress are also proposed (e.g. Howard et al. 1994; Tucker and Slingerland, 1997) and it may be expressed as:

$$E = C(\tau - \tau_{cri})^n \tag{2}$$

where τ and τ_{cri} are bed shear stress and critical shear stress, respectively. These models take into account the fact that erosion occurs only after the shear stress exceeds a critical value. Whipple et al. (2000) provided some discussion with regard to the threshold behavior but limited data are available for the critical stress parameterization.

A less empirical methodology was proposed by Annandale (1995, 2006) who used an index method to measure the resistance of rock to motion under a range of hydraulic conditions. Details can be found in Annandale (2006) or Greimann and Vandeburg (2008). Wittler et al. (1998) compared the stream power method of Annandale (2006) with the shear stress based method commonly used in sediment transport analysis. It was shown that the critical stream power method of Annandale (1995, 2006) is closely related to the critical shear stress used for granular materials. Therefore, it should be possible to use the critical shear stress formulation for hydraulic scour instead of the critical stream power.

The presence of sediment particles moving over bedrock is another mechanism to cause erosion due to collisions of particles with exposed bedrock. This mechanism is referred to as abrasive scour in this report. Both bed load and suspended load may contribute to abrasive scour. Most existing rock erosion models empirically incorporate the effect of abrasion into the framework of hydraulic scour as reviewed by Sklar and Dietrich (2006). Extra terms due to effects of grain size, sediment supply, and/or bed cover may be added. Further details are contained in Sklar and Dietrich (2006). These models are very empirical in nature.

A physically based abrasive model due to saltating bed load was developed by Sklar and Dietrich (2004). The bedrock scour rate is expressed as a product of three terms: the average volume of rock detached per particle impact, the rate of particle impacts per unit area per unit time, and the fraction of exposed bedrock. The erosion rate may be expressed as:

$$E_a = \frac{Y}{k_v \sigma_T^2} \frac{w_s^{\,2} q_s}{L_s} F_e \tag{3}$$

where E_a is the abrasive erosion rate due to bed load; w_s is the impact velocity of sediment particles; L_s is the saltation length of sediment particles; q_s is the sediment supply per unit width; Y is the modulus of elasticity of rock; k_v is a rock erodibility parameter; σ_T is the tensile strength of rock; and F_e is the fraction of exposed bedrock. The bedrock parameters σ_T and Y can be measured using laboratory tests of rock cores. Sklar and Dietrich (2004) attempted to

measure the value of k_v directly from laboratory abrasion tests using various rock types. In field situations, it is likely that k_v will be a calibration parameter. Sklar and Dietrich (2004) also provided expressions for w_s and L_s based upon flow and sediment characteristics.

Whipple et al. (2000), however, argue that the bedload saltation may play only a secondary role in abrasive scour on massive, unjointed rocks, and its contribution is mostly due to the plucking (hydraulic) process. Instead it is proposed that abrasion by suspended sediments plays an important role for massive, unjointed rocks. The conclusion that bed load abrasion is less important in larger river systems is supported by a number of field observations (Whipple et al. 2000). Abrasive scour due to suspended sediments was studied by Anderson (1986) and the following erosion rate was proposed:

$$E_a = \frac{S_a \rho_s}{2\rho_r} C U^3 \tag{4}$$

where S_a is the susceptibility of the bedrock to abrasion; ρ_s is sediment density; ρ_r is rock density; C is volumetric suspended sediment concentration; and U is depth-averaged flow velocity.

Recently, a total load abrasive scour model was proposed by Lamb et al. (2008). The bed load abrasive scour model of Sklar and Dietrich (2004) was extended to total load by additionally considering the suspended particle impact. The total load rate equation is expressed as:

$$E_a = \frac{A_1 Y}{k_v \sigma_T^2} \frac{q_t w_s^{\ 3}}{(UH\chi + U_b H_b)} F_e \tag{5}$$

where A_1 is a coefficient representing the fraction of particles impacting the bed; Y is the modulus of elasticity of rock; k_v is a rock erodibility parameter; σ_T is the tensile strength of rock; w_s is the impact velocity of sediment particles; q_t is total sediment supply per unit width; U is depth-averaged flow velocity; U_b is depth-averaged bed load velocity; H is flow depth; H_b is the bed load thickness; χ is an integral relating the suspended flux to U and H; and F_e is the fraction of exposed bedrock. The computational procedure for the impact velocity is complicated. The total load model above is physically based and seems to possess several attractive features. However, we think the model, in its present form, is impractical to be incorporated into a 2D model.

Reviews of existing models have also been carried out by Tomkin et al. (2003) and Sklar and Dietrich (2006). Various methodologies are reviewed to compute rock scour and are classified based upon the mechanism of erosion and whether they include the hydraulic forces, sediment abrasion, and the effect of sediment protecting the rock from scour.

A Proposed Rock Erosion Model

We propose that the hydraulic scour and abrasive scour should be modeled separately, however a combined formula should be developed. Field reconnaissance is recommended to

determine whether the study site is hydraulic scour dominant, abrasive scour dominant, or if both play important roles.

It is proposed that a combined rock scour rate model takes the following form:

$$E = k_P U \left(\frac{\tau}{\tau_{cri}} - 1 \right)^n \left(1 - \frac{c}{c_{tr}} \right) + E_a \tag{6}$$

where E is total rock erosion rate; k_P is hydraulic erodibility; U is depth averaged flow velocity; τ is bed shear stress; τ_{cri} is critical shear stress for hydraulic scour; c and c_{tr} are rock cover thickness and transition thickness, respectively; n is an empirical exponent; and E_a is abrasive scour rate.

The abrasive scour is based on the model of Sklar and Dietrich (2004) which may be replaced by the total load based model similar to Lamb et al. (2008) in the future. In this study, the following model is used:

$$E_a = \frac{0.08 R_b g Y}{k_v \sigma_T^2} q_s \left(\frac{\tau}{\tau_c} - 1 \right)^{-0.5} \left[1 - \left(\frac{u_*}{w_f} \right)^2 \right]^{1.5} F_e \tag{7}$$

where $R_b = \rho_s / \rho - 1$ (ρ_s is sediment density and ρ is water density); g is gravity; k_v is a rock erodibility parameter; Y is the modulus of elasticity of rock; σ_T is the tensile strength of rock; q_s is sediment supply per unit width; w_f is sediment fall velocity; u_* is shear velocity ($\sqrt{\tau/\rho}$); and F_e is the fraction of exposed bedrock.

The first term on the right hand side of (6) represents the hydraulic scour rate and it is set to be a function of the stream power (τU). The above form has the advantage of being dimensionally consistent as opposed to the dimensional equations used in many existing models such as that of Tomkin et al. (2003). It is also consistent in form to the cohesive sediment transport relationships used in the mobile-bed models. The c / c_{tr} term represents the cover effect, and $c_{tr} = 0.1m$ is used as a "critical" thickness above which zero rock erosion is expected. Also, $n = 1$ is used in this study as existing data is insufficient to support the use of nonlinear relations. Therefore, two empirical parameters are needed for the hydraulic scour: k_P and τ_{cri}.

The second term on the right side of (6) is the abrasive model. There are three parameters for abrasive erosion: k_v, Y and σ_T. k_v is a dimensionless parameter representing rock erodibility. It may be estimated in the laboratory as shown by Sklar and Dietrich (2004) or it may have to be calibrated for field applications. Y and σ_T may be measured in the field. Note that the fraction of the exposed bed is represented by F_e in equation (7). It may be the same as the hydraulic scour, i.e., $F_e = 1 - c / c_{tr}$. In the original model, however, $F_e = 1 - q_s / q_t$ is used to represent the fraction of bedrock exposure with q_t the sediment transport capacity per unit width.

It is possible that both hydraulic scour and abrasive scour are important at a particular field site. Under such circumstances, a total of five parameters are needed.

Numerical Model Description

The proposed rock erosion model is incorporated into the existing SRH-2D version 3.0 model, which is a 2D depth-averaged hydraulic and sediment transport mobile bed model for river systems developed at the Bureau of Reclamation. The flow simulation is the same as SRH-2D version 2 (Lai 2008) while its sediment module is based on Greimann et al. (2008). The robustness, accuracy and verification of SRH-2D have been demonstrated and documented by many projects. The flow modeling capability is documented by Lai (2008). Sediment transport modeling details and applications may be found in a number of papers such as Greimann et al. (2008), Lai and Greimann (2007), Lai and Greimann (2008a,b), and a number of project reports (check the following Reclamation website: http://www.usbr.gov/pmts/sediment/).

Governing equations and numerical methods of SRH-2D are omitted; only the implementation of the rock erosion model is described here. The bed material beneath the bed surface is divided into a number of sub-layers in the original SRH-2D and they may be spatially distributed. At each spatial point, every sub-layer has its own thickness and material type represented by granular composition. A new sub-layer material type is added, designated as the "erodible rock", to apply the rock erosion model. If there are granular materials on top of the erodible rock, they are eroded first; if the granular material thickness on top of an erodible rock is reduced below a critical depth, rock erosion would be initiated. The implementation allows the erodible rock to be placed anywhere in the river and located at any depth blow a bed surface. Any number of erodible rock types may be used with each type characterized by its erosion parameters discussed in the above section, "A Proposed Rock Erosion Model".

All governing equations are solved with the finite volume method that guarantees the mass conservation locally and globally. An implicit time marching scheme is used with the arbitrarily shaped unstructured mesh methodology of Lai et al. (2003). A detailed presentation of the numerical method for the flow hydraulics may be found in Lai (2008).

Test and Application of the Rock Erosion Model

The rock erosion model is applied to the river reach downstream of the Chi-Chi Weir on the Choshui River in Taiwan where up to 10 meters of rock scour has been observed since the construction and operation of Chi-Chi Weir in 2001. The calibration study is carried out using survey data from July 2004 to January 2007. Four scenarios are modeled: No-Rock, Hydraulic-Scour, Abrasive-Scour, and Mixed-Scour. The no-rock scenario assumes that the riverbed consists of granular sediment materials only. Results from this scenario would shed light on the role the bedrock plays in erosion control of the channel. The hydraulic-scour scenario assumes that hydraulic scour is the dominant mechanism and abrasive scour is set to zero. The abrasive-scour scenario assumes that abrasive scour is dominant and hydraulic scour is set to zero. Finally, the mixed-scour scenario assumes that both hydraulic and abrasive scours are important.

Solution Domain, Mesh, and Topography: The solution domain and the 2D mesh are displayed in Figure 1. The upstream inlet boundary is located at the Chilu Bridge about 2.06 km upstream of the Chi-Chi Weir and the downstream exit boundary is located at the Mingchu Bridge about 6.7 km downstream of the Weir. The total length of simulated reach is about 8.76 km. The solution domain is wide enough laterally that the domain would fully contain the

highest flow simulated. A 2D mesh was generated which has a total of 10,392 mesh cells. A majority of the cells are quadrilaterals and triangles are used only for mesh zone transition.

Cross sectional survey data were collected in July 2004 and these data are used as the initial bed topography. Another cross sectional survey at the same locations was performed in January 2007 and the data are used for comparison with the model results.

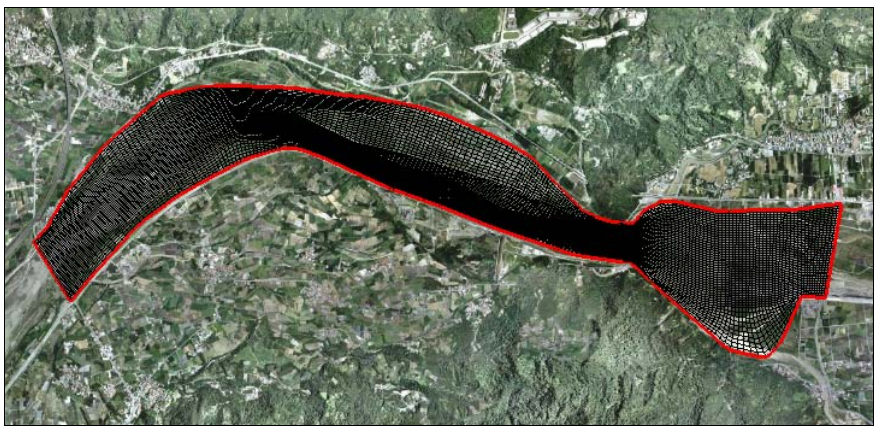

Figure 1. Solution domain and hybrid mesh used.

Representation of Flow Roughness and Bed Gradation: River bed properties, needed as model inputs, include Manning's roughness coefficient and bed sediment gradation. Both may be spatially distributed over the solution domain.

Flow resistance is calculated with the Manning's roughness equation in which the Manning's coefficient (n) is used as one of the model inputs. A constant coefficient of 0.04 is used based on the 2004 bed material analysis carried out by Taiwan engineers.

Bed gradation is spatially distributed according to survey data and a total of 10 zones are used (Figure 2). The first four zones are upstream of the Chi-Chi Weir and were based upon a gradation survey conducted in July 2005. The remaining six zones are downstream of the weir and were based upon a cross-sectional gradation survey conducted in 2004. The sediment size distributions for zones 1 to 8 excluding zone 4 are shown in Figure 3. Zone 4 has very fine materials with 99% of the sediments less than 0.074mm in diameter. Zone 10 represents the non-erodible bed where concrete is present immediately downstream of the weir. Zone 9 represents the erodible bedrock of interest in this study. In zone 9, erodible rock is assumed for all cases except for the no-rock scenario for which the bed material is assumed to be the same as zone 5.

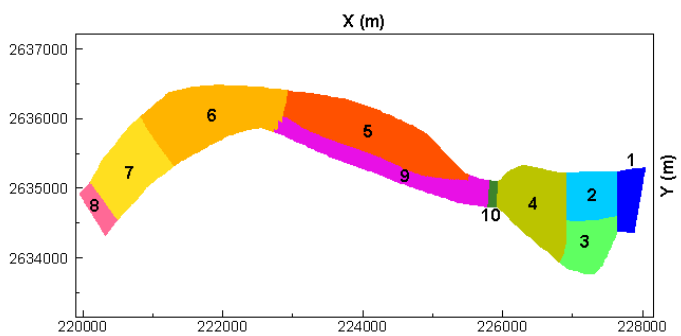

Figure 2. Bed gradation zones used by SRH-2D to bed material distribution

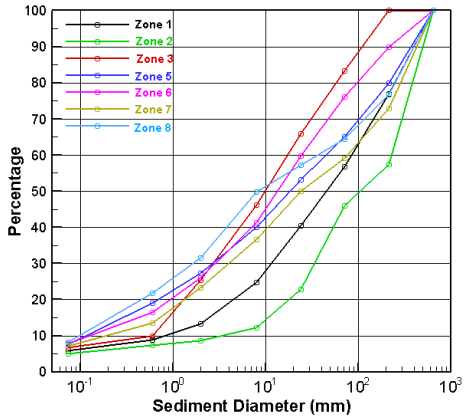

Figure 3. Cumulative sediment size distribution at different zones

Boundary Conditions and Other Sediment Parameters: At the upstream boundary, the flow discharge and sediment supply rate for each size class are needed. A time series flow hydrograph (Figure 4) is specified at the inlet boundary which represents the measured hourly flow data from August 1, 2004 to January 1, 2007. Only discharges above 600 cms are simulated as lower flows will not mobilize the bed sediments appreciably. The upstream sediment supply is set to be the sediment capacity rate.

At the downstream boundary, water surface elevation is specified. The measured rating curve is used to obtain the time variation of the water surface elevation (see Figure 4).

Eight sediment size classes (Table 1) are used to represent the sediments on the river bed and at the inlet. Each size class is transported and modeled individually.

Parker (1990) developed a bedload formula applicable to mixed gravel sediments and it is used to compute the capacity.

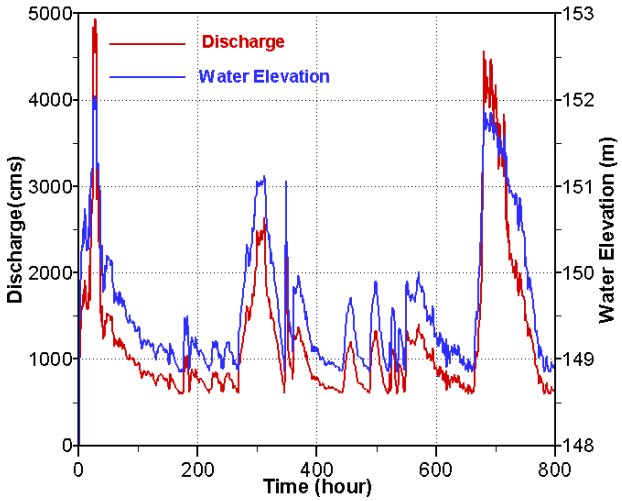

Figure 4. Flow hydrograph at the upstream boundary and water surface elevation at the downstream boundary.

Table 1. Size ranges of each sediment size class

Sediment Size Class	Size Range (mm)
1	0.001 to 0.074
2	0.074 to 0.6
3	0.6 to 2
4	2 to 8
5	8 to 24
6	24 to 72
7	72 to 216
8	216 to 648

Results and Discussion: The no-rock scenario is simulated first assuming that the riverbed in zone 9 consists of granular materials. This scenario, though imaginary, establishes a baseline to anticipate what would happen if no rock is present and helps define the extent to which bedrock controls channel erosion.

The predicted scour depth from July 2004 to January 2007 is shown in Figure 5 in terms of the net bed erosion depth (positive values are for erosion and negative values for deposition). The measured data are shown in Figure 9 where cross-sections (labeled as xs) are also shown for ease of discussion. The model predicts significant erosion for the first 500 meters downstream of the weir. In contrast, there is little erosion based on the measured data. The presence of rock in this short reach helps to stabilize the riverbed. The no-rock scenario modeling predicts erosion up to 4 meters between xs-116 and xs-115, deposition up to 4 meters at xs-114, and erosion between xs-113 and xs-111. The large deposition between xs-115 and xs-113 was not present in the measured data and must be due to the no-rock assumption. The river would reduce the riverbed slope significantly for the first 2.0 km downstream of the weir if there were no rock present. The rock in this reach maintains the bed slope in this reach and there is even an increase in slope due to erosion downstream of xs-116. Erosion pattern after xs-111 is predicted by assuming the bed is covered by granular sediments and the same bed gradations are assumed for all model scenarios. Therefore, results from the no-rock scenario are expected to be similar among all four scenarios simulated. It is seen that the predicted erosion pattern agrees qualitatively with the measured data but differs appreciably in details.

A rock erosion model is needed as demonstrated by the results of no-rock scenario. First, an attempt is made to use only the hydraulic scour model. The two model parameters within the hydraulic scour model are set as: $k_p = 2\times10^{-6}$ and $\tau_{cri} = 250Pa$. The simulated bed erosion pattern is shown in Figure 6. The model correctly predicts little erosion for the first 500 meters downstream of the weir. In comparison with the results of the no-rock scenario, the hydraulic scour model replicates this short reach well. Also, erosion of more than 7 meters is predicted by the hydraulic scour model between xs-116 and xs-114. This is in qualitative agreement with the measured data. However, small bed changes are predicted between xs-114 and xs-111 which is contrary to the data. This may indicate that hydraulic scour is a probable mechanism only for the reach of first 1.5 km downstream of the weir where the most significant erosion was recorded since the construction of the weir. The failure of the model to predict rock scour downstream of xs-114 may be attributed to two possibilities: the erosion mechanism is not due to hydraulic scour or the particular hydraulic model used is deficient. We conjecture that the hydraulic scour

is probably one of the causes for rock erosion at the site but the specific scour model needs to be improved.

Next, a simulation is carried out using only the abrasive-scour model. The model parameter for the erodibility is set as $k_v = 50.0$ while two parameters are $Y = 7.0MPa$ and $\sigma_T = 5.0e^4\ MPa$ based on field estimations. Simulated bed erosion pattern is shown in Figure 7. Similar to the hydraulic scour model, the abrasive model predicts correctly that there is little erosion for the first 500 meters downstream of the weir. The abrasive model predicts that erosion starts from xs-116 and persists downstream on the entire rock bed zone. The results are in agreement with the measured data. Differences between the prediction and measurement lie mainly in the lateral size of the incision. The model predicts rock incision with narrower width than the measured one. The results indicate that abrasive scour could potentially be an important mechanism for the entire reach. However, the quantitative difference in incision width points to a need for improvement. For example, the abrasive model of Sklar and Dietrich (2004) considers only the impact of bed load. It is possible that erosion due to suspended load should also be taken into consideration. It may also be possible that bank erosion is important.

Finally, a simulation is made for the mixed-scour scenario assuming both hydraulic scour and abrasive scours are important. The erosion model parameters are set as follows: $k_p = 1\times10^{-6}$, $\tau_{cri} = 225Pa$, $k_v = 75.0$, $Y = 7.0MPa$, and $\sigma_T = 5.0e4\,MPa$. The simulated bed erosion pattern is shown in Figure 8. As expected, results are a combination of the hydraulic scour and abrasive scour results discussed previously.

Concluding Remarks

A review was conducted for the rock erosion models and a specific rock erosion model is proposed and implemented into an existing 2D model: SRH-2D. The model is then applied to study the erosion downstream of the Chi-Chi Weir. The following conclusions may be drawn:

(1) Rock erosion has to be modeled in order to predict erosion characteristics downstream of the Chi-Chi Weir. If the riverbed is assumed to be covered with only granular sediments found nearby, the model is incapable of replicating the observed erosion pattern.

(2) The widely used stream power based hydraulic scour model predicts the erosion pattern reasonably well for only the first 1.5 km downstream of the weir. Negligible erosion is predicted for the remaining bedrock further downstream, which is contrary to the available data.

(3) The bed load based abrasive scour model of Sklar and Dietrich (2004) provides the best match in results with the measured data. It may suggest that abrasive scour is an important mechanism for the site. Quantitatively, the major difference between the prediction and measurement is that the predicted rock incision width is smaller than the actual. The discrepancy may be attributed to erosion model inaccuracy. It is possible that erosion due to suspended load should be considered or that bank erosion is important.

(4) It is unclear whether a mixed scour model is necessary for the study site. Practically, use of such models should be avoided unless there is clear field evidence supporting their use. More erosion parameters are needed for mixed scour models.

ABSTRACT

The reverse tainter valves in the culverts at John Day Lock have been failing structurally for the life of the project. Recently, district engineers have decided to redesign these tainter valves to reduce or eliminate cracking and other structural issues. In order to complete this redesign, three-dimensional (3D) simulations were conducted of the flows experienced through the culverts for several valve openings seen during a lock operation. These 3D simulations were performed with the 3D Navier-Stokes module of the numerical code Adaptive Hydraulics (ADH) (http://adh.usace.army.mil/) developed by the U.S. Army Engineer Research and Development Center, Coastal and Hydraulics Laboratory (CHL). This code models the complex 3D flows around hydraulic structures using adaptive meshing techniques on unstructured meshes. The flow variables, pressure and velocity, calculated at each node lying on the surface of the valve were exported for use as boundary conditions for a 3D structural model of the tainter valve.

INTRODUCTION

The John Day Lock is located on the Columbia River. The lock has a chamber that is 26.2 m wide by 205.7 m long and is classified as a very high-lift lock according to U.S. Army Corps of Engineers criteria (EM 1110-2-1604). The John Day Lock has the highest design lift of any lock in North America with a 33.5-m lift at normal pool. The filling and emptying culverts form what is commonly referred to as a split lateral system. Double skin-plated reverse tainter valves control the flow through the culverts. Each 3.7-m-wide by 6.1-m-high wall culvert supplies water to a set of ten manifolds aligned laterally to the lock centerline. The left culvert laterals are located on the upper one-third end of the lock chamber and the right culvert laterals are located in the lower one-third end of the chamber.

The John Day Lock filling system has presented problems since beginning operations in 1968. Prototype tests were conducted in 1973 (Neilson and Pickett, 1986). The prototype investigation was initiated because severe shock waves, vibration, and noise in the lock filling system had been experienced during valve opening. Damage to the filling valve was found in May 1971 and was believed to have resulted from these conditions. The damage consisted of bent skin plates and broken welds in the radial arms and sheared bolts across the top of the valve skin plate. Chanda and Perkins (1974) reported that excessive structural vibration caused failure of monolith joint water stops, damage to valve trunnion arms, and movement of a monolith. Neilson and Pickett (1986) note that the shock waves are not unique at John Day since similar problems have also occurred at the McNary, Ice Harbor, and Lower Monumental Locks. Information obtained at John Day was believed to be applicable to Ice Harbor and Lower Monumental since these locks have nearly identical filling systems and similar troubles during valve opening.

Lock operation produces noise and vibrations during filling. The pounding noise can be reduced by opening the filling valves in stages, so the valve operations have been changed from the design schedule to being operated in a stepped fashion. The two-valve filling operation was recommended by Neilson and Pickett (1986), wherein the valves are operated to one-third open in 40 sec, holding at one-third open for a 300-sec delay, and to fully-open in 80 sec.

Recently, a field inspection report was prepared by North (2006). He reiterated that operation and maintenance of the lock culvert valves have been hindered with problems essentially since completion of construction. Cracks have formed in the steel wrapper plate of the valve members and have been repaired numerous times. A recommendation (North 2006) has been made to replace the tainter valves.

It is generally agreed that before the tainter valves are replaced, an effort should be made to determine the cause of these cracks. CHL performed 3D flow analyses to determine how the structural members interact with the flow. The flow solutions include the pressures on the valve surface and culvert velocities during a lock operation. The computed pressures were to be used as boundary conditions for structural analyses of the current and any proposed valve designs.

NUMERICAL MODEL DESCRIPTION

The numerical flow solver used is the Navier-Stokes module of ADH. This code uses the Reynolds-Averaged Navier-Stokes (RANS) equations, which are the conservation of mass and the conservation of momentum, to calculate the pressure and velocity components throughout the flow domain. Mathematically, these are:

$$\nabla \cdot \boldsymbol{V} = 0$$

and

$$\left(\frac{\partial \boldsymbol{V}}{\partial t}+\boldsymbol{V}\cdot\nabla\boldsymbol{V}\right)-\boldsymbol{g}-\frac{1}{\rho}\nabla\cdot\left(\sigma-\sigma_R\right)=0\,.$$

The RANS equations are written in terms of the mean velocity, $\boldsymbol{V}(\boldsymbol{x}, t)$, and pressure, $p(\boldsymbol{x}, t)$, to reduce the modeling of turbulence to a set of quasi-steady-state equations. The Reynolds stress is used to represent the effect of turbulence on the mean flow. Following the suggestion of Boussinesq, the Reynolds stress tensor is expressed in terms of the strain rate as

$$\sigma_R=-\rho\nu_t\left(\nabla\boldsymbol{V}+\nabla\boldsymbol{V}^T\right).$$

Sufficiently small eddy viscosity has been found to adequately capture macroscopic flow features such as eddies.

GEOMETRY

The flow domain with the major geometric features is shown in Figure 1. The volume consists of a section of culvert beginning immediately downstream of the lock intake and extending thirty hydraulic diameters (137 m total) downstream of an 18.3-m roof transition. Portions of the filling system that do not align with the culvert, including the laterals that would supply flow to the lock chamber, were excluded. At the inflow boundary the culvert is 3.7 x 9.1 m and curves downward 17.1 m over 36.6 m. The culvert is 3.7 m wide and 4.3 m tall at the reverse tainter valve. The tainter valve has a nominal radius of 5.8 m, and the valve well is 3.7 x 6.2 m. The water surface in the valve well is a free surface. Two 4.3 x 0.7-m bulkhead slots, one upstream and one downstream of the valve are included in the model. The downstream bulkhead is capped, while the upstream bulkhead water surface is a free surface.

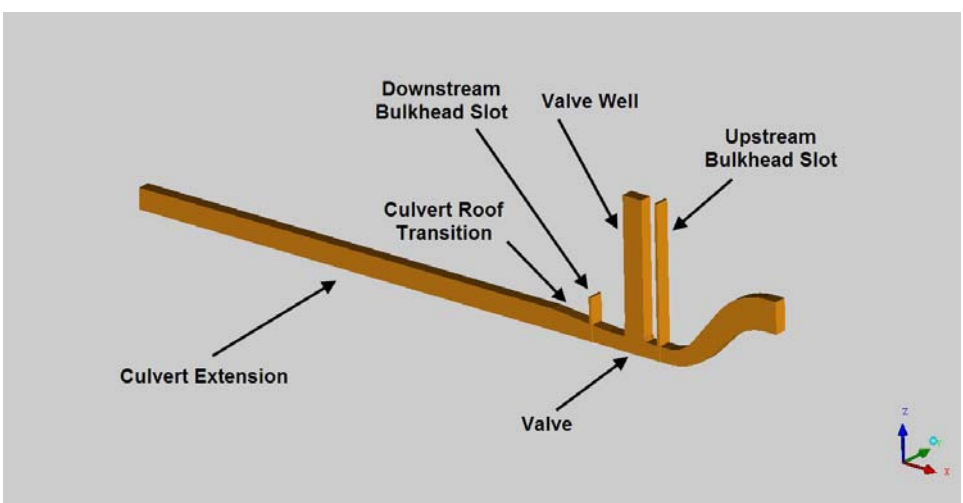

Figure 1. Flow domain.

Six valve openings were chosen for the analyses to represent the valve motion used during a lock-filling operation. Of these – 10, 35, 55, 65, 75, and 90% openings – certain valve openings represent a specific potential problem during a tainter valve operation. The 10% valve opening represents a time where the jet velocity is large and a potential for vibration exists. The 35% valve opening is the location in which the valve is held during normal operating conditions. This is the holding position on the stepped-valve operation schedule that was developed during the field study and adapted as operating procedure. The 55% opening represents the estimated valve opening for the maximum hoist load. Finally, the 90% valve opening represents the estimated opening for maximum variation of the hoist loads.

BOUNDARY CONDITIONS AND MESH DETAILS

The boundary conditions are shown in Figure 2. The model consisted of two flux boundaries – one inflow and one outflow. Hydrostatic pressures corresponding to the desired upper pool (81.7 m) and lower pool (47.2 m) elevations were applied to the inflow and outflow boundaries, respectively. The 34.4-m head differential applied at these boundaries determined the flow through the model. Free-surface boundary conditions were applied to the water surfaces in the upstream bulkhead slot and valve well, so the nodes on these surfaces could move vertically to the elevation corresponding to zero pressure. The water surface of the downstream bulkhead slot was treated as frictionless and stationary. All other model boundaries were specified as no flux boundaries with a uniform friction coefficient representing the surface roughness.

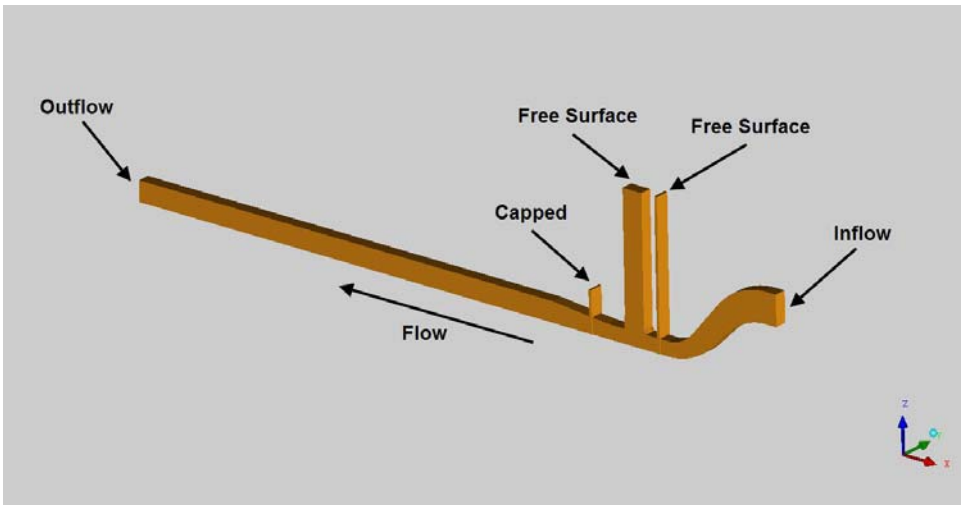

Figure 2. Boundary conditions.

Three-dimensional meshes of the flow volume for each valve opening were constructed from a CAD model using tetrahedral elements. Mesh elements have sides ranging from 13 mm (on the valve surface) to about 0.76 m (far from the valve). The smallest elements were necessary to capture the intricate valve details such as the valve lip, a dominant valve feature in determining flow separation downstream of the valve. In each mesh the valve surface is defined by about 20,000 nodes. Each mesh has between 143,000 and 220,000 nodes and between 706,000 and 1.2 million tetrahedral elements.

RESULTS

Steady-state flow solutions were calculated for each valve position. Table 1 summarizes the flow details from each flow solution. The discharges were calculated by integrating the nodal velocity solutions at the outflow boundary over the entire culvert cross-section. The discharge increases as the valve opening increases because the driving pressures, the hydrostatic pressures on the inflow and outflow boundaries, were constant for each valve position while the flow area underneath the valve opening was increased. The average velocity head of the flow underneath the valve increases as the valve opening is lowered causing the pressure head in the valve well to decrease. This lowering of the average pressure head at the valve well causes the valve well water surface to decrease as the valve is lowered. The maximum velocities occur immediately downstream of the valve lip, with the minimum velocities slightly further downstream.

Table 1. Discharge and water surface solutions for each valve position.

Valve Opening	Discharge (m^3/s)	Valve well WSE (m)	Upstream Bulkhead WSE (m)	Maximum velocity (m/s)
10%	33.4	81.2	81.4	26.2
35%	112.5	78.5	78.8	29.0
55%	200.7	72.4	73.0	30.5
65%	248.2	67.5	68.3	31.1
75%	302.1	61.0	62.0	30.5
90%	387.1	47.4	48.1	29.3

Although the culvert upstream of the valve is short the approach flow to the valve fairly uniform flow. The *x*-component of the flow velocity near the valve is shown in Figure 3. The velocities range from 30 m/s (directed downstream) at the invert to 10 m/s (directed upstream) at the culvert roof. The flow velocity is nearly zero throughout the valve well and bulkheads except for an eddy that forms slightly above the valve.

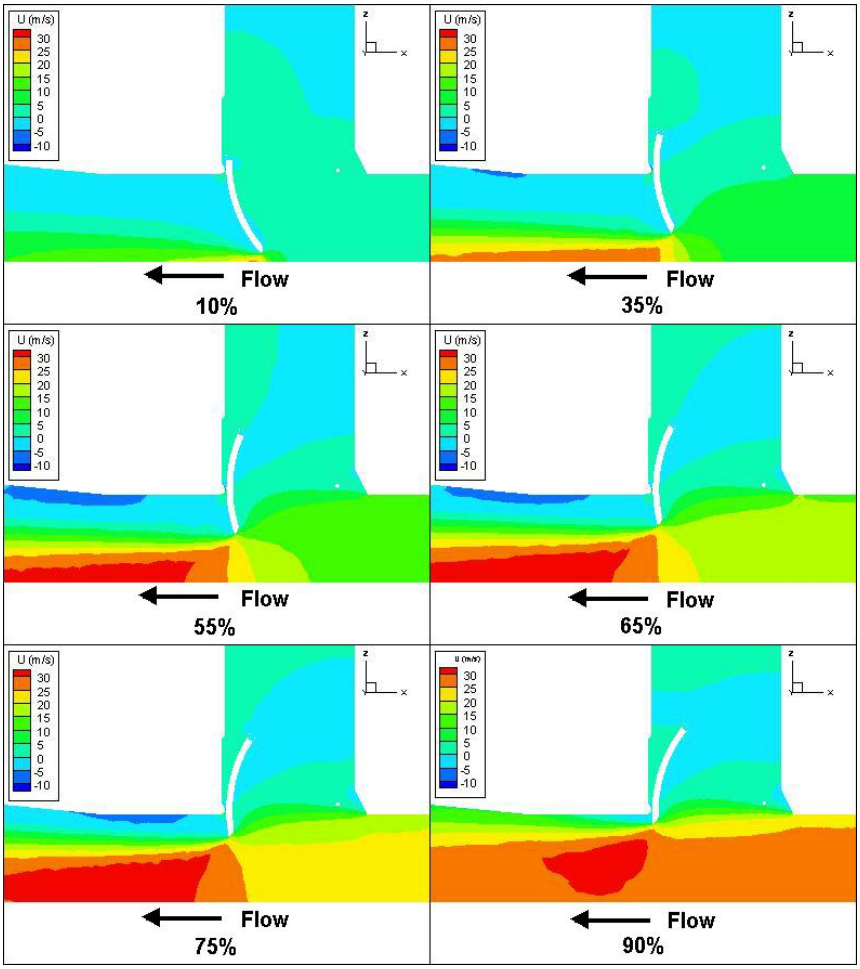

Figure 3. Velocity distribution near the valve.

Each valve opening produces eddies downstream of the valve. These eddies are shown in Figure 4. The largest eddy, caused by the 55% valve opening extends about 70 m downstream of the valve. The smallest eddy, which only extends about 1 m downstream of the valve, is created by the 90% valve opening. Such long eddies indicate that the flow, which separates at the valve lip, does not reattach until well downstream of the culvert roof expansion. Also, the approach flow for the laterals connecting the culvert to the lock chamber is not uniform when these large eddies are present. The only likely exceptions are the flows associated with the 10% and 90% valve openings.

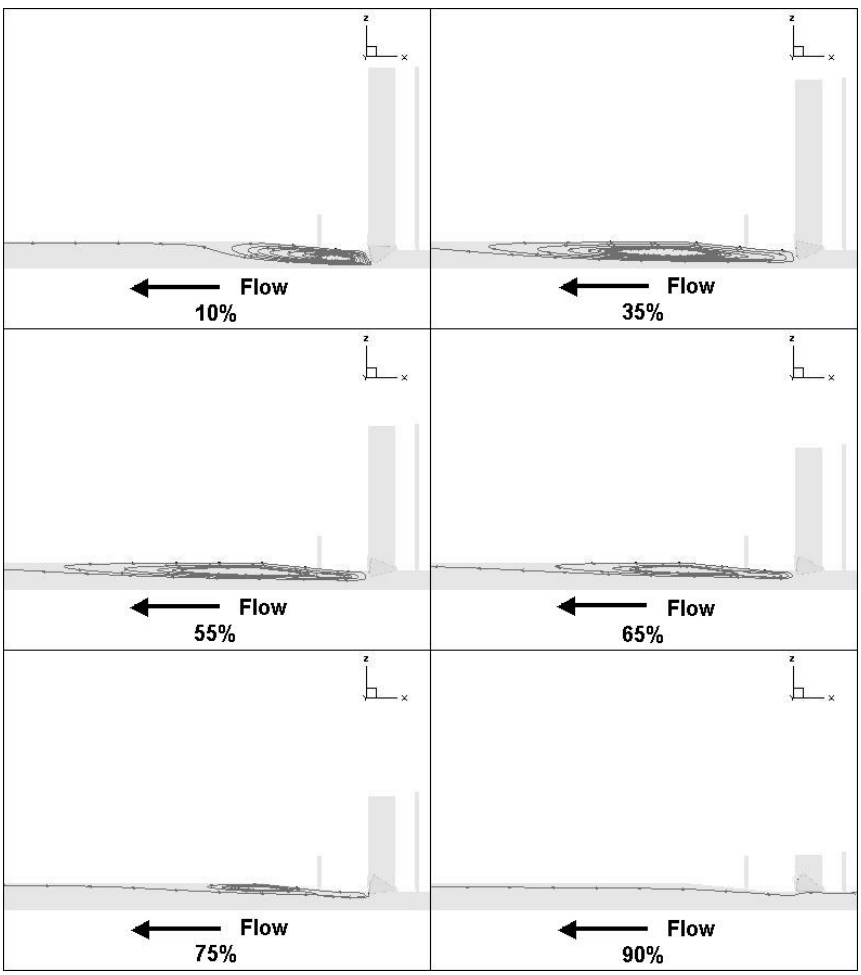

Figure 4. Eddies formed downstream of the valve.

The pressure distributions on the valve surface are shown in Figure 5. The pressures are highest at locations where the velocity near the valve are highest, particularly near the valve seal. The pressure solution was used to determine the pressure boundary conditions for a structural analysis of the entire valve geometry.

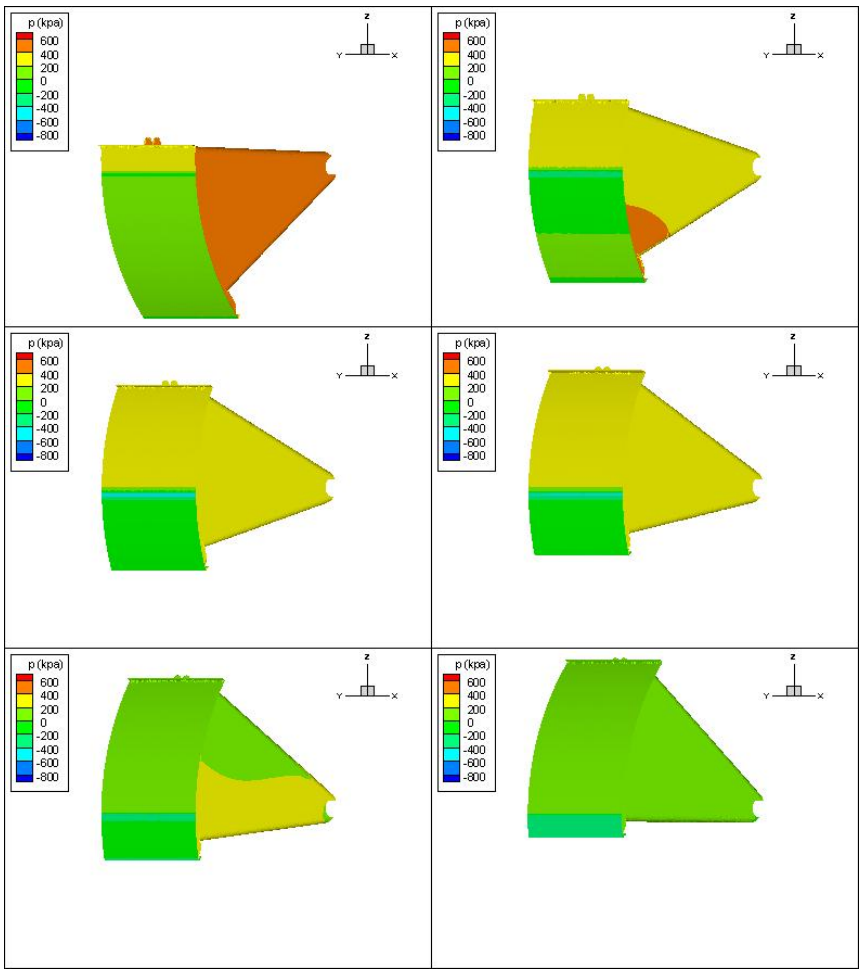

Figure 5. Pressure distribution on the valve surface.

Two different quantities, the discharge coefficient and the valve loss coefficient, were used to validate the flow solutions. Mathematically, these coefficients are

$$C_d = \frac{Q}{bW\sqrt{2gH_L}}$$

and

$$k_v = \frac{H_L}{\frac{v^2}{2g}}.$$

The discharge coefficients and valve loss coefficients are listed in Table 2. These loss coefficients compare well with the general research findings of Pickering (1981).

Table 2. Valve coefficients.

Valve Opening	Discharge coefficient (C_d)	Valve loss coefficient (k_v)
10%	0.83	146.62
35%	0.80	12.30
55%	0.98	3.45
65%	1.08	2.02
75%	1.24	1.16
90%	1.09	1.04

CONCLUSIONS

Pressure and velocity distributions in complex flow regimes, such as in navigation lock culverts, can be accurately calculated using the Navier-Stokes module of ADH. The eddies that form downstream of the valve may disrupt the distribution of flow in the laterals of the real system. The computational method used in this study is useful in situations where time and cost prohibit use of a physical model. The solutions produced in this study were used by Portland District to create loads used to evaluate the current valve structure (particularly the internal structure) and potentially modify the valve design.

The total force acting on the valve can be calculated from the pressure solution by integrating the pressures on the valve surface. The total hydrodynamic force acting on the valve can be couple with the valve weight to determine the uplift force, which can be used in selecting the mechanical components that control the valve movement during lock operation.

ACKNOWLDEGEMENT

The computations described and the results presented were obtained from research sponsored by the U.S. Army Corps of Engineers District, Portland and the Navigation Systems Research Program under the guidance of James E. Clausner, Program Manager. Permission was granted by the Chief of Engineers to publish this information.

LIST OF VARIABLES

$\boldsymbol{x}$ = spatial coordinate, with x and y lying in the horizontal plane and z being in the vertical direction
$\boldsymbol{g}$ = gravitational acceleration
t = time
ρ = fluid density
σ = $-p\mathbf{I} + 2\rho\nu_t\mathbf{s}(\mathbf{V})$
ν = fluid kinematic viscosity
s = $\frac{1}{2}\left(\nabla \boldsymbol{V} + \nabla \boldsymbol{V}^T\right)$
ν_t = fluid eddy viscosity
Q = discharge
b = valve opening height
W = culvert width
H_L = total head loss across the valve (sum of velocity head, pressure head, and elevation head)
v = average flow velocity in the culvert near the valve (3.7 x 4.3 m culvert)

A Three-Dimensional Numerical Model for Flow in a Lock Filling System

Richard L. Stockstill, F.ASCE[1] and R. Charlie Berger, F.ASCE[1]

[1]Research Hydraulic Engineer, U.S. Army Engineer Research and Development Center, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199.

ABSTRACT

The hydraulic performance of a navigation lock is difficult to evaluate because the unsteady flow is characterized by large variations in pressure and velocity. The lock system contains the interactions of free-surface and pressurized conduit flow. Currently, the filling and emptying system design must be carefully evaluated in a physical model which generally is expensive in terms of both time and money. A numerical model capable of simulating the flow in a navigation lock can provide an economical tool for detailed evaluation of lock systems and components. A flow model of a lock filling and emptying system must be capable of simulating the large- and small-scale flow features found in internal (conduit) flow and free-surface flow within the lock approach and chamber.

This paper describes the development of a complete three-dimensional (3-D) model of a sidewall port lock filling system. The Reynolds Averaged Navier-Stokes equations are used to describe the 3-D flow. The equations are discretized using the Galerkin Least-Squares finite element algorithm on tetrahedral elements with sizes varying over several orders of magnitude. The water-surface location is determined using a moving mesh method. The code is parallelized using Message Passing Interface (MPI) and is capable of adapting the mesh during flow calculations based on error estimations.

The project demonstrates model construction of a lock filling and emptying system that has complicated geometric features including culvert transitions and multi-ported manifolds. Boundary conditions are explained and the applicability of different error estimators is investigated. Computational and hydraulic engineering issues arising from the simulation of a lock filling operation are discussed.

INTRODUCTION

Whether it is new lock construction, rehabilitation of an existing lock, or operational changes to meet modified project objectives, innovative ideas regarding the filling and emptying of locks are being proposed. The problem is that often these ideas fall outside established design guidance. Perhaps some of these ideas, while economically feasible, may not provide the service required for safe navigation through the lock. Currently, the design concept must be carefully evaluated in a physical model, which generally is expensive in terms of both time and money.

A flow solver is being developed to provide an economical means of evaluating the hydraulic performance of a lock culvert system. The Reynolds Averaged Navier-Stokes equations are used to describe the 3-D flow. The equations

are solved using the 3-D Navier-Stokes component of the Adaptive Hydraulics (ADH) (http://adh.usace.army.mil/) code. The equations are discretized using the Galerkin Least-Squares finite element algorithm (Behr and Tezduyar 1994) on tetrahedral elements with sizes often varying over several orders of magnitude. The water-surface location is determined using a moving mesh method that employs space-time finite elements in a manner similar to that presented by Behr (2001). The code is parallelized using MPI and ParMETIS provides efficient mesh portioning. The ADH code is capable of adapting the mesh during flow calculations based on residuals. This automatic mesh refinement ensures suitable resolution in a computationally efficient manner.

NUMERICAL EXAMPLE

An example is provided with simulation of a navigation lock filling operation. The project is Webbers Falls Lock, on the McClellan-Kerr Arkansas River Navigation System about 5 miles (8 km) northwest of Webbers Falls, OK. A typical lock chamber on the Arkansas River is nominally 110 ft (33.5 m) wide by 600 ft (183 m) long. The filling and emptying system is a sidewall port design. A model of the Webbers Falls Lock, which has a 29-ft (8.8-m) lift at normal pools, is shown in Figure 1. It reproduces approximately 500 ft (150 m) of the upstream approach, twin sidewall intake manifolds, the lock chamber, valve wells, sidewall ports and culverts. The culvert system consists of 8-port 7.5-ft (2.29-m) wide by 10-ft (3.05-m) tall intake manifolds on either lock wall from which the flow transitions to 12-ft (3.66 m) by 12-ft (3.66 m) culverts in each wall. Flow is introduced into the lock chamber by 14 ports in each sidewall filling and emptying manifold. Each port is 3.5 ft (1.07 m) tall and has a throat width of 2.54 ft (0.774 m).

Computational Mesh. The initial finite element mesh has 229,090 nodes and 1,126,845 tetrahedral elements. The mesh resolution is illustrated by the surface mesh shown in Figure 2. Details of the mesh resolution at the intakes are shown in Figure 3. A representative sample of the volume mesh is provided in Figure 4, wherein tetrahedral elements are shown on a slice normal to the lock center line from the right wall culvert through a filling and emptying port and into the lock chamber. Figure 4 illustrates the variation in mesh resolution required to describe the geometry. Flow variations are resolved during flow simulations using mesh adaption. The mesh adaption consists of refinement and coarsening. The mesh is not allowed to become coarser than the initial mesh. Therefore, the minimum number of nodes and elements that occur during a simulation are those describing the initial mesh.

Initial and Boundary Conditions. The initial conditions for simulation of a lock filling operation were set with the lock empty and the chamber water surface was set at the lower pool elevation. Zero velocity and hydrostatic pressure were specified at each node. Boundary conditions applied at the inflow consisted of hydrostatic pressure (Dirichlet) and time-varying flux (via natural boundary condition) reproducing a hydrograph. The hydrograph varied linearly increasing from no flow

at the initial time up to the peak discharge of 5,088 cfs (144 cms) at 4 min and then decreasing to zero resulting in a filling time of 10 min.

A no flux boundary condition was applied to all solid boundaries. The free surface within the lock chamber was set as moving boundary while other surface nodes (culvert, intakes, etc.) were fixed boundaries. The nodes within the chamber volume were allowed to move in the vertical direction. Interior nodes moved as a function of surface node displacements. For this example the nodes on a horizontal plane in the lock chamber 6.5 ft (1.98 m) above the floor were fixed (no displacement) thus preserving the complicated geometry of the manifolds.

Conditions at the moving boundary representing the lock chamber water surface were specified as a constant pressure of zero on the nodes and stress-free conditions were enforced on the element faces.

Flow Solutions. The ten minutes of filling operation were simulated using a 5-sec time step. Flow variations within the chamber during filling are shown on Figures 5-7. These pictures show velocity contours at particular times during the simulation. The lock chamber water surface rises from the lower pool (initial conditions) to the upper pool as the lock fills. The jets issuing from the manifolds 1 min after filling started are shown in Figure 8. These velocity contours provide an insightful view of the flow distribution and jet interaction in the culvert manifold and chamber.

Mesh Adaption. Automatic mesh adaption allows the modeler to just focus attention on capturing geometric features when generating a mesh. This is particularly important in modeling hydraulic structures having complicated shapes such as lock filling systems. Mesh refinement required in regions due to flow conditions can be handled with mesh adaption during simulation runs. Adaption is triggered by a residual computed on an elemental basis. Two methods were used to calculate the residual. The first choice is essentially a check on the convergence of continuity. It is the norm of the divergence of the velocity evaluated over an element as shown in Equation 1.

$$\left(\int_{a_e} \left(\frac{\partial u_i}{\partial x_i} \right)^2 da_e \right)^{1/2} A_e \tag{1}$$

Here u_i is the discrete solution of velocity and A_e is the elemental surface area. Tests were conducted to evaluate the appropriateness of the "continuity" residual to indicate regions within the lock model that needed refinement. Residuals were calculated for each time step during a lock filling simulation with no mesh adaption. Values ranged from 0 to 0.00544 cfs over all the time steps. Most of the residual was found near the inflow boundary and in the center of the lock chamber on the chamber floor. Contours of the continuity residual within the sidewall manifolds and the lock chamber at 1 min into the filling operation are shown in the picture on the left of Figure 9. The region near the inflow boundary is where the original mesh is the coarsest. However, one would expect the solutions to be the smoothest in this area and so a coarse mesh might provide adequate resolution.

Another residual indicator was also evaluated. This indicator is related to velocity gradients and was termed the "gradient" indicator. This method of computing error estimation follows that developed by Zienkiewicz and Zhu (1987), which is often referred to as the Z^2 (or Z-Z) method. This method evaluates differences in velocity gradients over the element

$$\left(\int_{v_e} \left(\sigma_{ij}{}^2 \right) dv_e \right)^{1/2} V_e \tag{2}$$

Here σ_{ij} can be thought of as a term of the rate-of-strain tensor

$$\sigma_{ij} = \tfrac{1}{2} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right)^* \tag{3}$$

and V_e is the elemental volume. Again, the velocities are the discrete values. Each tensor term is actually the difference in the gradient obtained from an $L2$ projection of the velocity and that represented with linear basis function, ϕ_i.

$$\left(\frac{\partial u_i}{\partial x_j} \right)^* = \left(\frac{\partial u_i}{\partial x_j} \right)_{L2} - \left(u_i \frac{\partial \phi_i}{\partial x_j} \right) \tag{4}$$

Once more residual values were computed for each time step without mesh adaption. Values ranged from 0 to 0.19986 sec^{-1} over all the time steps. Contours of the residual calculated in this manner at 1 min into the filling operation, are shown in the picture on the right of Figure 9. The residual was found concentrated along the chamber center much like the continuity method found. However, there were regions within the culverts that had measurable values of gradient residual. Closer observation of the residual distribution found that the residual was large in the area of conduit bends (see Figure 10), where the solution is changing the most rapidly (i.e. large gradients).

Both methods may prove to be valuable for automatic mesh refinement. The continuity residual is more useful in regions where the flow is changing directions because the gradient residual will always be large in these areas. However, in an area such as the inflow boundary where the solution is not of interest was purposely made coarse, the gradient method would recognize that the solution there is smooth.

Based on the results shown in Figure 9 and Figure 10, choices of adaption residual triggers were selected. The models were run again with these residual triggers which are listed in

Table **1**. Each simulation employed 4 layers of refinement, two-level Additive Schwarz preconditioning with 4 blocks (see http://adh.usace.army.mil/ for explanation), and were executed using 64 processors on a Cray XT3. The maximum

number of nodes, which occurred near the time of peak discharge, indicates the amount of refinement that was performed by ADH during the lock filling cycles.

Table 1. Mesh adaption results during lock filling. Coarse (initial) mesh had 229,090 nodes and 1,126,845 tetrahedral elements.

Computational Factor	Residual method	
	Continuity	Velocity Gradient
Residual tolerance	0.001 cfs	0.030 sec^{-1}
Maximum number of nodes (rounded to nearest hundred) over all time steps, 4 levels of adaption	258,000	273,500

FUTURE WORK

Additional testing will determine the accuracy of simulating lock culvert flow (pressures, velocity profile, etc.) and lock chamber flow conditions (jet expansion, movement of free surface, etc.). Experiments will be conducted with the different methods of error estimation to determine efficient ways of acquiring accurate solutions with mesh adaption. A means of including the effects of flow control devices such as culvert valves will be added. Representation of moving mechanical equipment such as valves and gates must be added to the code before a full lock model study can be completed. Finally, the capability of modeling a vessel moored in the chamber during locking operations will be developed. A modeling system that accounts for a barge/ship in the lock chamber and that can calculate hawser forces during locking operations will be constructed.

ACKNOWLEDGEMENT

The computations described and the results presented were obtained from research sponsored by the US Army Corps of Engineers Navigation Systems Research Program under the guidance of James E. Clausner, Program Manager. Permission was granted by the Chief of Engineers to publish this information.

Abstract

Unsteady free-surface flow in open channels with or without in-channel structures are very complex. It is a difficult and challenging subject for civil engineering students to fully understand and comprehend. In this study three-dimensional numerical simulations were performed for several case studies of open channel flows and used to demonstrate several aspects of educational challenges of computational hydraulics. FLOW-3D, developed by the Flow Science, Inc., a three-dimensional computational fluid dynamics (CFD) software was utilized as "Virtual Lab" to study these complex flow phenomena. FLOW-3D utilizes a true volume of fluid (TruVOF) method to compute free surface motion and the fractional area/volume obstacle representation (FAVOR) technique to model complex geometric regions. In this study, flow simulations were presented on three case studies in various channel geometry and channel boundary conditions, and the cases include: the flow simulations of flow characteristics in the experimental channels having weirs with different heights in the middle of simulation domain; the flow simulations under complex channel bottom geometry from supercritical flow to subcritical flow with hydraulic jump due to tailwater effects in a laboratory channel; and the flow simulations of flow characteristics in a long river reach with a broad-crested weir located at the middle of the reach. The simulations demonstrate to use basic hydraulic principles to set appropriate boundary conditions, and conduct model comparison and calibration against results from theoretical equations, other numerical models and laboratory measurements. The detailed analyses revealed flow features of the unsteady free-surface flow in open channels under various boundary conditions. The impacts on water surface profile and flow velocities due to in-channel hydraulic structures were discussed. The study demonstrates challenges of computational hydraulics in how students and researchers critically analyze three-dimensional simulation results using basic one- and two-dimensional hydraulic theories and principles.

Introduction

Flow simulation is a common educational and research topic in broad fields such as fluid mechanics, aerodynamics, environmental and civil engineering and so on. Computational Fluid Dynamics (CFD) is a method of simulating a flow process in which standard flow equations such as the Navier-Stokes and continuity equations are discretized and solved for each computational cell in a simulation domain. Using a CFD code is in many ways similar to setting up a laboratory experiment that requires accurate representation of prototype and environment conditions. It is such a currently majority in flow simulation study not only because it is easy in modeling set up and making any change for the model but also for its efforts and money saving. CFD is taught through university graduate curriculum in civil/mechanical/aerospace departments

and through training workshops of CFD software development companies. Three dimensional flow simulations using CFD, especially for free surface flow, are challenge tasks to students and professional practitioners. In this study, we use a three-dimensional CFD software FLOW-3D developed by the Flow Science Inc. to demonstrate some of these challenges.

FLOW-3D solves the following continuity and momentum (Navier-Stokes) equations for the velocity components (*u, v, w*) and pressure as function of time (*t*) in the three dimensional Cartesian (*x, y, z*) or cylindrical (*r,* θ, *z*) coordinate system.

$$V_F \frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x}(\rho u A_x) + R\frac{\partial}{\partial y}(\rho v A_y) + \frac{\partial}{\partial z}(\rho w A_z) + \xi \frac{\rho u A_x}{x} = RDIF + RSOR \qquad (1)$$

$$\frac{\partial u}{\partial t} + \frac{1}{V_F}\left\{uA_x\frac{\partial u}{\partial x} + vA_y R\frac{\partial u}{\partial y} + wA_z\frac{\partial u}{\partial z}\right\} - \xi\frac{A_y v^2}{xV_F} = -\frac{1}{\rho}\frac{\partial p}{\partial x} + G_x + f_x - b_x - \frac{RSOR}{\rho V_F}u$$

$$\frac{\partial v}{\partial t} + \frac{1}{V_F}\left\{uA_x\frac{\partial v}{\partial x} + vA_y R\frac{\partial v}{\partial y} + wA_z\frac{\partial v}{\partial z}\right\} + \xi\frac{A_y uv}{xV_F} = -\frac{1}{\rho}\left(R\frac{\partial p}{\partial y}\right) + G_y + f_y - b_y - \frac{RSOR}{\rho V_F}v$$

$$\frac{\partial w}{\partial t} + \frac{1}{V_F}\left\{uA_x\frac{\partial w}{\partial x} + vA_y R\frac{\partial w}{\partial y} + wA_z\frac{\partial w}{\partial z}\right\} = -\frac{1}{\rho}\frac{\partial p}{\partial z} + G_z + f_z - b_z - \frac{RSOR}{\rho V_F}w \qquad (2)$$

where V_F is the fractional volume open to flow, ρ is the fluid density, *RDIF* is a turbulent diffusion term, and *RSOR* is a mass source term, A_x, A_y, and A_z are the fractional areas open to flow in the *x, y,* and *z* directions, respectively. The coefficient *R* depends on the choice of coordinate system. In these equations, (G_x, G_y, G_z) are body accelerations, (f_x, f_y, f_z) are viscous accelerations, (b_x, b_y, b_z) are flow losses in porous media or across porous baffle plates, and the final terms account for the injection of mass at zero velocity. FLOW-3D can be utilized as "Virtual Lab" to study complex flow problems such as free surface flows. FLOW-3D utilizes a true volume of fluid method (TruVOF) (Hirt and Nichols 1981) to compute free surface motion and the fractional area/volume obstacle representation (FAVOR) technique to model complex geometric regions (Flow Science Inc. 2005). FLOW-3D has been utilized in various civil engineering projects to investigate flow properties (Fang et al. 2007), such as spillway behavior (pressure distributions) (Savage and Johnson 2001), and high-resolution numerical simulation of flow through a highly sinuous river reach (Rodriguez et al. 2004), etc.

Simulations for 2-meter Laboratory Channel

In 2004, Faure, Buil, and Gay published a paper in the Journal of Hydraulic Research, and they used a commercial CFD package CFX (version 4) (CFX Inc. 1997) to develop a three-dimensional model for hydrodynamic and pollutant dispersion simulations for turbulent free-surface flow in open channels. Flow simulations were made with various customizations on how to track free surface and setting appropriate boundary conditions. Here we use FLOW-3D to develop numerical model for Faure's 2-meter laboratory channel (Faure et al. 2004) as a case study demonstrating our point of view. The channel is 2.2 m long (x direction), 0.25 m wide (y direction), 0.35m deep (z direction), and 0.7% slope along x direction (Canal 1 in Faure et al. 2004). Flow in half of the channel is simulated using FLOW-3D due to symmetry, and horizontal channel geometry was developed using FLOW-3D solid modeler. The channel has a flow control structure - a weir at 2.0 m downstream along x direction, and the weir is 0.02 m thick in x direction and 0.09 m high (z direction). In order to simulate effects of wall roughness,

the roughness height of three subcomponents is set as k = 0.001 m for the logarithmic law-of-the-wall turbulent boundary conditions (Flow Science Inc., 2005). The mesh size for the simulation is dx = 0.01 or 0.02 m (2 cm), dy = 0.005 to 0.02 m, and dz = 0.025 m (2.5 cm). The simulation domain covers 2.2 m, 0.125 m, 0.15 m in the x, y, and z directions, respectively. Since the mesh size in the z direction is much smaller than ones in x and y directions, line implicit pressure solver in the z direction is used. The slope of the channel was modeled by setting the gravitational acceleration component in the x direction as 0.06849 m/s^2 that is equivalent to 0.7% slope in the x direction. The gravitational acceleration components in the z and y directions were set as -9.81 and 0.0 m/s^2.

As usually, boundary conditions at the channel wall and bottom were set as the wall boundary, and the top surface of the simulation domain and the channel centerline surface are set as symmetry boundary (zero gradients on flow parameters). The first challenge for the case study is to appropriately set flow boundary conditions at upstream and downstream ends along x direction. For water surface profile simulation in an open channel, the boundary condition is at the downstream end for subcritical flow and at the upstream end for supercritical flow, because the location of the control section in a prismatic channel is generally governed by the state of flow, which in turn is determined by the slope of the channel (Chow 1959). In this case study, the channel has a slope of 0.7% and has a weir between upstream and downstream ends, and this will result the control section at the weir and a M1 water surface profile (Chow 1959; Roberson et al. 1998) approaching to the weir, but FLOW-3D and other CFD software require to set boundary conditions at both upstream and downstream ends of the channel. The second challenge (or a common shortcoming) is to accurately present technical information in technical writing. In the process of simulating flow properties and interpreting their results for Faure's channel, there are two problems encountered: (1) Faure's paper gives a discharge of 0.0036 m^3/s but did not specify clearly that the discharge is for half or full channel width; his numerical model used half of the channel width as simulation domain; (2) The y axis in Faure's Figure 3 (Faure et al. 2004) was labeled as "water depth" instead of "water level". The water level or water surface elevation refers to a specific datum, and for M1 water surface profile, the water depth increases along the flow (x) direction (Chow 1959), while Faure's Figure 3 shows almost horizontal water depth profile, which we think it should be labeled as water level. Several model runs were conducted and results are given below to reveal these challenges.

For this case study, the boundary condition at 2.0 meters downstream of the weir is set as stagnation pressure with fluid height of 9 cm (the same water depth in Figure 2 of Faure's study) or outflow boundary condition (flow leaving the simulation domain). Flow rates in the experimental channel were measured and given by Faure et al. (2004), but flow rates cannot be set as boundary condition for any three-dimensional model. In this case study, two types of upstream boundary conditions, specified velocity and specified pressure were tested using FLOW-3D; the simulated results are compared with the results of Faure's case study. Figure 3 of Faure's paper shows that the inflow water depth at the upstream end of the channel is about 0.126 m when the flow rate is 0.0036 m^3/s. In FLOW-3D model, two average velocities at the upstream cross section were calculated and used for FLOW-3D simulations in order to compare with Faure's simulated water surface elevation: one is 0.114 m/s that will result channel discharge of 0.0036 m^3/s for the whole channel width (0.25 m), another one is 0.228 m/s which will result channel discharge of 0.0036 m^3/s for the half of the channel width (0.125 m). The specified velocity boundary condition at upstream requires to set or specify both velocity and flow depth, but the specified pressure is to set pressure as equivalent fluid height (Flow Science

Inc. 2005). Simulated water surface profiles under different boundary conditions are shown in the Figure 1 including Faure's simulation results (red diamonds). Figure 1 clearly shows the discharge reported by Faure and others is for only the half of the channel width, and reports water surface elevation using the datum at the channel bottom of the upstream end. Simulated water surface elevations reported in Figure 1 are almost horizontal lines after considering (compensating) the channel slope, while simulated water depths (Figure 2) increase along x direction as M1 profile predicts. It is impossible for a horizontal water depth profile to occur as reported by Faure's Figure 3. If the outflow or continuative boundary condition is used at the downstream end, simulated water depth at downstream was very close to the normal depth (Qiu 2008). When the velocity boundary condition was used at upstream and specified pressure at downstream, simulated water level is about 1 cm lower than one with specified pressure at upstream and downstream boundaries (Figure 1). Simulated flow rates with two boundary conditions at three locations (inflow or near upstream boundary, pass at weir and outflow or near downstream boundary) were examined (Qiu 2008). The flow rates with specified velocities at upstream boundary are stable at about 15 sec. and 1800 cm^3/s for half of the channel width. When specified stagnation pressure is used as upstream boundary, the simulated inflow flow rates are not stable even the simulation time is up to 60 sec. and about 1600 cm^3/s. Therefore, when flow rate or discharge is given or known, specified velocity boundary condition should be used, and specified stagnation pressure most likely does not produce the flow rate we need.

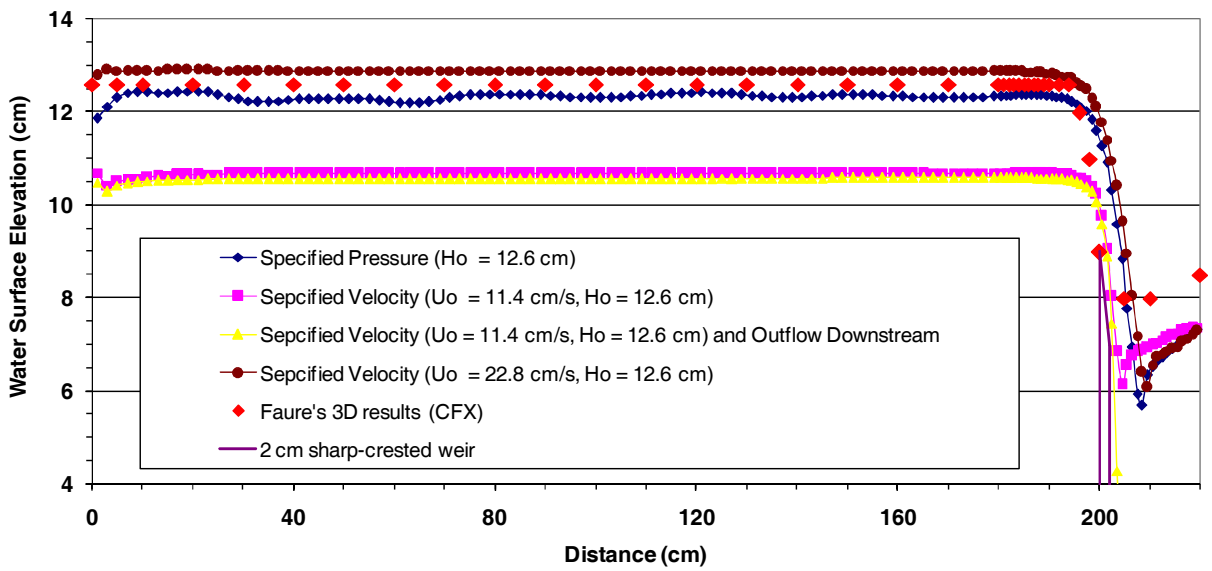

Figure 1. Simulated water surface elevations using FLOW-3D in Faure's Canal 1 with 9 cm high and 2 cm thick weir and 45 degree cut off at the top of the weir under different boundary conditions (dotted lines), and simulated water surface profile using CFX reported by Faure et al. (scatted dots) in 2004.

Because the control section is in the middle of the channel length, two steps are necessary and proposed to set appropriate boundary conditions for the upstream especially the flow depth is complete unknown at the upstream end. The hydraulic theory indicates that the critical flow occurs when flow passes over a weir (Roberson et al. 1998), and computed flow critical depth at the weir using given flow rate allows us to estimate water surface elevation at the weir and the upstream end assuming more or less horizontal M1 profile. When the flow rate is 1800 cm^3/s for

the half channel width, estimated water depth before the weir is about 11.76 cm and projected water depth at upstream end is 10.37 cm (using slope of 0.7% and 200 cm for upstream length) and average velocity of 13.89 cm/s. With projected upstream boundary conditions FLOW-3D run was conducted and water depth profile was smooth except near the upstream end. At the second step we used simulated water depth profile to linearly interpolate or project the water depth at the upstream end as 10.65 cm and mean velocity of 13.52 cm/s. The final runs were executed with updated upstream boundary conditions and give smooth water depth profile along x direction as shown in Figure 2 for three downstream boundary conditions (specified pressure at 9 cm and 5 cm and outflow boundary). These runs indicate that the downstream condition is not the control section for the problem if the flow submergence does not occur or does not impact discharge capacity of the weir. Another two runs setting the upstream fluid heights at 12.6 cm and 14.5 cm (much higher than 10.65 cm) with corresponding velocities to produce 1800 cm^3/s flow rate were conducted to approve the above point of view, and simulated water depth profiles were smooth except short distance near the upstream boundary where sudden/rapid drop on water depths occurred due to acceleration of gravity (Qiu 2008). An additional test run was conducted for discharge of 1800 cm^3/s with 6 cm broad crest rectangular weir using above two step procedures, and simulated smooth water depth profile is also given in Figure 2. The 6 cm broad crest weir pushes the water surface to be about 0.55 cm higher than the one for sharp-crested one under the same discharge, and this test clearly indicates that the control of the water surface profile is at the weir. These testing runs further approve, for this particular case study or physical setting, the control section of the water depth is at the weir and is dependent on inflow rate or how much flow or water is pushed to pass through the weir. Therefore, neither specified mean velocity nor specified fluid height at upstream boundary is the control parameter of the problem instead of the inflow rate (product of velocity, fluid height and channel width) and weir characteristics.

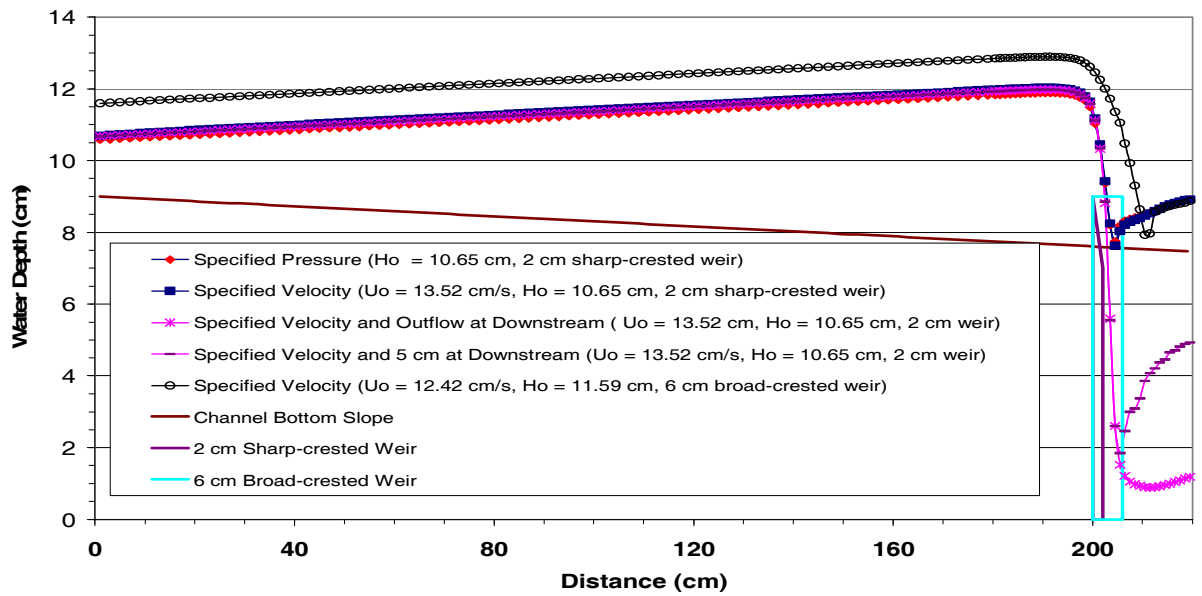

Figure 2. Simulated water depth using FLOW-3D for Canal 1 with 2 cm Sharp Crested Weir (Including 45 Degree Cut at the Top) and 6 cm Broad Crested Weir under Different Boundary Conditions.

Simulations for 4-meter Laboratory Channel

This case study used a 4-meter laboratory channel geometry in Faure's study, and it was named as Canal 2 in Faure's paper. Water depths simulated using CFX and measured in the laboratory for two weir heights are presented in Faure's Figure 2 (a) and (b), respectively. In FLOW-3D model study, channel geometry, mesh size, downstream boundary condition, and initial condition were set in the similar way as for 2-meter channel (Canal 1) presented above. The upstream boundary conditions are based on the flow hydraulic analysis to compute critical depth, water depth at the weir and to project water depth at upstream end, as summarized in Table 1. Figure 3 shows simulated water depths using FLOW-3D model for Canal 2 and simulated water depths match well with measured water depths at three locations (from Faure et al., 2004).

Table 1 Canal 2 flow hydraulic parameter analysis results

Weir height (m)	Channel Discharge (cm^3/s)	Channel critical depth (cm)	Water depth at the upstream of weir (cm)	Interpolated water depth at entrance of channel (cm)	Mean velocity (cm/s)
0.09	7350	7.06	16.06	14.98	39.25
0.12	9900	8.62	20.62	19.95	39.70

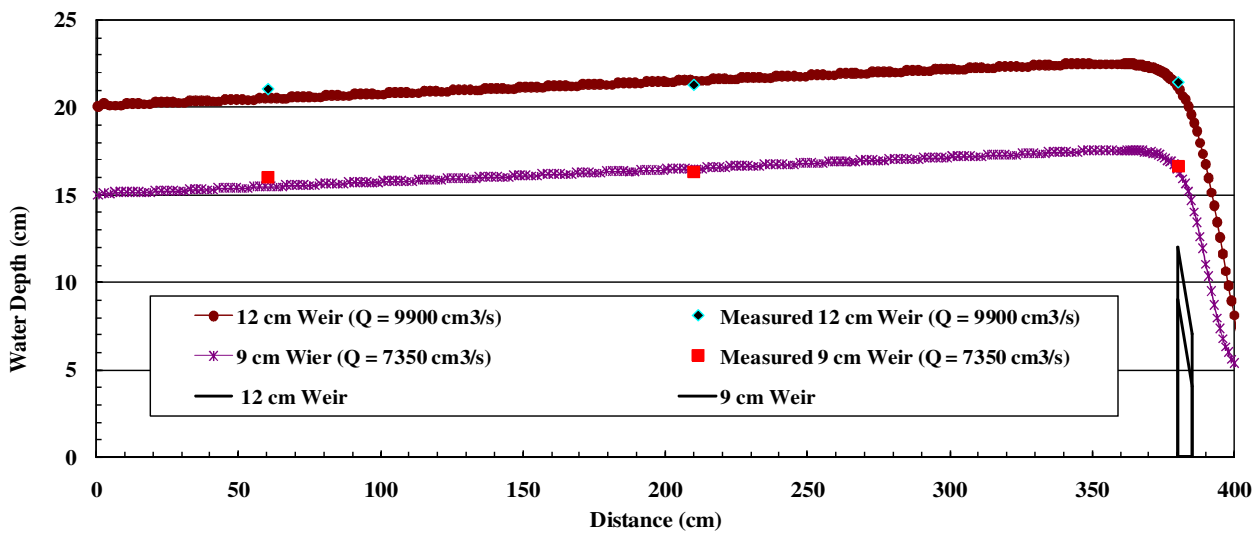

Figure 3. Simulated water depth in Canal 2 with 0.09 m and 0.12 m weirs at 45 degree cut off top of the weir under specified velocity at upstream boundary condition and outflow at downstream boundary condition, and measured points by Faure and Others (scatted dots)

Simulated flow rates were compared with the theoretical discharges of weirs (Roberson et al. 1998) by using the discharge equation for a rectangular weir, and the differences between simulated flow rates by FLOW-3D model and theoretical flow rates are 0.02% for 0.09 m weir and 0.33% for 0.12 m weir (Qiu 2008). The distributions of total velocity magnitude [$V = (u^2 + v^2 + w^2)^{1/2}$] along the water depth at five locations (distances) upstream from the weir in Canal 2 with 0.09 m weir are shown in Figure 4. It can be seen that velocities are different from the theoretical logarithmic profiles at two locations very close to the weir, which indicate that the weir will influence the flow and pressure distributions. The velocity distributions at 21.0 cm, 16.5 cm and 10.5 cm are smooth logarithmic profiles, but the velocity distributions at 0.5 cm and 2.5 cm have much large velocities above the top of weir (depth > 9.0 cm), and these large

velocities indicate water flowing over the weir to downstream due to specified inflow rate. The maximum velocity (occurring just above the weir) at 0.5 cm and 2.5 cm from the weir are 100.66 cm/s and 61.49 cm/s, respectively. At these two locations very near the weir, velocity decreases towards the water surface after it reaches the maximum value. Velocity profiles along z direction at different distances to the weir, along y direction at different water depths, and simulated flow velocity magnitudes in x-z plane were also examined and show that FLOW-3D model is able to capture the flow velocity features under the influence of the weir and simulation results strongly reveal three dimensional flow phenomena near the weir (Qiu 2008).

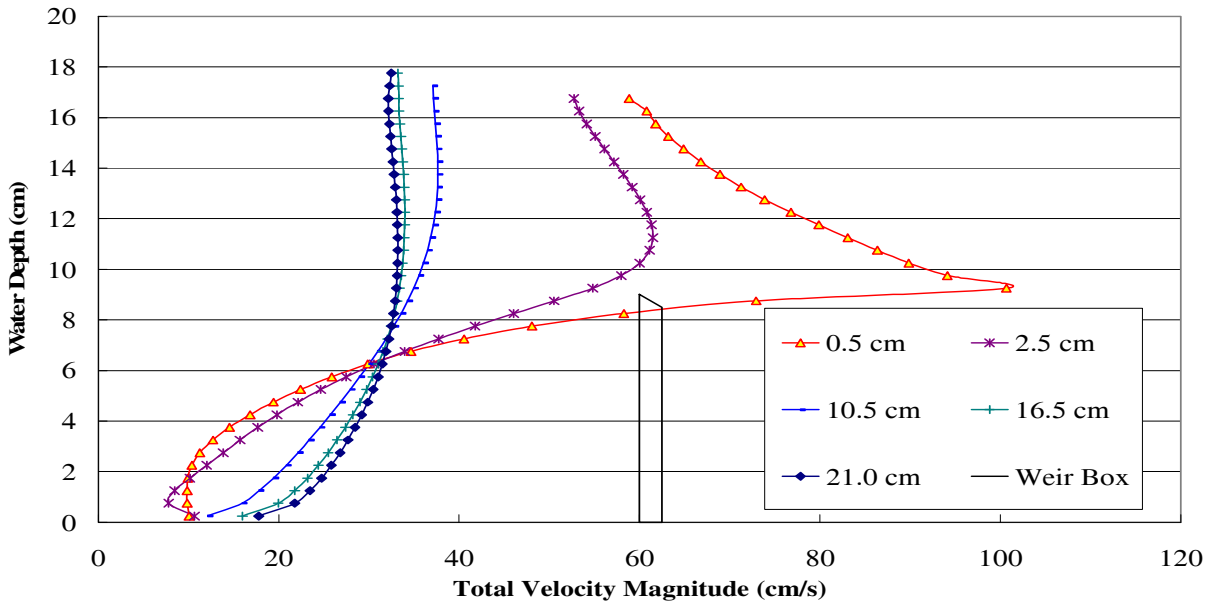

Figure 4. Simulated flow velocities in x-z plane at different distance from the upstream of weir and 2.5 cm from the wall of Canal 2 with 0.09 m weir.

Simulations for Laboratory Channel at Auburn University

Supercritical flows are frequently encountered in hydraulic structures, such as outlets, spillways, chutes, flood-relief canals, and storm water drainage channels (Chow 1959; Stamou et al. 2008). For further exploring FLOW-3D model in simulating such complex hydraulic conditions, such as supercritical flow, subcritical flow, hydraulic jumps, the third model testing is conducted by modeling a laboratory channel geometry build up at Auburn University, which can be used to measure flow hydraulic parameters under different flow boundary conditions, the channel geometry is a compound structure consisting of several kinds of components such as weir, channel (plane and inclined) and rotating tailwater gate (Figure 5). The channel geometry is developed as 7 subcomponents using FLOW-3D's solids modeler. Eight simulation runs are conducted with the same channel geometry but different rotating gate angles that created various tailwater conditions and slightly different inflow boundary conditions. The laboratory channel geometry is total 9.875 ft long in x direction (flow direction) and 1.0 ft wide in y direction (channel width). The channel bottom elevation varies from 0.04 ft to 0.407 ft at different locations. The rotating axis of the gate is set as zero in x and z directions (easy for setting rotation angle), and the channel bottom elevation is 0.083 ft (1 inch) above the rotating axis. The dimensions of each component can be described as: (1) a horizontal channel bottom: dimension of 9.875 x 1.0 x 1.083 ft; (2) a small step block: dimension of 0.167 x 1.0 x 0.04 ft; (3) a well

rounded broad-crested weir: dimension of 0.208 x 1.0 x 0.407 ft; (4) a block with incline plane surface: dimension of 6.042 x 1.0 x (0.04 ~ 0.407) ft, surface slope = 6.22 %; (5) a rotating gate with specified rotating angle: dimension of 0.677 x 1.0 x 0.083 ft. On mesh block (11.4 x 1.0 x 2.5 ft) was used with the mesh size in three directions of dx = 0.05 ft, dy = 0.05 ft, dz = 0.03 - 0.05 ft and having total mesh number of 182400. Specified velocity boundary condition based measured flow rate and fluid height and outflow boundary at the minimum z were used.

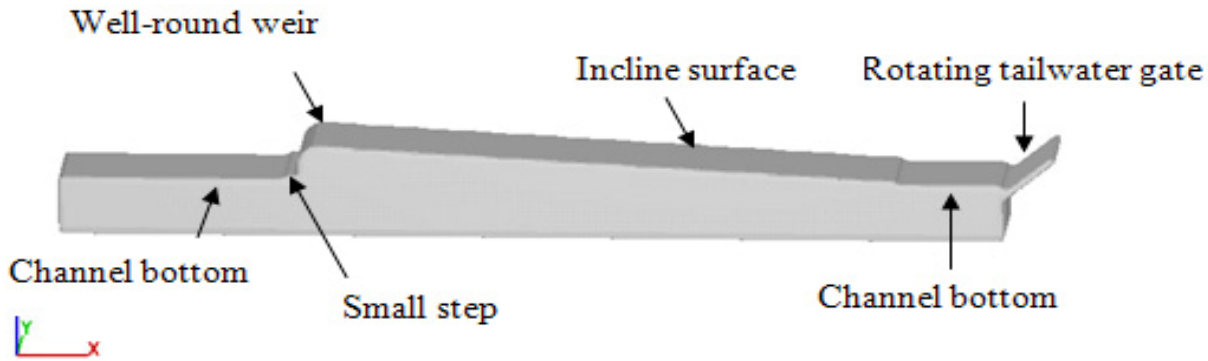

Figure 5. Geometry of FLOW-3D model for laboratory channel at Auburn University (rotating gate angle is 41.42° above the horizontal plane is shown).

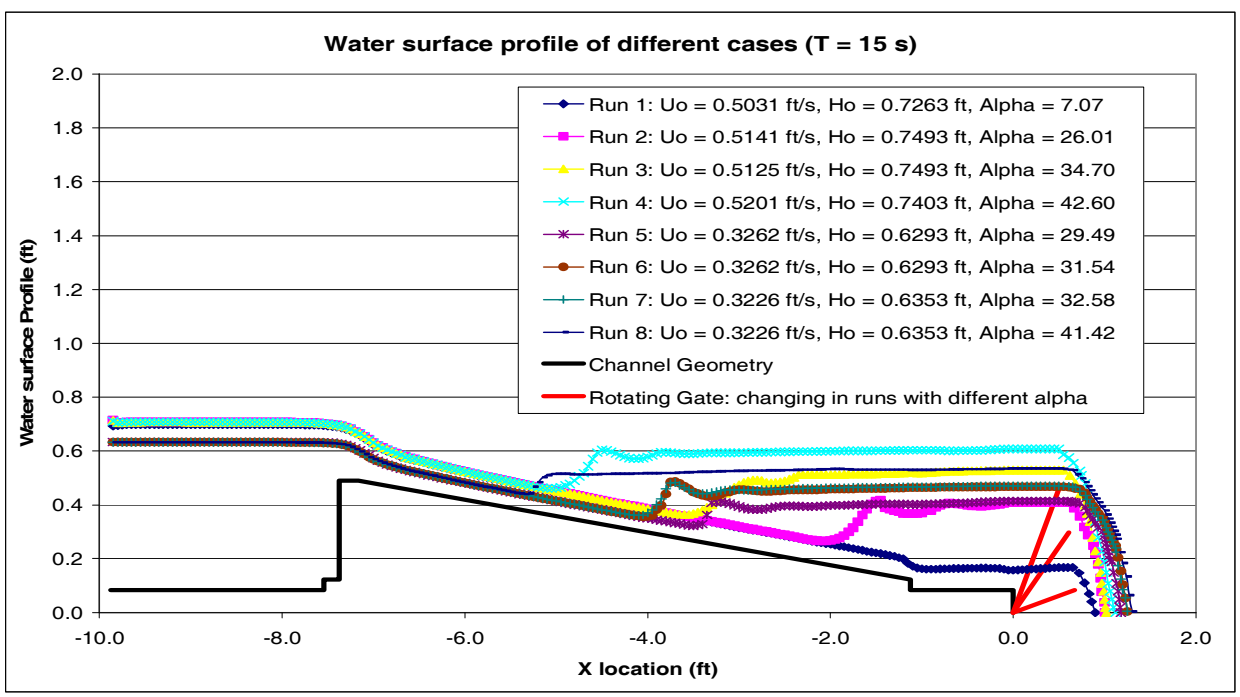

Figure 6. Simulated water surface profiles for Auburn channel under rotating angles.

Figure 6 shows simulated water surface profiles using FLOW-3D model for eight runs with various rotating angles (alpha) and different upstream flow rates. In Figure 6, FLOW-3D only outputs correct water surface profiles before rotating gate ($x < 0$) because FLOW-3D is not able to correctly report fluid height for multiple fluid surfaces. Water surface profiles after $x > 0$ (sharp drop) were manually estimated from 2-D plots with FLOW-3D. Figure 6 very clearly shows differences in water surface profiles among tailwater conditions and successfully simulates from subcritical flow before the step to supercritical flow along inclined channel, and

through hydraulic jump to subcritical flow created by rotating gate. There is no hydraulic jump simulated and observed for run 1 when the gate is almost horizontal. Locations of hydraulic jumps for other runs under influences of different tailwater conditions are clearly showed in Figure 6, and are compared with observed locations in laboratory tests with reasonable agreement (Qiu 2008). Water surface elevations at three fixed locations for all eight tests were measured and compared with FLOW-3D model results (Qiu 2008), and at x = -9.14 ft (0.733 ft downstream of the inflow boundary), the error in fluid height is from 0.73% to -5.53%; and at x = -7.14 ft where it is the highest point of the weir with critical flow condition, the error in fluid height is from 0.88% to -5.72%. At x = -3.77 ft that is a location close to the end of sloping channel bottom, the error in fluid height becomes greater and ranges from 15.54% to -19.88%. Projected location for hydraulic jumps have a relative error from -0.73% to 26.98%; and hydraulic jump location is very sensitive to simulated water surface height at subcritical flow region near the rotating gate (flow control section). In laboratory condition the open space after the rotating gate is not large enough for free fall of flow and the leak of water flow through the gate may result some of the differences between simulated and measured parameters.

Case for River Reach

The last case study is to simulate free-surface flow in a river reach - River 1 in Faure's study (2004) and River 1 with addition of two cylinder culverts through the broad crested weir. The river reach is 400 m long, 40 m wide, 3 m deep, and 0.05% slope. A broad crested weir is located halfway of the reach (x = 200 m) and has a dimension of 4 m thick (in x direction), 40 m wide, and 0.7 m height. The gravitational acceleration component in the x direction as 0.004905 m/s^2 for 0.05% slope. The simulation domain is 400 m x 21 m x 3 m with mesh size of dx = 1 or 2 m, dy = 0.5 - 2 m, and dz = 0.25 m. The geometry of culverts is 0.2 m radius, 4 m long, the central lines of two cylinder culverts are 5 m and 5.8 m in y direction respectively and 0.2 m in z direction. The mesh size is changed to smaller (e.g., dz = 0.1 - 0.25 m) in order to capture the flow features through the culverts. Again water depth was reported in their paper but should be water level, and this effects what boundary conditions can be used for FLOW-3D model and comparison between FLOW-3D's and Faure's results. Simulated water surface profile is very similar to one obtained using CFX by Faure et al. (2004), and the simulated water level at upstream from FLOW-3D model has about 0.15 m difference with CFX model results. Three-dimensional flow characteristics around the broad-crested weir without and with culverts were successfully simulated (Qiu 2008).

Conclusions

Several case studies have been presented to demonstrate that FLOW-3D can be utilized to model the unsteady free-surface flow in experimental channels and a river reach with weir and sluice gates with different boundary conditions. Comparison between simulated and measured flow properties shows reasonable accuracy. The first case study indicates the appropriate boundary condition at upstream for open channel flow study in civil engineering field is using specified velocity and fluid height; and this boundary sets flow rate into the simulation domain. Boundary condition as specified stagnation pressure in turn of fluid height using FLOW-3D does not produce exactly flow rate that the modeler wants or measured in the laboratory and field conditions. In this case study, the control structure is a weir in the middle of simulation domain; and two simulation runs are necessary to accurately define boundary conditions in FLOW-3D.

Simulation runs with sharp-crested and broad-crested weirs demonstrate that the flow capacity of the weirs directly controls upstream fluid height under the same flow rate. It is demonstrated that FLOW-3D can successfully simulate complex open channel flows from supercritical to subcritical with hydraulic jump under the influence of tailwater effects. It is easily to develop the model in FLOW-3D with a rotating tailwater gate at any opening angle. Complex flow simulation from supercritical to subcritical with hydraulic jump is a challenging task for hydraulic engineers, but does not require any customization in FLOW-3D and was simulated with simple boundary condition (specified velocity at upstream) and appropriate representation on channel geometry. The analysis results show that FLOW-3D provides accurate solution for complex open channel flows. This study for river reach indicates that FLOW-3D is able to reveal the complex flow dynamic phenomena near the hydraulic structures, such as flow over weir and through culverts. FLOW-3D can be a powerful vital simulation lab for a study of channel and river reach under various inflow conditions, but there are challenges to students and professional practitioners because it requires in-depth understanding in hydraulic theory and setting appropriate boundary conditions and accurately present the technical information (e.g., water level and water depth profiles).

Comparison of the Princeton Ocean Model and the Regional Ocean Modeling System Hindcasts in the Delaware River and Bay

Richard A. Schmalz, Jr.[1], F. ASCE

Abstract

The National Oceanic and Atmospheric Administration is in the process of developing a nowcast/forecast system for Delaware River and Bay. The Delaware Bay Operational Forecast System (DBOFS) will extend from the head of tide at Trenton, NJ through the Bay entrance out onto the continental shelf and will supplement the Delaware Bay Physical Oceanographic Real Time System (PORTS), which was installed in 2003 to provide observed, real-time water surface elevation, currents, temperature, salinity, and meteorological information. In conjunction with the DBOFS development effort, the Princeton Ocean Model (POM) and the Regional Ocean Modeling System (ROMS) have been applied with a common medium resolution grid in hindcast mode using common forcings to simulate two 15-day periods in March (high river flow) and September (low river flow) 1984. Herein, we compare and contrast the hindcast simulation results versus the National Ocean Service Delaware River and Bay 1984 Circulation Survey measurements of water surface elevation, currents, salinity, and temperature. The effects of a spatially varying bottom friction, subtidal water level forcings at the Chesapeake and Delaware Canal boundary, navigation channel bathymetry, and upriver storage areas on water level, current, and salinity response are considered. In conclusion, plans for further DBOFS development with ROMS using a finer resolution grid are presented.

Introduction

The National Ocean Service (NOS) installed a Physical Oceanographic Real Time System (PORTS) during 2003 to provide water surface elevation, currents at prediction depth (4.7m below MLLW) as well as near-surface and near-bottom temperature and salinity, and meteorological information at the locations shown in Figure 1. To complement the PORTS, a nowcast/forecast system is being developed within the Coastal Ocean Modeling Framework (COMF) as developed by Gross et al. (2006) and further discussed by Aikman et al. (2007). In conjunction with this effort, a Model Evaluation Environment (MEE) as described by Patchen (2007) was constructed

1 Oceanographer, National Oceanic and Atmospheric Administration, National Ocean Service, Coast Survey Development Laboratory, Marine Modeling and Analysis Programs, 1315 East-West Highway, Rm 7824, Silver Spring, Maryland 20910. (301)-713-2809 x104; e-mail: Richard.Schmalz@noaa.gov.

for the Delaware River and Bay based on the NOS 1984-1985 Circulation Data Survey (Klavans et al., 1986; Richardson and Schmalz, 2006). In the context of the Delaware River and Bay Nowcast/Forecast System (DBOFS), the MEE provides additional validation data particularly for currents and density that is not available within the PORTS. The following models were evaluated (Patchen, 2007):

1. Regional Ocean Modeling System (ROMS) as described in Shchepetkin and McWilliams (2005) and Haidvogel et al. (2008).
   On the Internet at: http://www.myroms.org
2. Princeton Ocean Model (POM) as described in Blumberg and Mellor (1987) and Blumberg and Herring (1987).
   On the Internet at: http://www.aos.princeton.edu/WWWPUBLIC/htdocs.pom
3. Finite Volume Coastal Ocean Model (FVCOM) as described in Chen et al. (2006).
   On the Internet at: http://fvcom.smast.umassd.edu/FVCOM/index.html
4. Semi-Implicit Eulerian-Lagrangian Finite Element Model (SELFE) as described in Zhang et al. (2004).
   On the Internet at: http://www.ccalmr.ogi.edu/corie/modeling

Based on the assessment of the MEE results, additional improvement in the water level and current response in the river section above Philadelphia, PA is needed by all of the models to meet the NOS skill requirements (NOS, 1999; Hess et al., 2003). To this end two 15-day periods were selected for further consideration. The first period, 27 March – 10 April, 2004 contained a coastal surge event as well as a high flow event. The second period, 10-24 September, 1984 was dominated by extremely low flow of order 3000 cfs at Trenton, NJ and represented a period of potential salinity intrusion. There also was very little storm activity along the coast and hence the period was dominated by astronomic tides and allowed for an assessment of the tidal response. In this paper, we focus on the first two models and present simulation results for each of these periods in an effort to lead toward improvement. To conclude the paper, we outline further development and testing.

Model Grid and Simulation Setup

The horizontal computational grid for both POM and ROMS, which is 150 (E-W) x 550 (N-S), is shown for the upper Delaware River in Figure 2 and for the lower Delaware River and Bay in Figure 3 with the finest grid resolutions approximately 50 m. Fifteen sigma coordinate levels are used in the vertical with uniform spacings below the surface level in POM, while 10 s coordinate levels are used in ROMS.

To move toward a more standard nowcast/forecast system set-up, the NOS Galveston Bay Operational Nowcast/Forecast System (GBOFS) was emulated but slightly modified using the approach developed during the Long Island Sound Study (LISS). In the LISS, a second section of the grid generation program was used to provide the initial density structure, the SST field at 15 to 30 day intervals, and the salinity and temperature boundary conditions for rivers and the ocean boundary (see Schmalz, 1994). In GBOFS

a ten-step set-up program is used to provide the forcing for each 24 hour nowcast, and for the 30 hour forecast (Schmalz and Richardson, 2002). Within this program, the density structure is updated at the beginning of each nowcast based on the observed PORTS measurements and the sea-surface temperature, salinity and temperature boundary conditions are then persisted over the nowcast/forecast period. Rather than employing this approach, the LISS approach for handling the initial and boundary conditions was used and then steps 6, 7, and 8 in the ten-step nowcast/forecast procedure were eliminated. The remaining steps are used to specify the simulation period (Step 1), generate harmonically reconstructed water surface elevation (Step 2) and currents (Step 3), place the observed data in the appropriate format for the graphics programs (Step 4), produce the subtidal water level signals at Chesapeake City, MD and Cape May, NJ (Step 5), generate the average daily inflows for the 12 rivers (Step 9), and use the Barnes (1973) interpolation from meteorological data at 10 stations (including 2 offshore National Data Buoy Center (NDBC) buoys) to provide the wind and sea-level atmospheric pressure fields. Note the subtidal water level signal at Cape May, NJ was applied to the entire ocean open boundary. Within the present operational NOS nowcast/forecast systems, the approach of applying a measured or forecast coastal subtidal water level to the entire open boundary has been used. In the present case with the open boundary extending to the shelf break this may not be valid. An alternative approach would be to reduce the extent of the grid on the shelf to perhaps the 20 to 50 m contour as used by Celebioglu and Piasecki (2006) or to use a shelf model.

In the MEE, the water level residual at the head of the Chesapeake and Delaware (C&D) canal was considered zero. Here, the water level residual signal at the Chesapeake Bay end of the C&D canal was based on Chesapeake City, MD as determined via a linear regression (bias=0.003, gain=0.784) from the Baltimore, MD water level residual over the four month period July-October, 1984. Monthly root mean square errors (RMSEs) were order 5 cm and storm periods were well produced.

Within the NOS operational nowcast/forecast systems water levels are specified with respect to the MLLW datum at each PORTS station. Within the Galveston Bay Nowcast/Forecast System the model datum is taken as MTL and at each station the tidal epoch adjustment from MTL to MLLW is added to the model prediction. Within the Delaware River and Bay system, two datums are used. Along the coast and within the Bay proper MSL is taken as the model datum, while above Philadelphia, PA mean river level (MRL) is assumed equal to NAVD-1988 and is taken as the model datum.

For the POM simulations, the following revisions to the initial set-up were employed:

1) The C&D canal width was adjusted to its actual channel width of 121.9 m. It was straightened and made one grid cell wide.
2) The United States Army Corps of Engineers (USACOE) project channel depths were specified for the navigation channels from the Bay to Philadelphia, PA from Philadelphia, PA to Newbold, PA and from Newbold, PA to Trenton, NJ.
3) Several upriver marsh areas were specified at depths of order 1 m.

4) SST was specified by using the nearest surface value of the CT moorings and CTD profiles.
5) A spatially varying bottom roughness was incorporated, such that over the continental shelf z_0 = 1 cm, from the Bay entrance to the river mouth z_0 linearly decreases to 0.3 cm, from the river mouth to below the Tacony Bridge, NJ it remains at 0.3 cm, and from there to the head of tide it linearly increases to 1.3 cm.

For the ROMS simulations, the following revisions were employed:

1) The C&D canal width was adjusted to its actual channel width of 121.9 m. It was straightened and made two grid cells wide to accommodate the higher order numerical scheme.
2) The USACOE project channel depths were specified using NOS bathymetric surveys.
3) Upriver marsh areas were not explicitly considered.
4) A full bulk flux formulation was used to provide the surface heat fluxes using the MEE forcing files (Patchen, 2007).
5) A spatially varying quadratic bottom friction coefficient set was used, such that over the continental shelf *rdr* = 0.007, from the Bay entrance to the river mouth *rdr* linearly decreases to 0.005, from the river mouth to the head of tide it linearly increases to 0.009.

High Flow Simulation

Wind speed and direction and atmospheric pressure were produced using Barnes (1973) interpolation at three hour intervals with wind speed and direction root mean square errors (RMSEs) order 2 m/s and 25 ^{o}T, respectively, and sea level atmosphere pressure RMSEs order 1.5 mb. Simulated water levels are compared with observations in Figure 4 at Trenton, NJ and in Table 1 with RMSEs increasing from order 15 cm at the Bay entrance to 25 cm at Philadelphia, PA with a maximum near the head of tide at Trenton, NJ of 37 cm for both models. In this and all subsequent tables, the relative error corresponds to the Willmott et al. (1985) dimensionless (0-1) relative error, with zero representing perfect agreement. Note for the time series plots (Figures 4-6) the indicator of agreement (IND AGMT), equal to one minus the relative error, is given.

Table 1. Water Surface Elevation-MLLW (m) High Flow Hindcast
27 March – April 10, 1984: ROMS Results / POM Results

Station	RMS Error (cm)	Relative Error (-)	Model Mean (cm)	Observed Mean (cm)

Trenton, NJ	37/37	0.04/0.04	200/204	191

Current speed and direction model predictions are compared against observations in Tables 2 and 3, respectively. The current strengths at Station 33 and within the river

sections are in reasonable agreement with observations. Current directions are reasonably represented within the Bay and river sections, where the currents are rectilinear. At continental shelf stations 16 and 17 the currents are rotary in nature and both model directions exhibit larger discrepancies from the observations.

Table 3. Current Direction (^{o}T) High Flow Hindcast
27 March – April 10, 1984: ROMS Results / POM Results

Station Model Level	RMS Error (^{o}T)	Relative Error (-)	Model Mean (^{o}T)	Observed Mean (^{o}T)
16 Level 6	57.77/86.25	0.64/0.78	179.40/194.21	228.85
17 Level 11	113.22/137.58	0.84/0.83	188.76/178.02	215.01
23 Level 4	40.63/31.54	0.05/0.03	234.56/239.16	254.61
33 Level 4	41.86/29.10	0.05/0.02	210.39/219.72	226.66
50 Level 9	48.80/36.06	0.08/0.04	173.56/170.13	176.83
52 Level 9	41.50/30.48	0.06/0.03	154.80/153.85	148.01

The simulated salinities at the corresponding POM model sigma levels (k=1, 15 with 1 representing the near surface) are compared with observations in Table 4. One notes as shown in Figure 5 at Station 33 in the region of large horizontal gradients, that a reasonable RMSE of order 3.0 PSU is achieved. The simulated temperature response is contrasted with observations in Table 5 for both models. With either the SST specification in POM or the bulk heat flux formulation in ROMS, the RMSEs are within order 2 ^{o}C.

Table 4. Salinity (PSU) High Flow Hindcast

Low Flow Simulation

To examine the effect of the above revisions under low flow conditions, the 10-24 September, 1984 period was simulated. Wind speed and direction and atmospheric pressure as produced by the Barnes (1973) interpolation at three hour intervals are compared with hourly observations and are of the same order RMSE as for the high flow period. Note that mean windspeeds are lower than during the high flow period and are quite gentle. Simulated water levels are contrasted with observations in Table 6. RMSEs are generally of the same order as obtained under high flow conditions particularly at Trenton, NJ, where the complete time series is shown in Figure 6. However, one notes at the Bay entrance and at Philadelphia, PA an increase of order 5 cm in RMSE. These results may be improved by reducing the grid extent and specifying the subtidal water level signal nearer the measurement location, but with a loss in the ability to predict the coastal current.

Table 6. Water Surface Elevation-MLLW (m) Low Flow Hindcast
September 10-24, 1984: ROMS Results/ POM Results

Station	RMS Error (cm)	Relative Error (-)	Model Mean (cm)	Observed Mean (cm)
Lewes, DE	18/17	0.04/0.04	71/62	70

Trenton, NJ	35/37	0.04/0.05	132/122	131

In Tables 7 and 8, the current speed and direction comparisons are given. One notes at Station 33 the current speed responses are very similar to those obtained for the high flow hindcast. Note that the current speeds are slightly under-predicted at upriver station 51. Current direction errors are comparable under both high and low flow conditions. In Table

9, the salinity response is compared with observations. At Station 33 in the region of large horizontal salinity gradients both model results are favorable but with POM order 1 PSU closer in agreement with observations. As shown in Table 10, the

temperature responses in both models also compare very well to the observations with POM order 1.0^{o}C lower in RMSE in the lower Bay.

Conclusions, Further Development and Testing

For both 15-day periods, the simulation results for water levels, currents, salinity, and temperature were very similar using either POM or ROMS. Note while the same horizontal grid was used, in the vertical POM uses15 sigma levels while ROMS has 10 s coordinate levels. The third order upstream horizontal advection schemes in ROMS as

opposed to the second order central differencing schemes in POM necessitated an extra day of model spin-up from rest. Both models used the Mellor-Yamada 2.5 level turbulence scheme and employed similar offshore boundary conditions. Both models were run with a 1 second barotropic time step with POM using a 10 second and ROMS a 20 second baroclinic time step. Additional modification of the bottom roughness zones both in value and extent is warranted. Here the bottom friction zones patterned after Walters (1992a; 1992b) were used in both models.

As noted by Johnson et al. (1988) and Galperin and Mellor (1990a; 1990b) a major issue is the representation of the C&D Canal and the river sections above Philadelphia, PA. Within the present grid structure, the C&D Canal is one grid cell wide in POM and two grid cells wide in ROMS. Also order 4 grid cells are employed within the upper river

sections with only 2 grid cells representing the river at Trenton, NJ. The treatment of the change in cross-sectional area with discharge due to the low lying marsh areas is extremely difficult to accomplish within the present grid. A higher resolution grid based on the Delft Hydraulics Laboratory grid generation software has been developed and additional ROMS simulations are being performed.

Abstract: A process-based two-dimensional model for simulating coastal wave, tide- and wave-induced currents, and coastal morphodynamic change is presented. The integrated model includes three different submodels: (1) wave model, (2) wave-induced current model and (3) sediment transport model. A phase-averaged wave model based on linear wave theory is used to simulate wave transformation, deformation and to calculate radiation stresses. The current model is based on the solution of the conservative form of the nonlinear shallow water equations and effects of the Coriolis force, wind stress, bottom irregularities and short wave-averaged radiation stresses are included. The forward Euler discretization is used for the unsteady term and the convective term is discretized using Godunov-type shock capturing method on non-uniform rectilinear grids. The hydrostatic flux is calculated using an equivalent water depth at each cell interface and the bed slope source term is treated in such a way that exact balance between hydrostatic flux and bed slope source terms is achieved under still water condition. The morphodynamic change is modeled by considering local sediment balance and anisotropic downstream gravitational effect. The three submodels are operated systematically and required parameter values are transferred to the respective submodels. This sequential computations are carried forward in a cyclic order till simulation time reaches to the end time. In order to test the applicability of the model, a severe storm attack on an ideal coast is simulated. The preliminary results show that the developed model can be applied to simulate wave-current-morphodynamic processes in coastal and estuarine zones.

Key words: Coastal inlet flow; Shallow water flow; Wave model; Finite volume method, Morphology.

1 Introduction

In recent years numerical flow models have been increasingly developed and applied to simulate coastal flows and morphological changes due to storm, wave surge or tsunami. Modelling the effects of these extreme events is important for engineering applications and optimum design of coastal structures, sediment management, shoreline protection, maintenance of navigation channel, etc. Such models can be used in a cost effective way comparing to physical model study to refine and optimize designs of coastal structures.

Coastal inlets along barrier islands are used to facilitate exchange of fresh and saline water, navigation and pathway for sediments, nutrients, water-borne materials etc. Such inlets and islands are often attacked by ocean waves, tides and storms, result in significant beach erosion, sediment transport, bed changes of inlet channel and instability of the shoreline. Ding and Wang (2007) and Militello and Kraus (2003) reported that morphodynamic response of an inlet to tides and storm waves can lead to ebb and flood shoals formation, navigation channel refilling, migration of the channel thalweg, skewing of ebb shoals, develop tip shoals, beach erosion, and scour holes inside the inlet and adjacent to the jetty tips. The hydrodynamic and morphodynamic processes associated to these problems may be investigated cheaply using numerical models.

The numerical models for simulating tides and short wave-induced currents as well as short and long term morphological changes must have capabilities to represent short-period waves, long-period tides and nearshore currents with different temporal and spatial scales. Some commercially available models such as MIKE21 (MIKE21 2006; Zyserman and Johnson 2002), DELFT3D (Lesser et al. 2004), SHORECIRC (Svendsen et al. 2003), CMS-M2D (Militello and Kraus 2003; Ding and Wang 2006a) have shown some of these capabilities to deal with flows and morphodynamic changes in coasts. In the present study, the authors have developed a shock-capturing hydrodynamic model to simulate all flow regimes and the new model is coupled with wave and sediment transport models available in the Surface Water Modeling System (SMS). All the three models are executed sequentially and systematically to simulate short waves, wave-induced currents and morphological changes.

The hydrodynamic model was extensively tested (Kuiry et al. 2008; Kuiry et al. 2009) before and hence the integrated model is applied herein to investigate simulation capabilities of severe storm surge, wave-induced currents and subsequently bathymetry changes in a hypothetical costal inlet. The inlet typically represents basic geometry and configuration of a natural inlet with offshore slope, wave and storm forcings. The numerical results correctly reproduce expected trends in hydrodynamic behaviour and morphological changes. Through the preliminary investigation, it can be concluded that the new model can be used to simulate

combined storm and wave-induced currents as well as morphological changes in coastal inlets.

2 Model description

In the present study an integrated model is developed based on the three other submodels (a) wave model, (b) wave-induced current model and (c) sediment transport and morphodynamic change model. The first and third models are readily available in SMS and the second model is developed in this study and integrated with the other models so that all the three models can be operated systematically. Thus the coastal process model uses several differential equations and they are solved in a decoupled way and the necessary values of the parameters are passed from one model to another systematically. The wave model is a phase-averaged model which includes diffraction term in order to represent wave fields in the lee of coastal structures. In the wave-induced depth-averaged current model radiation stresses obtained from the wave model are included so that longshore current can accurately be represented. The cross-shore and longshore sediment transport is calculated by a sediment transport model based on Lund-CIRP total load formulation. The models are briefly described below.

2.1 Wave Model

The CMS-Wave takes into account the effect of an ambient horizontal current or wave behaviour and solves the wave-action balance equation as

$$\frac{\partial\left(v_x N\right)}{\partial x}+\frac{\partial\left(v_y N\right)}{\partial y}+\frac{\partial\left(v_\theta N\right)}{\partial \theta}=\frac{\kappa}{2\sigma}\left[\left(CC_g\cos^2\theta N_y\right)_y-\frac{CC_g}{2}\cos^2\theta N_{yy}\right]-\varepsilon_b N-R \qquad (1)$$

where $N=E(\sigma,\theta)/\sigma$ is the wave-action density to be solved and is a function of frequency σ and direction θ. The spectral wave density $E\left(\sigma,\theta\right)$ represents the wave energy per unit water surface area per frequency interval. In Eq. (1), C, C_g = wave celerity and group velocity, respectively; x, y = horizontal coordinates in two directions; v_x, v_y and v_θ = characteristic velocity with respect to x, y and θ, respectively; N_y, N_{yy} = first and second derivatives with respect to y, respectively; κ = empirical constant representing the intensity of diffraction effect; ε_b = parameterization of wave breaking energy dissipation and R = source terms (e. g., wind forcing, bottom friction loss, nonlinear wave-wave interaction term). The term κ needs to be calibrated and optimized for structures.

The velocity components in Eq. (1) are given by

$$v_x = C_g\cos\theta + u \qquad (2)$$

$$v_y = C_g \sin\theta + v \tag{3}$$

$$v_\theta = \frac{C_g}{C}\left(\sin\theta\frac{\partial C}{\partial x} - \cos\theta\frac{\partial C}{\partial y}\right) \tag{4}$$

where u, v = depth-averaged horizontal current velocity components along x and y directions.

2.2 Wave-induced Current Model

A depth and shortwave averaged forms of the SWE are used for simulating currents induced by tides and waves (Ding and Wang 2006). The governing equations in conservative form can be written as follows:

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{E}(\mathbf{U})}{\partial x} + \frac{\partial \mathbf{G}(\mathbf{U})}{\partial y} = \mathbf{S}(x, y, \mathbf{U}) \tag{5}$$

In which,

$$\mathbf{U} = \begin{bmatrix} H \\ Hu \\ Hv \end{bmatrix}; \quad \mathbf{E} = \begin{bmatrix} Hu \\ Hu^2 + \frac{1}{2}gH^2 \\ Huv \end{bmatrix}; \quad \mathbf{G} = \begin{bmatrix} Hv \\ Huv \\ Hv^2 + \frac{1}{2}gH^2 \end{bmatrix};$$

$$\mathbf{S} = \begin{bmatrix} 0 \\ gH\frac{\partial h}{\partial x} + f(Hv) + \frac{\partial}{\partial x}\left(D_x\frac{\partial(Hu)}{\partial x}\right) + \frac{\partial}{\partial y}\left(D_y\frac{\partial(Hu)}{\partial y}\right) - \tau_{bx} + \tau_{sx} + \tau_{wx} \\ gH\frac{\partial h}{\partial y} - f(Hu) + \frac{\partial}{\partial x}\left(D_x\frac{\partial(Hv)}{\partial x}\right) + \frac{\partial}{\partial y}\left(D_y\frac{\partial(Hv)}{\partial y}\right) - \tau_{by} + \tau_{sy} + \tau_{wy} \end{bmatrix}$$

where $\mathbf{U}$ = vector of conserved variables; $\mathbf{E}$ and $\mathbf{G}$ = convective fluxes in the x- and y-directions, respectively; and $\mathbf{S}$ = source term. In addition, h = still water depth; η = deviation of the water surface from the still water level (Figure 1); $H = (h + \eta)$ = total water depth; u and v = depth-averaged current velocities parallel to the x- and y-directions; g = acceleration due to gravity; f = Coriolis force, $f = 2\omega\sin\varphi$, ω = angular frequency of earth rotation, φ = latitude. The other parameters in the x- and y-directions are: S_{0x} and S_{0y} = bed slopes; D_x and

D_y = diffusion coefficients; τ_{bx} and τ_{by} = bed shear stresses; τ_{sx} and τ_{sy} = wave stresses; τ_{wx} and τ_{wy} = surface wind stresses, respectively.

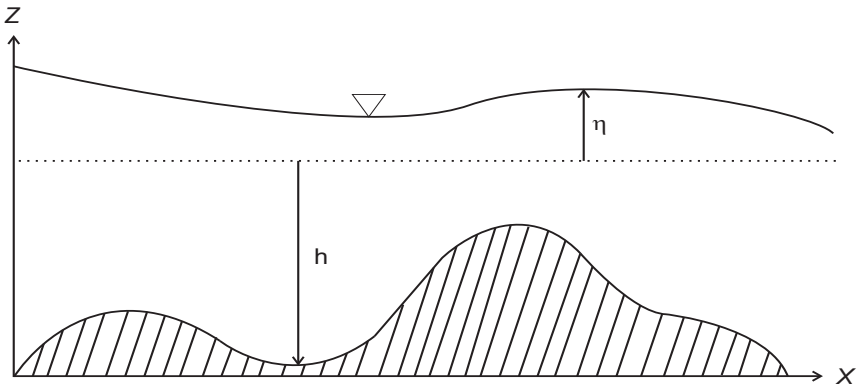

Figure 1: Definition sketch for bed topography, water depth and

2.3 Sediment Transport and Morphodynamic Change Model

The sediment transport model is based on the calculations of sediment transport rates and resultant changes in water depth (bottom elevation) through gradients in transport rates as proposed in Lund-CIRP formulations (Camenen and Larson 2005a, 2005b). Bed level changes are obtained from the sediment continuity equation:

$$\frac{\partial h}{\partial t} = \frac{1}{1-p}\left(\frac{\partial q_{bx}}{\partial x} + \frac{\partial q_{by}}{\partial x} + P - D\right) \tag{6}$$

where q_{bx}, q_{by} = bed load transport rate in the *x*- and *y*-directions, respectively and p = porosity of sediment. The term $\partial q_{bx}/\partial x + \partial q_{by}/\partial y$ represents the bed load component and the term $P - D$ corresponds to the suspended load component. While evaluating the bed changes by Eq. (6), time-averaged transport rates are used ($\overline{q}_{bx}, \overline{q}_{by}$). In this approach, instantaneous transport rates are computed at a time interval of Δt_{sed} and time-averaged transport rates and morphology changes are calculated at a time interval of Δt_{morph}. Also, the bed load components in Eq. (6) are corrected for the slope effect as

$$\overline{q}'_{bx} = \overline{q}_{bx} - D_s \left|\overline{q}_b\right|_x \frac{\partial h}{\partial x} \tag{7}$$

$$\overline{q}'_{by} = \overline{q}_{by} - D_s \left|\overline{q}_b\right|_y \frac{\partial h}{\partial y} \tag{8}$$

where $\overline{q}_b = \sqrt{\overline{q}_{bx}^2 + \overline{q}_{by}^2}$. Finally, Eq. (9) is solved to compute depth changes at the time interval Δt_{morph}.

$$\frac{\partial h}{\partial t} = \frac{1}{1-p}\left(\frac{\partial \overline{q}_{bx}'}{\partial x} + \frac{\partial \overline{q}_{by}'}{\partial x} + \overline{P} - \overline{D} \right) \tag{9}$$

Camenen and Larson (2005a) proposed a general transport formula for bed load under combined effect of wave and current as

$$\frac{q_{bw}}{\sqrt{(s-1)gd_{50}^3}} = a_w \sqrt{\theta_{net}}\,\theta_{cw,m} \exp\left(-b\frac{\theta_{cr}}{\theta_{cw}} \right) \tag{10}$$

$$\frac{q_{bn}}{\sqrt{(s-1)gd_{50}^3}} = a_n \sqrt{\theta_{cn}}\,\theta_{cw,m} \exp\left(-b\frac{\theta_{cr}}{\theta_{cw}} \right) \tag{11}$$

where subscripts *w* and *n* represents wave direction and direction normal to the wave, respectively; d_{50} = median grain diameter; θ_{cr} = critical Shields parameter; s = specific gravity; a_w, a_n and b = empirical constants and $\theta_{cw,m}, \theta_{cw}$ = mean and maximum Shields parameter respectively. The quantities θ_{net} and θ_{cn} represent the net contribution of the shear stress to the transporting velocity during a wave cycle in the direction parallel and normal to the waves, respectively.

The suspended load q_s is computed assuming an exponential concentration profile and a constant velocity over the water column and can be expressed as

$$\mathrm{q}_s = \mathrm{u}\, c_R \frac{\varepsilon}{w_s}\left(1 - e^{-\frac{w_s h}{\varepsilon}} \right) \tag{12}$$

where w_s = sediment settling velocity, c_R = reference concentration and ε = sediment diffusivity (or turbulent mixing coefficient). The transport q_s is considered to be taken place in the direction of current because the waves are assumed to produce a zero net drift and do not contribute to the suspended sediment transport.

3 Solution Methods

In order to simulate coastal hydro and morphological processes, the governing partial differential equations for the three submodels, i.e., the energy balance Eq. (1), the depth- and wave-averaged continuity nentum Eq. (5) and the seabed level

evolution Eq. (9) are solved numerically. The integrated model is developed on a non-uniform rectangular Cartesian coordinate system. Though the wave and morphodynamic change models are used directly from the SMS in the present study, a brief description of solution schemes of the submodels are presented in the following sections.

3.1 Wave Model

The energy balance Eq. (1) is solved by means of parabolic approximation, in which the waves are assumed to have a principal propagation direction from offshore to onshore. Therefore, the computations are carried out line by line from offshore to onshore. The first term of Eq. (1) is discretized by forward difference scheme, second and third terms are discretized by QUICK scheme, diffraction term is discretized by central difference scheme and the source term is obtained by solving algebraic equations. Consequently, Eq. (1) is expressed in a finite difference form and is solved explicitly. The implementation of the numerical scheme is described in detail in Mase (2001) and Mase et al. (2005).

3.2 Hydrodynamic Model

A cell centered finite volume method is used to discretize Eq. (5) over a non-uniform rectangular control volume in a Cartesian grid with the assumption that the dependent variables are represented as piecewise constants. It is useful to rewrite Eq. (5) as

$$\frac{\partial \mathbf{U}}{\partial t} + \nabla \cdot \mathbf{F}\left(\mathbf{U}\right) = \mathbf{S}(x, y, \mathbf{U}) \tag{13}$$

In which, $\mathbf{F} = (\mathbf{E}, \mathbf{G})$ is the flux tensor, in order to introduce integral form of the equations over a fixed control volume Ω:

$$\int_{\Omega} \frac{\partial \mathbf{U}}{\partial t} d\Omega + \int_{\Omega} \left(\nabla \cdot \mathbf{F}\right) d\Omega = \int_{\Omega} \mathbf{S} d\Omega \tag{14}$$

In the 2D approach, a discrete form of Eq. (14) is applied to each cell Ω with dimension $(\Delta x, \Delta y)$ so that the volume integrals represent integrals over the area of the cell and the surface integrals represent the total flux through the cell boundary Γ. Assuming $\mathbf{U}$ as the average value of conservative variables over the volume Ω at a given time, from Eq. (14) and applying Gauss divergence theorem to the second integral, the conservation equation can be written as

$$A \frac{\partial \mathbf{U}}{\partial t} + \int_{\Gamma} \left(\mathbf{F} \cdot \mathbf{n}\right) d\Gamma = A\mathbf{S} \tag{15}$$

where A is the cell area and $\mathbf{n}$ is the unitary outward normal.

A two-dimensional discrete finite volume formulation of system of Eq. (15) with explicit scheme, which applies forward Euler discretization to time derivative, on a non-uniform rectilinear grid with spacing $(\Delta x, \Delta y)$, leads to the inherently conservative method:

$$\mathbf{U}_{i,j}^{n+1} = \mathbf{U}_{i,j}^{n} - \frac{\Delta t}{\Delta x}\left(\mathbf{E}_{i+1/2,j}^{*} - \mathbf{E}_{i-1/2,j}^{*}\right) - \frac{\Delta t}{\Delta y}\left(\mathbf{G}_{i,j+1/2}^{*} - \mathbf{G}_{i,j-1/2}^{*}\right) + \Delta t \mathbf{S}_{i,j} \qquad (16)$$

in which $\mathbf{E}_{i\pm1/2}^{*}, \mathbf{G}_{i\pm1/2}^{*} =$ numerical convective flux functions through the cell interfaces $\Gamma_{i\pm1/2,j}$ and $\Gamma_{i,j\pm1/2}$ (Figure 2) respectively; $\Delta t =$ time step size and $\mathbf{S}_{i,j} =$ a discretization of the source term. In this study Roe's approximate Riemann solver (Roe 1981) is chosen for convective flux computation. The details of the Roe's Riemann solver and its application to two-dimensional shallow water equations may be found in Kuiry et al. (2008). One may refer to Kuiry et al. (2009) for detail discretization of the source term $\mathbf{S}$.

3.2.1 Balancing of Hydrostatic Flux and Bed Slope Term

The discretization of the bed slope source term for finite volume shallow water flow models has been the subject of numerous recent studies (Nujic 1995; Burguete and García-Navarro 2001; Zhou et al. 2001; Kuiry et al. 2008). In this work, this term is treated in a simple way, which also satisfies a compatibility relation with the hydrostatic flux term. In the absence of flows through the boundaries, the momentum equations reduce to

$$\int_{\Gamma}\left(\frac{1}{2}gH^{2}\right)n_{x}d\Gamma = g\int_{\Omega} H\frac{\partial h}{\partial x}d\Omega \qquad (17)$$

$$\int_{\Gamma}\left(\frac{1}{2}gH^{2}\right)n_{y}d\Gamma = g\int_{\Omega} H\frac{\partial h}{\partial y}d\Omega \qquad (18)$$

This indicates that the sum of the hydrostatic pressure forces on the vertical faces of a cell in a particular direction is numerically equal to the weight component of the water contained within the cell in the same direction. In the discretization procedure, each cell is assumed to be composed of two triangular sub-cells for which bed slopes are calculated and the flow depth in hydrostatic term at each cell face is replaced by an equivalent water depth (Kuiry et al. 2008). Therefore, the bed slope term is expressed as the summation of two source terms for two triangular sub-cells. The discretization technique can be expressed mathematically as:

$$\int_{\Gamma}\left(\frac{1}{2}gH^2\right)\cdot\mathbf{n}d\Gamma=\sum_{m=1}^{NE}\left(\frac{1}{2}gH_{eq}^2\right)\cdot\mathbf{n}\Delta\Gamma_m \tag{19}$$

$$g\int_{\Omega}H\left(\nabla\cdot h\right)d\Omega=g\sum_{s=1}^{2}H_{cs}A_s\mathbf{S}_{0s} \tag{20}$$

where $\Delta\Gamma_m =$ m^{th} edge length; $NE =$ total number of edges in the cell ($NE=4$); $H_{cs} =$ water depth at centroid; $A_s =$ area of the sub-cell; and $\mathbf{S}_{0s} =$ bed slope in the respective coordinate direction of the s^{th} sub-cell. The slope of each triangular sub-cell is computed considering the three vertices lying on a triangular plane (Kuiry et al. 2008). The discretization method described above exactly satisfies Eqs. (17) and (18) under still water condition.

3.2.2 Hydrodynamic Model Stability

The time integration scheme adopted is explicit and must satisfy the stability condition so that no wave resulting at an interface can travel beyond the extent of its stencil. The stability criteria adopted is

$$\Delta t=C_r\min\left[\min\left(\frac{\Delta x}{u+\sqrt{gH}}\right),\min\left(\frac{\Delta y}{v+\sqrt{gH}}\right)\right]_{i,j} \tag{21}$$

where $C_r =$ Courant number between zero and one. In this study $C_r = 0.75$ is used.

3.3 Sediment Transport and Morphodynamic Change Model

In the present study the Lund-CIRP model available in SMS is used to compute bed evolution. In this submodel, the sediment transport properties and transport rates are calculated at the cell centers. After transport rates are calculated by the Lund-CIRP formulae for all the cells in the domain, they are mapped back to the cell faces such that *x*-directed rate is located on the left face center and the *y*-directed rate is located on the bottom face center. These instantaneous transport rates are calculated at the

sediment transport time step Δt_{sed} and instantaneous rates averaged over the morphologic change time step are evaluated at the time step Δt_{morph}. The Eq. (9) is then solved for every cell by means of forward Euler scheme to compute the bed changes over the time period Δt_{morph}. The implementation of the model is explained in Buttolph et al. (2006).

4 Model application

Due to severe storm or hurricane, the flow field in and around of an inlet becomes complex and flow regimes may change from sub- to supercritical. The study of hydraulics of such flow field and morphological changes are important for engineering design of inlet structures. The present model is applied to such an idealized coast with an inlet of 30 m wide. The coast is designed in such a way that it represents the basic geometry, inlet entrance configuration, offshore slope, wave and storm forcings at a medium size inlet. Figure 3 shows the flow domain with bathymetry varying from 30 m at offshore to 3 m deep at the bay. The initial bathymetry does not include any developed flood or ebb shoal and therefore it represents a newly opened coastal inlet.

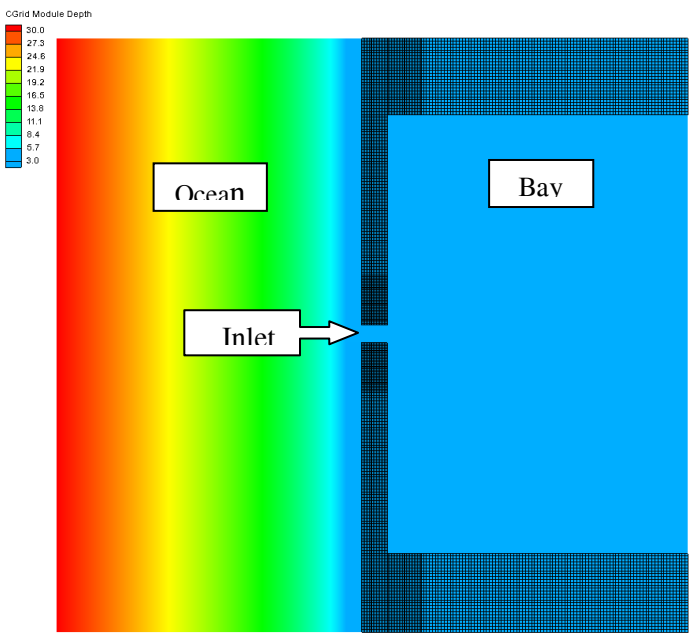

Figure 3: Idealized coast with initial

The wave-current-morphodynamic processes in the inlet are investigated when the inlet is hit by a severe storm at the offshore boundary. A rectangular mesh grid is generated for the flow domain with the help of SMS grid generator with the grid resolution 25 m in the channel and 50 m in the offshore. The three processes are

simulated sequentially by the steering option of the SMS package. An irregular spectral wave with significant wave height $H_s = 3.5$ m, a peak period $T_p = 9$ s, and mean incident angle $= 30^{\circ}$ (JONSWAP spectrum $\gamma = 3.3$) is imposed at the offshore boundary. The storm surge shown in Figure 4 with a peak of 7.0 m is also imposed at the offshore boundary. The other ocean boundaries are specified as free flow boundaries. The radiation stress gradients calculated from the specified wave is held constant throughout the simulation. The uniform grain size in the coast is specified as 0.2 mm. The Lund-CIRP formulations as presented before are used to compute the total sediment transport rate and the bed evolution is calculated using Eq. (10).

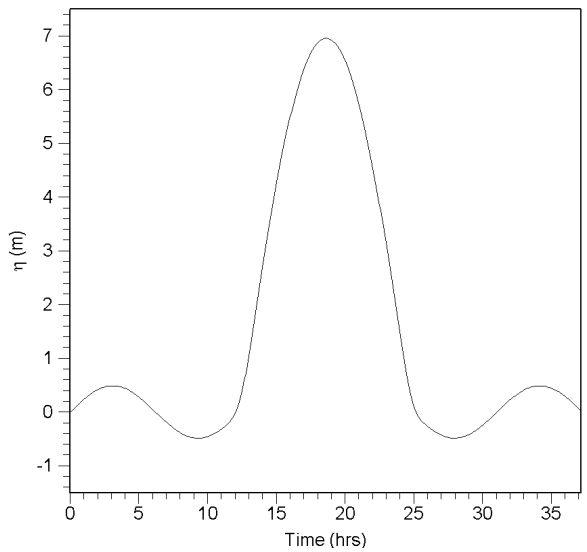

Figure 4: Storm surge imposed at the offshore

The results are reported at two time intervals at 19 hrs and 27 hrs, respectively. At 19 hrs, flood tide passes through the inlet and strong velocities are developed there. Figure 5 shows the morphology changes at 19 hrs and Figure 6 shows the computed bed elevations at the same time interval. The strong velocities cause significant erosion and develop scour hole at the entrance of the inlet and deposition at the bay side. Thus a flood shoal is created in the bay which is frequently observed in a real coastal inlet. Due to the strong flood tide at this time interval, the long shore currents from the south side of the domain also move into the channel while the long shore currents developed in the north side move to the north. At 27 hrs, during the ebb tide, flow passes from the bay to the offshore direction. At this instant, bed erosion takes place at the entrance of ebb tide in the bay side and deposition takes place at the offshore side. Ebb shoals are developed at the offshore due to deposition of the bed materials. It can be observed that the ebb shoals are asymmetric. Such asymmetric shape is expected due to the oblique incident wave which drives the long shore currents to the north. Figure 7 shows the computed bed elevations at 27 hrs. In both the cases, it is observed that significa akes place in and around the inlet.

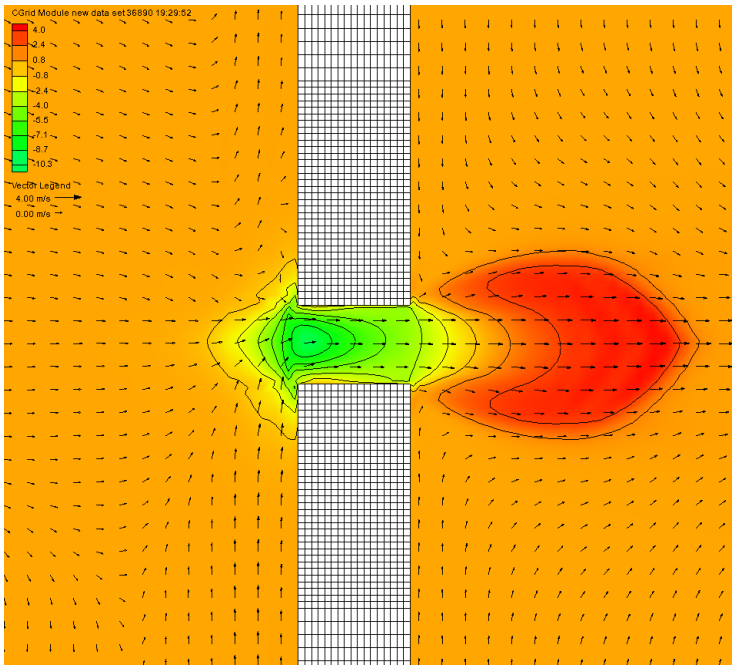

Figure 5: Bed elevation change at t = 19 hrs during flood tide

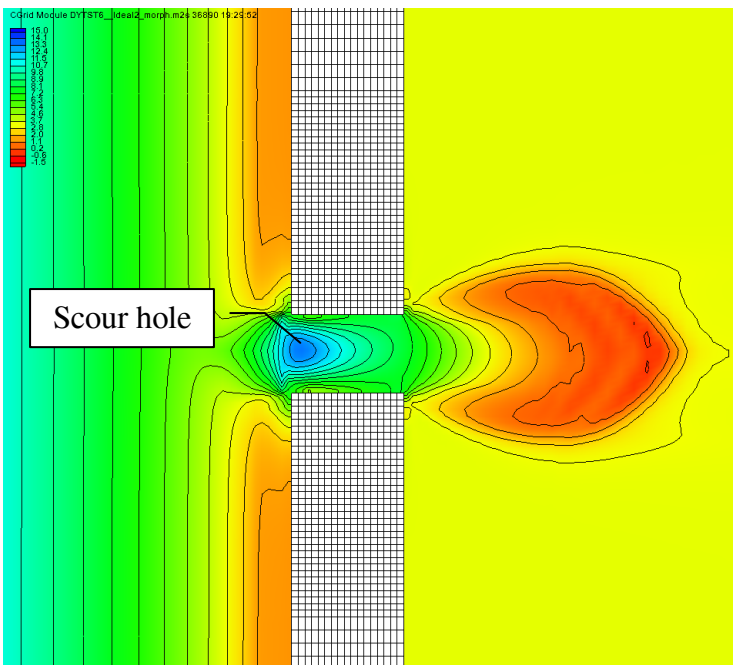

Figure 6: Computed bed elevation at t = 19 hrs during flood tide

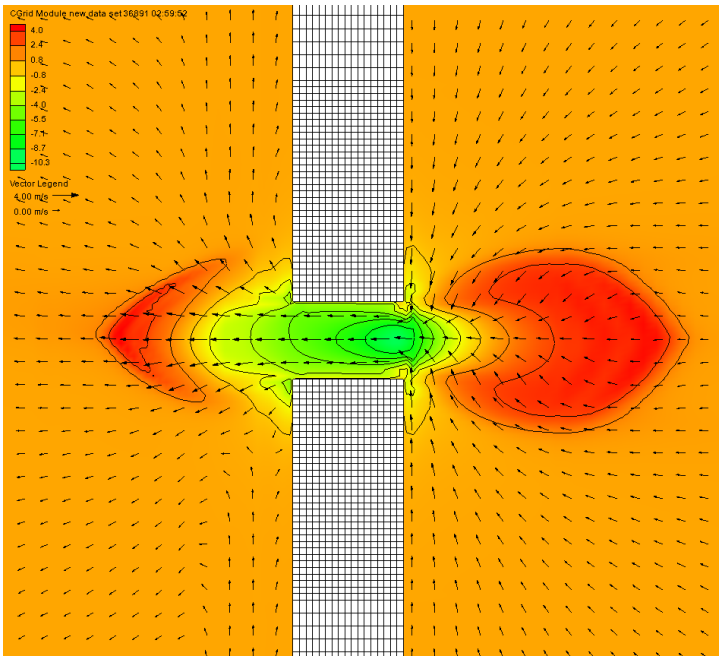

Figure 7: Bed elevation change at t = 27 hrs during ebb tide

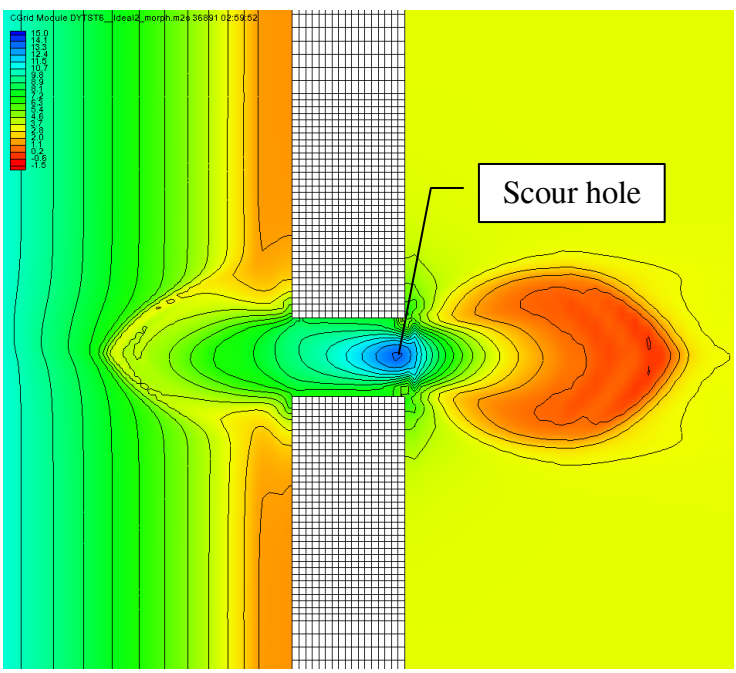

Figure 8: Computed bed elevation at t = 27 hrs during ebb tide

Though the results shown in this study need further investigations to determine the accuracy of the model, it can be stated that the present model can be applied to study wave-current-morphodynamic processes. The shock capturing property of the hydrodynamic model helps to simulate the complex flow scenario in the inlet when attacked by a severe storm.

5 Conclusions

A numerical model for systematic computations of wave-current-morphodynamic processes in two-dimensions is developed. The two-dimensional shallow water equations are solved by shock-capturing finite volume method considering the effects of short wave-averaged radiation stress, wind stress, Coriolis force and strong bottom irregularities. The hydrodynamic model is coupled with the CMS-Wave and morphodynamic models of SMS package in order to simulate wave deformation, transformation and morphological changes in coastal inlets and their adjacent coasts. The applicability of the model is tested by simulating a severe storm surge attacking an idealized coast with an inlet which represents the geometry of a medium size coast. The successful simulation shows that the storm surge causes significant bed erosion, deposition and formation of flood and ebb shoals. The effect of long shore currents is observed especially during the ebb shoal formation in the offshore. The overall results seem to be satisfactory and representative for preliminary investigation of applicability of such a process based numerical model and further study is required to examine the predictive accuracy of the model.

ABSTRACT

A lattice Boltzmann method (LBM) on high performance computing (HPC) environments for three-dimensional shallow water flow fields is developed. Recently, the LBM has become an attractive numerical method to solve various fluid dynamics phenomena. However, LBM has not been extensively applied to shallow water equations. The shallow water equations have wide applications in ocean and hydraulic engineering which can benefit from the advantages of the LBM. The standard LBM for two dimensional shallow water flows is extended to three dimensional flows by solving the multilayer shallow water equations. LBM is an attractive method for solving the multilayered shallow water equations because the extension to a multilayer formulation is straight forward and all simplicities and advantages of the LBM are retained. The performance of the LBM for the multilayer shallow water equations is investigated and optimized in HPC environments. We numerically demonstrate the applicability of the LBM in three dimensional shallow water flows and the LBM performance using OpenMP.

INTRODUCTION

In the last decade, the lattice Boltzmann (LB) method or LBM has become a powerful numerical method for simulating fluid flows (Chen and Doolen 1998). The method is based on statistical physics and models the fluid flow by tracking the evolution of distribution functions of the fluid particles in discrete phase (velocity) space. The essential approach in the LB method lies in the recovery of macroscopic fluid flows from the microscopic flow behavior of the particle movement. The benefits of this description are that the LBM does not involve the solution of global system of equations (locality), which makes it very suitable for parallel computing. Recently, this has become an important feature for numerical methods as high performance computing (HPC) systems are currently being designed to model large scale engineering problems.

The method has been shown to be effective for simulating flows in complicated geometries and implementation on parallel computer architectures (Kandhai et al. 1998). Furthermore, the method has become an alternative to other numerical methods like finite difference, finite element and finite volume methods in

computational fluid dynamics. Due to its attractive feature, recently the LBM has found a wide range of applications including wind-driven ocean circulation (Salmon 1999; Zhong et al. 2006), discontinuous flows with shocks (Zhou et al. 2004; Zhou 2007), and tidal flows on complex geometries with irregular bathymetry (Thömmes et al. 2007). Such practical flow problems of tidal flows in an estuary or coastal regions, rivers, reservoir, and open channel flows are not trivial to simulate since the geometry can be complex and the topography irregular.

In order to take advantage of the shallow water equations while avoiding the drawbacks of the depth averaged models, a multilayer system (Audusse 2005) was adopted in this study. The multilayer shallow water equations have been introduced solved by traditional finite difference, finite element and finite volume methods. Abgrall and Karni (2008) developed relaxation schemes to solve the two-layer shallow water equations. Audusse et al. (2008) extended previous works (Audusse et al. 2006; Audusse and Bristeau 2007) to simulate dam break problems using a finite volume solver.

The objective of this study is to extend the LB formulation to solve the multilayer shallow water equations for three-dimensional shallow water flow problems on irregular boundary geometry and bathymetry. We focus on the application of the multilayer shallow water equations to the problems of wind driven circulation. We implement the LB method on a shared memory HPC system, an IBM p575 in the Center for Computation & Technology, Louisiana State University. In this study, we develop our LB code written in Fortran 90 and parallelized with OpenMP (Chapman and Massaioli 2005) using domain decomposition and cache optimization.

MULTILAYER SHALLOW WATER EQUATION

A multilayer model is based on converting a three-dimensional problem into a number of coupled two-dimensional problems in layers as shown in Figure 1. The governing equations are similar to the traditional shallow water equations with additional terms for the transfer of momentum and mass flux between the layers. This results in the multilayer shallow water equations given as follows:

$$\frac{\partial h^{(\ell)}}{\partial t} + \frac{\partial \left(h^{(\ell)} u_i^{(\ell)} \right)}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial \left(h^{(\ell)} u_i^{(\ell)} \right)}{\partial t} + \frac{\partial \left(h^{(\ell)} u_i^{(\ell)} u_j^{(\ell)} \right)}{\partial x_j} + \frac{\partial}{\partial x_i} \left(\frac{1}{2} g h^{(\ell)} \sum_{m=1}^{M} h^{(m)} \right) = \nu \left[\frac{\partial^2 \left(h^{(\ell)} u_i^{(\ell)} \right)}{\partial x_j \partial x_j} \right] + F_i^{(\ell)} \tag{2}$$

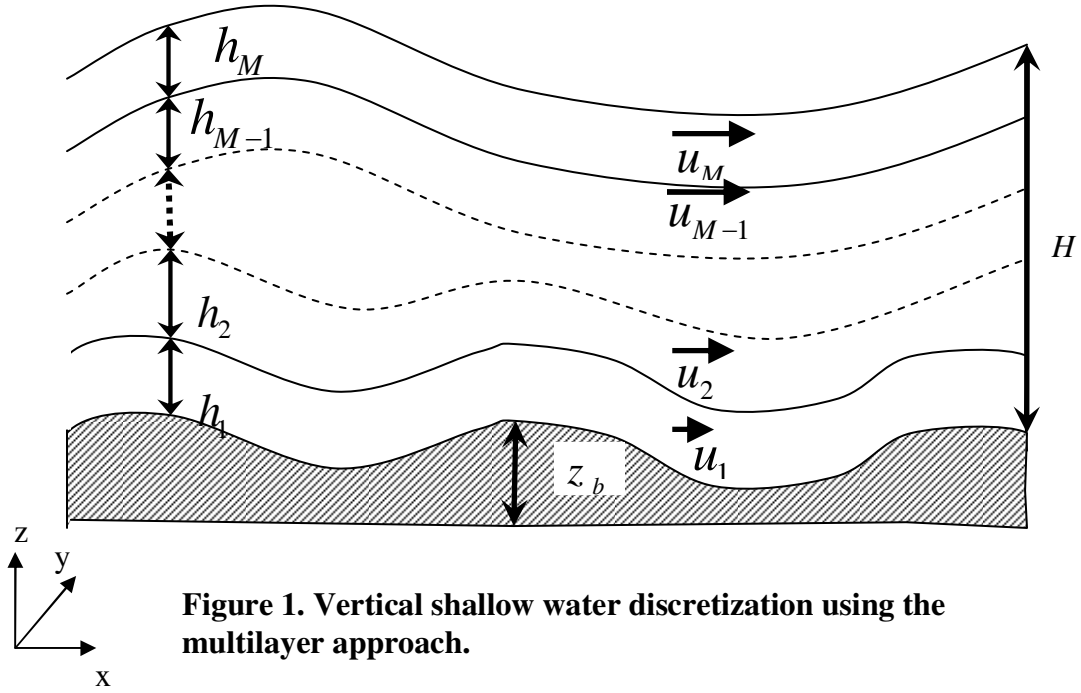

Figure 1. Vertical shallow water discretization using the multilayer approach.

where $h^{(\ell)}$ is the local water height in layer ℓ and $u_i^{(\ell)}$ is the local velocity component in the i direction in layer ℓ, $F_i^{(\ell)}$ is the external force acting on layer ℓ, g is the gravitational acceleration, ν is the dynamic viscosity, x_i is the Cartesian coordinate, and t is time. The external force consists of the wind driven forcing term (only for the top layer), $F_{wi}^{(\ell)}$, the bed slope forcing term, $F_{Pi}^{(\ell)}$, the vertical viscosity term, $F_{\mu i}^{(\ell)}$, and the Coriolis forcing term, $F_{Ci}^{(\ell)}$ as follows

$$F_i^{(\ell)} = F_{wi}^{(\ell)} + F_{Pi}^{(\ell)} + F_{\mu i}^{(\ell)} + F_{Ci}^{(\ell)} \tag{3}$$

$$F_{wi}^{\ell} = \delta_{M\ell} \frac{\rho_a}{\rho_w} C_W u_{Wi} \sqrt{u_{Wi} \cdot u_{Wi}} \tag{4}$$

$$F_{Pi}^{(\ell)} = -g h^{(\ell)} \frac{\partial z_b}{\partial x_i} \tag{5}$$

$$F_{\mu i}^{(\ell)} = -\kappa \delta_{1\ell} u_i^{(\ell)} + 2\mu \left(1 - \delta_{M\ell}\right) \frac{u_i^{(\ell+1)} - u_i^{(\ell)}}{h^{(\ell+1)} - h^{(\ell)}} - 2\mu \left(1 - \delta_{1\ell}\right) \frac{u_i^{(\ell)} - u_i^{(\ell-1)}}{h^{(\ell)} - h^{(\ell-1)}} \tag{6}$$

$$F_{Ci}^{(\ell)} = \begin{cases} f_c h^{(\ell)} u_y, & i = x \\ -f_c h^{(\ell)} u_x, & i = y \end{cases} \tag{7}$$

where $\delta_{1\ell}$ and $\delta_{M\ell}$ are the Kronecker delta function; κ is the bottom friction coefficient, and μ is the interfacial friction coefficient which acts between layers. The water depth is the sum of local water heights of all layers, i.e., $H = \sum_{m=1}^{M} h^{(m)}$.

LATTICE BOLTZMANN METHOD

The LB model is used to solve the shallow water equations for each layer. The LB equation is obtained by integrating the discrete Boltzmann equation:

$$\frac{\partial f_\alpha}{\partial t} + e_{\alpha i}\frac{\partial f_\alpha}{\partial x_i} + F_i\frac{\partial f_\alpha}{\partial e_{\alpha i}} = -\frac{1}{\lambda}\left(f_\alpha - f_\alpha^{eq}\right), \tag{8}$$

for describing dynamics of local particle distribution functions in a discrete velocity field, where f_α is the particle distribution function moving along α direction, f_α^{eq} is the equilibrium distribution function (EDF) along α direction, λ is the relaxation time, $\mathbf{e}_\alpha = \{e_{\alpha i}\}$ is the streaming velocity along α direction, F_i is the external force per unit mass in the shallow water equations, $\left(f_\alpha - f_\alpha^{eq}\right)/\lambda$ is the Bhatnagar-Gross-Krook (BGK) collision operator (Bhatnagar et al. 1954), which represents changes in f_α due to particle collisions. Each direction represents a characteristic direction for the corresponding particle distribution function.

The lattice Boltzmann equation for simulation of Equations (1) - (7) is obtained by integrating Eq. (8) in time along the α direction for each layer as follows:

$$f_\alpha^{(\ell)}\left(\mathbf{x}+\mathbf{e}_\alpha\Delta t, t+\Delta t\right) = f_\alpha^{(\ell)}\left(\mathbf{x},t\right) - \frac{1}{\tau}\left(f_\alpha^{(\ell)}\left(\mathbf{x},t\right) - f_\alpha^{(\ell)eq}\left(\mathbf{x},t\right)\right) + \frac{\Delta t e_{\alpha i}}{6e^2}F_i^{(\ell)}\left(\mathbf{x},t\right) \tag{9}$$

where $\tau = \lambda/\Delta t$ is relaxation time parameter, $e = \Delta x/\Delta t$ the lattice speed, Δx is the lattice size and Δt is the time step.

In each time step, the particle distribution functions arrive to their neighboring nodes at the same time through prescribed lattice connections. Therefore, the streaming velocity $\mathbf{e}_\alpha$ along α direction is determined by the lattice connection and size. In this study, we consider the two dimensional lattice with nine discrete velocities, known as the D2Q9 lattice, shown in Figure 2. The streaming velocity for D2Q9 is

$$\mathbf{e}_\alpha = \begin{cases} (0,0) & \alpha = 0 \\ e\left[\cos\left(\frac{1}{4}(\alpha-1)\pi\right), \sin\left(\frac{1}{4}(\alpha-1)\pi\right)\right], & \alpha = 1,2,3,4 \\ \sqrt{2}e\left[\cos\left(\frac{1}{4}(\alpha-1)\pi\right), \sin\left(\frac{1}{4}(\alpha-1)\pi\right)\right], & \alpha = 5,6,7,8 \end{cases}$$

The water depth and flow velocity for each layer are calculated as the zero and first moments of the distribution functions:

$$h^{(l)} = \sum\nolimits_\alpha f_\alpha^{(l)} \qquad\qquad h^{(l)}u_i^{(l)} = \sum\nolimits_\alpha e_{\alpha i} f_\alpha^{(l)}$$

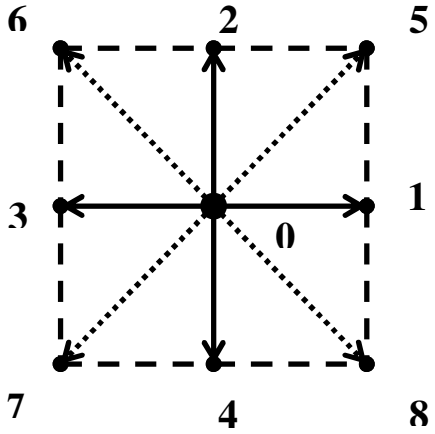

Figure 2. D2Q9 Lattice

The expressions for the EDFs are given by Chen and Doolen (1998):

$$f_\alpha^{(l)eq} = h^{(l)}\omega_\alpha\left(\frac{c_s^2}{e^2}+\frac{\mathbf{u}^{(l)}\cdot\mathbf{e}_\alpha}{e^2}+\frac{3}{2}\frac{\left(\mathbf{u}^{(l)}\cdot\mathbf{e}_\alpha\right)^2}{e^4}-\frac{1}{2}\frac{\mathbf{u}^{(l)}\cdot\mathbf{u}^{(l)}}{e^2}\right) \quad ,\alpha>0$$

$$f_\alpha^{(l)eq} = h^{(l)} - \sum_{\alpha=1}^{8} f_\alpha^{(l)eq}$$

where c_s^2 is known as the squared speed of sound, which in this study is a numerical parameter that relates to the wave celerity. For D2Q9, the weighting coefficients are $\omega_\alpha = 1/3 \quad ,\alpha = 1,2,3,4$ and $\omega_\alpha = 1/12 \quad ,\alpha = 5,6,7,8$.

To ensure that the LB model solves the multilayer shallow water equation with proper LB parameters, the Appendix performs the recovery of the macroscopic differential equation by Chapman-Enskog multi-scale analysis. We obtain $c_S^2 = \frac{1}{2}gH$ and $\nu = \frac{e^2}{3}\Delta t\left(\tau - \frac{1}{2}\right)$.

HIGH PERFORMANCE COMPUTING

OpenMP parallelization is a straightforward extension of serial coding, according to the simple recipe: a) add work distribution directives; b) carefully control variable scoping; c) if needed, choose the most suitable parallel loop scheduling; d) if needed, take care of false sharing of variables among threads. Although this approach works with some very simple codes, most programs parallelized in this way do not scale beyond a small number of processors. (Massaioli and Amati 2002). Often the same codes scale better when parallelized in Message Passing Interface (MPI) on the same symmetric multiprocessing (SMP) system, in spite of the fact that message passing causes memory to memory copies not needed

with shared memory parallelization. A computational advantage of the LBM is that its implementation leads to computational kernels that are very suitable for parallelization in both shared and distributed memory paradigms.

Parallel performance is often evaluated by two factors: parallel speedup, $S = T_1/T_N$, and efficiency, $E = S/N$, where N is the number of threads (processors), T_1 is the computation time for one thread and T_N is the computation time for N threads. Numerical simulations based on domain decomposition with cache optimization using OpenMP were performed. The simulations were run on grids of size $1024\times1024\times5$ for 1000 time steps. Table 1 shows the execution time, speed up and efficiency for explicitly controlled cache optimized implementations. The speed up and efficiency scale up to 16 threads (processors).

Table 1: LBM Performance

Threads	*Execution Time (s)*	*Speed up*	*Efficiency*
1	36.782	1	1
2	17.725	2.00	1.00
4	9.358	3.99	0.98
8	4.876	7.54	0.94
12	3.157	11.65	0.97
16	2.461	14.94	0.93

NUMERICAL RESULTS

We demonstrate the three dimensional multilayer shallow water LBM by simulating wind driven circulation in Lake Pontchartrain, Louisiana; an area of interest to coastal and environmental engineers. Lake Pontchartrain is an estuarine lake in Southeastern Louisiana with a mean depth of $3.8\,m\,(0.5\,m - 5\,m)$ and an area of approximately $1630\,km^2$. The LBM is applied to wind driven circulation to illustrate it its ability to handle irregular bathymetries and boundaries. A constant wind shear stress is applied throughout and a wind speed of $5\,m/s$ in the North West direction is used.

In the LBM formulation, the computational domain is covered by $272\times160\times5$ lattices with $\tau = 0.6$ $\Delta x = 250$ m, $\Delta t = 0.5$ s, and $e = 500\,m/s$. The initial conditions are applied by initializing the distribution functions to an EDF with the initial water depths defined above and velocities equal to zero, i.e. $f_\alpha = f_\alpha^{eq}\left(h = h^{init}, u_x = 0, u_y = 0\right)$. Free slip bounce-back boundary conditions are applied along the borders of the lake. The simulation was run up to time, $t = 20\,hrs$. Figure 3 shows the instantaneous surface velocity field at $t = 20\,hrs$.

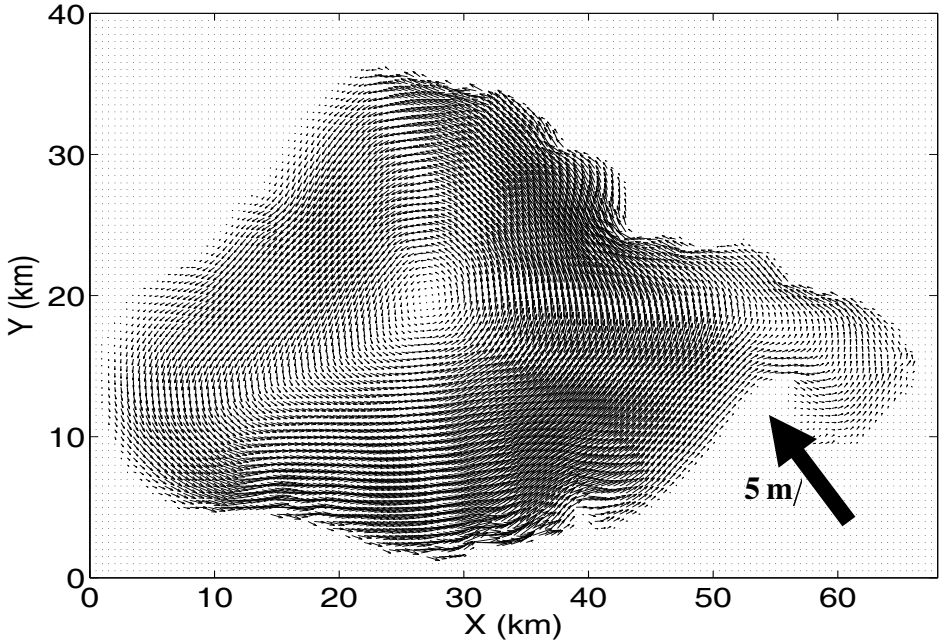

Figure 3. Instantaneous surface velocity field wind driven circulation in Lake Pontchartrain, LA at $t = 20$ hrs

CONCLUSION

The standard LBM for two dimensional shallow water flows is extended to solve the multilayer shallow water equations for three-dimensional shallow water flow problems on irregular boundary geometry and bathymetry. We numerically demonstrate the applicability of the LBM in three dimensional shallow water flows by simulating wind driven circulation in Lake Ponchartrain, LA. The LBM shows promising speedup and efficiency on a shared memory system up to 16 processors using OpenMP.

Two Dimensional Hydraulic Modeling of the Lower Skokomish River

Cassie Klumpp[1]

[1] U.S. Bureau of Reclamation, Sedimentation and River Hydraulic Group, Denver, Colorado, cklumpp@usbr.gov.

ABSTRACT

The Bureau of Reclamation's Sedimentation and River Hydraulics Group SRH-2D model was applied to the lower 10 miles of the Skokomish River, WA. This was in conjunction with a Geomorphic Study of the reach. The river is aggrading and is therefore limited in its ability to convey flood flows. The 2D model was used to identify channel capacity and areas within the reach where overbank flooding occurs. The model was applied to existing conditions in the reach, and may be used in the future for proposed changes to improve channel capacity.

INTRODUCTION

The Skokomish River is located in Washington at the southeastern portion of the Olympic peninsula near the southern extent of the Hood Canal. The river flows east from its headwaters in the Olympic Mountains and descends through narrow gorges to the Skokomish valley. The study area for modeling and geomorphic assessment is contained within the lower 10 miles of the river (see Figure 1).

The objective of the study was to construct a two dimensional (2D) hydraulic model to evaluate the present channel capacity and overbank flooding locations.

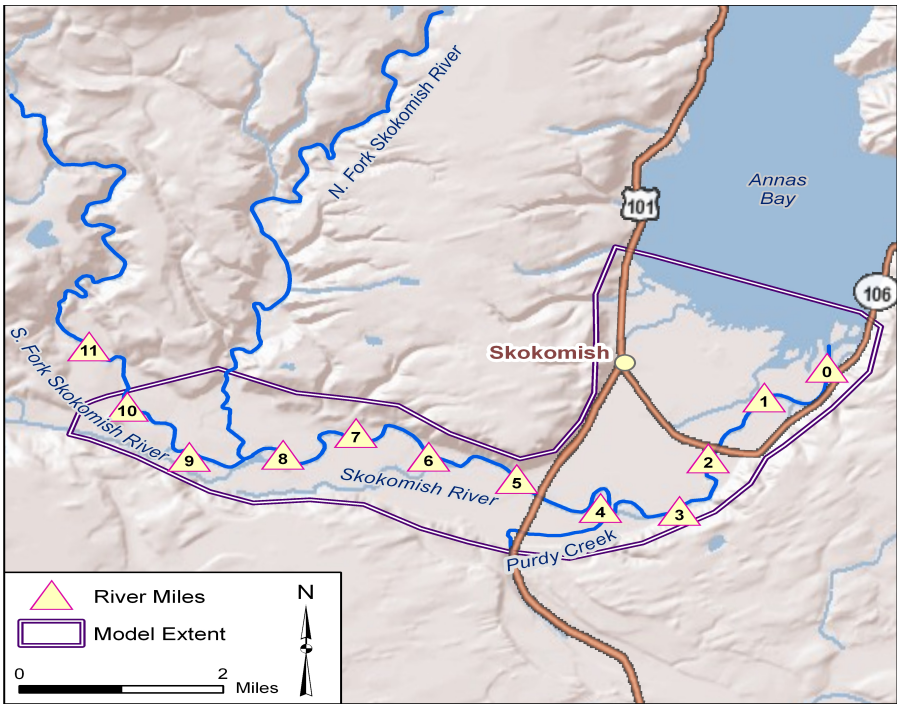

Figure 1-Project Location Map.

MODEL DESCRIPTION

SRH-2D is a 2D hydraulic model for river systems (Lai, 2007). SRH-2D is particularly useful for problems where 2D hydraulic effects are important. Examples include rivers with meander bends, a high level of connectivity with the floodplain, or multiple flow paths with varying elevations and alignments.

SRH-2D has been successfully applied to several Reclamation projects in recent years. The model version utilized in this study assumes static bed topography and, therefore, does not predict vertical incision or aggradation, or lateral migration of the channel through bank erosion. One of the major advantages of the SRH-2D model is the use of the arbitrarily shaped element method used for geometry representation. This unstructured meshing strategy allows for greater flexibility through the development of non-uniform mesh cells that can vary in size and density across the modeled area depending on the detail needed. This approach allows larger areas to be modeled while still preserving an increased density of smaller mesh cells in critical areas where more topographic detail is needed.

HYDROLOGY DATA

The Bureau of Reclamation (England, 2007) conducted a peak flow and flow duration analysis on five gages in the Skokomish basin. The gage utilized for the 2D model was the USGS gage on the Skokomish River at Potlatch (#12059500; Table 1). After 1994, the USGS no longer published peak flows at the Potlatch station for flows where the stage exceeded 15 feet (approximately 4,000 cfs) because the river

flowed out of the main channel. Return flood events were determined at the gage using the Expected Moments Algorithm methodology (England, 2007).

Table 1-Discharges for return period floods based on the USGS reference gage 12059500, Skokomish River near Potlatch, Wa for period of record 1844-2006. Gage has a drainage area 117 square miles, and is located just upstream of the U.S. Highway 101 Bridge.

Annual Exceedance Probability (%)	Return Period (years)	LP-Model Estimate (cfs)	Peak Discharge (cfs) 5 % Confidence Limit	95% Confidence Limit
75	1.33	13,500	11,900	15,000
66.7	1.5	14,900	13,300	16,500
50	2	17,500	15,800	19,300
20	5	23,400	21,300	25,900

MODEL GRID AND TOPOGRAPHY

A Surface Water Modeling System (SMS versions 9.2 and 10.0, Environmental Modeling Systems, 2008) pre-processor was used to generate the mesh. Polygon and triangular elements were used to delineate the unstructured mesh. Polygon boundaries, inside of which the mesh was generated, were initially based on roughness variations. These boundaries were then further sub-divided to allow for proper representation of flow lines, such as in meander bends. The final iteration in creating a surface representation was to increase the mesh cell density in areas where an improved representation of topographic breaks was needed.

The unstructured mesh contains 134,361 rectangular and triangular elements and 116,450 nodes. The mesh generated for the 2D model is shown in Figure 2.

Three different sources were used to obtain elevation values for the mesh:

- 1994 Photogrammetry
  Source: Bell Walker & Associates
  Description: A photogrammetry model was built with a stereoscopic drafting station using GPS registered aerial photography.
- 2002 bare earth Light Detection and Ranging (LiDAR) data
  Source: Puget Sound LiDAR Consortium
  Description: Bare earth LiDAR containing the X,Y,Z values of all the LiDAR returns classified as ground.
- 2007 In-channel ground survey data
  Source: USACE, October 2007

Description: Top of bank-to-top of bank cross section survey from RM 10 to 2.

A Triangular Irregular Network (TIN) was created from either a combination of the photogrammetry data and in channel survey data, or LiDAR data and channel survey data. The survey data was limited to cross-section lines. Additional points were interpolated between cross-sections and used to improve the quality of the TINs. The limitations of the topographic data sets were as follows:

- No survey data was available for the mainstem Skokomish channel just above RM 2.
- Hydraulic controls (riffles) that influence water surface elevation may have been missed if they were not captured by the cross section surveys.
- LiDAR data did not have vegetation removed in the bare earth model in densely vegetated areas.
- Photogrammetry appeared to have less topographic detail than LiDAR in overbank areas.
- Channel survey data for the North Fork, Vance Creek, and Purdy Creek were limited or not available.

A text file was imported into ArcGIS (Esri, 2008) as a point layer. Elevation data were added to the point features by interpolating elevation data from the TIN surface. The elevation data was then inserted back into SMS for input to the 2D hydrodynamic model. A typical example of the mesh topography is shown in Figure 3.

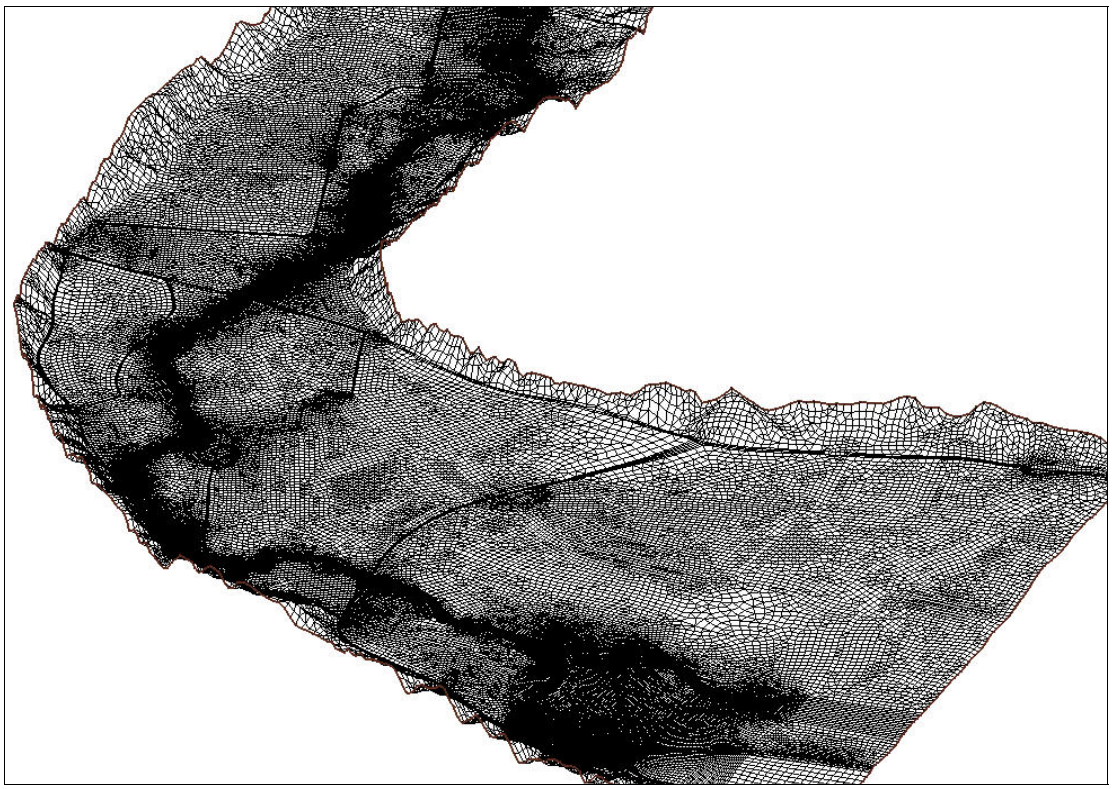

Figure 2-Grid for the lower portion of the model.

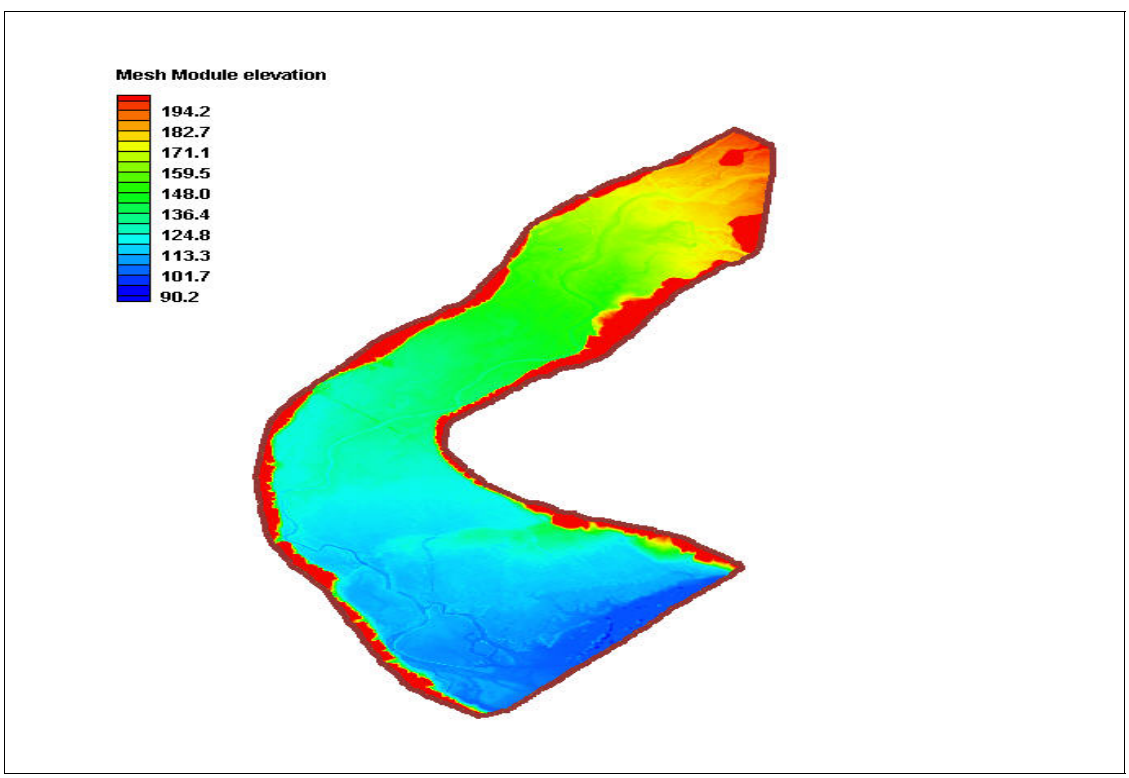

Figure 3-Typical mesh topography.

MODEL VERIFICATION

Comparisons between model results and measured data were made with LiDAR and photogrammetry data sets. The 2D model was calibrated to measured data for both low flow and high flow conditions. Measured low flow water surface elevation data were collected in late July and early August, 2007 (U.S. Army Corps of Engineers, 2007). Flow data during the same time period were based on the USGS gage, Skokomish River near Potlatch. High flow calibrations were based on measured flood data collected by the U.S. Army Corps of Engineers during the December, 2007 event. Manning's n roughness values were varied to validate model predictions. A comparison of measured and predicted data for the December flood are shown in Table 2.

Table 2. Comparison of measured high water surface elevations and model water surface elevations for the December Flood.

Point #	Mile Skok. Valley Rd.	HWM Elevation (feet)	Model WS Elevations (36,000 cfs) (feet)	Model WS Elevations (17,500 cfs) (feet)
20	4.98	80.97	82.0	80.2
14A	3.8	60.54	58.3	57.7
14B	3.8	60.54	59.7	58.6
13A	3.46	54.76	55.8	55.0
13B	3.46	54.76	55.8	54.0
10A	2.95	53.32	53.7	52.9
10B	2.95	53.32	53.7	52.9
8	2.5	47.9	47.0	46.7
4	1.75	41.49	40.7	36.6
3	1.45	36.07	38.0	35.4

MODEL RESULTS

Model simulations began with a dry channel bed. Simulations were continued until the model had reached a near steady state condition. The model was determined to have reached a steady state condition by comparing two model runs (point files as ascii data sets) at different simulation time periods in ARCGIS 9.2 (ESRI, 2008); the two data sets were joined together as shapefiles and velocities and or water depths were compared. The mean sum of the difference in water depths was less than 0.01 feet indicating an equilibrium condition had been reached. This was typically using a 3 second time step and running the model for 400,000 time steps.

One of the primary goals of the modeling was to determine current channel capacity and locations where a flow spills out of the channel. The current channel capacity based on the 2D model LiDAR topography appears to be around 2,000 cfs. The channel capacity for the photogrammetry topography appears to be slightly less than 2,000 cfs (Figure 4). Model results show the majority of the main channel flow losses occur between RM 8 and 5. A significant narrowing of the river occurs at RM 8 and flows have exited the channel here historically. Additional channel losses occur between RM 6 and 5 (at the U. S. Highway 101 Bridge).

High flow results (Figure 5) show significant flow loss from the main channel, especially for the 100-year flood of 36,000 cfs. For the 100 year flood, flows decrease significantly as you go downstream between RM 10 and 8. The channel narrowing at RM 8 affects all of the higher flows. Flows appear to increase between RM 5 and 2 as tributaries bring flows back into the main channel, especially for flows between 12,000 and 36,000 cfs.

The spatial distribution of flow (inundation) is shown in Figures 6-8 for a 6,000 cfs flow event. The majority of this flow remains in the channel until RM 8, when approximately 1,600 cfs leaves the channel on river left leaving approximately 4,500 cfs in the main channel; pinch points and channel narrowing affects flows at RM 8. Most of the flow returns to the channel at RM 7. Flow leaves the channel again before RM 6 and stays outside of the main channel until roughly RM 2. More flow is seen on river right between RM 5 and 6. Channel narrowing and levees are likely affecting the flows just above RM 6.

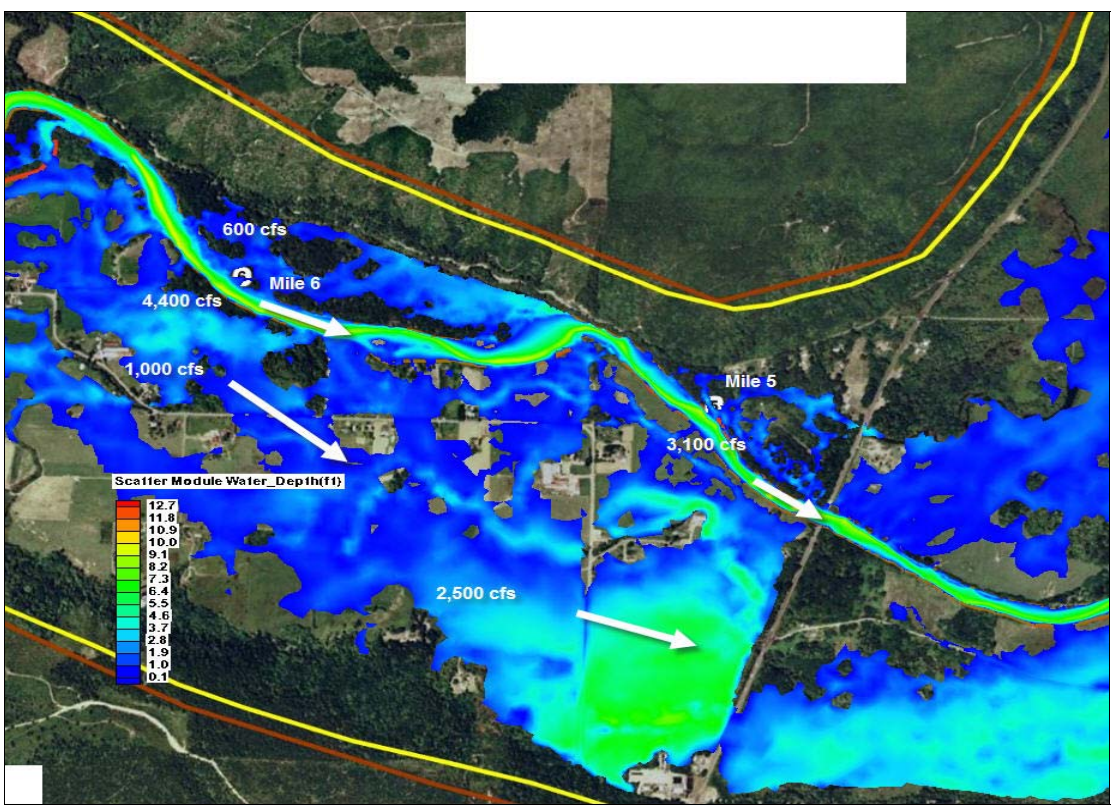

Figure 8- Spatial distribution of flow for 6,000 cfs near RM 5 and 6.

CONCLUSIONS

A two dimensional (2D) hydraulic model was applied to the lower Skokomish River reach in Mason County, WA. The purpose of the model application was to help identify the current channel capacity as well as to locate areas where flow spills out of the main channel. Significant flow exits the channel for discharges greater that 2,000 cfs. Model limitations include the lower reach from RM 2 to 0. Neither the LiDAR nor photogrammetry topography has the correct below water channel elevations. With refinement and collection of additional survey and tidal data, the base model grid can be modified to accommodate more current topography and flows.

The 2D model could be used as a tool to model future conditions including levee setbacks and flow changes for North Fork. The model can simulate a wide range of flows from a low flow of 370 cfs up to the 100-year flood (36,000 cfs). The model was validated in areas where measured data was available for both low and high flows.

USING COMPUTATIONAL MODEL – ADH TO EVALUATE RELATIONSHIP OF WATER SURFACE ELEVATION TO WING DIKES

Renjie Xia[1]

[1] Ph.D., P.E., Hydraulic Engineer, U.S. Army Corps of Engineers, Rock Island District, Clock Tower Building, P.O. Box 2004, Rock Island, IL 61204, (309) 794-5272, renjie.xia@usace.army.mil

ABSTRACT

The use of hydraulic structures, such as wing dikes, to control flow, increase the channel capacity to carry sediment, and reduce periodic dredging requirements is an important management tool utilized on the Upper Mississippi River. Wing dikes concentrate flow in the navigation channel, control flow into secondary channels, and influence the location of channel erosion and sedimentation. This study modeled the lower portion of Pool 22 of the Mississippi River from river mile 301.2 to 304.2 using the ADaptive Hydraulics (ADH) Modeling System. Alternatives, including no dikes and dikes in the main channel, were compared to evaluate the relationship of water surface elevation to wing dikes for a range of flow conditions. This study showed that (1) construction of new wing dikes initially alters the water surface elevation, but the change is small; (2) for flow discharges less than 160,000 cfs, with decreasing the river flow, the change of water surface elevation due to wing dikes decreases; and (3) for flow discharges greater than 160,000 cfs, with increasing the river flow, the change of water surface elevation due to wing dikes decreases.

ADH MODELING SYSTEM

The ADaptive Hydraulics (ADH) Modeling System, developed and supported by the Coastal and Hydraulics Lab of the Engineer Research and Development Center (ERDC) of the US Army Corps of Engineers (USACE), is a modeling package that can handle both saturated and unsaturated groundwater, overland flow, three dimensional Navier-Stokes flow, and two or three dimensional shallow water problems (ERDC 2006).

ADH is designed to work in conjunction with the Groundwater Modeling System (GMS) and the Surface Water Modeling System (SMS). The major benefits of ADH are: its use of adaptive numerical meshes employed to improve model accuracy without sacrificing efficiency; its use for supercritical flow; its rapid convergence of flows to steady state solutions; and its other features such as wetting and drying, coupled sediment transport, and wind effects (ERDC 2006).

Three files (the mesh file, boundary condition file, and hot star file) are needed to run a model in ADH. The mesh file should be constructed first and can be generated directly and quickly using the two or three dimensional GMS or the two dimensional SMS. ADH uses only triangular elements while GMS and SMS support triangular and quadrilateral elements. The mesh file created from GMS is designated with a .3dm extension while the mesh file created from SMS is designated with a .2dm extension then the user must simply change it to .3dm (ERDC 2006).

Once a mesh file has been constructed, the boundary conditions for the problem and operating parameters for ADH must be specified in the boundary condition file. This file contains a series of control cards, which fall into eight categories: operational parameters controlling the operation, iteration parameters controlling the iterative methods, material properties defining the flow and transport constants for each material, boundary strings defining the interior and surface boundaries of the problem, solution controls specifying the initial/boundary conditions, time controls specifying the time steps, output controls defining the times at which the output is printed, and series defining various parameters (ERDC 2006).

The hot start file is generated to establish the initial conditions of the problem. Initial conditions consist of depths and velocities at all nodes. Field data are often available and used to provide a starting point for many problems. A hot start file is a required part of a model; however, it may be a zero-length file (empty). For simple problems a cold start simulation (initial conditions of `0.0`) may be sufficient. Cold start problems in ADH are handled by leaving the hot-start file blank. If data types are not specified default values will be supplied (ERDC 2006).

ADH simulation provides the velocity and overland head distributions in the flow field. ADH allows the user to calculate the transport of noncohesive or cohesive sediments. The sediment is transported as suspended load and bed load, and ADH provides the bed changes and suspended sediment concentration distribution.

BACKGROUND OF POOL 22

Lock and Dam 22 is a unit of the Inland Waterway Navigation System of the Upper Mississippi River. Pool 22 extends from River Mile (RM) 301.2 at Saverton, Missouri to RM 324.9 at Lock and Dam 21 at Quincy, Illinois.

The main lock is 110 feet wide and 600 feet long with a maximum lift of 10.5 feet. The dam has a total length of 3,084 feet, including a gross length of gated sections (1,024 feet), a non-overflow earth dike section (460 feet) and an overflow earth dam section (1,600 feet). The dam is operated to maintain a minimum pool elevation of 459.5 feet in order to provide a nine-foot navigation channel (USACE 1996).

The average slope of the channel thalweg for the 23.7 river miles in Pool 22 is 0.17 foot per mile. Channel velocities vary from about 2.9 feet per second at normal conditions to about 5.9 feet per second at high flows (USACE 1996).

Dam 22 is operated to allow high water to recede naturally with the dam gates all open until an elevation of 459.5 feet is reached on the lock 22 pool gage; then, with decreasing flows, the dam is operated to maintain the elevation of 459.5 feet on the pool gage for all lower flows.

CASES INVESTIGATED

ADH was used to model the lower portion of Pool 22 from RM 301.2 to RM 304.2. This application demonstrates how ADH handles the two dimensional shallow water problems. The ADH finite element mesh was created based on bathymetric survey data (a set of coordinate

points with elevation Z values) provided by the Operations Division, US Army Corps of Engineers, Rock Island District.

The eddy viscosity was set for a value of 30 (ft^2/s) throughout different flow domains. The Manning's n ranged from 0.025 to 0.027 for the main channel and from 0.032 to 0.04 for aquatic, off-channel areas. The Manning's n for the area immediately downstream of the submersible tainter gates was assigned as 0.055 due to the presence of the stilling basin and large stone on the river bed used to control erosion.

Five flow conditions were investigated in this study (Table 1). The flow discharges of 60,000, 110,000, 162,000, 302,000, and 466,850 cfs represent the very low, low, normal, high, and very high flow (the peak of the great flood of 2008), respectively. For flow discharges less than 160,000 cfs, dam gates are closed to maintain a flat pool of 459.5 feet.

Table 1. Discharges and Water Surface Elevations at Upstream and Downstream Boundaries

	Upstream Boundary at RM 304.2	Downstream Boundary at Dam 22
Case 1	60,000 cfs	459.5 ft
Case 2	110,000 cfs	459.5 ft
Case 3	162,000 cfs	459.7 ft
Case 4	302,000 cfs	468.4 ft
Case 5	466,850 cfs	475.7 ft

The objective of this study is to evaluate the relationship of water surface elevation to wing dikes under various flow and wing dike conditions using ADH.

There are six existing wing dikes within the three-mile long river reach. Due to degradation over time, the elevations of the existing dikes are much lower than the original design elevations (Fig 1). In general, the top elevation of a dike is designed as 456.5 feet or three feet below the flat pool of 459.5 feet. Two conditions were used to test the relationship between the wing dike crest elevations and upstream river levels:

(1) The existing condition - the six wing dikes have elevations lower than 456.5 feet, and
(2) The rehabilitated wing dike condition - the six wing dikes have elevations restored to 456.5 feet (Fig 2).

For each condition, ADH simulation provides flow velocity and water surface elevation at each node, including these nodes (31 points) along the upstream boundary, which is three miles away from the Lock and Dam 22. Then, the cross-sectional average flow velocity and water surface elevation on the upstream boundary are calculated and compared.

PRIMARY RESULTS

The results were summarized in Table 2(a) to 2(e) and Table 3. It should be indicated that the results are primary, and just concluded from Pool 22 of the Upper Mississippi River. Table 2(a) to 2(e) show the changes of flow velocity and water surface elevation at each node along the

302k cfs & 468.4 ft	3.82	470.84	3.82	470.88	0.04
467k cfs & 475.7 ft	4.52	479.23	4.52	479.25	0.02

upstream boundary for the cases investigated. Table 3 compares the cross-sectional average flow velocity and water surface elevation along the upstream boundary between the existing and wing dike conditions.

Based upon the results shown in Table 3, the conclusions are:

(1) Construction of new wing dikes alters the water surface elevation, but the change is small.
(2) For flow discharges less than 160,000 cfs, with decreasing the river flow, the change of water surface elevation due to wing dikes decreases.
(3) For flow discharges greater than 160,000 cfs, with increasing the river flow, the change of water surface elevation due to wing dikes decreases.

ABSTRACT

ADH (ADaptive Hydraulics) is the modern, multi-dimensional hydraulic modeling program in development by the Coastal and Hydraulics Laboratory (CHL) of the Corps' Engineering and Research Development Center (ERDC). The model was publicly released in September 2007 but has been used by the Rock Island District (MVR) since January 2006. MVR and other Corps Districts have been successful using ADH for many 2D applications and have found the shallow-water (2-D) module of ADH to be very fast and stable compared to previously used 2D hydraulic programs (RMA2 and HiVel2D). As beta users of the software, MVR had the opportunity to provide feedback to ERDC to help shape the program towards user needs and has assisted in technology transfer to other Corps districts throughout the region by hosting training workshops.

The Navigation and Ecosystem Restoration Program (NESP) is the implementation program for the recommendations contained within the Chief's Report for the Upper Mississippi River and Illinois Waterway System Navigation Study. This presentation will discuss the advantages of ADH and how it was used for the NESP Lock and Dam 22 project. A range of modeling applications were addressed, including: design of approach channel improvements, guardwall porting design for a newly proposed guardwall, design of a fish passage structure through the existing spillway, velocity field calculations during different stages of construction, and the overall effects of sedimentation due to the proposed work. Ongoing modeling activities are evaluating the effects of multiple projects constructed within a river reach to support objectives for both navigation and ecosystem restoration.

ADH MODELING SYSTEM

ADaptive Hydraulics (ADH) Modeling System developed and supported by the Coastal and Hydraulics Lab of Engineer Research and Development Center (ERDC) of US Army Corps of Engineers (USACE) is a software package that can handle both saturated and unsaturated groundwater, overland flow, three dimensional Navier-Stokes flow, and two or three dimensional shallow water problems. ADH is designed to work in conjunction with the Groundwater Modeling System (GMS) and the Surface Water Modeling System (SMS). (ERDC 2006) SMS (the Surface-Water Modeling System) is used to view/create the model mesh and display results for 2D models; GMS (the Ground-Water Modeling System) is used for 3D models.

The major benefits of ADH are its use of grid adaptation during computations that can improve model accuracy, stability and speed. ADH has the ability to make use of multiple processors to

further increase speed. Three files are needed to run a model in ADH: the mesh file (*.3dm), the boundary condition file (*.bc), and the hot start file (*.hot).

Once a mesh file has been constructed, the boundary conditions for the problem and operating parameters for ADH must be specified in the boundary condition file. This file contains a series of one line control cards, which fall into eight categories: operational parameters controlling the operation, iteration parameters controlling the iterative methods, material properties defining the flow and transport constants for each material, boundary strings defining the interior and surface boundaries of the problem, solution controls specifying the initial/boundary conditions, time controls specifying the time steps, output controls defining the times at which the output is printed, and series defining various parameters. (ERDC 2006)

The hot start file is generated to establish the initial conditions of the problem. Initial conditions consist of the depths and velocity components. Field data are often available and used as a starting point for many problems. A hot start file is a required part of a model; however, it may be a zero-length file (empty). For simple problems a cold start simulation (initial conditions of `0.0`) may be sufficient. Cold start problems in ADH are handled by leaving the hot-start file blank. If data types are not specified default values will be supplied (ERDC 2006). It is the experience of MVR that the cold start method is much slower than using a hot start. Time differences were investigated and it was concluded that 2D river models should start with a sloping water surface estimate. Without this estimate a flat pool is assumed and computation times are much higher in order to converge upon a solution. More details of the time difference will be presented later in this paper.

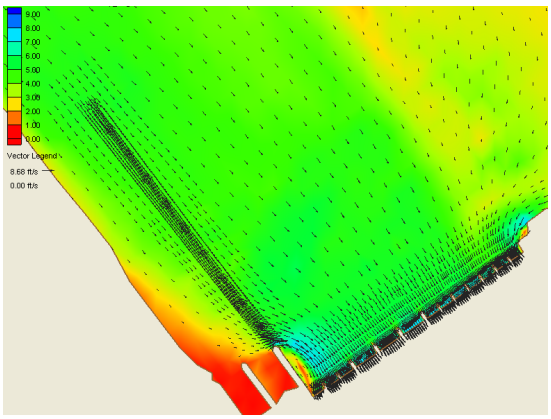
ADH simulation provides the velocity and overland head distributions in the flow field. The public release version (3893) can be found at http://chl.erdc.usace.army.mil/software, under "ADaptive Hydraulics Modeling (ADH)" and "ADH Downloads", and is intended solely for 2D swallow water applications. In a version still under development, multiple-grain sediments can be transported; ADH allows the user to calculate the transport of noncohesive or cohesive sediments. The sediment is transported as suspended load and bed load, and ADH provides the bed changes and suspended sediment concentration distribution. Currently, MVR, MVP and a few other Corps Districts have some experience with sediment ADH and are providing feedback to ERDC.

OLDER 2D FINITE ELEMENT MODELING SYSTEMS

RMA2

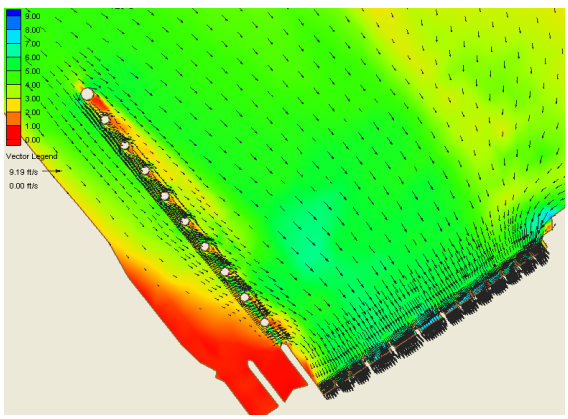
RMA2 is a 2D depth averaged hydrodynamic numerical model that computes the water surface elevations and horizontal flow velocities at nodal points of a finite element mesh that represents the river. RMA2 can be used to analyze both steady and unsteady state problems. TABS-MD was the predecessor to the RMA2 program and the names are often used interchangeably. In the past RMA2 was sometimes (erroneously) referred to as SMS, the interface to display mesh/model input and output. To run a hydro analysis, the GFGEN program was typically run first to pre-process the geometry file (mesh), then RMA2 was run to compute the hydrodynamic field. Since the computations of this finite element model are an implicit scheme, they are

performed simultaneously in a matrix form. Various RMA2 compilations were used to limit the matrix size to the number of nodes and elements in the model, which optimizes and improves computation speed. SMS (the Surface-Water Modeling System) is used to view/create the model mesh and display results. For 3D applications GMS (the Ground-Water Modeling System) is used. RMA2 was commonly used by MVR from 1995 to 2005. A common stability problem was the issue of wetting/drying elements. Modelers became experienced with troubleshooting techniques such as adding/refining elements, modifying eddy viscosities and using marsh porosity. RMA2 is no longer used at MVR due to the vast improvements in speed and stability seen with the ADH program.



HIVEL2D

HIVEL2D is a 2D numerical model used to analyze high velocity flow, and it has been adapted for use with both supercritical and/or subcritical flow fields with either lined or natural channels. HIVEL2D is a linear solver so only linear elements are created (no middle/side nodes). Using the command of Linear ↔ Quadratic in SMS, the RMA2 grid with quadratic elements can be easily converted to HIVEL2D grid with only linear elements. HIVEL2D was extended to include guard walls and was used to simulate the flow under and around the guard walls. Thus, HIVEL2D can be used to rapidly evaluate the navigation conditions in lock approaches for various guard wall configurations. HIVEL2D was the predecessor to ADH and it should now be considered obsolete.



CASE STUDY

In 2005 and 2006, the Rock Island District (MVR) developed and calibrated a 2D model of channel flow on the Upper Mississippi River near Saverton, Missouri as part of the Navigation and Ecosystem Restoration Program (NESP). The purpose of the study was to minimize impacts to navigation and the environment due to the proposed addition of a 1,200 ft lock chamber in the auxiliary bay of Lock and Dam 22 along with its associated approach walls. The base condition models formed the basis of comparison to future design alternative models. Future conditions modeling involved the addition of design features such as approach walls, dike fields, and a 1,200 ft lock in the auxiliary bay location. Future model results showed the effects of these design features on the river currents and how these changes might impact navigation. The numerical modeling was performed at the same time as physical navigation modeling at ERDC, and the two models complemented one another in various ways.

For the base condition models, numerical modeling was first performed using RMA2 and HIVEL2D. The HIVEL2D program was used in the pool because it was capable of modeling a proposed ported guardwall, an anticipated future conditions model (see Figure 1). Between each cell in the guardwall is a skirt that partially blocks off flow to eliminate excessive pinning forces upon approaching/exiting tows. HIVEL2D (and ADH) can place a local pressure field (“lid”) on the mesh. RMA2 was used in the tailwater due to higher computation speeds than HIVEL2D and the absence of a ported guardwall. The calibration was completed in December 2006 and base condition models were completed in 2006. Details of the calibration process and the base condition results are given in a study report dated 3/16/06 (Xia and Gambucci, 2006).

Without Guardwall

With Guardwall

Figure 1. Vectors of flow velocities (ft/s) near the guardwall area for 162,000 cfs, Pool 22 with and without guardwall cells.

In May of 2006, a new 2D hydraulic finite element solver named "ADaptive Hydraulics (ADH)" became available to MVR and the NESP team through ERDC. A few sample runs were made with ADH on converted RMA2 & HIVEL2D grids and it was evident that the software had great potential to increase computational speed and model stability. For the Lock and Dam 22 study, further runs produced the following speed advantages over the older software:

- RMA2 runs that were taking 2-4 hours of computation time now took 10-20 minutes using ADH.
- HiVel2D runs that were taking 8-12 hours of computation time now took 30-60 minutes using ADH.

Due to these dramatic speed increases, the desire to migrate to ADH was strong; however, testing for accuracy and stability was first conducted before the decision was made.

In June of 2006, a study was performed using ADH with the calibration discharge and comparing results to those of the earlier models RMA2 and HIVEL2D. Several cross sections were analyzed and found to be comparable to the former calibration study results; the results were nearly identical. ADH results were then checked against the Upper Mississippi River Flow Frequency Study (USACE, 2003) profiles for a range of discharges and found to be producing comparable water surface elevation slopes. Once these tests were complete, the decision was made by the NESP team to convert all base condition models to ADH models in both the pool and the tailwater of Lock and Dam 22. This saved computation time and provided direct comparisons to the future conditions models.

There are many techniques within ADH that can be used to save computation time. One of the most beneficial lessons learned has been the use of a sloping water surface hotstart file at the beginning of model calculations rather than using a flat water surface. This applies to 2D models in shallow water riverine environments. When modeling a stretch of river two to three miles

long, a flat surface starting assumption leads to prolonged computation times because the natural water slope can cause an elevation difference of one to two feet from the upstream boundary to the downstream boundary. The difference in starting elevation methodologies was investigated and it was later recommended to always start models with an estimate of the water slope rather than use a flat water surface. Below are some results of the investigation to quantify time saving benefits for the ADH model of Pool 22:

1) Initial timestep of 1 second versus an initial timestep of 2 seconds. Hotstart file based on a flat water elevation assumption with zero initial velocity. ADH run time for these two models was 1 hour 11 minutes and 1 hour 38 minutes.

2) Initial timestep of 10 seconds versus an initial timestep of 100 seconds. Hotstart file based on previous model output (depths and velocities) using 162,000 cfs. This modeling technique uses an initial flow rate of 162,000 cfs that was reduced to 130,000 cfs during the run (at timestep 1000). Run time for these two models was 3 minutes and 16 minutes, a significant improvement over the flat elevation hotstart assumption.

3) The velocity difference (plus or minus 0.5 ft/s) for the flat elevation hotstart model and the sloping elevation hotstart is shown in Figure 2. The sloping elevation came from the last timestep of a previous model run (including depths and velocities). Run time for these two models was 1 hour 11 minutes versus 16 minutes. Figure 2 shows that the difference in velocities is very similar to comparisons 1 & 2 above where only the initial timestep was altered.

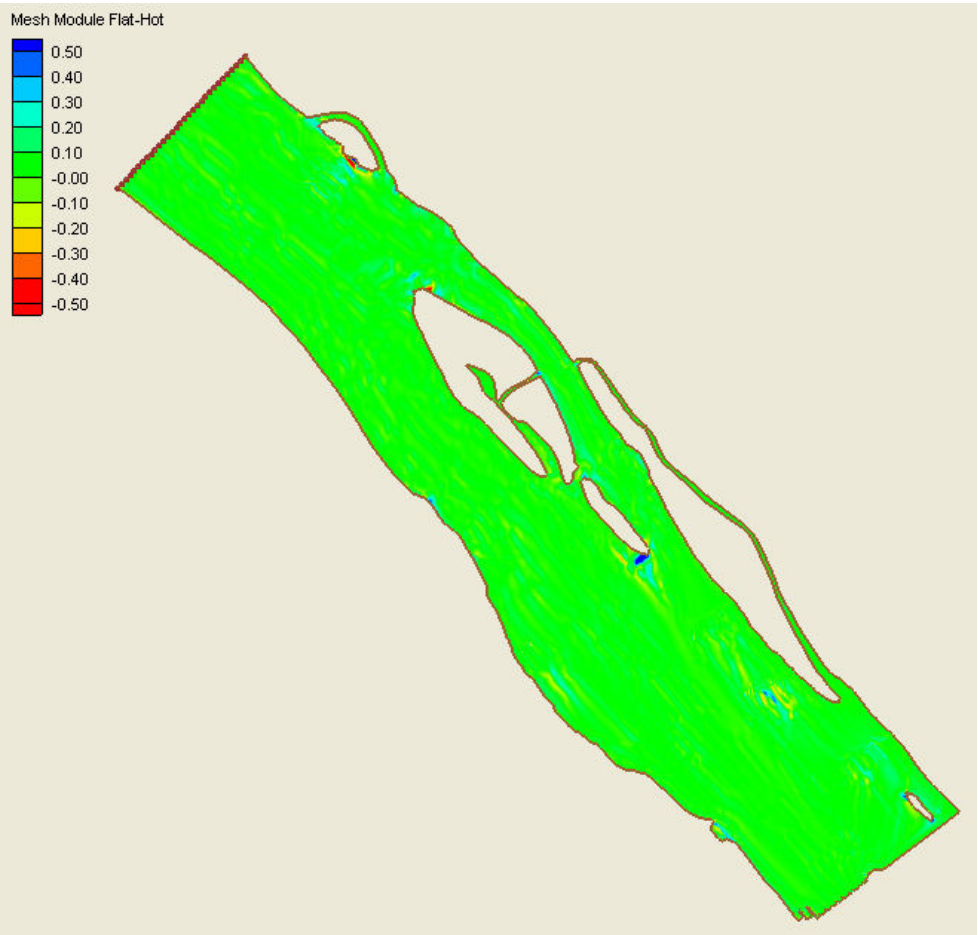


Figure 2. Pool 22 ADH Model Comparison: Velocity difference (plus or minus 0.5 ft/s) between a flat elevation hotstart file and a sloping elevation hotstart file.

Conclusion of sloping hotstart testing:
Starting ADH models with a hotstart file based on a sloping water elevation increases computational speed without changing the accuracy of the solution. The time savings is significant, approximately an hour per model run. This time savings was critical for the success of the construction sequencing modeling of Lock and Dam 22, a study that produced 141 ADH models for the final report (Gambucci, Xia, and Staley, 2008). ADH models should use initial starting conditions based off of a sloping water surface wherever possible in order to save time. A sloping water surface can be done based on an existing model run output files (OHD and OVL files), or if no existing model run exists MVP wrote up a procedure on how to create sloping surface hotstart files. If model output is available, ERDC has a program called "ADH_hot.exe" that allows for easy creation of hotstart files based on existing output files.

From 2006 to present, several Corps districts have used ADH including MVP, MVR, MVS, NWO, and MVN. Many tips and lessons learned have been shared within this initial ADH users group and feedback has been given to ERDC to help improve the program. MVR and MVP have hosted training workshops to facilitate technology transfer to the region with ERDC instructors to explain advanced features such as hydrodynamic vessel effects and sediment transport.

PRIMARY RESULTS

The Rock Island District (MVR) has seen vast improvements in speed and stability by using ADH and is no longer using the older programs RMA2 and HiVel2D for 2D shallow water applications. ADH has the potential to handle many other complex issues such as sediment transport, vessel movement, wind effects, and 3D applications including groundwater. Although the public release version of ADH does not yet support these features, it is recommended that users of RMA2 or HiVel2D make the transition to ADH for 2D shallow water applications. It is very simple to convert RMA2 and HiVel2D meshes into ADH format. The new mesh may be manually refined or modified using SMS, and during ADH computations the automatic grid adaptation of ADH will address areas of the mesh that are unstable.

ABSTRACT

A detailed study of seven historic backflow from the Chicago Waterway System (CWS) to Lake Michigan events (including the 2nd and 4th largest since 1965) was done to evaluate changes in waterway operation procedures to determine if backflows could be avoided or reduced in volume. The study applied a dynamic-wave simulation model to the CWS at a 15-minute time step combining measured inflows for the major tributaries, combined sewer overflow (CSO) pump stations, and water reclamation plants with simulated gravity CSO flows computed by the U.S. Army Corps of Engineers. The simulated CSO inflows were confirmed against a detailed mass balance approach for four storms and the peak flows from the two approaches were found to be remarkably similar. It was found that the hydraulic capacity limitations of the Chicago Sanitary and Ship Canal (CSSC) prevented changes in operations at the Lockport Powerhouse and Controlling Works from substantially reducing backflows. The maximum discharge through the CSSC is around 19,500 cfs whereas inflows may peak at 40,000 to 50,000 cfs and flows cannot drain away fast enough to avoid having to allow backflows to Lake Michigan. These backflows cannot be avoided until the reservoirs of the Tunnel and Reservoir Plan (TARP) are completed.

INTRODUCTION

The Chicago Waterway System (CWS) is composed of the Chicago Sanitary and Ship Canal (CSSC), Calumet-Sag Channel, North Shore Channel (NSC), lower portion of the North Branch Chicago River (NBCR), South Branch Chicago River (SBCR), Chicago River Main Stem, and Little Calumet River (North). In total, the CWS is a 76.3 mi branching network of navigable waterways controlled by hydraulic structures in which the majority of flow is treated sewage effluent. The dominant uses of the CWS are for commercial and recreational navigation and for urban drainage, i.e. draining combined sewer overflows (CSOs), stormwater runoff, and treated wastewater from the Chicago area away from Lake Michigan. The Calumet and Chicago River Systems are shown in Figure 1.

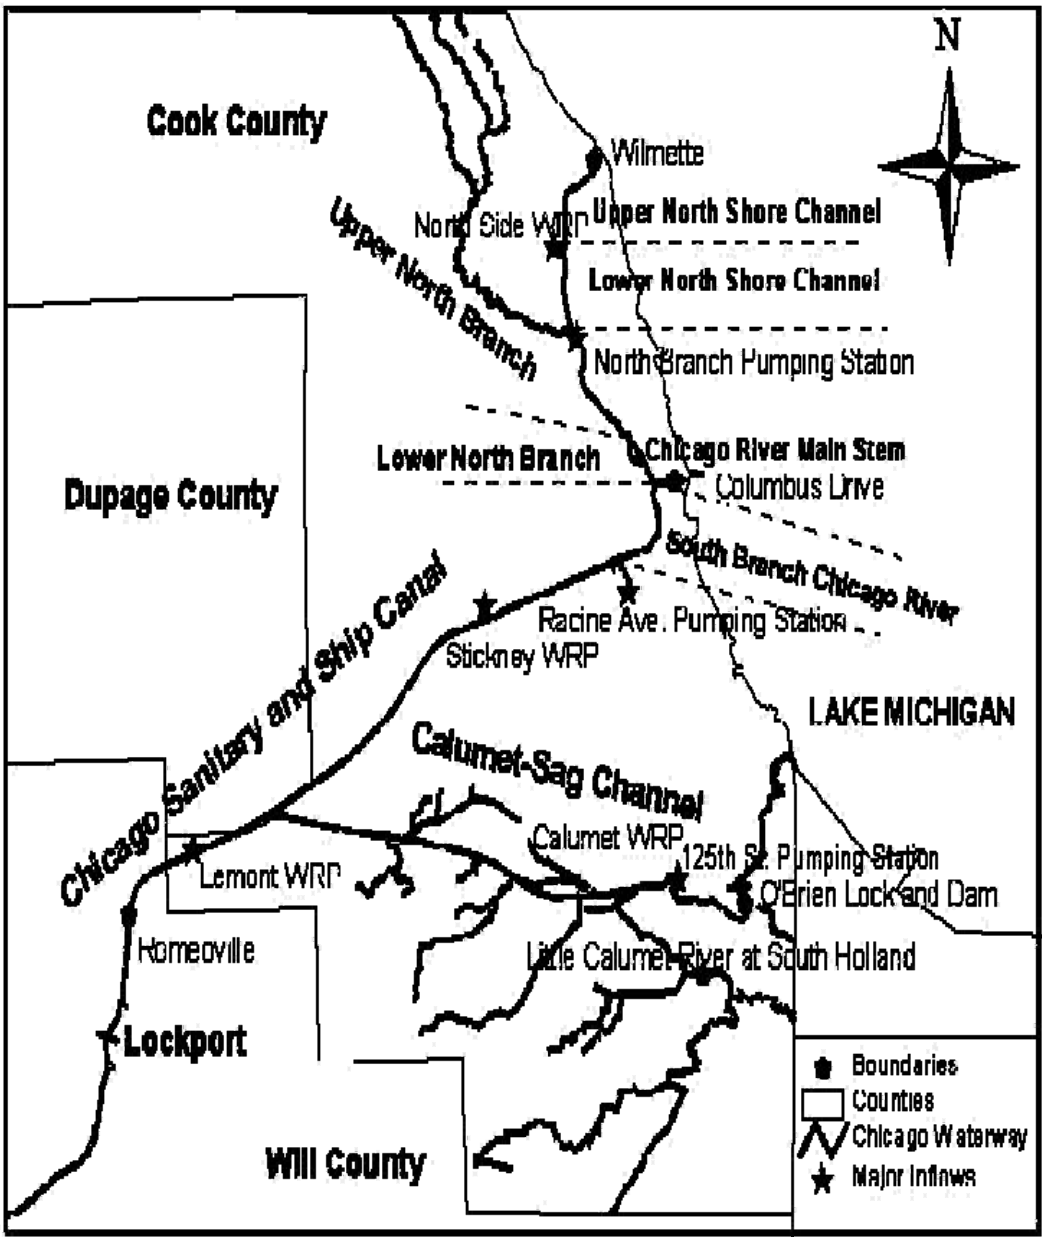

Figure 1. Schematic diagram of the Calumet and the Chicago River Systems.

Minimizing the occurrence of backflows of storm runoff and sewage to Lake Michigan through the lakefront sluice gates and locks is a high priority for the Metropolitan Water Reclamation District of Greater Chicago (MWRDGC). Backflows can potentially affect the water supply of Chicago, the accessibility of beaches to the public, and the general environment of Lake Michigan. Since the O'Brien Lock and Dam were completed in 1965 forty-nine storms have caused the MWRDGC to open the sluice gates or locks at the lakefront and allow water to flow to Lake Michigan. Thirty two of these occurred before 1986 when the first of the Tunnel and Reservoir Plan (TARP) tunnels went on-line for a pre-TARP rate of 1.5 per year and a post-TARP rate of 0.73 per year. The decrease in frequency of

backflows reflects the reduction in flood flows resulting from the TARP tunnels. However, the volumes of the backflows since 1990 have been large with 6 of the 10 largest backflow volumes from 1965 to 2007 occurring since 1990 (Table 1). The objective of this study is to evaluate 7 historic backflow events (1997-2002) to see if changes in operation procedures at the Lockport Powerhouse and Controlling Works can avoid or reduce the volume of backflows.

Table 1. Flow volume of backflow events (in million gallons) from 1990 to 2007.

HYDRAULIC MODEL DESCRIPTION AND VERIFICATION

The DUFLOW (2000) unsteady-flow model for the CWS was calibrated and verified by the Marquette University in 2003. The ability of the model to simulate unsteady flow conditions was demonstrated by comparing the simulation results to measured data for eight different periods between August 1, 1998 and July 31, 1999 (Shrestha and Melching, 2003). Shrestha and Melching (2003) calibrated the model using hourly stage data at three gages operated by the MWRDGC along the CSSC and at the downstream boundary at Romeoville operated by the U.S. Geological Survey (USGS), and using daily flow data collected by the USGS near the Chicago River Controlling Works (CRCW) and O'Brien Lock and Dam upstream boundaries. For the evaluation of the backflow events, the DUFLOW model was extended from Romeoville to the Lockport Controlling Works, LCW, (3 miles downstream from Romeoville and 2.2 miles upstream of the Lockport Power House, LPH, and Lock). The model was run at a 15-min. time step and measured and simulated stage values were compared for a 60-min. time interval. Assumptions, data used, and results are presented in the following subsections.

Measured inflows, outflows, and water-surface elevations. During the study period the USGS operated discharge and stage gages at three primary locations where water is diverted from Lake Michigan into the CWS. These locations are:

i) The Chicago River Main Stem at Columbus Drive (near CRCW)
ii) The Calumet River at the O'Brien Lock and Dam

iii) The North Shore Channel at Maple Avenue (near the Wilmette Pumping Station)

The data from the Chicago River Main Stem at Columbus Drive, the Calumet River at the O'Brien Lock and Dam and the North Shore Channel at Maple Avenue gages were used as the primary flow versus time (5-minute) upstream boundary conditions for the unsteady-flow model. Water-surface elevation versus time data (on a 1-hr basis) from the MWRDGC gage on the CSSC at the LCW were used for the downstream boundary condition.

During the backflow events, MWRDGC estimated the volume of backflows and the USGS measured them with acoustic velocity meter (AVM) gages. It was found that simulations with the volume of backflows estimated by MWRDGC resulted in better water-surface elevation estimates in the CWS than simulations using the USGS measurements. Thus, just during backflow events USGS flows were adjusted to match the MWRDGC backflow volume estimates. This approach is reasonable because the USGS never made discharge measurements during a backflow with which the AVM gages could be properly calibrated at the Lakefront structures (Jim Duncker, USGS, personal commun., 2007).

The data from the USGS gage of the Little Calumet River (South) at South Holland provide a flow versus time upstream boundary condition for the model. Two tributaries to the Calumet-Sag Channel are gaged by the USGS, Tinley Creek near Palos Park and Midlothian Creek at Oak Forest. The USGS gage on the Grand Calumet River at Hohman Avenue at Hammond, IN measures flow on a tributary of the Little Calumet River (North). Flow on the NBCR is measured just upstream of its confluence with the NSC at the USGS gage at Albany Avenue.

Hourly flow data are available from the MWRDGC for the treated effluent discharged to the CWS by each of the three Water Reclamation Plants—North Side, Stickney, and Calumet. In addition, hourly flows discharged to the CWS at three CSO pumping stations—North Branch, Racine Avenue, and 125th Street—were estimated from operation logs and rated pump capacities for these stations.

Estimation of flow for ungaged tributaries and combined sewer overflows. Flows on Midlothian Creek were used to estimate flows on ungaged tributaries on an area-ratio basis as was done in the model calibration (Shrestha and Melching, 2003).

There are nearly 240 CSOs in the modeled portion of the CWS drainage area. Since it is practically difficult to introduce all CSO locations in the modeling, 28 representative CSO locations were identified. In this study, simulated CSO flows were obtained from the U.S. Army Corps of Engineers (Corps), which are calculated on an annual basis in support of the Lake Michigan Diversion Accounting. Detailed discussion of the Corps models (a combination of the Hydrological Simulation Program-Fortran, Special Contributing Area Loading Program, and Tunnel Network Model) is given in Espey et al. (2004). The flow simulations are driven by precipitation data from a network of 25 precipitation gages throughout the Chicago area established by the Corps in 1990.

Channel geometry and roughness coefficient. The channel geometry is represented as a series of 231 measured cross sections. The DUFLOW model uses Chezy's

roughness coefficient, C, to calculate hydraulic resistance. The calibrated C values vary between 6 and 60 and the equivalent Manning's n values range from 0.022 to 0.165. Complete details on the calibrated values of Chezy's C and the equivalent Manning's n value are listed in Table 4.2 of Shrestha and Melching (2003).

Model verification. Although flows in the various branches of the CWS are not measured, water-surface elevation data recorded at different locations were used for calibration and verification of the model. The water-surface elevations recorded at Columbus Drive, O'Brien Lock and Dam, Wilmette, Western Avenue, Willow Springs Road, Southwest Highway, and Sag Junction by the MWRDGC and at Romeoville by the USGS were used for model verification. Details of the calibration and the verification results are given in Alp and Melching (2006), Neugebauer, and Melching (2005), and Shrestha and Melching (2003).

In order to evaluate the backflow events, the DUFLOW model was applied for the following simulation periods:

February 1 - March 30, 1997
August 1 - September 30, 1997
June 1 - June 30, 1999
July 1- November 9, 2001
August 1 – September 23, 2002

As an example of the output, Table 2 lists the statistical analysis for July 1 to November 9, 2001 of the difference between the measured and simulated stages. It can be seen that the errors are below 10 % relative to the depth (where depth is measured from the thalweg of the channel) of the water for all of the values except for simulations at Wilmette and Lawrence Avenue. These high percentages of small errors and close agreement between the simulated and the measured water-surface elevations especially during backflow events at the boundaries indicate an excellent hydraulic verification of the model. Similar results for the other simulation periods are presented in Alp and Melching (2008).

Table 2. Correlation coefficient and percentage of the hourly water-surface elevations for which the error in simulated versus measured elevations relative to the depth of flow (measured from the thalweg of the channel) is less than the specified percentage for July 1, November 9, 2001.

July 1-November 9, 2001		Percentage		
Location	Correlation Coefficient	<±2% of D	<±5% of D	<±10% of D
Wilmette	0.81	0	4	75
Chicago River Controlling Works	0.82	87	99	100
O'Brien Lock and Dam	0.69	97	100	100
Lawrence Avenue (NBCR)	0.65	8	48	83
Western Avenue (CSSC)	0.84	94	99	100
Willow Springs (CSSC)	0.78	97	99	100
Southwest Highway (Cal-Sag)	0.77	84	99	100
Sag Junction	0.80	98	99	100
Romeoville (CSSC)	0.96	95	100	100

EVALUATION OF OPERATION SCHEMES FOR LOCKPORT GATES

Actual operation schemes for the Lockport Gates. Records for 1998-2002 of the opening of the LPH pit gates and LCW sluice gates were obtained from the MWRDGC. These were compared with the measured water-surface elevations at the LCW to establish typical water-surface elevations for various combinations of gate openings. There are 9 LPH pit gates and 7 LCW sluice gates. Comparison of the water-surface elevations at LCW with the various gate openings for the selected storms are detailed in Alp and Melching (2008). The MWRDGC gradually opens the pit gates at the LPH when a larger storm is anticipated and LCW sluice gates are also opened when higher discharges and water-surface elevations are observed. When the 9 LPH pit gates are open, water-surface elevation at the LCW goes down to -5.9 ft CCD on average and when all the gates (LPH and LCW) are open, water-surface elevation goes down to -9.3 ft CCD on average. Different combinations of gate operations result in water-surface elevations ranging from -4 ft CCD to -9.3 ft CCD on average.

Simulation of the Lockport Gate Operation Procedures. Four sets of simulations representing various Lockport gate operation procedures were evaluated and throughout the text some abbreviations explained below are used to describe the simulations:

i) *Before CSO*: Lockport Gates are open 6 to 12 hrs before CSO to bring the water level down to -3, -5, or -7 ft CCD at the LCW and the water level is kept higher than -3 and -4 ft CCD at CRCW and Sag Junction, respectively, as required by navigational regulations. When CSO starts, actual gate operations and LCW water-surface elevations are used. During the backflow event, upstream boundaries are set to zero discharge to see how high the water could rise.

ii) *During CSO*: Gates are open 6 to 12 hrs during CSO event to bring the water level down to -9 ft CCD at the LCW and the water-surface elevation is kept higher than -3 and -4 ft CCD at CRCW and Sag Junction, respectively. Prior to the CSO events, actual gate operations and LCW water-surface elevations are used. During the backflow events, upstream boundaries are set to zero discharge.

iii) *No limit*: Lockport Gates are open 6 to 12 hrs before CSO to bring the water level down to -5, -7, or -9 ft CCD at the LCW without regard to the water-surface elevation limits at CRCW and Sag Junction. When CSO starts, actual gate operations and LCW water-surface elevations are used. During the backflow event, upstream boundaries are set to zero discharge.

iv) *Baseline*: During the backflow events, upstream boundaries are set to zero discharge.

Simulation Results. The results of the *"Before CSO"* simulations reflecting hypothetical gate operations to prevent backflows were compared with the *Baseline* simulations. In these simulations, water-surface elevations were lowered at the LCW while maintaining minimum allowable water-surface elevations at CRCW and Sag

Junction. Outcomes of the simulations show that lowering the water-surface elevations at Lockport to -3 to -5 ft CCD for 6 hours before the CSO event do not provide enough storage for the CSOs in the CWS to prevent backflows. The effect of lowering water-surface elevations at Lockport decreases as locations farther from Lockport are considered with reductions at CRCW ranging from negligible to 0.56 ft and at Wilmette from negligible to 0.43 ft. Even though this practice helps to lower the water-surface elevations in the CWS before the CSO events, the peak water-surface elevations during CSO events are far higher than the levels at which backflows to Lake Michigan are necessary.

In the *"No limit"* simulations, the downstream boundary condition at the LCW was lowered to -5 to -7 ft CCD for an extended 12 hour period before the CSO event and water-surface elevations were allowed to be lower than minimum water-surface elevations limits at CRCW and Sag Junction. Decreases in the peak water-surface elevations of 0.32 to 1.18 ft resulted at Wilmette and decreases on the order of 1.5 ft resulted at CRCW for the events resulting in backflows. However, at both locations peak water-surface elevations were not low enough to prevent backflows to Lake Michigan for all events except October 13, 2001 at Wilmette. Figure 2 shows the water-surface elevation reductions for the *"No limit"* simulations for the August 2, 2001 event, which had the largest decrease at Wilmette among the 7 storms. Similar figures for all storms and scenarios are included in Alp and Melching (2008).

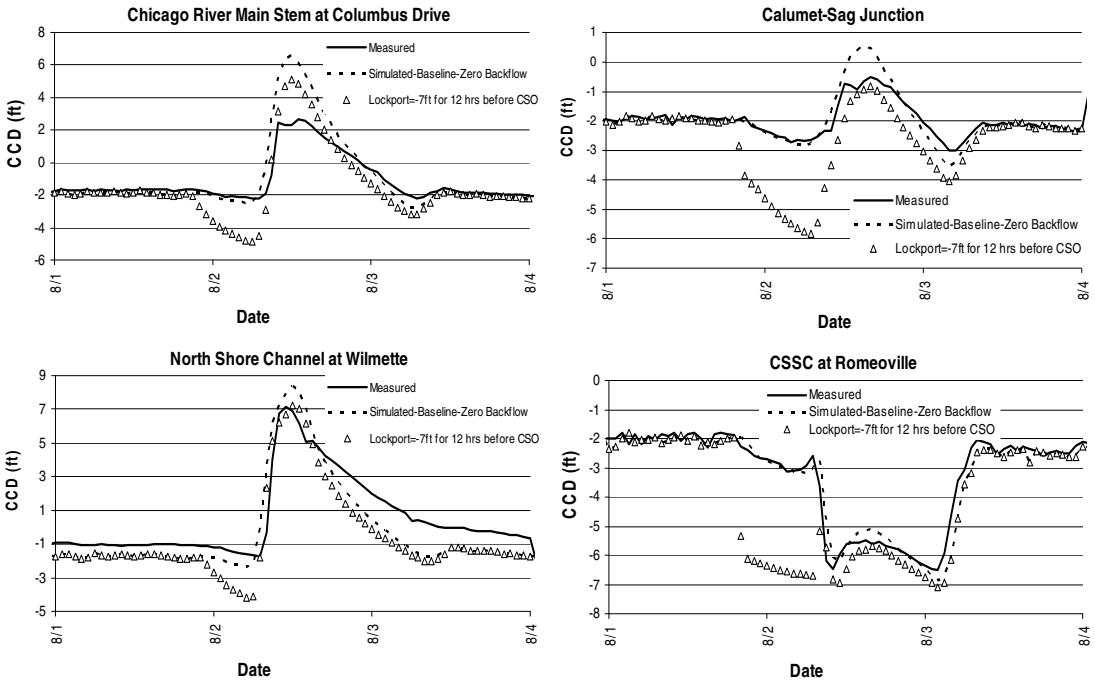

Figure 2. Water-surface elevations at different location in the Chicago Water System for "*No Limit*" simulations for August 1-4, 2001.

In the last set of simulations, water-surface elevations were allowed to go down to -9.0 ft CCD at Lockport to increase the water-surface slope and flow rate in the CSSC just as CSO starts during backflow events. Since, in the actual case (*Baseline*), all Lockport gates were open and water-surface elevations were allowed

to decrease to -9 ft CCD, these simulations resulted in very close peak water-surface elevations to the *Baseline* simulation results.

Inflow-Outflow Comparison. In order to understand the lack of effectiveness of the various simulated changes in gate operations at Lockport in reducing water-surface elevations at the lakefront boundaries, a comparison of the inflows to and outflows from the CWS was done. The measured and estimated inflows were summed on an hourly basis for each backflow event and the summation is compared with the measured outflows at Romeoville in Figure 3 for the August 2, 2001 event. For this event, the peak inflow is nearly 45,000 cubic feet per second (cfs) while the measured peak outflow was 15,479 cfs. This comparison shows that with the inflow being up to 30,000 cfs higher than the outflow for several hours the storage space created by lowering the CWS is quickly filled and the CSSC and/or NSC and NBCR are not capable of draining the CWS fast enough to avoid backflows at the CRCW and Wilmette, respectively, despite changed gate operations at Lockport. Similar results for the other 6 backflow events are shown in Alp and Melching (2008).

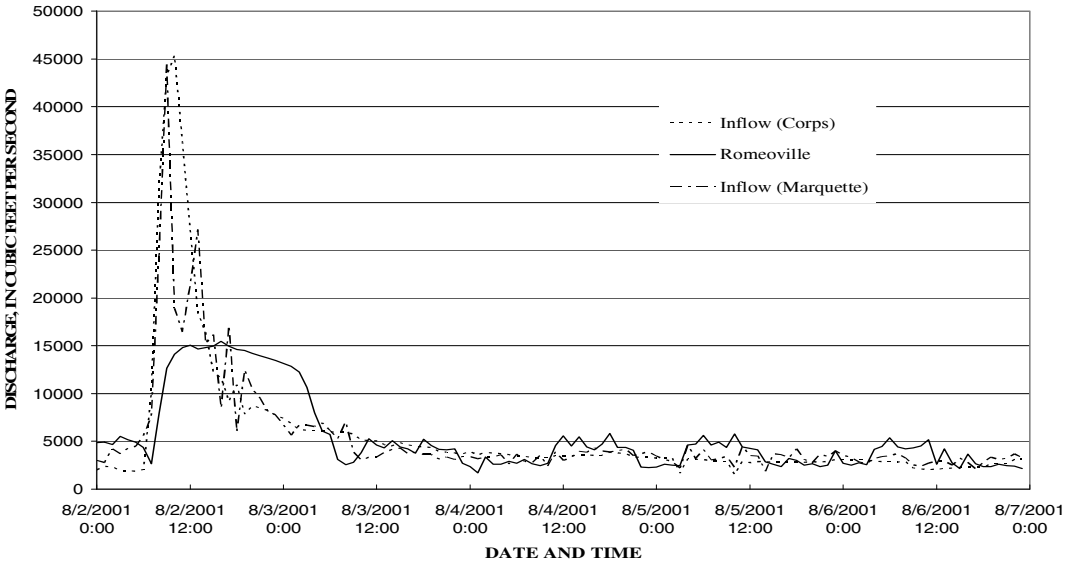

Figure 3. Measured and estimated inflow to the Chicago Waterway System and measured outflow at Romeoville, IL, for August 2 to 6, 2001.

It may be speculated that the inflows estimated by the Corps models are too high, and, thus, the inability of the CWS to drain away high storm flows is overstated in Figure 3. Figure 3 also includes the estimate of total inflows to the CWS based on Marquette University's original estimates of the gravity CSO flows. The Marquette estimates are based on the daily water balance for the CWS and the amount of gravity CSO flow and flow at the lakefront boundaries (where water-surface elevation boundary conditions were used in the original model) needed to match measured water-surface elevations throughout the CWS (Shrestha and Melching, 2003). The peak inflows from the Corps models and Marquette estimates are very close, within 2% for the August 2, 2001 event. The peak flow also was within 2% for the August 31, 2001 event, within 8% for the August 2002 event, and within 18% for the October

2001 event (Alp and Melching, 2008). Differences in volumes are greater, but in general, the agreement between the output of the Corps models and the Marquette estimates is sufficient to conclude that during larger storms the inflows to the CWS overwhelm the drainage ability of the component channels of the CWS.

Measured Water-Surface Elevations. The measured water-surface elevations at different locations on the CWS for the August 2, 2001 event, the second largest backflow event that occurred between 1990 and 2007, are shown in Figure 4 (measured water-surface elevations for the other 6 flow reversal events have similar patterns to those shown in Figure 4). Figure 4 shows that measured water-surface elevations at the locations above Sag Junction are all higher than -2.0 ft CCD even though minimum water-surface elevations at Romeoville and Lockport are around -6 and -9 ft CCD, respectively.

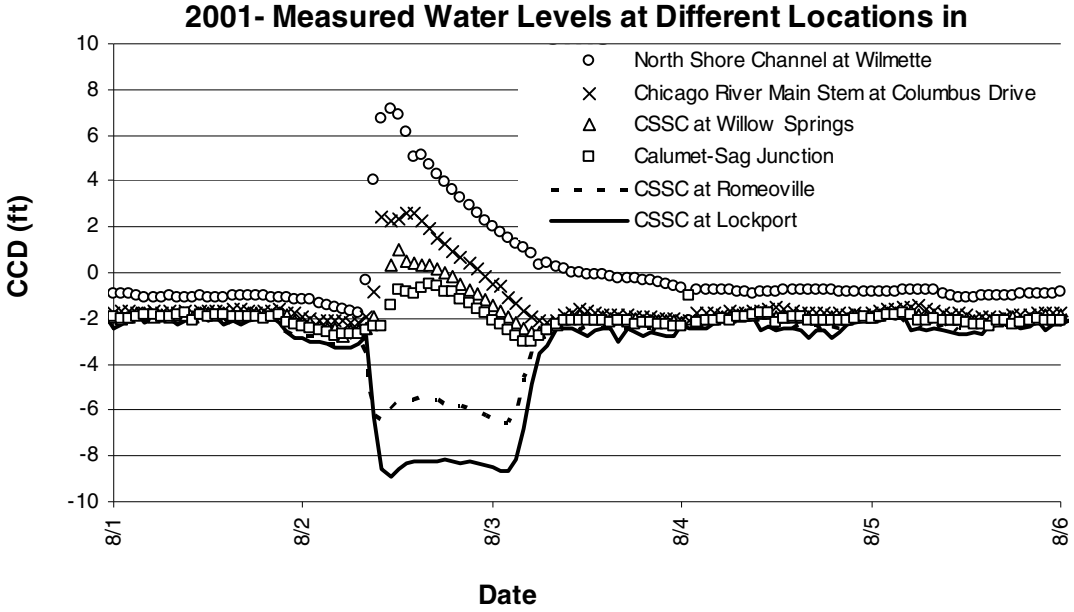

Figure 4. The measured water-surface elevations at different locations in the CWS for the August 2, 2001 backflow event.

For the August 2, 2001 event the maximum difference in water-surface elevation between Wilmette and Columbus Drive (14 mi) is around 5 ft, between Columbus Drive and Sag Junction (23.2 mi) is around 3 ft, and between Sag Junction and the LCW (10.2 mi) is around 8 ft. Thus, a large water-surface slope is present on the CSSC from Sag Junction to the LCW in order for this reach to transport the large storm flows coming from the upstream CSSC and Calumet-Sag Channel. The CSSC was not constructed anticipating the construction of the Calumet-Sag Channel, and the geometry of the CSSC is the same upstream and downstream of Sag Junction. Thus, a two lane highway of water is narrowed to one lane, causing water to back-up each of the two lanes (the upstream CSSC and Calumet-Sag Channel) resulting in low water-surface slopes and flow capacities. Thus, the inability of the CWS to drain high storm flows away from lakefront areas resulting in backflows can be seen in the records of the measured water-surface elevations.

CONCLUSIONS

Changed operations of the gates at Lockport cannot prevent backflows to Lake Michigan because the flow capacity of the CWS is not large enough to drain away high storm flows. These high storm flows quickly fill storage space created by lowering the CWS by opening the gates at Lockport in anticipation of a large storm, and the water-surface elevations at the lakefront rise quickly to flood levels necessitating backflows. It is likely that the MWRDGC's policy of lowering the CWS in anticipation of storms may help avoid backflows for smaller storms, but this possibility was not explicitly evaluated in this study. Finally, there appears to be nothing that the MWRDGC can reasonably do to avoid future backflows until the reservoirs of TARP come on line and the volume of CSO flows is further reduced.

Modeling the Evolution of Incised Streams in Hammar Mesopotomian Marsh with emphasis on the Contribution of Tidal Flow in the Filling Requirements

A. H. Alkaabi[1] A. Ramamurthy[2] H.A. Al-Thamiry[3] A.A. Ali[3]

1 Introduction

Tidal flow may contribute significantly in the amount of water to be considered in the restoration of wetlands, particularly when these wetlands were subjected to a drying process and there are shortages in the availability of water coming from highlands. The Mesopotamian marshes (The Iraqi Wetlands) are Al-Hammar Marsh, Al-Huwaiza Marsh, and Central Marshes (Al-Qurna). These marshes were subjected during the last two decades to a drying process for mostly political reasons. The present study concerned with the Al-Hammar Marshes. After the last war in 2003 the aim of the new Iraqi authorities is to restore these marshes and their unique ecosystem. Many studies had been conducted and other still in progress concerning different aspects of the drying process impacts and the identification of the most suitable strategies for this restoration. Although the quality of water available for marshes restoration is of vital importance, the water quantity is also important and essential for the purpose of ecosystem restoration. Some of these studies were concerned directly or indirectly to the availability of water quantity aspects. United Nation Environmental Program (UNEP) and American University Beirut (AUB) (1988) had conducted a study for supporting the environmental management of these marshes. The effects of water deficiency in Tigris and Euphrates Rivers due to Turkish and Syrian water management strategies were investigated indicating the effect of these strategies on water quantity of Tigris and Euphrates Rivers water especially for the restoration of the Mesopotamian Marshes associated with the reduction of flows. UN and the World Bank (2003) had conducted a study of water and sanitation in Iraq, with its relation to marshes restoration process. The study indicates the high TDS values at south of Iraq near the marsh area compared to those values at the Iraqi-Turkish and Iraqi-Syrian borders. The Italian Ministry of the Environmental and Territory and The Free Iraq Foundation (2006) had conducted a hydrological study for an integrated water resources management study in Iraq related to the restoration process. Al-Samarai (1999) had conducted a study of evaluation of the irrigation and drainage projects that had been constructed after the drying process in the marshes area. The UNEP (2003) had conducted a desk study on the environment in Iraq identifying some effects on the marshes environments due to the drying process. The Iraq Foundation (2003) had conducted a study for building a scientific basis for restoration of the Mesopotamian Marshlands. The study

indicate the need of conducting restoration process during high flow periods to flush out the salts and contaminants from the flooded area which means that at the beginning of the restoration process the water salinity going to be high. UNEP (2003) had conducted a progress report of environment in Iraq mentioning some environmental effects of the drying process. The study had concluded that the water quality will get better as the restoration process continued year after year. UNEP (2001) had conducted a study of the Mesopotamian Marshlands a demise of an ecosystem. The study had focused on the different impacts of the drying process on the ecosystem of the marshlands. The US Agency of International Development (2004) had conducted a study of Iraq marshlands restoration program. The part of this study which concerned with water quantity had indicated high shortages in water according to season. AMAR International Charitable Foundation (2003) had conducted a study of the human and environmental aspects of Iraqi Marshlands. The study had also concluded the shortage of water availability.

The main conclusions of reviewing the above mentioned studies are the deficiencies in Tigris and Euphrates Rivers flow. This deficiency has to be considered in the restoration of the Mesopotamian Marshes. The planning target of the new Iraqi authorities and the international environmental agencies is to restore this ecosystem again. The center for restoration of Iraqi marshes (CRIM) is one of the establishments of the ministry of water resources in Iraq. This center is responsible of conducting the studies and the required activities for marshes restoration. The present study was conducted with the corporation of CRIM for the Al-Hammar Marshes and devoted for the study of the Arabian Gulf tidal flow control to contribute to Al-Hammar Marsh. A mathematical model for the flow in this domain was built. HEC-RAS Software (version 3.1.3) and HEC-GeoRAS extension under Arc-View GIS software are adopted in the implementation of this model. The model runs give an estimate of the percentage of water flowing in or out from the marsh. For a full restoration the need of this study is essential.

2 Materials and Methods

Study Site Description

Hammer Marsh is the largest marsh among the Mesopotamian Marshes located on the right side of Euphrates River just before the confluence with Tigris River at Qurna City to form Shat AL-Arab River. The marsh starts from the ends of Euphrates River branches at Nasiriya. These branches are Ghlaiween, Safha, Okeka and Beni-Hassan Rivers, and then downstream Sook AL Sheyukh the AL-Hafara River. Karmet beni-seed and Om-Nakhla Cross Regulators are exist to control the water entering the marsh from these branches. In addition, there are escapes and culverts below AL Nasiriya-Qurna Road to allow Tigris River flow from the Central Marshes at Qurna to Hammar marsh during flood season.

The south petroleum company has executed embankments to protect oil fields. This embankment became a central road connecting north part of Hammer Marsh with the south part at Rumaila. This road has 334 culverts with total length of 4350 m. The design capacity of these culverts is a flood of 100 years return period, which is the same of 1969.

Before drying, in the eightieth of the last century, The Hammar Marsh is part of a complicated interconnected system for water exchange between Tigris, Euphrates, shat AL-Arab Rivers. The branches of Euphrates River are the main feeding sources for Hammar Marsh. The flows of these branches are controlled by several regulators of a fluctuating capacity between 50-500m^3/s. In addition to the above regulators as a feeding control structures, there is also a direct

feeding from the opening through the right embankments of Euphrates River with a capacity of 500m³/s. During the flood season of Tigris River, the water is flowing from Central Marsh to Hammar Marsh through escapes and culverts. These escapes are either a pipe or series of pipes or flow in culverts under bridges. Jehala escape is the largest one with 84 m water way. Sometime the water flow overpasses the road parallel to Euphrates River conveying water from Central Marshes to Hammar Marsh. During flood season, Hammar Marsh becomes a connected lake, while during dry season; it becomes disconnected shallow small lakes.

Figure 1: Location of Study Area

The water depths in these lakes are 0.2-0.5m. In this process, the surface area changes from 3000 km² with 5 km³ flood season storage capacity to a 600 km² with 0.2 km³ storage capacity during dry season.

The accumulated water of Hammar Marsh is discharged as an outflow to Shatt Al-Arab River by Al-Shafi, Al-Ghameej and Garmet Ali Rivers. The Arabian Gulf tidal effect reaches the location of the marsh outlet into Shatt Al-Arab River. The problem is to estimate the amount of water flowing in or out from the marsh during a year.

The drying process of a 90% of the marsh area after 1990 has caused a considerable change in all the topographical features of Hammar Marsh.

Raising Euphrates River shoulders played an important role in the drying of marshes. High level embankments were executed on both sides of Euphrates River with length reaching 94 km in addition to shoulder rising of Ghlaiween, Ekeka and Bani Hassan Rivers. These branches were combined to form assignee channel which meets Euphrates River near Al Fuhood village. This was done to prevent the water from reaching the marsh. Shoulder rising were also executed on several other rivers which have indirect role in the process of the drying operation.

In order to complete the process of drying, Al-Huriya river was executed with maximum discharge of 300m³/sec which draws great part of the Euphrates River flow in Nasiriya to be transported far from Hammar Marsh and discharges in Main Outfall Drain. Basra water supply project which crosses the marsh causes obstruction to the movement of water inside the marsh

The declared goal of this drying process was to obtain agricultural land for operating of about 500,000 donums. This area is distributed between Al-Shafee, Al-Malha and Um-Nakhla Irrigation Projects.

Hydrological Data Analysis

In the present study the hydrologic data is the tool in the evaluation of the existing hydraulic boundary conditions of the study area. The data of precipitation, evaporation and water resources are collected from the Directorates of MOWR records, Meteorological stations records and that available in the literatures and in previous studies.

The rainy seasons in Iraq are from October to May. The months January and February have the maximum rainfall. The analysis of the precipitation data of marshland area for the period (1987-2005), for Nasiriya and Basra governates showed that the average precipitation in Basra for the last 19 years is 144 mm/year, while in Nasiriya is 124mm/year.

The evaporation rates represent the main water losses. The evaporation is effected by air humidity, wind speed and air temperature. Evaporation of the Southern Iraq zone is studied for the last 19 years. The locations of the meteorological stations of Nasiriya are (Lat 31 1, Long 46 14) and Basra station (Lat 30 25, Long 44 50). Moreover the evapo-transpiration, the combined effect of evaporation and water used by plants, must be taken into consideration in the study. The evapo-transpiration has higher values than evaporation only especially in the hot seasons. According to (New Eden Plan, 2006), the monthly evapo-transpiration for Hammar marsh area was calculated using Penman equation with the data of the meteorological stations. The evaporation in Nasiriya is 2874 mm/year, while in Basra is 2253 mm/year. The reason of this difference is the low humidity in Al-Nasiriya. The averaged yearly evaporation is 2563.5 mm, while the averaged evapo-transpiration is 2909.3 mm in the same region. The above figures provide an idea that the evapo-transpiration in study area is 12% higher than the evaporation. So, these values will be considered in the model.

To estimate the required inflow to balance the evaporation in the marsh, the evaporation and precipitation data are used. The required discharge to balance the evaporation for an area of 1000 km^2 in Al-Hammar is about 88m^3/sec.

The main source of water in the Hammer marsh area is Euphrates River. The averaged maximum monthly discharge for the period (1980-1997) is 1429m^3/s, while the averaged minimum monthly discharge for the same period is 71m^3/s.

Garmat Ali River can also be considered as an additional feeder in the restoration of Hammar Marsh through the high tide period of Shat Al-Arab River. Shat Al-Arab River is a tidal river and the tidal effects reach the upstream end of this river. The tidal pattern in the estuary is a mixed type, mainly semi-diurnal; there are two high and low water a day. The tidal period at river estuary is 24.83 hrs. The discharged water into Shatt Al-Arab River is the summation of discharge of Euphrates Tigris in Al-Qurna. Shatt Al-Arab works as a drainage canal for sat water coming from Al-Huwayza marsh and Swaib project area. So, the discharged water into Shatt Al-Arab from Tigris River must be present in the study. The averaged maximum monthly discharge of Tigris River for the period (1980-2004) is 280m^3/s, while the averaged minimum monthly discharge for the same period is 32m^3/s. Exploration the effect of Garmat Ali River in the restoration of Hammar Marsh through the high tide, the stage hydrograph of Shatt Al-Arab River in the nearest station to Garmat Ali River or at the station of available hydrological records is needed. AL Ma'aqal station will be chosen as a boundary condition of Shatt Al-Arab River. The daily two high and two low water levels in Shatt Al-Arab at Ma'aqal in 1997; for example the data of Feb, 1997; as in Table(1).

Topographical Data Analysis

The topographical information is consists of two parts; The collected data from different sources and the topographical survey with ground equipments. During the surveying, collected data from different sources are available. The team focus attention towards newly satellite images that providing a scope details of Hammar Marsh, the length and location of channels or rivers, the intersection of the existing rivers or channels with each others, and specifying the location of the existing hydraulic structures. Using the ground equipments, 50 cross sections and 7 profiles are surveyed. The location of the 50 surveyed cross sections is in Al-Hammar marsh inner and outer boundaries with seven longitudinal profiles. 15 cross sections of Shatt Al-Arab River had been collected from MOWR, the Directorate of Gages which have been surveyed in 2006. These cross sections are started from Al-Qurna towards Al-Maqal. Table (2) shows the GPS of the collected cross sections.

Table (2) Location of Shatt Al-Arab River Cross Sections

DEM and Storage Curves

These surveying details are used to create the updated digital elevation model (DEM) concerning the Hammar Marshes. The DEM of Hammar Marsh is shown in Figure 3. With the help of Arc-View software, the updated DEM will provide a powerful background for the analysis, particularly the stage-volume and area-elevation curves of the marsh area within any scenario of inundation. In addition to that, DEM grids are necessary in the construction of the numerical model as a geometric data.

The stage-volume and area-elevation curves are shown in Figures 15 and 16. The increment in surface area due to the water level variation gives good idea about the best required amount of water to inundate a reasonable area of the marsh. From the percentage increment of surface area, water level of 2.7 m AMSL is the goal of our study. This water level will provide storage of 1477milion m^3 with a surface area of 1331 Km^2.

3 Model Results and Discussion

Studying the tidal effect of Shatt Al-Arab on Hammar Marsh through Garmat Ali River needs an estimation of the discharged tidal water into the marsh during the high water tide. A hydrologic routing model and steady / unsteady hydrodynamic circulation model (RMA2) were prepared to analyze flow pattern inside the marsh.

A finite element meshes of about 4000 elements have been developed over an area of 1552 km^2 is shown in Figure 4. The model inlets are presented along the direction of the proposed locations of feeding, the first location is the ends of Um Nakhla project canals, the second location is the main canals of Al-Malha project and the last location is the main two canals of Al-Shafi and Al-Ghumaeech project. The outlet is located near the drying embankment in the south-east part of the marsh near Garmat Ali River. The culverts along Ar Rumailla road are also considered. The meshes are built using an adaptive tessellation technique for triangle elements and a patch technique for rectangular one.

A total number of 80 cross sections were constructed and obtained from the DEM through the Arc-View GIS with HEC- GEO-RAS extension. These cross sections are covering the marsh area with different spacing according to the hydraulic requirements. The hydrologic data of the recent years have been used in the implementation of the hydraulic model. The existing marsh hydraulic structure (Ar Rumaila culverts are taken into Consideration in the model. The boundary conditions are defined as a flow hydrograph in all feeding locations while the downstream boundary condition is considered as a stage hydrograph taken into consideration the tidal effect to investigate the location of stagnant and to estimate the amount of water that may enter from the tidal phenomena with and without a hydraulic structure. The Manning n is to be taken 0.045 for non vegetated portion when the water depth becomes more than 2 m; while it is equal to 0.070 for vegetated areas when the water depth becomes less than 2 m. The value of eddy viscosity affects stability and turbulent fluid characteristics. Ultimately, more than one technique was adapted in the definition of the eddy viscosity number.

Depending on the results of model, a construction of a head regulator on Garmat Ali River with a designed discharge of 500m^3/ sec near the navigation locks on the drying embankment is necessary to control tidal flow, as well as a gated structure in Ar Rumaila road site instead or with the existing 334 pipes. The designed discharge of the structure is 600m^3/sec. The locations of the proposed hydraulic structures are shown in Figure 5.

The effect of tidal wave on discharged water into or out of the marsh without a hydraulic structure at the down stream end is shown in Figure 6. The net inflow water into the marsh is started when water level at Garmat Ali River is higher than 2.1 m. The period of 25 days will provide an extra storage of 64.8 million m^3 within the marsh area during the high water tide. In other words it represents about 15% reduction in the required inflow discharges from all feeders for the purpose of restoration.

The depths of water, inundated areas and velocity trace are shown in figures 7, 8, 9, 10, 11 and 12. The green color in the all figures concerning water depth represents the shallow regions while the blue color represents the deep areas. The velocity circulations are inserted as a hyperlink to explain the locations of stagnant velocities, locations of high velocity and the inundated areas within the marsh. It is worthwhile to notice that the vegetation effects have been taken into consideration in the analysis of flow circulation within the region in terms of short velocity vectors and islands. These figures are repeated for three different discharge scenarios:

- The normal required discharge of 200m3/sec.
- The minimum required discharge of 80m3/sec.
- The maximum Flood discharge of 600m3/sec.

4 Conclusions

1- 15% reduction in the required inflow discharges from all feeders for the purpose of restoration can be acheived.The net inflow water into the marsh is started when water level at Garmat Ali River is higher than 2.1 m. The period of 25 days will provide an extra storage of 64.8 million m^3 within the marsh area during the high water tide.

2- Construction of a head regulator on Garmat Ali River with a designed discharge of $500m^3$/ sec near the navigation locks on the drying embankment is necessary to control tidal flow, as well as a gated structure in Ar Rumaila road site instead or with the existing 334 pipes. The designed discharge of the structure is $600m^3$/sec.

ABSTRACT

This paper presents a simulation approach for assessment of the impacts of sea level rise (SLR) on an estuary under complex hydrological conditions such as storm wave, tide, river flood, and sediment transport from rivers to estuary and coast. An integrated coastal/estuarine processes model is used to simulate hydrodynamic and morphodynamic responses to several scenarios of SLR and hazardous storms. Numerical results indicate that this model enables to simulate coastal flooding/inundation, shoreline retreat, and morphological change and respond correctly the interactive impacts of SLR and storms; it is therefore applicable to coastal/estuarine water planning and management for the purpose of flood prevention and erosion protection against the global mean SLR and hazardous storms.

INTRODUCTION

Global mean Sea Level Rise (SLR) is one of the significant impacts of global climate changes since the 20th century. A continued global SLR has been referred by various studies (Gibeaut 2007, Walton Jr. 2007, Williams et al. 2008, Feldman 2008, Gill et al. 2008, Batten 2008). The sea level is not only rising, but also accelerating due to the increasing emission of greenhouse gases, for instance carbon dioxide. Most climate modeling work is based on the increasing rate of SLR. In a more recent study, the Intergovernmental Panel on Climate Change (IPCC) reported that the average global mean sea level rose at an average rate of 1.8 mm per year from 1961 to 2003 and at an average rate of 3.1 mm per year from 1993 to 2003 (IPCC 2007).

Sea level rise may increase the susceptibility of coastal populations and ecosystems through the permanent inundation of low-lying coastal regions, amplification of episodic flooding events, and increased beach erosion and saline intrusion. Ultimately, this may lead to the retreat of millions of people, severe damage to coastal infrastructure and property, and a considerable loss of coastal ecosystems (Nicholls and Lowe 2004). Under a local SLR condition, more frequent extreme hydrological events such as hazardous storms, hurricanes, and high tides may cause more severe damages due to flooding/inundation and coastal erosion than ever on coastal infrastructure, shoreline, wetland, and ecosystem.

SLR will modify hydrodynamic processes and morphological features at coasts and estuaries. Therefore, SLR will change storm wave heights and lengths, and tidal prisms and currents. The magnitude of this effect depends on bathymetries, tide ranges, as well as properties of wave and wind. This effect can be reproduced by using hydrodynamic models provided that the modeling process and parameters are properly based on flow conditions since the modeled conditions represent projected future scenarios beyond the calibrated conditions (ASCE Task Committee on Sea Level Rise and Its Effects on Bays and Estuaries 1992). In addition, SLR may change the morphological equilibrium between the mean sea level and sediment supply which is related to the local bed changes and shoreline relocation (retreat/accretion). The increase in sea level will change not only the coastal landscape due to inundation, but also bedform due to the retreated shores and approaching storm waves; it is therefore important to investigate the changes of hydrodynamic and morphodynamic processes due to both SLR and storms in coastal and estuarine waters for assessment of environmental impacts of SLR in combination with storms, typhoons, or hurricanes.

The study of hypothetical SLR scenarios to assess the SLR-related impacts has been performed in previous studies (CCSP 2008; Cooper et al. 2005). For example, CCSP (2008) used three assumed SLR scenarios (0.3, 0.5, and 1.0 m of SLR by 2100) to evaluate several aspects of SLR impacts for the mid-Atlantic US coast using a range of elevation data sets which have large variations in vertical resolution and horizontal accuracy. Cooper et al. (2005) applied digital elevation models to study the impact of projected sea level rise to the New Jersey coast. They used two relative sea level rise projections, 0.61 meter and 1.22 meter to study what areas could be chronically inundated. The used maps however do not reflect the flooding or inundation that could occur at a precise location. Unfortunately, most of the previous researches have neglected the primary SLR impact on morphological changes due to sediment transport and increased storm waves.

The goal of this study aims to simulate hydrodynamic and morphodynamic responses to SLR and storm by using a two-dimensional coastal hydrodynamic and morphodynamic simulation model, CCHE2D-Coast. This study did not estimate how much the SLR will be; instead, it used different hypothetical local SLR scenarios which are broadly based on recent SLR forecasting studies combined with historical storm as hydrological forcings. In this study, the application of CCHE2D-Coast demonstrated the predictions of the morphological changes in an estuary due to a storm flood event and five hypothetical SLR scenarios.

MODEL DESCRIPTION

CCHE2D-Coast, a coastal/estuarine process model developed in the National Center for Computational Hydroscience and Engineering (NCCHE) has been utilized to assess the impacts of the SLR on coasts and estuaries under combined hydrological conditions such as storm waves, tides, river flood, as well as sediment transport from river reaches to the offshore (Ding and Wang 2007; Ding et al. 2007). This integrated coastal process model is composed of three integrated submodels to simulate waves, tidal and wave-induced currents, and sediment transport and morphological change.

The CCHE2D-Coast wave model enables to simulate irregular wave deformations including refraction, diffraction, wave breaking, etc. The hydrodynamic model is capable of computing tide, wave-induced currents, and wave-current interaction due to different physical forces, for example, tides, waves, river inflow, wind, bottom roughness, and Coriolis force. The morphodynamic process model is to simulate sediment transport and morphological change due to combined waves and currents driven by river flows, tidal flows, and nearshore currents. The integrated model has been built in a developed and well validated simulation package, CCHE2D (Jia et al. 2002). The three submodels can support a non-orthogonal mesh so as to efficiently simulate complex geometry in coastal and estuarine areas. CCHE2D-Coast has been extensively verified and validated by a number of previous studies. One may refer to Ding et al. (2006) and Ding and Wang (2008) for the details of model development and validation.

COMPUTATIONAL DOMAIN AND BOUNDARY CONDITIONS

The study site is a medium-sized estuary, which is located at the west coast of Taiwan Island, and has a river mouth sand bar, two inside islands, and two rivers as shown in Figure 1. The estuary is subjected to various hydrological forcings such as river inflows, waves, tides, winds, etc. The sediments in the estuary can be transported due to river flows, longshore currents, tidal flows, wave breaking, etc. In addition to flooding and inundation, severe morphological changes such as scours at the river mouth, depositions in the tidal river reaches, may take place due to river flood, storm waves and surges.

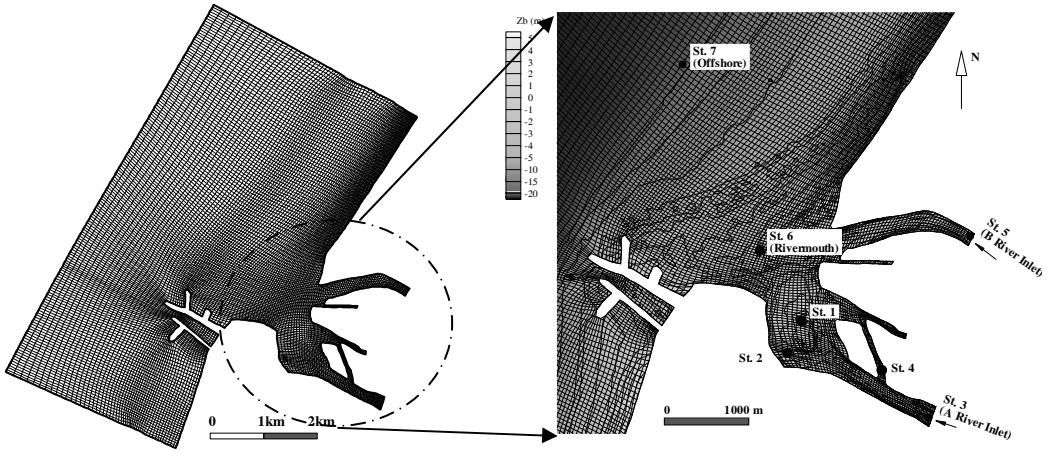

Figure 1. Computational domain and close-up view of the estuary

Possible SLR may cause disastrous flooding and inundation in this area during storm periods due to dense population in the coastal community. In order to examine the impacts of SLR during storms on the estuarine area, a computational domain was set up to cover the investigated estuary (Figure 1). A real storm (typhoon) which attacked this coast during a period from 8/31/2005 to 9/2/2005 was used as the storm event for the study. The storm flood inflows from the two rivers were applied to the

two river inlets as the river inflow boundary conditions. As shown in Figure 2, the two hydrographs at the inlets of the two rivers were produced beforehand by simulating respectively the storm flood flows in the two rivers from far upstream down to the estuary using a one-dimensional river flow model. The peak discharge was 2013.67m^3/s in the river at south and 992.66m^3/s in another river at north, respectively, in which the peak flood in the north river remained two hours of delay in comparison with the one at south.

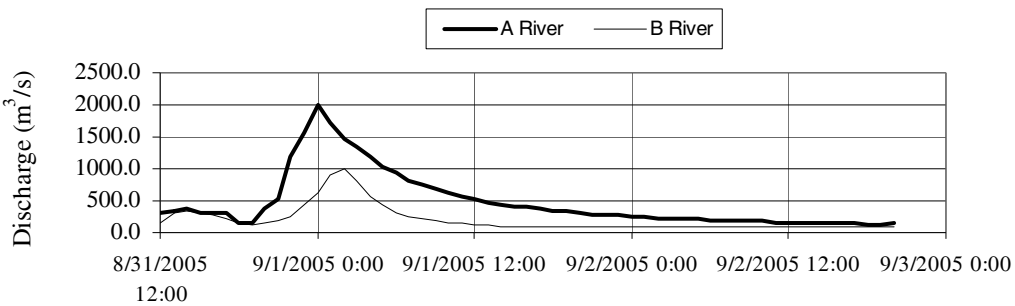

Figure 2. Hydrographs at two river upstream inlets during a storm flood event

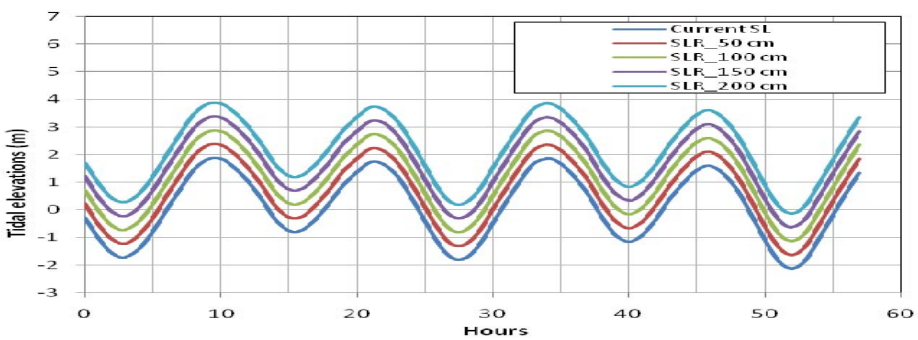

Figure 3. Tidal elevations boundary conditions at offshore

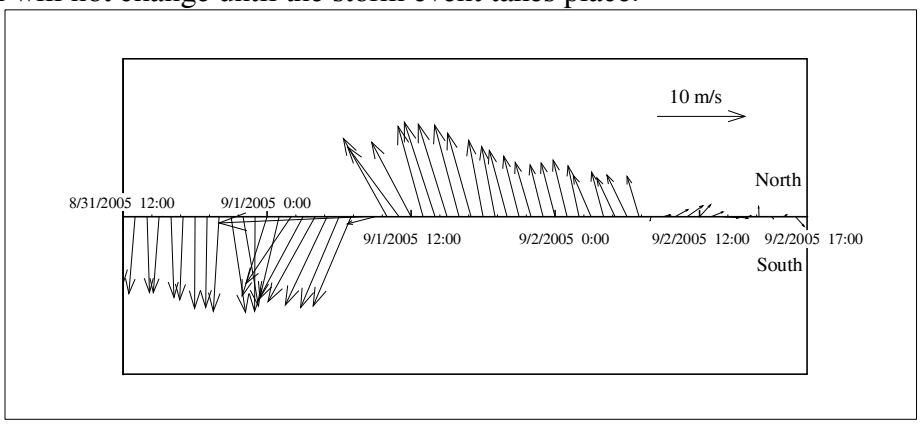
In this study, CCHE2D-Coast was applied to simulate flood flows and morphodynamic processes in the estuary due to the storm event and five hypothetical SLR scenarios (i.e. 0.5, 1.0, 1.5, 2.0 meters, and a case without mean sea level change) to reflect the increases of mean sea level. The mean SLR cases can be considered as the different scenarios of tidal elevations at the open sea. The SLR was added to the measured tidal elevations during the storm period to simulate the tides under the conditions of the SLR. Figure 3 shows five cases for tidal elevations at offshore which were applied to simulate the five different hypothetical SLR scenarios. The boundary conditions of the tidal elevations at offshore over the storm period were produced by computing ocean flows over a much larger regional grid covering the estuary using a two-dimensional ocean flow model. As the boundary conditions of wave model at offshore of the estuary, the wave properties (i.e. significant heights, averaged periods, and mean directions) at offshore were computed by using the SWAN wave model. The obtained significant wave heights varied in the range from 0.5 m to 1.6 m during the flood event. Meanwhile, Figure 4 shows the time series of prevailing wind speed and direction which has been used in this study as surface wind forcing over the estuary. The wind speed varies from 0.3 m/s to 16.4

m/s. Because the complexity and uncertainty of the future evolution of current bathymetry, this study assumed the current bathymetry within the computational domain will not change until the storm event takes place.



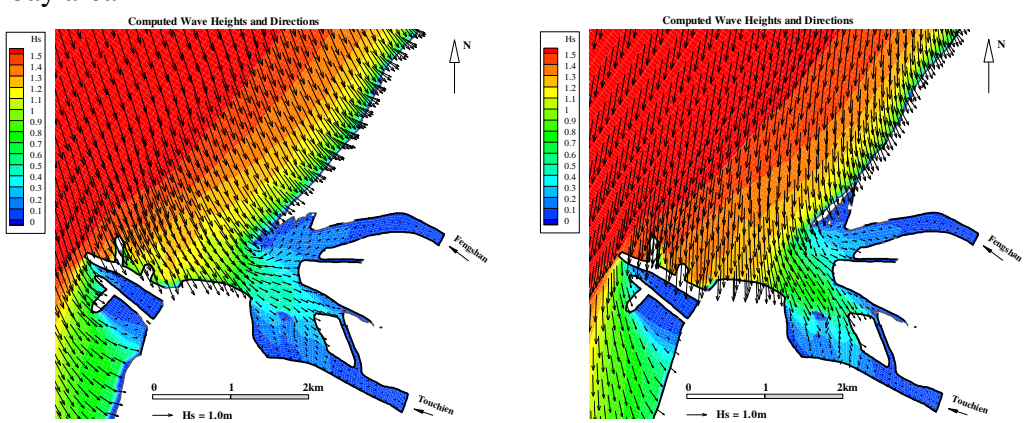


Figure 4. Wind speed and direction over the estuary during the storm event

NUMERICAL RESULTS OF HYDRODYNAMIC AND MORPHOLOGICAL CHANGES

In this section, the computed results of wave, current, sediment transport, and morphological change under the selected SLR scenarios are presented.

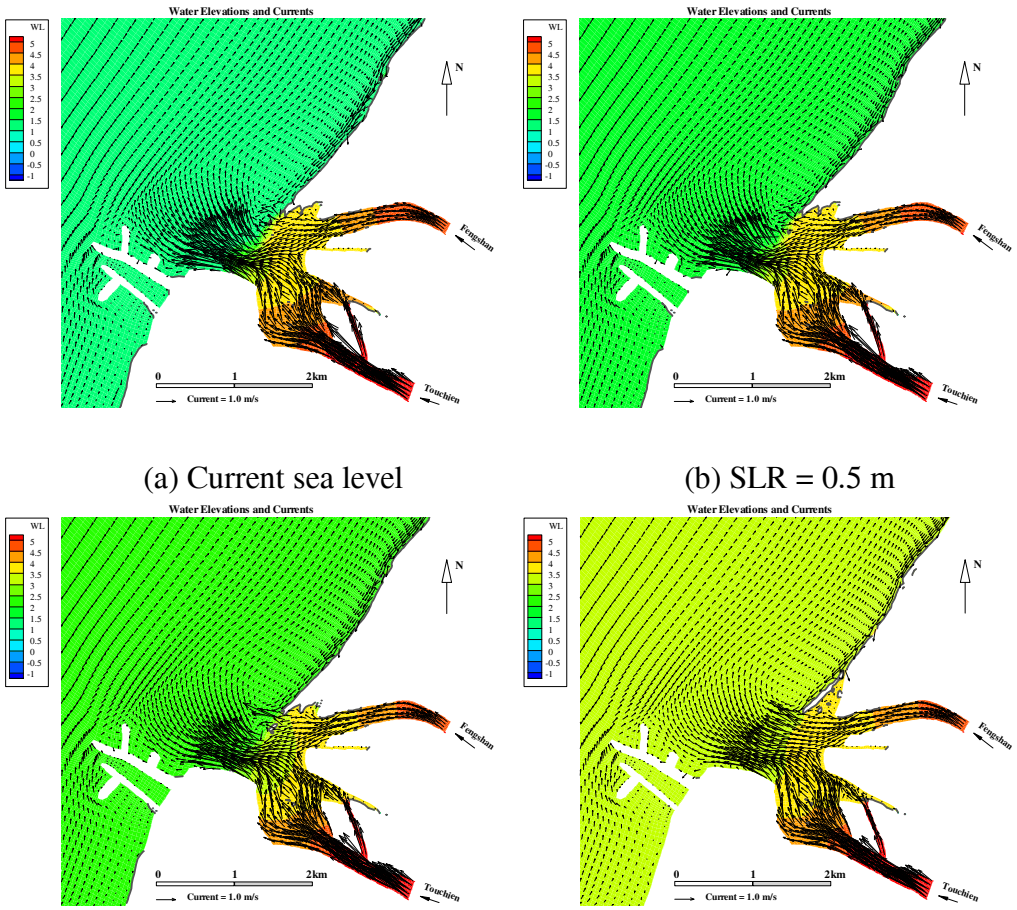

Figure 5 shows the distributions of computed wave properties (i.e. significant wave heights and mean directions) at the flood peak under the SLR conditions. Along with the increase of the mean sea level in the estuary from the current sea level (no SLR) to 2-meter SLR, the offshore waves could invade the estuarine area from the river mouth toward the estuarine river reaches. In comparison with the case for the current sea level (Figure 5a), sea level rises from 0.5 m to 2.0 m would promote the invasion of offshore waves inside the estuary for longer periods during the storm event, and further increase the flooding area and change the morphological features in the bay area.

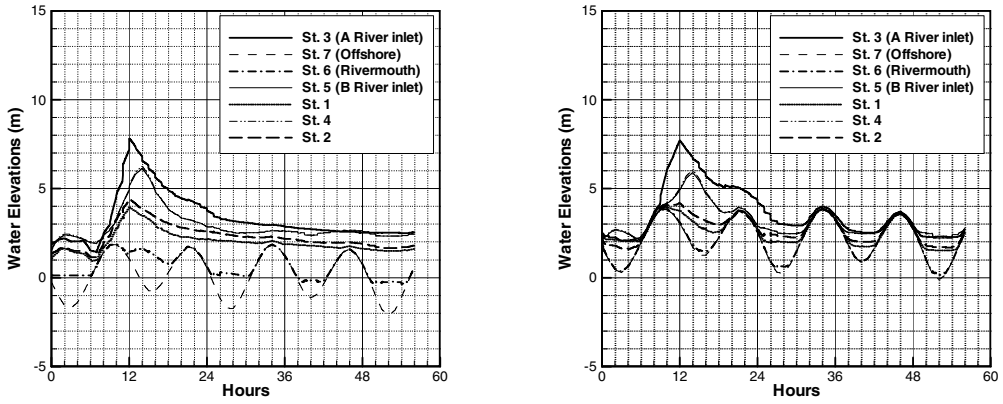
(a) Current sea level (b) SLR = 2.0 m

Figure 5. Comparison of computed wave height and directions at flood peak

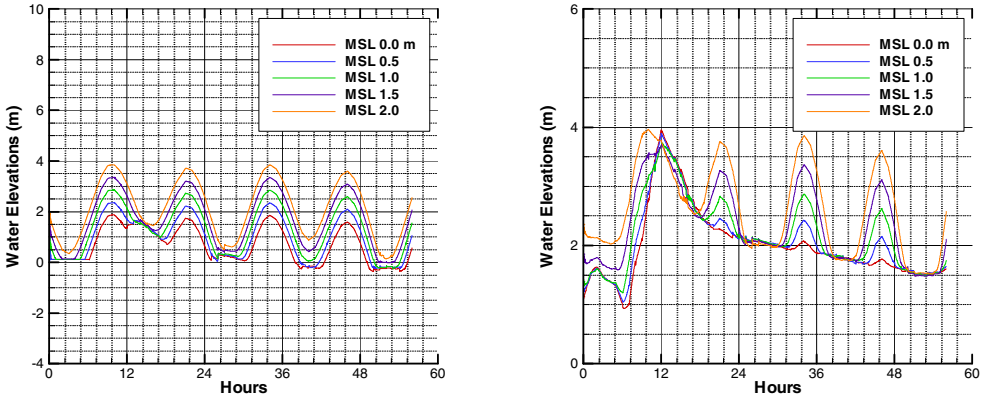
Figure 6 shows the comparison of the computed current fields at the flood peak due to different SLR cases over a range from the current sea level to 2.0 m SLR. The results show that there are significant increase in water elevations, offshore water invasion inside the estuary, and widening inundation areas along with the continual increase of SLR. Furthermore, the river mouth bar is increasingly inundated by overflowing waters for longer period.



(a) Current sea level (b) SLR = 0.5 m

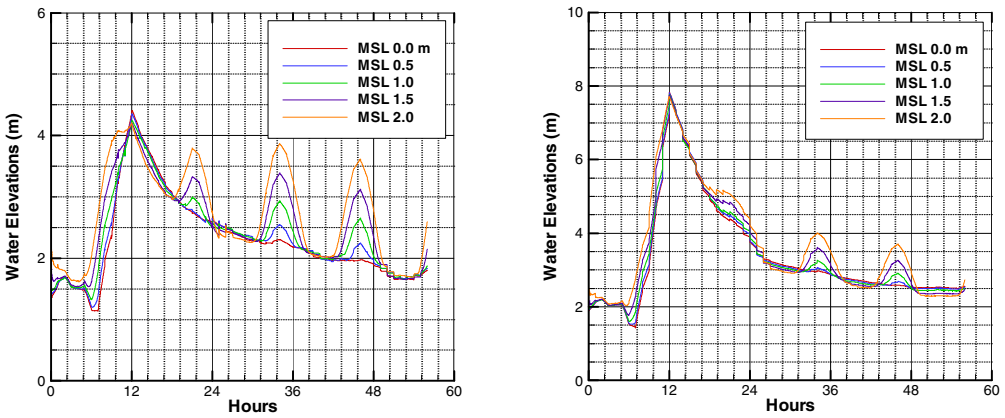
(c) SLR = 1.0 m (d) SLR = 2.0 m

Figure 6. Comparison of computed water elevations and currents at the flood peak



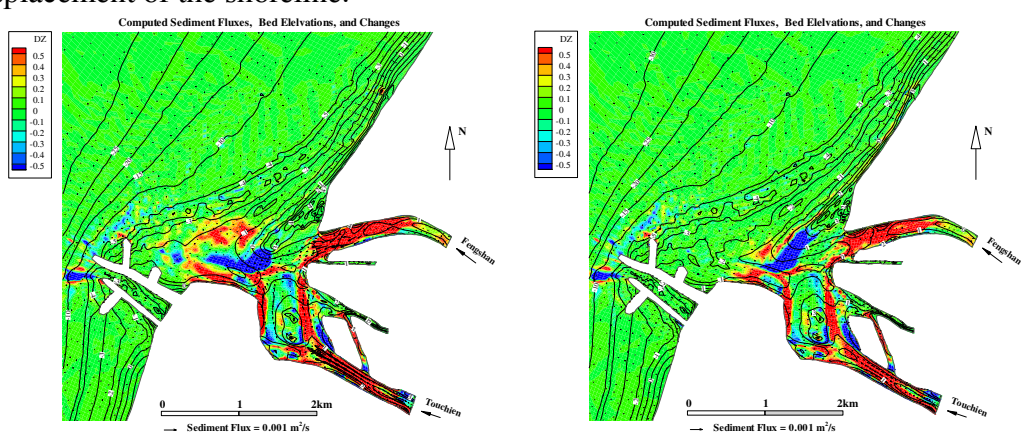
The differences of water elevations at seven different monitoring stations due to different SLR scenarios have been examined. As shown in Figure 1b, these stations represent offshore, river mouth, three upstream cross sections and two inlet locations. As an example, for only two cases, the time series of water elevations at all stations are plotted in Figure 7. Furthermore, the inter-comparisons of water elevations at four stations under the five SLR scenarios are shown in Figure 8. The following remarks can be summarized from these plots/graphs: (1) there are obvious wet/dry cycle change at all upstream monitoring stations (Stations 1 to 5) due to the continual increase in SLR. For example, by comparing Figures 9a and 9b, the oscillation of water elevations for stations 1 and 2 has been induced due to the increased effect of offshore tidal waves. This effect is spreaded for other upstream stations by continual

increase in SLR as plotted in Figures 9c and 9d. (2) As it can be seen from Figure 10a, there is significant inundation effect at the river mouth bar due to continual increase in SLR and the river mouth area behaves like offshore station after SLR 1.5 m. (3) The upstream river area is more susceptible to the tidal effect as it is shown in Figures 9c, 9d and 10d. For example as shown in Figure 10d for A River inlet, the continual increase in SLR promote the invasion of tidal waves inside the rivers and increase the water elevations.



(a) Current sea level (b) SLR = 2.0 m

Figure 7. Comparison of computed water elevation at seven stations due to different SLR scenarios



(a) Station 6 (Rivermouth) (b) Station 1

(c) Station 2 (South bank) (d) Station 3

Figure 8. Computed water elevation at different stations

The morphodynamic process is complicated in the investigated estuary due to the existence of the two inside island, which affects the river course and then the erosion/deposition processes. However, the model was effectively able to simulate these processes as depicted in Figure 9, which shows that there are significant changes in erosion/deposition areas due to different SLR. It also shows the gradually reducing areas of deposition in the estuary region for increasing SLR at offshore. This could occur due to the increased sediment transport capacity of flow with continual increase in SLR. The results indicate that with the increasing of SLR, the river mouth bar is increasingly eroded, which consequently will cause a significant landward displacement of the shoreline.

(a) Current sea level (b) SLR = 2.0 m

Figure 9. Comparisons of computed bed changes after the storm flood (The unit of bed change DZ in the legend: m)

CONCLUSIONS

This paper presents a simulation approach for assessment of the impacts of sea level rise (SLR) on an estuary under complex hydrological conditions such as storm wave, tide, river flood, and sediment transport from rivers to estuary and coast. By using the CCHE2D-Coast, the hydrodynamic results show that there are obvious wet/dry cycle changes at all upstream monitoring stations. Furthermore, there is a significant inundation effect at the river mouth bar in case of SLR higher than 1.5m. In addition, the river area is more susceptible to the tidal effect at SLR 0.5m. The morphodynamic results show that there is apparent change in erosion/deposition areas due to SLR. Especially, the river mouth bar is more exposed to be eroded, which consequently could cause landward shoreline retreat due to inundation and waves approaching to inland.

The preliminary test results of the study demonstrate that the CCHE2D-Coast model is able to effectively simulate the complex hydrodynamic and morphodynamic processes in coasts and estuaries under different SLR scenarios. Therefore, the deployed model can be effectively used in coastal regions planning and management to predict the eroded and inundated areas due to the global mean SLR and hazardous storms. The results are promising for future more detailed analysis, which may incorporate land subsidence effects.

ACKNOWLEDGMENT

This work was a product of the research partially sponsored by the National Center for Computational Hydroscience and Engineering at The University of Mississippi. The authors would like to thank Dr. Keh-Chia Yeh for their help to collect the boundary conditions for the study.

ABSTRACT

The Hydrologic Engineering Center's River Analysis System (HEC- RAS) is a one-dimensional computer model intended to perform hydraulic calculations for a network of open channels. This model is widely available, free of cost and is the most commonly used hydraulic model in the United States. Most HEC-RAS models are steady state. Unsteady flow analysis in HEC-RAS differs in many ways from the traditional steady state analysis. The largest difference involves the ability to input a full hydrograph to analyze the response of the river system to flows (and tailwater conditions) that vary with time.

InfoWorks RS is a hydrologic and hydraulic modeling package by Wallingford Software that is intended to provide a more comprehensive analysis than HEC-RAS. The 2D Module provides detailed surface flooding analysis for overland flows. In addition, the unsteady solution within InfoWorks is reported to be more stable than HEC-RAS. The capabilities of this software package also extend into several areas that HEC-RAS does not; including data management and hydrology calculations inclusive in the model. InfoWorks RS is commonly used in Europe and is being used more frequently in the US in especially complicated modeling and flood forecasting scenarios.

This is a case study on Lower Mountain Creek in Grand Prairie, Texas. The study area is between Mountain Creek Lake and the confluence with the West Fork Trinity River. This area offers many challenges to a traditional HEC-RAS analysis, including relatively flat channel slope, a wide floodplain with split flows through multiple bridge openings, and considerable shallow overbank flooding. A comparison of the results using Steady HEC-RAS, Unsteady HEC-RAS and InfoWorks RS (IWRS) will be presented. The comparison will include not only differences in computational results, but differences in model structure, input requirements, and methodology.

INRODUCTION: LOWER MOUNTAIN CREEK

The flooding risks for Lower Mountain Creek in Grand Prairie, Texas were studied in detail. The hydrologic analysis encompasses the drainage areas of Mountain Creek between Joe Pool Lake Dam and the confluence with the West Fork Trinity River.

The hydraulic analysis of Mountain Creek includes 22,350 linear feet of channel between Mountain Creek Lake Dam and the confluence with West Fork Trinity River. The hydraulic analysis of Thompson's Branch, a tributary to Mountain Creek, includes 4,940 linear feet of channel between Idlewild Street and the confluence with Mountain Creek.

There are three flooding sources in the project area, these are; 1) local flooding, 2) Mountain Creek, and 3) the West Fork Trinity River. Local flooding refers to water falling directly on the area considered or flowing to it on a minor tributary or stream. Mountain Creek flooding refers to water within the main channel and overbanks of Mountain Creek. The West Fork Trinity River can also flood property along Mountain Creek even in the absence of significant flows on Mountain Creek itself.

HISTORY OF HEC-RAS

The US Army Corps of Engineer's (USACE) Hydrologic Engineering Center (HEC) released HEC-2, Water Surface Profiles in 1968. HEC-2 was one of the first open channel hydraulics programs available and could incorporate bridge and culvert analyses and other hydraulics modeling components. HEC released a replacement program in 1995, HEC-RAS (River Analysis System). HEC-RAS incorporated a graphical user interface (GUI) that greatly facilitated input and display of model results. Updates to HEC-RAS are still being actively developed. Among the improvements since the initial version of HEC-RAS are channel modification analysis, mixed-flow capabilities, bridge scour analysis, lateral and inline weir analysis, hydraulic simulation of gated structures, modeling of changes in Manning's "n" in the vertical direction, and geographic information system (GIS) integration capabilities. Full unsteady flow analysis capabilities were integrated in HEC-RAS in 2001.

HEC-HMS (Hydrologic Modeling System) is usually used in conjunction with HEC-RAS to perform the hydrologic computations and determine flow rates and hydrographs used in the hydraulic analysis. HEC-HMS and HEC-RAS have limited GIS capabilities. Two additional programs; HEC-GeoHMS and HEC-GeoRAS are used (in conjunction with ESRI ArcView or ArcMap) to extract GIS data into HEC-RAS or HEC-HMS. For example, HEC-GeoRAS can be used to lay-out and populate the bulk of a HEC-RAS model. The model itself is then fine tuned and the analysis performed within HEC-RAS. The results are then exported back to HEC-GeoRAS to develop floodplains and other visual representations of the analysis results.

STEADY HEC-RAS DETAILS

The Mountain Creek model was created initially using the HEC-2 effective model from the FEMA Flood Insurance Study. Cross-section locations and bridge data were brought into a new HEC-RAS model and then updated with field survey and recent LIDAR topographic data using HEC-GeoRAS. See Figure 1 for the HEC-RAS

model layout. The hydrology was updated in a new HEC-HMS model and flows were applied to specific channel cross-sections.

Conveyance Issues

The Lower Mountain Creek floodplain has been characterized as a "bathtub" because it is relatively flat with a very wide floodplain. As rainfall and runoff increase a large portion of the floodplain is inundated quickly. Flow increases up to and including the 100-year design storm event do not significantly increase the extent of flooding but do increase in depth, hence the "bathtub" analogy. Manning's "n" values for much of the overbanks were set high to account for extensive tree cover in undeveloped areas and for fences and buildings in developed areas

The study area is crossed by three major elevated roadways and one railroad line with two to four bridge openings each. Existing development has blocked or restricted flow access to all but one of the off-channel bridge openings under Jefferson Road and Main Street (Hwy 180). The channel connecting these bridge openings has also been blocked upstream and downstream from direct connection to Mountain Creek; therefore conveyance was restricted on these secondary structures within the HEC-RAS model.

Thompson's Branch

The hydraulic model for Thompson's Branch was created as a separate model and not included in the Mountain Creek flood analysis. The model of this tributary was used primarily to assess the effectiveness of the channel to convey local flows because this area is more severely inundated by the Mountain Creek flood flows perpendicular to the Thompson's Branch channel.

UNSTEADY HEC-RAS DETAILS

Unsteady flow analysis in HEC-RAS differs in many ways from the traditional steady state analysis. The largest difference involves the ability to input a full hydrograph into the model to analyze the response of the river system to flows that vary with time. Additional differences are listed below:

Table 1. Comparison of Steady to Unsteady Solutions

Steady Solution	Unsteady Solution
Energy – profiles computed based on energy losses	Momentum – profiles computed based on sum of forces
Internal energy losses estimated by Manning's and Form Loss equations	External boundary shear represented by Manning's equation
Steady Flow is input (Q=VA) and Inflow = Outflow	Unsteady flow is based on continuity equation (Outflow = Inflow – Storage)

In addition to the computational differences between steady and unsteady HEC-RAS, there are many other differences that require attention when running an unsteady model.

Pilot Channel
A slight modification had to be incorporated into the HEC-RAS geometry to produce a stable unsteady HEC-RAS run. For model stability, a small pilot channel was added to the geometry to guarantee flow in the downstream direction and reduce the effective slope for low flow rates with no impact to maximum calculated water surface elevations.

Flow Locations
The HEC-HMS data was applied to the model differently than for the steady model. It was not appropriate to use the calculated confluence hydrographs within the study reach since these quantities include modified Puls routing information generated by the steady HEC-RAS model. Using these flows would result in double-counting valley storage and over-estimating peak attenuation. Therefore, the individual sub-basin hydrographs within the study reach were added as lateral inflow hydrographs.

Hydraulic Property Tables (HTAB)
The steady HEC-RAS analysis uses the energy equation for an exact hydraulic calculation for each cross section and structure (internal boundary). Due to different requirements of the momentum equation, hydraulic properties are pre-computed for each cross section and structure in the unsteady model. To complete the flow simulation, one must execute the geometry preprocessor to build these rating curves. The Hydraulic Property Table (HTAB) can be viewed for each structure and internal boundary. Any incongruities shown by the HTAB must be resolved prior to attempting the full flow simulation.

Initial Conditions/ Minimum Flow Rate
To avoid sudden changes and computational problems for HEC-RAS, initial conditions must be defined. This is typically represented as a stable flow scenario in the river system prior to the start of the flood simulation desired. The unsteady flow simulation cannot run dry so a minimum flow rate was assumed for the inflow hydrograph at the upstream limit of the model. It is also possible to use the output of a previous simulation to resolve stability problems at the beginning of a run

Time Step
Stability and accuracy can be gained by trying to satisfy the Courant Condition when selecting the computational time step. Generally, a smaller time step will produce a smaller incremental change within the computation and result in a more stable model. For the 1% unsteady model a time step of 20 seconds was selected for a total run of 48 hours.

HEC-RAS RESULTS

The differences between the steady state results and the unsteady results in HEC-RAS were significant. These differences are most likely the cause of different routing techniques. The effects of valley storage and related peak attenuation are accounted for by using modified Puls routing in HEC-HMS in the steady state model and are

calculated by HEC-RAS in the unsteady model. In addition, the unsteady HEC-RAS model shows storage impacts and calculated effects for each individual cross-section, while the steady model is limited to the larger routing reaches as defined within HEC-HMS. The existing condition 1% annual chance event water surface profile was compared to the effective FEMA model results. Generally the results from this study were very similar to the effective model. See Figure 3 for the profile comparison.

HISTORY OF INFOWORKS RS

InfoWorks RS (IWRS) was launched in 2002 with the release of InfoWorks v4.0 as the successor to well established ISIS river modeling software. The first release of InfoWorks RS offered the 1D flow and hydrology simulation capability inside the InfoWorks environment and enhancements included updating the ISIS data model to be geo-referenced; the addition of ground modeling functionality; and the development of an automated flood mapping capability. The GIS functionality of the InfoWorks GUI allowed flood maps to be overlaid on top of ground model data, topographic maps or aerial photography to provide a detailed method of viewing the model results.

Development of InfoWorks v4.5, released during August 2002 saw the inclusion of water quality, sediment transport and PDM conceptual soil moisture runoff model. The ground modeling functionality was enhanced to support both grid based and TIN (Triangular Irregular Networks) based ground models. Most recently, the release of v9.0 has provided a step change to functionality of InfoWorks RS with the inclusion of the InfoWorks 2D module and the HR Breach methods. Representing the flows in 2D provides more detail and accuracy, particularly for local water levels and velocities and is useful for flood damage assessment and analyzing risk from flood inundation. The HR Breach methods allow for simulation of the failure of embankments and dams providing completely integrated 1D, 2D and breach simulation functionality in a single product (single model networks, single data storage, single simulation and single results analysis and post-processing).

INFOWORKS RS DETAILS

InfoWorks RS v.9.0 modeling software is an integrated modeling package that is the equivalent of packaging HEC-HMS, HEC-GeoHMS, HEC-GeoRAS, AND HEC-RAS into one model. It calculates the hydrology and hydraulics from information input and/or developed within the model environment by the user on the GUI interface to integrate with a GIS-based terrain model stored within a common database. One major advantage of IWRS is the ability to generate, for instance, cross-section information, then use it, change it, manipulate it, etc. without impacting the plotting of the data.

Initial Conditions

The model uses a base flow in the steady state condition to generate initial conditions for the full unsteady solution. This is essentially the same as the initial conditions required for the HEC-RAS unsteady model with very similar base flow values. This steady state run is used to solve most of the instability issues that arise as the model begins and because, as in HEC-RAS unsteady, the unsteady model cannot run "dry".

Model Components

The physical components of an IWRS model consist of nodes and links. Nodes are the physical components that include channel sections, flow input, weirs, storage areas, junctions, spill units, etc. The channel sections are generally limited to the stream channel with limited overbanks instead of sections that extend across an entire floodplain as in HEC-RAS. Spill Units are ridge lines or similar flow boundaries (weir, bridge deck, etc.) that will allow "spill" from one node to another. Links are the connections between nodes. All nodes must be linked correctly. The interface includes a validation tool that must be run when changes are made to the nodes and links. This tool allows the user to quickly locate problems and correct them. The model will not "run" until all of the critical validation issues have been corrected. Figure 2 show the IWRS model network.

Importing HEC Model Data

IWRS 9.0 allows the import of data sets from HEC-HMS and HEC-RAS models. One can import rainfall incremental data and/or computed hydrographs. Computed hydrographs can be applied to specific nodes or can, in some cases, be input as lateral flow proportioned across more than one node. One can also import channel cross-section data sets. However, the HEC-RAS bridge details cannot be imported at this time because of significant differences in modeling methodologies.

Bridge Modeling

Bridge modeling methodology is one area, in these users' opinion, that is more user-friendly and accurate in the HEC-RAS model. In IWRS a bridge link applies to the bridge opening only. It can be modeled as one or more arch or rectangular openings between piers or it can be a rectangular opening with the total width and type of piers specified. It will not allow the input of a sloping low chord (bottom of bridge) although it can be reasonable simulated with a series of openings. The bridge deck is a separate node (spill unit) connected to the channel sections with links other than the bridge. The bridge deck or weir if specified must be one elevation. The alternative is to define the deck as the section replacing the underlying ground model points.

Time Step

The steady state event analysis for initial conditions was run using direct input of runoff. The unsteady analysis may be run using either a fixed time step set by the user or an adaptive (variable) time step determined by the program. Use of the adaptive time step reduces some of the instability that may occur in a HEC-RAS unsteady run by allowing the model to test, iterate and determine the most workable solution.

Model Issues

There are only two major issues, at this time, to utilizing IWRS for a flood analysis. The first is that FEMA does not generally accept IWRS as a model for flood map amendments. FEMA will only accept the model if certified by a Cooperating Technical Partner (CTP). The City of Grand Prairie is a CTP thus the impetus for this model and the comparison to the previously completed HEC-RAS model and the cooperation of Wallingford Software in providing this demo copy of the IWRS v.9.0.2 software and limited technical support.

The other disadvantage is the model development learning curve. The differences between modeling with HEC software and InfoWorks are akin to switching between AutoCAD and MicroStation software for drafting. The mentioned drafting programs are different enough that there is a significant learning curve when a long-time user of one switches to drawing with the other. A similar learning curve was found in this comparative analysis with one very notable additional hindrance. The HEC suite of models developed in the US use technical terminology developed here, whereas IWRS, developed in the United Kingdom, uses some different the technical terminology. The confusion found is as basic as a sign that says "WAY OUT" (UK) meaning "EXIT:" (US) or "MIND THE GAP" (UK) instead of "WATCH YOUR STEP" (US). Once the user understands the "language" differences then the model construction becomes more intuitive.

INFOWORKS RS RESULTS

For this preliminary analysis, the IWRS modeling concentrated on the hydraulic analysis using the 1D methodology. The hydrology was input as flood hydrographs previously developed in the HEC-HMS model for Mountain Creek as point and/or lateral nodes approximating the drainge area locations. Cross-sections were imported from HEC-RAS for the existing conditions on Mountain Creek. Overbank length of each section was reduced to limit overbank input in the channel flow and maximize the use of storage areas in the west overbank only because the east side is in the Dallas City Limits and the floodplain extent in there is limited. Figure 2 shows the IWRS model structure.

Unlike the HEC-RAS analysis, the Thompson's Branch channel cross-sections were also imported and modified. A third set of channel sections was developed for the side channel extending from Thompson's Branch to Jefferson Road. This channel was not modeled in HEC-RAS because it is graded from Jefferson Road down to Thompson's Branch (upstream direction for Mountain Creek).

All bridge openings and culverts not located on the main channel of Mountain Creek were input as spill units and/or orifices connecting storage areas and section nodes. Model results are shown on comparative graphs in Figure 3 and Figure 4. Figure 3 shows the 1% (100-year) water surface profiles for each model. The IWRS model shows a substantially lower elevation for any given location. Because this is a preliminary model there may be some additions corrections needed to the offline

structure parameters. Figure 4 shows the calculated maximum flow for each model for Mountain Creek channel sections. This comparison is deceiving because it looks like the IWRS model has "lost" a substantial potion of the flow volume. In the HEC-RAS analyses flow is input to the channel first then apportioned to the overbanks when the channel capacity is exceeded. Because the HEC-RAS sections cover the full extent of the floodplain they include the total volume. The IWRS plot only includes that potion of the event volume carried within each limited channel section. In the model, flow can "spill" to adjacent storage areas depending on water surface elevation. Other flow nodes such as those for Thompson's Branch and/or drainge areas west of the main channel do not reach the Mountain Creek channel until all flow is funneled to it upstream of the IH-30 roadway.

CONCLUSIONS

The previous study on Mountain Creek has already shown the advantage of the HEC-RAS unsteady analysis versus the steady analysis. This paper analyzes those results compared to those modeled by the 1D unsteady results generated by InfoWorks RS 9.0. The preliminary results from IWRS show the potential for more accurate accounting of flow movement and storage outside the main stream channel.

A preliminary analysis of the model results as depicted in Figures 3 and 4 show that the offline bridge openings, especially those under westbound Jefferson Road, may provide more flow capacity than previous anticipated. Greater conveyance through these structures reduces the upstream flood levels and the extent of inundation. Viewing the simulation as it progressed, we noticed that the overbank area located between the railroad line and Main Street (Hwy 180) began to be inundated much earlier in the event than previously thought and was one of the last areas to "dry out" after the rainfall ended. This effect has been corroborated by eye-witness accounts of area flooding.

Despite the learning curve issues we found that the IWRS model does provide an intuitive method to link the various physical features and allow for flow to follow a more "natural" path than may be modeled easily in HEC-RAS. The greatest advantages are the functionality of having all hydrologic, hydraulic, and terrain data in the same database with seamless interaction that allows more rapid analysis, correction, and publishing of results. It appears that the more complex the overbank shallow flooding becomes, the more advantageous IWRS becomes relative to HEC-RAS.

ABSTRACT

One of the goals of the current Everglades restoration effort is to reduce the delivery of stormwater runoff to Lake Okeechobee from the drainage basins located south of the lake. The S-4 Basin is one of these drainage basins that has not yet been diverted. An analysis was performed to determine the feasibility of diverting S-4 Basin drainage southward, away from Lake Okeechobee. Unsteady flow hydraulic models of the diversion alternatives were developed using the Corps of Engineers HEC-RAS program. These models are relatively complex with the numerous canals, pump stations, gated culverts and other structures. This paper covers the project background, model setup and the challenges faced by the modelers as well as some of the results obtained through the modeling effort.

INTRODUCTION

The Florida Department of Environmental Protection (FDEP) and the South Florida Water Management District (SFWMD) have established policies that seek to limit the discharge of phosphorus contained in stormwater runoff to Lake Okeechobee. In Florida's 1994 Everglades Forever Act (EFA), several drainage districts located on the south shore of Lake Okeechobee are specifically required to install conveyance systems that would divert at least 80 percent of the drainage historically discharged to the lake southward into one of the SFWMD's primary conveyance canals. Through these canals, this drainage is delivered to one of the existing stormwater treatment areas (STA) for treatment prior to its discharge into the sensitive Everglades ecosystem.

The S-4 Basin is one of the water management basins located along the south shore of Lake Okeechobee, but none of its component drainage districts are required in the EFA to install diversion systems. However, in light of pending regulations that may further limit phosphorus discharges to Lake Okeechobee, it is anticipated that this basin's discharges to the lake may be restricted in the future as well. For this reason, the Everglades Agricultural Area Environmental Protection District (EAAEPD) commissioned the S-4 Basin Feasibility Study to investigate alternatives

to reduce discharges to Lake Okeechobee from the S-4 Basin. This study was co-funded by SFWMD (Burns & McDonnell, 2006, 2008).

The potential diversion of stormwater drainage from the S-4 Basin is complicated by one fundamental constraint: the performance of the existing drainage systems in the S-4 and receiving basin(s) cannot be compromised during flood events. This constraint requires first that any potential diversions into adjacent drainage basins must not cause or exacerbate flooding within these receiving basins. Therefore, the allowable diversion rate into these basins is highly variable depending on the amount of local runoff. Secondly, because the allowable diversion rate from the S-4 Basin can be zero at times, this constraint also requires that any proposed diversions not interfere with the basin's existing drainage system. Therefore, due to the dynamic nature of this constraint it was necessary to model the hydraulics of the primary conveyance canals within the S-4 and receiving basins to assess the potential performance of the various diversion alternatives.

PROJECT HYDRAULIC MODEL

Because of the flat topography, stormwater drainage within south Florida is accomplished primarily through a system of man-made canals with numerous control structures and pump stations. The flow in these canals is very dynamic, with flow reversals and even looped flow common. Therefore, the computer model chosen to simulate the operation of the S-4 and adjacent drainage basins must be capable of simulating these unsteady flow conditions.

At the time this study was initiated, Version 4.0 of the Corps of Engineers River Analysis System (HEC-RAS) was available only as a beta release and the writers were not yet familiar with its new capabilities. Therefore, the first attempts to model the proposed diversion system used a version of the U.S. Environmental Protection Agency's Storm Water Management Model (SWMM). Although this model has many fine features, it is probably better suited for use on enclosed stormwater systems. Even after inclusion of an optional real-time control module, this model's ability to simulate the operation of gated control structures proved to be problematic. Some of these structures have multiple stage triggers that cause them to be opened or closed. In order to simulate these triggers, it was sometimes necessary to introduce dummy structures that operated in series and/or in parallel to the real structure. Because of this complicated model architecture, the SWMM model often had trouble converging to a solution and execution times were excessive.

The hydraulic modeling for this study was eventually switched to HEC-RAS, Version 4.0 after the writers became aware of its new capabilities for control of gated structures. Although the new sediment transport features of Version 4.0 have been widely publicized, the new gate control features are equally significant. In prior HEC-RAS versions, gate control was accomplished by simple stage or flow triggers tied to a single reference location, typically immediately upstream or downstream of the structure. In Version 4.0, gate operations can be controlled using script-style rules that can employ multiple if/else if /else logic structures. These new control rules allowed direct control of a structure's gates given stage or flow conditions at multiple reference locations, which was vital to successfully model the proposed diversion

system. The new gate control rules also allow one to implement seasonal, time of day and other complicated rule sets.

Consistent with the requirements in the EFA for diversions at other drainage districts, the goal of the proposed S-4 Basin diversion system is to divert an average of 80 percent of its historical discharges to Lake Okeechobee. Because of the dynamic nature of these diversions, the diversion efficiency of the alternative diversion schemes was demonstrated by simulating system operations over a 15-year continuous period (water years 1993–2007) using a 5-minute simulation time step.

BASELINE CONDITIONS MODELING

The first modeling task in this study was to estimate baseline conditions. Currently, the S-4 Basin and potential receiving basins for diversions (C-139 and S-3/S-8 basin) are not hydraulically connected. Figure 1 shows the general orientation of these basins and the existing culverts and pump stations that control flow between them. Because these basins are not currently interconnected, the baseline HEC-RAS models for the S-4 Basin and C-139 and S-3/S-8 basins were developed separately.

The S-4 Basin (Figure 2) includes all or part of five special drainage districts (Clewiston Drainage District, Disston Island Conservancy District, East Hendry County Drainage District, South Florida Conservancy District and Sugarland Drainage District) plus a large farm area owned by the U.S. Sugar (Townsite). Drainage from these districts is discharged into the one of the basin's major canals: Clewiston, C-20/21 or LD-1. From these canals, basin drainage is currently discharged to Lake Okeechobee through the S-310 lock or S-4 pump station. Drainage also exits the basin through S-235 culverts into the C-43 Basin.

The C-139 Basin is logically divided into north and south subbasins, which are separated at the G-150 control structure. The northern C-139 subbasin drains into the L-1 Canal and the southern subbasin into the L-2 and L-3 canals. These canals run along the northern and eastern perimeter of the C-139 Basin. Discharges from the northern basin occur at G-136 into the S-3/S-8 Basin and into the southern subbasin at G-150. Southern basin discharge occurs primarily at the four G-342 culverts into STA-5. A planned enlargement of STA-5 will soon be under construction. With this enlargement, a new inflow pump station (G-508) will also be installed. G-406 is a bypass structure that opens only when required flow exceed the capacity of STA-5.

Discharge from the C-139 Basin through G-136 enters the L-1E Canal. This canal connects with the Miami Canal at structure G-212. The Miami Canal is the principal conveyance canal in the S-3/S-8 Basin, connecting Lake Okeechobee at S-3/S-354 with Water Conservation Area 3A (WCA-3A) at the S-8 pump station. The majority of the discharge into the S-3/S-8 Basin is delivered to STA-3/4 for treatment prior to being discharged into WCA-3A.

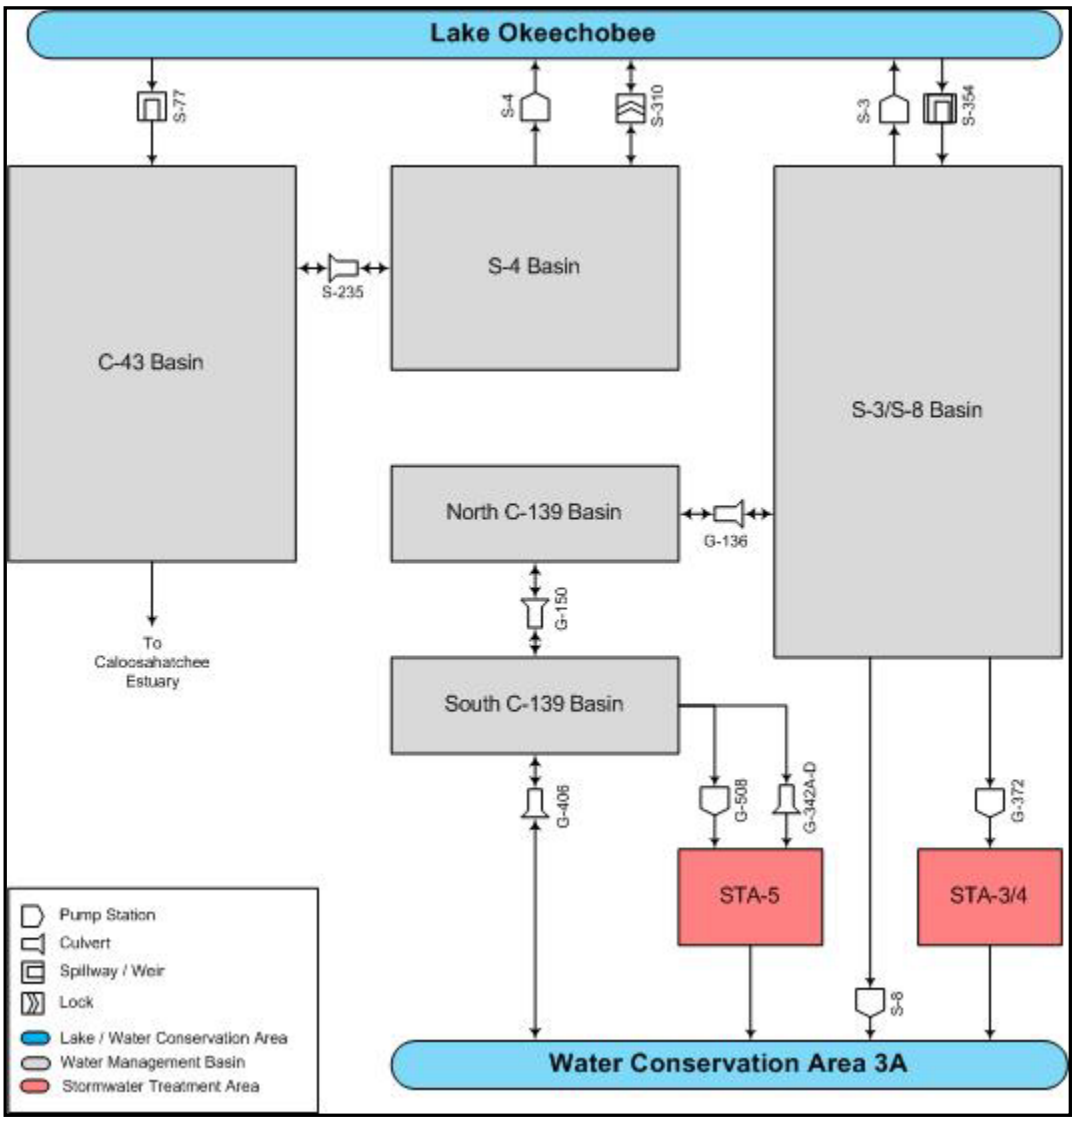

Figure 1: Project Area Schematic

The baseline hydraulic models for these basins include only the major canals in each basin. The numerous secondary canals, laterals and sublaterals in these basins are not represented explicitly in the model. Stormwater runoff from these basins into the primary canal system was treated as a point sources where it occurs as a specific structure or canal confluence or as a uniform inflow when it is distributed over a long canal reach. A dataset derived from historical mean daily flow records was used to define the inflow hydrographs at each of these points.

The boundary conditions used in the HEC-RAS model consist of estimated stage hydrographs at each model domain boundary. These boundaries included Lake Okeechobee stages, tailwater stages in the C-43 Canal below S-235, G-212 tailwater stages in the Miami Canal, stages in STA-5 and G-406 tailwater stages.

Table 1 is a summary of the average annual basin discharges under baseline conditions. This table lists both estimated discharge volumes and the corresponding total phosphorus (TP) loadings.

Table 1: Average Annual Discharge for Baseline Conditions

Basin	Destination	Volume (acre-feet)	TP Load (kg)
S-4	C-43 Canal @ S-235	57,544	16,104
	Lake Okeechobee @ S-310	16,859	4,973
	Lake Okeechobee @ S-4	28,038	7,961
	Total Lake Okeechobee	44,897	12,934
C-139	L-1E Canal @ G-136	17,745	4,688
	STA-5 @ G-342A-D+G-508	162,946	42,389

ALTERNATIVES

Three different diversion alternatives — alternative schemes for delivering S-4 Basin drainage southward — were identified in this study. In addition, two different treatment alternatives were considered (that is, delivery of diverted drainage to STA-5 or to STA-3/4), for a total of six diversion/treatment combinations. The diversion alternatives were numbered 1-3 and the treatment alternatives A or B, so the complete alternatives were named 1A, 1B, 2A, etc.

As an example, Alternative 2A is featured below. Figure 2 is a schematic for this alternative with the new, relocated or modified structures shown in red. In this alternative, S-4 Basin diversions are delivered southward via two new connections. Drainage discharged into the Clewiston Canal is diverted through a southward extension of this canal. This extension requires relocation of pump station EPD-06 (EPD-06A), a new control structure at the confluence of this canal extension and the L-1E Canal (G-136B) and a new divide structure in the L-1E Canal (G-136C). Diversions delivered to this point flow westward into the L-1 Canal and then southward.

Drainage from the Sugarland Drainage District would be delivered directly into the L-1 Canal through a new gated culvert designated G-96A. Stages in the L-1 Canal are often lower than stages to the south in the L-2 Canal so a new pump station is included to lift flow from the L-1 into the L-2 Canal. Without a new G-150A pump station, potential diversion amounts would be severely limited.

MODELING RESULTS

Table 2 compares the average annual discharge volumes for Alternative 2A with those for baseline conditions. As shown, this alternative would reduce Lake Okeechobee discharges by approximately 60 percent. The diversion efficiencies of the other "A" alternatives (1A and 3A) were respectively 51 and 64 percent. Therefore, none of the "A" alternatives were able to achieve diversion efficiencies near the desired 80 percent target.

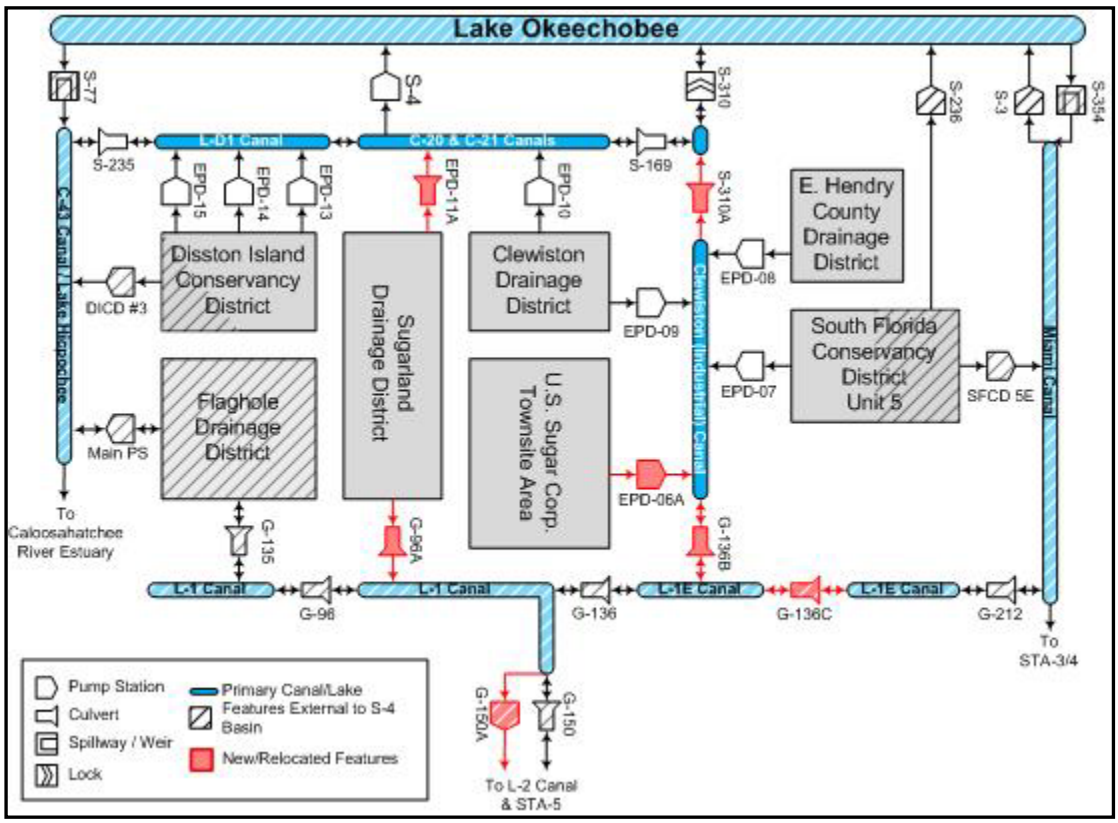

Figure 2: Schematic for Alternative 2A

Table 2: Average Annual Discharge Comparison for Alternative 2A

Basin	Destination	Discharge Volume (acre-feet)		Percent Difference
		Baseline	Alternative 2A	
S-4	C-43 Canal @ S-235	57,544	53,636	-6.8
	Lake Okeechobee @ S-310	16,859	8,103	-51.9
	Lake Okeechobee @ S-4	28,038	9,828	-64.9
	Total Lake Okeechobee	44,897	17,931	-60.0
C-139	L-1E Canal @ G-136	17,745	17,683	-0.3
	STA-5 @ G-342A-D+G-508	162,946	196,493	+20.6

In the "B" alternatives, S-4 Basin diversions are transported eastward in the L-1E Canal to the Miami Canal. From this confluence, these diversions would flow southward in the Miami Canal to STA-3/4. This flow path is less restrictive from a hydraulic perspective than the path required to deliver these diversions to STA-5. The diversion efficiencies for the three "B" alternatives (1B, 2B and 3B) were respectively 81, 85 and 74 percent. However, based on conditions that existed at the start of this study, SFWMD staff stated that there was no surplus treatment capacity at STA-3/4. Therefore, it is possible that additional STA capacity in the S-3/S-8 Basin would be required to accommodate diversions from the S-4 Basin.

USING HEC-RAS 4.0 FOR UNSTEADY FLOW MODELING

To this point, this paper has presented a discussion of the S-4 Basin diversion project and an example of the HEC-RAS hydraulic modeling completed for this project. The balance of this paper will focus on some of the problems and limitations encountered.

Many readers will be familiar with using HEC-RAS, and its predecessor HEC-2, to estimate steady-flow water surface profiles. For those who may be unfamiliar with HEC-RAS, particularly when using unsteady flows, some background information is provided.

HEC-RAS is designed to perform one-dimensional hydraulic calculations for a network of natural or man-made channels. The stream network is defined as one or more stream reaches, with each stream reach in turn represented by a series of stream cross sections. For this project, the unsteady flow capabilities of HEC-RAS were used to simulate the operation of the S-4 Basin system over a 15-year period. In this mode, HEC-RAS routes flow through the system by solving the St. Venant equations for each model time step; this project used five-minute time steps. HEC-RAS is able to route flow through the drainage network, modeling the effects of backwater, flow reversal, surcharging, looped connections, and pressure flow. The model network can also include weirs, gated and ungated culverts, and pump stations that are located in inline or lateral structures. HEC-RAS can also be programmed to operate pump stations and gates using complex logic based on flow rates, velocity, or stages (U.S. Army Corps of Engineers, 2008).

Model Setup

Many of the requirements for setup of the project HEC-RAS models are common to all similar hydraulic models. In the case of this study, there were many proposed canal extensions, canal enlargements and new control structures. Finding optimum sizes for these improvements can be relatively time consuming using an unsteady flow model. In this study, the writers found it useful to start with a steady flow model, with flow rates equal to design maximums to help size these improvements. The benefits of this peak flow analysis were fourfold:

- Obtained a better understanding of the flow characteristics of the existing drainage system, especially in areas of limited geometric information;
- Identified problem areas thus allowing these problem areas to be corrected or avoided (that is, by taking an alternate path);
- Identified potential target stages for the diversions; and
- Facilitated selection of structure type (that is, pump station vs. gated, gravity flow structure) at certain locations.

Initial Conditions

By default, HEC-RAS will determine the initial state of an unsteady flow model (water surface elevations and flows) by finding a steady flow solution to the model using initial flow rates. In an unsteady flow model it is not uncommon for this steady flow solution to fail. These failures were often the most frustrating because HEC-RAS would quit without ever generating any useful results or error messages that could be used for debugging. Under these conditions, it is often necessary to

force HEC-RAS to set startup conditions using an initial conditions file (alternately referred to as a hot start or restart file). This file contains the initial water surface elevations at each cross section within the model.

When specified, HEC-RAS will write a restart file at a specified time (usually after the last model time step), but it is necessary to have a working model first. This is accomplished using a special hot start model. This model will employ the same geometric data as the production model but different model boundary conditions. The typical procedure is to increase the initial water surface elevations at the model boundaries to levels higher than may be physically possible and then gradually reduce these elevations down to the real initial conditions.

Raising the initial water surface elevations effectively drowns out the model, which prevents the most common reason for a model crash, a dry channel. In HEC-RAS, the solver will become unstable and crash if the water surface elevation at any cross section should drop to its invert elevation. If the hot start model should fail, then it is easy to find out when, where and why this occurred. In the HEC-RAS models developed for this study, startup problems were typically caused by one of two conditions: an error in the cross section data or improper gate control logic, which allowed canal stages to fall below target levels. Once a successful hot start model run has been made, the restart file written at the end of this model can be used to specify a valid starting solution for the production model run.

Data Storage System

In an unsteady flow model, HEC-RAS uses the Corps of Engineers' Data Storage System (DSS) for storage of the model input flow and stage hydrographs and storage of model output. DSS was specifically designed for efficient storage and retrieval of regular-interval scientific data (for example, daily streamflow hydrographs or hourly precipitation data). The DSS viewer program (HEC-DSSVue) will export data to or imported data from Microsoft Excel, making this system very user friendly (U.S. Army Corps of Engineers, 2006).

Unfortunately, for the S-4 Basin study the HEC-RAS/DSS interface proved to be problematic. During execution of an unsteady flow model, HEC-RAS writes the model results to a scratch disk file. Once the actual simulation finishes, HEC-RAS launches the DSS Writer program. It appears that this program initializes the specified output DSS file. It was found that this program would tend to crash as the models became more complex (more structures and stream cross sections) and simulation periods increased. This appears to be a limitation of the DSS Writer program only, not a problem with the simulation engine in HEC-RAS or of the DSS file format.

A simple work around was found for the DSS Writer problem, split the entire simulation period into smaller pieces. In this study, a 15-year simulation period was used. It was found that a model run between four and five years long would execute just fine; therefore, each model run was divided into four sets so no single model run was longer than four years. To preserve model states from one model subset to the next, it was necessary to write a hot start file at the end of each model subset (except the final one) and use these hot start files to set the initial conditions for the next subset in series.

With a 15-year simulation period and 5-minute time step, the hydraulic models for this study generated over 1.5 million data points at each structure and cross section. To reduce the magnitude of these data by half, the HEC-RAS models were configured to save the results for every other time step only. This still left a prodigious amount of data to analyze for each model run. This volume was reduced to a manageable level by using the HEC-DSSVue engine to calculate average daily values from the detailed modeling results. This left less than 5,500 daily values for each run, which could be easily manipulated and summarized using Microsoft Excel.

Irrigation Withdrawals

The canals within the S-4 and adjacent water management basins serve not only to carry away excess drainage but also to supply irrigation water during dry periods. There are no explicit records of irrigation withdrawals but the magnitude and timing of these withdrawals were estimated by calculating a daily water balance for each canal reach. These irrigation withdrawals were represented as negative values in the canal inflow hydrographs.

These irrigation withdrawals proved to be problematic at times when the gates at both ends of a canal reach were closed. If these withdrawals were of sufficient magnitude to lower canal stages to or near its invert the unsteady flow solver would often crash. The solution to this problem was fairly straightforward: modify the gate control logic to open a gate slightly if canal stage fall to danger levels.

Lateral Structures

One of the most finicky structures found in HEC-RAS 4.0 were lateral structures. Gated lateral structures were sometimes used to serve a dual purpose: to mimic the flow control provided by a typical inline control structure and to also connect a new canal or lateral to an existing canal reach without splitting the existing canal reach and adding a new junction. Although using lateral structures in place of a true junction made network changes easier, these lateral structures did not always work as planned. In some instances, HEC-RAS did not properly maintain the flow balance across a lateral structure. That is, the flow upstream of the lateral structure less the flow downstream did not always equal the net lateral flow through these structures. The lesson learned here is that it is generally better to take the time to insert a true junction in a model reach to connect to a lateral canal and then place an inline control structure in this canal when necessary rather than using a lateral structure.

Gate Operating Rules

One important lesson learned from the general types of model errors discussed above is that there is value in keeping gate control rules as simple as possible. Of course this goal is not always possible because some of the structures in the S-4 Basin have complex, multi-condition operating criteria. The more complex these operating rules, the more likely it is that there may be unintended conflict with other structures in the system. Often these adverse situations were found only by trial and error.

CONCLUSIONS

HEC-RAS, Version 4.0, proved to be an excellent modeling tool for use in this study and would be similarly applicable to any of the man-made drainage systems common in south Florida and elsewhere. In fact, the new gate operating rule feature added in this latest program version was found to be essential to effectively implement the complicated operating rules required at some structure.

However, the HEC-RAS model is not without some faults. The problem mentioned above with the DSS Writer when modeling complex systems or with long simulation periods is frustrating but not difficult to work around. Another suggested enhancement to the HEC-RAS model would be to implement a rule-based control system for pump stations, similar to that now available for gated structures.

ACKNOWLEDGEMENTS

The writers wish to thank the Everglades Agricultural Area Environmental Protection District for its sponsorship of the S-4 Basin Feasibility Study and the prior S-4 Basin Diversion Study. The S-4 Basin Feasibility Study was also co-funded by the South Florida Water Management District. EAAEPD and SFWMD staff and consultants provided valuable direction and comments that greatly improved the quality of these studies.

Abstract

The Hydrologic Engineering Center's River Analysis System (HEC-RAS) is widely used for computing water surface elevations with results processed using GIS to determine inundation extent and flood depths. These floodplain boundary and flood depth results are used to establish flood insurance rate maps, analyze severe flood events, establish emergency action plans, estimate flood damage losses, and evaluate habitat restoration alternatives. New floodplain delineation tools in HEC-RAS provide the capability to develop inundation maps utilizing water surface profile results and a model of the ground surface. This delineation capability allow the modeler to visualize the resulting floodplain directly within HEC-RAS, providing a more efficient environment for hydraulic model refinement than processing results in GIS. The resulting floodplain boundary and flood depths may then be used in other modeling software to evaluate floodplain impacts.

Introduction

The Hydrologic Engineering Center's River Analysis System (HEC-RAS) is widely used for computing water surface elevations for steady-flow profiles and unsteady-flow simulations. Floodplain boundary and flood depth results are used to establish flood insurance rate maps, analyze severe flood events, establish emergency action plans, estimate flood damage losses, and evaluate habitat restoration alternatives. It is commonplace to create these inundation maps using automated methods within GIS (or CADD)-based software; however, this method requires the additional expense of purchasing an external piece of software. Even with such software as HEC-GeoRAS (HEC, 2005), which is designed to work seamlessly with HEC-RAS output with in ArcGIS (ESRI, 2004), the user must acquire the requisite knowledge to use the software.

Working with the Federal Emergency Management Agency and the National Institute for Building Sciences, HEC has to improved the use of HEC-RAS output with HAZUS-MH and developed methods for directly computing inundation maps within the HEC-RAS. The addition of floodplain delineation capabilities provides the modeler with an integrated system for computing geospatial data from simulation results, visualizing

results, and refining model input. Further, inundation boundary and depth data results may then be used in GIS software and combined with additional data to perform additional analysis and map publishing.

HEC-RAS Improvements

Generation of floodplain boundary maps from HEC-RAS simulation results using automated GIS methods began in the mid-1990s with arc macro language (AML) scripts. Previously, scripts had been developed using HEC-2 output. In March 1999, the first GIS interface built specifically to assist HEC-RAS modeling (HEC-GeoRAS) was publicly released (HEC, 1999). HEC-GeoRAS was a simple interface that provided barebones tools to the user for creating geometric data for import and performing floodplain delineation using HEC-RAS output. Over the years, GIS software has greatly improved allowing the once complex, command line arguments to become simple push-button activities. This has allowed the field of river hydraulics field to use significantly improved the tools for creating and evaluating hydraulic models. Complex river networks can be laid out within the GIS and results can be visualized using background data layers to assist the process. The benefits of using a GIS to assist in hydraulic modeling are well known. Today, modelers no longer need to be versed in only river hydraulics and HEC-RAS, they must also be experienced GIS users.

New floodplain delineation tools in HEC-RAS increase the efficiency of analysis and refinement within a single modeling environment. Results are visualized immediately through a RAS interface that plots the underlying geometric data and ground surface.

Geometry Requirements

The new version of HEC-RAS creates two new files for use with the mapping portion of the software. These files are created in an easily readable/parseable extensible markup language (XML) format. HEC-RAS geometry is written in GML (geography markup language), the format supported by the Open Geospatial Consortium (OGC) (http://opengeospatial.org). Currently, the river network, cross sections, bank stations, and storage areas are written for use in mapping. Water surface elevations (and other simulation results) are written to a simple XML file for each cross section. These files may also be used to provide as inputs to other software for floodplain delineation and mapping outside of the HEC-RAS program.

A digital terrain model in form of a grid is required to represent the land surface. Currently, HEC-RAS supports the binary raster floating-point value format. This float format is a non-proprietary format that consists of two files, the binary floating point file (.flt) and the support ASCII header file (.hdr). Many software packages support the import or export of this format. HEC-RAS supports either a single terrain model or multiple terrain tiles that covers the area of interest. New capabilities in HEC-RAS are implemented so that the entire dataset does not have to be read into memory; therefore, there is not a limitation on the size of the terrain model that can be processed. Users, however, are encouraged to use multiple terrain tiles to reduce the extra null space (i.e. no

data cells) where the terrain is not needed for analysis. Individual terrain tiles should be created at the user's discretion to minimize file size and computation times because once loaded into HEC-RAS, the terrain tiles are managed as a single terrain layer within the interface. The HEC-RAS mapping interface is shown in Figure 1 with a tiled terrain, river, cross section, and storage area layers.

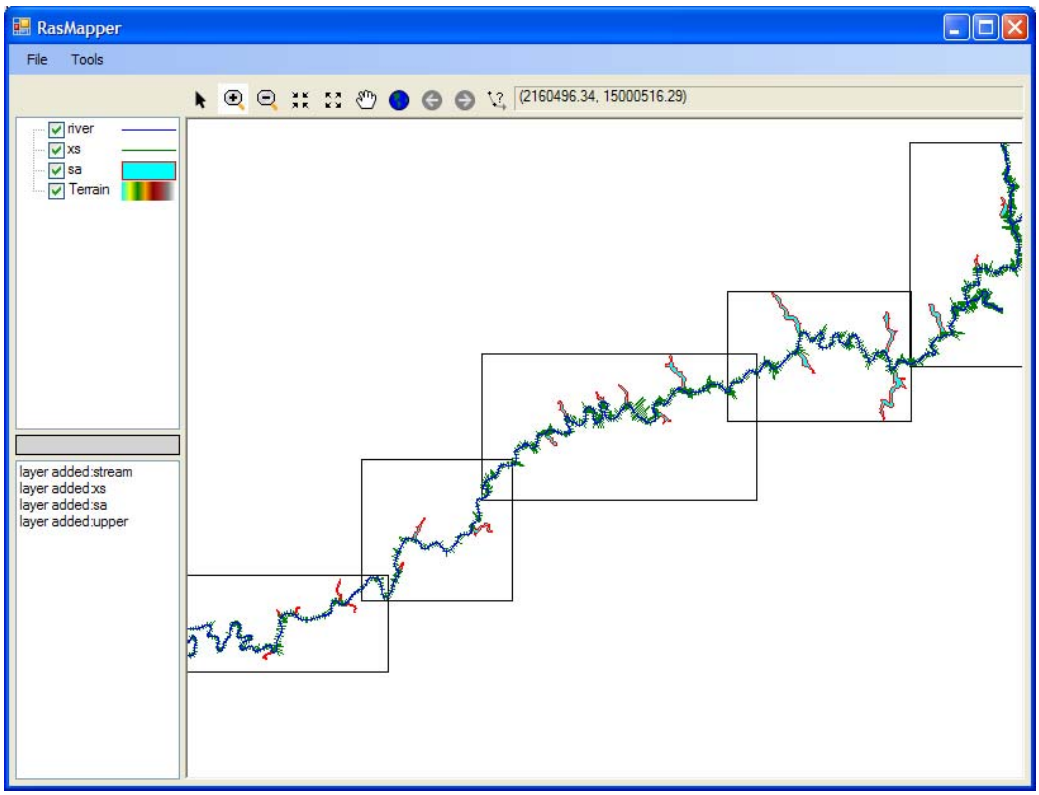

Figure 1. The HEC-RAS mapping interface showing tiled terrain models with model geometry.

Geometric Data Preparation

Geometric data are used to create an interpolation surface for assigning water surface elevations throughout the model area prior to computing the floodplain boundary. The interpolated surface is created for each terrain tile by creating interpolation regions between each set of cross sections based on the cross section layout, location of the bank positions on the cross sections, and the shape of the river centerline. The shape of the river centerline is applied to the bank station locations to create bank lines that approximate the meander of the river channel between cross sections. Closer cross section spacing improves the representation of the channel limits. The shape of the river centerline is also applied to the outer edge of the cross sections to create model bounds that attempt to include the floodplain throughout the bends of river's meander. Interpolation regions are created in areas bounded by cross sections, bank lines, river centerlines, and model limit lines. An example region generated for the area between the river centerline and bank stations is shown in Figure 2.

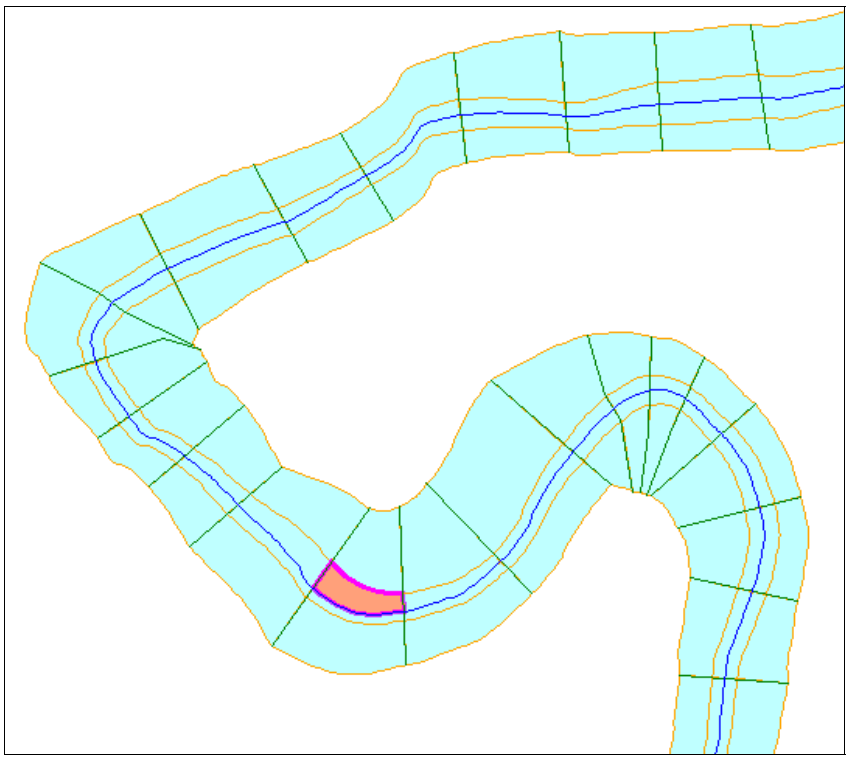

Figure 2. Interpolation regions (example highlighted) are created between cross sections using bank lines and model limit lines based on the shape of the river.

Interpolation regions are used to define boundaries for interpolation of the underlying terrain surface grid. Interpolation of grid-cell values within each region is performed using a nine-point finite-difference approach. Cross-section weighted values (from zero to one) are computed based on cell proximity to bounding cross sections. The surface within the interpolation region is obtained by solving the potential equation. This produces a smooth transition in water surface values from cross section to cross section. Known boundary conditions are provided for cells along each edge of the interpolation region. For edges shared with a cross section, boundary cells are given a value of zero or one; thus the value of a grid cell which is located directly on top of a cross section line is solely influence by that cross section. Along the river line and a bank line, the boundary condition is set based on the distance along the line between the bounding cross sections. Boundary condition values used at the model limit lines are given by setting the slope normal to the bounds to zero.

Results from the interpolation surface are stored to disk to allow for repetitive use during the floodplain delineation process. Not only can the interpolation surface be used for floodplain mapping, it can be used for distributing additional hydraulic parameters computed by RAS such as velocities, water temperature, shear stress, stream power, and ice thickness. The RAS Mapping window allows the user to select the input geometry and output layers to be generated, as shown in Figure 3.

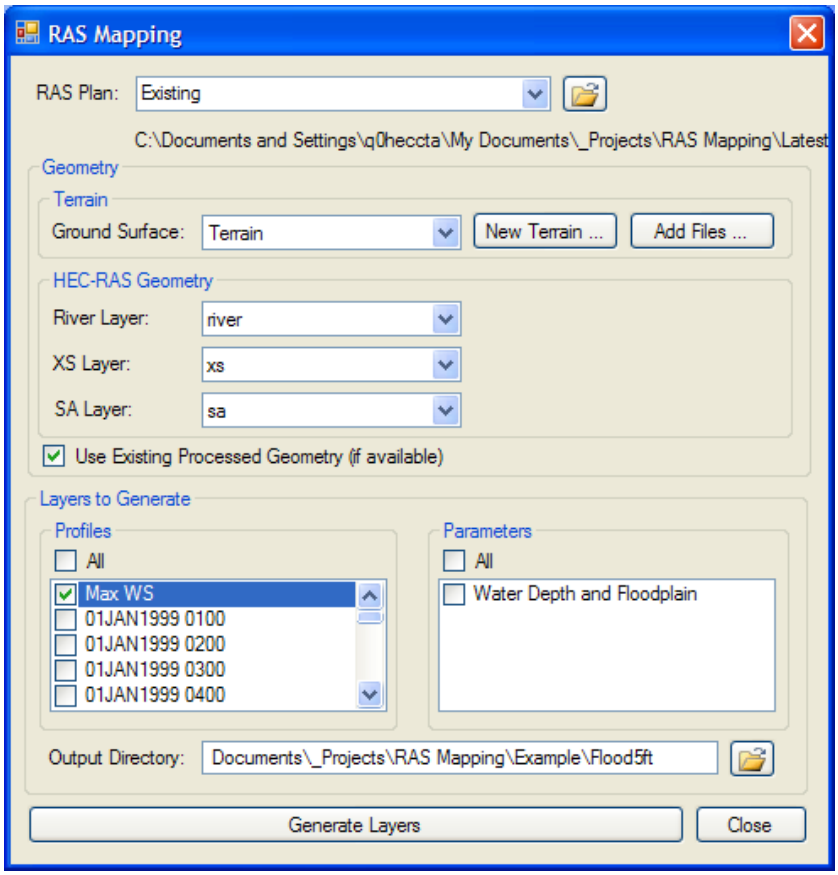

Figure 3. The RAS Mapping window is used to select input and output parameters for processing.

Floodplain Delineation

Once computed, the interpolation surface facilitates efficient mapping of HEC-RAS results at individual cross sections on to the entire model domain. Water surface elevations through the model limits are computed by applying the HEC-RAS water surface elevations results. If storage areas are present, the water surface elevation for the storage area is added to the water surface elevation grid. A flood depth grid is then created by comparing the water surface elevation and ground surface at each grid cell. Depth grids are stored in the binary float format based on the original properties of the underlying terrain grid.

A floodplain boundary polygon is computed by contouring the depth surface at zero depth. A final floodplain boundary is then achieved using a flood fill algorithm to connect the floodplain area. The floodplain boundary polygon is stored in the Shapefile format (ESRI, 1998).

Initial testing on a dataset with 600 million cells took approximately three minutes to compute the cross-section weighted interpolation surface with an additional seven minutes to create the depth grid. In general terms, the tiled terrain dataset covered about 120 river miles and using a 5-foot grid-cell size and took up 2.5 gigabytes of disk space.

Data Visualization

Floodplain delineation results have been added to the RAS mapping interface to assist modelers evaluate the impact of model results spatially. Flood depths and boundaries can be evaluated in the context of the cross section layout to identify areas of discontinuity helpful in model refinement. Development of visualization tools have focused on efficient memory usage. Grids are rendered quickly because only the data visible in the mapping window is loaded, allowing modelers to easily navigate the model area using the available pan and zoom tools. An example inundation map displayed with model geometry is shown in Figure 4.

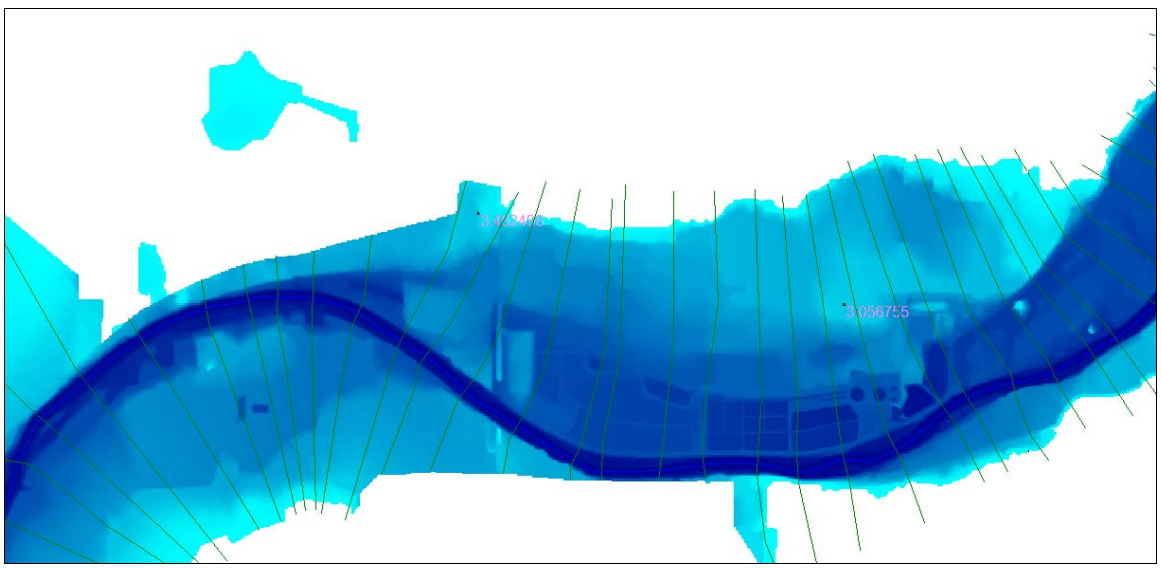

Figure 4. Example RAS display of a flood depth grid overlaid with model geometry.

Summary

The new floodplain delineation capabilities in HEC-RAS do not intend to replace the capabilities of a GIS, but to assist engineers in performing hydraulic analysis in a more integrated environment. Because the delineation tools exist within a single software package, modelers will be able to more efficiently produce hydraulic models and spatial data for use in analysis and mapping. Because the resultant spatial data is stored in published formats, this data is readily accessible for use in related disciplines such as flood damage analysis, ecosystem restoration, flood warning preparedness, and hazard evaluation. Further, the methods implemented by HEC-RAS for handling digital terrain models attempts to manage very large datasets that are being created with the latest remote sensing techniques, by only reading portions of the gridded data as needed.

While these new HEC-RAS mapping tools greatly improve the process of mapping simulation results, there is still progress to be made. Software is rapidly evolving to

include mapping of numerous output variables such as velocities, water temperature, and shear stress. Adding the ability to exclude selected locations of high ground not included in the terrain model, delineating areas outside the bounds of the cross sections that are flooded due to backwater areas, and improving data handling are planned improvements and just a few of many features to be considered.

Abstract

The NOAA National Weather Service (NWS) Office of Hydrologic Development (OHD) is investigating two approaches to transition NWS operational hydraulic models from FLDWAV to HEC-RAS: (1) transform existing FLDWAV and DWOPER models into HEC-RAS and (2) modify and calibrate existing HEC-RAS models created for a purpose other than real-time forecasting. We evaluated these two approaches in the lower part of the Tar River, NC, and the lower Columbia River, OR. We also developed procedures and utility programs to assist with model conversions. The results are mixed. For the relatively simple Tar River, direct duplication of FLDWAV cross-sections and Manning's roughness specifications within HEC-RAS resulted in similar simulations. Also, a model built with more detailed cross-sections but the same roughness parameters from FLDWAV model could produce comparable simulation with some simple Manning's *n* adjustments. For the lower Columbia, approximate duplication of geometry requires more Manning's *n* adjustments, but still offers a viable pathway toward model conversion. Further work on the lower Columbia model is needed to see whether more precise representation of storage areas will improve results.

Key words: St. Venant Equations, calibration of hydraulics model, Tar River, Columbia River. FLDWAV, HEC-RAS

1 Introduction

In 2007, a team of National Weather Service (NWS) hydrologists reviewed several well-known hydraulic models to identify methods to improve hydraulic modeling capabilities for NWS operational forecasting (NWS, 2007). NWS forecasters currently use Flood Wave Dynamic Model (FLDWAV) and Dynamic Wave Operation (DWOPER) (Fread, 1998) for operational hydraulic modeling. NWS (2007) recommends including the United States Army Corps of Engineers (USACE) Hydrologic Engineering Center-River Analysis System (HEC-RAS) in the operational environment, testing FLDWAV and HEC-RAS on identical data sets, and developing methods to transform FLDWAV models to HEC-RAS. Compared to FLDWAV, the study found that HEC-RAS offers a much more user friendly GUI, better documentation, training, and the option to specify more detailed cross-section and hydraulic structure information. Based on those conclusions, NWS managers have decided to replace FLDWAV and DWOPER with HEC-RAS. This

proposal is based on two basic assumptions: (1) HEC-RAS can provide equivalent functionality capable of replacing existing FLDWAV and DWOPER models (with relatively minor HEC-RAS enhancements), and (2) through collaboration with HEC, it will be more economical to maintain and enhance HEC-RAS alone, rather than independently maintaining HEC-RAS and FLDWAV. Efforts are underway to include the HEC-RAS software in the NWS Community Hydrologic Prediction System (CHPS). CHPS is the software infrastructure intended to replace the NWS River Forecast System (NWSRFS). Because the NWS has defined an aggressive schedule to transition from NWSRFS to CHPS, River Forecast Centers (RFCs) need simple and inexpensive procedures to convert or replace DWOPER and FLDWAV models with HEC-RAS models.

Here we report on investigations into two approaches to meet this need: (1) transform existing FLDWAV and DWOPER models into HEC-RAS and (2) modify and calibrate existing HEC-RAS models created for a purpose other than real-time forecasting (e.g. HEC-RAS models for Federal Emergency Management Agency (FEMA) flood insurance rate maps). In this study, we developed and compared HEC-RAS models for the lower part of the Tar River, NC, and the lower Columbia River, OR, using these two approaches.

During the evaluation, we developed procedures and utility programs to assist with model conversions. Some model conversion challenges included determining equivalent hydraulic representations for cross-section geometry, ineffective areas, bridges, and specifying channel roughness factors. The procedures described here include an expeditious calibration strategy for RFC implementations when needed. This paper presents a subset of finding from a larger, ongoing Office of Hydrologic Development (OHD) project to facilitate the transition from FLDWAV to HEC-RAS. Additional information and a more detailed report can be found at http://www.weather.gov/oh/hrl/hsmb/hydraulics/index.html.

2 Models

2.1 FLDWAV

DWOPER is the initial model developed by Fread (1978). Later, in an effort to combine DWOPER with a stand alone NWS dam break program (DAMBRK), FLDWAV emerged as a comprehensive dynamic hydraulic model that can be used to simulate network of rivers with several hydraulic structures including an option to simulate dam failure or series of dam failures. FLDWAV is being used in day to day forecasting on over two dozen of large rivers over the United States and several rivers elsewhere in the world. The model is based on the implicit finite difference solution of the complete one-dimensional Saint-Venant equations of unsteady flow.

The two basic equations are the continuity and momentum equations 2.1 and 2.2, respectively.

$$\frac{\partial Q}{\partial x} + \frac{\partial s_{co}(A + A_o)}{\partial x} - q = 0 \qquad 2.1$$

$$\frac{\partial (S_m Q)}{\partial t} + \frac{\partial (\beta Q^2 / A)}{\partial x} + gA\left(\frac{\partial h}{\partial x} + S_f + S_e + S_i\right) + L - W_f B = 0 \qquad 2.2$$

Where Q is the flow, h is the water-surface elevation, A is the active cross-sectional area of flow, A_o is the inactive off channel storage area, S_{co} and S_m are sinuosity factors, x is longitudinal distance along the rive channel, t is the time, q is the lateral inflow or outflow, β is the momentum coefficient for velocity distribution, g is the acceleration due to gravity, S_f is the channel flood-plain boundary friction slope, S_e is the expansion-contraction slope, S_i is addition friction slope for viscous fluids and debris flow, B is that active low top width and W_f is the effect of wind resistance on the surface of flow.

Among the slopes that are listed in the above equation, it is important to describe the S_f as it is central to the model parameterization.

$$S_f = \frac{n^2 |Q| Q}{\mu^2 A^2 R^{4/3}} = \frac{|Q| Q}{K^2} \qquad 2.3$$

In Equation 2.3 n is the Manning's n coefficient of frictional resistance, M is a unit conversion factor *1.49* for English units and *1.0* for SI units, R is the hydraulic radius and K is the conveyance. The equations are solved using the well known four-point implicit box finite difference schemes documented by (Fread,1988).

2.2 HEC-RAS

Hydrologic Engineering Center-River Analysis System (HEC-RAS), is an integrated system of software comprised of a graphical user interface (GUI), separate hydraulic analysis component, and data storage management (Brunner, 2002). Though the system has several modules, in this paper we focus only on the unsteady flow simulation.

The unsteady flow model solves essentially the same equations as FLDWAV (Equations 2.1 and 2.2), except that the current version of HEC-RAS does not include the wind effects term, the expansion and contraction slope term (S_e), or the viscous fluid term (S_i). Similar to FLDWAV, HEC-RAS uses a four-point implicit finite difference scheme to generate a set of finite difference equations. However, HEC-RAS solves the finite difference equations using linearization and a sparse matrix linear algebra solver while FLDWAV applies a Newton-Raphson iteration technique to solve the nonlinear equations.

2.3 Major differences between HEC-RAS and FLDWAV

Although the two models solve the same basic hydrodynamic equations, there are many differences in the model parameterization and solution techniques. Our detailed report

will describe these differences. Here we focus on a few major differences that have the biggest impacts on simulations.

Both models include different options to describe the physical characteristics of the system (Gee and Brunner, 2005). For example, FLDWAV represents cross-section geometry using elevation-top width pairs, which results in a symmetric channel for most FLDWAV implementations. HEC-RAS cross sections can be symmetric but are most often irregular to match the natural landscape. Also, FLDWAV and HEC-RAS differ in the methods available to calculate the friction slope S_f. Both FLDWAV and HEC-RAS compute a composite conveyance K in each cross section to solve for S_f, however, the available methods to calculate the composite K differ. Differences in how Manning's n values are specified and differences in the definitions of left and right overbanks result in conveyance differences.

3 Methodology

3.1 Study Areas and Models

Two rivers were used to evaluate differences between FLDWAV and HEC-RAS water level simulations: the lower Tar River in North Carolina and the lower Columbia River which forms the border between Oregon and Washington.

3.1.1 Tar River

Tides influence water levels in the lower Tar River starting form its inlet at Pamlico Sound upstream to USGS Gauge 02083893 at Rock Springs, NC (approximately 30 miles) (Figure 1). Because of the tidal influence, the NWS needs to run dynamic hydraulic models to provide water level forecasts at locations such as Washington and Greenville, NC. Use of a dynamic hydraulic model is also a pre-requisite for eventually providing dynamic flood mapping services.

In this study, we model a single reach of the Tar River between Tarboro and Washington, NC. Riverside Technology (RTi) set-up and calibrated a FLDWAV model for this reach (RTi, 2007). The simulated reach covers of 48 miles with 102 cross-sections spaced at about 0.5 miles on average. RTi derived cross-sections for FLDWAV using cross-section data obtained from the North Carolina Floodplain Mapping Program and originally derived by the North Carolina US Geological Survey (USGS). The model accounts for the impacts of ten bridges. Four of these are modeled explicitly using bridge geometry while the other six are modeled approximately using constricted cross sections along with expansion and contraction coefficients. The parameters used in FLDWAV for the four bridges were used directly in HEC-RAS. However, for those bridges approximated by the expansion and constriction coefficients, we used the cross-sections without coefficients since HEC-RAS does not use these coefficients in the unsteady flow model. The lateral flows were originally generated using a distributed hydrologic model (Koren et al., 2004) on 4-km grid cells but later aggregated into seven inflows. We converted this FLDWAV model to HEC-RAS as described below.

We also took the steady flow HEC-RAS model with more detailed channel geometry developed by the NC USGS and converted it to an unsteady flow model. To cover the same domain as the FLDWAV model, the detailed model was modified to include five additional cross-sections from Grimesland to Washington. The channel geometry for these five sections was duplicated from FLDWAV and the overbank elevations derived from LiDAR elevation data.

The boundary condition and internal calibration/validation points on the Tar River are plotted in Figure 1. The discharge record at the Tarboro site is used as the upstream boundary condition, while the stage record at the Washington gauge is used as the downstream boundary condition. Tar River simulations are run from July 1, 1999, to August 31, 2005. This period includes a wide range of hydrological conditions, with noticeably high stage cases during Hurricanes Floyd (Sept 1999) and Isabel (Sept 2003). All simulations were run at an hourly time step using hourly input data.

Figure 1. Lower Tar River Modeled Reach

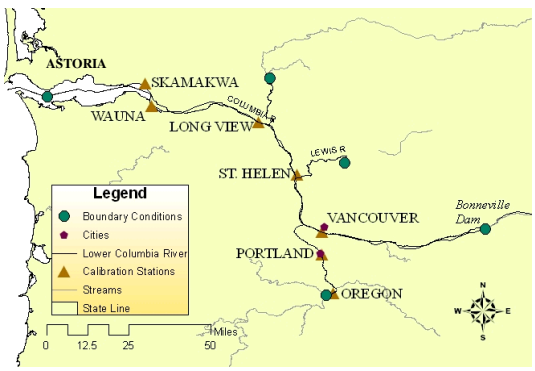

Figure 2. Lower Columbia

3.1.2 Columbia River

The NWS Northwest River Forecast Center operational DWOPER model of the lower Columbia River extends from Bonneville Dam to Astoria, OR (Figure 2). The model includes three major tributaries: the Willamette River, the Cowlitz River, and the Lewis River. The main channel of the lower Columbia River covers 127.5 miles, while the Willamette, Cowlitz, and Lewis segments cover 32 miles, 23 miles, and 19 miles respectively. The main river has 22 cross-sections with an average spacing of 6 miles. The Willamette, Cowlitz, and Lewis have 33, 20, and 26 cross-sections respectively. The boundary condition and internal calibration/validation points on the Columbia River and tributaries are plotted in Figure 2. For the Columbia River, discharge records from Bonneville dam define the upstream boundary condition and tide observations at Astoria, OR, define the downstream condition. Discharge records are also used at the upstream boundaries for the three simulated tributaries. A lateral inflow is applied at the river-mile 114.7 on the Columbia River and a second lateral inflow is applied at the river-mile 25.3 on the Willamette River. These two lateral flows are applied to represent tributaries, which are not modeled as rivers. An internal boundary condition represented as a rating

curve on the Willamette River at Oregon City was used to represent a 50 ft fall. The simulation runs are from Feb 1, 1995 to Feb 28, 1996.

Although NWRFC uses DWOPER for operational runs, we created a nearly identical FLDWAV model of the lower Columbia model as a reference to facilitate study over our year long calibration period. We then created a symmetric HEC-RAS model duplicating the DWOPER/FLDWAV parameterization and model layout.

A HEC-RAS model with more detailed channel geometry for the Columbia River system was obtained from the Hydrologic Engineering Center (HEC). The model was originally developed by the USACE Portland District and later modified by HEC. The initial model contains 604 cross-sections of which 330 describe the lower Columbia River from Bonneville to Astoria, 86 the Willamette River, and 3 the Cowlitz tributary; the remaining 185 are located in distribution channels along the river. There are no bridges specified in the model; however, ineffective areas are specified in 61 river cross-sections.

The detailed HEC-RAS model was modified to cover the exact same domain as the DWOPER and symmetric HEC-RAS models. We extended the Cowlitz tributary and added the Lewis Tributary. These additions used the cross-section information from the symmetric model.

3.2 FLDWAV to HEC-RAS Parameter Conversions

3.2.1 Cross-sections

The representation of the cross-section is different in the FLDWAV and HEC-RAS models. In the FLDWAV models, a river cross-section is approximated by a predefined number of pairs of top width (BS) and elevation (HS). The total number of pairs in FLDWAV (NB) is fixed for a given model and typically five to eight pairs are required to define a cross-section. HEC-RAS represents cross-sections using station-elevation (X-Z) pairs. Figure 3 shows a FLDWAV and HEC-RAS representation of the same cross-section from our Tar River model. The validity of using simplified cross-sections for large river routing has been established (Fread, 1998; Hicks, 1996). The complexity of the channel is fully represented in the detailed cross-section, which may be advantageous in areas where there are flood mapping needs. We compare simulations from the symmetric and detailed cross-section models to assess the added value of having detailed cross-sections for modeling at NWS river forecast points.

In order to represent the symmetric cross-sections of FLDWAV in HEC-RAS, the BS versus HS pairs are translated to station versus elevation. To facilitate the conversion of the cross-sections from FLDWAV to HEC-RAS, we developed a program called *fld2ras*. In addition to converting top width-elevation pairs to station-elevation pairs, *fld2ras* (1) reorders station numbering (if necessary) to be compatible with the HEC-RAS convention to decrease from upstream to downstream, (2) converts distances between cross-sections from miles to feet, (3) assigns default bank station locations required by HEC-RAS, (4) modifies the cross-section shape to account for the FLDWAV AS

parameter (explained below), (5) creates HEC-RAS ineffective areas to approximate FLDWAV ineffective areas defined by the FLDWAV BSS parameter (optional, explained below), and (6) creates a text file formatted for import into HEC-RAS.

An important feature in the FLDWAV/DWOPER model of the lower Columbia River is a parameter that represents the active channel cross-sectional area below the lowest HS elevation. This parameter helps to define the area subject to the deposition and scour processes below the river line, in lieu of using the exact cross section. The parameter is known as *AS*. In HEC-RAS, this *AS* parameter is not available. Therefore to account for the area, at each cross-section, an additional active area is added by assuming a rectangular bottom with same width as the lowest HS value. The depth of the additional area is calculated using *Depth = AS/BS(1).* The elevation of the lowest point is then calculated as *Lowest Elevation= HS(1)- Depth.*

3.2.2 Roughness

The FLDWAV model has the option in which the user can define a stage or flow versus Manning's *n* relationship. Flow is preferred to stage because the calibration of Manning's *n* for different flow levels is relatively straightforward for long reaches, and the geomorphology literature supports the assumption that breaks in channel properties occur at consistent flow levels along a reach. If calibration causes Manning's *n* values to depart from published ranges, the modeler knows to check other parts of the model for errors.

In typical HEC-RAS applications, Manning's *n* values vary horizontally along a cross-section with higher values typically assigned in the floodplain. This can produce a similar effect to the typical FLDWAV application of defining composite Manning's *n* values that tend to increase when high flows reach the floodplain, reflecting the physical presence of brush, trees, or man-made structures in the floodplain. Assigning fixed Manning's *n* values that do not vary with depth or flow can be reasonable for design applications (e.g. when models are calibrated against only single events using high water marks); however, this approach cannot properly represent the physics for unsteady modeling across a range of flows. Therefore, HEC-RAS also provides the option to specify flow roughness factors as a function of flow. Using this feature we reproduce FLDWAV Manning's *n* parameterizations within HEC-RAS. Note that in HEC-RAS 4.0 specification of flow roughness factors is limited to uniform flow increments. Through a Memorandum of Agreement between HEC and NWS, HEC has added the option to define non-uniform flow increments and made this capability available for this study via HEC-RAS 4.0.1 Beta.

Figure 4, shows the FLDWAV Tar River model calibrated Manning's *n* values versus flow for calibration reaches defined in the model. The calibration strategy used to subdivide the reaches and change Manning's values manually or automatically is described by Fread et al. (1986) and RTi (2007).

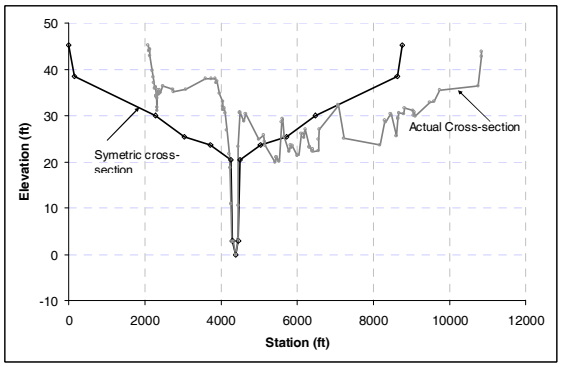

Figure 3. A symmetric and detailed representation of a cross-section of Tar River. While the detailed cross-section is obtained from 105 survey points, the symmetric cross-section is represented by only 16 points which were derived from FLDWAV (eight pairs of top width (BS) and elevation (HS)).

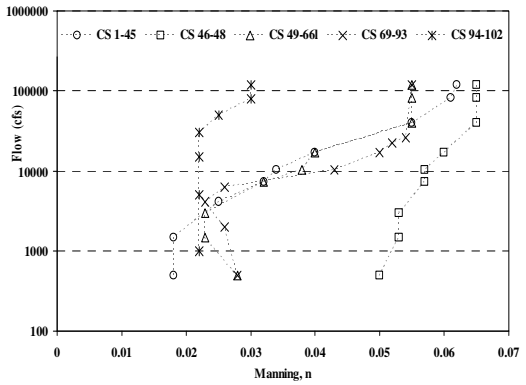

Figure 4. Variation of Manning's *n* versus flow for five cross-section reaches that are designated by the calibration gauges for the Tar River.

3.3 Experiments

For the Tar River we simulated five sets of stages using 1) the FLDWAV model, 2) the HEC-RAS symmetric model with FLDWAV Manning's *n*-flow parameters (SYM), 3) the HEC-RAS detailed model with raw Manning's *n* values from the USGS steady flow analysis (DET_RAW_n), 4) the HEC-RAS detailed model with Manning's *n*-flow parameters from FLDWAV (DET_FLDWAV_n), and 5) the detailed model with calibrated Manning's *n* values (DET_CAL_n).

Similarly, for the Columbia River, we simulated five sets of stages using 1) the FLDWAV model, 2) the HEC-RAS symmetric model with FLDWAV Manning's *n*-flow parameters (SYM), 3) a calibrated version of the HEC-RAS symmetric model (SYM_CAL), 4) the HEC-RAS detailed model with FLDWAV Manning's *n*-flow parameters (DET_FLDWAV_n), and 5) the HEC-RAS detailed model with some additional calibration (DET_CAL_n). In both the Tar and lower Columbia, the calibrated Manning's *n* values were determined through manual calibration by comparing observed and simulated stages at several points along the rivers.

4 Results

Table 1 summarizes statistical results for four validation stations on the Tar River. The FLDWAV and symmetric HEC-RAS model (SYM) exhibit similar overall bias and RMSE and examination of the hydrographs (not shown here) showed acceptable results over all flow ranges. This result was achieved through direct conversion of model geometry and FLDWAV Manning's *n* parameters and no further calibration. We did not attempt further calibration of the HEC-RAS symmetric model, although additional fine tuning can be easily done within HEC-RAS. On the other hand, the detailed HEC-RAS model with raw Manning's *n* values specified for steady state applications

(DET_RAW_n) produced much higher RMSE statistics compared to the other two models. It therefore required more additional work. To achieve a more reasonable result with the detailed model, we first replaced the Manning's *n* values with those from FLDWAV (DET_FLDWAV_n). This yielded some improvements, but additional calibration was necessary to produce acceptable results comparable to those from FLDWAV (DET_CAL_n).

Table 2 summarizes statistical results for the validation stations on the lower Columbia River. For the lower Columbia, direct conversion of model geometry and DWOPER Manning's *n* values did not produce results as satisfactory as those for the Tar River. Although RMSE statistics (SYM) relative to observed stages come close to the FLDWAV results for most stations (the Oregon station is the big exception), examination of the hydrographs (Figure 5) shows that the HEC-RAS symmetric model and FLDWAV simulations deviate substantially from each other. One possible reason for more differences between FLDWAV and HEC-RAS SYM in the lower Columbia compared to the Tar River is that our conversion of the AS parameter is only an approximation. Independent experiments running FLDWAV with and without the AS parameter show that AS values have a very large impact on simulation results (not shown here). Table 2 also shows that some manual calibration effort with the symmetric HEC-RAS model (SYM_CAL compared to SYM) produces improved results at all stations except Portland on the Willamette tributary. We also found that using the detailed model with FLDWAV Manning's *n* parameterizations (DET_FLDWAV_n) provides a good starting point, but some manual calibration produces dramatic improvements (DET_CAL_n). Figure 5 highlights the improvements from calibration in the lower Columbia models both for a station that is highly affected by inflow hydrographs (Vancouver) and for a downstream station dominated more by tides (Wauna).

Table 1 Bias and (RMSE) both in ft (ft) for the Tar River

		HEC-RAS			
Stations	FLDWAV	SYM	DET_RAW_n	DET_FLDWAV_n	DET_CAL_n
Tarboro	.03 (.32)	.04 (.34)	1.71 (2.03)	-0.15 (0.60	0.04 (0.38)
Rcksp	.12 (.51)	.16 (.63)	0.88 (1.20)	-1.13 (1.45)	-0.43 (0.68
Grnvl	.00 (.90)	.36 (1.11)	1.86 (2.30)	-0.55 (1.05)	-0.40 (0.86)
Grim	.16 (.28)	.00 (.22)	1.96 (2.25)	0.00 (0.22)	0.11 (0.24)

* Note that the time period for statistical evaluation is shorter for Rock Springs and Grimesland due to a more limited duration of observed data.

Table 2 Bias and (RMSE) both in (ft) for the Columbia River

		HEC-RAS			
Stations	FLDWAV	SYM	SYM_CAL	DET_FLDWAV_n	DET_CAL_n
Vancouver	0.72 (1.04)	-0.44 (1.06)	-0.17 (0.76)	-054 (1.17)	-0.17 (0.79)
St. Helen	1.12 (1.37)	0.63 (1.08)	0.38 (0.91)	-0.31 (1.11)	0.76 (1.27)
Long View	0.48 (0.87)	0.31 (0.77)	-0.08 (0.62)	-2.21 (2.53)	0.04 (0.85)
Wauna	0.19 (0.84)	0.27 (0.86)	-0.04 (0.80)	-0.61 (1.01)	-0.51 (1.00)
Skamakwa	0.35 (0.85)	0.28 (0.74)	0.14 (0.74)	0.03 (0.69)	-0.00 (0.80)
Oregon	0.77 (1.23)	1.76 (2.27)	0.04 (1.31)	-0.51 (1.09)	-026 (0.80)
Portland	0.57 (0.94)	-0.58 (1.08)	-0.85 (1.24)	-0.51 (1.09)	-025 (0.82)

5 Conclusions and Future Work

We investigated two approaches for replacing FLDWAV models with HEC-RAS models for use in operational forecasting. The first is conversion of existing FLDWAV models and the second is acquisition and modification of HEC-RAS models originally developed for other purposes. Both approaches can save time over building a new model from scratch because they take advantage of cross-section geometry and hydraulic feature data developed by others. The second approach requires more effort than the first because the available model domain and boundary conditions may not exactly match RFC needs, the roughness values assigned for other applications may not be suitable for continuous modeling over a wide range of flows, and the model may not be stable under all flow conditions of interest.

We have developed simple techniques to convert FLDWAV geometry and Manning's *n* parameters from FLDWAV to HEC-RAS models. For the Tar River, there is considerable value in transferring both the FLDWAV geometry and Manning's *n* parameters into HEC-RAS. After this transfer, minimal Manning's *n* adjustments are required to attain equivalent results. In a case when we use more detailed cross-section geometry data in place of FLDWAV geometry, there is still value in using previously calibrated Manning's *n* values. However, considerably more Manning's n adjustments are required. This is true even if the detailed and symmetric models were originally derived from the same elevation data.

For the Columbia River, direct conversion of model geometry and Manning's *n* was not as successful in replicating FLDWAV results. The main difference between the Tar and Columbia models is that the Columbia model includes an *AS* parameter for which there is no direct equivalent in HEC-RAS. Despite this difference, the calibrated Manning's *n* values from FLDWAV provided good initial estimates for further calibration both with the symmetric geometry from FLDWAV and the detailed HEC-RAS model.

In our two case studies, the more detailed models (e.g. more cross-sections, more detailed cross-sections, and more explicitly defined storage areas and structures) did not show substantially improved simulations or provide for easier calibration than the simpler, symmetric models. There are still potential benefits from more detailed models, but use of simpler models makes the most sense until these benefits are proven. More detailed models may be more amenable to accurate flood forecast mapping if the models are properly geo-referenced. With more study, the more detailed lower Columbia model will likely help us to more properly represent off channel storages. It may be that calibrated Manning's *n* values are compensating for physical inaccuracies in the simpler models; however, this would be difficult to prove.

Results from this study suggest that converting FLDWAV models into HEC-RAS is a viable option and likely to be less work than acquiring a more detailed HEC-RAS model from another source and modifying it. Additional work is required to rigorously evaluate stability of the models to make sure models are stable over a range of conditions for

operational needs. The model validations described here were done in simulation mode. Our next step is to validate these models in operational mode and running them side-by-side with the existing operational models. This is particularly important for the lower Columbia where we believe we can still improve the HEC-RAS model.

Numerical simulation of dissolved oxygen concentration in the downstream of Three Georges Dam

Xiangju Cheng[1], Xuewei Chen[1], Yongcan Chen[2]
[1]School of Engineering, Research Center of Ocean Engineering, Sun Yat-sen University, Guangzhou 510275, China
[2]Department of Hydraulic Engineering, Tsinghua University, Beijing 100084, China

Abstract: Strong colliding between the flow discharged from spillway and the water-body in the stilling basin will produce a lot of air bubbles in the downstream of the Three Georges Dam. Bubble mass transfer will be dominant and can cause total dissolved gas (TDG) supersaturation. Elevated TDG levels can have an adverse effect on aquatic organisms in the form of gas bubble trauma (GBT). TDG concentration is changed with distance from the spillway crest and depending on hydraulic and operating conditions. Dissolved oxygen (DO) transport model is developed in this paper and used to simulate the physical processes of gas transfer coupled with the air-water two-phase mixture flow model. Supersaturated DO concentration in the water-body downstream along with distance is successfully calculated during spillage when the water level is 139m in the Three Georges reservoir.
Keywords: bubble interface mass transfer, supersaturated DO concentration, numerical simulation, Three Georges dam.

1. Introduction

Hydropower projects usually have more functions such as flood control, navigation, irrigation and electricity production. However, total dissolved gas will be supersaturated in the water-body of downstream during high flow periods. Suppersaturation of dissolved gas which typically occur between April and September can have an adverse effect on aquatic organisms in the form of gas bubble trauma (GBT). Such trauma is typically exhibited by the formation of gas bubbles within the tissue and circulatory systems of aquatic organisms which may lead to mortality under extreme conditions. According to the observation data provided by the water environmental monitor centre of the Three Gorges project, DO concentrations at the river sites of Dong Yue temple, Huang Lin temple, and Nan Jingguan are over 110% during high flow periods when the water level is 135m or 145m in the Three Georges reservoir [1]. With the increasing of water level in the reservoir, surface and deep gates are spilling at the same time. More and more air bubbles will be produced due to the strong mixing between air and water. TDG levels in the water-body of downstream will be increased even supersaturated. Anadromous fish species such as paddlefish and mullet are important natural resources in the middle reach of Yangtze River. So it is essential to predict the trend of dissolved gas supersaturation during spillage at Three Georges Dam.

The complete process of air entrainment into the water flow and the mass transfer through air bubbles and free-surface have been studied previously by researchers [2, 3]. Earlier works used a material control volume approach to calculate the dissolved gas concentration [4, 5]. Although this approach allowed the calculation of the

depth-averaged dissolved gas at some point downstream of the spillway but the models are unable to predict the most dangerous regions for the fish. Therefore it cannot be used to evaluate different spillway modifications designed to alleviate the supersaturation problem. A recent work by Urban et al [6] calculated the concentration field of dissolved gas downstream of a spillway. One-dimensional mass transport equation for imcompressible flow is used in those models. However, the turbulence kinetic energy and gas void ratio in the equations are estimated from some empirical equations and some depth-averaged values. It can be easily seen that those studies collected at the dams less than 50m height and some specific hydropower projects.

The work presented in this paper is a part of efforts to reduce the impact of hydropower dams on fish in Yangtze River. The air-water two-phase mixture model has been implemented to calculate the values of some important factors such as gas void ratio, turbulence kinetic energy and water flow velocities. Dissolved gas concentration transport equation is used to calculate the concentration distribution of TDG in the liquid phase. The bubble interface mass transfer coefficient is calculated based on Ref. [7]. Due to lack of observed data for the concentration of TDG, the DO concentration is represented to the TDG concentration here. Two-dimensional numerical results are compared with the measured data in the downstream during spillway operations for Three Georges Dam.

2. Mass transfer equations and definitions

DO transport model is obtained using a mass balance of the gas dissolved in the liquid phase in a control volume. The dimensionless DO transport equation reads:

$$\frac{\partial(\rho C)}{\partial t} + \nabla \cdot (\rho \vec{U} C) = \nabla \cdot [\rho(\nu + \frac{\nu_t}{\sigma_t})\nabla C] + \rho S_C \tag{1}$$

where C is DO concentration in a control volume expressed as a percent of saturation concentration, U is the flow velocity, S_c is the DO source due to the overall air transfer from the bubbles to the liquid and from the atmosphere to the liquid, ν is the molecular diffusivity of air in water, ν_t is the turbulence diffusivity of air-water mixture liquid, ρ is the density of air-water mixture, and σ_t is the turbulence Schmidt number.

Considering that the density of air-water two-phase flow is changing with time and space in Eq. (1), Zarrati *et al* [8] took two-phase flow as laminar flow and simulated the flow field of air-water two-phase flow under different values of σ_t. It showed that the simulated results are similar when the value range of σ_t is between 0.5 and 2. So the value of σ_t is between 0.5 and 2 in this paper.

It has been generally recognized that supersaturation is caused by the higher pressures which is exerted on the bubbles in the stilling basin. It makes bubbles have a higher saturation concentration. As large numbers of bubbles travel to various depths, the combined effect of the corresponding pressures has been termed "effective saturation concentration C_{se}", named by Hibbs and Gulliver [9]. There are, however, two types of interfaces available for gas transfer: one is the free surfaces and the other

is the bubble-water interface. The two types of interfaces have different saturation concentrations. The two saturation concentrations S_c can be written as

$$S_C = K_{\mathrm{L,B}} a_{\mathrm{B}} (C_{\mathrm{se}} - C) + K_{\mathrm{L,s}} a_{\mathrm{s}} (C_{\mathrm{s}} - C) \tag{2}$$

where $K_{\mathrm{L,B}}$ is mass transfer rate coefficient across the air bubble interface, $K_{\mathrm{L,s}}$ is the mass transfer rate coefficient across the air-water interface , a_{B} and a_{s} are surface areas of air bubbles and air-water interfaces respectively.

The effective saturation concentration (C_{se}) can be expressed by the increased transfer potential between air bubble and surrounding water under hydrostatic pressure. It is a combination of the atmospheric saturation concentration and the increased transfer potential due to hydrostatic pressure.

$$C_{\mathrm{se}} = C_{\mathrm{s}} (1 + \frac{\gamma d_{\mathrm{eff}}}{p_{\mathrm{atm}}}) \tag{3}$$

where d_{eff} is the effective depth which is experienced by the bubbles, γ is the specific weight of water and p_{atm} is the atmospheric pressure. Hibbs et al [10] found that an effective depth would be function of the specific discharge q. For a very small flow rate, the spillway flow may not penetrate to the stilling basin floor and air bubbles move down to an effective depth. The ability of air bubbles releasing air into water will be decreased. The maximum effective depth can be estimated as 2/3 depth of tailwater. For a large hydraulic structure such as Three Georges dam or Ge Zhouba dam has a 10 m deep or greater stilling basin, so C_{se} will be twice greater than atmosphere saturation.

Due to the strong entrainment of air bubbles, the endured large hydrostatic pressure, and long subsistent time in water of air bubbles, the bubble-water interface transfer is the main source of DO in the downstream. Fumio Takemura et al [7] studied a small spherical bubble rising through stagnant water and the gas-liquid mass transfer coefficient was estimated from observed bubble diameter versus time. Though the results were studied under the Reynolds number of flow less than 100, however, even the Reynolds number is larger enough, and the transfer characterization of air bubble-water interface is nearly unchanged. So based on the results and taken some modification of the equation presented by Fumio Takemura, the numerical equation of air bubble-water interface transfer coefficient in this paper can be expressed as

$$K_{L,B} = \beta \cdot \frac{\nu}{R_b \sqrt{\pi}} \left\{ 1 - \frac{2}{3} \frac{1}{(1 + 0.09 Re^{2/3})^{3/4}} \right\} Pe^{1/2} \tag{4}$$

where R_b is the air bubble diameter, Pe is the Peclet number and equal to $2R_b v_r / D_m$, Re is the Reynolds number and equal to $2R_b \sqrt{2k/3} / \nu_t$, v_r is the air bubble rising velocity and equal to a constant 0.25m/s, k is the turbulence kinetic energy, β is an uncertain constant which is taken to be a calibrated parameter in the present study.

To simplify the model, the air bubble diameters are assumed to be the same in this paper. The air bubble-water interfacial surface area can be expressed as

$$a_B = n \cdot A_g \tag{5}$$

where n is the numerical density of air bubble in water, A_g is the surface area of one air bubble ($=4\pi R_b^2$). According to the definition of gas void ratio, it can be obtained

$$\alpha_a = \frac{V_a}{V_m} = \frac{N}{V_m} V_b = n \cdot \frac{4}{3} \pi R_b^3 \tag{6}$$

where α_a is the gas void ratio in air-water two-phase flow, N is the air bubble number in volume of V_m, V_b is an air bubble volume in which the bubble diameter is R_b. So the air bubble-water interfacial surface area can be expressed as

$$a_B = \frac{3 \cdot \alpha_a}{4\pi R_b^3} \cdot 4\pi R_b^2 = 3\alpha_a / R_b \tag{7}$$

When the aqueous concentration of oxygen is supersaturated, surface mass transfer will decrease the supersaturated DO concentration as time goes on. The transfer is estimated by Cheng [11] combined with the flow velocity and turbulence kinetic energy.

$$K_{L,s} = 0.002436 U^{(-5/3)} k^{(4/3)} \tag{8}$$

where U is the flow velocity, k is the turbulence kinetic energy, and

$$a_s = \frac{A_s}{V_m} \approx \frac{1}{\Delta Z} \tag{9}$$

where A_s is the water surface area, V_m is the surface flow volume, Δz is the surface thickness. Li [12] showed that the difference of computed DO concentration was less than 1% whetherΔz is equal to 0.005m, 0.01m, 0.02m or 0.03m. In this paper, the height of grid cell is about 0.5m, so theΔz is equal to the height of grid cell. The position of the air-water surface of flow over spillway is discussed by Chanson [13]. He considered that the gas void ratio at the air-water free interface is equal to 0.9 can favorably reflect the characteristics of air-water interface.

Hydrodynamics variables (U, ν_t, k, α_a) will be changed as the flow moves downstream. These variables will be calculated for each control volume using the air-water two-phase mixture model and RNG k-ε model. The description of the mixture flow model for air-water two-phase flow and RNG k-ε model is presented in Ref. [14].

3. Numerical method

The mixture model for air-water two-phase flow is solved using commercial flow simulation software Fluent 6.2 and the DO transport model is solved using User Defined Scalars [15]. A six-equation, two-fluid, dispersed turbulence model is constructed. The control-volume-based technique is used to solve the equations. The calculation domain is divided into discrete control volumes by the structured grid. The convective fluxes in the mean volume fraction, momentum and turbulence closure

equations are discretized by employing a conservative, second-order accurate upwind scheme. The pressure-velocity coupling algorithm is the pressure-implicit with splitting of operators (PISO), which is based on the higher degree of the approximate relation between the corrections for pressure and velocity and may also be useful for transient calculations on highly skewed meshes.

4. Application example

The results of the models are compared with field data measured at the Three Georges dam on the Yangtze river. DO data are provided by the water environmental monitor centre in the Three Gorges project construction company.

4.1. Solution domain

The Three Georges Dam has width of 483m spillway with 23 deep gates and 22 surface gates. The elevations of deep gates and surface gates are 90m and 158m respectively. Water discharge takes place in 14 powerhouse existed in the east and north direction respectively. DO concentration is measured in the sections of Dong Yue temple about 2 km far and Huang Lin temple about 12 km far downstream of the spillway when the water level of the Three Georges reservoir is 139m. In this work, 2D simulations are performed in a cross-section which includes the reservoir, spillway of deep gate and stilling basin (shown in Fig.1). The design curves of vertical section of deep spillway are presented in Ref. [15]. Although 3D effects are unavoidable, 2D simulations are less expensive. It should present most of the physical features of the flow in the DO production area. 3D simulations will be performed in the later study.

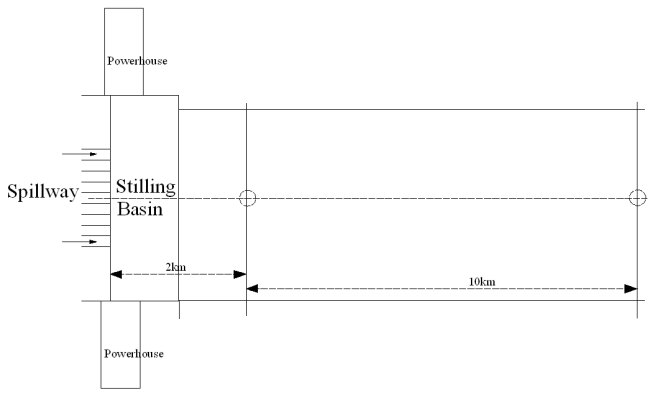

Fig. 1. Spillway of Three Georges dam and the numerical domain downstream of spillway

There are two simulation conditions in the present work. Case 1: Measured time is July 20, 2004. Only 12 deep gates discharged and flow rate is 17200m^3 per second. There are 8 generating electricity sets working and the flow rate is 7100 m^3 per second. Water level is 66.97 m and water depth is about 28 m at the downstream of the Three Georges dam. Water level of Three Georges reservoir is 139 m. Case 2: Measured time is August 23, 2005. Only 20 deep gates discharged and the flow is 30530m^3 per second. There are 13 generating electricity sets working and flow rate is 11447 m^3 per second. Water level is 66.97 m and water depth is about 29 m at the

downstream of the Three Georges dam. Water level of Three Georges reservoir is 139 m.

Non-uniform structured grids are used in the present work. Grid size is about 0.5m where the water jets are falling into water-body of downstream. The grid size is properly coarsened where the air entrainment nearly does not exist in the downstream of river and is about 2 m along with the direction of water flow.

4.2. Boundary conditions

The inlet section consists of the inlet of water on the lower part and the inlet of air on the higher part upstream of the spillway. The water inflow velocity can be calculated according to the discharge and the water depth at the inlet. The air boundary is setting as pressure-inlet conditions on which atmospheric pressure is assumed. Due to the boundary between water and air at the downstream outlet can not be distinguished, it is defined as a pressure boundary or free-flow condition. All of the walls are set as the stationary, non-slip wall. The viscosity layer near to the wall is dealing with as the standard wall function. The initial flow field over the spillway is full of air. Through the time-dependent simulation, the water flows over the spillway and produced air-water two-phase flow.

4.3. Some assumptions

As discussed earlier, the bubble interface mass transfer coefficient is a function of the diameter of the bubble. Meanwhile, DO concentration is affected by the discharge from the powerhouse. Focusing on oxygen transfer, the following assumptions simplify the numerical model in the paper.

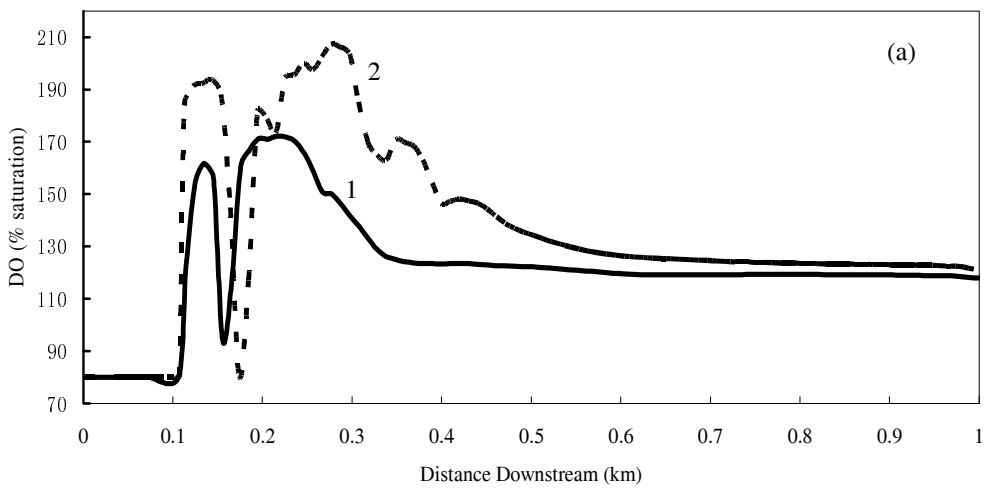
(1) The process of gas transfer across the bubble surface and the water surface is the only way by which interfacial mass transfer takes place;

(2) The initial bubble shape is spherical and it retains its original shape during its travel through the water column. The bubbles are single-sized bubbles and the diameter of bubble is 5 mm;

(3) DO concentration in the water discharged from the powerhouse is not changed and equal to the concentration in the reservoir. Taken the discharge from powerhouse into account, DO concentrations of downstream water-body during spillage at the Three Georges Dam may be expressed as

$$C_d^{'} = \frac{C_u Q_1 + C_d Q_2}{Q_1 + Q_2} \tag{10}$$

where C_u is DO concentration at the upstream of the spillway, C_d is DO concentration in the water after discharged from spillway, Q_1 is the flow rate discharged through the powerhouse, Q_2 is the flow rate discharged through the spillway, $C_d^{'}$ is DO concentration at the downstream of the spillway after water is complete mixed between the flow discharged through the spillway and through the powerhouse exits. So the C_d is can be simulated by use of the air-water two-phase mixture model and the DO transport model. Then $C_d^{'}$ can be computed based on the Eq. (10). It is the actual



DO concentration in river. $C_d^{'}$ will be used to compare with the measured DO concentration in this paper.

5. Results and discussion

5.1. Model Calibration

The models were calibrated using field data of DO concentration at the downstream of the water during the spillage at the Three Georges dam. The only coefficient β in Eq. (4) will be determined after the simulated DO concentration is calibrated by the field data.

Fig. 2 compares the DO concentration between model prediction and field data, as a percent of saturation, and the scatter dots are the field data. Field data are measured at the 2 km and 12 km downstream of the Three Georges dam. It can be seen that the two types of results are nearly close to each other and the standard error between simulation and field data is less than 0.5%. Fig. 3 compares model prediction and field data of DO concentrations along with the water depth at 1 km section downstream of Three Georges dam. The scatter dots are the field data. It can be seen that the standard error between simulation predictions and field data is less than 1%. The results show that the model in this paper and the numerical method to simulate supersaturated DO concentration are reasonable and feasible.

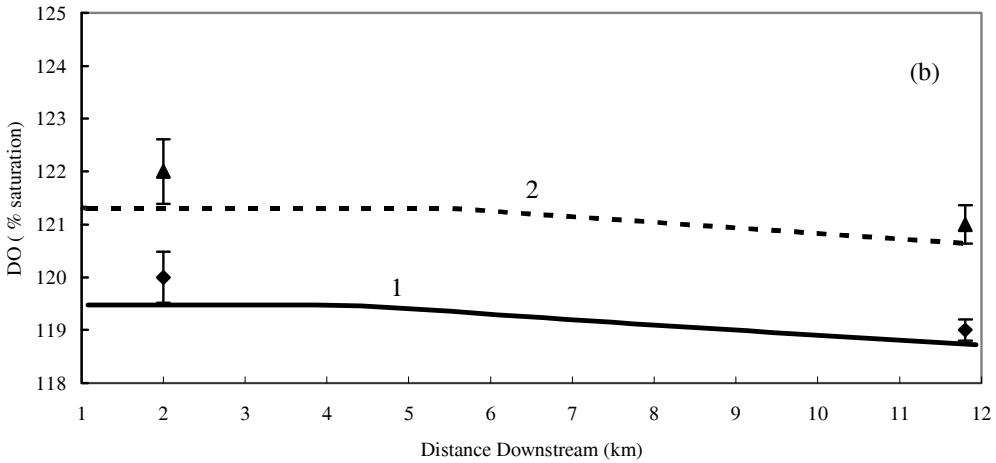


Fig. 2. Model prediction and field data of DO concentration along with the direction of water flow in the downstream of Three Georges Dam. Curves 1 and 2 represent the model prediction data of case 1 and 2, respectively.

For the two flow conditions, the distribution of DO concentrations along with distance is similar to each other. DO concentration in reservoir is nearly 80% of saturation. When water jets impact the water cushion pool, because the impacting time is very short and the water jets haven't mixed with the water cushion pool adequately, the temporary decrease of DO concentration appears. However, with the adequate mixing between the water jets and the downstream water cushion, turbulence, high gas void ratio and hydrostatic pressure lead to rapid transfer through bubble interface and eventually DO concentration reaches a maximum. With the flow tending to stable, water turbulence being weakened and air bubbles being disappeared, DO concentration will be decreased and eventually plateau in the downstream tailwater. The effect of the spillway and stilling basin on transfer process diminishes with distance and the change of DO concentration becomes minimal. It is shown from Fig. 2 that DO concentration is nearly 120% of saturation when flow reaches to 1 km and it remains 119% when flow reaches to 12 km in the case 1. That is to say, DO concentration just dissipates 1% in the range of 11 km. Some field data show that supersaturated DO concentration will decrease 6~8% of saturation in the range of 100 km. The results show again that the model in this paper to simulate supersaturated DO concentration is reasonable. The results also show that once DO concentration is supersaturated in water, it will need fairly long time and distance to recovery to the normal level before super-saturation.

Because the flow rate in case 2 is more than that of in case 1, peak of DO concentration in case 2 is also higher than that of in case 1 and DO concentration along the distance is also higher than that of in case 1.

It is worthwhile to mention that water depth is one of the important factors to affect the supersaturated DO concentration. As seen from Fig. 3, DO concentrations are not obviously being stratified along water depth. There is only 5% of saturation in the

range of 28 m water depth. DO concentrations still remain supersaturated under 28 m. It is maybe that the adequate mixing in the stilling basin can be used to explain this un-stratified phenomenon of DO concentration. Based on the field results, DO concentrations is nearly equal to each other along with the water depth in a section no matter it is at the water surface or at 30m deep under the water surface.

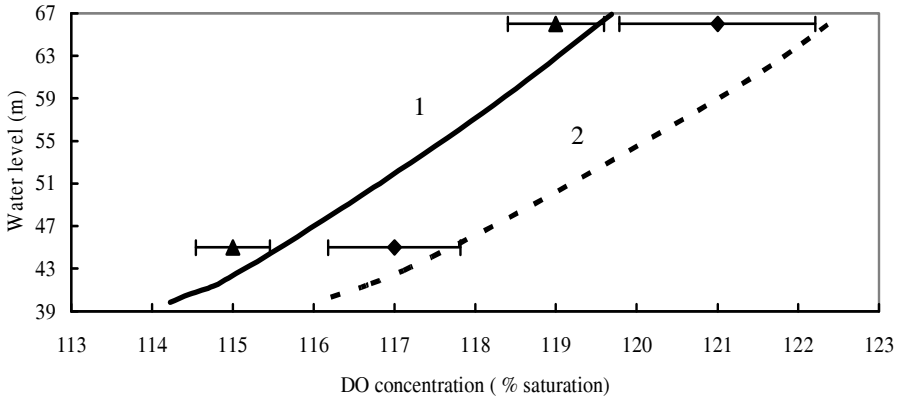

Fig.3. Model prediction and field data of DO concentration along with the water level at 1 km section in the downstream of Three Georges dam. Curves 1 and 2 represent the model prediction data of case 1 and 2, respectively.

5.2. Volumetric mass transfer coefficient of air bubble

Fig. 4 shows the air bubble volumetric mass transfer coefficients in two cases. The values of air bubble volumetric mass transfer coefficients change from 0 to 0.26. Many other authors also studied the volumetric mass transfer coefficients of air bubbles by means of numerical simulation and experiments under different Reynolds number [16, 17]. They found that when the Reynolds number of water flow is between 4000 and 40000, the air bubble volumetric mass transfer coefficients will change from 0 to 0.3. The Reynolds numbers are nearly equal to 30000 at the conditions of the two cases in this paper. The distribution in the volumetric mass transfer coefficients is very similar to that of DO concentration in the downstream of the Three Georges dam. So it is shown that the predicted volumetric mass transfer coefficient of air bubble is available in this paper. In the domain of water jets impacting with the stilling basin, high turbulence produces a lot of air bubbles which increase the air bubble interface area and transfer quantity. So the volumetric mass transfer coefficient reaches to maximum. At the same region, DO concentration reaches to maximum (See Fig. 2). With the flow gradually becomes calm, mass transfer through air bubble surface is decreased along the downstream of the stilling basin due to less air bubbles, lower turbulence, decreased gas void ratios and smaller hydrostatic pressure. Bubble transfer is no longer dominant and the mass transfer coefficient to across the air-water surface interface becomes important in this region. So the DO concentration is increased along with the flow direction due to the mass transfer at air-water surface.

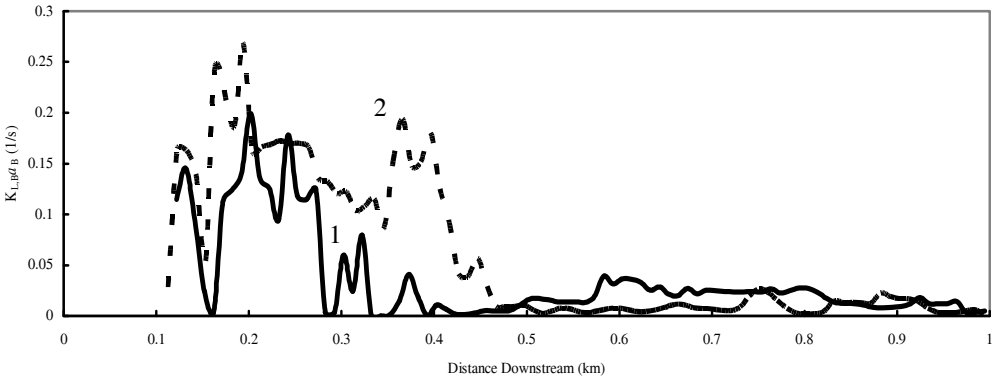

Fig. 4. Air bubble interface mass transfer coefficients downstream of Three Georges dam. Curves 1 and 2 represent the model prediction data of case 1 and 2, respectively.

6. Conclusions

The findings in this paper are summarized as follows:

(i) This study presented a numerical model to predict the DO concentration of the downstream water of the Three Georges dam during spillage. It is based on air-water mixture flow approach and allowed to the computation of the gas source on the DO transport equation. There is a good agreement between the model predictions and field data. In order to study the supersaturated TDG in the downstream of the Three Georges dam, the numerical methods in this paper have a great benefit in practice.

(ii) The numerical results have shown that the dissipating rate of supersaturated DO concentration in water-body is too slow. In the range of 10 km of river, the DO concentration is only 1% decreased. So DO concentration is once supersaturated in river, it will need fairly long time and distance to recovery to the normal level before super-saturation. Consequently, to search a realizable method for decreasing DO concentration is a key scientific problem for protection fish in river.

(iii) It is worthwhile to mention that the presented work is the initial step toward the development multidimensional simulation tools for the analysis of the problem of DO levels in the downstream of spillways. Next step work will consider the effect of air bubble size distribution and bubble number density on DO concentration. Besides the DO, the DN and total dissolved gas are all affect the fish living. So determination of the relationship of these three kinds of concentrations is also the next step work.

Abstract

Government regulators on many rivers have specified acceptable temperatures based upon habitat and biological criteria. These temperature thresholds impose constraints on reservoir operations and can limit water deliveries and power generation. Existing tools based on low-order modeling simplify a river to a simple line with limited spatial distribution of inputs and poorly represent physics of the river processes. The limited spatial extents restrict the usefulness of low-order modeling for such features as agricultural returns, gravel pits, groundwater upwelling, side channel activation, and streamside vegetation. It also imposes limitation on fish habitat assessment and reoperation outside the range of the calibration datasets.

This study develops a two-dimensional (2D) temperature module for an existing 2D hydraulic model, SRH-2D version 2. The 2D model incorporates data with both lateral and longitudinal geographic extents rather than lumping results into a point-to-point or uni-directional representation. The objective was to improve the representation of spatial features where low-order models resort to empiricism for a lumped treatment. Better representation of processes leads to increased accuracy and higher confidence.

The SRH-2D temperature model utilizes meterological data as inputs (solar radiation, cloud cover, air temperature, dewpoint temperature and wind speed). Physical processes modeled include solar radiation, terrain and vegetation shade, atmospheric radiation, water back radiation, heat exchange between water and river bed, water surface evaporative and conductive losses.

The model formulation, along with governing and process equations, is discussed first. The model is then tested and verified with simple cases having analytical solutions. The model is finally verified by applying to flows on the McKay Creek downstream of the McKay Dam.

Introduction

Water temperature is a key element for water quality studies and for some cases the most important attribute for stream analysis (Bartholow, 2002). Stream manipulation may lead to changes in water temperature which in turn may affect aquatic systems in many ways. Stream modifications may include reservoir discharge, release temperature, irrigation diversion, riparian shading, channel alteration, thermal loading, etc. Since many rivers have temperature compliance criteria for habitat and biological reasons, understanding of the temperature change due to stream manipulation becomes important. With climate change and growing emphasis on maintaining biological function in addition to water deliveries, the impact of thermal criteria in constraining water operations is expected to increase.

Assessment and prediction of stream manipulation consequences on water temperature for shallow streams are often carried out with numerical temperature models. Example models include SNTEMP (Theurer et al., 1984), SSTEMP (Bartholow, 1990), and ADYN/RQUAL (Hauser and Schohl, 2003), among others. Most existing tools are based on low-order modeling that represent a channel as a line of homogeneous longitudinal elements with limited spatial distribution of inputs. Some physical processes are poorly represented. Limited spatial extent restricts the usefulness of the model by neglecting spatial features such as tributaries and agricultural returns, gravel pits, groundwater upwelling, side channel activation, and streamside vegetation are highly parameterized or not included. The simplified picture of interactions requires inferring or estimating the real processes through conversion to lower order dimensions by the use of a number of empirical parameters used as abstract calibration coefficients. These coefficients increase the difficulty of model usage as well as the uncertainty, because most rivers do not have sufficient data to calibrate the independent effects of different features. Further, coefficients not tied to physical processes do not apply across a broad range of conditions. Predictive capability is limited to circumstances within measured ranges and cannot estimate the impact from changes on how the system operates. Example coefficients include: adjustments for estimates of velocity distributions (travel times) in the main channel, multiple flow paths, lateral inflows (surface or subsurface), and storage areas.

In this presentation, a two-dimensional (2D) temperature module is developed which incorporates geographic extents both laterally and longitudinally. A 2D representation provides a more direct and quantitative estimate of temperature impacts using the same spatially distributed area as is significant for biological characteristics. The developed 2D temperature module is then incorporated into an existing 2D hydraulic flow model, SRH-2D version 2 (Lai, 2008). The SRH-2D flow model is based on SRH-W (Lai, 2006) and has been widely applied by Reclamation and by external institutions. Many restoration projects in recent years apply 2D flow models to assess stream habitat suitability (e.g., Moir and Pasternack, 2008). Therefore, a temperature module would be a valuable addition where temperature is an important water quality element.

2D modeling provides accurate flow hydraulics which eliminates the need for abstract travel time adjustment coefficients and flow routing. When there are multiple flow paths, such as with gravel pits or side channels, flow moves at different speeds

along the different paths and, as a results, heats or cools at different rates. The difference in flow velocities between the river centerline and banks is also captured, eliminating the need to calibrate for cross section averaging. Spatially distributed sources of heat and cooling (ground water, solar, wind, vegetation) are directly transferable to the model and do not require grouping by reach. As a result, the spatially explicit results may show acceptable areas within generally unacceptable conditions and permit compromises where simplified models might indicate temperature violations. A process model can indicate the most critical component of the more critical areas to focus solutions. Grouping and lumping with abstract coefficients obscures the actual steps preventing temperature compliance.

Multi-dimensional tools for temperature modeling of reservoirs and lakes exist, for example, the 2D laterally averaged model CE-QUAL-W2 (Cole and Buchak 1995) and three-dimensional (3D) model U^{2}RANS (Lai et al. 2004). However, they are not applicable to typical streams. 2D laterally averaged reservoir models neglect lateral effects in favor of vertical stratification and are mostly limited to impounded areas; 3D models can accurately simulate temperature but the scale limits application to small areas. This paper focuses on shallow water streams where vertical stratification is negligible and complete vertical mixing is assumed.

Governing Equations and Process Models

The 2D depth-averaged flow equations are based on the assumptions that stream flows are shallow compared to width and the effect of vertical motion is negligible. Details of the equations and their numerical solution procedure may be found in Lai (2008) and are omitted here.

Conservation of thermal energy leads to the 2D depth-averaged temperature equation expressed as:

$$\frac{\partial hT}{\partial t}+\frac{\partial hUT}{\partial x}+\frac{\partial hVT}{\partial y}=\frac{\partial}{\partial x}\left[\frac{h\nu_t}{\sigma_t}\frac{\partial T}{\partial x}\right]+\frac{\partial}{\partial y}\left[\frac{h\nu_t}{\sigma_t}\frac{\partial T}{\partial y}\right]+\frac{\Phi_{net}}{c_w\rho_w}+\frac{q_{sp}}{A_{sp}}(T_{sp}-T) \quad (1)$$

In the above, T is depth averaged water temperature [C], x and y are horizontal Cartesian coordinates [m], t is time [s], h is water depth [m], U and V are depth-averaged velocity components [m/s] in x and y directions, respectively, ν_t is the turbulent viscosity and dispersion [m^2/s], σ_t is the thermal Prandtl number, ρ_w is the water density [kg/m^3], c_w is the specific heat of water [J/kg/C], q_{sp} is the spring water flow rate [m^3/s] into the stream (zero if spring flows out), A_{sp} is the area [m^2] of the spring water inflow, T_{sp} is the spring water temperature [C], and Φ_{net} is the net heat exchange [W/m^2] between water column and its surroundings (through water surface and streambed).

The turbulent eddy viscosity (ν_t) is computed with a turbulence model (Rodi 2003). Two turbulence models may be used in SRH-2D: the depth-averaged parabolic

model or the two-equation k-ε model (Lai 2008). The Prandtl number is computed as follows (Bowie et al. 1985; Fischer et al. 1979; Kim and Chapra 1997):

$$\frac{\nu_t}{\sigma_t} = C_d h u_* \tag{2}$$

where u_* is the bed frictional velocity and C_d is a constant coefficient which may be case dependent.

The net heat flux, Φ_{net}, consists of six contributions as follows:

$$\Phi_{net} = \Phi_{ns} + \Phi_{na} + \Phi_{bed} - \Phi_{br} - \Phi_e - \Phi_c \tag{3}$$

where

Φ_{ns} = net solar radiation entering water surface
Φ_{na} = net atmospheric radiation entering water surface
Φ_{br} = heat loss by back radiation from stream
Φ_e = evaporative heat loss at water surface
Φ_c = conductive heat loss at water surface
Φ_{bed} = heat flux into stream at channel bed

The net solar radiation at a water surface incorporates five thermal processes: extra-terrestrial solar radiation, attenuation due to atmosphere, correction for cloud cover, reflection by water surface, and correction due to terrain and vegetation shade. The processes are described fully in a number of reports and textbooks on hydrology (e.g., Huber and Harleman 1968; Eagleson 1970; Brutsaert 1991).

If measured solar radiation (Φ_{Sm}) at water surface is available, the net solar radiation is computed as (Hauser and Schohl 2003):

$$\Phi_{ns} = \Phi_{Sm} R_S \tag{4}$$

where Φ_{Sm} is measured solar radiation (shade free solar radiation at the water) and R_S is reflection and terrain and vegetation shading factor which is computed by the following equations (Hauser and Schohl 2003):

$$R_S = R_{sm} \quad \text{if } X_n \le B \text{ (shade free)} \tag{5a}$$

$$R_S = 0.2 \quad \text{if } X_n > B + W \text{ (full shade)} \tag{5b}$$

$$R_S = R_{sm}\frac{B + W - X_n}{W} + 0.2\frac{X_n - B}{W} \quad \text{if } B < X_n \le B + W \text{ (partial shade)} \tag{5c}$$

In the above:

$R_{sm} = 1 - a(57.3\alpha)^{-b}$ = shade-free reflection factor (a and b see Table 1)

α = solar altitude in radians
W = width of the stream cross section
B = distance from trees to water edge
$X_n = H_b \cos\beta / \tan\alpha$ = normal distance from trees to shadow edge
H_b = tree/bank height from water surface
$\beta = \left|\theta - \frac{90}{57.3}\right|$ = angle between sun and stream axis normal in radian
$\theta = \left|A_{zs} - \frac{A_{zr}}{57.3}\right|$ = angle between sun and stream axis in radian
A_{zr} = river azimuth, clockwise from north to direction of flow in degree
$\cos(A_{ZS}) = -\frac{\sin(\phi)\sin(\alpha) - \sin(\delta)}{\cos(\phi)\cos(\alpha)}$ = sun azimuth in radian

Table 1. Coefficients of solar radiation reflection

Cloud Cover	a	B
0-0.05	1.18	0.77
0.05 – 0.5	2.20	0.97
0.5 – 0.92	0.95	0.75
0.92 – 1.0	0.35	0.45

The solar altitude (α) is computed, assuming a spherical geometry, as follows (Huber and Harleman, 1968):

$$\sin\alpha = \sin\phi \sin\delta + \cos\phi \cos\delta \cos h \tag{6}$$

where ϕ is site latitude in radians, δ is sun declination (between the sun and equator) in radians, and h is the sun hour angle in radians.

If solar radiation is not measured, it can be computed using semi-empirical relationships. The approach follows Huber and Harleman (1968) is described in detail by Lai et al. (2004).

The net long-wave radiation emitted by the atmosphere is computed as:

$$\Phi_{na} = 5.16432 \cdot 10^{-13}(1 + 0.17C^2)(T_a + 273.16)^6 \tag{7}$$

where $C = (1 - S/S_0)^{3/5}$ is cloud cover and T_a is dry bulb air temperature [C].

The outgoing black-body radiation emitted from the water surface is a function only of the water temperature, and it is given by (Huber and Harleman 1968):

$$\Phi_{br} = \varepsilon_w \sigma (T_w + 273.16)^4 \tag{8}$$

where T_w is water-surface temperature [C], ε_w is emissivity (0.97 by Huber and Harleman 1968 and 0.98 by Tung et al. 2006), and σ is Stefan-Boltzman constant (5.672e-8 W/m^2/K^4).

The evaporative heat loss is computed by:

$$\Phi_{evp} = \rho_w L(a1 + b1W_a)(e_s - e_a) \tag{9}$$

where:

$L = (597 - 0.57T_w) * 4184$ = the latent heat [*J/kg*]

T_w = water temperature in Celsius

a1, b1 = constants: a1=0.0 to 4.0e-9; b1=1.0e-9 to 3.0e-9

$e_a = 2.171 \cdot 10^8 \exp\left[\frac{-4157}{T_d + 239.09}\right]$ = saturation vapor pressure [mb]

T_d = dewpoint temperature in Celsius.

$e_s = \alpha_j + \beta_j T_w$ = saturation vapor pressure [mb] with coefficient in Table 2

Table 2. Coefficients to compute saturation vapor pressure

T	j	αj	βj
0-5	1	6.05	0.522
5-10	2	5.10	0.710
10-15	3	2.65	0.954
15-20	4	-2.04	1.265
20-25	5	-9.94	1.659
25-30	6	-22.29	2.151
30-35	7	-40.63	2.761
35-40	8	-66.90	3.511

The conduction heat loss is:

$$\Phi_{cond} = \rho_w L(a1 + b1W_a) \cdot 0.61 \cdot 10^{-3} P(T_w - T_a) \tag{10}$$

where P is air barometric pressure in mb.

Heat exchange between stream bed and stream water is significant for shallow streams and it consists of two contributions: conduction from bed to stream and net solar radiation entering bed. It is computed by the following expression:

$$\Phi_{bed} = \frac{\kappa_b}{0.5\delta_b}(T_b - T_w) - (1 - A_b)(1 - \beta)\exp[-\eta(D - 0.6)]\Phi_{ns} \tag{11}$$

where κ_b is the thermal conductivity of the streambed bed material, δ_b is the effective bed thickness used for hear conduction computation, T_w is the water temperature, T_b is the effective stream bed temperature which is updated each time step by $T_b = T_b^{old} - \frac{\Phi_{bed}\Delta t}{\rho_b c_b \delta_b}$ with ρ_b and c_b the density and specific heat of the bed materials and Δt is the time step for simulation, A_b is albedo of bed material, β is fraction of solar radiation absorbed in the top 0.6m of surface water, η is extinction coefficient in water [1/m], and D is water depth [m].

Numerical Method

A detailed presentation of the numerical method is omitted here. Basically, the flow equations are solved with the finite volume method that guarantees the mass conservation locally and globally. An implicit time marching scheme is used with the arbitrarily shaped unstructured mesh methodology of Lai (2003). A detailed presentation of the numerical method for the flow hydraulics may be found in Lai (2008). The temperature equation is discretized and solved similar to the momentum equation.

Test and Verification with Cases Having Analytical Solutions

The following three test cases solve the unsteady 1D temperature equation:

$$\frac{\partial T}{\partial t} + \frac{\partial UT}{\partial x} = k(T_{eq} - T) \tag{12}$$

The purpose is to test and verify the implementation and solution of the unsteady temperature equation within SRH-2D. The above equation has the following exact solution:

$$T(t,x) = T_0(t-\tau)e^{-\kappa\tau} + T_{avg}(1-e^{-\kappa\tau}) + \kappa T_\Delta \frac{\cos[\omega(t-\tau)]}{\omega^2+\kappa^2}\left[\omega e^{-\kappa\tau} - \omega\cos(\omega\tau) + \kappa\sin(\omega\tau)\right]$$
$$+ \kappa T_\Delta \frac{\sin[\omega(t-\tau)]}{\omega^2+\kappa^2}\left[-\kappa e^{-\kappa\tau} + \kappa\cos(\omega\tau) + \omega\sin(\omega\tau)\right] \tag{13}$$

In the above, $T_0(t)$ is boundary condition at x=0, κ is a first-order rate constant which is a function of meteorological parameters and water depth, $T_{eq} = T_\Delta \sin\left(\frac{2\pi t}{P_\Delta}\right) + T_{avg}$ is water temperature, $\tau = x/U$, and $\omega = \frac{2\pi}{P_\Delta}$.

The first case has the following parameters: a constant flow velocity of U=1.0 mile/day, a zero equilibrium temperature $T_{eq} = 0$, and a constant coefficient k=0.2/day. A 100 mile straight channel is assumed for SRH-2D modeling. The mesh has 100 mesh cells in the flow direction and 2 cells in the lateral. Initially temperature is 20 Celsius everywhere and the temperature at $x = 0$ is held at 20 Celsius all the time. Simulation is carried out for 50 days with a time step of one hour. The temperature at $x = 100$ miles is compared in Figure 1 between the model solution and the exact solution. A good agreement is obtained for this simple case.

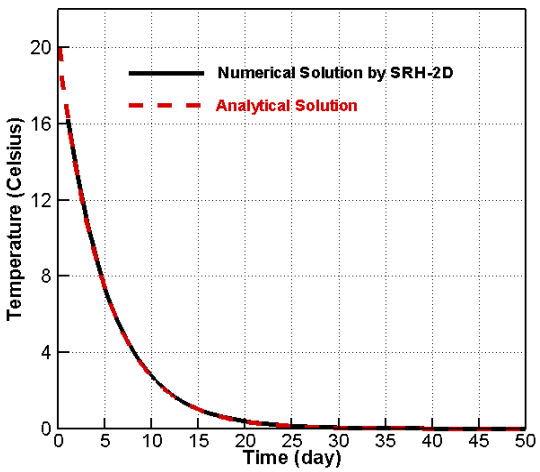

Figure 1. Comparison of temperature at 100-mile location between model and analytical solution for case 1.

Test case 2 has the following parameters: a constant flow velocity of U=1.0 mile/day, a zero equilibrium temperature $T_{eq} = 0$, and k=0.0. A 100-mile straight channel is assumed. The initial temperature is zero everywhere but the temperature at $x = 0$ is changing with time according to $T(x=0) = 10 + 10\sin\left(\frac{2\pi t}{P}\right)$ with the period P = 20 days. The same mesh is used as case 1. The computed temperature at $x = 40$ miles is compared with the exact solution in Figure 2. The computed temperature remains at zero until about day 35. Theoretically, the temperature wave reaches the location at day 40. The discrepancy is due to the numerical diffusion caused by discretization error as zero diffusion is assumed in the analytical Solution.

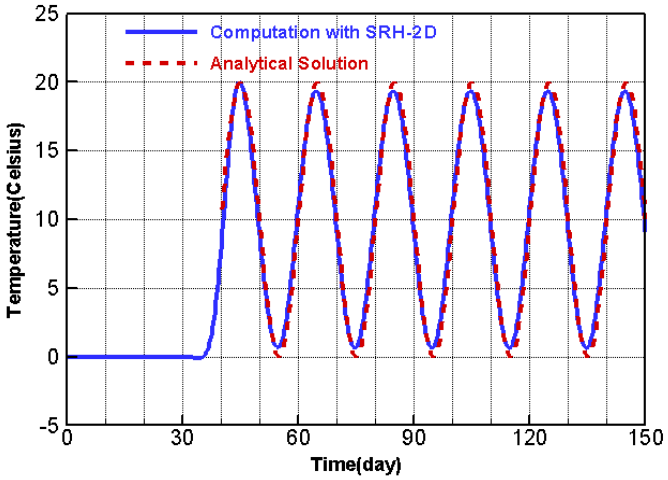

Figure 2. Comparison of simulated temperature and the exact solution at a location of 40 miles for case 2.

Test case 3 has the following parameters: a constant flow velocity of U=1.0 mile/day, $T_{\Delta} = 10$, $T_{avg} = 15$, $P_{\Delta} = 360$, and a constant coefficient k = 0.2/day. A 100-mile straight channel is assumed for SRH-2D modeling. The mesh has 100 or 300 mesh cells in the flow direction and 2 cells in the lateral. Initially temperature is 11.51 Celsius everywhere and the temperature at $x = 0$ is $T_0(t) = 10\sin(\frac{2\pi t}{10}) + 10$. Simulation is carried out for 150 days with a time step of 6 minutes. The temperature at $x = 4.5$ *miles* is compared in Figure 3 between the model solution and the exact solution. A good agreement is obtained.

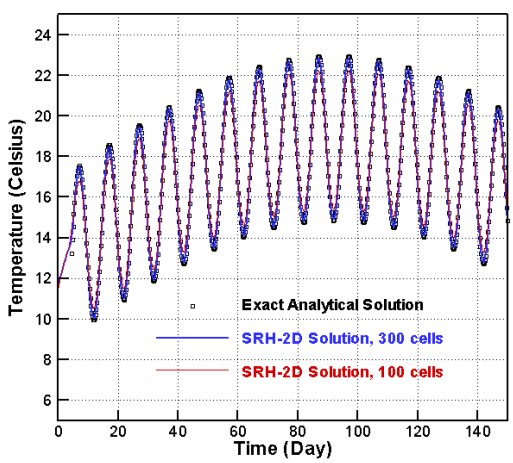

Figure 3. Comparison of simulated temperature and exact solution at channel mile 4.5 for case 3.

Temperature Modeling for the KcKay Dam Tailwater

The SRH-2D temperature model used a river reach downstream of the KcKay Dam for model verification and application. A reach along the McKay Creek and the first 2.57 miles of the Umatilla River has been studied by Bender (2001) with the 1D temperature model ADYN/RQUAL.

Case Description: McKay Dam and Reservoir are located on McKay Creek about 6 miles south of Pendleton, northeast Oregon. Downstream of the dam, the McKay Creek flows into the middle Umatilla River (at about RM 52). The Umatilla River drains into the Columbia River at about Columbia River Mile 289. The 2.57-mile reach of the Umatilla River from the confluence of the Umatilla River and the McKay Creek to the Reith Bridge could be managed to provide a water temperature to benefit the fishery. In particular, the flat slope and pools within the first mile of the Umatilla River downstream of the confluence with McKay Creek provides potential habitat for fish.

Cross-sectional channel survey downstream of the McKay Creek was conducted in March and November 2000 by Reclamation staff. The U.S. Army Corp of Engineers (Walla Walla District Office) provided sparse cross-section data of the Umatilla River collected in 1950. Around 64 cross-sections were assembled by Bender (2001) to carry out the temperature study for a 9-mile reach from McKay Dam to downstream of the Reith Bridge on the Umatilla River. The same cross sectional data are used to construct a 2D model for SRH-2D modeling in this study.

The model simulation starts from midnight July 27, 2000 and continues for 5 days. Temperature measurements at selected locations provide a comparison between model predictions and measured data. Continuous McKay Creek and Umatilla River temperature data were collected by the Umatilla tribes at the following four locations: Scheeler's Bridge (McKay RM 3.7), McKay School Bridge (McKay RM 1.9, Fish Barrier at the confluence (McKay RM 0.0), and Reith Bridge (Umatilla RM -2.57).

Mesh and Model Input Parameters: The simulation domain consists of about 6 miles of McKay Creek downstream of the McKay Dam and 3 miles of Umatilla River downstream of the confluence between McKay Creek and Umatilla River. The developed 2D mesh consists of 4,024 cells with both quadrilateral cells and triangular cells. The topography is interpolated from the cross sectional survey data.

Boundary conditions include water discharge and temperature downstream of the McKay Dam and upstream of the confluence in the Umatilla River. The hourly McKay Dam release discharge and temperature are used as upstream boundary conditions for the modeling period. The discharge downstream of the McKay Dam varies from 242 to 257 cfs and temperature ranges from 8.3 to 9.1 Celsius. The hourly flow, from 40 to 49 cfs, at Pendleton, Oregon is used as the upstream condition of the Umatilla River. The temperature, ranging from 24 to 27 Celsius, at the Umatilla River is based on a synoptic survey taken on July 28, 2000.

Initial conditions of the modeling used a steady state flow discharge of (257 cfs) at midnight of July 27, 2000. The initial temperature varies depending on the location of the cross section from 8.4C downstream of the McKay Dam to 23.0C at the Reith Bridge.

Hourly meteorological data, including cloud cover, air temperature, dewpoint temperature, air pressure and wind speed, are based on the national Weather Service (NWS) data from Pendleton, Oregon; and Agrimet solar radiation data are from Hermiston, Oregon (station HMRO).

Vegetation shade data includes the azimuth angle, tree height, tree distance to water edge at each cross section. They are delineated based on the aerial photo map.

Results and Discussion: Simulation is carried out from midnight of July 27, 2000 and lasts for five days. The simulated temperature is cross-sectionally averaged at five locations where measured temperature is available. Comparisons of the simulated and measured temperature are shown in Figure 4 to Figure 8 at measurement five locations.

It is seen that agreement is favorable for all locations with the maximum difference less than one degree Celsius. This comparison is encouraging as little effort is spent to locally calibrate the model to achieve a good match. Default values are used for most thermal processes and the few parameter values that are calibrated are constant for the entire reach modeled.

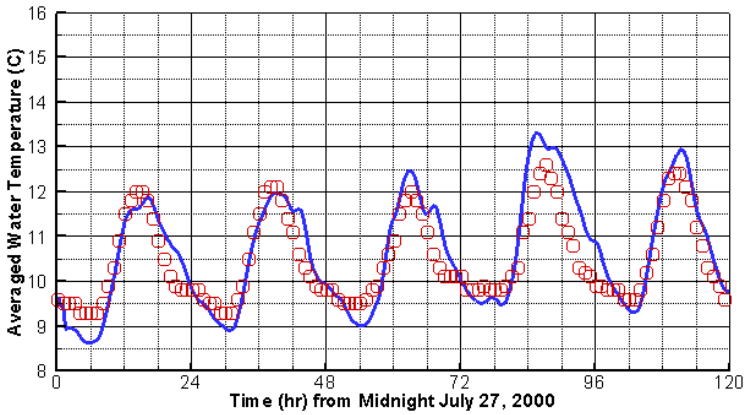

Figure 6. Comparison of temperature at School (McKay RM 1.9) from July 28 through August 1, 2000; Solid Line: Simulated; Symbol: Measured

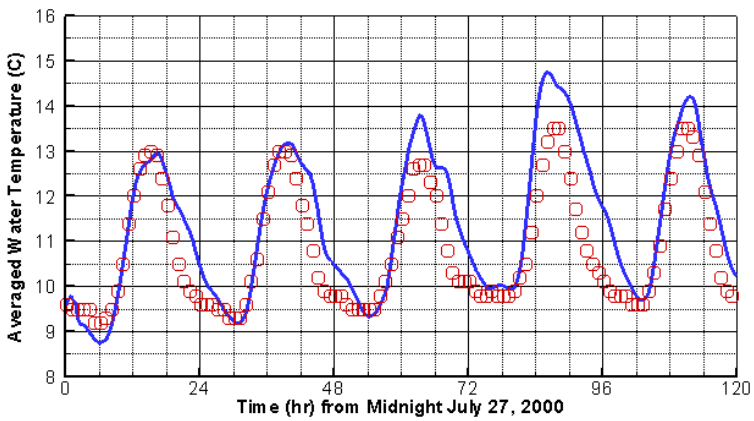

Figure 7. Comparison of temperature at Fish Barrier (McKay RM 0.01) from July 28 through August 1, 2000; Solid Line: Simulated; Symbol: Measured

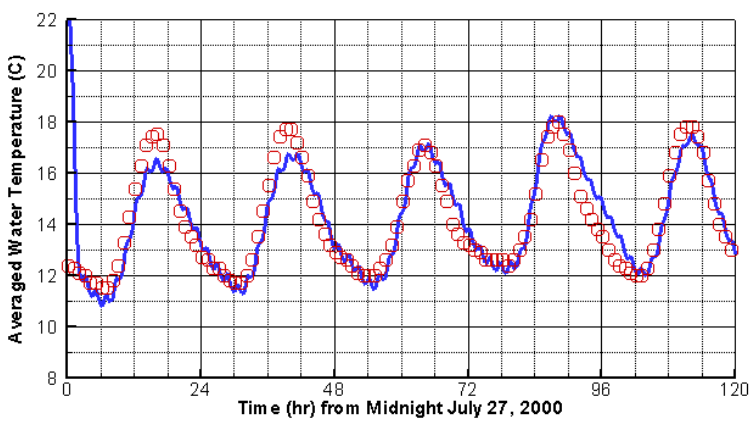

Figure 8. Comparison of temperature at Reith Bridge (RM -2.57) from July 28 through August 1, 2000; Solid Line: Simulated; Symbol: Measured

Concluding Remarks

A 2D depth-averaged temperature module is developed and incorporated into the existing SRH-2D model to simulate both flow hydraulics and diurnal temperature change. Such a model would be useful for habitat modeling, particularly for cases where spatial features such as agricultural returns, gravel pits, groundwater upwelling, side channel activation, and streamside vegetation are present.

Only development, testing, and a verification study are reported. The model is shown to reproduce the cases with exact solutions accurately; the model also matches a 9-mile reach downstream of the McKay Creek Dam in Northeast Oregon. Comparison between the model and the measurement is encouraging. The next step for development will collect lateral measured data on the San Joaquin River to compare against simulated data.

Acknowledgements

This study is partially funded by Reclamation's Science and Technology Program. Technical assistance by and discussion with Merlynn Bender at the Technical Service Center, Bureau of Reclamation are acknowledged, who also provided the data for the McKay Creek case. Peer review by Blair Greimann at the Bureau of Reclamation is appreciated.

ABSTRACT

The present study focuses on understanding the transport and fate of dissolved waste from aquaculture pens in near-coastal environments using the hydrodynamic code SUNTANS, which employs unstructured grids to compute flows at very high resolution. We perform simulations of the dissolved waste field and study the effects of different flow conditions (tides and currents) on the evolution of the waste plume. The fish pen causes partial blockage of the flow, leading to the deceleration of the approaching flow and the formation of a downstream wake. Results of the concentration field for an oscillatory flow condition superimposed on a mean current are presented and compared with the concentration resulting from a unidirectional flow field. The simulation results highlight the complex (and different) circulation patterns that occur around a submerged fish pen under oscillatory flow conditions and provide an understanding of the impact of aquaculture fish pens on coastal water quality.

1. INTRODUCTION

The rapid growth of marine aquaculture in the last few years poses a major threat to ocean ecosystems. For example, wastes and nutrient levels from aquaculture pens alter the character of the surrounding ecosystem. A recent comprehensive review on aquaculture by Naylor and Burke (2005) highlights some of the ecological impacts of marine aquaculture. The dispersal of wastes from pens released into the coastal ocean may not necessarily be "Gaussian" (monotonically decreasing from the source in all directions), and 'dilution may not be the solution'. The evidence from previous field and laboratory studies (Crimaldi *et al*., 2002) suggests that waste maybe transported in plumes, which retain their coherence and possess relatively high concentrations over large distances. This pattern of dispersal could result in much

higher concentrations of wastes at certain points on the coastline, even at considerable distances from the source.

In the present study, our focus is to understand the dispersal of dissolved wastes such as nitrogen from an aquaculture pen using high-resolution two-dimensional (in the *x*-*y* horizontal plane) numerical simulations under different time-varying flows. Previous work by others (Chatwin 1975, Smith 1982 and Kay 1997) has shown how strong oscillatory effects dominate the character of the plume over time intervals of several wave periods. However, these studies do not consider the presence of a porous obstacle in the flow field, which has the added complexity of a downstream wake. Our emphasis in this study is to understand the behavior of the plume evolution under oscillatory flow conditions superimposed on a constant mean current compared to the classical spreading that would occur under unidirectional flow conditions in the "near-field" downstream of an aquaculture pen. The layout of this paper is as follows: in Section 2, we briefly discuss the computational approach we employ for this study and provide an overview of the problem set-up. We present results of the dispersion of a continuous pollutant source emanating from an aquaculture pen under unidirectional as well as oscillatory flow conditions in Section 3. We draw our conclusions and provide directions for future work in Section 4.

2. NUMERICAL METHOD AND PROBLEM CONFIGURATION

We employ the SUNTANS code developed by Fringer *et al.* (2006) to perform highly resolved simulations of flow through and around a fish pen in the domain shown in Figure 1, in a water depth of 50 m. SUNTANS is an unstructured, finite-volume, parallel coastal-ocean simulator that solves the incompressible three-dimensional nonhydrostatic Navier-Stokes equations with the Boussinesq approximation. It also solves equations for the free-surface as well as scalar transport of salinity and temperature. This code has been applied to a host of coastal problems and processes such as the generation and evolution of internal waves in Monterey Bay (Jachec *et al*., 2006) and the South China Sea (Zhang and Fringer, 2006) and high-resolution simulations of estuarine hydrodynamics (Wang and Fringer, 2006).

At the boundaries of the domain shown in Figure 1, we impose a velocity field of the form

$$u = U_m + U_t \sin(\omega t), \tag{1}$$

where $U_m \geq 0$ is the amplitude of the mean current; U_t is the amplitude of the sinusoidal tidal component of the flow field with forcing frequency ω; and u is the horizontal (x) velocity component at the boundary. Boundary conditions for the horizontal velocity u are free-slip at the lateral walls. The horizontal component in the y-direction of the velocity field v has no-flux boundary conditions on the lateral walls, and the scalar field has gradient-free boundary condition on all walls. The unstructured mesh has a total of 72,500 cells, with grid refinement near the fish pen as shown in Figure 1. The resolution near the pen is roughly 1 m, while that in the farfield is stretched to 15 m. The fish pen centered at x = 100 m and y = 200 m is cylindrical in shape with a diameter of D = 20 m. A drag law formulation is employed to account for the flow reduction inside the pens and the resulting decrease in

momentum downstream of the pens. This drag formulation is given by a quadratic drag-law on the right-hand side of the *x*- and *y*-momentum equations of the form

$$F_{D,x} = -\frac{pC_D\left(u_x^2 + u_y^2\right)^{1/2}}{D}u_x, \qquad F_{D,y} = -\frac{pC_D\left(u_x^2 + u_y^2\right)^{1/2}}{D}u_y, \tag{2}$$

where C_D=1 is the drag coefficient, u_x and u_y are the easterly and northerly components of the velocity, and p=1 inside of the pens while p=0 outside of the pens. We use a horizontal eddy-viscosity of $\nu_h = 10^{-3}$ m^2 s^{-1}, and a quadratic bottom drag law formulation with a drag coefficient of $C_{D,bottom}$=0.0025. An estimate of the Reynolds number based on a characteristic velocity scale of 0.1 m s^{-1} and the specified values of D = 20 m and $\nu_h = 10^{-3}$ m^2 s^{-1} is Re = 2000. A continuous pollutant (scalar) point source is placed at the pen location as an approximation of the effluent waste discharged from the pen.

An important non-dimensional parameters for the simple model flow problem defined by Eq. (1) is the ratio of the tidal to mean flow given by

$$\eta = \frac{U_t}{U_m}, \tag{2}$$

which compares the amplitude of the oscillatory flow to the amplitude of the mean current and is an important parameter that determines the shape of the contaminant plume (Purnama and Kay 1999). A second important parameter is the non-dimensional tidal excursion lengthscale given by

$$K = \frac{2U_t}{\omega D}, \tag{3}$$

where U_t is the amplitude of the tidal current, ω is the forcing frequency and D is the pen diameter. This represents the ratio of the tidal excursion to the pen diameter and is analogous to the Keulegan-Carpenter number used in wave-structure interaction studies. In this study, we have used $U_t = U_m$ = 0.1 m s^{-1}, which is representative of typical coastal flow current magnitudes.

3. RESULTS AND DISCUSSION

We carried out a series of two-dimensional simulations with a forcing frequency $\omega = 8.73\times10^{-4}$ *rad s*$^{-1}$ corresponding to a wave period of T = 2 hours and a non-dimensional excursion lengthscale K = 11.5. In what follows, we present results for two cases, namely: Unidirectional flow case with U_t / U_m = 0 and an oscillatory plus uniform flow case with U_t / U_m = 1.

3.1 Unidirectional Flow Case

The case of a steady uniform flow past an obstacle such as an isolated cylinder has been studied extensively. Here we consider a similar situation except that the fish pen permits some flow through it. We account for the reduction in momentum in the flow

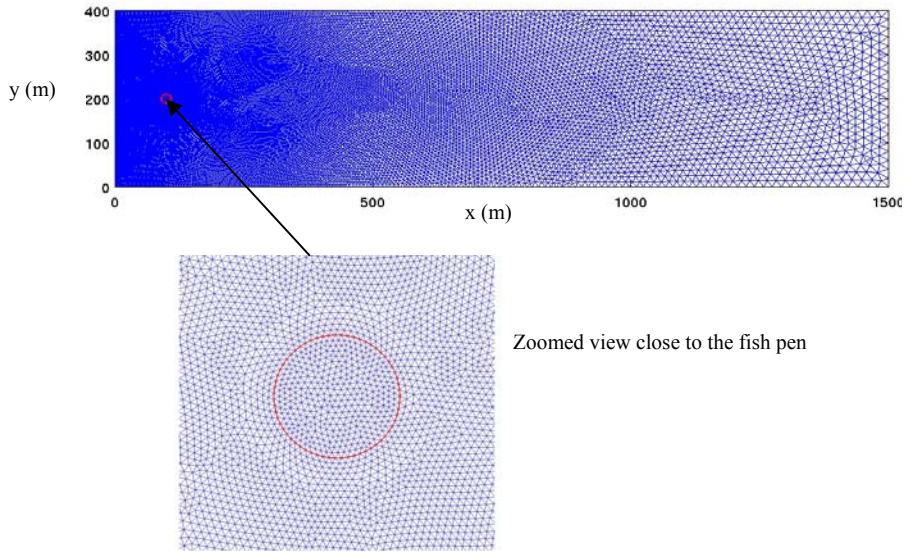

Figure 1. Unstructured computational mesh showing the domain used in the simulations for this study. A velocity described by Eq. (1) is imposed at the left boundary of the domain with frequency $\omega = 8.73 \times 10^{-4}$ *rad* s^{-1} in a depth of d = 50 m.

inside the pen using a drag law formulation with a drag coefficient $C_D = 1$. We further assume that the concentration of the waste discharged is uniform inside the pen based on the justification that mixing occurs within the pen as result of the swimming motion of the fish. We impose a mean current of $U_m = 0.1$ m s^{-1}.

The mixing and transport of a continuous point source collocated within the fish pen is shown in Figure 2 using a time sequence of the concentration field over a time period of nearly three wave periods (with $T = 2$ hours) under uniform flow conditions. Figure 2(a) shows the initial condition at time $t = 0$. As time progresses, the fish pen causes partial blockage of the flow, leading to the deceleration of the approaching flow and the formation of a downstream wake as would be expected. Initially, a recirculation zone with closed streamlines develops just past the fish pen and is termed the primary wake by White and Nepf (2003), as shown in Figure 2 (b), (c) and (d). Eventually the wake becomes unstable resulting in unsteady and periodic vortex shedding (see Figure 2(e) onwards). Further in time, the wake becomes more or less fully developed (Figure 2(l)), thus defining a "mixing zone". Downstream of this mixing zone, it may be expected that far-field mixing governed by simple advection due to the ambient current and turbulent diffusion will control the mixing of the pollutant field.

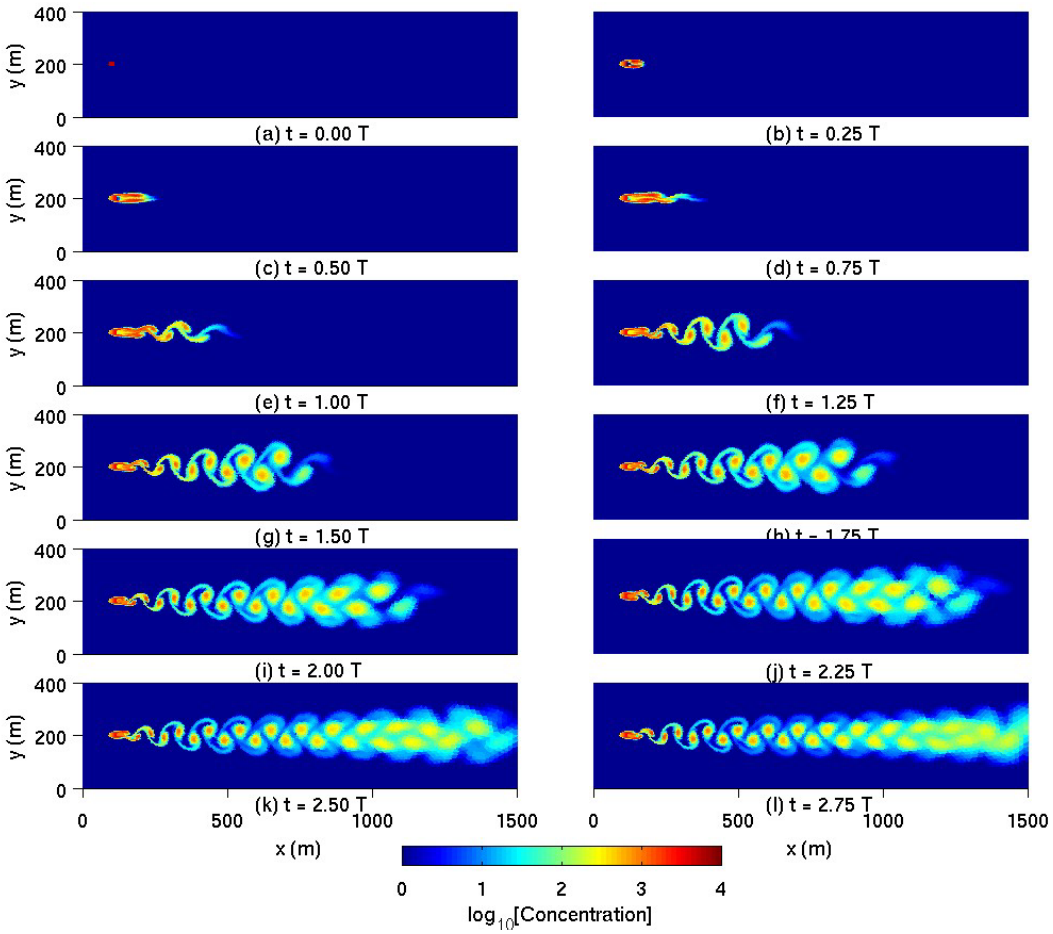

Figure 2. Normalized concentration field (shown in color) for a uniform flow case (U_t/U_m = 0). The continuous point source is located within the perimeter of the fish pen. Time is normalized by the wave period T = 2 hours.

3.2 Oscillatory Plus Uniform Flow Case

Here we consider a case with an oscillatory component in Eq. (1) with magnitude equal to the mean component (i.e. U_t/U_m = 1). All other parameters are exactly the same as for the uniform case discussed in Sec. 3.1. Here, the flow will stagnate at certain points in time when the tidal velocity exactly negates the mean velocity. It should be noted that for U_t/U_m >1, the fluid will reverse direction twice during each tidal cycle and in the special case when U_t/U_m = ∞, the vortex wake created during each half cycle will sweep past the fish pen during each subsequent half cycle (Williamson 1985).

The results for the case U_t/U_m = 1 are shown in Figure 3. When the tidal component is in phase with the mean current, the flow evolves in a similar manner to that of the unidirectional flow case discussed in Sec. 3.1 (see Figure 3 (a) - (c)). Soon after the initial vortex shedding begins, the flow starts to retard as the tidal velocity reverses direction and increases in amplitude. This causes the plume to contract in the longitudinal direction with a simultaneous dispersion in the lateral direction as shown

in Figure 3(d) & (e), and in subsequent wave cycles in Figure 3(h), (j) & (l), respectively. Note how the vortex shedding is also attenuated during this period. This behavior was first described by Chatwin (1975), where he points out that the contaminant cloud appears to be periodically expanding and contracting. The plume is stretched during the period of high flow during the first half tidal cycle and contracts during the second half-cycle (see also Smith 1982). We note that as the extent of the plume reaches the lateral boundaries, the no-flux boundary condition used at these boundaries results in the non-physical longitudinal spreading that is observed as shown in Figure 3(i) and (j).

These results indicate that the mixing and dispersion of the pollutant field under oscillatory flow conditions is very different from the unidirectional flow case and could result in plumes of waste with relatively high concentration occurring at considerable distances from the source.

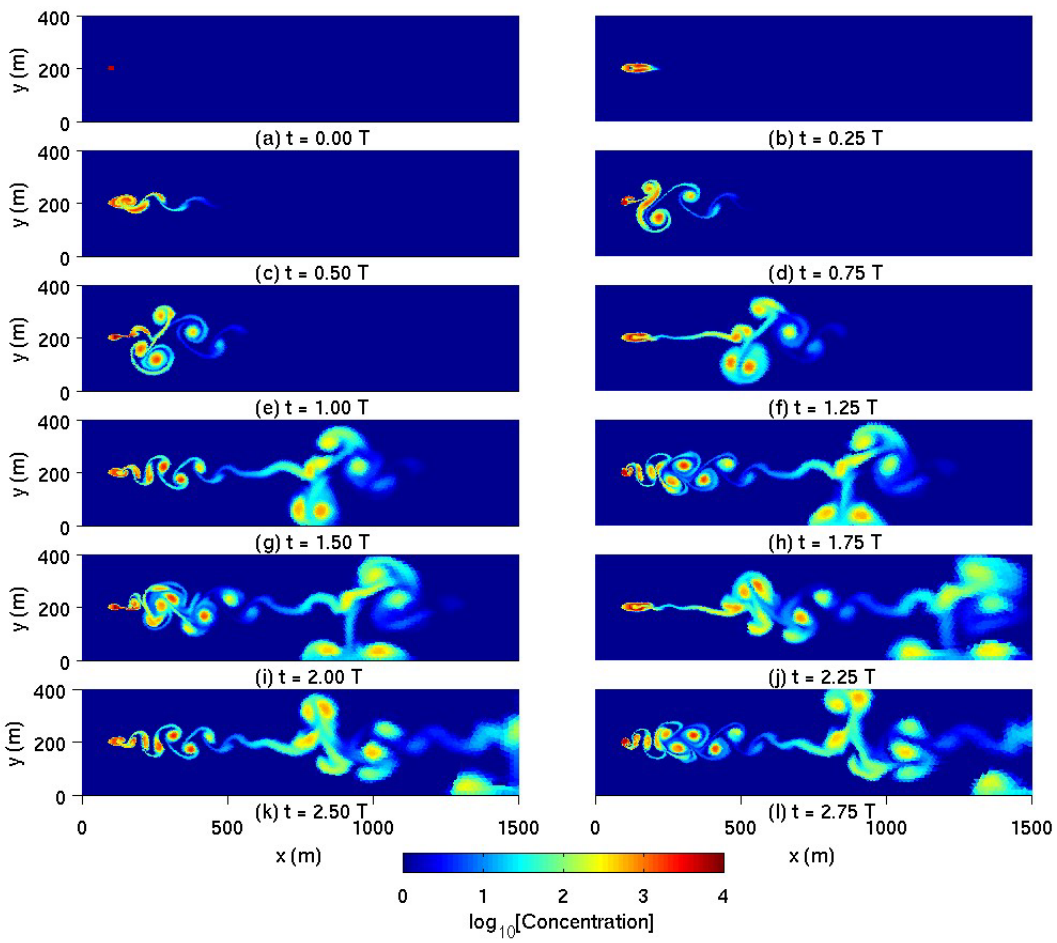

Figure 3. Normalized concentration field (shown in color) for an oscillatory flow case (U_t/U_m = 1). The continuous point source is located within the perimeter of the fish pen. Time is normalized by the wave period T = 2 hours.

4. CONCLUSIONS AND FUTURE WORK

We have presented results from highly resolved two-dimensional numerical simulations of the mixing and transport of a continuous point source of waste from an aquaculture pen. To our knowledge, this is the first detailed numerical study of the evolution of a waste plume downstream of a porous obstacle under oscillatory flow conditions. The emphasis of this study was to highlight the complex and different plume dispersion patterns that occur under such flow conditions, with concentration profiles that are not necessarily Gaussian.

This study is a first step towards understanding the complex three-dimensional flow structure that would occur in the vicinity of aquaculture pens. We are currently carrying out a detailed study to quantify the dependence of the horizontal dispersion coefficient on the two non-dimensional numbers η and K for a wide parameter space using two-dimensional simulations. We are also performing highly-resolved three-dimensional nonhydrostatic simulations to understand the plume structure resulting from the complex flow patterns that occur due to flow separation over and under a submerged aquaculture pen. Further extensions of this study will address the mixing and dispersion of the waste plume from a single aquaculture pen under stratified flow conditions. We will also explore cases with multiple aquaculture pens where we expect the flow field to be significantly modified due to hydrodynamic interference effects. This would be a useful extension of the present work and would provide a basis to examine the issues of spacing of aquaculture pens.

The Importance of In-stream Hydraulics in River Water Quality Models: Lessons from the Blackstone River

Abstract

Water quality models of rivers often include three fundamental components: inflows and pollutant loads from point sources and watershed runoff, in-stream hydraulics, and in-stream water quality processes. In many cases, model development focuses mainly on the first and third components, while less attention is given to the in-stream hydraulics. An existing hydrologic model was used as a basis to develop a water quality model of the Blackstone River. Although the original model was calibrated to daily streamflow records, the hydraulics of the model proved to underestimate the travel time of the river. Initial attempts to calibrate the water quality model were unsuccessful since many of the parameter values governing in-stream processes were forced outside of acceptable ranges to compensate for the underestimated travel times.

In order to develop a more robust water quality model, the mainstem of the river was resegmented into a greater number of reaches such that each reach represented a uniform hydraulic profile. The resegmented model resulted in a longer travel time more representative of the actual conditions of the river. Subsequent calibration of the water quality model yielded realistic parameters values, which were within an acceptable range and similar to those used for other rivers in the region. This work illustrates the importance of developing a good hydraulic, and not just hydrologic, representation of a river as the foundation for a water quality model.

Introduction

Water quality models of rivers often include three fundamental components: inflows and pollutant loads from point sources and watershed runoff, in-stream hydraulics, and in-stream water quality processes. In many cases, model development focuses mainly on the first and third components, while less attention is given to the in-stream hydraulics. However, water quality processes (physical, chemical and biological) are closely tied to in-stream hydraulics through the travel time in the river, which is the time it takes on average for a parcel of water to travel down the river

before being discharged to a receiving water body. Rivers that have a short travel time from the headwaters to the outlet are less prone to algal blooms than rivers of similar length that flow more slowly, simply because there is less time for algae to grow. Therefore, the hydraulics of a model, which govern the travel time, are an important control on in-stream water quality processes.

In addition to travel time, simulation of water quality processes is controlled by a set of model parameters. These parameters define the rate at which each process occurs as a function of ambient conditions such as nutrient availability, light, or temperature. Most model parameters are based on some physical, chemical or biological process that can be measured directly in a controlled setting. These measurements define an acceptable range of values for each parameter. In most cases, a model is considered a credible and robust tool for making management decisions when it is an accurate representation of the processes that it is simulating. To achieve this, each parameter value should be within an acceptable range as determined from laboratory experiments or from measurements in similar systems.

During model calibration, the value of each parameter is adjusted until simulated concentrations match those measured in the field. In the case of algae, parameters that govern the growth rate are adjusted until a suitable match between the simulated and observed concentrations of algae (or chlorophyll a) is achieved. If the initial model results produce too little algae, the growth parameter may be increased until the observed concentration of algae is attained. However, since parameters are not explicitly limited to an acceptable range in most models, calibration may result in a parameter value that is outside of its acceptable range. One reason this may occur is if the travel time simulated in the model is too short. Instead of turning up the algae growth parameter, the hydraulics may need to be modified to increase the travel time of the river and allow more time for the algae to grow.

A case study from the Blackstone River in southern New England illustrates the importance of using a good hydraulic model as the basis for the development of a water quality model. Initial efforts to calibrate the dynamic water quality model were unsuccessful due to an inaccurate hydraulic representation of the river, which yielded an underestimated travel time, especially under low flows. In order to achieve an acceptable water quality calibration, the model was resegmented into shorter reaches which improved the travel time and resulted in parameter values that were within acceptable ranges.

Study Overview

The Blackstone River is 77 km (46 miles) long, and runs from Worcester, MA to Narragansett Bay in Providence, RI (Figure 1). Mean annual discharge near the

outlet of the river in Pawtucket, RI is about 24 m^3/s (850 cfs). The watershed is 1,230 km^2 (475 mi^2) in area, with about two thirds of the area in Massachusetts and the rest in Rhode Island. Land use in the watershed is primarily forested (51%) and residential (21%) (Barbaro and Zarriello, 2007).

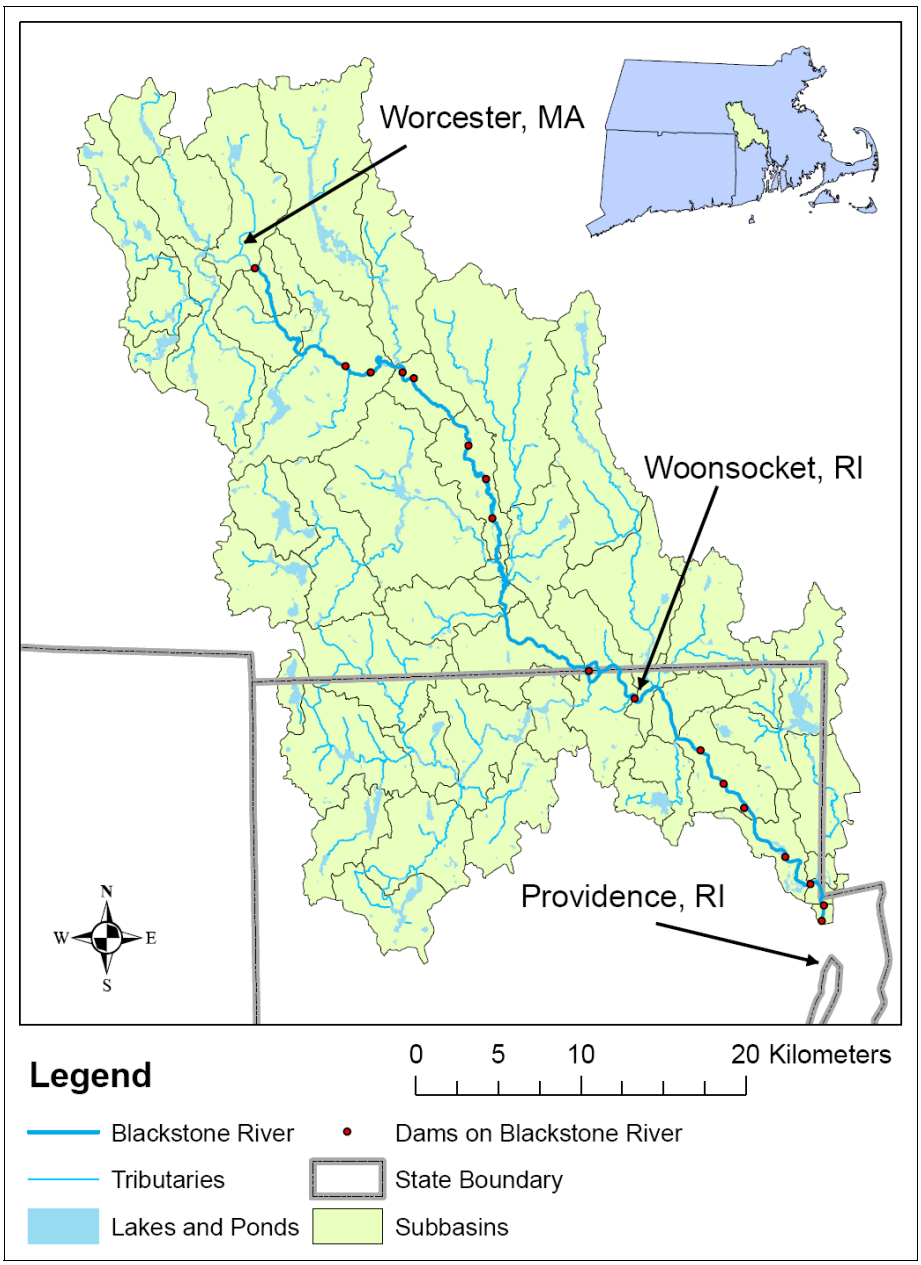

Figure 1. Map of the Blackstone River Watershed.

Throughout the 19th and 20th centuries, dams were constructed along the river to support developing industries, especially textiles. Today, there are 17 dams along the river, which create a series of impoundments from the headwaters to the river outlet. These impoundments lower the velocity of the river and are believed to have significant impacts on the water quality, such as algal blooms and resulting low dissolved oxygen levels.

In 2004, the Upper Blackstone Water Pollution Abatement District (UBWPAD) initiated the Blackstone River Water Quality Assessment to assess the impacts of watershed management strategies on in-stream water quality through a comprehensive field sampling program and the development of a dynamic water quality model. The study was focused on quantifying nutrient loads from point and non-point sources, and evaluating the impacts of various watershed management strategies to reduce nutrient loads to the river. The field sampling program and development of the water quality model were conducted by researchers at the University of Massachusetts in Amherst, MA (UMass Amherst) with technical support and project oversight provided by CDM. The focus of this paper will be on the water quality model development and calibration, for which water quality data from the field sampling program was used.

Model Development

In 2006, the United States Geologic Survey (USGS) developed a rainfall-runoff model to evaluate the impact of water management alternatives on in-stream flows in the Blackstone River (Barbaro and Zarriello, 2007). The model was developed using Hydrologic Simulation Program – FORTRAN (HSPF), which is a widely used tool that is recognized and accepted by regulatory agencies for policy-level decision guidance (Bicknell et al, 2000). This hydrologic model was used as a basis for development of the Blackstone River HSPF water quality model.

In the USGS hydrologic model, the mainstem of the Blackstone River was delineated into 14 reaches, with an additional 36 reaches representing the tributaries to the mainstem. In HSPF, each river reach is simulated as a uniform segment with constant depth, slope and cross-sectional area. Water is routed downstream from one reach to the next based on stage-discharge relationships, which reflect the in-stream hydraulics of the reach.

The original 14 mainstem reaches varied in length from 1.2 – 13.0 km (0.75 – 8.1 miles) with an average length of 5.0 km (3.1 miles). Many of the mainstem reaches included a mix of deep, slow-moving impoundments and shallow, swift riverine segments. While this discretization was suitable to meet the objectives of the hydrologic model, it underestimated the travel time along the river. Travel time is a

major factor controlling water quality processes since it determines, for example, the amount of time during which nutrients in the water are available for algal growth. To improve the travel time simulation, the model was resegmented into more reaches of shorter length such that each reach represented an approximately uniform hydraulic behavior.

An existing Hydrologic Engineering Centers River Analysis System (HEC-RAS) model was used to resegment the HSPF model. The HEC-RAS model was developed by CDM for updating Federal Emergency Management Agency (FEMA) flood plain maps of the watershed and included over 700 cross-sections along the mainstem of the river. Since this model did not include the tributaries to the Blackstone River, the HSPF model resegmentation effort focused only on the mainstem. The HEC-RAS model was used to generate a longitudinal profile of the river that showed the changes in slope and depth, which were used along with the original reach boundaries and locations of dams and tributary inflows to delineate the new reach boundaries. The new reaches were limited to a maximum length of 0.8 km (0.5 miles). Resegmentation increased the number of mainstem reaches from 14 to 110. The resegmented reaches were considered to better represent observed hydraulic variability along the river than those in the original model delineation.

Once the new reaches were defined, the HEC-RAS model was used to simulate the water surface elevations of each reach at the full range of observed flows. The results of these simulations were used to develop the relationship between depth, surface area, volume and outflow that is used for hydraulic routing in each new reach in the resegmented HSPF model. To ensure that resegmentation of the model did not disrupt the hydrologic calibration, the simulated flows of the new model were compared to those of the old model as well as the historical records at the streamflow gages. Statistical comparisons showed that the resegmented model performed slightly better than the original model, likely due to the finer resolution of the river reaches and the improved hydraulics and stage-discharge relationships.

Time of Travel Comparisons

The travel times along the river were compared between the original and resegmented models to evaluate the impact of resegmentation on the river hydraulics at the full range of flows. The greatest difference between the two models occurred at low flows, with the original model predicting a total travel time (from headwaters to outlet) of 3 days and the resegmented model predicting 30 days at the 99% exceedence flow (Figure 2). This change in total travel time was considered more realistic given the length of the river and the observed velocities at low flows. At higher flows, the difference between the two models was less significant with the

original model predicting1.3 days and the resegmented model predicting 2.1 days at the 1% exceedence flow (Figure 3).

Figure 2 shows how the model resegmentation improved the representation of impoundments and their impact on the total travel time of the river under low flows. The slope of the cumulative travel time curve between each reach boundary is related to the residence time of that reach, which is the average time that a parcel of water takes to travel through the reach. The residence time is equal to the reach length divided by the average cross-sectional velocity. Segments with greater residence times have greater slopes in the cumulative travel time curves in Figure 2 since it takes more time for a parcel of water to travel through the segment per unit distance. The steeper segments of the resegmented model curve indicate locations of impoundments, where the residence time is longer due to the restriction of flow by the impounding dam. The cumulative impact of these impoundments increases the total travel time of the river from the headwaters to the outlet. The travel time curve of the original model does not reflect these impoundments as indicated by its approximately constant slope.

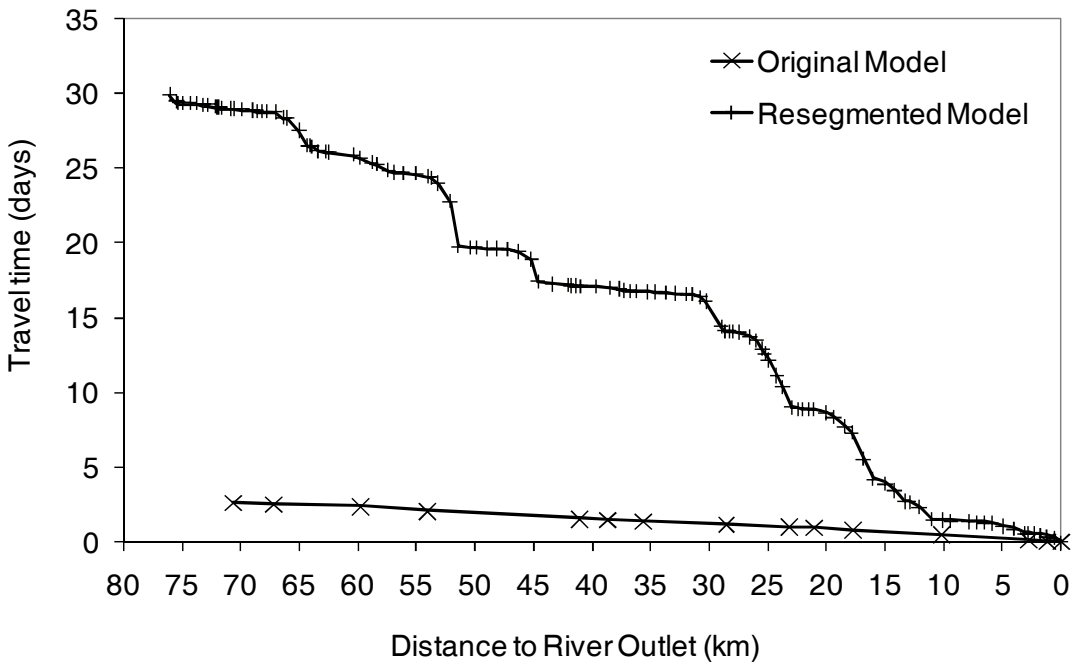

Figure 2. Travel time for original and resegmented models under the 99% exceedence flow. Markers indicate reach boundaries.

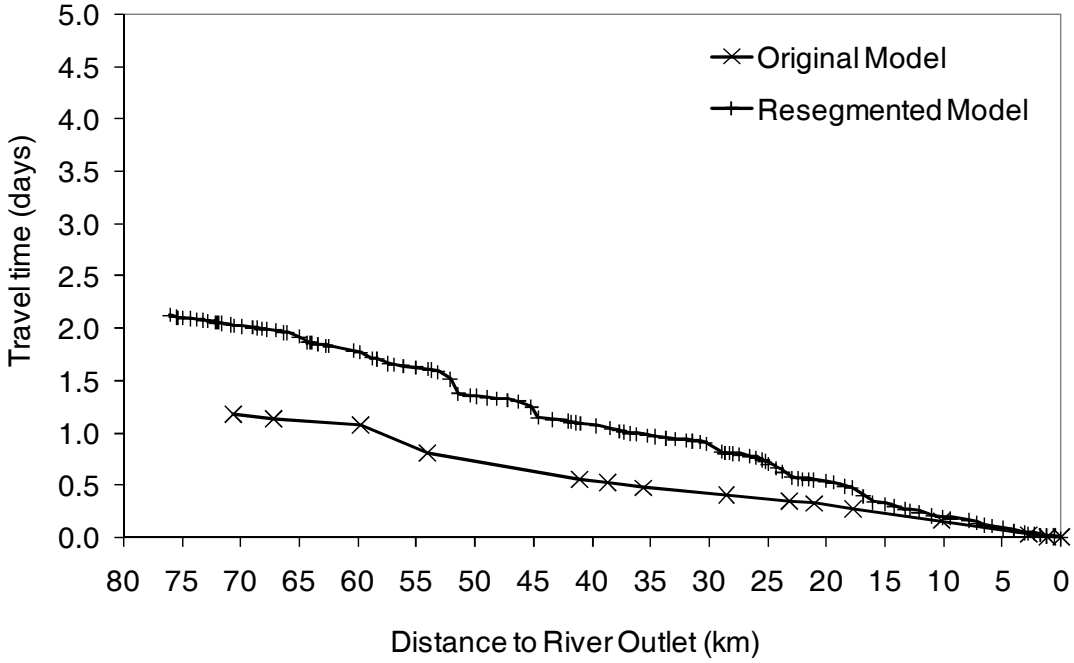

Figure 3. Travel time for original and resegmented models under the 5% exceedence flow. Markers indicate reach boundaries.

Water Quality Calibration

With the improved travel time representation in the resegmented model, the simulation of in-stream water quality processes was more reflective of the actual dynamics of the river (UMass Amherst and CDM, 2008). Prior to resegmentation, initial efforts to calibrate the water quality model required parameter values that varied by reach in order to compensate for the differences in residence time of the reaches. For example, a reach that included a large impoundment required a higher value for the algal growth rate in order to reflect the additional growth observed in that reach, which was in fact due to the increased residence time of the reach and not the biological processes inherent to algae in that reach. Many parameter values were assigned to compensate for the underestimated travel time, and as a result these parameters varied by reach in the model. In reality, most parameters, such as algal growth, do not vary along a river – algae will grow at the same rate in any reach given identical ambient conditions such as light and nutrient availability. Model resegmentation corrected this issue and allowed for the use of global parameter values for most parameters.

Some parameters, such as sediment oxygen demand (SOD), continued to be reach-variable. In reality, these processes do vary by reach since they are determined

by discharge of organic matter upstream. For example, a reach that receives discharge from a wastewater treatment facility would likely have higher SOD due to the high levels of organic matter in treated wastewater. Impoundments are also frequently observed to have higher SOD due to accumulating organic matter in the sediments behind a dam.

In addition to the implementation of global parameter values, resegmentation also resulted in parameter values that were within acceptable ranges. For example, in the initial model calibration, the maximum algal growth rate parameter varied between 1.4 – 10.1 d^{-1}. A review of multiple water quality models suggests that an acceptable range for the maximum algal growth rate is between 1 – 3 d^{-1} based on the EPA's *Rates, Constants, and Kinetics Formulations in Surface Water Quality Modeling* (Bowie et al., 1985). In the resegmented water quality model, the maximum algal growth rate was set globally to 1.9 d^{-1} in all reaches. This value is also similar to those used in models of similar systems in the region. By improving the hydraulics of the model through resegmentation, the in-stream water quality processes were considered more robust for making watershed management decisions.

Conclusions

In river water quality models, in-stream processes are dependent on both model parameter values that define the process rates as well as in-stream hydraulics and resulting travel times. Without a sound hydraulic model to serve as the basis for the water quality model, calibration can result in parameter values that must compensate for unrepresentative travel times in order to match simulated concentrations with those measured in the field. When these values exceed acceptable ranges based on laboratory measurements or experience in other systems, confidence in the accuracy of the model to represent the actual system dynamics is diminished. Development of the Blackstone River water quality model highlights the importance of using an accurate hydraulic model as the basis for developing the water quality model. Future work will include continued calibration of the water quality model and the use of tracer studies to confirm the accuracy of simulated travel times in the model.

ABSTRACT

The National Weather Service (NWS) recently began providing static inundation maps at selected river forecast points through the Advanced Hydrologic Prediction Service (AHPS) web pages. Positive feedback has motivated efforts to expand the forecast mapping program. In order to expand this mapping program efficiently and effectively, we need a more objective basis for determining where static forecast mapping is acceptable and where real-time, dynamic forecast mapping is required. With the current static forecast mapping approach, we do not have quantitative guidance specifying how far away from forecast points the maps are valid. This pre-print describes a methodology to develop this type of guidance and better understand sources of forecast mapping uncertainty. For this pre-print, we present limited results from an example case study on the Tar River, NC, comparing water surface profiles generated from steady and unsteady flow hydraulic models. Results that are more comprehensive will be presented at the conference.

INTRODUCTION

The National Weather Service (NWS) recently began providing static inundation maps at selected river forecast points through the Advanced Hydrologic Prediction Service (AHPS) web pages. The static map libraries serve the public by providing information about the approximate extent of flooding associated with river stage forecasts at pre-defined stage increments. Positive feedback has motivated efforts to expand the forecast mapping program. In order to expand this mapping program efficiently while producing accurate maps, we need a more objective basis for determining where static mapping is acceptable and where real-time, dynamic forecast mapping is required. We also need improved verification methods to assure the accuracy of forecast maps and better understanding of the associated uncertainties. Specifically, the static inundation mapping techniques currently used may have limited validity as one moves away from the forecast point where they are calibrated. We expect dynamic forecast mapping techniques to be more accurate and applicable to longer river reaches. Here, we describe a methodology to quantify the errors associated with the static forecast mapping assumptions relative to a more robust dynamic forecast mapping approach. We also plan to look at the impacts of elevation data accuracy on mapping errors. Our first study area is the Tar River, NC, where we compare water surface profiles and inundation maps generated from steady and

unsteady flow hydraulic models. Initial mapping verification efforts are focused on Hurricane Floyd, 1999, due to the availability of unique flood observations.

In this study, we use the US Army Corps of Engineers (USACE) Hydrologic Engineering Center (HEC) -River Analysis System (HEC-RAS) and the HEC-GeoRAS pre- and post-processor. HEC-RAS was used to generate the existing static map libraries and the NWS is working with HEC to include HEC-RAS as an operational forecasting tool in the next generation NWS hydrologic software referred to as the Community Hydrologic Prediction System (CHPS).

BACKGROUND

What static inundation mapping services does the NWS currently provide?

The Advanced Hydrologic Prediction Service (AHPS) currently provides inundation maps for 33 of the 4257 NWS forecast points (http://www.weather.gov/ahps/inundation.php). The AHPS maps are often based on modeling done by Federal Emergency Management Agency (FEMA) mapping contractors. Under the "Inundation Mapping" tab on the web page for a given forecast point, three data type screens are available (Figures 1a-c) for each location.

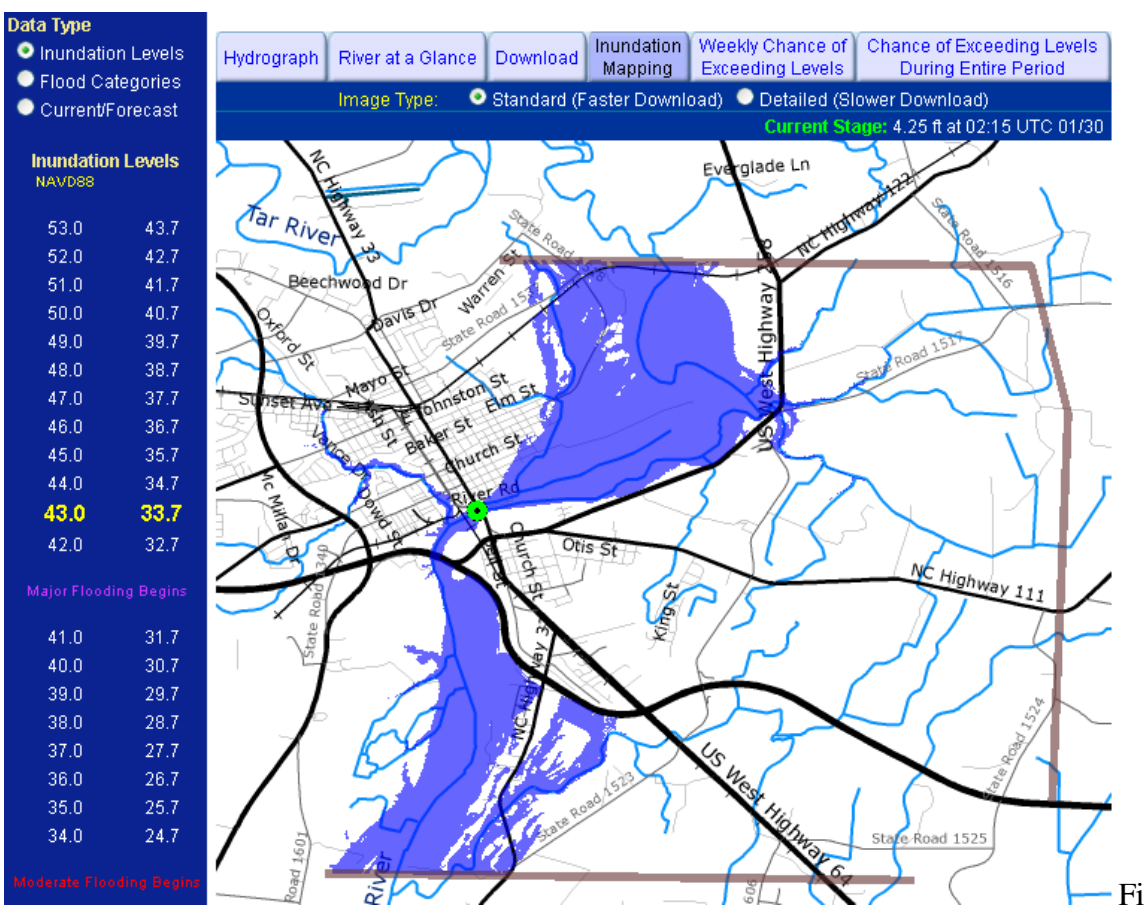

Figure 1a: Inundation levels for the Tar River at Tarboro, NC (TARN7)

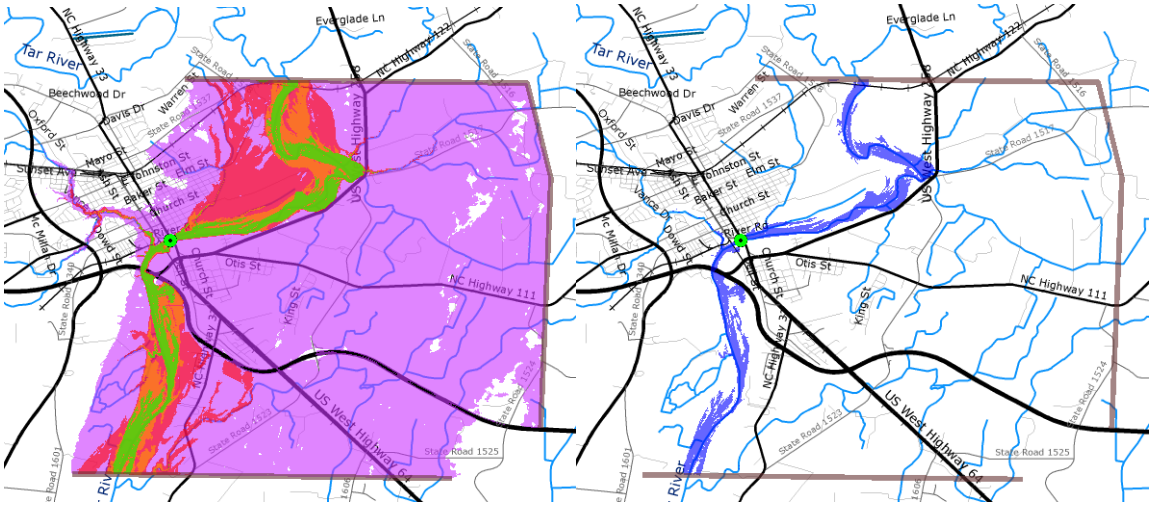

Figure 1b: Flood categories for TARN7 Figure 1c: Current/Forecast for TARN7

Figure 1. (a) The user can mouse-over different stages to see the corresponding inundation levels. (b) The NWS defines the five flood categories "Below Flood Stage" (green), "Action or Near Flood Stage" (yellow), "Minor Flood Stage" (orange), "Moderate Flood Stage" (red) and "Major Flood Stage" (purple) for each river forecast point location. "Action or Near Flood Stage" may coincide with "Minor Flood Stage" depending on each location. (c) Inundation map associated with the most recent forecast stage.

Where available, the 100-year flood, the 500-year flood and the floodway data layers from the Federal Emergency Management Agency (FEMA) can be turned on for reference. The inundation levels stored in the static map library begin at "Action or Near Flood Stage" with one foot increments and end at the historic recorded crest level. The transparency of each layer can be adjusted and basic zooming or panning features exist.

The Current/Forecast Data Type screen (Figure 1c) automatically displays the static map layer that corresponds to the current, maximum forecast stage at a gauge location. Because all of the map layers representing different inundation levels were pre-calculated and are being stored in the map library, computational requirements are minimal and the flood forecast map display changes immediately when a new stage forecast is available.

What techniques are used to create these maps?

One dimensional hydraulic models are used to create water surface profiles and GIS-based post-processors are used with digital terrain data to create inundation maps. Most of the static map libraries are created using steady-state models. Using this approach, modelers will adjust the flow until a profile with the desired stage at the forecast point of interest is reached. This ties a forecast stage to a map layer.

An alternative approach was used to create static maps for the Lower Colorado River in Texas. For the Lower Colorado, profiles corresponding to stages of interest at NWS forecast points were interpolated from profiles developed for FEMA's National Flood Insurance Program (NFIP). The input FEMA profiles correspond to design floods (e.g. 2, 5, 10, 25, 50, 100, and 500 year floods) generated using design storms, hydrologic models, and unsteady HEC-RAS models. Both steady and unsteady approaches to generate static libraries are relatively simple and can leverage data and models from FEMA's National Flood Insurance Program (NFIP).

The hydraulic models generate water surface profiles extending upstream and downstream from forecast points of interest; however, the validity of steady flow modeling diminishes with distance from a forecast point. In the case of the Lower Colorado, the pre-defined profiles generated from unsteady models may also differ from dynamically generated profiles if the real-time conditions do not match the assumed conditions in generating the profiles. The distances upstream and downstream for which these static maps are valid will vary from site to site and have not been rigorously quantified. NWS (2007) suggests only a general guideline to apply models for no more than one to two miles upstream or downstream from the forecast point.

Another limitation of static forecast mapping is that static maps will not be available for stages that exceed the historic flood.

What is dynamic inundation mapping?

Dynamic forecast mapping addresses limitations of static forecast mapping. Dynamic forecast mapping involves re-computing maps based on real-time conditions that may be different from the conditions assumed when creating the static maps. If a NWS River Forecast Center (RFC) runs an unsteady hydraulic model for forecasting, dynamically generated water surface profiles from this model can be used to generate forecast maps that are valid all along a river.

Unsteady hydraulic models, as opposed to hydrologic models, are required to create accurate stage forecasts at locations with looped rating curves (a single stage may correspond to two different flows). Channels with large flood plains and mild slopes often have looped rating curves. For points that have single valued rating curves, hydrologic models can predict flows and a rating curve can convert flows to stages. In both cases, the static maps are tied to a stage rather than a flow and therefore are valid at the forecast point. However, at locations away from the forecast point, deviations between the true water surface profile and the statically mapped profile may occur in either case due to differences in the actual flood wave from the conditions assumed when creating the static maps.

Two drawbacks of dynamic forecast mapping are an increase in the computational requirements and that more human resources are required to quality control model outputs.

METHODOLOGY

Static versus Dynamic Forecast Mapping

In this study, we compare flood maps from a static forecast mapping approach to those from a dynamic forecast mapping approach. To generate example static maps, we run a steady flow model, generate a water surface profile and create a map. We then run an unsteady model for the same reach. From the unsteady model and for the forecast point of interest, we can identify times when the simulated stage matches the stage predicted by the steady model. We output instantaneous profiles at these times, generate maps and compare these maps to those from the steady model.

We used HEC-RAS to generate water surface profiles and HEC-GeoRAS to map the extent of the flooding. HEC-GeoRAS intersects the modeled water surface with digital terrain data to determine the inundated area. HEC-RAS includes both Steady Flow and Unsteady Flow modules. The Steady Flow module computes profiles using the standard-step approach based on the Energy equation and the Unsteady Flow module solves the Saint-Venant Continuity and Momentum equations. The HEC-RAS Steady Flow module uses empirical contraction and expansion coefficients to compute energy losses at contracting and expanding sections. The Unsteady Flow module accounts for expansions and contractions only through changes in cross-sectional flow area through the Momentum equation. This approach cannot account for all the forces caused by large scale eddies that occur with expansions and contractions. Because of this, HEC-RAS Steady Flow elevations will generally be higher than Unsteady Flow results even if the same flows, model geometry, and roughness parameters are being used (Brunner, personal communication).

Here, we wish to isolate the differences between static and dynamic forecast mapping approaches. Therefore, we wish to eliminate any differences in unsteady and steady flow computational techniques. To do this, we generate steady flow results in this study by inputting constant flow time series into the HEC-RAS Unsteady module. Identical channel geometry and roughness parameters are used for both steady and unsteady runs. For the same reason, we do not use the existing maps on the AHPS web site as examples for our steady state runs. Although we are using the same underlying cross-section data, other parameters in our HEC-RAS model are different from those used to create the AHPS maps and, in the case of the North Carolina points, we are using different software to convert the water surface profiles into maps. It will be useful to compare the overall accuracy of the AHPS maps to those we create from our unsteady model but that is not our purpose here.

Study Area

We plan to study several forecast points in North Carolina where static inundation mapping services are already available. Figure 2 shows the NWS forecast locations where static maps are available. Figure 2 also shows the locations of high water marks that were collected by the US Army Corps of Engineers after Hurricane Floyd (USACE,

1999). These data will help in evaluating the quality of our mapping results. To the extent possible, we will also use post-event aerial photography obtained from the U.S. Geological Survey (USGS) Earth Resources Observation and Science (EROS) Center for qualitative verification.

For this pre-print, we present example results near Greenville, North Carolina. To do this, we use an unsteady HEC-RAS model developed for approximately 48 river miles of the Tar River from Tarboro, NC to Washington, NC (area highlighted in red on Figure 2). To build this model, we obtained the cross-section data in HEC-RAS format from the North Carolina USGS via the North Carolina Floodplain Mapping Program. The cross-sections were originally produced from a combination of Light Detection and Ranging (LIDAR) data and USGS field surveys. Moreda et al. (2009, this proceedings) describe this model in more detail, including how the unsteady flow model was calibrated. The calibration period spanned several years, July 1 1999 through August 31 2005. Observed stage data at four observation stations were used in calibration. In the example presented here, we focus on the USGS Station near Greenville, NC and on the flood peak generated during Hurricane Floyd (September, 1999).

The initial HEC-RAS model we obtained was not geo-referenced. To correct this, we imported a geo-referenced river centerline into HEC-RAS to replace the existing straight centerline. In this process, HEC-RAS geo-references all cross sections starting from the upstream boundary following the new river centerline downstream and assuming that all cross sections were originally cut at 90 degree angles. The distance between the cross sections is based on the distances (river miles) entered in the hydraulic model.

NED versus LIDAR Data

Two sources of digital terrain data are available for the Tar River study area. The USGS National Elevation Dataset (NED) is readily available for the whole country and relatively easy to process on a personal computer; however, the data accuracy may be inadequate for flood mapping in some areas (http://ned.usgs.gov/). LIDAR data are more accurate and more precise than the NED data but are not available for the whole country. LIDAR data used in this study are available from the North Carolina Floodplain Mapping Program. We will create inundation maps using both sources of elevation data in this study and compare the results. This will give us some idea as to the importance of collecting more accurate elevation data relative to developing a dynamic forecast mapping capability with the existing lower accuracy data. Another factor to consider is that with the HEC-GeoRAS software, the processing of each map is much more computationally expensive when the LIDAR data are used. This may be alleviated with more efficient mapping algorithms or conversion of the raster LIDAR data into a Triangulated Irregular Network (TIN) format.

RESULTS AND DISCUSSION

Figure 3 shows a simulated rating curve from the unsteady HEC-RAS model at Greenville, NC. This curve was built from hourly simulations spanning July 1, 1999 to

August 31, 2001. The looped section of the curve is comprised of data from the Hurricane Floyd event. At a river stage of 20 ft, the flow can be approximately 36,400 cfs while the flood is rising but 8,000 cfs lower when the flood is falling. Clearly, the flood profile is dynamically changing during the event at moderate to high flood levels. At Greenville, flooding begins at 12 ft, moderate flooding begins at 16 ft, and major flooding begins at 18ft.

During Hurricane Floyd, our calibrated unsteady model simulates the peak stage at Greenville to be 25.9 ft (on September 22, 1999 at 0500z) while the observed stage is 25.8 ft. At this time, the simulated flow from the unsteady model is 65,809 cfs. To emulate the static forecast mapping approach, we used trial and error to identify a constant flow input so that the steady flow model predicts the same stage as the unsteady model. The flow required to produce a matching stage was 64,108 cfs.

We repeated this procedure for a smaller flood peak that occurred on October 25, 1999 at 0900z. For this event, the unsteady model simulated peak was 12.8 ft and the observed stage was 13.1 ft. The simulated flow from the unsteady model was 16,816 cfs at this time. A constant flow of 18,329 cfs was applied in the steady state model to generate a matching stage.

For both of these events, we are interested in the difference between the steady and unsteady water surface profiles as one moves away from the Greenville gauge. Figure 4 shows the water surface profiles predicted for approximately a six mile stretch of river centered on Greenville for the September (3a) and October (3b) events. Note that the unsteady profiles are instantaneous profiles predicted at the peak of the flood. Figure 4a shows that the water surface profiles corresponding to the September peak stage are very similar. This may be because the flood was so large that storage areas that would normally be filled with a steady model but not with an unsteady model are filled up in the unsteady model. The fact that the rating curve (Figure 3) is not looped for the highest stages supports this hypothesis. We would expect greater differences in the profiles if these instantaneous profiles were selected during the rising or falling limbs of the hydrograph.

Figure 4b shows that steady and unsteady water surface profiles differ more for the smaller October event. Here, the unsteady result is also the instantaneous profile at the event peak. In this case, the static forecast mapping approach produces errors up to 0.33 ft for distances within 3 miles of the forecast point and up to 0.25 ft for distances within 2 miles.

Due to last minute changes in our methodology, we were unable to create and compare the inundation maps corresponding to the profiles in Figure 4 for this paper. For this reason, we also do not present our verification results using the high water mark data and aerial photography data at this time. These maps and more results will be presented at the conference. To develop a robust set of results, we plan to create and quantitatively compare similar maps at several forecast points and for several stages.

PERFORMANCE EVALUATION OF ARTICULATED CONTRETE MATTING (ACM) SPILLWAY AT LAKE ODESSA, IOWA

Thomas Gambucci[1]

[1] P.E., D.WRE., Hydraulics Engineer, Regional Technical Specialist MVD - Navigation and Flood Control, U.S. Army Corps of Engineers, Rock Island District, Clock Tower Building, P.O. Box 2004, Rock Island, IL 61204, (309) 794-5848, thomas.r.gambucci@usace.army.mil

ABSTRACT

Use of Articulated Concrete Matting (ACM) for overflow spillways has great ability to resist high overflow velocities, yet use of ACM for this purpose is rare at the Corps of Engineers. This presentation draws attention to the importance of ACM spillway design to the HH&C community and how it performed at Lake Odessa, Iowa during the Flood of 2008.

Many Environmental Management Projects are protected from flooding by perimeter levees. Typically these levees offer 10-year or 25-year protection and are frequently overtopped causing major damage to levees that can be very expensive to repair following each flood. Levee breaches may also produce adverse impacts on the ecosystems that they are intended to protect. The addition of spillways on perimeter levees can drastically reduce or eliminate overtopping damage to levees. From experience in the Rock Island District, head differences of less than one foot between the exterior and interior water levels will result in insignificant levee damage during overtopping events. A simple but effective spreadsheet technique was used to size the spillways according to this design assumption. The final spillway design made use of articulated concrete matting (ACM) to resist anticipated shear forces versus the more conventional techniques of riprap or concrete spillways. Construction of the spillway was completed in the winter of 2006 by the Corps of Engineers, making the Lake Odessa spillway the first substantial ACM spillway project by the Corps of Engineers. The flood of 2008 overtopped the ACM spillway twice allowing Rock Island District and Resource Agency personnel to monitor water levels. This paper evaluates the performance of the ACM spillway at Lake Odessa and presents lessons learned from the Flood of 2008.

BACKGROUND

The Lake Odessa Wildlife Refuge is located on the Iowa side of the Mississippi River between River Miles (RM) 434.5 and 441.5. It is surrounded by a perimeter levee approximately 8 miles long that was originally built in 1913 by local farmers for flood protection of agricultural land. The levee was enhanced in 1954 including two water control structures for low level water management. Both the inlet and outlet structures were rebuilt following damages sustained by the Flood of 1993. Spillways were added to the project in 2004 and 2006 to allow flood water to fill the interior prior to uncontrolled overtopping of the perimeter levee. Lock and Dam 17 is located at RM 437.1 and ties into the perimeter levee at approximately its mid-point. The Iowa River enters the Mississippi River at RM 434.5, which is just downstream of the refuge. See Figure 1 for an overview of project features.

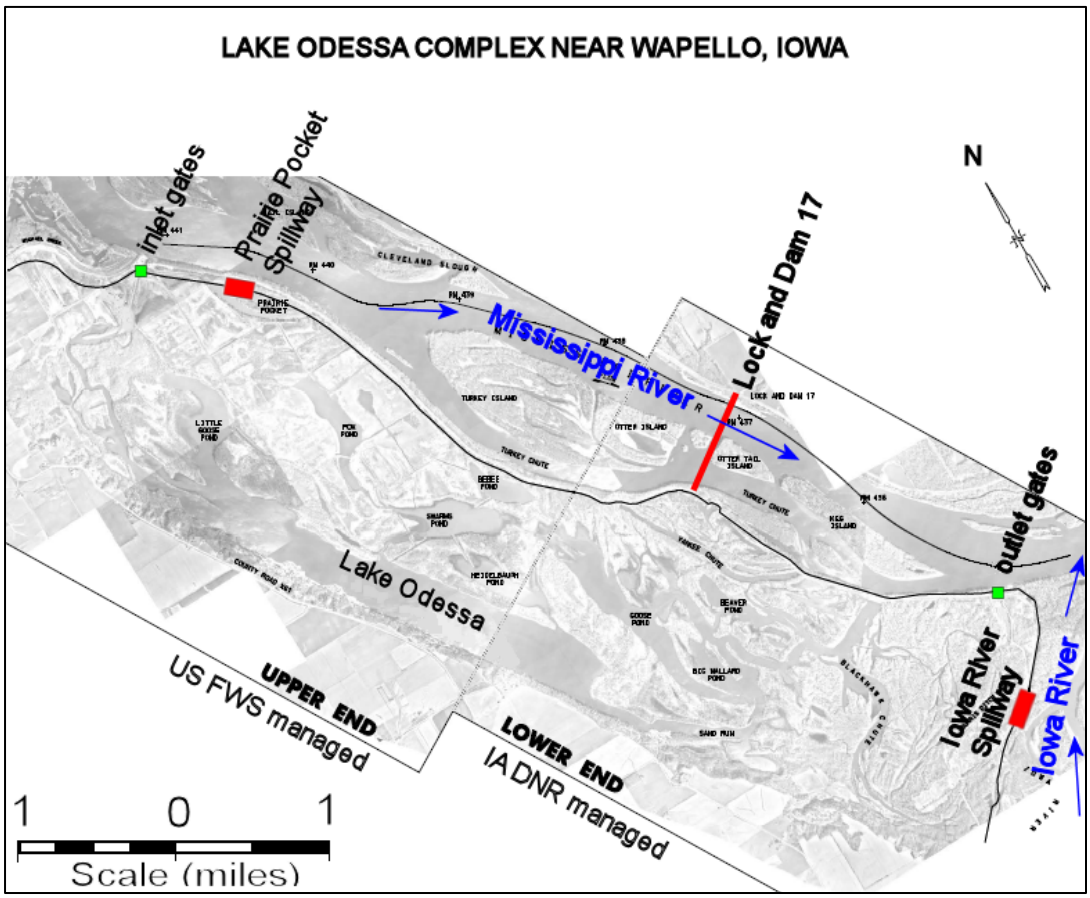

Figure 1. Lake Odessa EMP, Project Overview Map

MANAGEMENT

The U.S. Fish and Wildlife Service (USFWS) manages the levee upstream of RM 438, while the Iowa Department of Natural Resources (IDNR) manages the downstream portion of the levee. Management of the interior is similarly divided by the two agencies. The northern portion of the Lake Odessa complex is part of the U.S. Fish and Wildlife Service (USFWS) Mark Twain National Wildlife Refuge Complex, Port Louisa National Wildlife Refuge, Louisa Division. The Iowa Department of Natural Resources (IDNR) through a cooperative agreement with the USFWS manages the southern portion of the area, the Lake Odessa State Wildlife Management Area. The project area is comprised of a large lake (Lake Odessa), several other backwater bodies of water, wooded land, and open fields, and many archeological sites (DPR 2005).

During non-flood conditions, water enters the refuge through the northern inlet structure in Pool 17, flows through Lake Odessa, and exits through the outlet structure downstream of Lock and Dam 17. During rising waters, these gates are normally closed off to keep the interior at desired water levels; however, when a flood is forecasted, the gates are opened according to an operation plan (DPR 2005, Appendix I Section J) to help fill the interior prior to uncontrolled overtopping of the dam. Based on experience from the Flood of 2008, the gate operation plan has been revised.

SPILLWAY DESIGN

From experience at the Rock Island District, head differences across levees of less than one foot between the exterior and interior water levels result in insignificant or no levee damage. A simple but effective spreadsheet technique was used to size the spillways in order to meet this design assumption. The rate of rise of the Mississippi was chosen to be 0.75 ft per day in the elevation band from the crest of the spillway to the crest of the perimeter levee. This value is very close to the rate of rise experience in the Flood of 1993, but is slower than the rate of rise in both 2001 and 2008 (approx. 1.0 ft/day). The higher rate of rise fills the interior approximately 12 hours faster than the design rate of rise; both rates meet the design criteria of less than one foot of head differential at the time of uncontrolled overtopping. Figure 2 shows the response of interior water levels due to spillway overtopping for various design assumptions.

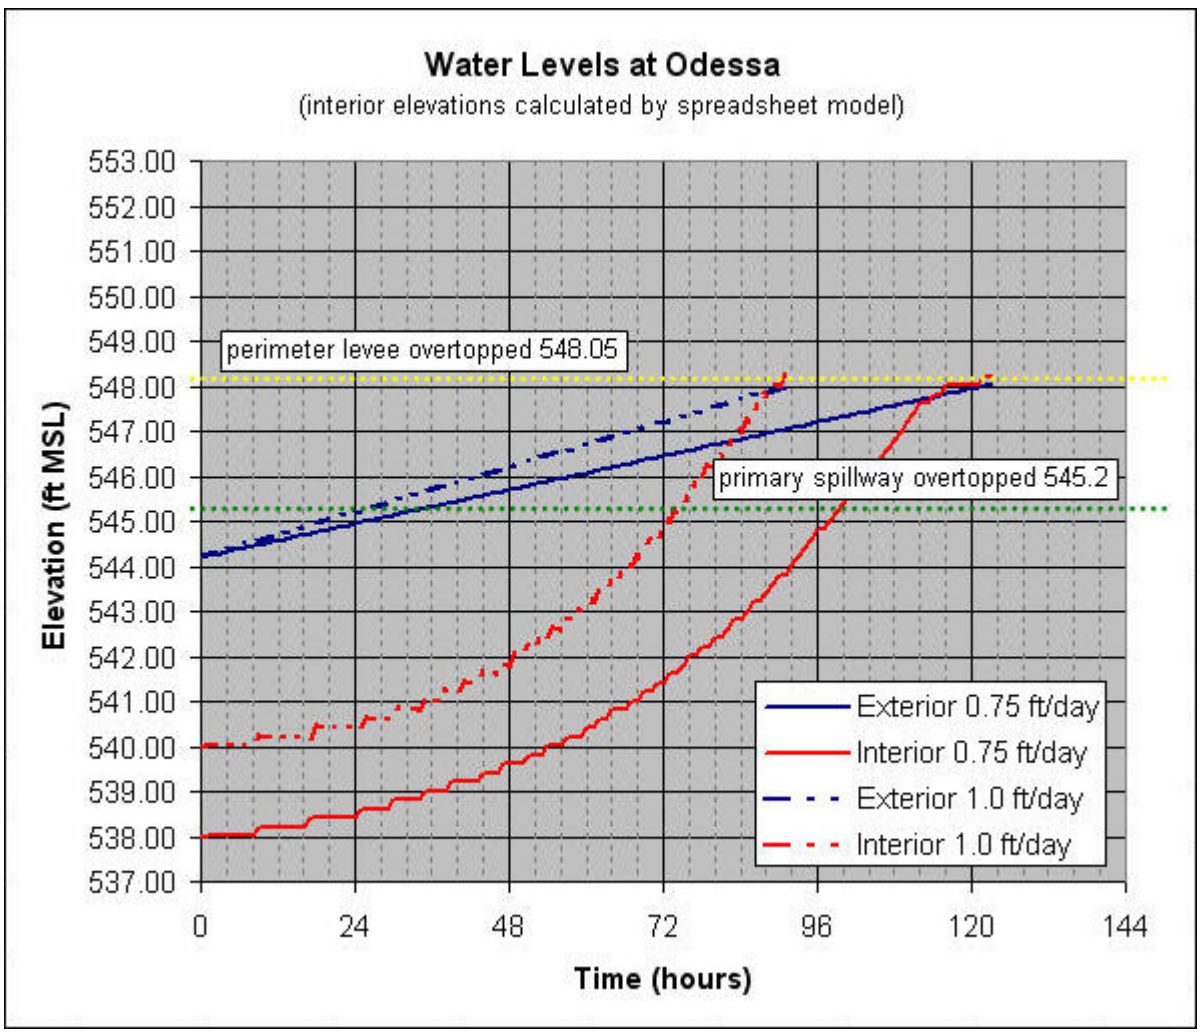

Figure 2. Interior Water Level Response for Final Spillway Design

Final spillway parameters from the analysis are a 1,100-foot long spillway at the downstream end (RM 434.8, the Iowa River Spillway) and a 700-foot long spillway at the upstream location (RM 440.4, the Prairie Pocket Spillway) of the perimeter levee. Crest elevations are 545.2 ft (1912 datum) for the downstream spillway and 545.8 ft (1912 datum) for the upstream spillway. These crest elevations have an estimated risk of overtopping per year of 10% for the downstream spillway (overtops first) and 6% for the upstream spillway. The annual risk of overtopping the perimeter levee is 4% at the downstream location and 2% at the upper end; this sloping (frequency) of the levee is designed to reduce damages by filling of the interior from the lower end. Frequencies are based on the 2003 Mississippi River Flow Frequency study.

An analysis of historical flooding was made in 2003 with the spillway design to investigate if flooding on the Iowa River could overtop the lower spillway without a flood occurring on the Mississippi River. Large flows on the Iowa River typically happen when the Mississippi River stages are also high, but "if the Mississippi River stage were normal, and a very large flood occurred on the Iowa River, there would be adequate flood storage available at the mouth of the Iowa River to reduce flood peaks and avoid overtopping the 545.2 feet (1912 datum) lower spillway crest." (DPR Appendix I) After the historical analysis and DPR were complete, the proposed location of the "lower spillway" was changed from a location near the confluence of the Mississippi River and Iowa River to a location approximately a half mile upstream on the Iowa River tieback levee. This new location was necessary because of archaeological concerns since the old location was located in an area formerly known as Burris City. The new location was adopted but the design crest of the spillway was kept the same due to lack of information about the influence of the Mississippi River upon the water surface slope of the Iowa River.

ARTICULATED CONCRETE MATTING (ACM) SPILLWAY

The spillway design made use of Articulated Concrete Matting (ACM) due to its ability to handle expected shear stresses, its cost relative to traditional (riprap) spillways, and its environmental appeal (it allows vegetation to grow through the matting). The original design head of 7 ft made riprap size too large without special handling and expense; however, smaller riprap was used on the exterior slope to handle outflow from Lake Odessa during flood recession. Construction was completed in the spring of 2007 (Figure 3), making the Iowa River Spillway at Lake Odessa the first substantial ACM spillway for the Corps of Engineers.

The upstream ACM spillway was completed by the USFWS in the winter of 2005 (Figure 4) to assist in filling the interior. It also allows a portion of the Mississippi River to flow through the Lake Odessa Complex during times of flood. This flow establishes a sloped water surface through the interior that reduces head differential (and thus erosion potential) across the levee crest in the upstream-most areas of the perimeter levee.

Figure 4. Prairie Pocket Spillway, 700-ft long, crest 545.8 ft, River Mile 440.4

THE FLOOD OF 2008

The Flood of 2008 overtopped the Iowa River Spillway on April 27 (Figure 5) and on June 12. As can be seen on Figure 5, the levee adjacent to the spillway is unvegetated and was recently under construction. This was not uncommon elsewhere on the perimeter levee and some areas were lower than design grade. Multiple areas of erosion to the crown of the perimeter levee occurred during the flood, as well as three larger blowouts.

Figure 5. Iowa River Spillway overtopping on April 27, 2008, River Mile 440.4

Prior to the Flood of 2008, a staff gage was established on the interior to monitor rising water levels. The spillway functioned as expected to raise interior water levels according to design; however, due to ongoing levee repair efforts the spillway did not have the full design time (three days) to fill the interior prior to uncontrolled overtopping of the perimeter levee. The low spots in the levee started overtopping two days after the ACM spillway started filling the interior. This led to a greater than 1 ft head difference and erosive forces for more than 24 hours. It is assumed that most of the breaches started forming on April 29, 2008.

Surveys were performed on April 23 and on June 6 to capture the slope of the Iowa River at both a high and low tailwater (Mississippi River) condition near the time of overtopping of the primary ACM spillway (Iowa River Spillway). This data was later used to update the gate operation plan and to modify the design crest of the tieback levee. Survey points are shown in Figure 6 along with levee profiles and a computed historic profile from 1993.

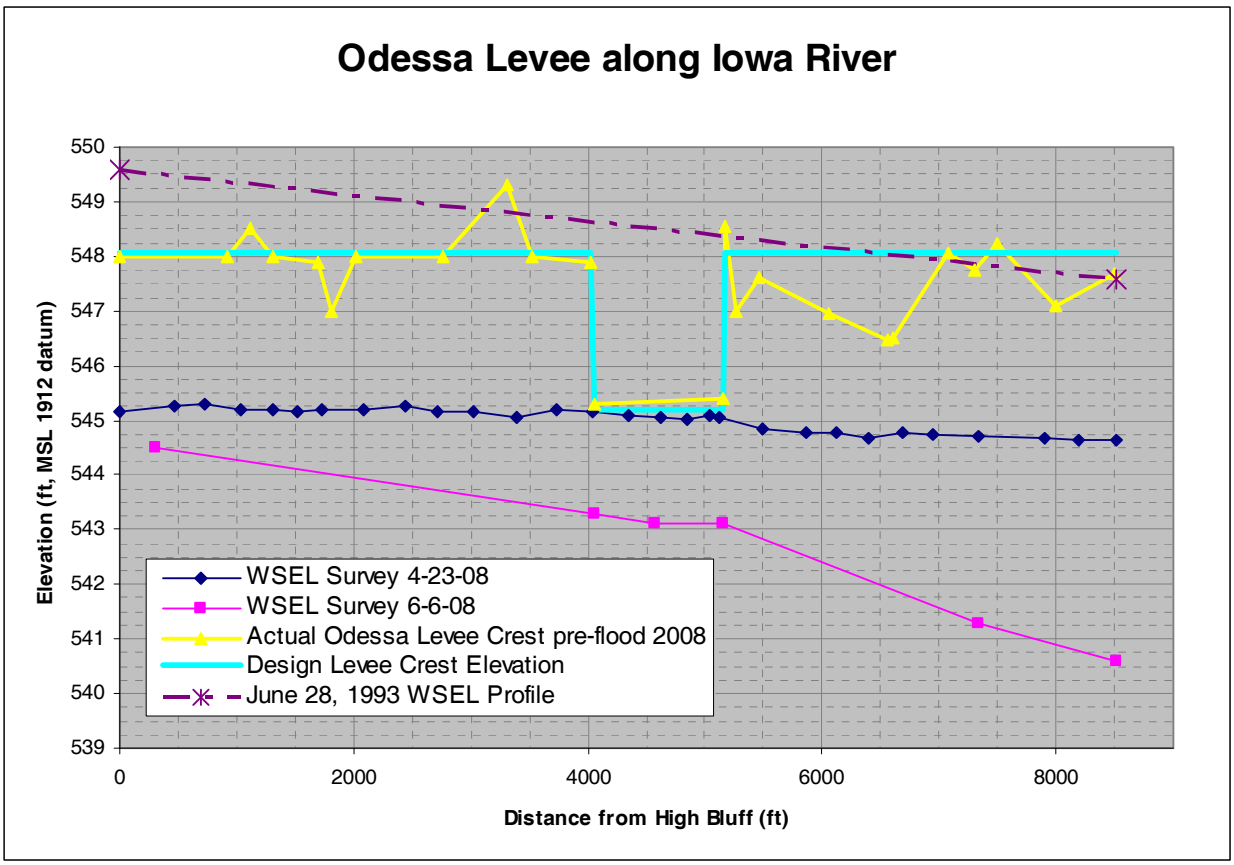

Figure 6. Water Surface and Levee Profiles along the Iowa River Tieback Levee, Lake Odessa

Station "0" in Figure 6 represents the "high bluff" and Station "8000" is near the levee bend where the Iowa River joins the Mississippi River. Based on this survey data, the spillway overtops at a Lock and Dam 17 tailwater stage of 18.5 ft.

Due to the water slope along the Iowa River, the levee at the high bluff is recommended to be raised to elevation 549.5 ft and sloped down to 548.5 ft at the spillway. Sloping the levee in this fashion will help reduce uncontrolled overtopping near the high bluff.
Both ACM spillways functioned well and were not damaged during the Flood of 2008. The Iowa River Spillway did not have vegetation established and the soil was pulled out of the void spaces (See Figure 7). Soil will need to be replaced and seeded in 2009. The extended apron on the spillway is meant to be used as a roadway, and the spaces were filled with crushed stone. This stone was washed out of the spaces during the Flood of 20008 and it is now recommended to replace the stone with vegetated soil. Figure 7 shows the Iowa River Spillway after the first hydrograph peak of the Flood of 2008.

Figure 7. Iowa River Spillway following the Flood of 2008, Lake Odessa

PRIMARY RESULTS

The Articulated Concrete Matting (ACM) spillways at the Lake Odessa Complex performed well during the Flood of 2008. There was no damage to the spillways during the two overtopping events and the size of the Iowa River Spillway allowed interior water levels to rise at the expected rate. The damages that occurred to the perimeter levee in 2008 were located in areas containing unvegetated sand and in areas that were below design grade (or under construction) prior to the flood. ACM should be considered a dependable choice for medium-sized spillways (5-10 ft of head) where the size of traditional riprap design might become prohibitively costly.

While levee damages due to the Flood of 2008 have not yet been calculated, it is assumed that the presence of spillways at the Lake Odessa Complex helped reduce levee damages. During the Flood of 2001, the spillways did not exist and the gated structures could not adequately raise interior water levels prior to overtopping. This gave a much greater head difference at the time of uncontrolled levee overtopping. All of the breaches in 2001 were large levee blowouts that were expensive to repair; most of the breaches in 2008 were small breaches or minor crown erosion. It is expected that damages will be reduced or eliminated after the Lake Odessa perimeter levee is repaired to its design grade and has a well vegetated clay cap along its length.

Abstract

This study will develop a computational framework capable of rapidly classifying microbial surface water quality for the protection of public health. Three classification tools will be developed using multivariate linear regression (MLR), artificial neural networks (ANN), and linear vector quantization (LVQ). The MLR and ANN approaches first quantify the microbial concentration followed by classification, while the LVQ approach directly classifies the water quality. The algorithms will be applied to microbial and hydrologic data associated with the Charles River Basin using antecedent rainfall over the previous 24 and 168-hrs and lag-1 fecal coliform concentrations as explanatory variables. Preliminary results with the MLR algorithm illustrate very good classification when the observed data is below the appropriate water quality standard (true negative rates $> 95\%$). Unfortunately, the MLR classification approach does not perform as well when the observed data is greater than the standard (true positive rates $\sim 50\%$). Additional studies will be focused on evaluating the architecture and performance of both the ANN and LVQ approaches for classifying the microbial water quality, and the best performing algorithm identified.

1 Introduction

The use of recreational surface waters can pose a public health risk due to elevated pathogens from various point and non-point sources. For over a century, bacterial indicator organisms have been used in the USA to assess the presence of pathogenic organisms in drinking and recreational waters (NRC, 2000). Unfortunately, laboratory analysis of water quality samples, which typically require at least 24 hrs after sampling to provide microbial quantification, eliminates the possibility of providing a rapid response to alert the populous of any potential public health risk.

Data-driven modeling approaches (e.g., linear regression and artificial neural networks) have been developed to provide rapid predictions of microbial quantity. Previous studies (Christensen, Jian, and Ziegler, Christensen et al.; Eleria, 2002;

Eleria and Vogel, 2005; Ferguson et al., 2003) have developed multiple linear regression models to relate bacteria concentrations to explanatory variables for streams and estuaries. Neelakantan et al. (2001) developed an ANN tool to relate peak Cryptosporidium and Giardia concentrations with the other biological, chemical and physical parameters in the surface water. Mas and Ahfeld (2007) compared the performance of ordinary least squares, binary logistic regression methods, and artificial neural networks for the prediction of surface water faecal coliform concentrations in a mixed land-use watershed. These model-based approaches predict the microbial concentrations, which are then used to assign a warning level or classification based on the predicted concentration. Unfortunately, these approaches tend to suffer from high false-negative rates due to uncertainties in predicting high microbial concentrations.

The objective of this study is to develop a forecasting tool based on a neural approach called linear vector quantization (LVQ). LVQ is a class of self-organizing map that seeks to cluster similar sets of explanatory variables based on their desired classification. The advantage of the LVQ approach is that the output of the algorithm is a classification, rather than a concentration, thus potentially removing the uncertainties associated with the prediction step. The performance of the LVQ classification approach will be compared with those based on linear regression and ANN models. The comparison will be performed using the same data and explanatory variables as the model proposed by Eleria and Vogel (2005).

2 Methodology

2.1 *Study Area*

The Charles River Basin, the final nine-mile stretch of river from Watertown Dam to New Charles River Dam in Boston, Massachusetts encompasses a watershed of 36.1 square miles with a population of 500,000. It is one of the most heavily used recreational areas in the country (Eleria, 2002). Even though proper measures were taken by controlling the flows from combined sewer overflows, the public may still be exposed to risk due to pathogens entering the water after hydrologic events (e.g., after a storm) via combined sewer overflows, which is mostly untreated waste, and run-off, which consists of various wastes from impervious surfaces.

Eleria (2002) proposed models for the four flagging monitoring sites (North Beacon Street Bridge in Brighton, Larz Anderson Bridge in Cambridge, Boston University Bridge in Boston, and Longfellow Bridge in Boston) on the Charles River using different combinations of meterological and hydrological explanatory variables. The model developed in this paper is with respect to the Larz Anderson Bridge site.

2.2 *Data Source*

The fecal coliform data (log transformed) and the explanatory variables of antecedent rainfall during the previous 24and 168 hrs, and lag-1 bacteria concentra-

tions are the same as mentioned in Eleria and Vogel (2005). Further information associated with data sources and exploratory analysis can be found in Eleria and Vogel (2005). The original dataset contains 142 samples collected from mid-June through mid-October of 2000-2001. Because bacterial data were not collected every day, the final data set using the lag-1 bacteria concentrations was reduced to 78 samples.

2.3 *Data Classification*

According to the Massachusetts surface water quality standards, fecal coliform bacteria are used as a measure to classify recreational water quality (314 CMR 4.00, 2007). The Charles River is classified as a Class B Warm Water designated as a habitat for fish, other aquatic life and wildlife, and suitable for primary contact recreation, such as swimming, fishing and windsurfing, and secondary contact recreation, such as canoeing, boating etc. For primary contact recreation the geometric mean of fecal coliform bacteria concentration should not be more than 200 colony-forming units (cfu) per 100-mL of the sample. In any case, no more than 10 percent of the samples should exceed 400 cfu/100-mL. For secondary contact recreation, the geometric mean of the fecal coliform bacteria concentration should not be more than 1000 cfu/100-mL and, in any case, no more than 10 percent of the samples should exceed 2000 cfu/100-ml.

2.4 *Multivariate Linear Regression*

2.4.1 *Experimental Design*

The regression coefficients are estimated using the entire data set. The overall performance of the model is evaluated using the mean square error (MSE) and precision in classifying the water quality. The precision is considered using the true negative (TN), true positive (TP), false negative (FN), and false positive (FP) rates. The MATLAB Statistical Toolbox, Version 6, is used to estimate the model coefficients.

2.5 *Artificial Neural Networks – Backpropagation*

2.5.1 *Introduction*

ANN, also referred to as Neural Networks, are a class of computational tools that mimic biological processes of the brain. A neural net consists of a large number of simple processing elements called neurons, units, cells or nodes. Each neuron is connected to other neurons by means of directed communication links, each with an associated weight. The weights represent information being used by the net to solve a problem. Neural nets can be applied to a wide variety of problems, such as storing and recalling data or patterns, classifying patterns, performing general mappings from input patterns to output patterns, grouping similar patterns, or finding solutions to constrained optimization problems. Each neuron has an internal state, called its activation or activity level, which is a function of the inputs received. Typically, a neuron sends an activation signal to

several other neurons. While a neuron can send only one signal at a time, that signal may be broadcast to several other neurons. This leads to neuron layers associated with the inputs and outputs, as well as hidden layers between the two for transforming the input data into the appropriate outputs. The presence of a hidden unit, together with a non linear activation function, gives it the ability to solve more problems that can be solved by a net with only input and output units. On the other hand, it is more difficult to train (i.e., find optimal values for the weights) a net with hidden units. Haykin (1998) can be referred to for a detailed discussion of ANN.

2.5.2 *Experimental Design*

A multi-layer, feed forward network consisting of one input layer, one hidden layer and one output layer was used. The number of nodes in the input layer is fixed by the number of model inputs (i.e three), whereas the number of nodes in the output layer equals the number of model outputs (i.e one). The Tan sigmoidal and linear transfer functions are used in the hidden and output layers. Since there is no accepted rule for the selection of the number of hidden nodes, the number of hidden neurons is decided by simulation experiments. For a range of hidden neurons (3 - 8), ANN models were developed using the leave-one-out method suggested by Haykin (1998). Out of the 78 data samples, one sample is withheld to be used for validation and the ANN weight estimated. Thus, 78 models can be developed for each number of hidden neurons to be evaluated. The range of hidden neurons to be investigated is based on a rule of thumb associated with the number of training samples to the number of connection weights (Masters, 1993). Ultimately, the number of required neurons in the hidden layer are determined based on the overall performance of all models with respect to a particular number of neurons. The MATLAB Neural Network Toolbox, Version 5.0.2 was used to design and implement the network.

2.5.3 *Training*

In this study, the Levenberg-Marquardt optimization method with mean square error as the performance function with a maximum of 1000 epochs is used during training. Prior to training, network interconnections were assigned random initial weights. A technique called early stopping was used during model training to avoid overfitting and subsequent poor generalization (Demuth et al., 2007).

2.6 *Linear Vector Quantization*

LVQ is a pattern classification method in which each output unit represents a particular class or category (several output units should be used for each class). The network contains an input layer, single Kohonen/competitive layer and an output layer. The output layer has many processing elements to translate the information for the competitive layer into the appropriate class. For each class there are a number of grouped processing elements in the Kohonen layer, which learns and classifies with the help of a training set (i.e., supervised learning).

Whenever an input vector is submitted to the network, the euclidian distance from each of the processing elements in the Kohonen layer is determined, and the nearest processing element declared the winner; there will be only one winner for the layer and this element will be "fired." If the wining element is in the expected training class then the weights are modified to draw near to the training vector. If the winning element is not in the expected class, then weights are updated to move away from the training vector. The process is repeated that, in turn, generates one output signifying a particular class found by the network.

2.6.1 *Experimental Design*

As mentioned in the previous section, the LVQ network has a first competitive layer and a second linear layer. The competitive layer learns to classify input vectors in much the same way as the competitive layers of Self-Organizing Maps (Demuth et al., 2007). The linear layer transforms the competitive layer classes into target classifications defined by the user. The number of nodes in the competitive layer plays an important role in classification, and is determined through simulation experiments. A range of neurons (10 - 40) is evaluated and the appropriate number of neurons determined by evaluating the performance based on the error in classification. The MATLAB Neural Network Toolbox, Version 5.0.2 was used to design and implement the network.

2.6.2 *Training*

A target class (1 for not violating a standard and 2 for violating a standard) is predefined for all the input pairs based on the fecal coliform swimming standard (200 cfu/100-mL). Then the network is trained using the LVQ training rule (Demuth et al., 2007). After training, the LVQ net classifies an input vector by assigning it to the same class as the output unit that has the weight vector (reference vector) closest to the input vector. A similar process is repeated for the boating standard (1000 cfu/100-mL). The entire dataset is used for testing to evaluate the ability of the LVQ algorithm to generalize the data set.

3 Results and Discussion

3.1 *Multivariate Linear Regression*

The explanatory variables used are the antecedent rainfall (24 hrs and 168 hrs) and lag-1 fecal coliform bacteria concentrations (log transformed). *Figure 1* illustrates the observed and predicted microbial data from the linear regression model. The regression model has an MSE of 0.2301 and explains 56 percent of the variability in fecal coliform concentration. The performance of the model with respect to both standards is presented in *Table 1* and *Table 2*. Overall, the model performance in classifying water quality with respect to the boating standard (1000 cfu/100-mL) is similar to that of the swimming standard (200 cfu/100-mL). Both standards are correctly identified in over 90% of the samples (TP rates of 94.6% and 98.6% for the 200 and 1000 cfu/100-mL standards, respectively). However, the regression

model has approximately a 50/50 chance of correctly classifying conditions that exceed the standard (TN rates of 54.5% and 50.0% for the 200 and 1000 cfu/100-mL standards, respectively). From Figure 1, the performance of the regression model at low concentrations (approximately 100 cfu/100-mL) is not satisfactory, although the data are generally not misclassified.

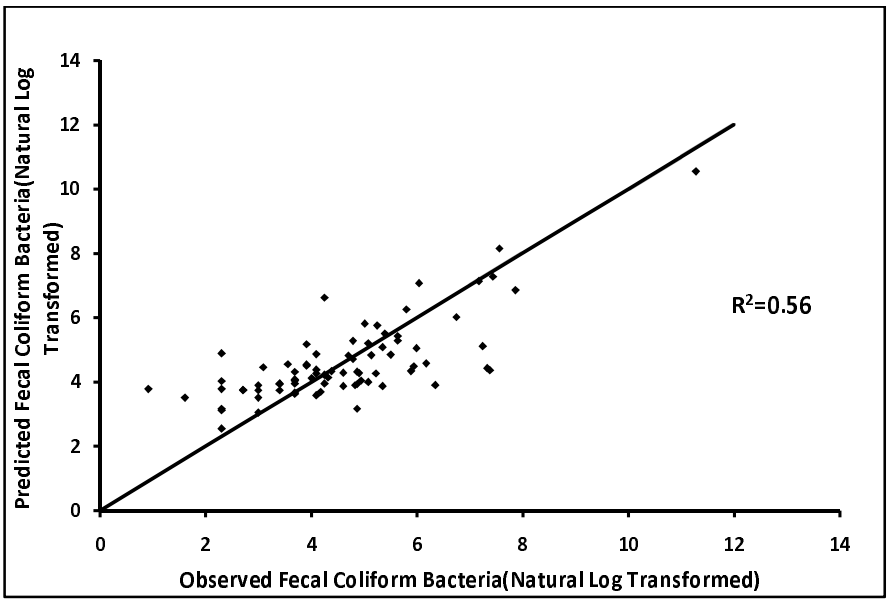

Figure 1: Observed Versus Predicted Fecal Coliform Bacteria Concentrations at Larz Anderson Bridge

Table 1: MLR Model Results (Swimming Standard) - Number of Observations Versus Number of Predictions

		Observed	
		Met Swimming Standard	**Exceeded Swimming Standard**
Predictions	**Met Swimming Standard**	94.64(53)	54.55(12)
	Exceeded Swimming Standard	5.36(3)	45.45(10)

Table 2: MLR Model Results (Boating Standard) - Number of Observations Versus Number of Predictions

		Observed	
		Met Swimming Standard	**Exceeded Swimming Standard**
Predictions	**Met Swimming Standard**	98.57(69)	50(4)
	Exceeded Swimming Standard	1.43(1)	50(4)

4 Summary and Future Work

The present study is intended to develop a tool to classify the recreational water quality in the Charles River Basin using Linear Vector Quantization (LVQ). The performance of the LVQ approach will be compared with the results from multivariate linear regression and artificial neural networks. Bacterial predictions are made using three explanatory variables, antecedent rainfall data from the previous 24 and 168 hrs, and lag-1 bacteria data. The entire data set is used for training and assessment of the individual model architecture to evaluate the ability of each approach to generalize the observed data. The performance of the algorithms will be assessed using the mean square error and the rates associated with correct/incorrect classifications.

The linear regression approach provides similar performance for both the boating and swimming standards. When the bacterial concentrations are below the appropriate standard, the regression model has a high true negative rate. However, when the standards are violated, the regression model has true positive/false negative rates near 50%. The evaluation and development of the artificial neural network and LVQ approaches will continue to be investigated. The performance of these approaches will be compared to the regression analysis and the "best" approach determined.

Abstract

Currently, building a small dam located 1.16km downstream from Geumnam Bridge is being considered in order to improve the riverine scenery of the site for Sejong City and to create a hydrophilic space. The purpose of this research is to present the appropriate dimensions of a small dam by reviewing the flood control reliability of the Geum River after the small dam is built. To establish this purpose, changes in the flood water level were compared and analyzed by changing the installation height of a small dam using HEC-RAS and FESWMS models. HEC-RAS and FESWMS models were applied to perform the hydraulic analysis of the reach. The results showed that flood control reliability was guaranteed when the installation heights of the small dam were 7 meters and 5 meters using HEC-RAS and FESWMS models respectively. From the FESWMS model, a more accurate result can be developed because the model could provide a two dimensional hydraulic analysis. The results can be used to determine the appropriate dimensions of a small dam for Sejong City.

Introduction

There is a recent increase in the occurrence of floods exceeding the design for hydraulic structures in Korea due to climate change such as global warming. Several types of small dams are installed on many rivers in Korea for various purposes such as water storage, transportation, and flood control. In addition, plans of small dam installation on the rivers within areas where cities will be built have been made to improve riverine scenery and to create hydrophilic spaces.

River barriers such as small dams are major structures affecting water level variation. Significant rise in water level during flood increases the possibility of flooding the surrounding area as a result of water overflowing from riverbanks. Taking this into account, accurate and comprehensive hydraulic analysis of the river dimensions should be completed prior to small dam installation due to uncertainties in rainfall characteristics.

In this research, changes in the characteristics of hydraulic flows due to the small dam, which will be installed on Geum River in Sejong City, were analyzed. To establish this, hydraulic analysis was performed using a one-dimensional model and a two-dimensional model with a 200-year frequency flood design for the target section. The main purpose of this paper is to determine the appropriate size of small dam based on the results of hydraulic analyses contingent upon the installation of small dams.

Background

Study Area

A 10.39km section located in the middle region of the Geum River from Miho stream confluence to Daekyo stream confluence was selected for the hydraulic analysis of the reach after the small dam is built. Building the small dam 1.16km downstream from Geumnam Bridge is being considered in order to improve the riverine scenery of the site for Sejong City and to create a hydrophilic space(Korea Land Corporation, 2007). The Geum River basin, one of the five major rivers in Korea, encompasses a total area of 9,810.4km^2 with a total reach length of 397.79km. Figure 1 illustrates the study section.

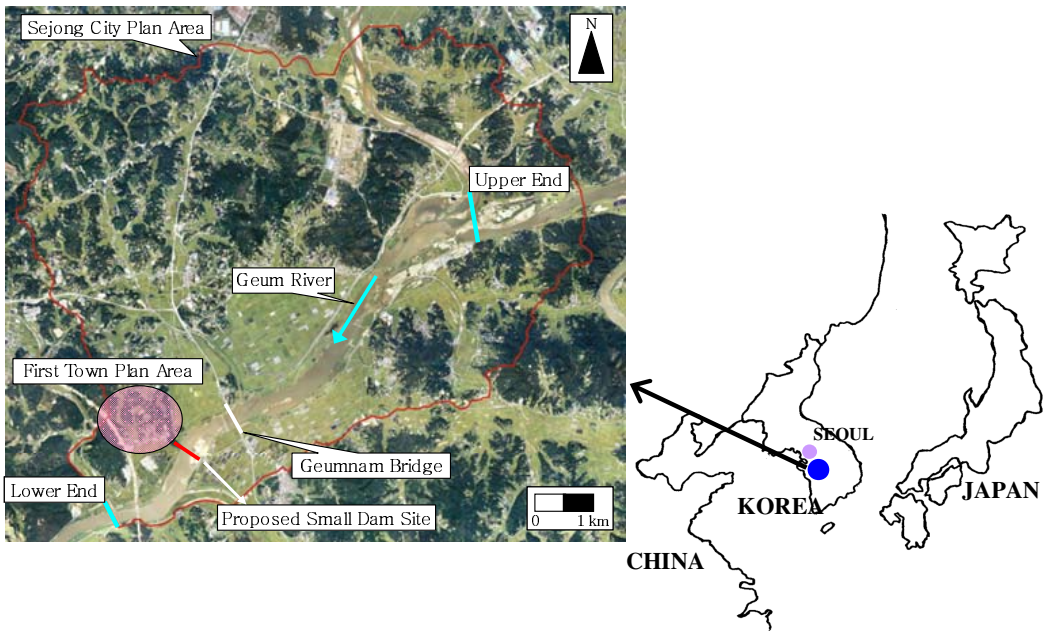

Figure 1. Study section of the Geum River in Sejong City.

Model Description

One-dimensional HEC-RAS and two-dimensional FESWMS were used in order to perform hydraulic analysis for the installation of hydraulic structures. The FESWMS is a model designed by the U. S. Federal Highway Administration in order to simulate flows near road facilities that cross rivers. The FESWMS is an ideal model for simulating flows near one or more than one hydraulic structure. The previous models have not been able to simulate these kinds of flows. Thus, this program is very helpful for analyzing the flows of the complex topography of rivers where river-crossing structures are installed.

Hydraulic Analysis

Changes in flood water level were compared and analyzed by changing the installation height of a small dam using HEC-RAS and FESWMS models. As shown in Table 1, the installation heights of small dam were set into seven scenarios based on the normal water level of the cross section 1.16 km downstream from Geumnam Bridge. Hydraulic analysis for each scenario was then performed. In addition, the results for both one-dimensional and two-dimensional models were compared for each section of the study area and then were analyzed.

Table 1. Height of the small dam for each scenario.

Scenarios	Height(m)	Crest elevation (EL. m)	Remarks
CASE 1	0	6.13	Normal water level (9.66 EL. m)
CASE 2	4	13.66	
CASE 3	5	14.66	
CASE 4	6	15.66	
CASE 5	7	16.66	
CASE 6	8	17.66	
CASE 7	9	18.66	

Input Data

Upstream and downstream boundary conditions, roughness coefficient, contraction coefficient, and expansion coefficient, etc., were used for the HEC-RAS model, whereas upstream and downstream boundary conditions, roughness coefficient, turbulent exchange coefficient, acceleration of gravity, and water temperature, etc., were used for the FESWMS model. Table 2 shows the input data used for the HEC-RAS and FESWMS models.

Table 2. Input data for HEC-RAS and FESWMS.

Models / Parameters	HEC-RAS	FESWMS
Upstream boundary condition (Miho stream confluence)	12,960 m^3/sec	12,960 m^3/sec
Downstream boundary condition (Daekyo stream confluence)	EL. 23.84 m	EL. 23.84 m

Roughness coefficient	0.027	0.027
Contraction coefficient	0.1	-
Expansion coefficient	0.3	-
Turbulent exchange coefficient	-	1,500 N·sec/m^2
Acceleration of gravity	-	9.8 m/sec^2
Water temperature	-	15 ℃

For the upstream boundary condition of both one-dimensional and two-dimensional models, 200-year frequency flood flow at the Miho stream confluence was used. Whereas for the downstream boundary condition, 200-year frequency flood water level at the Daekyo stream confluence was used. Moreover, the roughness coefficient of the target area was determined using the "Geum River Basin Maintenance Plan (by the Ministry of Land, Transport and Maritime Affairs, MLTM, established in 2002)" due to the extensive length of the study reach and data limitation. Since the target area is located between Daecheong Dam in Jojeongji and Ji stream confluence, the roughness coefficient of the said area, as indicated in the MLTM plan, was applied.

The turbulent exchange coefficient needed for the two-dimensional FESWMS was determined through the User's Manual. The turbulent exchange coefficient for regular rivers, with a value of 1,500 N·sec/m^2, was applied(Environmental Modeling Research Laboratory, 2000). Using this coefficient, the simulation results indicated a significant convergence with a stable solution.

Geometry data

The geometry data were developed using the cross sectional and longitudinal section data from the "Geum River Basin Maintenance Plan" (MLTM, 2002) and a digital map with the scale of 1:5,000. Table 3 indicates the geometry data used for the HEC-RAS and FESWMS models.

Table 3. Geometry data for HEC-RAS and FESWMS.

Models / Geometry data	HEC-RAS	FESWMS
Cross section	22 cross sections	-
Cross section lenths(mean)	495 m	-
Nodes	-	9,110
Elements	-	2,498

As illustrated in Figure 2, the geometry data of HEC-RAS was established with a total of 22 cross sections over the entire study reach, and the finite element mesh of FESWMS was organized with a total of 9,110 nodes and a total of 2,498 elements over the whole study section. Figure 3 shows the finite element mesh made over the study section.

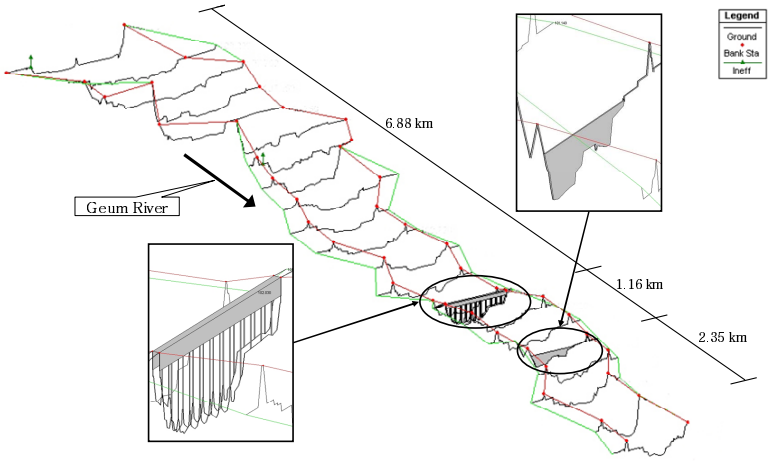

Figure 2. Cross section of the study reach (HEC-RAS model).

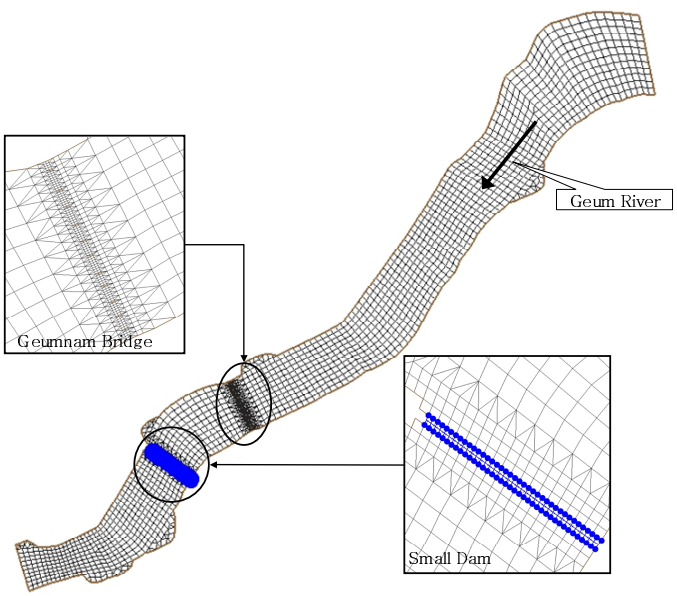

Figure 3. Finite element mesh of the study reach (FESWMS model).

Results and Discussion

Reviewing the Applicability of Models

Since actual water level measured for a 200-year frequency flood is not available, the calculated and measured value cannot be verified. Therefore, the calculated flood water level of the one-dimensional model was compared with that of the two-dimensional model to review the applicability of the models. Consequently, as shown in Table 4, the difference was -0.18m to 0.07m in CASE 1. The percentage of the difference ranged from -0.72% to +0.29%. In CASE 7, a difference ranging from -0.27m to 0.21m was obtained giving a percentage difference from -1.06% to +0.88%. The percentage of difference was observed to be highest in CASE 7. This

indicated that the higher the installation height of the dam, the greater the difference between the calculated values. However, the percentages of the differences were within the range of ±2% in both CASE 1 and CASE 7. Overall, the calculated flood water levels of HEC-RAS and FESWMS were close. The deviation between the calculated values maybe accounted to the difference in parameter and geometry data used for the one-dimensional and two-dimensional model.

Table 4. Flood water level for HEC-RAS and FESWMS model.

Distance from downstream (km)	CASE 1(EL. m)		Difference (%) [(A-B)/A]x100	CASE 7(EL. m)		Difference (%) [(A-B)/A]x100

* Geumnam Bridge cross section
** Small Dam cross section

Results of HEC-RAS model

The developed one-dimensional HEC-RAS model implies that as the installation height of small dam increases, upstream flood water level also increases. Consequently, downstream flood water level for each case was the same. Calculated flood water level of CASES 1 until 5 did not exceed the designed flood water level, suggesting that small dam installation height of these cases are safe from overflowing. On the other hand, calculated water levels for CASES 6 and 7 exceeded the designed flood water level. Therefore, these two cases indicate possibility of water overflowing the small dam. With regards to the flow rate, results indicate that

as the installation height of the small dam increases, the upstream flow rate decreases. Additionally, downstream flow rate for all cases were the same. Figure 4 provides the comparison of flood water levels in each scenario of the one-dimensional HEC-RAS while the comparison of the flow rates is given by Figure 5.

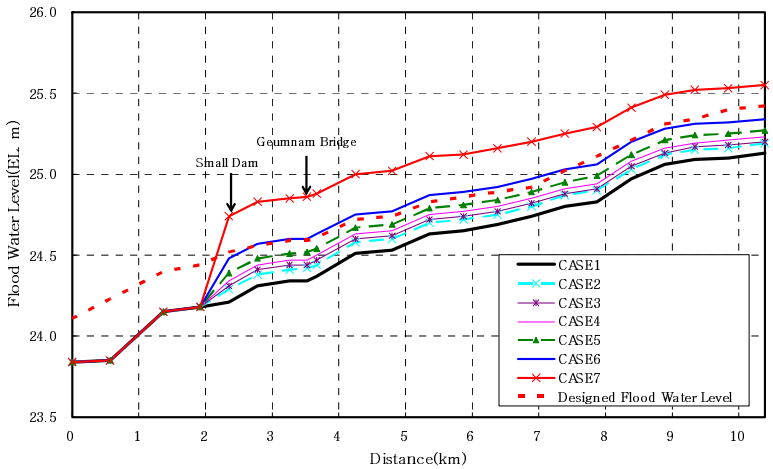

Figure 4. Flood water level for each scenario (HEC-RAS model).

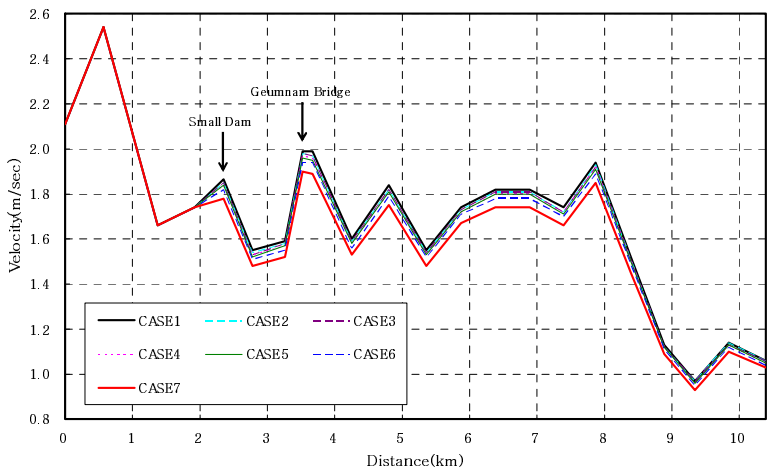

Figure 5. Velocity for each scenario (HEC-RAS model).

Results of FESWMS model

Simulation of the two-dimensional FESWMS model showed that the higher the installation height of the small dam, the higher the upstream flood water level. Downstream flood water levels, on the other hand, have small converging changes. After the convergence, the flood water level remained the same. Calculated flood water levels for CASES 1 to 3 did not exceed the designed flood water level, indicating that these small dams will not overflow. While results of CASE 4 until CASE 7 were higher than the designed flood water level. Thus, allowing water to

overflow during flood. Immediately downstream of the small dam, it can be observed that as the small dam installation height increases, the flood water level decreases. This can be due to the increase in flow rate as the dam is overflown with water.

Considering the flow rates, it is evident that as the installation height of the small dam increases, the upstream flow rate decreases. Moreover, a converging flow rate from the immediate downstream of the small dam is obtained. Consequently, after the convergence, flow rate is almost the same for all cases. Immediately downstream of the small dam, results implies that the higher the installation height of the small dam, the higher the flow rate. The reason for this was that severe flow disturbance occurred downstream due to a larger dam. Figure 6 shows the comparison of flood water levels in each scenario of the two-dimensional FESWMS whereas Figure 7 illustrates the comparison of flow rates.

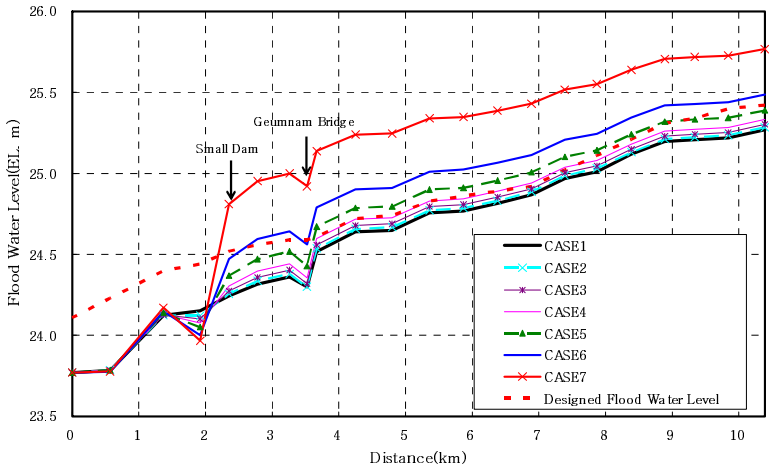

Figure 6. Flood water level for each scenario (FESWMS model).

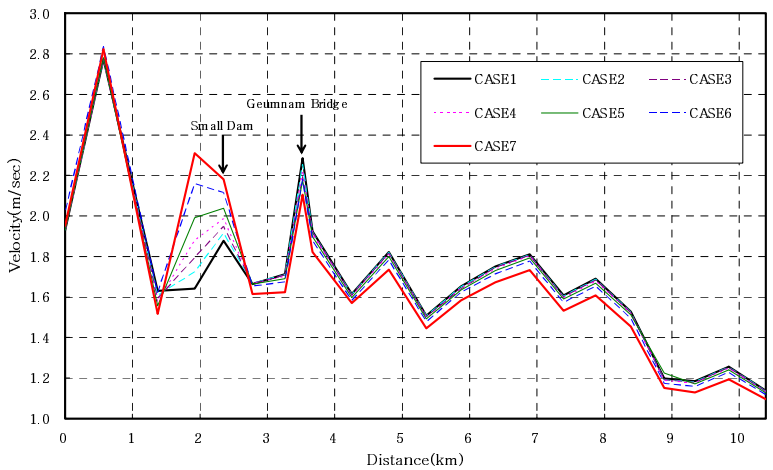

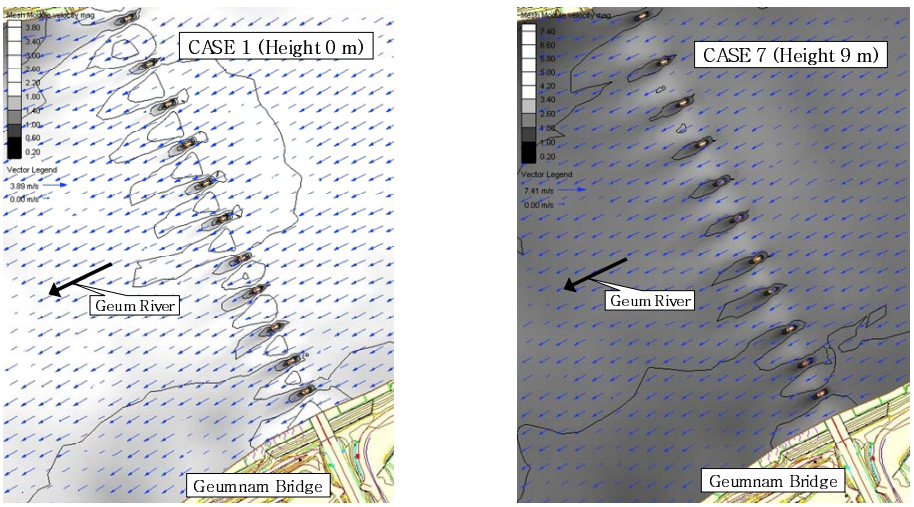

Figure 7. Velocity for each scenario (FESWMS model).

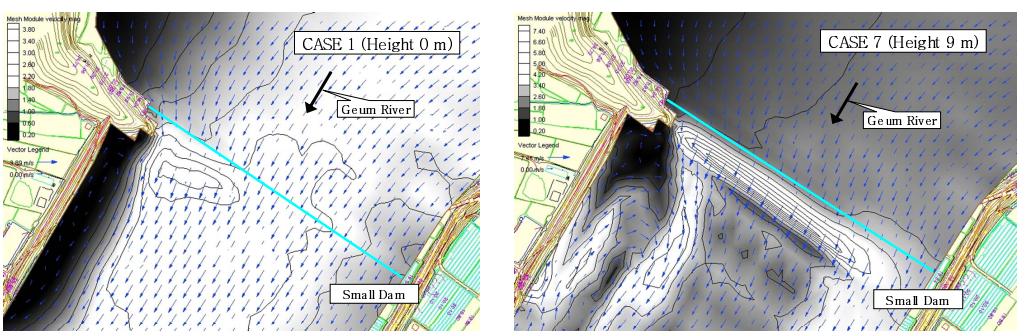

In this research, changes in the flow of the two-dimensional FESWMS in each scenario were analyzed for the section of Geumnam Bridge, where a hydraulic structure existed, and that of the small dam. As for the bridge section, high velocity occurred in between the piers of the bridge. The reason for this was considered to be the decrease in the cross sectional area of flow due to the piers. Figure 8 presents the velocity vector at the section of Geumnam Bridge.

As for changes in flow at the small dam section, results suggest that the small dam installation height is inversely proportional to the upstream flow rate. Downstream, flow rate increased and flow disturbance occurred. In this section also, there was a change in river width located at the bend. The flow rate of the main channel was very different from that of both banks. Specifically, that of the right bank downstream from the small dam, where water flowed backwards. Figure 9 presents the velocity vector for the section of the small dam.

(a) CASE 1 (b) CASE 7

Figure 9. Velocity vector for Small Dam cross section.

Conclusions

In this paper, changes in the characteristics of hydraulic flow on rivers depending on the installation of small dams were analyzed in order to propose the size of a small dam, which was safe from overflowing. As a result of performing hydraulic analysis for each scenario using the one-dimensional and two-dimensional models, the conclusions below were established:

(1) One-dimensional hydraulic analysis results considering the installation of small dams suggested that the designed flood water level was not exceeded in the cases that the small dam is 0m to 7m high. When the height of the small dam was 8m or higher, water will overflow.
(2) Two-dimensional hydraulic analysis results considering on the installation of small dams indicated that the small dams were safe from overflowing with the condition that installation height is between 0m to 5m high. When the height of the small dam was 6m or higher, the small dam will overflow.

Based on the results of one-dimensional and two-dimensional hydraulic analyses, it is concluded that it is appropriate to design the height of small dams at 5m or less in order to be safe from overflowing.

The size of small dam safe from overflowing was proposed by performing hydraulic analysis for rivers contingent upon the installation of small dams. They are expected to be used for determining the sizes of small dams in the future. In addition, validity in terms of water utilization and environment, research shall be reviewed and research shall be made in order to review the effects of small dams.

ABSTRACT

In a computer implementation, a water network model is represented by a set of network data (values of parameters) and a set of equations (physical operation of the model). The fundamental model is formulated using the laws of physics. Subsequently, different models can be derived by mathematical manipulation. For water network models three physical laws are employed: flow continuity, head-loss continuity and component equations (head/flow law).

Industry and academia have made a significant investment in the research and development of computer algorithms for the design, modelling and control of water supply networks. The industrial use of many of these algorithms is commonplace and they are complex procedures used to solve systems of equations. Therefore, powerful numerical algorithms used to solve the model equations are crucial in terms of their computational complexity i.e. requirement of average number of iterations for finding a solution with a required accuracy.

Along with physically simplified networks representing certain aspects of reality, neglecting other aspects with a smaller number of components than the original network, effective solution methods for water supply networks become common practice. To do this, first we must form a mathematical model representing the physical system; second, we need to set up an efficient solution implementation which is specific to the equation systems and finally we must visaliuze and post-process the results.

Keywords

Water Supply Networks, Water Distribution Networks, Conjugate Gradient Method

1. INTRODUCTION

A water supply network [6] is a system of engineered hydrologic and hydraulic components, including a raw (untreated) water reservoir (above or below ground) where the water gathers, such as a lake, a river, or groundwater from an underground aquifer; transmission from treatment, through pipes to treated water storage, that may be either elevated or ground level; and distribution through piping/watermains from storage to consumption (at houses, fire hydrants, industrial use points, etc). Figure 1 [2] illustrates an example model of network supplying water to more than 76,000 inhabitants. A conceptual model of a water network can be presented as an input-output system with input and output variables, demand, initial conditions and a mathematical model as shown in Figure 2 [1]. Input variables are source inflows, source heads and initial reservoir levels, output variables are flows in pipes and heads and demands are node outflows representing water consumption. Initial con-

Figure 1: Example model of water supply network

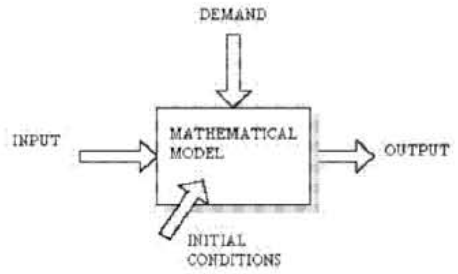

Figure 2: Input-output model (conceptual model) of a water network

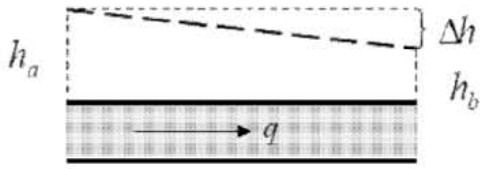

Figure 3: Example of a single tube

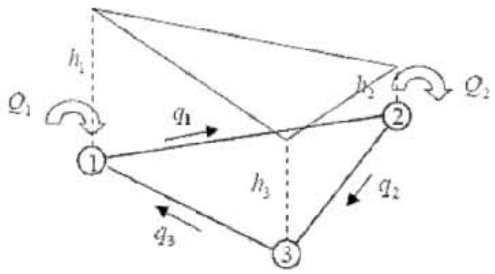

Figure 4: Example of a 3 tube with 3 node

ditions comprise the initial reservoir levels, and finally water network mathematical model is the set of mathematical equations modelling the behaviour of the physical system.

2. ANALYSIS OF THE PHYSICAL PROBLEM

We present the underlying physical problem that can be demonstrated in the example of a single tube, which is flown through by a fluid as shown in Figure 3 [3]. The loss of hydraulic head Δh in the tube depends on the velocity v of the flow:

$$\Delta h = \lambda \frac{l}{d} \frac{v^2}{2g}$$

where l is the length of the tube, d the diameter and $g = 9.81 m/s^2$ the acceleration due to gravity. The factor λ describes the roughness of the tube material, and can be assumed for *laminar* flow as:

$$\lambda = \frac{64}{Re}, \quad Re = \frac{v.d}{\nu} = \frac{v.d}{1.10^{-6}}$$

With $v = \frac{q}{A} = \frac{4.q}{d^2\pi}$ we get:

$$\Rightarrow \quad q = \frac{\pi.g.d^4}{128.\nu.l} \Delta h_i = \frac{\pi.g.d^4}{128.\nu.l} (h_a - h_b)$$

$\frac{\pi.g.d^4}{128.\nu.l}$ is B the permeability of the tube. Finally we get a linear relation between the flow and the difference in hydraulic head:

$$q = B.(h_a - h_b)$$

To demonstrate the procedure calculating the flow distribution in a pipe network, an example with 3 nodes and 3 tubes is shown below Figure 4 [3]: The system must fulfill the constraint that the sum of inflow and outflow has to be 0 in every node:

$$\begin{aligned} q_1 - q_3 - Q_1 &= B_1.(h_1 - h_2) - B_3.(h_3 - h_1) - Q_1 = 0 \\ -q_1 + q_2 + Q_2 &= -B_1.(h_1 - h_2) + B_2.(h_2 - h_3) + Q_2 = 0 \\ -q_2 + q_3 &= -B_2.(h_2 - h_3) + B_3.(h_3 - h_1) = 0 \end{aligned}$$

This leads to a linear equation system:

$$\underline{\underline{B}}\ \underline{h} + \underline{Q} = \underline{0}$$

$$\begin{bmatrix} B_1 + B_3 & -B_1 & -B_3 \\ -B_1 & B_1 + B_2 & -B_2 \\ -B_3 & -B_2 & B_2 + B_3 \end{bmatrix} \begin{bmatrix} h_1 \\ h_2 \\ h_3 \end{bmatrix} + \begin{bmatrix} -Q_1 \\ +Q_2 \\ 0 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$$

where $\underline{\underline{B}}$ is the global permeability matrix, and $\underline{Q}$ denotes the flow vector. The equation system shown here is singular, i.e. it has no unique solution. This is due to the fact that all formulas are based on the difference in hydraulic head between two nodes, but an absolute height of the system is not specified. Therefore, we have to include such a boundary condition by defining the absolute height of one node (e.g. height of first node $h_1 = 0$). This can be enforced, for example, by setting the off-diagonal entries $B_{1,i}$ and $B_{i,1}$ of the coefficient matrix and the entry Q_1 of the right hand side vector to 0, while setting the diagonal entry $B_{1,1}$ to 1.

3. REQUIREMENT SPECIFICATIONS

3.1 Functional Requirements

To understand the needs of the project, assess feasibility, prevent ambiguity, and reach a valid project, the most important actions to be taken are determination and engineering of the requirements. The most important issues we considered during requirement specifications are:

- To make requirements consistent with the objective of the project.
- To specify requirements at proper level of abstraction.
- To state bounded and unambiguous requirements.
- To prevent conflicting requirements.
- To state technically achievable requirements.

3.1.1 *General Requirements*

The software application calculates the flows in the tubes of a network. The pipe network consists of nodes and tubes between the nodes.

- A node is defined by its coordinates x, y and a flow Q (inflow: $Q<0$; outflow: $Q>0$).
- A tube with diameter d lies between two nodes a, b.

The application should be with the following functionality:

- All input data for the nodes and the tubes is to be read from an ASCII file.
- The resulting fluxes shall be computed.

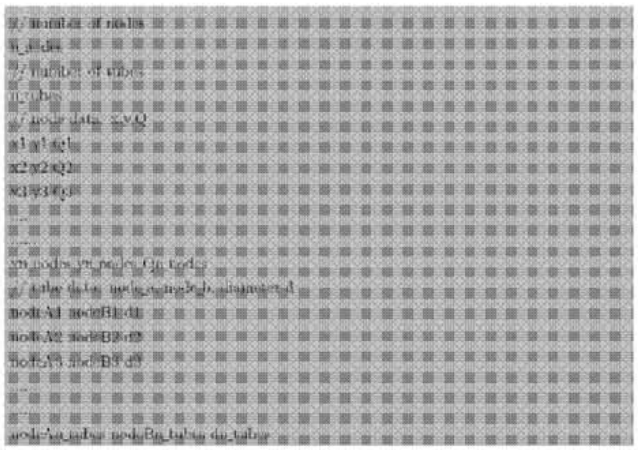

Figure 5: Example of an input file

- Output the results either on screen or in an output file.

The input file containing the network data is divided into three parts:

- The number of nodes and tubes has to be specified.
- The nodes are given with the x-coordinate, the y-coordinate and the amount of inflow/outflow.
- The tubes are given with the start node, the end node and the diameter.

The input file has to be saved as a simple text file. The input file will look like below shown in Figure 5:

3.2 Non-Functional Requirements

3.2.1 Usability

In developing our application, some of the most important issues to be considered are making the user easily adapt the application and learn the application. Considering these aspects, we plan to design the application as simple as possible. The controls will be simple, adjustable and enough for the actions to be taken.

3.2.2 Reliability

The application should be as bug free as possible. All components should work synchronously, so that, any error or problem caused by one of the components should not block other componentsŠ workflow.

3.2.3 Portability

Our application will work on different platforms, such as: Linux and Windows.

3.3 Software Requirements

Our application will work on different operating systems, such as: Windows XP or Linux operating systems.

3.4 Hardware Requirements

Our application will work on a PC having at least Pentium 4 class CPU.

4. DESIGN

4.1 High-Level Design

4.1.1 Class Structure

We present the input data that shall be saved in a class structure given figure below:

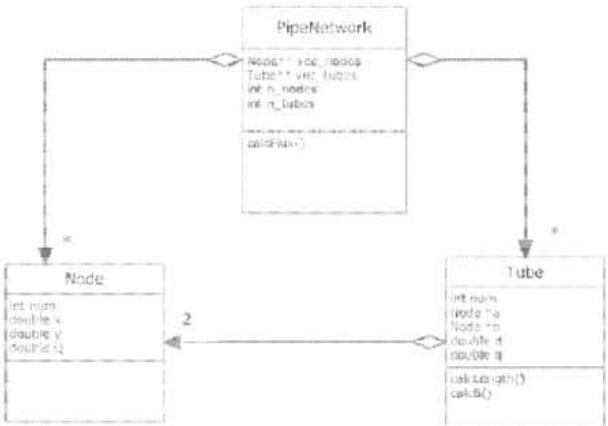

Figure 6: Class Structure

4.1.2 Class Descriptions

The descriptions of the classes are given below:

Node

Usage:

```
Node (int i, double x, double y, double Q):
Creates node i with discharge Q on coordinates
(x, y).
```

Parameters:

```
i:  Index of the node.
x:  X coordinate of the node.
y:  Y coordinate of the node.
Q:  Discharge of the node.
```

Tube

Usage:

```
Tube (int i, node* a, node* b, double q):
Creates tube i with discharge q with a and b nodes.
```

Parameters:

```
i:  Index of the tube.
a:  Start node of the tube.
b:  End node of the tube.
q:  Discharge flowing in the tube.
```

Methods:

```
calcLength():  Calculates the length of the tube.
calcB(double l):  Calculates the permeability of the
tube with length l.
```

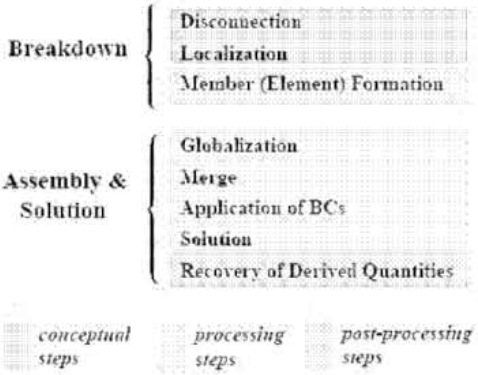

Figure 7: Implementation Steps

PipeNetwork

Usage:
```
PipeNetwork(const char* filename):
Reads the input file.
```

Parameters:
```
filename:  The name of the input file.
```

Methods:
```
calcFlux():  Calculates the flux in each tube.
```

Variables:
```
vec_nodes:  Pointer array which stores the node
information created by Node.
vec_tubes:  Pointer array which stores the tube
information created by Tube.
n_nodes:  Number of nodes.
n_tubes:  Number of tubes.
```

4.2 Low-Level Design

4.2.1 Implementation

The implementation steps of the software, major and minor, are summarized in Figure 7. The two major processing steps are **Breakdown**, followed by **Assembly & Solution**. The first 3 substeps are: *a*) disconnection, *b*) localization and *c*) computation of tube permeability equations. Collectively these form the *breakdown*. The first two are flagged as *conceptual* in Figure 7 because they are not actually programmed as such: they are implicitly carried out through the user-provided problem definition. Processing actually begins at the tube permeability equation forming substep.To carry out the first breakdown step we proceed to *disconnect* or *disassemble* the system into its components in order to effectively deal with a local tube.The first substep in the assembly & solution major step, as shown in Figure 7, is *globalization*. This operation is done tube by tube. It refers the tube permeability equations to the global system so it can be merged into the global permeability. The globalized tube permeability matrices for the network can now be obtained by inserting appropriate local permeability factors and inserting the boundary conditions.

4.2.2 Functional Algorithm

In the following algorithm a framework of the function, which calculates the flux distribution is shown:

PipeNetwork::calcFlux():

- `create the permeability matrix B(n_nodes)`
- ∀ `tubes i:`
  - `get the bounding node numbers n_a, n_b`
  - `calculate the local permeability factor B_i`
  - `assemble B_i to the global permeability matrix:`
    - ◇ `B(n_a,n_a) += B_i ; B(n_b,n_b) += B_i`
    - ◇ `B(n_a,n_a) -= B_i ; B(n_b,n_b) -= B_i`
- `create the flux vector Q(n_nodes)`
- ∀ `nodes i:`
  - `Q(i) += Q_in(i)`
- `insert the boundary condition h(1)=0.0, for (i=2,...,n_nodes):`
  - `set B(i,1) = B(1,i) = 0.0`
  - `set Q(1) = 0.0`
  - `set B(1,1) = 1.0`
- `solve the linear equation system`
- `postprocessing: calculate the flux in every tube,` ∀ `tubes i:`
  - `q_i = B_i*(h_node_a - h_node_b)`

4.2.3 Solution

Because memory efficiency and time consumption are important factors for solving large systems of linear equations, we present the conjugate gradient method (CG) which is an effective method for symmetric positive definite systems. CG is an iterative method minimizing quadratic form of the equation system $Ax = B$.

$$Ax + b = 0, \quad a \in R^{n,n}, \quad \textit{symmetric and positive definite}$$

$$Q(x) := \frac{1}{2} x^T Ax + b^T x \ \rightarrow Min$$

where Q is quadrative form, $\underline{\underline{A}}$ is a matrix and $\underline{x}$ and $\underline{b}$ are vectors. The method [4] proceeds by generating:

- vector sequences of iterates (i.e., successive approximations to the solution),
- residuals corresponding to the iterates, and
- search directions used in updating the iterates and residuals.

Although the length of these sequences can become large, only a small number of vectors needs to be kept in memory. In every iteration of the method, two inner products

are performed in order to compute update scalars that are defined to make the sequences satisfy certain orthogonality conditions. On a symmetric positive definite linear system these conditions imply that the distance to the true solution is minimized in some norm. The iterates $x^{(i)}$ are updated in each iteration by a multiple a_i of the search direction vector $p^{(i)}$:

$$x^{(i)} = x^{(i-1)} + a_i p^{(i)}$$

Correspondingly the residuals $r^{(i)} = b - Ax^{(i)}$ are updated as:

$$r^{(i)} = r^{(i-1)} + a_i q^{(i)}$$

where $q^{(i)} = Ap^{(i)}$. The choice $a_i = \frac{r^{(i-1)^T} r^{(i-1)}}{p^{(i)^T} Ap^{(i)}}$ minimizes $r^{(i)^T} A^{-1} r^{(i)}$ over all possible choices for a. The search directions are updated using the residuals:

$$p^{(i)} = r^{(i)} + \beta_{(i-1)} p^{(i-1)}$$

where the choice $\beta_i = \frac{r^{(i)^T} r^{(i)}}{r^{(i-1)^T} r^{(i-1)}}$ ensures that $p^{(i)}$ and $Ap^{(i-1)}$ (or equivalently $r^{(i)}$ and $r^{(i-1)}$) are orthogonal. In fact, one can show that this choice of $\beta^{(i)}$ makes $p^{(i)}$ and $r^{(i)}$ orthogonal to all previous $Ap^{(j)}$ and $r^{(j)}$ respectively. In the CG, two coupled two-term recurrences are used; one that updates residuals using a search direction vector, and one updating the search direction with a newly computed residual. This makes the CG quite attractive computationally.

Accurate predictions of the convergence of iterative methods are difficult to make, but useful bounds can often be obtained.

The method involves one matrix-vector product, three vector updates, and two inner products per iteration. Some slight computational variants exist that have the same structure. [5] The steps of CG can be summarized as in Figure 8: The pseudocode for the preconditioned conjugate gradient method is given below. It uses a preconditioner M. For $M = 1$, one obtains the unpreconditioned version of the conjugate gradient algorithm. In that case, the algorithm may be further simplified by skipping the "*solve*" line and replacing $z^{(i-1)}$ by $r^{(i-1)}$ and $z^{(0)}$ by $r^{(0)}$.

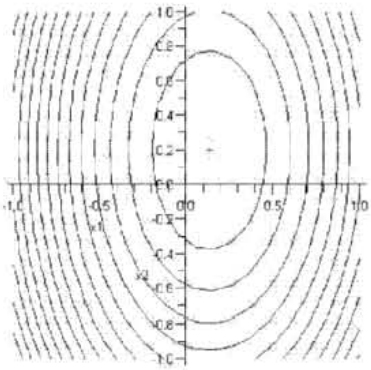

Figure 9: Contours of the quadratic form

Pseudocode:

Compute $r^{(0)} = b - Ax^{(0)}$ for some initial guess $x^{(0)}$
for i = 1, 2, ... do
Solve $Mz^{(i-1)} = r^{(i-1)}$ $\rho^{(i-1)} = r^{(i)^T} z^{(i-1)}$
if $i = 1$ then
$p^{(i)} = z^{(0)}$
else
$\beta_{(i-1)} = \frac{\rho_{(i-1)}}{\rho_{(i-2)}}$
$p^{i} = z^{(i-1)} + \beta_{(i-1)} p^{(i-1)}$
end if
$q^{(i)} = Ap^{(i)}$
$a_i = \frac{\rho_{(i-1)}}{r^{(i)^T} q^{(i)}}$
$x^{(i)} = x^{(i-1)} + a_{(i)} p^{(i)}$
$r^{(i)} = r^{(i-1)} + a_{(i)} q^{(i)}$
Compute convergence; continue if necessary.
end for

Figure 9 and Figure 10 are contours of the quadratic form that each ellipsoidal curve has constant *Q(x)* and graph of the quadratic form *Q(x)* that the minimum point of this surface is the solution to $Ax = B$, respectively, for a simple problem where $\underline{\underline{A}} = \begin{bmatrix} 3 & 0 \\ 0 & 1 \end{bmatrix}$, $\underline{b} = \begin{bmatrix} -0.4 \\ -0.2 \end{bmatrix}$. For this case x will be $\underline{x} = \begin{bmatrix} -0.133333 \\ 0.2 \end{bmatrix}$ Gradient iteration for convergence to the solution and error analysis will respectively be as given in the Figure 11 and Figure 12 for the same simple problem.

5. NUMERICAL EXAMPLE

In this section, a numerical example is presented in order to demonstrate the properties of the proposed project. The main point of this example is to investigate the procedure presented in this report. The topology of example network is depicted in Figure 13. The example has 9 nodes and 12 tubes with inflow at the nodes 1, 3 and 7 and outflow at the node 9 (minus sign designates the inflow and plus sign designates the outflow). All tubes have the same diameter of 0.5m. For the given example model the input file will look like in Figure 14. The solution of this model which calculates the flows in each tube of the network is depicted in Figure 15 (minus sign in the results shows that the flow direction must

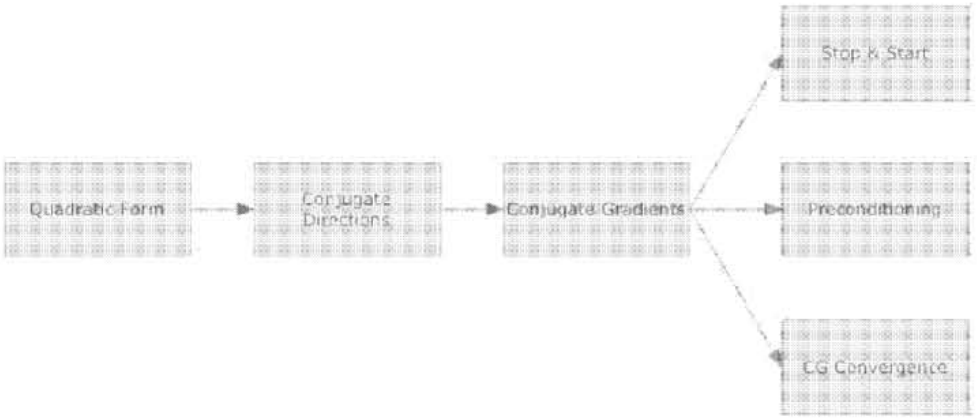

Figure 8: CG Steps

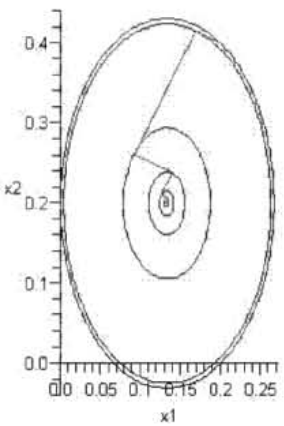

Figure 11: Graph of iterations

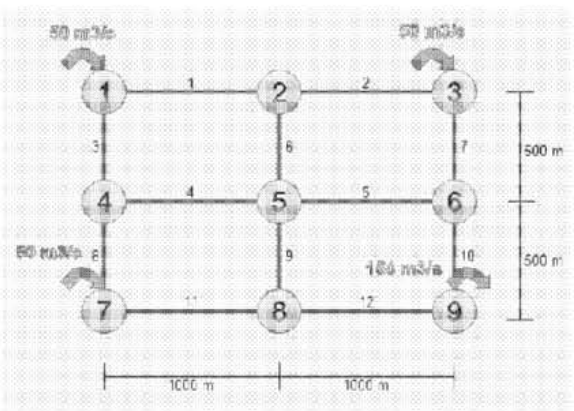

Figure 13: Simplified model of example network

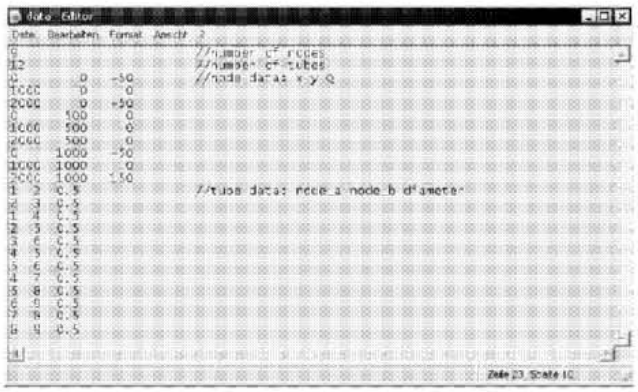

Figure 14: Input file

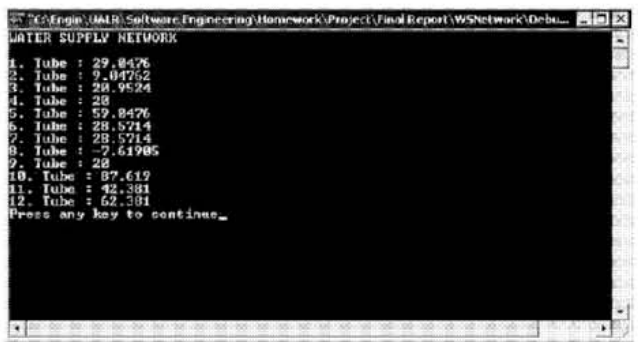

Figure 15: Output results

be opposite of the initial assumed direction. For instance, for the 8th tube, at first, flow direction is considered from node 4 to node 7 in the input file. But as a result it must be the opposite, from node 7 to node 4).

6. CONCLUSION

Type of mathematical model, numerical algorithms used to solve the model equations, initial conditions, computational complexity, form of solution and post-processing requirements for analysing the results can be counted as evaluation criterias for the solution of water supply networks. Additionally, factoring of sparce matrices may be impossible due to limited memory, and will be time-consuming as well; even the backsolving step (like in Gauss Elimination) may be slower than iterative solution. On the other hand, CG is very memory-efficient and run quickly with sparse matrices. Therefore, we present a solution for water networks, meeting all these requirements above.

Comparison of Mean Flow and Turbulence around Experimental Spur Dike

Jennifer G. Duan[1] and Li He[2]

ABSTRACT

An acoustic Doppler velocimeter was used to measure flow and turbulence around an experimental spur dike in a flat and a scoured bed. Differences of mean velocity, turbulent intensity and Reynolds stresses between these two flow fields were compared and analyzed. Upon the formation of scour hole, mean flow velocities in the downstream and lateral directions were reduced, but increased in the vertical direction. The turbulence intensities (*u'* and *v'*) are much larger, and the vertical component (*w'*) is smaller than that in the flat bed. Bed shear stresses determined from near-bed Reynolds stresses in the scoured bed were smaller than that in the flat bed. These results indicated that local scour has not only significantly reduced bed shear but also contributed to the increase of turbulence intensities in the scouring zone.

INTRODUCTION

Spur dikes are hydraulic engineering structures for preserving the desired water depth, deflecting the main current in the harbor channels and rivers, and protecting river banks. Flow field passing through a spur dike is characterized with the separation of approaching flow in three dimensions (3D) from upstream to the horse shoe vortex downstream of the dike. The complexity of flow field increases as the scour hole develops [9].

Local scour is caused by the erosive forces from flow turbulence acting on the erodible bed in the vicinity of an obstacle or structure placed in a stream, such as a spur dike, a bridge pier. Mean flow and turbulence properties are equally important for sediment entrainment, suspension, transportation, and deposition [4]. The scour mechanism involves two interactive elements, one is 3D unsteady flow field near the boundary, especially turbulent fluctuations and the resultant bed shear stresses; and the other is the morphology of sediment particles on bed surface [4]. The transport of sediment particles in turbulent flows depends on the interactions between the particles and the coherent turbulent structures [7]. Bey et al. [4] found turbulence fluctuations and mean flow features directly influence the scour process.

Mean bed shear stress or near-bed velocity were traditionally used for estimating the rate of sediment transport in well developed boundary layer flows [11]. For flows with developing boundary layers of sufficient non-uniform topography or roughness, sediment transport does not directly correlate to mean flow properties [11]. Researches found near-bed turbulence structure played a significant role in

transporting sediment through a combination of micro-ADV, LDV, PIV and high-speed motion picture photography [11]. Recent measurements found that hydraulic forces acting on various sized sediment particles vary according to bed configurations. Measured turbulent flow field (e.g., turbulence intensities, Reynolds shear stresses) at various azimuthal planes around a 45° wing-wall and vertical-wall abutment concluded that the near-bed Reynolds stresses are more accurate for estimating sediment transport rate [8,9]. Sterk et al. found normal Reynolds stresses ($\rho\overline{u'^2}$ and $\rho\overline{w'^2}$) contributed more than the Reynolds stresses $-\rho\overline{u'w'}$ to sand transported by saltation in two-dimensional flows. Experiments of Nelson et al. [10] and Williams et al. [13] both showed that $-\rho\overline{u'w'}$ poorly correlates to sediment entrainment in turbulent boundary layers, however turbulent bursts by u' and w' components played a significant role in producing shear stresses. Normal stress $\rho\overline{u'^2}$ is a better predictor for the entrainment of coarse sand and gravels than $\rho\overline{w'^2}$ and $-\rho\overline{u'w'}$ in 2D flows because there was a strong positive correlation between the transport rate and near-bed instantaneous streamwise velocity [6,10]. The most effective events that move sediment are those with a large u'. Therefore, sediment flux can increase even when bed shear stress decreases [10] (Nelson et al., 1995). Applying concepts derived from steady uniform flow to non-uniform flows of developing boundary layer are problematic [9,10].

The present experimental study aims to quantify the differences of mean and turbulence flow field between a flat and scoured bed. Turbulent flow passing through an emergent spur dike on a flat and a scoured bed were measured, respectively, by using a SonTek 25-MHz MicroADV. Time histories of velocities in all three spatial dimensions were recorded at cross sections parallel to the dike. These measurements were used to study time-averaged, downstream primary flow and cross-sectional flow properties, as well as turbulence properties (e.g., turbulence intensities) at the upstream and downstream sections of the dike. Impacts of the dike on flow structure include flow convergence, locally increased bed-shear stress and increased turbulence in the vertical, which explains the initiation of local scour and sorting of sediment in the scour hole.

EXPERIMENTAL DATA

Experiment set-up

Experiments were conducted in a 12.8-m-long and 60.8-cm-wide flume located at the St. Anthony Falls Laboratory, University of Minnesota. A valve was used to control discharge. The channel sides are glass walls, and bed slope was 0.0004. Bed surface had a roughness height about 0.4 mm. A 20-cm-long, 4-mm-thick, and 40-cm-height metal plate was installed at 6m downstream of the flume inlet and protruded from the right hand side of the flume to serve as a model dike structure, and it emerged from the water surface during all experimental runs. Two experiments

were performed: firstly channel bed was fixed; secondly, bed surface was covered with a well-sorted sand and gravel mixture having a median grain diameter of 1.59 mm.

A downward looking microADV was used to measure instantaneous velocity field. MicroADV has been commonly used in measuring point-wise 3D velocity fields through recording the Doppler shift produced by targeted material in the flow. The acoustic sensor consisted of one transmitter and three receivers. The receivers are aligned to intersect with the transmit beam at a small sampling volume located about 50 mm from the probe tip. The sample volume is a cylinder of diameter 4.5 mm and height of 5.6 mm. The sampling frequency of the ADV was 25 Hz, with a sampling duration of 1-1.5 minutes in each measuring location. It can measure mean flow velocities from 1 mm/s to 2.5 m/s with an accuracy of $\pm 1\%$ of the measurement range. The microADV was attached to a point gauge fixed on an instrument carriage that was mounted on horizontal steel rails and moved on wheels. The ADV can move along the flume automatically driven by an electric motor, and also manually in the transverse and vertical directions to measure flow velocities at any location near the dike.

Nine cross sections shown in Fig. 1, including three upstream of the dike, one at the dike tip, and five downstream of the dike, were measured. Nine vertical profiles at intervals of 5 cm were measured at each cross section, and each vertical profile had 7–9 points with 1 cm spacing. At each measuring node, about 1,500 instantaneous velocities at three respective directions were recorded. Flow depth was measured at locations where velocity was measured with a laser profiler attached to the instrument carriage. These measurements of velocities and surface elevations were used to determine mean velocities, turbulence intensities, Reynolds stresses, and bed-shear stresses.

Data Processing

In the data analysis, the origin of the Cartesian coordinate is at the upstream side of the dike on the right wall of the initial bed surface elevation, thus the *x* axis is the downstream direction, *y* axis is pointing to the left bank in the transverse direction, and *z* axis is towards the water surface in the vertical. The *z*=0 plane was the flume bottom in the flat bed run, but the initial bed surface in the erodible bed run. The velocity components are denoted as u_j, v_j, and w_j, respectively.

The friction velocity of approaching flow was calculated by fitting the velocity profiles with the logarithmic law. Because of the effects of side wall the maximum mean-velocity $\bar{u}$ occurred slightly below the free surface, indicative of the dip phenomenon [2] when a rectangular channel had a low flow width to depth ratio ($B/H \le 5$) [2]. The shear velocity, u_*, and zero velocity level, z_0, were determined by assuming the von Karman constant is 0.41. Flow is hydraulically rough with $ks = 1.20\ mm$ in the flat-bed runs. Whereas in the erodible bed run, the shear velocity

was $u_* = 5.55\ cm/s$ and the roughness height was $ks = 1.59\ mm$, which was much greater than the thickness of viscous sublayer $\delta = 11.6\frac{\nu}{u_*} = 0.234\ mm$. Therefore, flow in the erodible bed runs was also hydraulically rough. The mean velocity of approaching flow is 59.43 cm/s.

At solid walls, all mean and turbulence velocities and Reynolds stresses are zero. Because of the complex turbulence flow near the dike, this study linearly interpolated these properties at each vertical line. The duration of the experimental run was 48 hours to allow the local scour reach an asymptotic state so that bed surface was completely armored. Contour lines of the scoured depth were shown in Fig.2 in which the zero contour line is the initial bed surface and also the edge of the scouring hole. The total scour volume was 0.0081 m^3. The maximum scour depth is 8.87cm at x=15.4cm, y=25cm.

RESULTS AND DISCUSSION

Mean Velocity

The contour lines of dimensionless time-averaged velocity components $\overline{u}$, $\overline{v}$ and $\overline{w}$ at different cross sections of the flat and scoured bed are shown in Fig.3 (a) and (b), respectively. The distributions of downstream component of mean velocity are similar, but the distributions of lateral and vertical components of mean velocities are very different. In both cases the maximum downstream mean velocity occurred slightly below the free surface [3]. This dip phenomenon is noticable because of the small flow aspect ratio in the present experiments [2]. The small channel aspect ratio together with the presence of free surface induces the secondary flow that dampens the vertical velocity fluctuations [2].

Flow separation begins at the dike tip in both runs, and shifts slightly towards the right bank, and then turns back to the left side wall as shown in Fig.4. The length of flow separation in the asymptotic state is about 3.5 times the dike length, much shorter than that for non-erodible flat bed. Flow reattached immediately at the end of the scour hole. The detached shear layer has nearly zero mean downstream velocity, and coincides with the thalweg of bed surface, especially at sections with $0.5<x/L<3.5$. One can find that the maximum scour depth developed along the path of the detached shear layer where the turbulence intensity is the maximum.

In the scoured bed, the mean velocity component, $\overline{u}$, at the contraction section is about 1.2 times as large as the mean velocity of approaching flow, while in the flat bed, the mean velocity at the contraction is about 1.3 times as that of the approaching flow. This shows that the streamwise component of mean velocity has been reduced after the scour hole is formed as observed by Thompson [12]. In the meantime, the

downstream component of mean velocity near the bed was increased in the primary flow zone and reduced in the recirculation zone where negative velocities (in blue color) as shown in Fig. 3(a). The increase in $\bar{u}$ and the extent of recirculation zone are much larger in the flat bed than that in the scoured bed. However, the mean velocity of recirculating flow is less than 10% of the approaching flow velocity.

The mean downstream velocity, $\bar{u}$, reaches its maximum at the dike section in the scoured bed. The streamwise velocity has been greatly reduced in the scoured zone. At the zone above the initial bed where $z/L>0.0$, the distribution of mean flow velocity is similar to that in the plane bed. Flow contracted at the dike section, and consequently the contour lines of $\bar{u}$ showed the existence of a pronounced skewness in the $\bar{u}$ component. This attributes to the effect of the horse shoe vortex and the associated helicoidal flow around the dike.

In both cases, the transverse component of mean velocity increases as flow approaches to the dike. At the dike section the transverse velocity in the primary flow reaches the maximum near the bed, and it is towards the left bank. The transverse velocity reverses its sign in the flow recirculation zone. The apparent difference in the distribution of $\bar{v}$ is that the maximum $\bar{v}$ in both the primary and the recirculation flows in the flat bed are larger than that in the scoured bed, which implies the reduction of flow intensity as the local scour forms.

The mean vertical velocity, $\bar{w}$, approximately is zero at regions upstream of the dike impacted zone. As flow approaches the dike, the negative values of $\bar{w}$ upstream of the dike corroborate the existence of a strong downward flow in the scoured bed, while the mean vertical flow is upward at the tip of the dike in the flat bed. This phenomenon showed that the helicoidal flow originated at the dike tip in the flat bed has shifted to the upstream after the scour hole was formed. The magnitude of $\bar{w}$ decreases as the helicoidal flow attenuates downstream of the dike. The mean vertical velocity is the maximum at approximately the middle of flow depth and decreases towards both the surface and the bed. At $x/L=5.0$, Fig. 3(a) showed a strong upward flow where hydraulic suction may take place that dislodges bed sediment downstream of the dike. Further downstream $\bar{w}$ diminishes rapidly.

In summary, after the scour hole is formed, the mean downstream velocity was reduced primarily due to the enlarged cross sections. On the other hand, the mean transverse velocity has increased near the bed surface in the scour hole, and the mean vertical velocity reverses its direction towards the flow surface in the scour hole. The

increases in the lateral and vertical mean flow indicated sediment entrainment and transport towards the left bank.

Turbulence Intensity

Reynolds decomposition into mean and fluctuating portions is commonly employed in analyzing turbulence velocity fields [1]. The contour lines of dimensionless turbulence intensities in 3D, symbolized as $\sqrt{\overline{u'^2}}/u_*$, $\sqrt{\overline{v'^2}}/u_*$, $\sqrt{\overline{w'^2}}/u_*$ at different cross sections were shown in Fig.4. In the flat bed, the turbulent intensities in three directions are nearly the same with a similar distribution. Turbulent intensities increase as the distance from the dike increases, while the largest turbulent intensity occurred at the center of each section.

After local scour reaches the asymptote state, the distributions of $\sqrt{\overline{v'^2}}$ and $\sqrt{\overline{w'^2}}$ are very similar to that of $\sqrt{\overline{u'^2}}$. The magnitude of $\sqrt{\overline{v'^2}}$ is larger than that of $\sqrt{\overline{u'^2}}$, and the magnitude of $\sqrt{\overline{w'^2}}$ is smaller than both. The magnitudes of $\sqrt{\overline{v'^2}}$ and $\sqrt{\overline{u'^2}}$ were increased at the dike tip in the scoured bed, but no noticeable increment was observed in the flat bed. At the contraction section, the turbulence intensities are the largest where $\sqrt{\overline{u'^2}}$ has nearly the same magnitude as U_0, while $\sqrt{\overline{v'^2}}$ is 1.65 times U_0. Downstream of the dike, the dimensionless $\sqrt{\overline{u'^2}}/u_*$ is larger than that in the flat bed. The increase of $\sqrt{\overline{v'^2}}$ in the local scour zone is not as apparent as that of $\sqrt{\overline{u'^2}}$. The turbulence intensity, $\sqrt{\overline{w'^2}}$, has increased in the area immediately above the bed upstream of the dike in the scour hole, while there is limited increase near the right-hand side wall in the flat bed. While downstream of the dike, $\sqrt{\overline{w'^2}}$ has increased in the primary flow zone, and reduced in the flow recirculation zone.

CONCLUSIONS

Mean flow and turbulence fields around a spur dike in a flat and scoured bed surface were compared and analyzed. As the scour hole forms, flow separation zone in the lee of the dike was shortened. The mean streamwise velocity has been reduced, but both the lateral and vertical mean velocities are increased. In the meantime the turbulent intensity $\sqrt{\overline{w'^2}}$ near the bed has increased so much that the Reynolds stress $-\rho\overline{u'w'}$ near the bed is less important than the corresponding

turbulent intensity. At the dike section, the transverse mean velocity $\bar{v}$ has also increased due to flow contraction, which is accompanied with a large increase of $\sqrt{\overline{v'^2}}$ and $\sqrt{\overline{u'^2}}$. Downstream of the dike in the primary flow zone, turbulent intensity $\sqrt{\overline{u'^2}}$ has increased more than that of $\sqrt{\overline{v'^2}}$, while the increase in $\sqrt{\overline{w'^2}}$ primarily resides in the recirculation zone.

ABSTRACT

Synthetic velocity profiles are used to determine guidelines for sampling discharge with acoustic Doppler current profilers (ADCPs). The analysis allows the effects of instrument characteristics, sampling parameters, and properties of the flow to be studied systematically. For mid-section measurements, the averaging time required for a single profile measurement always exceeded the 40 s usually recommended for velocity measurements, and it increased with increasing sample interval and increasing time scale of the large eddies. Similarly, simulations of transect measurements show that discharge error decreases as the number of large eddies sampled increases. The simulations allow sampling criteria that account for the physics of the flow to be developed.

INTRODUCTION

Traditional methods for measuring discharge in rivers include mechanical instruments such as Price AA meters and tracer measurements using salt or dye. Acoustic Doppler current profilers (ADCPs) offer the advantage of increased spatial and temporal resolution of the velocity field, but sampling requirements regarding parameters such as the number of profiles, number of transects, and total measurement duration must be considered for transect measurements, in which velocity is measured as the instrument moves across the river, and mid-section measurements, in which velocity is measured by sampling at several fixed points.

Current practice in the U.S. Geological Survey (USGS) is to average results from four transects except when the flow changes rapidly (Oberg et al. 2005), but as Oberg and Mueller (2007) noted, no research had been done to support that choice of the number of transects. They compiled data from laboratory experiments and field measurements and concluded that the key parameter controlling the measurement uncertainty is the measurement duration rather than the number of transects. From the

data available to them, they suggested collecting at least two transects over a total duration of at least 720 s.

Although a criterion based on the measurement duration captures a key part of the sampling procedure, measurements of discharge also depend on the velocity profile, instrument characteristics, turbulence, and other sampling parameters. The profile of depth-averaged velocity is described by the channel width B, cross-sectional average velocity U, and the shape of the profile. The instrument noise, which will be taken to be Gaussian noise, can be characterized with the standard deviation σ_u. At a minimum, the turbulence must be described by a velocity scale, length scale, and kinematic viscosity ν. For open channel flow, the velocity and length scales of the large eddies can be related to the shear velocity u_* and depth H, respectively. To complement the work of Oberg and Mueller (2007) for transect measurements of discharge and augment it for mid-section measurements, we use synthetic profiles to account for some of these factors and provide guidelines for measuring discharge with ADCPs.

METHODS

The synthetic velocity profiles are constructed as the sum of a mean velocity profile $\bar{u}(y)$, ADCP noise $u_n(y,t)$, and turbulence $u'(y,t)$, where y is the transverse coordinate and t is time. The mean velocity is computed from the theoretical profile developed by Seo and Baek (2004):

$$\frac{\bar{u}(y)}{U} = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)}\left(\frac{y}{B}\right)^{\alpha-1}\left(1-\frac{y}{B}\right)^{\beta-1} \tag{1}$$

where $\Gamma(z)$ is the gamma function and α and β are parameters. The two parameters α and β determine the skewness and kurtosis of the profile: When $\alpha = \beta$, the skewness is zero; that is, the profile is symmetric about the channel centerline; as α increases in this case, the profile becomes more peaked. When $\alpha \neq \beta$, the profile is skewed; as α increases past β, the peak shifts from one side of the centerline to the other. Typical values of α and β range from 1 to 4.5 (Seo and Baek 2004).

ADCP noise is assumed to follow a normal, or Gaussian, distribution (Stacey et al. 1999)—that is, $u_n = N(0,\sigma_u)$, where $N(\mu_x,\sigma_x)$ is the normal random variable with mean μ_x and standard deviation σ_x. For the simulations using the data in Oberg and Mueller (2007), the standard deviation σ_u was taken to be 1 cm/s for modes 5 and 11, and it varies between 14 and 32 cm/s for mode 1. For mode 12 it varies between 6 and 115 cm/s, with a mean of about 29 cm/s. These values are somewhat larger than the specifications for the RD Instruments Workhorse Rio Grande (RD Instruments 2003).

A synthetic turbulent signal was constructed using an approach like that of García et al. (2005). This approach involves making a velocity signal that has a specified one-dimensional energy spectrum $E_{11}(k_1)$, where k_1 is the wavenumber in the streamwise direction. The spectrum can be computed from a model energy spectrum function $E(k)$, where k is the magnitude of the wavenumber (Pope 2000);

we use a form due to W.C. Reynolds, which rises as k^2 for wavenumbers smaller than some wavenumber k_L, includes an inertial subrange, and has a sharp cutoff at a viscous wavenumber k_v.

Specifying the energy spectrum requires specifying the turbulence Reynolds number $R_T = q^4/(\varepsilon\nu)$, or—given a value of the kinematic viscosity ν—the turbulent kinetic energy $q^2/2$ and ε, the rate of dissipation of turbulent kinetic energy. However, for practical use, these quantities should be related to easily measured or estimated parameters, such as the mean velocity and the depth. Relations from Nezu and Nakagawa (1993) can be used to compute depth-averaged values of turbulent kinetic energy and dissipation in terms of the shear velocity u_* and H:

$$\frac{\bar{q}}{u_*} \approx 2.03 \qquad \text{and} \qquad \frac{\bar{\varepsilon} H}{u_*^3} \approx 8 . \tag{2}$$

The shear velocity can be related to the depth-averaged velocity $\bar{u}$ by assuming a logarithmic velocity profile over a rough bed with equivalent sand grain roughness k_s:

$$u_* = \frac{\kappa \bar{u}}{\ln\left(H / e z_0\right)}, \tag{3}$$

where $z_0 = k_s/30$. The logarithmic dependence of the shear velocity on the relative roughness z_0/H shows that the shear velocity does not depend strongly on k_s.

For mid-section measurements, velocity signals at each point were constructed. Averaging the signals over enough samples and integrating the results across the channel yields the discharge estimate for the case of no turbulence and ADCP noise. Therefore, this procedure was used to determine the number of samples, or the averaging time, required for the average to converge to within 5% of the ultimate value. Because this averaging time itself is a random variable, the calculations were repeated 1000 times to determine a distribution, as well as mean and standard deviation.

For transect measurements, the simulations can help to evaluate and extend the work of Oberg and Mueller (2007), who used many sets of transect measurements collected in the field to recommend sampling criteria. Because the shape of the velocity profile is not given, two cases were considered: one with $\alpha = \beta = 1.25$ and one with $\alpha = \beta = 5$. Sample intervals were taken to be 0.5 s for mode 1, 0.6 s for modes 5 and 11, and 0.7 s for mode 12.

MID-SECTION MEASUREMENTS

Mid-section measurements offer the advantage of resolving the velocity profiles well at particular points. With enough samples, mid-section measurements with ADCPs will provide estimates of discharge that converge to the value obtained with perfectly measured velocity profiles, but that value is subject to the error in measuring the profile at a limited number of points, which can be determined from these simulations. In other words, the uncertainty in discharge caused by ADCP noise

and turbulence can be driven to zero by collecting more samples, but error caused by discretizing the profile will remain.

The simulations allow the averaging time for mid-section measurements to be determined and its dependence on various parameters to be investigated. For the examples given in Figs. 1a and b, averaging times for each profile vary from 50 to about 340 s. These values exceed the 40 s duration recommended for each velocity measurement in a mid-section measurement of discharge (Rantz et al. 1982, p. 141). The histograms of the averaging time, which was taken to be the arithmetic mean of 1000 values, are skewed to high values. For ADCP measurements, the practical implication is that for a particular realization or measurement, the required averaging time can be much larger than the mean from many realizations.

Except at smaller depths, the averaging time increases with increasing depth in both the case with fixed sample interval Δt and varying maximum velocity u_{max} and the case with fixed $u_{\max}$ and varying Δt. The averaging time also increases as the maximum velocity decreases (Fig. 1a). The larger averaging times required for larger depths and smaller velocities result from an increase in the time scale of the largest eddies. In the free surface region of channel flow, the length of the largest eddies scales as the depth H (Nezu and Nakagawa 1993, p. 71). The velocity of the largest eddies scales either with the mean velocity or the shear velocity u_*, which is proportional to the mean velocity. In either case, a relevant time scale can be formulated as $H/\bar{u}$, and therefore, as the time scale of the turbulence increases, the averaging time increases. In other words, the measurement must sample enough large eddies of the flow.

The averaging time increases as the sample interval increases (Fig. 1b). That is, even for measurements with the same large eddy time scale, the sample interval—or equivalently, the number of samples, affects the averaging time. One might expect that if all other parameters are fixed, the number of samples must be some particular value. However, at different depths, the averaging times in Fig. 12b vary by a factor that depends on Δt. The data in Figs. 1a and b can be collapsed somewhat by a dimensionally inhomogeneous expression, and a more satisfying expression that can be generalized is being sought.

TRANSECT MEASUREMENTS

Transect measurements offer the advantage of better spatial resolution. While the usual USGS guidelines for mid-section measurements require 25-30 sections, the transect measurements used in Oberg and Mueller (2007) had between 130 and 1250 points per transect. Therefore, the error in discretizing the velocity profile can be much smaller for transect measurements. The disadvantage is that far fewer samples are collected at each transverse location; the maximum number of transects in the sets compiled by Oberg and Mueller (2007) was 33 for a comparison between the ADCP and a Price AA meter. In normal practice, however, a typical number of transects in a discharge measurement is four.

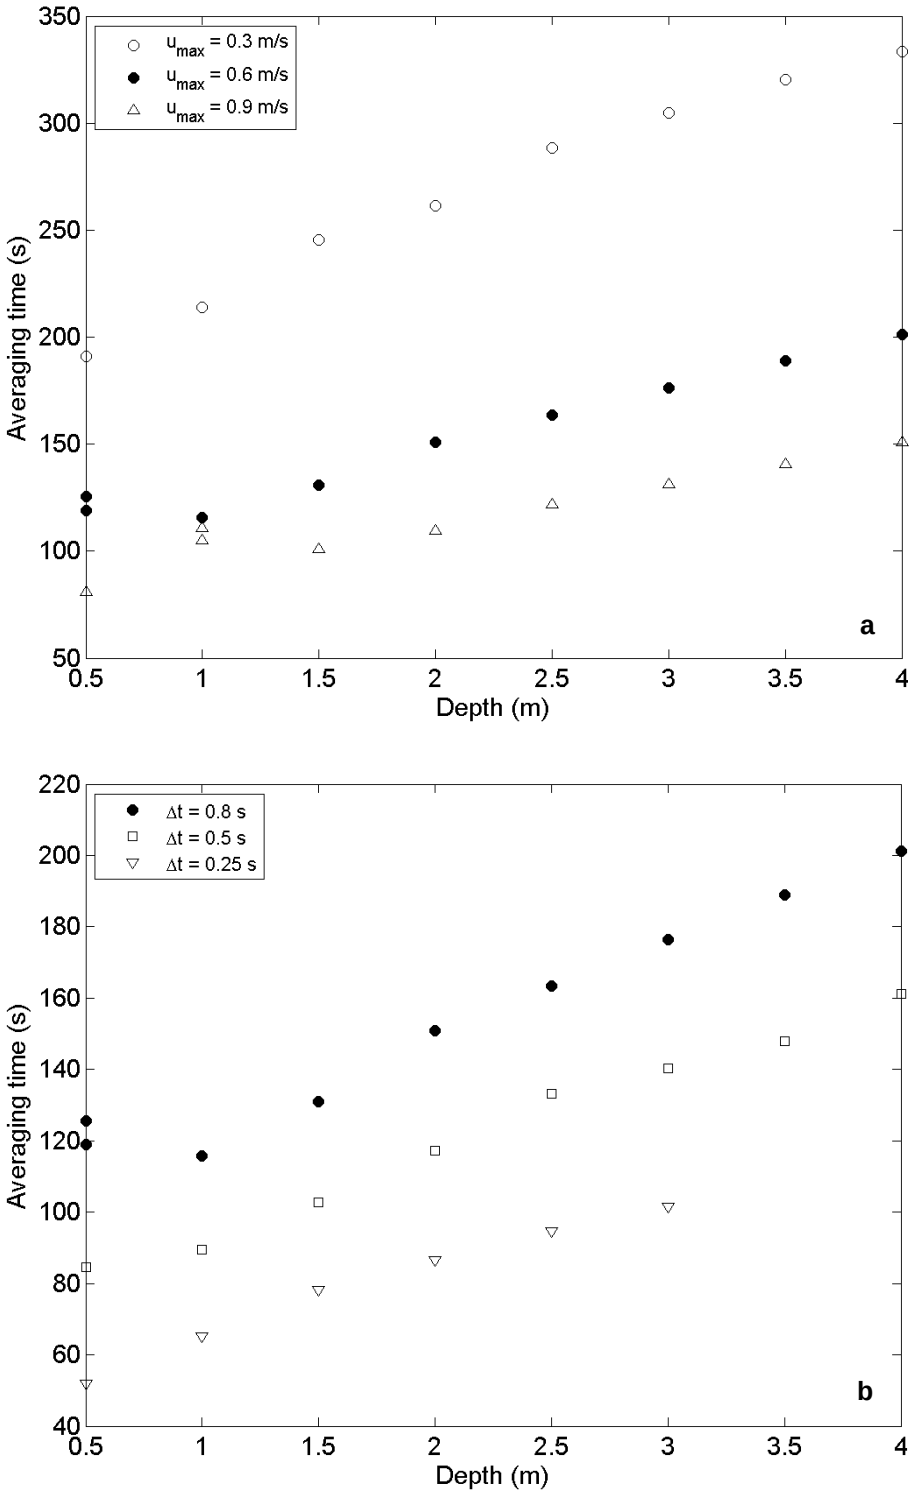

Fig. 1. Averaging time from the simulations of the section-by-section measurements. Each value is an arithmetic average over 1000 realizations. For both cases, $\alpha = \beta = 1.25$, $\sigma_u = 1$ cm/s, $k_s = 1$ mm, and the number of profiles was 10. In (a) the sample interval was set at 0.8 s, and the maximum velocity was varied, while in (b) the maximum velocity was set at 0.6 m/s, and the sample interval was varied.

As in Oberg and Mueller (2007), discharge error decreases with increasing total measurement duration. While the current guidance for discharge measurements specifies the number of transects, the field measurements collected by Oberg and Mueller (2007) showed that measurement duration was more important in determining uncertainty than number of transects. The simulations illustrate also this point (Fig. 2): Simulations with more transects but shorter durations can have larger uncertainty. The spread is smaller for the more uniform velocity profile ($\alpha = \beta =$ 1.25), but in both cases only a few cases with duration greater than the 720 s recommended by Oberg and Mueller (2007) have discharge error greater than 5%.

The discussion of the mid-section measurements and the potential usefulness of a dimensionless formulation suggest that testing other approaches is worthwhile. Two important time scales aside from the overall measurement duration T_s that emerged from the analysis of mid-section measurements were the sample interval and the time scale of the large eddies. Therefore, the discharge error could be analyzed in terms of the total number of samples $T_s/\Delta t$ or the ratio $u_* T_s/H$, which can be interpreted (up to a constant factor) as the number of large eddies sampled. Regarding the latter parameter, the discharge error decreases as $u_* T_s/H$ increases (Fig. 3); that is, as more large turbulent structures are sampled, the estimate of discharge improves. Although small error can occur for values of $u_* T_s/H$, except for three cases, errors do not remain less than 5% until $u_* T_s/H > 20$ when profiles are more uniform ($\alpha = \beta =$ 1.25) and until $u_* T_s/H > 40$ when profiles are less uniform ($\alpha = \beta = 5$).

The advantage of criteria based on total measurement duration or number of samples is that they are simple to apply. A possible disadvantage is that—even though the field data from Oberg and Mueller (2007) covered rivers with wide ranges of drainage areas, widths, depths, and velocities—the criteria might not apply generally. Because the criterion $u_* T_s/H > 40$ was developed from the same set of parameters, it also might not be general. Furthermore, it is more difficult to apply: One must estimate the shear velocity from a force balance for steady, uniform flow, from a logarithmic velocity profile (as in equation 3), or from some other approach. Fortunately, the depth and mean velocity can be estimated from preliminary ADCP measurements in the field, and the shear velocity does not depend strongly on the bed roughness, measured with either k_s or z_0. The key advantage of a criterion based on the value of $u_* T_s/H$ is that it accounts for the physics of the flow being measured. Therefore, it may be more general than a criterion based on measurement duration or the number of samples.

CONCLUSION

Synthetic velocity profiles were used to examine sampling schemes for discharge computed from mid-section measurements and transect measurements. Although field measurements provide the most reliable test of sampling schemes, the simulations allow the effects of some parameters or sampling issues to be isolated and studied systematically. The study of mid-section measurements with ADCP noise and turbulence focused on the time required for the average error to converge to the value in the absence of noise and turbulence; for the parameters considered, the averaging

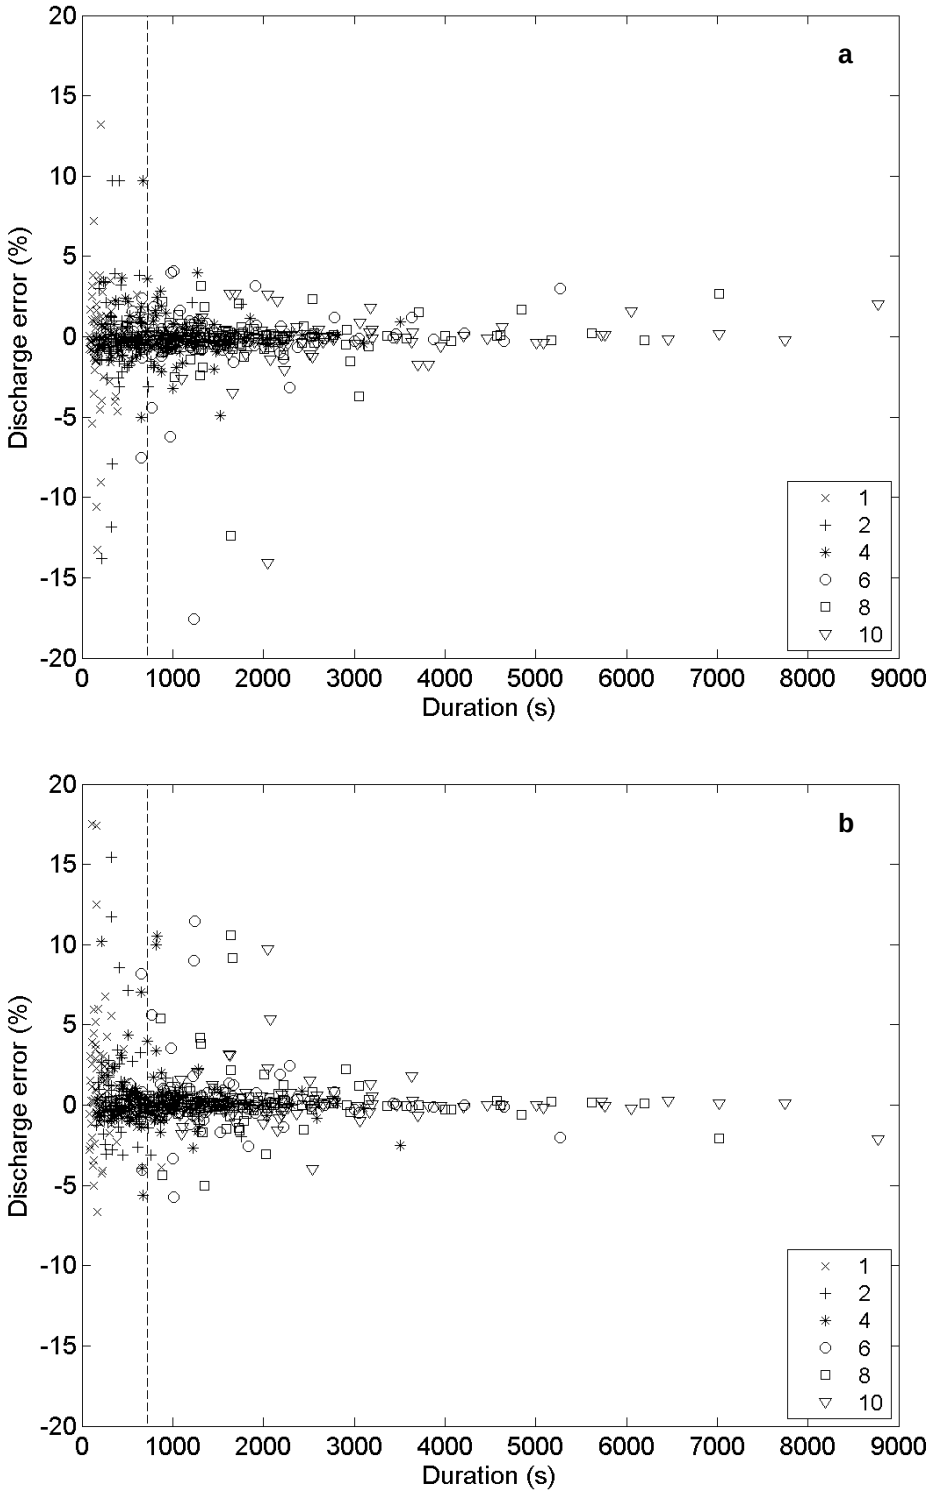

Fig. 2. Effect of measurement duration on discharge error. These plots are analogous to Fig. 5 of Oberg and Mueller (2007): (a) $\alpha = \beta = 1.25$, (b) $\alpha = \beta = 5$. The dashed line is the duration of 720 s recommended by Oberg and Mueller (2007), and the symbols indicate the number of transects in the average.

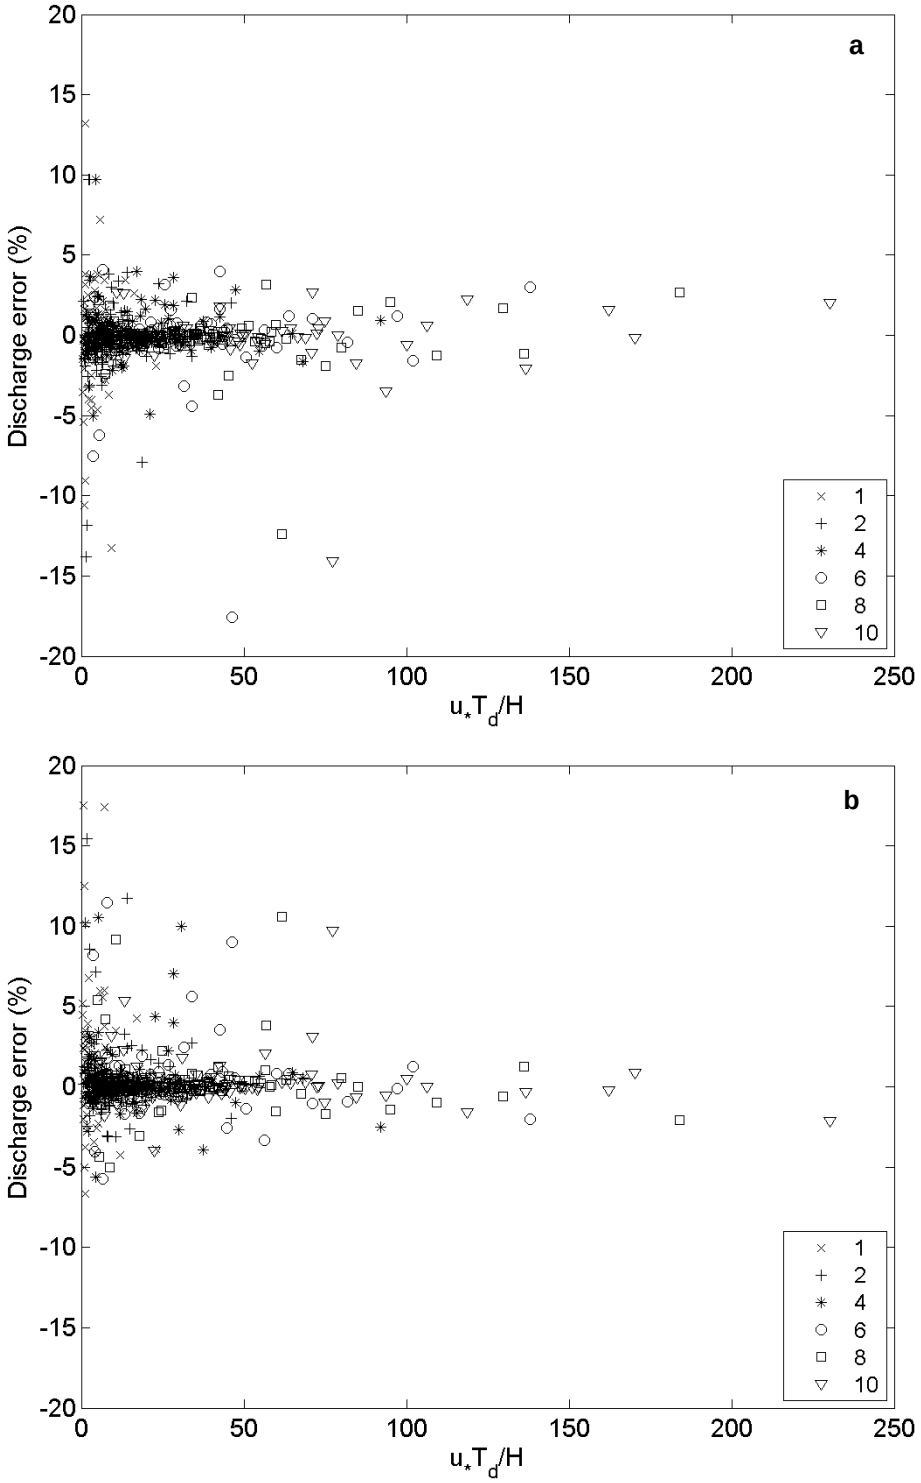

Fig. 3. Effect of the ratio of measurement duration and large eddy time scale on discharge error: (a) $\alpha = \beta = 1.25$, (b) $\alpha = \beta = 5$. The symbols indicate the number of transects in the average.

time required for a single profile measurement always exceeded the 40 s usually recommended for velocity measurements. The averaging time increases as the time scale of the large eddies, which is proportional to H/u_*, increases, and it also increases with sample interval. In general, mid-section measurements must sample enough large eddies of the flow.

Simulations of transect measurements with noise and turbulence complement and extend the analysis of field data by Oberg and Mueller (2007). Calculations mostly support the duration of 720 s recommended by Oberg and Mueller (2007). Also, the discharge error decreases as u_*T_s/H, which is related to the number of large eddies sampled, increases. For the cases simulated, most errors are less than 5% when $u_*T_s/H > 40$. Although the latter criterion requires some effort to apply, its key advantage is that it accounts for the physics of the flow being measured and therefore may be more general than a criterion based on measurement duration or number of samples.

ABSTRACT

The meta-heuristic techniques are optimization methods that allow the search beyond local minimums, which extends in many occasions the search field, and therefore, the capacity to obtain good solutions. The Harmony Search (HS) is a heuristic technique of optimization used for water distribution networks design.

Initially, the work displays the results of the HS on a water network studied in the literature (network of Hanoi). The results show the kindness of the method. Also is made a statistical analysis of the obtained solutions. This analysis allows verifying the values of the harmony parameters more suitable for the proposed method.

The second part analyzes the influence of harmony parameters in the velocity of the algorithm. The aim is to find the most suitable configuration of the problem, so that good solutions are obtained in the less time.

INTRODUCTION

The design of water distribution networks is extremely complex. It is well-known that when the diameters of the conductions are chosen as decision variables, the restrictions are implied functions of these variables of decision, so the space's region of solutions is a no convex type and the objective function becomes multimodal. Traditionally, water distribution network design, upgrade, or rehabilitation has been based on engineering judgement. Traditionally, water distribution network design, upgrade, or rehabilitation has been based on engineering judgement.

Howewer, in the last three decades a significant amount of research has focused on the optimal design of water distribution networks. Initially, researchers have used linear programming to optimize a design of a pipe network (Alperovits and Shamir, 1977). Later studies applied nonlinear programming to the network design problems. Some examples are Su et al (1987) that used non linear programming to optimize looped pipe networks or Lansey and Mays (1989), whose model was able to simulate pumps, tanks and multiple loading cases.

The application of heuristic techniques of optimization allows the search beyond these local minimums, which generally ample the field search and with it the capacity to obtain better solutions. The evolutionary algorithms are methods of search of solutions that are based in the natural beginning of the evolution. Inside the evolutionary algorithms, we can find Genetic Algorithms (GA), Particle Swarm Optimization (PSO), Ant Colony, Harmony Search (HS) and so on.

Some investigators have compared these techniques to each other (Zecchin et al, 2007), but it is difficult to say that one of them is clearly better than the others.

The Harmony Search Algorithm imitate the process of a band´s improvisation searching the perfect state of "harmony" (Geem, 2001). The Harmony Search has been applied successfully in many optimization problems (Lee, 2004; Mahdavi, 2006). In this case we apply the method to water distribution design, and the final solution will correspond to the combination of diameters that provides the smaller cost in a network. Previous works like those of Geem (2002, 2006) demonstrate the utility of the method for this kind of problems.

In the same way, other authors have tried to do improvements in the original algorithm, increasing the efficiency in the search minimums or in the speed. For example, Omran and Mahdavi (2007) present modifications on the original algorithm (Global-best HS). These modifications try to obtain a more efficient work of the algorithm in continuous and discreet problems.

The aim is to minimize the necessary costs of investment for the implantation of a certain system, starting from the topological layout and the demands and requirements of pressure in the nodes. This cost is associated to a goal function that will be evaluated in each algorithm iteration. Thus, each one of the possible diameters will represent a musical note and each one of the network conductions will be represented by an instrument. The combination of instruments and musical notes will provide a music sheet (solution) in each iteration.

Initially, the work show the kindness of HS method on the network of Hanoi. Also is made a statistical analysis of the obtained solutions. As it is a water network of important size and with a real layout, there is a wide range of solutions obtained with different models of design in the literature, which has allowed us to compare the results of the different models of design.

The statistical analysis of the solutions allows to optimize the HS parameters, so that we can establish the most suitable for the proposed method. A suitable combination of parameters not only provides better results in the cost of the network, but allows to make a smaller number of iterations until reaching the final solution. In this way the influence in the method of the parameters Harmony Memory Size (HMS), Harmony Memoy Considering Rate (HMCR) and Pitch Adjusting Rate is analyzed (PAR).

METHODOLOGY

Most of heuristic techniques are based on the imitation of natural processes. HS tries to imitate the improvisation process of a music band. The process consists of finding every time a better music sheet, which is represented by an objective function that there is to minimize.

The notes of every musical instrument determine the quality of the music sheet and the value of the objective function is the combination from all the musical notes that represent values of the decision variables.

The random character of the method does not guarantee a complete exploration of the space of solutions, nor supposes guarantee to reach a minimum of the objective function. However, the method offers a set of good solutions that try to improve.

In the method each one of the decision variables can have a rank of possible different solutions, which is represented with an alphanumerical variable (music note). The combination of these notes (variables of decision) composes a music sheet, that will be improved in the next iteration (to see figure 1). A music sheet represents a solution to the problem. This solution is constituted by a serial of notes that defines a unique solution of the optimization process

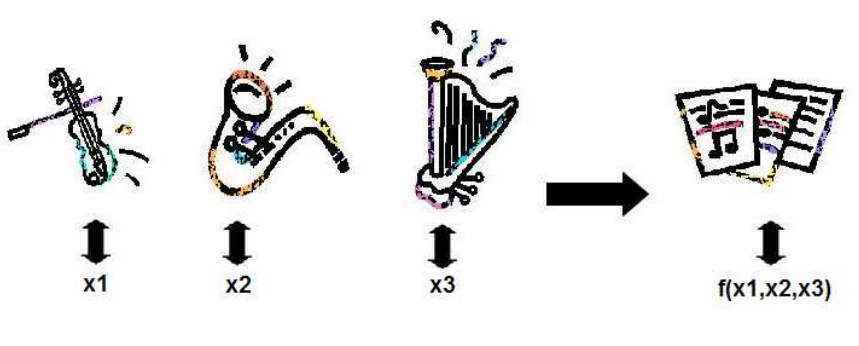

Figure 1. Composition of a music sheet

In the design of water distribution networks, each gene is represented with a number or a letter, that identifies the diameter of each one of the lines. In this paper the only network components that are considered are the pipes, but it is possible incorporate elements as pumps, tanks, valves and reservoirs without invalidating the algorithms.

In order to solve the optimization problem it is necessary to have a discrete set of possible solutions (musical sheet). This set of musical sheets is what also forms the harmony memory size. In HS a generic music sheet X is constituted by an equal number of notes to the number of decision variables (N_{VD}), so that generic sheet i of a memory is defined as a vector of numerical values.

$$X^i = \left\{X_1^i, X_2^i, \ldots, X_{N_{VD}}^i\right\}$$

The characteristic that measures "kindness" or capacity of a certain music sheet's survival regarding the others is known like aptitude. The aptitude of a certain generic sheet is identified through the value that adopts the objective function for the codified solution. In the case of the algorithm proposed for design and extension of distribution networks this objective function is defined as

$$F(X^i) = \sum_{j=1}^{N_{VD}} C_j\left(X_j^i\right) \quad L_j + \lambda \quad \sum_{s=1}^{N_S}\sum_{k=1}^{N_R} \delta_{k,s} \quad \left(H_{min,k} \quad H_{k,s}\right)$$

where C_j is the associated unit cost to the decision variable's value contained in link j of music sheet i; and L_i is the length of conduction of pipe j. Moreover, they are N_R imposed restrictions that must achieve the possible solutions of the problem. These restrictions have been including through a penalty in the total cost of the solution that later affects the aptitude of the music sheet. The restrictions that must be fulfilled are the derived ones to satisfy the restrictions with minimum pressure height ($H_{min,k}$) in each node k. These restrictions must be verified in all the analyzed scenes N_S, that usually are the on-speed operation of the system and its operation under the scene of failure of some of the conductions. The function penalty represents the difference between the

head height of the node k in scene s ($H_{k,s}$) and the required minimum height ($H_{min,k}$). In order to compute this penalty two variables are defined. One of them ($\delta_{k,s}$) is a binary variable that adopts value 1 if $H_{k,s} < H_{min,k}$, and it adopts null value in opposite case. The parameter λ represents a weight function that establishes the penalty's value for not verifying the restrictions of minimum pressure in the nodes. Pressure is considered as a hard constraint, and λ is big enough (10^7) for reject all solutions that violates the constraint.

The proposed method tries the evolution of a random population throught a parallelism similar to the improvisation process of a band in the search of a perfect music sheet. All the parameters of adjustment for HS will be specified from the beginning of the problem. For it an adjustment of three parameters of extreme importance is possible, as they are the harmony memory size (number of musical instruments), the Harmony Memory Considering Rate (HMCR) and the Pitch Adjustment Rate (PAR).

HS works with a sequential form. Thus, once given the value of the different parameters from optimization an assembly of scores is created of random way. Each one of these music sheets is composed by so many notes as variable of decision we have in the problem. A complete musical sheet provides a solution for the problem, with a certain value for the objective function.

The following iteration of the algorithm improvises a new music sheet X^i from the previous, considering HMCR and PAR. HMCR is the probability of choosing one value from the historic values stored in the harmony memory, and (1-HMCR) is the probability of randomly choosing one feasible value not limited to those stored in the harmony memory. An HMCR value of 1 is not recommended because of the possibility that the solution may be improved by values not stored in the harmony memory.

Every component of the new sheet is examined to determine whether it should be pitch-adjusted. This procedure uses the PAR parameter that sets the rate of adjustment for the note X^i_j. PAR is the probability of a note X^i_j changes it value. Thus, if the note is modified, the pitch adjust will be:

$$X^i_j \rightarrow X^i_j \pm \alpha$$

where based on the value of α the X^i_j note will increase (α =1) or will decrease (α=-1).

This way, the harmony memory size will have to be enough in order to guarantee the diversity of solutions, and, in addition, it must grow with the number of music sheet's bits. The main problem that is generated when using high memories is that convergence time of the algorithm is bigger. Therefore it is necessary to reach a commitment solution depending on the approach of the problem.

The following sections analyze the capacity of the proposed HS method to obtain equal or better solutions to the existing ones in the references. It has been analyzed the Hanoi network, determining the minimum cost of design them. Thus, working on the network of Hanoi, the influence of the different parameters has been analyzed on the final solution, dividing the work in two phases: First stage where the best combination of parameters in the obtaining of the minimum cost for the network is analyzed, and one second phase, where the influence of the parameters in the number of iterations is analyzed until reaching the final solution.

APPLICATION EXAMPLE

The analysis of the proposed model has been made on the network of Hanoi (to see Figure 4), propose by Fujiwara and Khang (1990). As it is a water network of important size and with a real layout, there is a wide range of solutions obtained with different models of design in the bibliography, which has allowed us to compare the results of the different models of design.

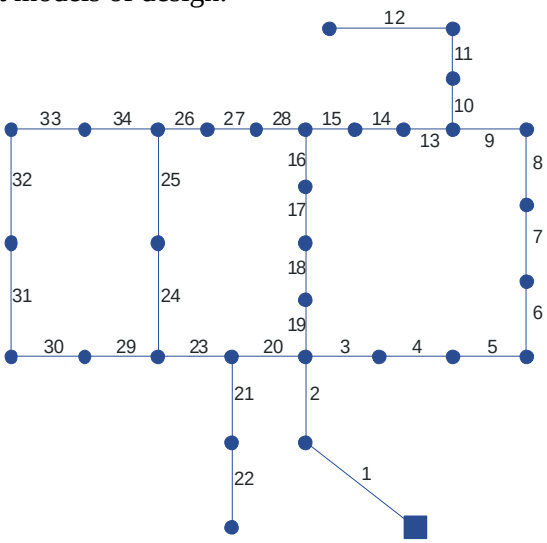

Figure 2. Network of Hanoi.

One of the characteristics that contribute to define the optimal solution of the network is the range of diameters used. For the study we used the original range of the bibliography.

Original range		
Nº Diameter	Diameter (mm)	Cost (um/m)
A	304'8	45'73

Highlighted in grey the diameters that are different from the proposed solution of Savic & Walters, that verifies the restrictions of pressure in the nodes..

Table 2. Comparison of diameters (mm) obtained as solution for the network of Hanoi.

If we rely on the obtained minimum value, we observe that the HS improves those of all his competitors but the one of Savic[2], in terms of the used heuristic method does not fulfill the pressure specifications. HS obtains like minimum cost 6.081 thousands of um. The rest of solutions that shows the table fulfills these specifications, consisting of which all the nodes have a pressure over 30 mca

ANALYSIS OF THE RESULTS

One of the main characteristics of HS is that it works in a random way. The characteristics of the method do not guarantee with certainty the obtaining of the optimal value of the system. In addition, the obtained result can suffer sometimes certain variations. In order to analyze this randomness it is necessary to make statistical analyses that will study the influence that have the different parameters from the HS algorithm proposed in the solution of the analyzed network, with the purpose of optimizing them to increase the probability of obtaining the minimum.

In a first study, the harmony memory size, HMCR and PAR were modified were modified to study the influence of parameters. For it they have been made 54000

simulations altogether. For the calculation of these simulations we use a computer system in parallel with 23 computers AMD Duron to 1400 MHz and 128 MB of ram.

The initial values are the recommended ones by Geem (2001). The harmony memory size go from 15 to 135 individuals, varying the HMCR between 0.88 and 0.92, and PAR between 0.05 and 0.015.

The histogram of figure 3 represents the total of simulations. This graph incorporates the accumulated probability of the obtained solutions. The graph allows to detect the more frequent solutions, as well as to determine the probability of obtaining a given solution better to one given. It is important to consider that the histogram represents the totality of obtained costs, and so they are including all the possible combinations of size of memory, HMCR and pitchrate, those that worse work, reason why it is even logical that the number of values corresponding to the minimum cost is not very high.

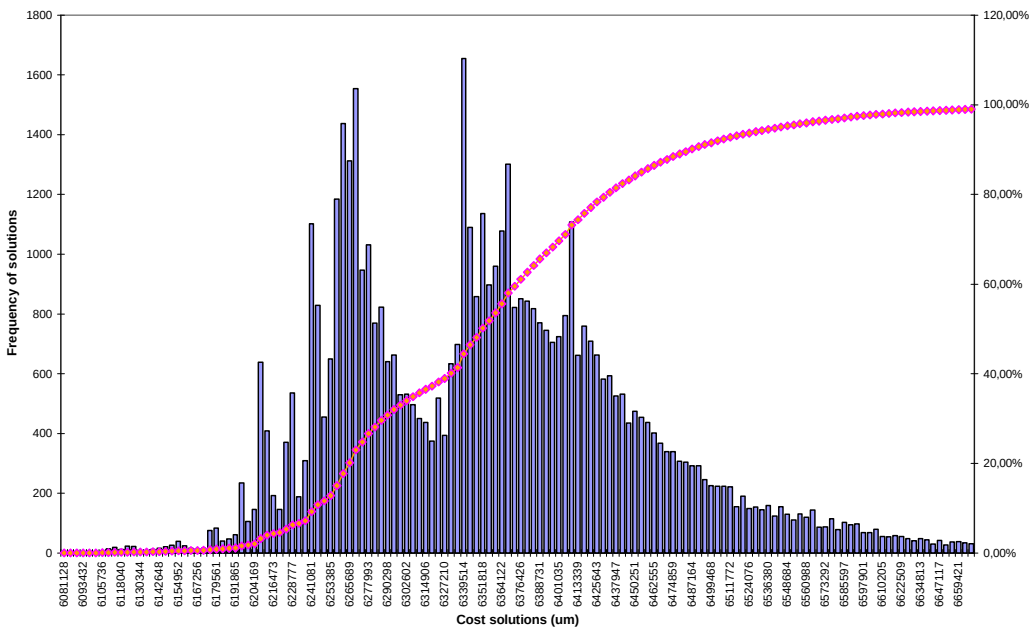

Figure 3. Histogram

In order to determine the influence of the different parameters in the obtaining of the minimum cost value, we adopted the solution corresponding to 6081 thousands of monetary units. This minimum was considered the optimal value of design. The optimal value of design is obtained only four times in the 54000 simulations that were realised. The concept of "good solution" is introduced now. One of the characteristics of the heuristics methods in general is the capacity to obtain not only one single optimal value, but to obtain a set of "good solutions" on the design problem. In this work "good solution" is defined with whose cost is over the minimum cost until in a 3%.

Figure 4 indicates the probability of obtaining a “good solution” for each combination of memory size and HMCR.

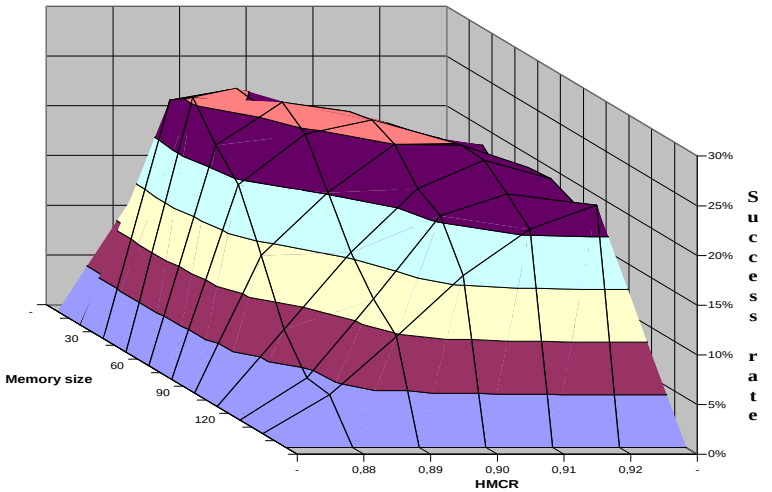

Figure 4. Probability of obtain a “good solution” (Memory Size vs HMCR)

Figure 4 shows that sizes of memory over 45 and below 120 are those that provide better results. In the same way, these memory sizes, combined with values HMCR of 0.89 and 0.90 give rates of success over 25%. This shows the capacity of the method not only to obtain minimum values, but also to obtain with relative frequency values very near the optimal one defined. Thus, Figure 5 indicates the probability of obtaining a “good solution” for each combination of memory size and PAR

Figure 5 shows that the used values of PAR do not have a great influence on the result of the simulation. In the other way, the results confirm that harmony memory size has a great influence in the final result of the simulation, since in the analyzed network sizes of memory between 45 and 90 provide higher probabilities of success.

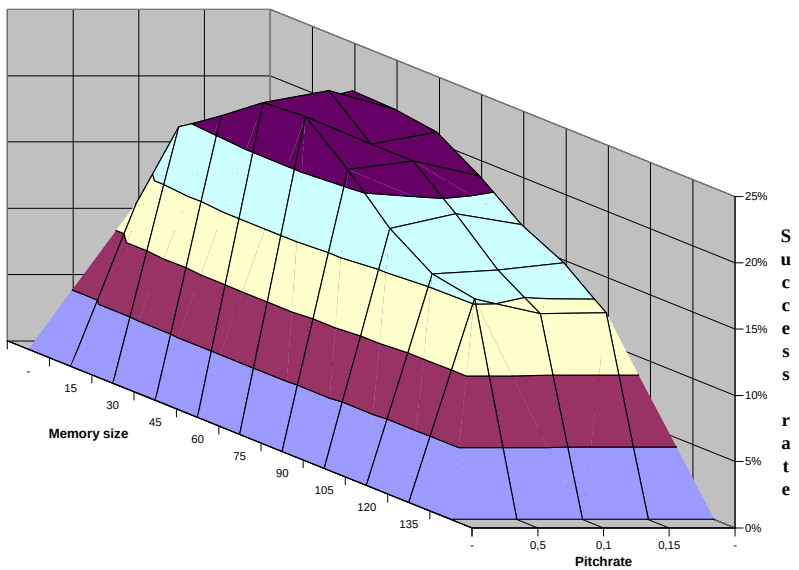

Figure 5. Probability of obtain a “good solution” (Memory Size vs PAR)

Another factor to consider when the optimal parameters of the method are chosen is the speed with which it calculates HS, since to choose values or others it influences in

the number of total iterations that HS makes before reaching the final solution. The graphs 6 and 7 represent the number of iterations that the algorithm realises in each case.

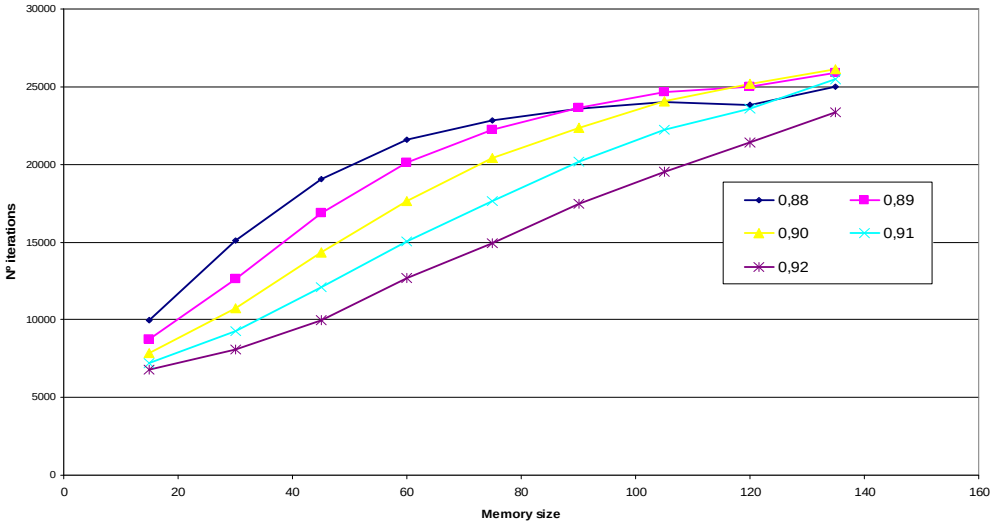

Figure 6. Number of iterations according to HMCR

Figure 6 shows that at the most great is the used size of memory greater number of iterations realise the algorithm before finding the final solution, and so the HS is slower. Thus, higher values of HMCR bring about an increase of the number of realised iterations in every simulation.

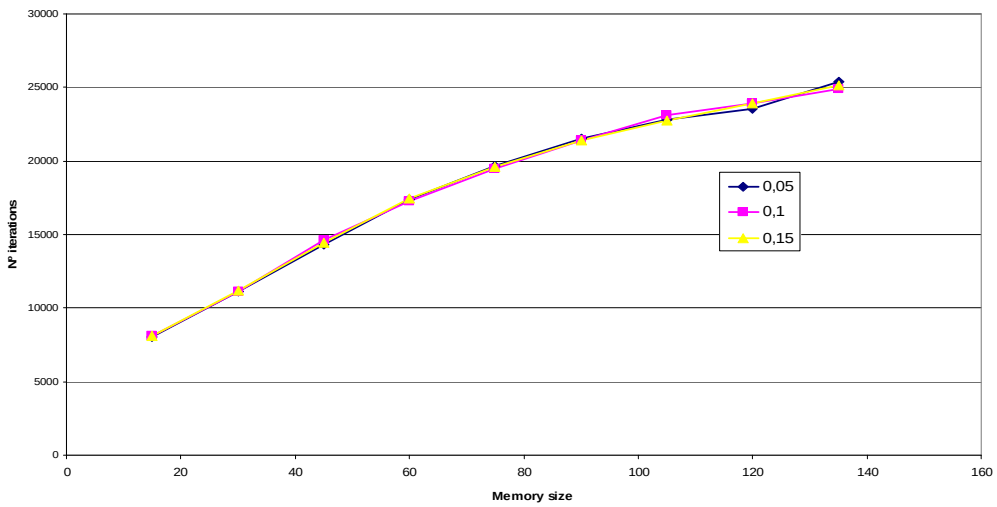

Figure 7. Number of iterations according to pitch rate

Figure 7 confirms the increase of the number of iterations realised by the algorithm when the size of memory is greater. Nevertheless, pitchrate in the studied values have not any type of influence in the number of made iterations, since the three series studied are superposed.

CONCLUSIONS

The economic design in the Water Distribution Networks is of great interest, as it allows us to choose a solution between the different alternatives that verify the imposed hydraulic conditions. In this work, the main objective consists of making the design of a water distribution network, using for it a method based on HS.

The objective of the economic design is to find the minimum cost for the analyzed network. However, it is possible to define the concept of "good solution". The statistical analysis for the different parameters from HS allows to conclude that:

- The size of the memory has a key influence in the obtaining of good solutions, because harmony memory sizes too high or too low make worse the yield of the algorithm.

  Thus, whichever greater is the memory size, greater is the number of iterations that the algorithm realises until finding the minimum, which makes the process slowly.

- For the studied values, PAR does not represent a great influence in the optimization process.

- In the studied network, values around 0.90 HMCR are the most suitable if the objective considers only to obtain good solutions of design. In the other way, whichever minor is HMCR greater number of iterations realises the algorithm, which makes the calculation slowest.

- The results are valid in the network of Hanoi. It is necessary the verification of these hypotheses in other models.

ABSTRACT

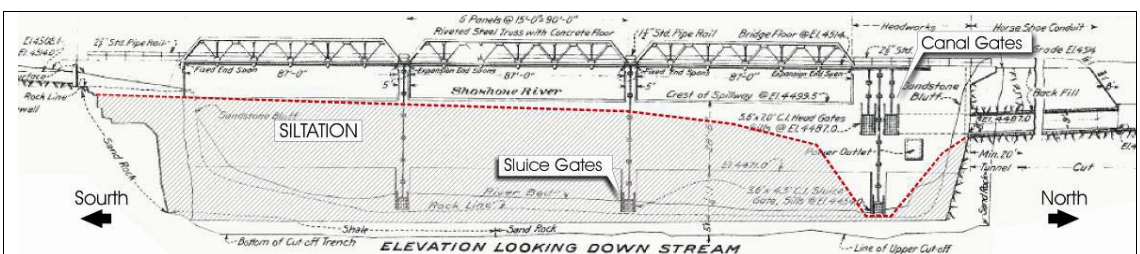
Willwood Dam was built in 1924 as a diversion dam for irrigation. It is a run-of-the river reservoir located at a developing point bar in Wyoming, U.S.A. Based on current operating criteria, the release flow is restricted by an allowable turbidity increase of 10 Nephelometric Turbidity Units (NTU) from upstream to downstream of the dam. Currently, two of the three sluice gates have been clogged by siltation. These limited sluicing capacities have increased the sedimentation within the reservoir and the irrigation canal network.

In this study, de-siltation alternatives combining dredging, sluicing, and flushing were recommended to achieve the dam's operation goals and restrict sediment accumulation. Three operation curves and three dredging alternatives were used to evaluate sediment flushing/sluicing performances by using GSTARS 3.01 models. This study presents an efficiency analysis of the de-siltation alternatives, the expected operation life, and recommendations for this dam rehabilitation project.

1. INTRODUCTION

1.1 General Information

Willwood dam is a concrete gravity dam, built in 1924 as a diversion dam for the Shoshone Irrigation Project. The dam is located on the Shoshone River in Park County, Wyoming, USA, as shown in Figure 1. Flow is diverted through the two 5.5 ft by 7.0 ft gates into the Willwood Canal which was initially designed to carry a flow of 320 cfs. The irrigation system covers an area of approximately 12,000 acres in the Willwood Irrigation District (WID).



Willwood Dam has a height of 70 ft, a weir crest length of 271 ft, and a total crest length of 476 ft. The weir crest is at elevation 4499.5 ft. Besides the two diversion gates, the dam has three sluiceways controlled by 3.6 ft by 4.5 ft cast iron sluice gates. The dam is founded on sandstone and partly shale.

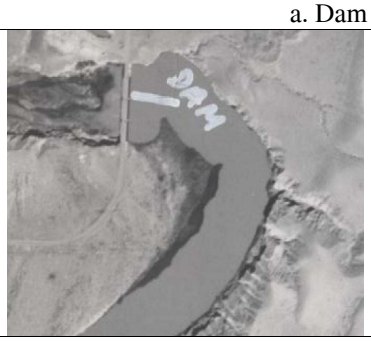


Figure 1. Location map of Willwood Dam in Wyoming.

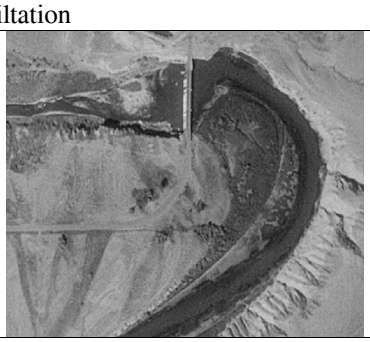
1.2 Fully Filled Siltation



Most upstream sediments have been trapped in the Buffalo Bill Dam. Sediment materials transported between the Buffalo Dam and the Willwood Dam are from channel bed erosion and bank erosion. Willwood Dam is located downstream of a sharp channel bend. A massive fluvial point bar has developed and narrowed the channel width from the left bank. The right bank is predominantly high and vertical rock cliff (Figure 2.a). Currently, only the diversion gates and the north sluice gate can be operated.

a. Dam face and current siltation

b. July, 1962

c. September, 1994

Figure 2. Willwood Dam siltation and field pictures

Siltation has nearly filled the dam and blocked the center and south sluice gates. The existing topography indicates that a flushing cone has formed in front of the north gate. Sedimentation is occurring at the toe of the south apron. Aerial photos from 1962 and 1994 (Figures 2.b and c) illustrate the progression of the point bar upstream of the dam. The siltation is impacting the function of the Willwood diversion system and poses a threat to the stability of Willwood Dam.

1.3 Reservoir Desiltation Studies

Building new reservoirs is rather difficult due to the new environmental regulations, high cost of construction, and lack of suitable dam sites. Therefore, techniques for reservoir desiltation have received increasing attention recently (Lai and Shen, 1996).

Some case studies for sediment routing, especially using flushing/sluicing, were done by Zyrjanov (1973) for the Ouchi-Kurgan Reservoir of USSR, Xia and Ren (1980) for the Heisonglin Reservoir of China, Wei (1986), Hong and Chen (1992), and Qian et al (1993) for the Sanmenxia Reservoir of China, Lin (1992), Hu (1995), and Su (1995) on sluicing activities in China, Un Ji (2006) in Korea, and Locher and Wang (1995) at Cowlitz Falls Dam in USA.

Reservoir sluicing and sediment management is often in conflict with water-use management (Brandt 2000, Fan and Jiang 1980). Three approaches, i.e., sluicing, flushing, and dredging can be used to remove reservoir sediments (Lai and Shen, 1996; Atkinson, 1996; and Talebbeydokhti and Naghshineh, 2004). These approaches are defined as (Atkinson, 1996, Morris and Fan, 1997, Brandt, 2000, and Talebbeydokhti and Naghshineh, 2004):

Sluicing: To discharge incoming sediments through the reservoir during high flows with heavy sediment concentrations without necessarily drawing down the water level.

Flushing: To erode and transport reservoir-sediment accumulation through the reservoir with drawing down the water level.

Dredging: To remove the reservoir sediment by mechanical means such as dredging and siphoning.

These methods were employed to evaluate the siltation removal alternatives in Willwood Dam. Desiltation by regulating flow is illustrated in Figure 3 for this study.

The Generalized Sediment Transport model for Alluvial River Simulation version 3.0 (GSTARS3) was developed by US Bureau of Reclamation (USBR) in 2002 (Yang and Simões, 2002). It is a semi-two-dimensional model using stream tubes, and can simulate sediment transport at a channel bend.

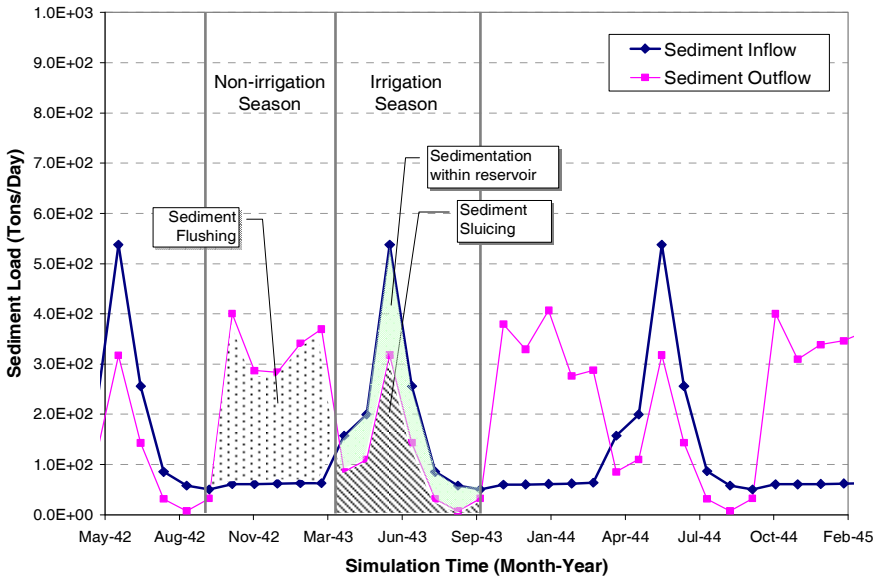


Figure 3. Sediment-graphs of sediment inflow and outflow by regulating flow.

1.4 Study Objectives and Scopes

Reservoir sedimentation has negative impacts on irrigation and environmental demands. Reservoir sediment removal can improve dam stability and dam operation, satisfy irrigation demand, extend dam operation life, optimize dam management and maintenance cost, etc. The scopes of this study are to analyze siltation impacts on dam safety and channel hydraulics; to evaluate the siltation impacts on current dam operations; to provide preliminary alternatives of siltation removal; and to suggest future studies to facilitate the dam rehabilitation project.

2. DAM OPERATION AND SILTATION DEVELOPMENT

The current Willwood Diversion Dam Operating Criteria was revised in 1982. The water level in the pool is maintained between the dam crest elevation of 4,499.5 ft and an elevation 4,500 ft. This is accomplished by first adjusting the irrigation intake gates to obtain the desired canal flow and then adjusting the sluice gates. The water level is maintained by opening the north gate first, then the center gate, and finally the south gate. From hydraulic sediment transport view points, this operation accelerated the point bar development at the left bank.

During the non-irrigation season, the criteria specifies that the water level should be held below the sill bottom of the irrigation canal gates to prevent the damages from ice forming. Since 1982, operations of Willwood Dam have been subject to an agreement executed by Bureau of Reclamation, Wyoming Department of Environmental Quality, and the Willwood Irrigation District. The increase of turbidity is limited to 10 Nephelometric Turbidity Units (NTU). When the increase of turbidity is more than 10 NTU, the sluice gate openings shall immediately be decreased until the increasing turbidity return to the legally allowable level. Consequently, the water level would exceed the canal gate sill, and additional suspended materials would be trapped within the reservoir.

The following comments were taken from Willwood Hydroelectric Project Feasibility Study (Stone & Webster Engineering Corporation, 1982):

> *"However, it is quite likely that this will seriously restrict sluicing as practiced in the past, resulting in a more filled-in reservoir with lower trap efficiency and higher sediment content in the irrigation system."*

The reservoir is almost entirely filled by siltation. Because of this, the Willwood Dam has lost its abilities of performing water level operations, siltation flushing and sluicing, and flow releasing. It cannot comply with the current operating criteria with only one sluice gate. During irrigation seasons, the north gate is completely shut down to refill water in the reservoir. River flows downstream over the dam crest, and a desired irrigation flow is taken from the canal gates. In winter, the water stages are several feet below the dam crest and higher than the top of the canal gates. Due to the high water stage, the sluice gate cannot flush sediment efficiently during winter causing accelerated sediment deposition in the reservoir. A dam inspection was made by the Bureau of Reclamation in 1982 indicated a significant loss of concrete downstream of the north sluice gate due to flow and ice passing over the crest. In order to improve the current conditions and achieve the operating goals, there is a need to increase the sluicing capacity and lower the water level during non-irrigation season.

3. AVAILABLE HISTORICAL DATA AND STATISTICAL ANALYSES

Flow discharges were gauged by U.S. Geological Survey (USGS) and USBR during different time periods. Sediment data were measured by USGS between 1979 and 1982. Flow turbidities were measured by WID between 1982 and 1989. A rating table of the sluice gates was referenced from the Willwood Dam Operating Criteria (1982). These records are explained and analyzed below.

3.1 USGS Flow and Sediment Concentration Data

Flow and sediment data from November 1979 to October 1982 were measured at USGS Gauge Station 06283800 (http://nwis.waterdata.usgs.gov/nwis/). The sediment samples show the measured suspended load and particle size distribution of the suspended material (Figure 4). The average particle size is approximately 0.063 mm which is classified as coarse silt.

The following empirical relationship between discharge and daily suspended load was developed using USGS suspended sediment data with a correlation coefficient of 0.73:

$$Q_s = 0.0015 \cdot Q^{1.7674} \quad (1)$$

where Q_s = total sediment load in tons per day, and Q = flow discharge in cubic feet per second.

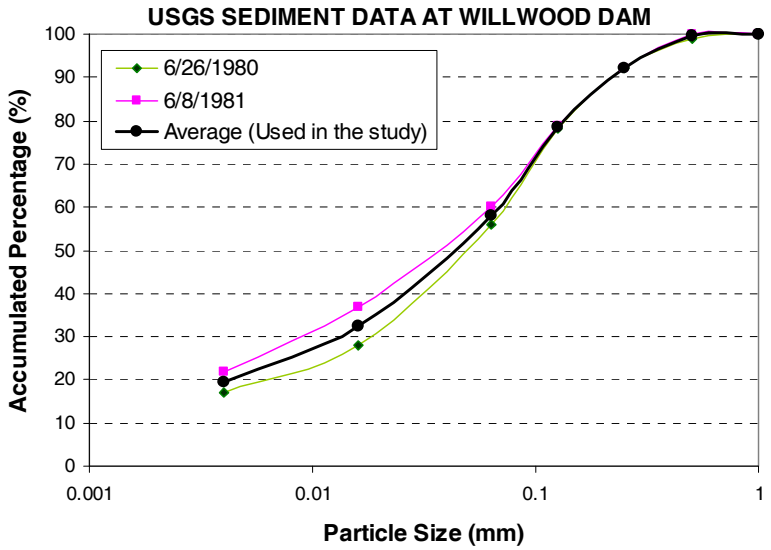

Figure 4. Particle size distribution of suspended material.

3.2 USBR Flow Data and Design Flow

USBR Gauge Station SRWY is located at the Willwood Dam crest and diversion canal to measure flows during irrigation seasons since 1996. The average river inflow is about 732 cfs during irrigation season. In non-irrigation season, river flow is primarily released from upstream Buffalo Bill Dam. According to the report of Willwood Hydroelectric Project (Stone & Webster Engineering Corporation, 1982), the flow in Shoshone River below Heart Mtn. Power Plant is 350 cfs in normal years.

Currently, the water demand for WID already exceeded this initial design capacity. In this study, the canal discharge record from 2005 to 2007 shows that the mean canal flow is about 320 cfs, and a flow of 400 cfs is approximately the maximum irrigation demand of WID. In this study, the monthly mean flows and a design irrigation flow of 400 cfs were used as design inflows during irrigation season. A constant flow of 350cfs was used as stream flow during non-irrigation season. Table 1 shows the monthly design flows used for sediment removal alternative simulations. Using Eq. 1 and monthly flows, sediment inflow of Willwood Dam is approximate 21,616 tons per year.

Table 1. Table of design flow for sediment transport modeling (Unit: cfs)

	Jan	**Feb**	**Mar.**	**Apr.**	**May**	**Jun.**
Canal Flow	0	0	0	400	400	400
Design Inflow	350	350	350	694	793	1386
	Jul.	**Aug.**	**Sep.**	**Oct.**	**Nov.**	**Dec.**
Canal Flow	400	400	400	400	0	0
Design Inflow	913	514	432	400	350	350

3.3 Willwood Irrigation District Flow Turbidity Observation

Generally, flow turbidity is proportional to suspended particles. However, only the flow discharges and NTU at upstream and downstream sampling points had been monitored and recorded without sediment concentration observation from 1982 to

1989. During this period, there are 497 records available. The relationship of flow discharge and NTU was studied and shown in Figure 5. When the release rate is less than 400 cfs, the passing percentage of the increasing NTU of less than 10 is 85%. This flow was used for design released flow during non-irrigation season.

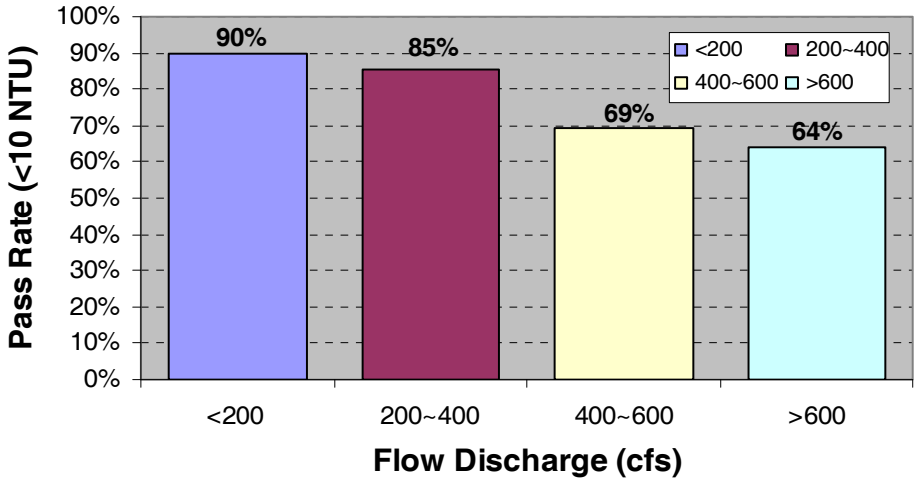

Figure 5. Flow and passing percentage of the increasing NTU's less than 10

3.4 Sluice Gate and Spillway's Rating Curves

3.4.1 Flow-Stage Rating Curve Equation of the Sluice Gates

Based on the flow rating table, on the Willwood Dam Operating Criteria (1982), the following sluice gate rating curve equation is obtained.

$$Q = C \cdot A\sqrt{2gH} \tag{2}$$

$$C = -0.0197 \cdot A + 1 \tag{3}$$

where Q = flow discharge in cfs; C = discharge coefficient; A = gate opening area in ft^2; g = 32.2 ft^2/sec, gravitational acceleration; and H = water depth from gate invert to water surface. Eq. (2) has a correlation coefficient $R^2 = 0.99$.

3.4.2 Flow-Stage Rating Curve Equation of Over-Topping Flow through the Dam Crest

The following standard weir formula is used to estimate the over-topping discharge through the dam crest. The discharge coefficient, C_w, is determined using USBR gauge flow data.

$$Q_{spillway} = C_w L H^{3/2} \tag{4}$$

$$C_w = 0.5619 \cdot \ln(H) + 2.1372 \tag{5}$$

where $Q_{spillway}$ = weir flow discharge in cfs; C_w = discharge coefficient; L = length of the spillway crest in ft; and H = upstream water head above the spillway crest in ft. The regression equations indicate close correlations with observed data with a correlation coefficient $R^2 = 0.70$.

4. PROPOSED DAM OPERATION

4.1 General Operation Constraints and Requirements

First, the sequence of operation of the three gates should be reversed to reduce the point bar development after dredging.

Second, WID requires approximate 55% of the mean daily river flow for irrigation during irrigation season. In order to satisfy all ecological and management objectives, three operation plans are recommended for this study, one for irrigation season and two for non-irrigation season.

Third, in order to reduce the possibility of cavitation or erosion at the gate sills, the sluice gates should remain open at least one foot.

4.2 Proposed Sluicing Plan and Dam Operation Curves

Sluicing can pass high flow with heavy sediment concentration during irrigation season and can also be used to reduce the probability of flow overtopping the spillway. By drawing down the water level, the flushing of sediment can be very effective in removing previous accumulated sediment and also to pass sediment inflow. It will be used during non-irrigation seasons. An efficient dam operation would present the maximum allowable flushing flows and minimum operation costs.

4.2.1 Irrigation Season Operation Curve

The south gate will be raised 1 foot initially when the reservoir water surface exceeds the dam crest. The discharge is approximately 200 cfs under this condition. The water surface should be stabilized at this elevation by adjusting gate opening. The recommended sequence of operations for the three gates and the relationship of flows and water stages are shown by an operating chart in Figure 6. Based on this operating, when released flow is greater than 2,200 cfs, all gates will be completely opened, and consequently, the water stage will exceed the dam crest.

4.2.2 Non-Irrigation Season Operation Curves

According to historical records, mean flow rate of 350 cfs should be maintained during non-irrigation season with a maximum released discharge of 400 cfs through the sluice gates. This would satisfy the limit of increasing 10 NTU. Flow would overtop the spillway crest when it exceeds 400 cfs. Two proposed operation plans were designed for non-irrigation season. The first plan is the normal operation by opening south and center gates. The operation chart is shown in Figure 7. In cases when the increase of NTU exceeds 10, the second plan will be take place using the south gate only. The operating chart is shown in Figure 8. The first plan has higher efficiency for sediment flushing than the second plan. Because of the limit of the increasing 10 NTU, a reduced released flow rate through gates will increase water stage within the reservoir.

Based on the proposed water level operation, the water stage is controlled at elevation 4499.5 during irrigation season, and at the elevation 4479.0 with a flushing discharge of 400 cfs during non-irrigation season. These values were used as the sediment transport model inputs.

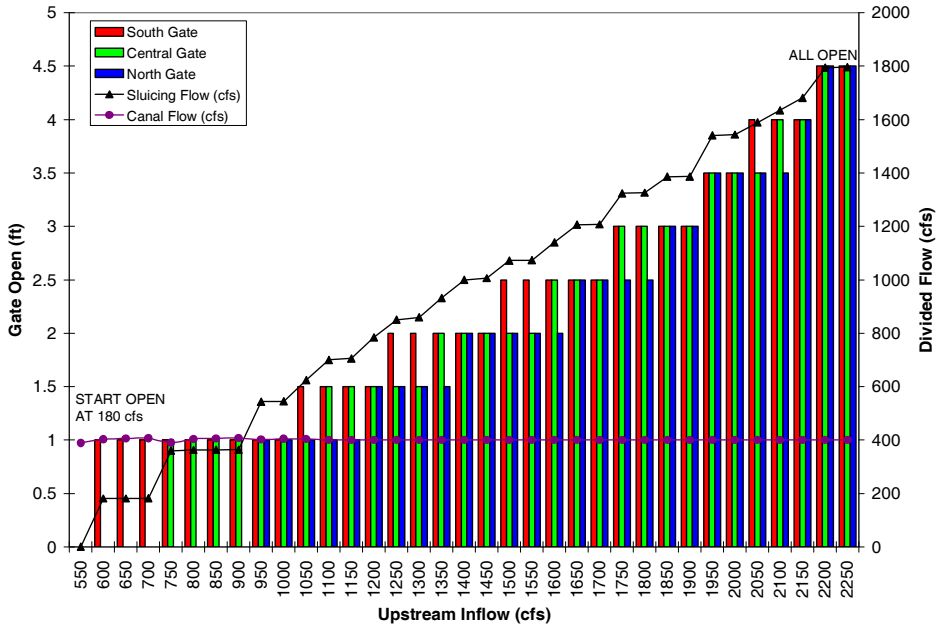

Figure 6. Proposed operation sequences of sluice gates during irrigation season.

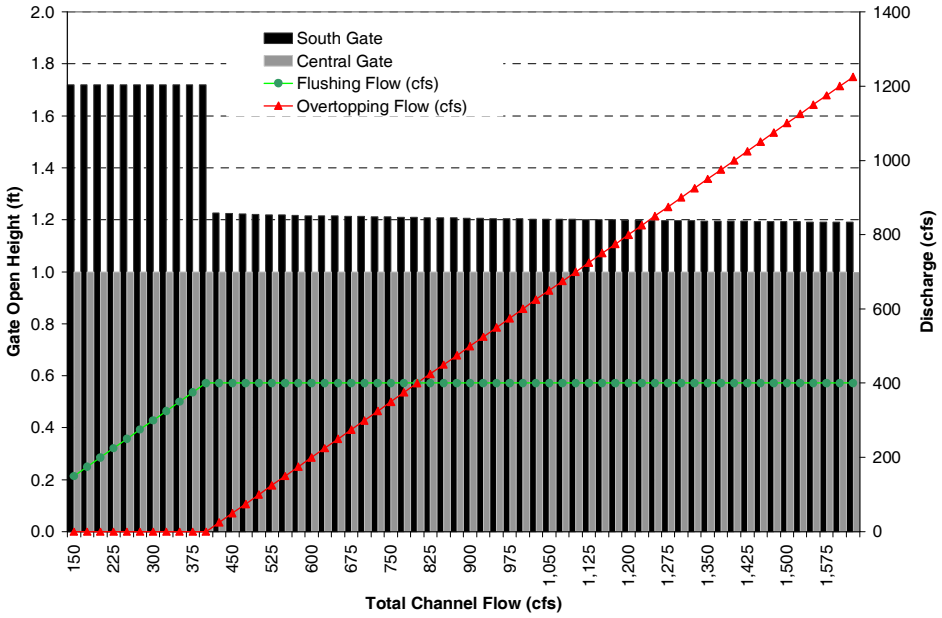

Figure 7. Proposed operation sequences of sluice gates during non-irrigation season (Increasing NTU <10).

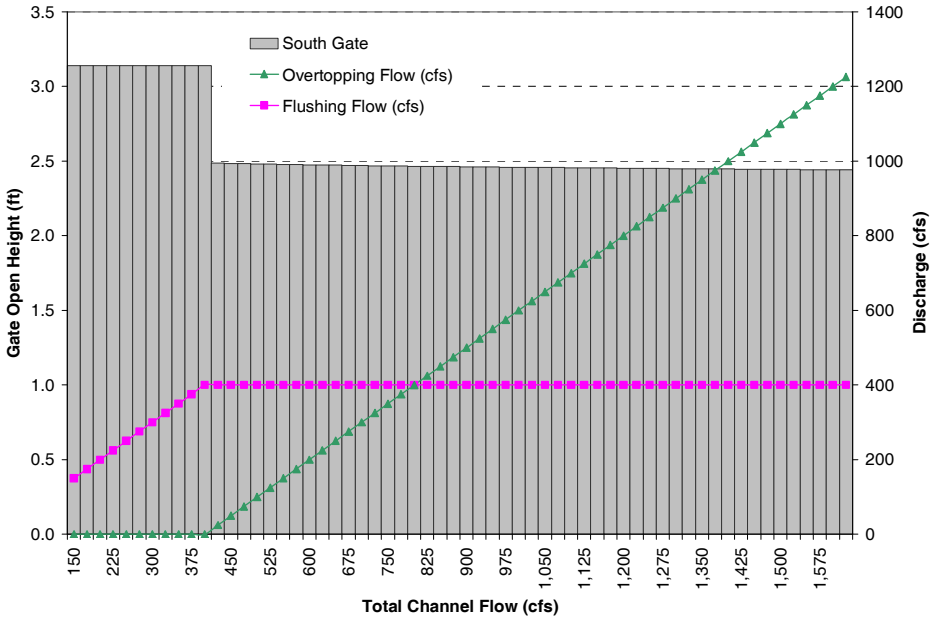

Figure 8. Proposed operation sequences of sluice gates during non-irrigation season (Increasing NTU >10).

5. SILTATION DREDGING ALTERNATIVES

The siltation threat at the upstream face of the dam is one of the primary concerns. For Willwood Dam, sluice gates are the only devise to remove sediment by river flow. Without removing the siltation in front of the clogged sluice gates and replacing sluice gates, Willwood Dam cannot restore its abilities of sediment sluicing and flushing. In order to accomplish the goals of rehabilitation and extend operating life, sediment removal is the first phase of the project. The proposed sediment dredging alternatives are described in the following sections.

5.1 Alternative I. Full Scale Removal

This alternative proposes to rehabilitate the reservoir storage using full scale dredging. It would construct a thalweg slope of 2% connecting the sluice gate invert to the existing channel bottom at the upstream end (Figure 9). Rock banks on both sides of the bank would be exposed in the initial design. Large quantities of sediment will be removed from the existing point bar while maintaining stable bank slopes. This alternative indicates that approximately 365,000 cubic yards of sediment would need to be removed. The rehabilitated reservoir storage would be 211,000 cubic yards at the canal gate sill (EL.= 4,487.0) and 396,000 cubic yards at the dam crest (EL.= 4,499.5). Simulated bed profiles are shown in Figure 9.

5.2 Alternative II. Partial Siltation Removal

The simulated results from Alternative I are used as inputs to a sediment transport model. The simulated results conclude an approximately equilibrium bed elevation of 4,480 will form at the dam in approximate 5 years. According to this equilibrium condition, Alternative II would dredge out sediments in front of the sluice gates and above the elevation of 4,480 ft (Figure 11). This alternative indicates that

approximately 255,000 cubic yards of sediment would need to be removed. The proposed reservoir storage would be 99,900 cubic yards below the canal gate sill and 276,500 cubic yards below the dam crest. After the gates begin sluicing, the reservoir bed condition would reach a balance condition.

5.3 Alternative III. Limited Siltation Removal in Front of Sluice Gates

Alternative III would minimize the dredging cost and replace the clogged sluice gates. This plan would remove minimal amount of siltation in front of the dam (Figure 13). No siltation removal would occur at the current point bar. This alternative indicates that approximately 45,500 cubic yards of sediment would need to be removed. The proposed reservoir storage would be 32,300 cubic yard at the canal gate sill and 90,000 cubic yards at the dam crest.

6. SEDIMENT TRANSPORT AND DESILTATION SIMULATION

Four simulations combining the reservoir routing and the sediment flushing/sluicing routing were used to determine the proposed operating life of Willwood Dam. The first three simulations are to individually use the dredging alternatives with the proposed water level operation. An additional simulation using current water level operating criteria with the full scale dredging plan was estimated to compare with other proposed alternatives. In this study, USBR GSTARS3 was revised and utilized to evaluate the sediment removal performance of each simulation. Routing including the use of sluice gate, operating curves, spillway, and diversion was developed and included into the revised GSTARS 3.01 (Yang and Shih, 2009). Detail procedures and simulation results are described below.

6.1 Model Input and Assumptions

The geometric inputs of three proposed dredging plans were utilized in the sediment transport models. Particle size distribution and resulting sediment rating from Eq. 1 were used for sediment inputs. Upstream conditions incorporate monthly mean flow discharges for river inflows. For downstream conditions, the proposed operation curves and current operating criteria were used for time-related controls of released flows and stage storage. Flow stage and discharge equations for spillway and sluice gate provided hydraulic facility inputs. Flow viscosity was calculated using an average water temperature of 53ºF. To simulate flow and sediment transportation distribution, three stream tubes were applied in the sediment sluicing/flushing modeling. Sluice gates are the only devise used to discharge sediment in the simulations.

The rock foundation of Willwood Dam at an elevation of 4454 feet was used as an erodible limit for modeling purposes. Based on the proposed channel alignment, a radius of 410 ft was used to compute the effects due to the channel bend. The time interval for flow hydraulics modeling is one month based the design monthly flows. The time interval of sediment transport modeling was 15 seconds. Total computed duration was 100 years for determining de-siltation efficiencies and a proposed operating life.

6.1.1 Canal Outlet Gate Rating Curve

A stage-discharge rating curve is required to simulate the WID canal gates. For this study, the following standard orifice equation is used.

$$Q = C \cdot A\sqrt{2gH} \tag{6}$$

where Q = flow discharge in cfs; C = discharge coefficient; A = gate opening area in ft^2; g = 32.2 ft^2/sec, gravitational acceleration; and H = water depth from gate invert to water surface. A discharge coefficient of 0.6 is a commonly suggested value and can be modified by observed data, if needed.

6.1.2 Sediment Transport Simulation

Willwood Dam is a run-of-the-river reservoir and is hydraulically characterized by a river mechanism. Because the sediment particles are mainly silt and sand, the sediment transport equation, revised Ackers and White equation (Wallingford, 1990, and Yang and Simoes, 2002), was used to represent sediment transport capacity within the study reach. It is

$$C_w = A \cdot G\frac{d_s}{h}\left(\frac{V}{u_*}\right)^B\left(\frac{C}{D}-1\right)^E \tag{7}$$

where, C_w = sediment concentration by weight; d_s= particle size; u_* = shear velocity; h= flow depth; G=specific gravity of sediment, and

$$C = \frac{{u_*}^B}{\sqrt{(G-1)gd_s}}\left[\frac{V}{\sqrt{32}\log(10h/d_s)}\right]^{1-B} \tag{8}$$

For 1.0< dimensionless particle diameter, $d_* = \left(\frac{(G-1)g}{\upsilon^2}\right)^{1/3} d_s$ <60,

$$\log A = -3.46 + 2.79\log d_* - 0.98(\log d_*)^2 \tag{9}$$

$$B = 1.0 - 0.56\log d_* \tag{10}$$

$$D = \frac{0.23}{d_*^{0.5}} + 0.14 \tag{11}$$

$$E = \frac{6.83}{d_*} + 1.67 \tag{12}$$

For d_* >60

$$A = 0.025 \tag{13}$$

$$B = 0 \tag{14}$$

$$D = 0.17 \tag{15}$$

$$E = 1.78 \tag{16}$$

6.2 Simulation Results and Comparison

6.2.1 Results of Alternative I: Full Siltation Removal

The simulated profile shown in Figure 9 illustrates that a wedge-shaped deposition and flushing cone would form near the upstream face of the dam. The top elevation of the siltation wedges is approximately 4,478 ft. Figure 10 shows the simulated cross section variations at the channel bend. While siltation is rising, secondary flow effect at the channel bend is becoming more significant. A new cross-sectional pattern within the main channel is formed by cutting into the deposits near the right bank after siltation elevation reaches the drawdown water level. Therefore, the flow during non-irrigation season is the dominant flow for the new channel forming. Consequently, the sediment along the left bank would be accumulating faster than at the right bank. As the cross section narrows, secondary flow will enhance the point bar development at the inner bank. The point bar sedimentation is mainly developed during irrigation season because of a higher operating water level. The channel thalweg will meander closer to the right bank mimicking current conditions.

6.2.2 Results of Alternative II: Partial Siltation Removal

The simulated profile and cross section variations for Alternative II are shown in Figures 11 and 12. A wedge-shaped deposition and flushing cone would form near the upstream face of the dam. Due to secondary flow effect, the simulated cross sections indicate that the channel thalweg would also meander closer to the right bank after siltation elevation reaches the drawdown water level.

Comparison between the Alternatives I and II indicates that Alternative I provides more reservoir storage than Alternative II. With Alternative I, siltation would take approximate 10 years to fill the reservoir volume and reach the elevation of 4,478 ft. In Alternative II, sedimentation would accumulate faster than Alternative I.

6.2.3 Results of Alternative III: Limited Siltation Removal in Front of Sluice Gates

The simulated profiles of for Alternative III are shown in Figures 13. Because the dredged profile cannot provide an efficient slope for sediment flushing, the siltation would raise up to the elevation of approximate 4,491. Refer to Figure 14, the simulated cross sections indicate that the new siltation would deposit on top of the historical siltation. A high and steep flushing corn would appear in front of the dam. These indicate that this alternative might form an unstable bed profile and flush high sediment concentration during non-irrigation season.

Compare to Alternatives I and II, Alternative III does not provide any storage for sedimentation. Based on this alternative, a high concentration flushing would require government permitting or agreements to perform the short duration flushing during non-irrigation season. In addition, there is still a high risk for the new sluice gates to become blocked in the near future.

6.2.4 Results of Simulation Using the Current Operating Criteria with a Full Siltation Removal

The simulated profile and cross section variations are shown in Figures 15 and 16. Because the current operating criteria require higher operating water levels than the proposed, the flow profile hydraulically performs a less sediment flushing efficiency than the proposed water level operation. A higher wedge-shaped deposition and flushing cone would form near the upstream face of the dam. Siltation would be quickly accumulated and reach the canal gate invert in approximate 10 years. The simulated cross sections of 80 year and 100 year are approximately similar with the current siltation in the field. Comparison of the current operating criteria and the proposed reservoir operation, the simulations indicate that using the proposed operation with the proposed dredging alternatives would perform at lower elevations of the siltation top. This indicates that the drawdown water level of sediment flushing is a significant factor for sedimentation geometry within the reservoir.

6.2.5 Comparison of desiltating efficiencies

Efficiency of flushing sediment through the reservoir is important in determining the feasibility of flushing operations (Talebbeydokhti and Naghshineh, 2004). With respect to the amount of water usage and the value of flushed sediment, flushing efficiency F_e is defined as (Lai and Shen, 1996, and Brandt, 2000)

$$F_e = \frac{V_{os} - V_{is}}{V_w} \tag{17}$$

where V_{os} = volume of flushed sediment in the time interval Δt; V_{is} = newly-added volume of deposits from the upstream sediment supply in Δt, and V_w = water volume used in Δt. In this study, flushing efficiency of the four cases are estimated over time as shown in Figure 17. The flushing efficiency is approximately less than 0.01% in average because of the constraints of a low flow during the non-irrigation season and the limit of turbidity by increasing 10 NTU. The results indicate that Alternative II with using the proposed reservoir operation appears to be the most efficient de-siltation plan using river flow. The worst efficiency in the first 60 years is the one using the current operating criteria. The flushing efficiency of Alternative III with using the proposed operation would decrease over time and then, become the worst than other plans after 60 years.

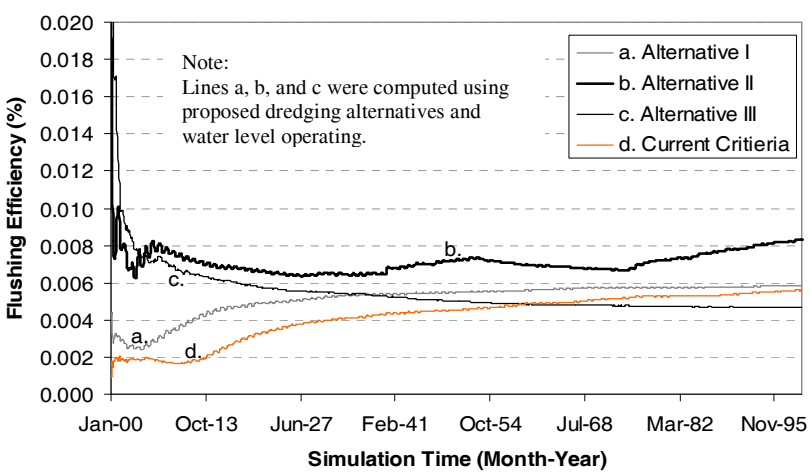

Figure 17. Flushing efficiency v.s. simulation time.

6.3 Proposed Operating Life

The challenge in the evaluation of projects which promote sustainability of reservoirs is to determine realistic reservoir life (Palmieri etal, 1998). Based on the considerations of the proposed dam operation, sediment transport modeling, the general design life of the mechanical equipments, siltation stability, and upstream condition changes, a proposed operating life selecting Alternatives I or II with the proposed reservoir operation is estimated to be at least 50 years.

VII. CONCLUSIONS AND RECOMMENDATIONS

The conclusions and recommendations are described in following sections.

7.1 Conclusions

1. In order to restrict the point-bar development and increase the sediment flushing/sluicing efficiency, a combination of siltation dredging and revising the reservoir operation were recommended to perform a long term operation. According to water turbidity samples, the maximum allowable released flow of 400 cfs should be used in conformity with environmental regulations during non-irrigation season and to optimize sediment sluicing and irrigation during irrigation season. These revisions could result in a better flushing efficiency than the current dam operating criteria and would decrease the expense of regular maintenance.
2. Based on limit information available, GSTARS 3.01 model was used to simulate the processes of sediment transport and siltation sluicing/flushing behind the Willwood Dam as well as simulated the sediment transport at the channel bend by using stream tubes.
3. According to simulations based on the dam operations and siltation dredging alternatives, the proposed reservoir operation and the siltation dredging Alternative II would perform the best flushing efficiency and would provide an estimated operating life of at last 50 years
4. Reservoir operation significantly affects siltation formation in the reservoir. According to simulation results, they indicate that siltation elevation at the upstream face of the dam is mainly dominated by water level drawdown during non-irrigation season.

7.2 Future Phases

To evaluate possible alternatives, operating revisions, study reliability, and expected project goals, the following items need to be addressed to provide a comprehensive study plan for this project: 1. Sediment sampling for sediment transport model revision and calibration based on past-rehabilitation conditions.; 2. Canal gate flow discharge coefficient calibration.; and 3. Dam operating criteria revision.

Acknowledgements

This paper is based partially on work supported by Engineering Associates, Willwood Irrigation District, and Wyoming Water Development Commission, Wyoming, U.S.A. The authors appreciate the supports and cooperation of the irrigation district manager, Tom Walker, and his staff with useful historical information and data. The financial

support provided by Chris Abernathy, Project Manager of the Wyoming Water Development Commission was critical to the study.

Abstract

Reservoirs store water for many important purposes in today's world, including culinary, irrigation, recreation, and flood control. In order to ensure that this valuable resource is wisely utilized, the discharge from reservoirs must be managed through accurate flow measurement. Unfortunately many reservoirs do not have measurement structures that allow flows to be monitored or accurately managed. It is not uncommon to have reservoir discharge set by historical arbitrary methods, such as opening a valve a certain number of turns on a certain day or keeping downstream river banks or channels at a certain elevation. While historical methods are better than nothing, consistent releases in these cases usually depend on constant reservoir head or stable stream beds.

In cases where reservoir discharge flow measurement equipment is available, special care must be taken to ensure that the flow measurement equipment is properly maintained and the flow measurements are performed correctly. Multiple methods or types of flow measurement are commonly used to measure discharge release from reservoirs. These include but are not limited to rated sections, flumes and weirs for open channel discharge or magnetic and ultrasonic meters for pressurized pipes. This paper discusses various types of measurement errors that are commonly found in field applications and the need for regular calibration and maintenance. The paper also addresses when standard calibrations or discharge rating tables can be used, and when custom calibrations are necessary. Small inaccuracies may appear to be insignificant, but over time can accumulate to large volumes of mismanaged water. Field data is used to demonstrate and contrast both accurate and inaccurate flow measurements and how each affects water users and contributes to reservoir management.

Introduction

Most dry and arid regions of the world deal with problems related to limited water resources. To enable water to be stored and used over time dams are constructed to create water storage reservoirs. Reservoirs were built in large quantities during the mid-twentieth-century, when the United States built a large number of dams on all scales (Nicklow, 2007). Where dams are built to release water over time it is essential that the release of reservoir water be accurately monitored to enable appropriate distribution over the longest available period. Releasing too much or too little water may result in shortages or unexpected losses due to mismanagement. Unfortunately no work has been found by the authors that directly discusses reservoir release and its accuracies. This paper will discuss the types of measurement devices that are available for monitoring reservoir releases, their expected accuracies, and what can be done to correct any inaccuracies.

Measurement Methods

It is not uncommon for reservoirs to have no accurate method to measure the discharge or release from the reservoir. In some cases, historical methods are the only way known to manage the reservoir. From field experience it has been found that one common type of historical reservoir management is to open the low level outlet valve a certain number of turns on a certain day. The same method issued from year to year is passed down from one reservoir operations manager to another. It may even be recorded or written on the wall next to the low level outlet works. Another common method that has been found in the field is to mark a height in the downstream channel and release water according to the depth of flow during a certain period of time. Although historical and habitual methods are better than nothing, great inaccuracies can occur using these approaches and water is easily mismanaged. To help water distributors and reservoir operators manage the release of water, many open channel and closed conduit measurement structures or devices are available. These structures should be designed and built during construction but in necessary, can be added to already existing systems.

Open Channel Measurement Methods –

Open channel measurement structures vary widely depending on specific applications. Even though many open channel measurement devices are available, this section focuses on just rated sections, long throated or ramp flumes, and parshall flumes.

Rated Sections – Rated sections consist of stage height vs. elevation charts or graphs. These charts and graph are site specific and are created using the velocity-area principle (USBR, 2001). Current meters are often used to determine the mean velocity of the channel or stream. The mean velocity is then multiplied by the area of the cross section at the particular stage. Several stages must be completed and combined to form a rating curve for the specific site. Rated sections can be accurate

to +/- 10 percent, but this accuracy often decreases over time unless consistent ratings are performed (USBR, 2001).

Long Throated or Ramp Flumes – These flume types are emerging as a new and efficient open channel flow measurement device because of their simple shapes and ease of install (Bos et al., 1991). Long Throated flumes are typically site specific having unique dimensions and sizes based on channel geometries or design discharges. Long throated flumes often consist of a ramp placed into the bottom of a channel with a staff gauge and stilling well installed upstream to measure head. When properly calibrated long throated flumes can be accurate to +/- 2 percent up to 90 percent submergence (USBR 2001).

Parshall Flumes – Parshall flumes were developed at Colorado State University from 1915-1922 as a simple way to measure discharge in open channels (Cone, 1917; Parshall, 1926; Merkley, 2008). Parshall Flumes consist of a flat sill that is converged to a set throat width that correspondingly forces the water to pass through critical depth. Parshall flume sizes are available from 1 inch to 50 feet, and unlike many other structures geometric similarity does not exist, meaning that a 1-foot flume is not a scaled version of a 20-foot flume. Because of the lack of similarity, each specified flume size has its own calibration and corresponding rating curve. Parshall flumes can be accurate to +/- 3_to_5 percent up to 50 percent submergence on flumes with 3 inch throats or less; and +/- 3_to_5 percent up to 80 percent submergence on flumes with throats greater than 8 ft (USBR, 2001).

Pressurized Conduit Measurement Methods –

Another common method for flow measurement occurs in pressurized conduits. These measurement devices are often installed on the outlet works of the reservoir. Many different devices are available for measuring flow in pressurized conduits. This section focuses on two of the most commonly used devices to monitor reservoir release; magnetic flux and ultrasonic flow meters.

Magnetic Flux Meters – These meters use the principle of Faraday's law of induction to calculate a flow passing through a closed conduit. As a fluid passes through an applied magnetic field an electrical voltage is generated that is directly proportional to the speed of the passing fluid (Repas, 2007). Magnetic Flux meters contain no moving parts and can vary in size from 0.1 to 72 inch. When properly installed and calibrated, magnetic flow meters can be accurate up to +/- 0.25 percent of the upper range flow boundary (Miller, 1996).

Ultrasonic Meters – These meters emit sounds waves that propagate through the fluid and can be installed without intrusion of the flow area. Ultrasonic meters come in two varieties doppler and transit time. Doppler ultrasonic meters send ultrasonic signals across the pipes and measure the frequency change due to the movement of particles in the fluid. Transit time ultrasonic meters send sound waves across the conduit and measure the time difference between the sound waves traveling upstream

compared to those traveling downstream (Miller, 1996). Ultrasonic meters are available from 1 to 108 inch depending on transducers and meter type, and offer accuracies of up to 1_to_5 percent of the upper flow boundary (Miller, 1996).

Open channel and closed conduit flow measurement devices are installed in the stream bed immediately downstream of the reservoir, or the low level outlet works to reservoirs respectively. Unfortunately, flow measurement devices require that design specifications and installation procedures be correctly followed, if not accurate flow measurements are rarely possible. Table 1 below contains a summary of the flow measurement devices discussed in this paper and their specified accuracies if design requirements are met.

Table 1 - Summary of Flow Measurement Devices

Measurement Device	Type	Accuracy
Historical Methods	Either	-
Rated Sections	Open Channel	+/- 10%
Long Throated Flumes	Open Channel	+/- 2%
Parshall Flumes	Open Channel	+/- 3_to_5%
Magnetic Flux Meter	Pressurized Conduit	+/- 0.25%
Ultrasonic Meter	Pressurized Conduit	+/- 1_to_5%

Determining Flow Measurement Accuracies

Flow measurement devices are capable of certain levels of accuracy when installed and operated under specified design conditions. It is uncommon for flow measurement devices located downstream of reservoirs to be installed under ideal conditions because most small to medium sized dams were not initially designed to have flow measurement. Because current water resources have become an item of consistent legal and political discussion, accurate flow measurement on water distribution and reservoir release have become increasingly important in this day and age. Consequently many reservoirs have added flow measurements structures to exiting channels and pipes to provide opportunities for real time flow measurement from the structure. A study conducted at Utah State University, Utah Water Research Laboratory (UWRL) has investigated the accuracies of flow measurement on reservoir releases in Utah. The following describes the methods used to determine the accuracies for open channel and pressurized pipe flow measurements.

Open Channel Flow Measurements –

Where applicable, open channel flow measurements made at thirteen sites in the state of Utah were evaluated by current metering. A pygmy meter and counter attached to a four foot top set rod were generally used unless special equipment was necessary. A cross section was selected perpendicular to the stream or channel flow, and was divided into several sections called verticals. The average velocity in each vertical

section was determined by the six-tenths-depth method, which, as stated by the Water Measurement Manual from the Bureau of Reclamation consists of measuring the velocity at 0.6 of the depth from the water surface. Each vertical section had two or more velocity measurements taken over 40 second intervals for repeatability. Discharge was then calculated at each flow rate using the Mid Section Method (Figure 1), which utilizes the area-velocity principle. The discharge is calculated in each section by multiplying the section's average velocity by the area. Corrections for edge sections are applied and the total discharge is found by summing the discharge in each vertical section (SonTek/YSI, 2007; ISO, 2007; Merkley, 2008; USBR, 2001).

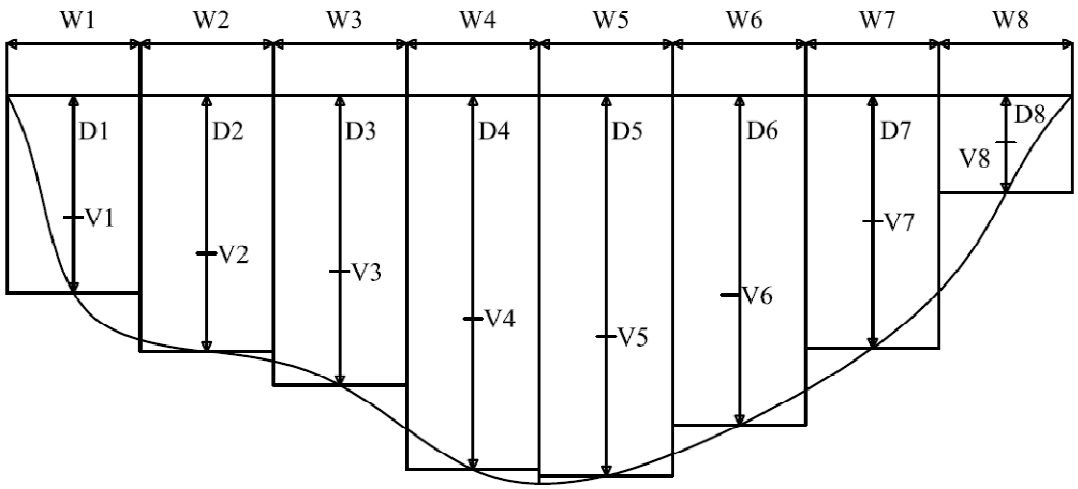

Figure 1 - Mid Section Method Calculations Illustration

Pressured Pipe Flow Measurements –

To evaluate the accuracy of pipe flow measurements at eight sites in the State of Utah, a Fuji Portaflow X ultrasonic meter with FLD-41 transducers was used as a reference meter. The Fuji meter was selected because of its ease of installation, portability, wide range of pipe sizes and accuracy. The reference meter was calibrated at the UWRL, producing output flow to +/- 3% without calibration and +/- 1% after calibration and maintaining less than 0.25% uncertainty. Where available, the Fuji meter was laboratory calibrated on pipes similar to field installation before field testing took place. Laboratory calibrations of the Fuji reference meter were performed on nine sizes of pipe, including: 6, 12, 14, 16, 18, 20, 24, 36, and 42-inch steel. In all cases the reference meter was installed according to manufacturer specifications. Calibrating the reference meter on such a wide range of pipes confirms the accuracy of the meter on possible pipe sizes encountered in the field. Transducers were installed according to the manufacturer's specifications, so that at least 10 diameters of straight pipe were provided both upstream and downstream of the transducer location from the nearest obstructions. This specification ensured that acceptable flow conditions occurred at the reference meter location. Flow and time were logged for each test allowing synchronization of time and flow from each meter.

Discussion of Errors and their Corrections

Flow discharge accuracies from twenty-one reservoirs have been investigated during the UWRL study. Of the twenty-one reservoirs, five used magnetic meters, three used ultrasonic meters, and thirteen used parshall flumes to measure reservoir releases. Each reservoir discharge was determined for accuracy as described previously. Table 2 contains a summary of the results. Of the twenty-one measurement devices that were tested, three of the five magnetic meters, all three ultrasonic meters, and seven of thirteen parshall flumes were not measuring flow to the levels of accuracy that design specifications claim.

In addition to the twenty-one flow measurement structures, many other sites were visited that a calibration were not possible because of dangerous conditions, lack of access to pipe or deep channels, insufficient pipe or upstream channel, or constraints on time. When these conditions existed design specifications were verified as much as possible and discrepancy and possibilities of error were noted. When variable reservoir discharge was possible, multiple flows were calibrated. The minimum and maximum errors are reported in Table 2 columns 3 and 4. In most cases the reservoir release was not able to be adjusted and only one flow rate was checked three times. These values are reported in Table 2 column 5.

Table 2- Summary of Results

Site	Type of	Measured Error		
#	Measurement Device	Min	Max	Average
(1)	(2)	(3)	(4)	(5)
1	Magnetic	-	-	14.29%
2	Magnetic	-	-	-17.14%

Unfortunately, a complete description of the results and problems associated with each individual site is not possible in this document. Accordingly, only a brief overview of findings and possible errors associated with the different measurement devices tested will follow.

Open Channel Measurement Devices –

The following items were found to affect accuracy in open channel measurement devices during this study.

Correct rating – Using the correct rating is essential to rated sections, long throated and parshall flumes. If the incorrect rating is used then substantial errors can occur. Incorrect ratings are often used due to poor record keeping, poor communication, ignorance, and out of date calibrations. Changing channel geometry and upstream flow conditions can also cause ratings to change. For these reasons, rating curves for the measurement structure should be regularly verified.

Correct placement of staff gauge – Most manufacturers specify the correct location of staff gauges and stilling wells for their devices. If the staff gauge or stilling well is located at a different location than specified by the manufacturer, the standard rating will not give accurate flow measurements. For example the correct location for the staff gauge or stilling well on a parshall flume is 2/3A upstream from the throat, where A is defined as the length of the approach section (Parshall, 1926; USBR, 2001). If the staff gauge of stilling well is at a different location, then the associated rating will not be accurate and a calibration of the device will be necessary.

Approach Conditions – Most open channel measurement structures specify sub-critical upstream flow. If approach flows are not sub-critical upstream of the structure or approach flow is skewed due to sediment or debris, accurate head readings are difficult to obtain and the standard rating may not apply. To enable uniform sub-critical flow upstream of the device a settling or stilling basin can be dug upstream to increase the depth and slow velocities; however it is recommended that if the control width is greater than 50 percent of the approach channel, then 10 average approach flow widths of straight unobstructed approach are required. If the control width is less than 50 percent, then 20 control widths of straight unobstructed approach are required (Bos et al., 1991; USBR, 2001). If sediment or debris has been deposited upstream of the structure, removing the sediment prior to a re-calibration of the device is suggested.

Correct Dimensions – Design specification must be followed to obtain accurate flow measurements. This is especially important for parshall flumes which are not geometrically similar. One cause of incorrect geometry arises when installation procedures are not closely monitored and specifications are not checked. This can occur when construction workers are not informed of the importance to have tight

tolerances. When dimensions of field installation do not match standard flume geometries, custom calibrations are necessary.

Submergence – If design submergence levels are exceeded, then corrections must be applied to obtain accurate flow measurements. If submergence corrections are not applied, errors up to 60 percent are possible (USBR, 2007). When submergence criteria has been exceeded it is necessary to use a rating curve created under submerged conditions (USBR, 2001).

Settlement – Many individuals have looked at the effects of settlement in parshall flumes (Abt and Staker, 1990; Abt et al, 1994; Genoves et al, 1993; Apt et al, 1995). The results of these studies apply corrections to settlement of small flumes, and corrections for a combination of settlement and submergence. Settlement of +/- 10 % can amount to 32 percent deviation in flow rate (Abt and Staker, 1990; Genoves et al, 1993). When mixed with submergence, errors can be substantially higher (Abt et al, 1995). Corrections to settlement with and without submergence are available and must be applied in order to achieve accurate flow measurements.

Pressurized Conduit Measurement Devices –

Correct Inside Diameter – One of the largest sources of error for Ultrasonic meter installations is not having the correct pipe material, wall thickness or inside diameter entered into the meter program. Errors often occur because the user does not have an acceptable method for measuring the ID of the pipe or it is incorrectly entered in the device. This is a relatively simple correction to perform if the proper pipe wall thickness measurement equipment is used.

Approach Conditions – All meter manufacturers supply upstream and downstream straight pipe requirements for correct meter installation. Typically, ten diameters of straight unobstructed pipe upstream of the meter provide acceptable flow conditions, although many hydraulic texts suggest 20 diameters. If excessive turbulence and flow disturbances are upstream of the meter, errors in flow will occur. New installations should specify adequate straight pipe for metering. Existing installations may require custom calibrations, with field pipe conditions reproduced in a laboratory.

Cavitation – Cavitation causes excessive levels of vibration and turbulence into pressurized pipe flow and may cause errors to arise in flow measurements. Installing a meter downstream of a pump or control valve often results in large errors.

Correct installation – To enable accurate flow measurements all pipe meters must be installed according to manufacturer's specifications. Many Ultrasonic meter manufacturers specify that transducers be installed on pipe that is free of excessive rust and scaling and in the correct locations to receive strong signal strength. If the installation does not meet manufacturer's specifications, the meters will not measure flow accurately.

Reservoir discharge flow measurement errors may seem small and insignificant, but over time these errors accumulate to large volumes of mismanaged water. For example, site 17 uses a parshall flume to measure reservoir discharge and at the time of the field calibration indicated a -6.54 percent deviation in flow measurement accuracy from the actual flow. This means at the time there was more water being released from the reservoir than the staff gauge reading indicated. For example, if the staff gauge reading indicates 4.71 cfs from the flume (0.55 ft), the actual flow would be 5.03 cfs. Consider a 6 month irrigation season supplied from a 1000 ac-ft reservoir with an average reservoir release of 5 cfs and the error in measurement similar to site 17, the total volume of excess water released would be around 117 ac-ft. At first glance 117 ac-ft doesn't seem substantial, but in actuality the 117 ac-ft of excess water released is over 10 percent of the reservoirs capacity. In comparison, a separate study conducted at the Utah Water Research Laboratory determined the accuracy of reservoir release of a larger reservoir to be around the same as site 17. When the flows were monitored over a single month (July) 2000 ac-ft more water was released than supposed (Barfuss and Jensen, 2007).

Conclusions

In order to ensure that reservoir water is wisely utilized, the discharge from reservoirs must be managed through accurate flow measurement. Both open channel and pressurized pipe measurement devices can accurately measure reservoir releases if proper design criteria are followed. Of twenty-one sites investigated in Utah only 13 were measuring within accuracy levels specified by manufactures and flow measurement manuals. Inaccuracies occur in many field installations because reservoirs were not initially constructed with flow measurements in mind. When existing reservoirs have flow measurement devices installed later, ideal or design specification may not be available and flow measurement devices may need custom calibrations. Other errors were caused from improper installation to lack of maintenance or improper operation. Over time, flow measurement errors can accumulate to large volumes of mismanaged water. Management of reservoir releases is becoming more important today due to the increased need for water resources and the proper management of those resources. If flow measurement devices are properly maintained and corrections are made to structures producing inaccurate results, then flow reservoir management will be improved and less water will be wasted.

ABSTRACT

Dez dam is one of the key dams in Iran. It is 203 m high with a reservoir of 2.3 BCM volume. This double arch dam has been constructed in a narrow gorge in 1962, southern west of Iran. It has three irrigation outlets at level of 222.7 m asl, two power intakes at elevation of 270 m asl. No bottom outlet have been designed and installed for Dez dam and consequently the sediment-entering reservoir cannot be evacuated easily. Considering an annual 15.8 million cubic meter sediment inflow into the reservoir, the bed level is increasing about 1.2 meter per year and therefore it is very necessary to take an appropriate measure saving dam reservoir.
One of existing method to save dam reservoir is to flush the sediment out through existing bottom outlets.
In this study, the feasibility and efficiency of pressure and free flow sediment flushing techniques have been studied and some good points are presented. The results of present study shows that the flushing method cannot resolve the sedimentation problem of Dez dam and it must be applied jointly by other methods to save the reservoir from being decommissioned.

INTRODUCTION

In the present study, the Wallingford (Developed by HR Wallingford, UK) model has been applied to Dez dam sedimentation problem to evaluate the efficiency of flushing method solving this problem. 36 different scenarios, for three different case: full desiltation of reservoir (against annual inflow sediment), evacuation of annual deposited inflow sediment by turbidity currents, and releasing the sediment accumulated in the area close to dam annually (within 1000 m distance from dam) are considered and simulated by this simple empirical model. Consequently, 108 different test case has been considered, and the flushing efficiency of all cases are evaluated.
On the basis of HR Wallingford recommendations, as model developer, the results of this model should be interpreted in an appropriate way by a specialist team to avoiding any wrong conclusion. Accordingly, the results will be presented along with related interpretations.

MOST EFFECTIVE PARAMETER AFFECTING THE FLUSHED SEDIMENT

In this study, analysis on various scenarios shows that the most effective parameter of flushing is the water level gradient in reservoir at the beginning and end of flushing. One other effective parameter is the duration of flushing and flow discharge from outlets.

Figure 1 shows the effect of water level gradient on the volume of sediment released from reservoir and figure 2 illustrates the discharge effects on the volume of released sediments.

The water scarcity is notably important for KWPA and therefore just pressure flushing is possible for Dez dam not free flow flushing. In Pressure flushing, during flushing the water level will lowered but free flow through reservoir won't happen and so relatively small amount of sediment will be release and a wedge shape cone will shape just in front of flushing device entrance. The shape of this wedge will soon be stable and outflow water will be clear as well. In free flow flushing, the water level will be drawn down during flushing even till a river shape flow through reservoir to be created. Such shape of flow through reservoir naturally follows by high turbulence flow capable to remove huge amount of sediment from reservoir (in comparison to pressure flushing). This type of flushing will have tremendous impact on environment and also needs huge amount of water to be flushed out of reservoir. Thus, in this report, the flushing meant by pressure flushing not free flow flushing.

BRIEF DESCRIPTION OF MODEL

a basic equation is used in Wallingford model to estimate the sediment discharge from outlets during flushing process. This equation is an empirical relation derived and verified with field data in different countries.

$$Q_S = \psi \frac{Q_f^{1.6} S^{1.2}}{W^{0.6}} \quad (1)$$

Where

ψ : Constant related to sediment type, size and flushing type which is 1600 for this case

Q_f : Flow discharge

S : water level slope during flushing

The output table of Wallingford modeling results (table 1) contains: Column 1 is scenario number, column 2 is flow discharge, column 3 is flushing duration, water level during flushing in column 5 to 7 and maximum sediment released out volume at column 8.

The trap efficiency of Dez dam reservoir by Wallingford model has been estimated 91.2 percent.

OUTPUT TABLE OF WALLINGFORD MODEL

The results of flushing modeling by Wallingford model is presented through a table of results. The main important items in this table to decision making and evaluation of flushing efficiency are column 9 to 14 (see table 1) and the most important one is column 9 in which the *SBR* function is presented. The *SBR* shows the ratio of total output sediment during flushing to annual inflow sediment (during pressure flushing). If *SBR* is greater than 1 then a sustainable solution will achieved by this method otherwise another method should be tried.

By the way, the SBR_d function shows the same concept of *SBR* but for free flow flushing type and is not applicable here.

Based on the previous column results, the feasibility of flushing method for each scenario is interpreted in the end column. In this column, *F, V/H/E* means feasible with very high efficiency; *F, H/E* means feasible with high efficiency; *F, almost E*

means feasible almost efficient; and *N.F* means not efficient and need to find another sustainable way to release entering sediments.

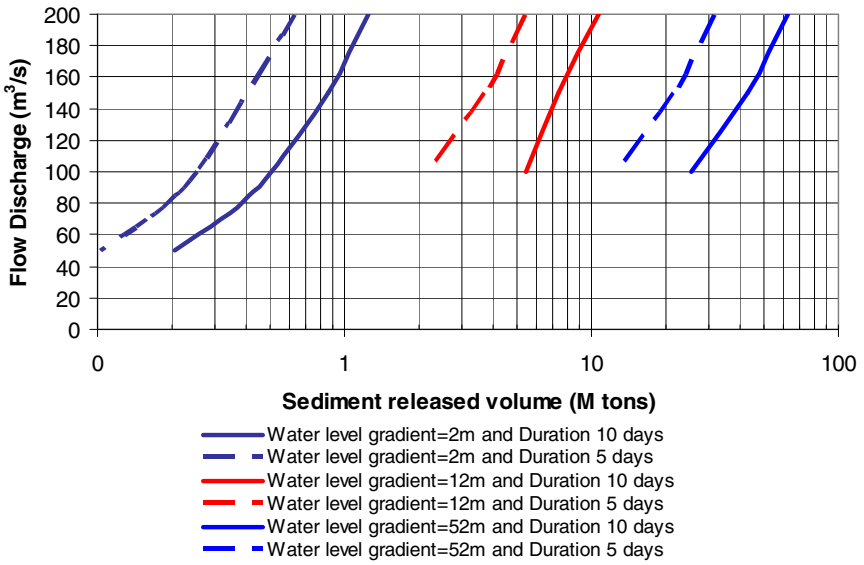

Figure 1. Water level gradient and flushing duration effects on sediment flushed out volume

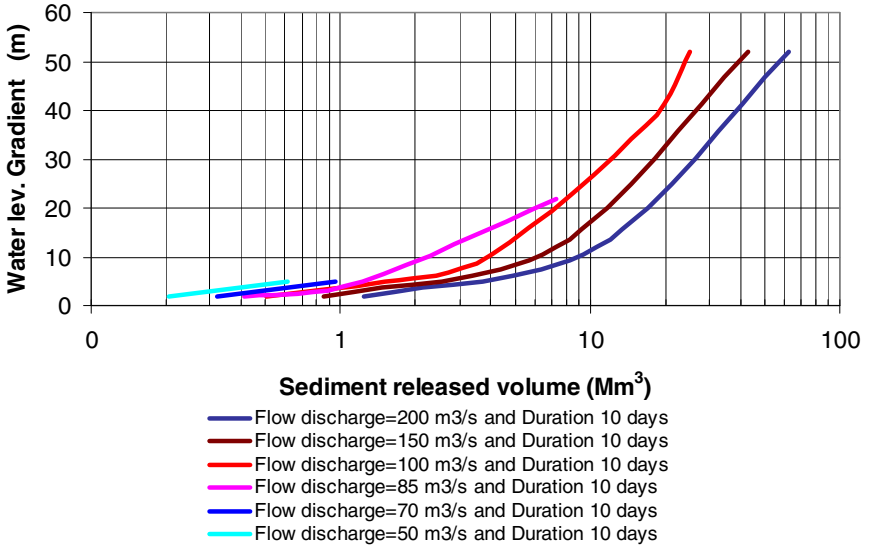

Figure 2. Water level gradient and flushing duration effects on sediment flushed out volume

EVALUATING THE EFFICIENCY OF FLUSHING METHOD TO RELEASE TOTAL INFLOW SEDIMENTS, IN DEZ DAM RESERVOIR

Total inflow sediment into reservoir, on the basis of foregoing studies is some 17,500,000 tons. Based on the results of Wallingford model, the flushing method will be sustainable if the water level gradient is more than 37 meter which requires huge

amount of water to be released and practically impossible. Furthermore lots of other difficulties will rise during flushing with such a 60 km long reservoir. By the way, the results of these cases are shown in the table 1. As it is already mentioned, the obtained results by this model should first be analyzed by experts and then taking into account. The interpretation of this writer is that the flushing method is not capable to solve the Dez reservoir sedimentation problem.

Table 1. Results of Wallingford Model for different scenarios of releasing total annual inflow sediments; SBR >1 efficient, <1 not efficient; F, V/H/E: feasible with very high efficiency, F, H/E: feasible with high efficiency, F: feasible almost efficient, N.F: not efficient, needs another sustainable way to release entering sediments

EVALUATING THE EFFICIENCY OF FLUSHING METHOD TO RELEASE INFLOW TURBIDITY CURRENT, IN DEZ DAM RESERVOIR

Total inflow sediment into reservoir, on the basis of foregoing studies is some 17,500,000 tons and the fraction related to inflow density currents is estimated by Akcres about 11 to 13 percent of total. Although, the present feasibility study on the

previous data including hydrography maps, bed longitudinal profile, height-surface-volume curve of reservoir shows that the inflow sediment volume by density current is more than 50 percent of total and it is so underestimated by Akcers. Even though one considers the inflow sediment of 11 percent of total for density current, then inflow volume of sediment is about 2,000,000 tons which should be released to have a sustainable solution for dez dam sedimentation. Because, on the basis of present studies sediment coming by turbidity current can only reach the dam area.
By considering the inflow annual sediments equal to this value of 2,000,000 then the table 2 show the results of modeling by Wallingford method. As it shown in the table 2, even in this case the pressure flushing could not create a sustainable solution.

Table 2. Results of Wallingford Model for different scenarios of releasing annual inflow sediments by turbidity currents (11% of total volume); SBR >1 efficient, <1 not efficient; N.F: not efficient, needs another sustainable way to release entering sediments

EVALUATING THE EFFICIENCY OF FLUSHING METHOD TO RELEASE THE DEPOSITED SEDIMENTS IN THE AREA NEAR DAM (IN 1000 M DISTANCE FROM DAM)

For such a case, the annual sediment volume (coming by density current and depositing near dam) considered to be released is about 250,000 tons (base on the reservoir geometry in the area close to dam, annual rate of bed level rising and the length of interesting area).
The Wallingford model results for this case, in table 3, show that for this case flushing can be a solution and the annually released sediment will be more than what annually will come to the area.
But the important point is that by this strategy, just the sediments near dam will be removed annually and after some years the sediment masses, accumulated right upstream of flushed cone area, will collapse into created wedge cone blocking

flushing tunnel. Then, however it's a temporary solution but, for sure, it's not a sustainable and reliable solution.

Table 3. Results of Wallingford Model for different scenarios of releasing sediments deposited near the dam (within 1000 m); SBR >1 efficient, <1 not efficient; F, V/H/E: feasible with very high efficiency, N.F: not efficient, needs another sustainable way to release entering sediments

Scenario N°	Discharge (m^3/sec)	Duration (day)	Mean annual sediment inflow (ton)	Mean water level during flushing (m)	Water gradient (m)	Water level before flushing (m)	Max. sediment released D/S (ton)	SBR	LTCR	DDR	FWR	TWR	SBR_d	Feasibility and efficiency

CONCLUSIONS

In the present study, for three different cases including fully desiltation of reservoir, evacuation of the sediments deposition due to density current and evacuation of sediments deposited in the area close to dam (within 1000 m from dam), flushing process of Dez reservoir has been modeled by a simple empirical model of HR Wallingford. 108 series of modeling cases by Wallingford model have been done and for each the efficiency of flashings was assessed. The below shows the achieved results in brief:

- *Based on the achieved results in this study, the flushing method is not relevant to desilting the incoming annual sediments and it may not lead to a sustainable solution.*
- *Even if, it is assumed that the volume of incoming sediments by turbidity currents into reservoir is about 11% of total incoming sediment (Ackers report for phase I), then the annually deposited sediment (due to density current) may not be release by flushing method completely, neither.*
- *However, by flushing method, it is possible to release the sediment volume deposited in the area close to dam up to 1000 m from dam, but it must be noted that this approach cannot be a sustainable solution and the sediment mass sliding will very soon happen, blocking the flushing devices.*
- *According to all fore mentioned analysis, it is concluded that a combination of turbidity current venting methodology and mild flushing (cleaning the area closer to outlet devices) could produce bring into being a sustainable solution to Dez dam sedimentation crisis.*

ABSTRACT

Hydro-Electric project are generally operated as peaking plant. This induces diurnal variation of flow in the downstreams of the dam even in a run-of-the-river scheme. Lower Subansiri Hydel project, proposed on the Subansiri River of Assam, India, is one of the major Hydel projects of India. Reservoir Simulation Model has been developed with a prime objective to assess extent of flow variation in the downstream of the dam. The simulation study has revealed that during lean period the discharge in the downstrem increases significantly during the peaking hour and the flow discharge become almost zero during the non-operating period. While the high discharge may cause erosion and can create flood like situation, the low discharge may have several adverse impact like increase in pollutant concentration. Scope of adopting structural and non-structural measures for minimizing deviation of flow from its normal condition has been investigated and encouraging result has been found.

INTRODUCTION

The technique to generate hydropower by conversion of mechanical energy into electrical energy is the oldest technique known to the mankind. Though traditional definition of the hydropower is a renewable, non-polluting and environment friendly source of energy, in the present context this definition needs some revision. Hydropower project induces significant ecological disturbances at upstream (u/s) and downstream (d/s) of the dam and therefore, perhaps can no more be considered as a non-polluting and environment friendly source of energy. Though impact of a dam on its upstream could draw attention of planners and researcher, its d/s impacts remained unrecognized, misunderstood and underestimated. Only recently, issue of d/s impact of a hydropower project has been addressed by researchers. The d/s impacts of dams on river biota have been documented since eighties by some of the researchers (e.g., Ward and Stanford (1979), Lillehammer and Saltveit (1984), Petts (1984), Craig and Kemper (1987)). Brookes in 1994 classified these impacts as first and second order impacts. Petts (1980) observed two kinds of impacts; one immediate and obvious and others are gradual and subtle. Environmental, economical and social impact of the dam at d/s has been reported by Word Commission of Dam (2000). Wohl and Rathburn (2003) found that the sediment entering the reservoir creates sediment-depleted conditions at d/s leading to channel adjustment in the form of bank erosion, bed erosion and channel plan form change.

The direct or indirect source of the above mentioned impacts in the d/s of the dam can be due to the high variation of flow rate in d/s caused by the dam operation. Ecological problem caused on river ecosystem due to hydro power project has been pointed out by Maiolini et al. (2005). Riggsbee et al. (2007) presented the impact on d/s of the dam due to dewatering or removal of the impounded water behind the dam. The degree, however, to which any project, especially hydroelectric, affects a river, varies widely. In the present study an attempt has been made to visualize the changed flow scenario at down stream of Lower Subansiri Hydro Electric Project (LSHEP) due to operation of reservoir in order to generate electricity. Objective of the study is to evolve measures to minimize deviation of d/s flow from its natural condition so that environmental impact can be minimized.

Study area: Subansiri Basin

This project is located in the Assam-Arunachal boarder near North Lakhimpur town of Assam. The project area lies in the Lower Subansiri District of Arunachal Pradesh and Dhemaji District of Assam, India. The river Subansiri, originates from the south of the Po Rom peak (Mount Pororu) at an elevation of 5059m in the Tibetan Himalaya. After flowing for 190km through Tibet, it enters India. It continues its journey through the Himalaya of India for 200km and enters into the plains of Assam through a gorge near Gerukamukh. The Subansiri is the largest tributary of the Brahmaputra. Its total length up to confluence of Brahmaputra River is 520km. Its drainage area up to its confluence of the River Brahmaputra is 37, 000sq.km. The river maintains an almost stable course in the hilly terrain but becomes unstable as soon as it enters into the alluvial plains of Assam.

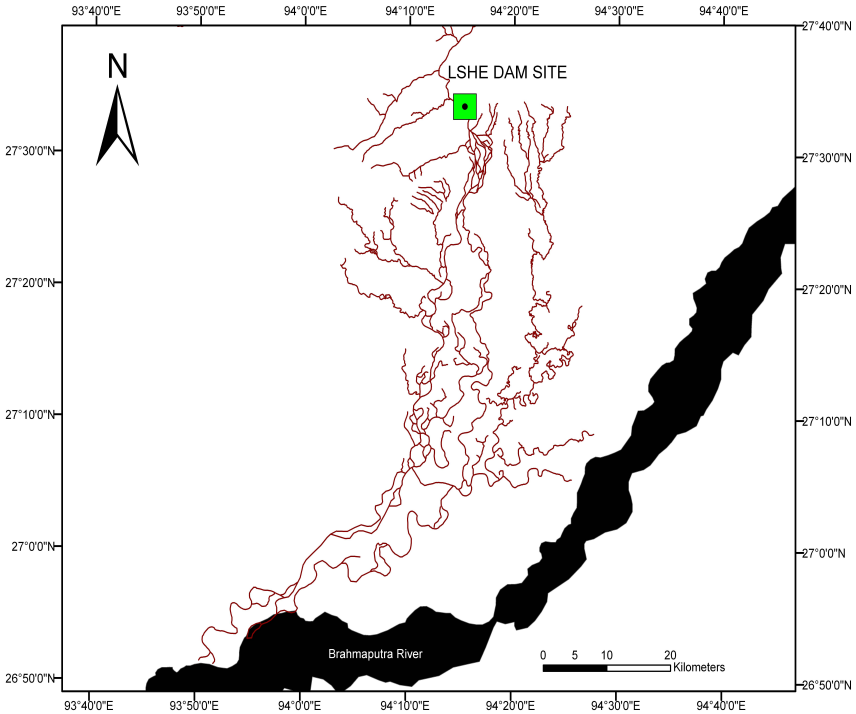

Figure1. Location of Dam Site

RESERVOIR SIMULATION STUDY

To visualize reservoir operation using simulation model is one of the best techniques to foresee the impact of a reservoir on flow scenario on d/s of the dam. According to Warbs (1973), simulation is a process of representing a system with a set of mathematical equations. Simulation, though is not an optimization method, can give optimal or near-optimal solution (Simonovic, 1992). Several simulation models have been discussed in the state of the art review presented by Yeh (1985), Wurbs et al. (1985), and Wurbs (1991). A Reservoir Simulation Model (RSM) has been developed in this study to visualize some important aspects of the River-Reservoir system at any time period. General demand oriented reservoir operating policy is considered to simulate the reservoir operation for twenty years using synthetic stream flow data. Meeting power demand of peak hours generally becomes an objective of a hydropower project in the lean period. This leads to significant diurnal variation at d/s of the dam, which in turn leads to serious ecological problem.

Data used in the development of RSM

Synthetic ten daily stream flows of twenty years provided by National Hydropower Power Corporation (NHPC) have been used as inflow series for the simulation study. Mathematical relationship of Storage-Elevation and Area-Elevation derived from the curve supplied by the NHPC has been used to calculate the reservoir capacity and elevation for each time period. Necessary climatic and reservoir related data were obtained from the NHPC.

Reservoir simulation has been carried out to achieve the following objectives: (1) To visualize changes in the flow scenario at the d/s of LSHEP; (2) To examine scope of flood moderation; and (3) To estimate power production and to analyze pattern of power production.

Development of Reservoir Simulation Model (RSM)

Simulation Algorithm

Following steps has been followed to decide the release at any time period t in the proposed RSM

Available Net Head (H_{nt}) at any time t is calculated based on elevation of reservoir at time t (El_t), elevation of normal tailrace water level (El_{tail}) and head loss due to friction. Head loss of the system can influence power generation considerably. Frictional head loss at time t (h_{ft}) has therefore been computed in this study dynamically based on the actual discharge at time t (Q_{dt}) flowing through the system.

1. Minimum desired release at time t (Rtd) for producing the target power for the peaking hour (*pk*) is calculated

$$R_{td} = Q_{dt} \times 36 \times p_k \div 10^3 \quad (1)$$

2. Maximum possible release at time t (Rtm) for producing the target power round the clock is calculated

$$R_{tm} = Q_{dt} \times 36 \times 24 \div 10^3 \quad (2)$$

3. Actual release is calculated based on the constraints of; (a)Maximum permissible reservoir elevation at that time considering scope of absorbing flood

$$R_{ta} = S_{t-1} + I_t - K_{El} - E_t - R_m \quad (3)$$

Where R_{ta} is available release at time t, S_{t-1} is storage of reservoir at the beginning of time t, I_t is inflow at time t, K_{El} is capacity of reservoir at time t, E_t is evaporation time t, R_m is minimum release provided

(b)Minimum drawdown level

$$R_{ta} = S_{t-1} + I_t - S_d \quad (4)$$

4. New storage at time t (St) at the end of the time period t is calculated based on the release computed in step 4.

$$S_t = S_{t-1} + I_t - R_{ta} - S_p - E_t - R_m \quad (5)$$

Where S_p is spill from the reservoir

5. New reservoir elevation at time t (Elnt) is calculated using storage-Elevation relationship
6. Net head is then calculated taking average of the initial elevation (Elt) at beginning of time period t and the new elevation (Elnt) at end of the time period t, and the entire calculation from step 1 is repeated to obtain the actual discharge in an iterative way (accuracy of 0.0001cumec is considered in this study)
7. Spill at every time is computed
8. Water balance is also checked in all these computation to ensure computational accuracy. After obtaining the actual discharge in step 7, the hours of operation of the turbine, power generated through the turbine (Po) in MW, Total power generated per hour (Poh) in KWh and TDF is calculated.

RESULTS AND DISCUSSION

RSM is used to study three different cases:(I) Reservoir operation with demand oriented standard operating policy (II) Reservoir operation with structural

measures to reduce diurnal variations (III) Reservoir operation to reduce diurnal variations through non structural measures. Detail discussion with necessary figures of the results obtained is give below:

Case-I: Demand oriented standard operating policy

Here reservoir is operated with an objective of generating target power of 2000MW for as many hours as possible without violating the given constraints. Synthetic ten daily stream flow series of 20 years has been used for the purpose. Output of the RSM has revealed that little variation will occur in ten daily total volume of dam released flow as compared to the total flow volume in without dam condition. Figure 2 shows the plot of Inflow series and TDF series for 20 years. To have a close view of these two series, plot of first year of flow is presented in Figure 3.

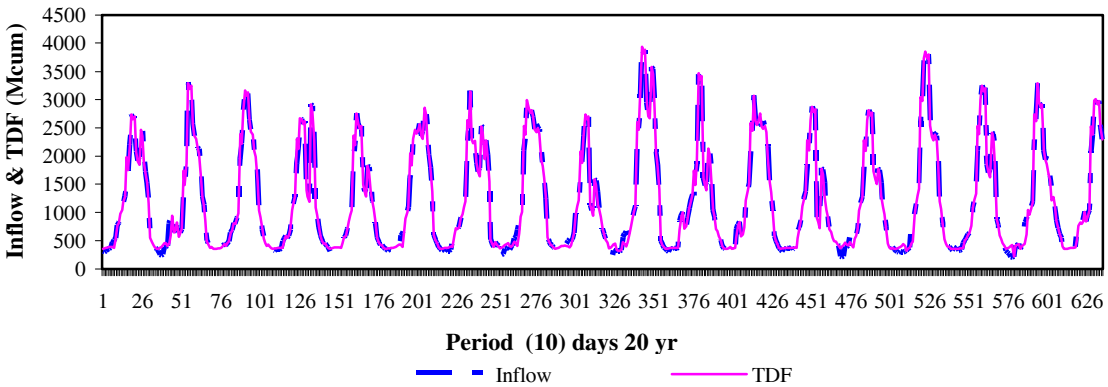

Figure 2. Inflow and TDF series of 20 years10 daily analyses

Figure 3 depicts that the Natural Inflow in ten days and the ten daily TDF after construction of dam are of same order. Visible variation has been observed only in the month of May-June, as the reservoir is drawn down during that period to keep sufficient space for the accommodation of high discharge during monsoon period, which will also provide opportunity of moderating high flood of small duration. It has been observed that though total flow volume in ten days remains more or less same before and after construction of dam, rate of flow in the d/s varies significantly.

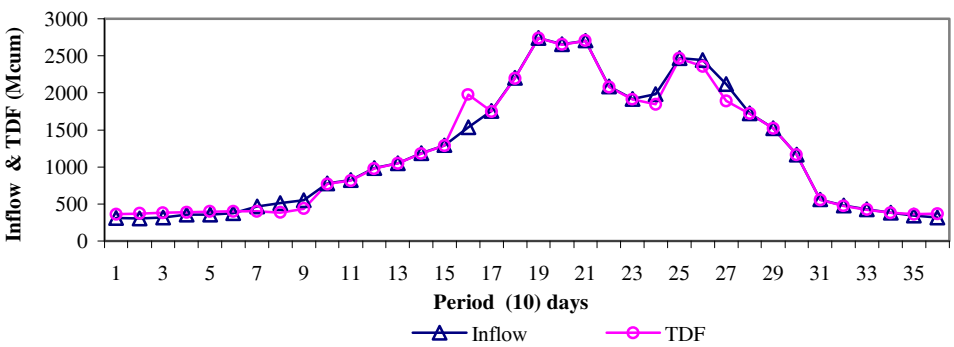

Figure 3. Simulation of the proposed policy for 1st yr

Figure 4 shows the power production series on ten daily bases. Figure 5 show close view of pattern of total power production for through first year. Figure 6 and 7 show the flow situations in d/s of the dam along with the duration of such flow. Average natural flow condition is also plotted in the same figure to have a visual comparison. Figure 7 shows the plot of inflow, turbine discharge, rate of total d/s flow, minimum flow rate at d/s and duration (Hr) of turbine discharge.

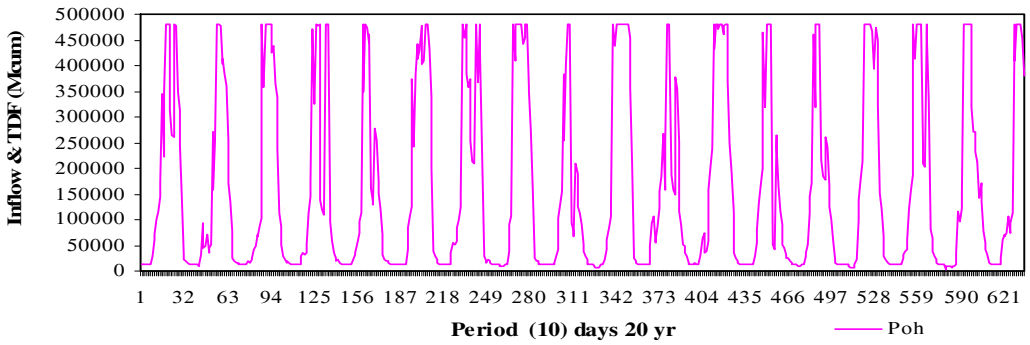

Figure 4. Power-hour series of 20 years for 10 daily analyses

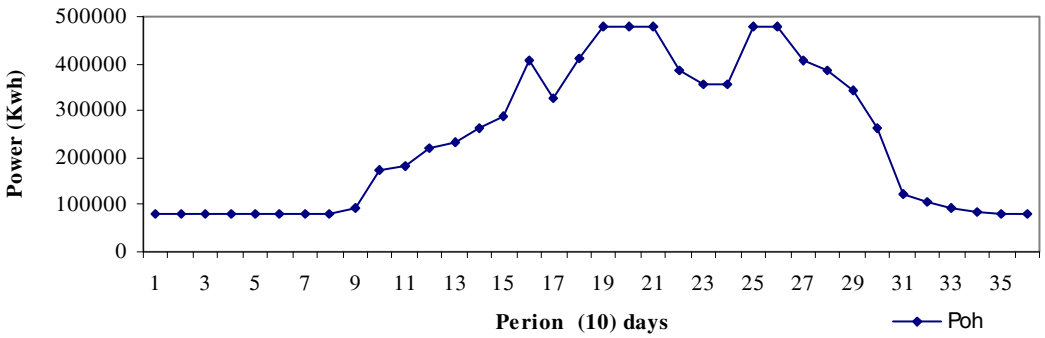

Figure 5. Power production pattern for proposed policy for the 1st yr

From these figure it is clear that the difference in flow rate is quite significant in the lean period, where the maximum out flow rate becomes 2400cumec and minimum flow rate becomes 6cumec, while the average inflow rate in the lean period in natural situation is in the order of 300 to 500cumec. Such diurnal variation in the lean period is of great concern as will cause ecological disturbance at the d/s. Such variation may also induce river bank erosion at d/s.

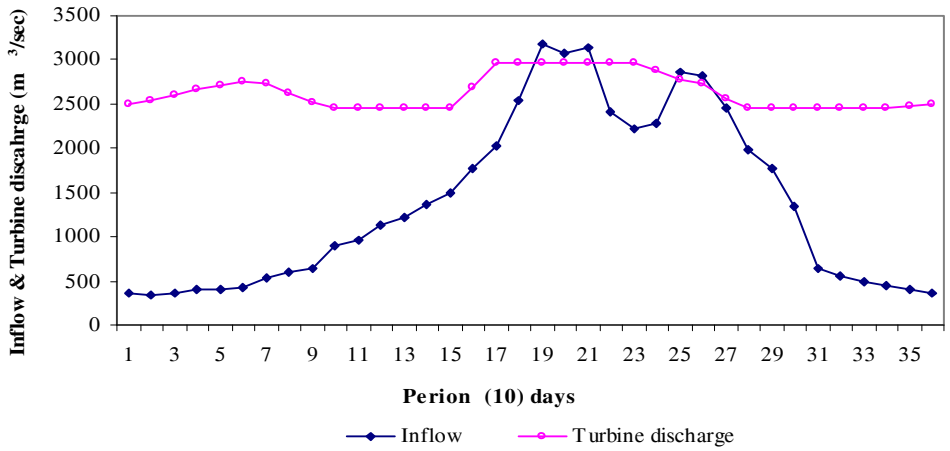

Figure 6. Diurnal variation observed for 1st yr

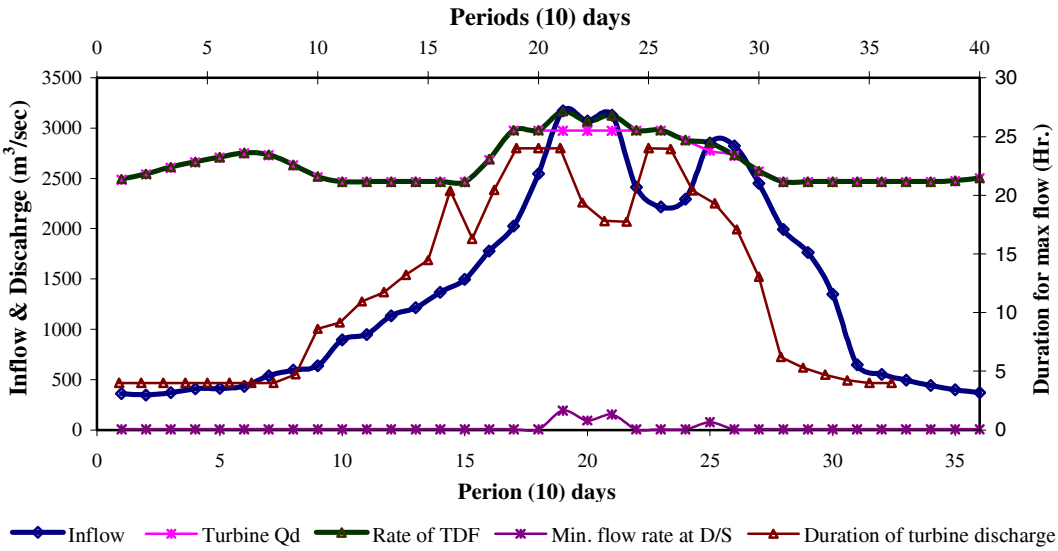

Figure 7. Proposed different concept (structural measure) for 1st yr

To minimize such variation, several measures have been thought about and simulation has been carried out to visualize the effect of such measures. Structural and non-structural measures proposed in this study for minimizing diurnal variation are presented below.

Case –II Policy considering structural measures to reduce diurnal variations

Effect of introducing a small capacity pond in d/s of the reservoir was investigated to explore possibility of minimizing diurnal variation and to analyze its performance. Simulation study has sown that diurnal variation of flow can be significantly minimized by creating a d/s storage of 36MCM. Figure 8. shows the curves showing the ranges within which the d/s flow will vary if a 5m high barrier covering the entire width at 4Km d/s of the dam is placed along with gated marginal embankment, so as to allow flow contribution of small stream during lean period.

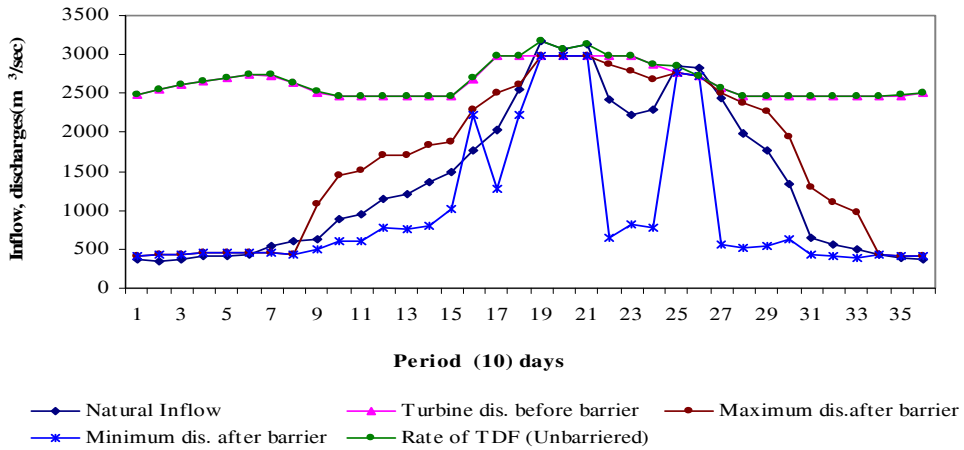

Figure 8. Proposed concept for non structural measure for 1st yr

Case –III Policy considering non structural measures to reduce diurnal variations

Operating one turbine continuously and rest at a time

Another option of providing minimum flow of around 300cumec in the lean period to produce 250MW power continuously by running one turbine for the entire day and to produce 1750MW with the remaining water for the possible period shown in Figure 9. and Figure 10. This will ensure minimum flow of 300cumec throughout the day in the lean period with maximum flow of around 2400cumec for the peaking duration, which will not be less than 2 hours per day even in the lean period.

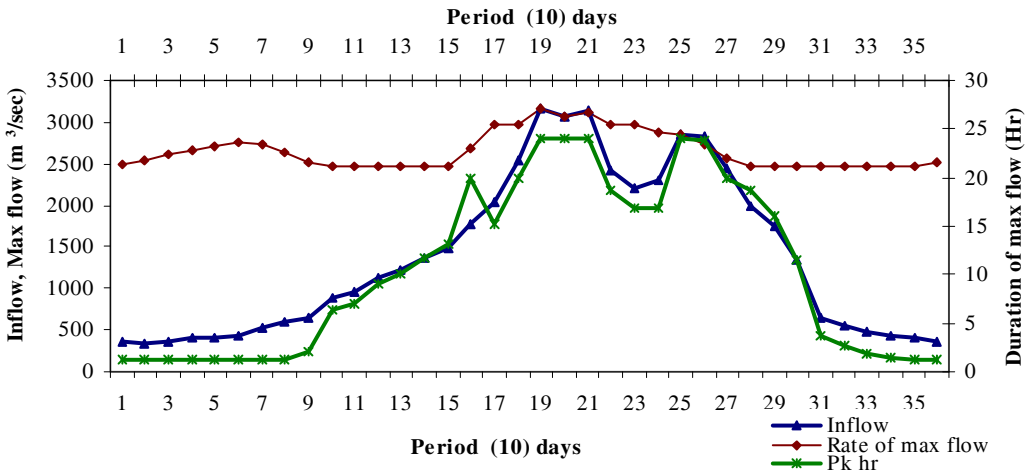

Figure 9. Peaking hour maximum d/s flow and natural inflow rate with one turbine running continuously

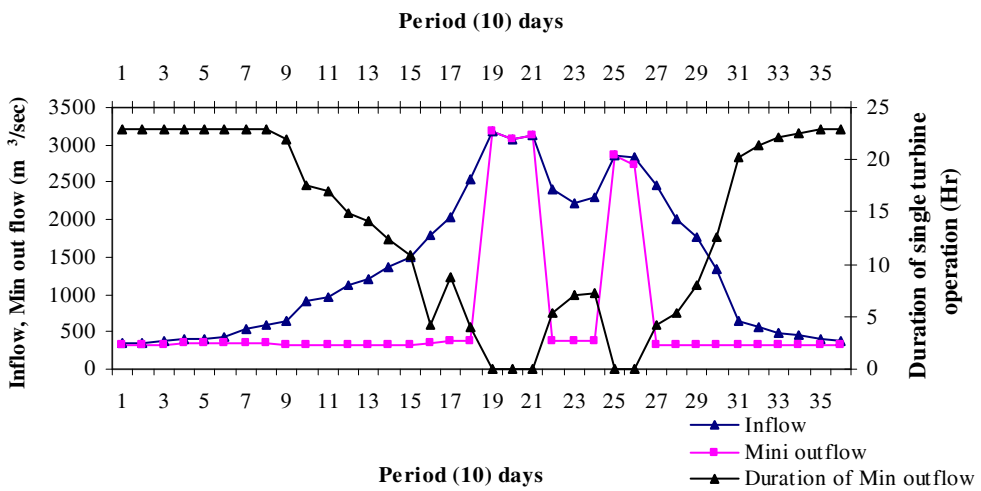

Figure 10. Minimum d/s flows, its duration in a day and natural inflow rate with one turbine running continuously

Operating one turbine continuously and increasing number of turbine one by one

Another option of utilizing the available water by running one turbine continuously and then increasing the number of turbine one by one for maximum possible hours of operation for each of the added turbine. This will restrict maximum rate of flow, of course with a compromise with peaking power. Figure 11. shows the maximum and minimum rate of flow through turbines along with the plot of natural inflow.

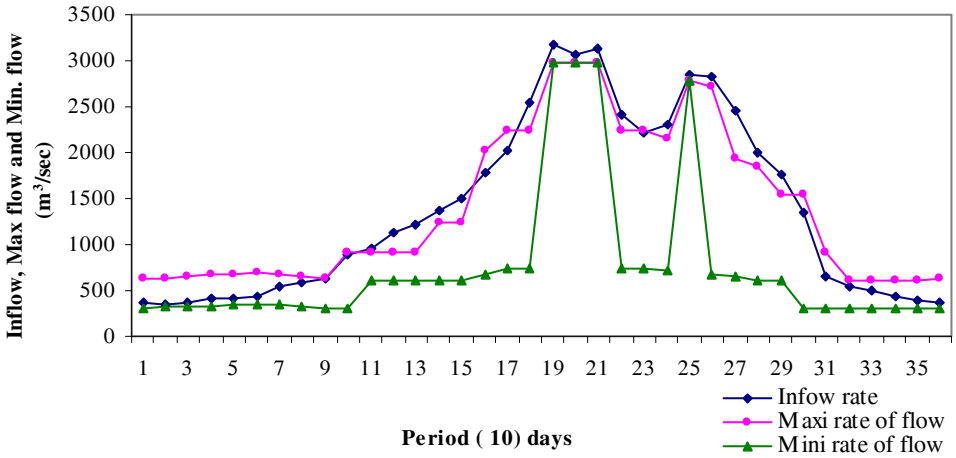

Figure 11. Inflows, Maxi. Turbine Discharge and Min.Turbine discharge for 1st yr

CONCLUSIONS

A reservoir simulation model has been developed to investigate augmented flow scenario d/s of a dam, so that necessary corrective measures can be suggested to minimize d/s environmental impact. The developed simulation model has been applied to the Lower Subansiri Dam, located in the state of Assam and Arunachal Pradesh of India. The simulation study has shown that with the present proposed power production schedule, i.e., with peaking hour of minimum 4hours, flow rate at d/s of the dam will change with a diurnal variation between 6cumec to 2400cumec in the lean period. Natural flow during lean period being in the order of 300cumec, such variations will have adverse effect in the d/s. During flood period diurnal variation induced by the reservoir operation is not that significant and will not create any adverse effect as such. Several alternate operating policy and structural measures have been analyzed to minimize the diurnal variation in the lean period. While implementation of structural measures needs favorable site condition, additional initial investment and running cost, modification of operating policy has been found to be quite convenient. A policy with one turbine running continuously and producing peaking power with the remaining water has been found to be quite convenient. This policy will ensure about 300cumec of flow in the lean period throughout the day of course with a higher discharge of around 2400cumec for a short duration of about 2 hours in the lean period. Another policy of generating power by choosing number turbines to be run based on the available water has also been analyzed. This policy will lead to a flow situation where variation between maximum and minimum flow rate will reduce but the project will not be able to meet the peak demand, as this will lead to almost uniform power production throughout the day.

Optimal Design and Operation of Fuse-gates Considering Water Loss due to Gates Tilting

Abbas Afshar[1], Zeinab Takbiri[2]

1. Email address : a_afshar@ iust.ac.ir
2. Email address : ze_takbiri@civileng.iust.ac.ir

Abstract: Installation of fuse-gates on free spillways might be a safe and reasonably simple solution to increase reservoir capacity compared with the expensive alternative of dam heightening. This research aims at optimum design of fusegates considering the flood routing process in the reservoir. Owing to the fairly complicated performance of fusegates in flooding condition, its optimum tilting control is a challenging task. The overall expected cost which includes expected cost of water loss and gates replacement as well as the initial gates installation cost is considered as the objective function of the optimization problem. Moreover, an efficient mixed Genetic Algorithm model is utilized to minimize the overall cost. Type of gates, their height and first tilting head are explicitly treated as decision variables. A case example is used to assess the applicability of the proposed optimization scheme. The results indicate that consideration of flood routing could have a significant effect on the optimum design of gates.

Keywords: fusegates; flood routing; genetic algorithm; tilting head; spillway

1. INTRODUCTION

In recent years, with growing the water demand beside the global draught events the world water crisis develops and therefore many alternatives are proposed to cope with this problem. As a practical alternative, one may focus on increasing water supply of existing reservoirs. Dams heightening, dredging the reservoir of existing dams, and gate installation on the existing spillways are some of the possible ways to increase the reservoirs storage.

In 1989 Hydroplus invented fusegate which may be a simple and cost-effective way to increase the water supply capacities of reservoirs as well as spillways capacities depending on the conditions (Falvey and Treille 1995). The fusegates applied on more than 40 dams such as Allan dyke, in France, Beni Amrane dam in Algeria, Black Rock dam in USA, and Terminus dam in USA.

Falvey and Treille (1995) elaborated the discharge characteristics and hydraulics design of fusegates. Chevalier. S, Hydroplus, France (2004), Alla (1996), Jones et al., 1996 discussed about advantages of fusegates in different conditions. Afshar et al., 2003 employed a linear optimization model to minimize the overall cost of gates without considering the replacement cost and effect of installation of fusegates in routing process.

In this study, an efficient Genetic Algorithm model is presented to minimize the total project cost. It includes the expected costs of water loss and replacement cost which is not considered yet, as well as installation and excavation cost under structural, hydraulic, and operational constraints. The type and height of the gates as well as tilting head of first gate are explicitly treated as decision variables. In this proposed model the flood routing affected by installation of fusegate is considered. All gates have an equal height and type. Application of the model to Zarine Roud Dam in Iran, demonstrates applicability and efficiency of the proposed modeling scheme.

2. Hydraulic design of fuse-gates

There are three main components with any fusegate. the water retaining structure, the pressure chamber and the water collecting well. The water retaining element is a concrete or steel structure with a downstream abutment block to prevent the gate sliding. The pressure chamber receives water from water collection well causing an uplift pressure. Collection well ensures that water can enter the chamber when the reservoir water level exceeds the inlet elevation (Falvey and Treille 1995).

When the tilting moment exceeds the stabilizing moment caused by the weight of the fusegate body and water, the fusegate tilts around the downstream edge, imposing water loss and substitution gate replacement cost. The water los initiates when the first fusegate tilts. With tilting the fusegates, they may break and be unusable. Therefore the replacement cost of destroyed fusegates after tilting, should be considered to attain the real expected cost of this project. Because of considering replacement cost, it is important to prevent the tilting of fusegates simultaneously. To control the tilting level of fusegates, the inlet of each gate is set at a different elevation.

Fusegates are commercially available in three standard types designated by ratio of the width of the gates to its height as being wide (W) or narrow (N) and by the tilting range as being low head (LH) or high head (HH) (Falvey and Treille 1995).

Discharge of flood over a non-tilted fusegate may be computed (Rouse 1960) as

$$Q = (2/3)\sqrt{2g}\,C_d L_c h_i^{3/2} \quad (1)$$

where Q = discharge; g = acceleration of gravity; L_c = crest length of the fusegate; and h = difference in the reservoir and the crest elevation of gates; and C_d = the discharge coefficient which is a function of the crest length on the fusegate, and the ratio of h to the total head (depth of flow) over the sill. The best-fit Equation for the discharge coefficient is given by Falvey and Treille (1995):

$$C_d = C_1((h/H) - C_2)^{C_3} \quad (2)$$

where H = height of the fusegate, and C_1, C_2, and C_3 are experimentally determined constants for values of h/H greater than 0.1. The coefficient C_2 is a surface-tension-type term that becomes negligible as the flow depth over the fusegate increases. Discharge coefficients for various types of fusegates are presented in Table 1

Table1. Empirical discharge coefficients for fusegates (Adapted from Falvey and Treille 1995)

Type	c_1	c_2	c_3
WLH(NHL)	0.320 ± 0.004	0.0010	-0.292 ± 0.006
NLH	0.254 ± 0.012	0.0005	-0.319 ± 0.018
WHH	0.315 ± 0.009	0.0375	-0.258 ± 0.005

When water level reaches to a predetermined value and gate tilts, the discharge can be obtained from Equation (2) by letting L_c = the crest length of the fusegate, and C_d = the discharge coefficient for weirs defined as (Rouse, 1960),

$$C_d = 0.611 + 0.075\,(h/P) \quad (3)$$

where P = height of the crest above the upstream approach channel invert elevation. In addition to height and type of gates, the tilting head of each fusegate should be determined for computing the discharge-elevation curve and subsequently outflow hydrograph. It is obvious that with tilting the first gate the whole extra water supply which is saved with fusegates installation is wasted. Furthermore tilting of each gate imposed the replacement cost to the model. Therefore it is important to control the gates tilting with a well managed and planned scheme.

The Figure 3, illustrate a sample inflow and outflow hydrograph for the reservoir with 50 meters wide spillway covered by sixteen fusegates with 3.10 meters width. The peak of entering flood is approximately 4000 cms. It is assumed that all fusegates tilt at

the same time. With tilting all gates at the same time, a significant jump is made in outflow hydrograph that is not desirable.

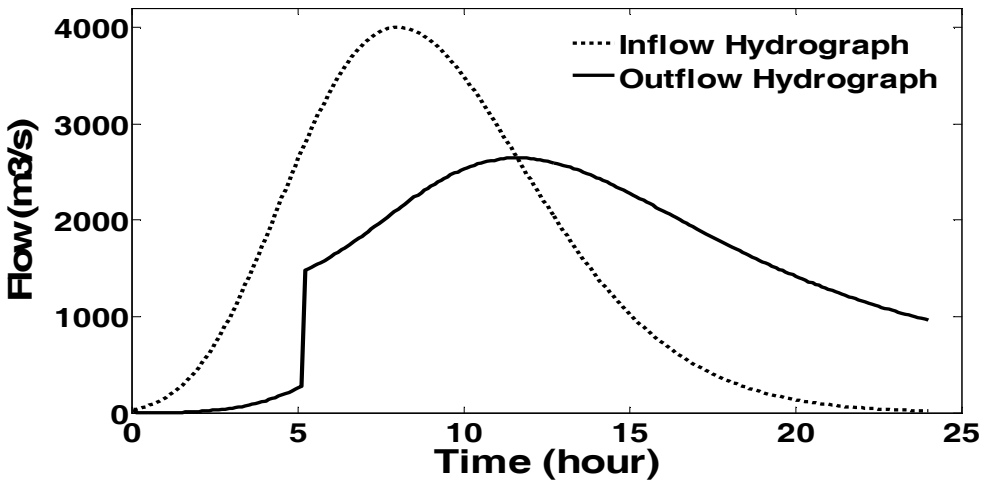

Figure3.a sample Inflow and Outflow Hydrograph of the floods

To avoid a great flood discharging in downstream and high imposed replacement cost of gates, it might be better to prevent the simultaneous tilting of all gates.

3. Optimization model

The total annual expected cost is expressed as

$$TAEC = \sum_{i=1}^{N} [CRF.(CO_{E_i} + CO_{F_i}) + (CO_{W_i} + CO_{RF_i})] \quad (4)$$

In which i refer to the gates number, CO_{E_i} = the excavation cost, CO_{F_i} = fusegate cost, CO_{W_i} = expected annual cost of water loss, CO_{RF_i} = expected annual gate replacement cost, and CRF = capital recovery factor (Peterson 2005)

$$\begin{aligned} CO_{E_i} &= g_e(ED_i) \\ ED &= H - INWL \\ CO_{F_i} &= C_{fuse} \\ CO_{W_i} &= 1/Tr_1 \times V_W \times UCW \\ CO_{RF_i} &= 1/Tr_i \times URC = 1/Tr_i \times g_{Rfuse} \end{aligned} \quad (5)$$

where T = fusegate type, H = fusegate height, h= tilting head, ED = excavation depth, Tr = flood return period associated with tilting head of any gate, Tr_1 = return period for the first tilting, $INWL$ = desired increase in normal water level, V_W = water loss due to gate tilting, UWC = unit water cost, and URC = unit replacement cost.
The objective function is subject to the following physical and operational constraints:

$$\begin{aligned} &Type = NLH \text{ or } WLH \quad \text{for which} \quad 0.3 \le h_i / H \le 0.6 \\ &Type = WHH \quad \text{for which} \quad 0.8 \le h_i / H \le 1.4 \end{aligned} \tag{6}$$

In the propose approach, the tilting head of the first fusegate is treated as decision variable and the tilting heads of other gates are determined as addressed in equation 7.

$$\begin{aligned} &delta = {(h_{\max} - h_{first})}/{(n-1)} \\ &h_1 = h_{first} \qquad h_i = delta + h_{i-1} \\ &if \quad Type = NLH \quad or \quad WLH \quad then \quad \max h = 0.6.\ H \\ &if \quad Type = WLH \quad then \quad \max h = 1.8.\ H \\ &h_{\max} = \max imum \begin{cases} \max h \\ MWL - INWL \end{cases} \end{aligned} \tag{7}$$

where h_{first} = tilting head of the first gate obtained by genetic algorithm, n = number of installed gates, and MWL = maximum water level after routing the design flood before installation of fusegates. In fact the difference between tilting head of the first and last gates are divided into equal increments. Tilting head of a gate is determined as the summation of the fixed increment and the tilting head of the previous gate.
An appropriate version of genetic algorithm is tailored to cope with the combination of the discrete and real-value decision variables of the proposed model. This proposed algorithm is coupled with a simulation model which carries out the routing in the reservoir.

4. Model application

To test the performance of model, Zarineh Rud dam in Iran is used to and its result is present in Fig.6. The Zarineh Rud dam in north-western Iran has 50 meters height and total storage volume of approximately 650 *MCM*. It is desired to increase the total active storage volume by 106MCM, which associates with an increase of 2.35 meter in *NWL*.

The width of the original spillway in Zarineh Rud is 148 meters with spillway design head of 6 meters. Furthermore the maximum design flood with return period of 10000 years has a peak of 5321 cms (Afshar *et al.* 2003).

$$\begin{aligned} &Type = \ NLH: \quad C_{fuse_i} = 0.75 \times 10^5 H_i \ \ dollares \\ &Type = \ WLH: \quad C_{fuse_i} = 1 \times 10^5 H_i \ \ dollares \\ &Type = \ WHH: \quad C_{fuse_i} = 1.25 \times 10^5 H_i \ \ dollares \end{aligned} \tag{8}$$

Replacement cost of a tilted and destructed gate is assumed to be 10 times of the initial installation cost. It is further assumed that one cubic meter of lost water cost 0.5 U.S. dollar, the interest rate, *i* is assumed as 0.1, and the construction period is 24 months.

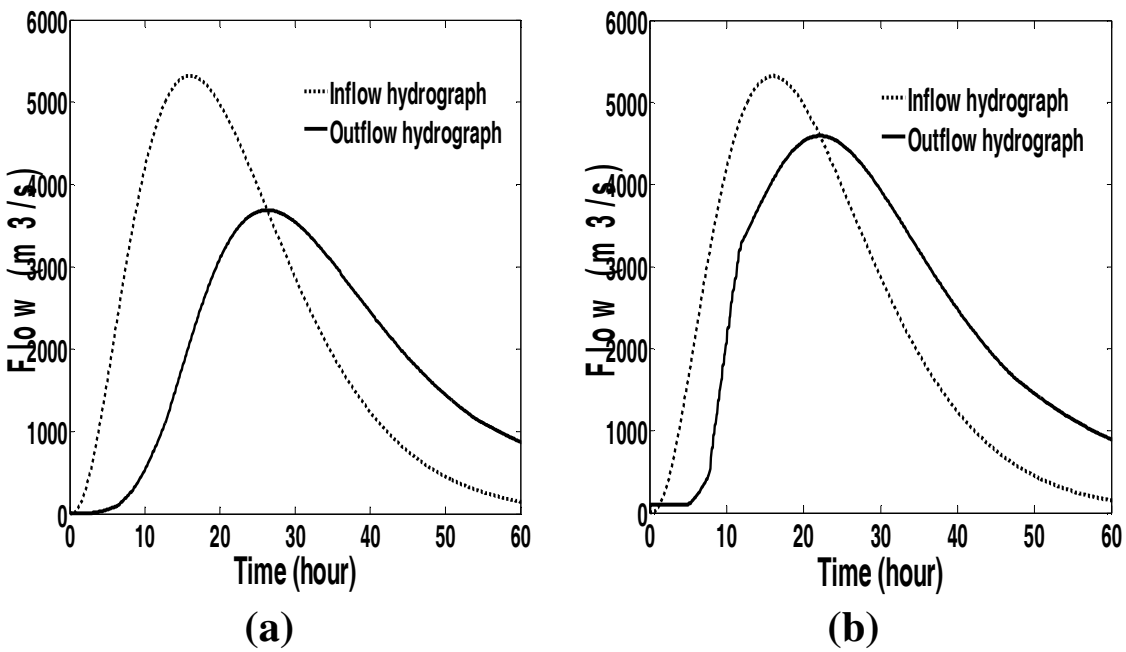

Figure 2.The inflow and outflow hydrograph for design flood (a) when the original spillway used (b) after installation of fusegates

The peak of entering design flood is 5321 cms which reduces to 4593 cms after routing through the reservoir with fusegate installation. Peak outflow before fusegate installation was determined as 3668 cms. The significant difference between these values is made by the jumps affected by tilting the gates step by step, while maintaining the same safety

measures. This figure illustrate that the routing effect in fuse-gated spillways is too important to be ignored. To enhance dam safety, the maximum water level after routing the design flood through the fuse-gated spillway must be known precisely. As presented in Fig.2(b), the maximum water level in fuse-gated spillway may exceed that of original free spillway (i.e., 5.65 m. compared to 5.98 m.). In this case, the gate installation should be modified to confine the maximum water level to that of the initial design.

The proposed simulation-optimization scheme is employed to develop optimal solution to a fairly complex fusegate design for increasing reservoir storage while enhancing dam safety.

A summary of the results of the solution to the model are presented in Table 2.

Table2. The optimum characteristic of selected fusegates

Cost of water units ($)	Height	Type	Number of installed fusegates	Tilting head of first fusegate	Tilting head of last fusegate	Cost of project 10^8 ($)
0.5	3.10 (m)	WLH	30	0.99 (m)	1.86 (m)	7.59

To test the sensitivity of the design to varying input parameters, the proposed simulation-optimization model was employed for different values of water unit cost. The results are presented in Table 3.

Table3. The optimum characteristic of selected fusegates for various costs of water unit

Cost of water units ($)	Height (m)	Type	Number of installed fusegates	Tilting head of first fusegate (m)	Tilting head of last fusegate(m)	Cost of project 10^8 ($)
0.05	3.10	NLH	45	0.93	1.86	7.40
5	3.75	WLH	24	1.50	2.25	8.23
50	4.60	WLH	14	1.60	2.76	9.51
500	4.60	WHH	11	4.10	5.9	10.95

Table 3 shows that with increasing the unit cost of water, the model selects the fusegates with larges heights with reduced tilting heads. Therefore the tall fusegates tilt with larger incoming floods with longer return periods, compared to short gates. According to

Equation 5, the expected cost of lost water decreases with increasing the return period of fusegates design. As the unit cost of water increases the model tries to find the solution with tall gates with relatively larger tilting heads. Although the volume of lost water for high head gates are larger than that of small gates, yet the expected value of lost water may be reduced.

6. Conclusion

An efficient genetic algorithm is used to minimize the overall cost of fusegate project which includes the installation cost and excavation cost as well as expected water loss and replacement cost. A simulation model was applied to computing the outflow hydrographs for any entering flood to reservoir with combination of type, height, and tilting heads of selected fusegates. The effect of installation fusegates on original width of spillway was illustrated in routing process. The results indicated that with installation of fusegates the peak of outflow hydrograph may increase, compared to the original case. Moreover with increasing the unit cost of water the heights of selected fusegates increase to cope with the expected lost water caused by tilting the first fusegate.

ABSTRACT

A two-dimensional, physical model was constructed to evaluate the energy dissipation on a 4(H):1(V) slope spillway chute. Step heights of 38 mm (1.5 inches) and 76 mm (3.0 inches) were evaluated, and energy losses created by these steps were compared. Model unit discharges ranging from 0.11 $m^3/(s \cdot m)$ (1.2 cfs/ft) to 0.82 $m^3/(s \cdot m)$ (8.9 cfs/ft) were tested. Water surfaces, bed surfaces, velocities, and void fractions in the flow were measured during the tests. The findings from this research show that a relationship developed by Hubert Chanson can be used to determine the inception point for slopes as flat as 4(H):1(V). With increasing step height, the energy losses at similar locations within the spillway chute also increased. The results for energy losses for the 38 mm (1.5 inches) and 76 mm (3.0 inches) steps showed similar linear trends upstream of the inception point, with near zero percent energy loss at the spillway crest to approximately 30% at the inception point. Downstream of the inception point for the two smaller step heights, the results showed a more logarithmic trend from 30% at the inception point or when a normalized length, L/L_{i*}, equals one to 73% when L/L_{i*} equals 3.5. This research is expected to assist engineers with the design of stepped spillways applied on relatively flat embankment dams and the associated stilling basin located at the toe of the spillway.

INTRODUCTION

Many small earthen embankments are faced with hazard classification changes due to urbanized growth within the watershed. Increased infrastructure around an existing dam typically generates more runoff and changes the hydrologic conditions. Often times this creates inadequate spillway capacity for the existing embankment. To bring the dam into compliance with state and federal dam safety laws, rehabilitation of the structure is often necessary. Roller compacted concrete (RCC) stepped spillways are becoming a popular choice in these rehabilitation situations because the spillway capacity can be increased with few or no additional changes to the existing embankment dimensions. RCC stepped spillways are also selected because of the dollars and time saved in the construction of these structures. Yet, design guidelines for RCC stepped spillways applied to small earthen embankments are limited, especially for chute slopes of 2(H):1(V) and flatter. Energy dissipation upstream of the inception point on these flatter sloped stepped spillways are important for determining the size of stilling basin because in many instances air entrainment is not fully developed prior to entering the basin for these small structures.

Stepped spillway research for flatter sloped applications (2(H):1(V) or flatter) has been quite limited, and design guidelines are scarce. Stepped spillways having flatter chute slopes are more typical for rehabilitation projects of existing embankment dams. Model studies can provide insight to engineers faced with designing these structures. Without these studies, the safety and integrity of the stepped spillway designed for these applications may be questioned, and/or it may result in the design engineer being overly conservative, leading to a more expensive project. The United States Department of Agriculture (USDA)-Agricultural Research Service (ARS) Hydraulic Engineering Research Unit (HERU) has focused a fraction of research to stepped spillways applied on existing embankment dams. Air entrainment and energy dissipation in flatter sloped stepped spillways may affect the design of the spillway training walls and the stilling basin differently than steeper stepped spillways. So the USDA-ARS HERU is currently working on a generalized model study to evaluate the effects a 4(H):1(V) slope stepped spillway chute has on the inception point location, the energy dissipation, and velocities for a specified range of flows that are within the skimming flow regime. This paper specifically compares the impact two different step heights have on energy dissipation. This research is expected to assist engineers in the design of these structures.

BACKGROUND

Design engineers have a vested interest in the affects air entrainment and energy dissipation has on the design of stepped spillways and the associated stilling basin applied to embankment dams. In most dam rehabilitations, stepped spillways are placed over the existing earthen embankment; thus, the slope of the spillway is the same as the downstream slope of the dam. Typical slopes for earthen embankments are 2(H):1(V) or flatter, but most of the research to date on stepped spillways has been for chute slopes greater than 2(H):1(V). Strides for improving RCC technology to flatter slope applications are being made.

Rice and Kadavy (1996), Yasuda and Ohtsu (1999), Chanson (2002), Boes and Hager (2003a and 2003b), Hunt and Kadavy (2006, 2007, 2008a, and 2008b), and Felder and Chanson (2008) among others have researched flat-sloped (2(H):1(V) or flatter) stepped spillways. Each has contributed to the engineering of these structures in some fashion. For instance, Rice and Kadavy (1996) along with others have indicated that energy dissipation was significantly more in stepped spillways when compared to smooth spillways of similar design parameters. Chanson (2002) has contributed extensively to the research of stepped spillways by compiling a data base of literature. Chanson's (2002) text on the subject also outlines research he has conducted on scaling effects in stepped spillway modeling, differences in nappe and skimming flow regimes, and development of relationships with regard to inception point location and energy dissipation that occurs in the stepped spillway chute. Boes and Hager (2003a and 2003b) conducted extensive research on air concentration and velocity distributions in stepped spillways, and their work has provide a relationship with regards to identifying the inception point location. It should be noted that the inception point relationships developed and provided by Chanson (1994a and 2002) and Boes and Hager (2003a and 2003b) define the inception point in two different locations. Chanson (1994a and 2002) defines the inception point as the location

where the turbulent boundary layer reaches the free surface whereas Boes and Hager (2003a and 2003b) indicate that the inception point is the location where the air concentration near the chute bed surface is 0.01. Both relationships were primarily developed using steep chute (2(H):1(V) or greater) data, yet Hunt and Kadavy (2006, 2007, 2008a, and 2008b) has found that Chanson's relationship has some applicability to slopes as flat as 4(H):1(V). Hunt and Kadavy (2006, 2007, 2008a, and 2008b) also provide information regarding the determination of energy dissipation both upstream and downstream of the inception point on a 4(H):1(V) stepped chute for a single step height.

The objective of this paper is to compare the effect step height has on the energy dissipation of a 4(H):1(V) stepped spillway, so this paper will summarize data related to velocity, air concentration, and energy loss in stepped spillways. In some cases, fully developed air entrained flow is not achieved in stepped spillways applied to embankment dams because the spillway chute is relatively short. Most energy dissipation data available for stepped chutes are in this highly air entrained zone. Therefore, this research is critical for the design of stepped spillways and their associated stilling basins applied to small embankment dams where this air entrainment may not be developed.

EXPERIMENTAL SET-UP

A two-dimensional (2-D) 1:8 scale model of a stepped spillway was constructed specifically for a study of Renwick Dam in North Dakota. This same model served the purpose for the generalized study on stepped chutes described herein. The primary objectives of the generalized study are to evaluate the inception point, energy losses, and velocities associated with flood flows on flatter sloped stepped spillways. Figure 1 illustrates a schematic of the two-dimensional model used for both the specific and generalized model studies.

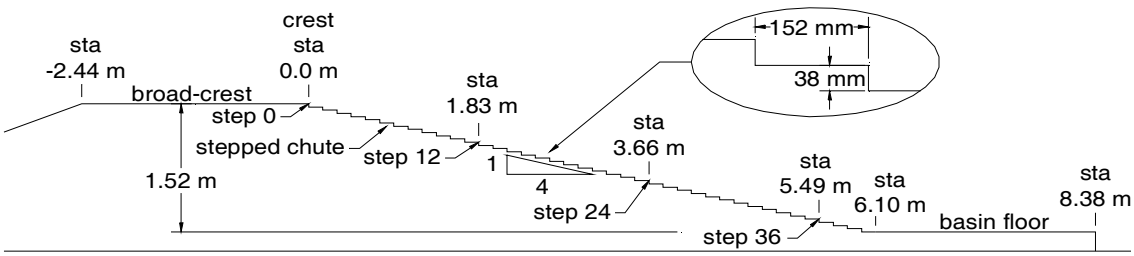

Figure 1. Schematic of stepped spillway model with the 38 mm (1.5 inch) high steps.

The 2-D model was constructed across the full width of a 1.8 m (6 ft) flume. The flume walls are 2.4 m (8 ft) tall, and the spillway model has a vertical drop of 1.5 m (5 ft). Figure 2 illustrates the two-dimensional model as it was originally constructed in the flume. A broad-crested weir served as the entrance conditions to the stepped spillway chute with the downstream edge of the weir corresponding to station 0.0 m (0.0 ft) and step 0. The chute slope was 4(H):1(V). Model step heights of 38 mm (1.5 inches) were originally tested, and later every other step was removed to create a stepped spillway chute with step heights of 76 mm (3.0 inches).

Water surface elevations and velocity measurements were taken throughout testing. Figure 3 illustrates a manually operated point gage attached to a moveable

carriage that was used to measure centerline water and bed surface elevations. Cross-sectional velocity profiles along the broad crested weir were collected with an acoustic Doppler velocimeter (ADV) that was attached to the point gage. The velocities and flow depth measurements at the broad crested weir were used to develop a calibration curve of the flow versus upstream head. The carriage was also used in centerline velocity measurements along the crest section. A second set of rails was attached to the inside of the flume walls and set parallel to the chute slope; thereby, allowing velocity and water surface measurements along the centerline of the chute to be taken perpendicularly to the chute slope. Unit discharges of 0.11, 0.21, 0.28, 0.42, 0.62, 0.82 $m^3/(s \cdot m)$ (1.2, 2.2 3.0, 4.5, 6.6, 8.9 cfs/ft) were tested.

Figure 2. 2-D stepped spillway model with the original 38 mm (1.5 inch) steps.

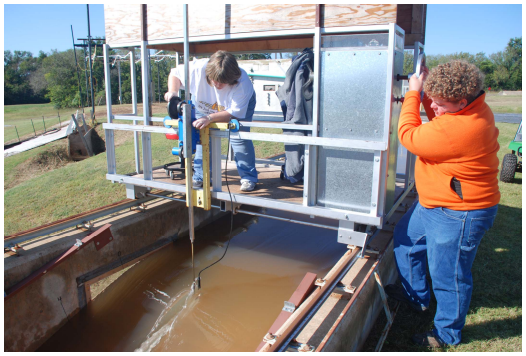

Figure 3. Data collection using a mobile carriage.

Scale effects can be expected when modeling highly air entrained flows when viscous forces and surface tension are not properly accounted for in the modeling. Scale effect is a term used to describe slight distortions that are introduced by ignoring viscous forces and surface tension in highly air entrained flows. Chanson (1994a), Boes and Hager (2003a and 2003b), and Takahashi, et al. (2006) have provided guidance to other researchers on modeling techniques for reducing scale effects associated with air entrained flows. Generally, a scale of 10:1 or larger is an accepted scale for modeling stepped spillways (Chanson, 2002). Boes and Hager (2003a) recommend a minimum Reynolds number of 10^5 and Weber number of 100 to minimize scale effects. Takahashi, et al. (2006) state that the Morton number must be considered to minimize scale effects. Morton's number accounts for both viscous forces and surface tension and is a product of both Reynolds and Weber numbers. For this model study, the Reynolds numbers ranged from 9.6×10^4 to 7.3×10^5, and the Weber numbers ranged from 112 to 234 for unit discharges ranging from 0.11 to 0.82 $m^3/(s \cdot m)$, repectively (Hunt and Kadavy, 2008a and 2008b).

Velocity profiles and flow depths were collected along the centerline of the spillway using three separate measuring devices: 1) an ADV, 2) a pitot tube (PT) coupled with a differential pressure transducer, and 3) a two-tip fiber optical (FO) probe and data acquisition system. Figures 4a, 4b, and 4c show the velocity instrumentation in use during the tests. Each device has a unique range of velocities it captures during operation. The ADV was limited by a maximum velocity of 4.6 m/s (15 ft/s), and it could only be used in non-turbulent flow conditions. The ADV

was primarily used to measure velocities at the broad-crested weir for model calibration. The PT coupled with a pressure transducer captured higher velocities that the ADV could not measure and verified some of the velocity measurements that were collected with the ADV. The two-tip FO probe was used to measure velocities and void fraction (C) in air entrained flows. The two-tip FO probe also allowed a comparison to some of the PT data. In some cases, the PT is not suitable to measure velocities in air entrained flows, but Matos, et al. (2002) reports that a backflushing PT is capable of measuring velocities in air entrained flows if the air concentrations are less than 70%. So to achieve a more accurate velocity measurement in air entrained flows, the PT was backflushed before each measurement to avoid air bubbles in the tube and the lines to the pressure transducer. The void fraction data collected by the FO probe was used to determine the equivalent clear water depth. The equivalent clear water depth is the depth of flow without the presence of air and is relevant to determining the energy loss in the spillway chute.

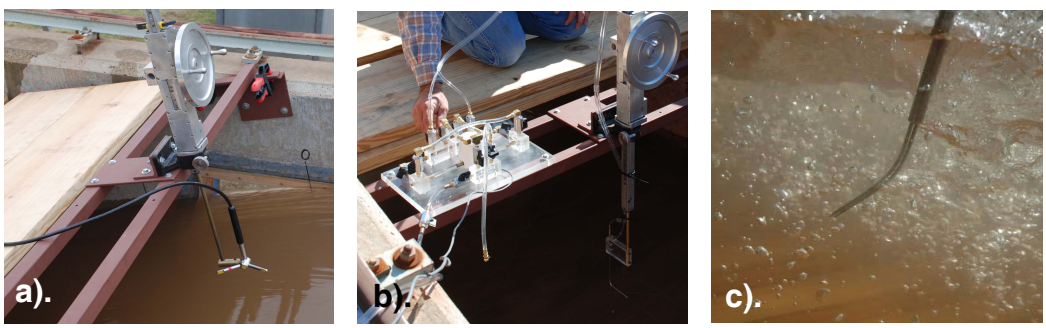

Figure 4. a). ADV flow tracker, b.) Pitot tube with a differential pressure transducer, c.) Two-tipped fiber optic probe.

Velocity profiles were taken normal to the spillway crest surface along the centerline at horizontal stations -2.4, -1.8, -1.2, -0.61, 0.0 m (-8, -6, -4, -2, and 0 ft) with the ADV. Centerline velocities profiles normal to the spillway chute slope were taken at horizontal stations 0.0, 0.61, 1.2, 1.8, 2.4, 3.0, 3.7, 4.3, 4.9, and 5.5 m (0, 2, 4, 6, 8, 10, 12, 14, 16, and 18 ft) with the ADV when applicable, with the PT for all stations along the chute slope, and with the FO probe when air entrainment was present. These horizontal stations correspond to the downstream edge of every fourth step for the stepped spillway having 38 mm (1.5 inch) high steps and every other step for the stepped spillway having 76 mm (3.0 inch) high steps. Figure 1 defines the stations as they relate to the stepped spillway model.

RESULTS AND DISCUSSION

Energy dissipation in a spillway chute is valuable information to the design engineer when it comes to designing the stilling basin. Stepped spillways dissipate a significant amount of energy when compared to traditional smooth chute spillways. Consequently, the stilling basin size for a stepped spillway is traditionally smaller than a stilling basin for a smooth chute spillway if the two spillways are based on similar design parameters.

To determine the energy loss in the spillway chute, velocity must be determined. Figure 5 illustrates typical velocity profiles expected in a stepped spillway. The profiles transition from near uniform at the crest section to a one-sixth

power law distribution near the inception point (Hunt and Kadavy, 2008a; Boes and Hager, 1998; and Chanson, 2000). Figures 6a and 6b present typical depth-velocity and depth-void fraction (C) profiles slightly upstream of the inception point at station 3.05 (10 ft) and downstream of the inception point at station 5.49 m (18 ft) for the stepped spillway having step heights of 38 mm (1.5 inch), respectively. Figures 6a and 6b show both PT and FO data. Air concentrations near the spillway chute bed surface as illustrated in Figure 6a were relatively non-existent and therefore undetectable by the FO probe. The PT was used to capture these velocities. The PT and FO data collected near the inception point yielded similar results with data points clustered closely together. In Figure 6b, distinction between the two profiles are more noticeable, yet the average velocities for the PT and FO data are 3.70 m/s (12.15 ft/s) and 3.69 m/s (12.12 ft/sec), respectively. Based on this outcome, the air concentration in the flow appears small enough that it does not significantly affect the average velocity.

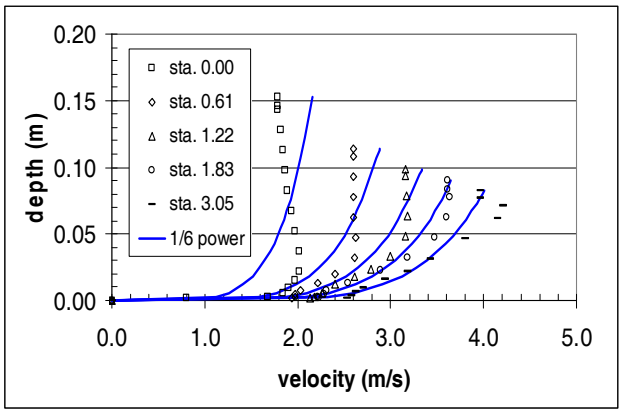

Figure 5. Velocity profiles for a unit discharge of 0.28 $m^3/(s \cdot m)$ (3.0 cfs/ft) transition from a uniform distribution at the crest and approach a one-sixth power law distribution near the inception point.

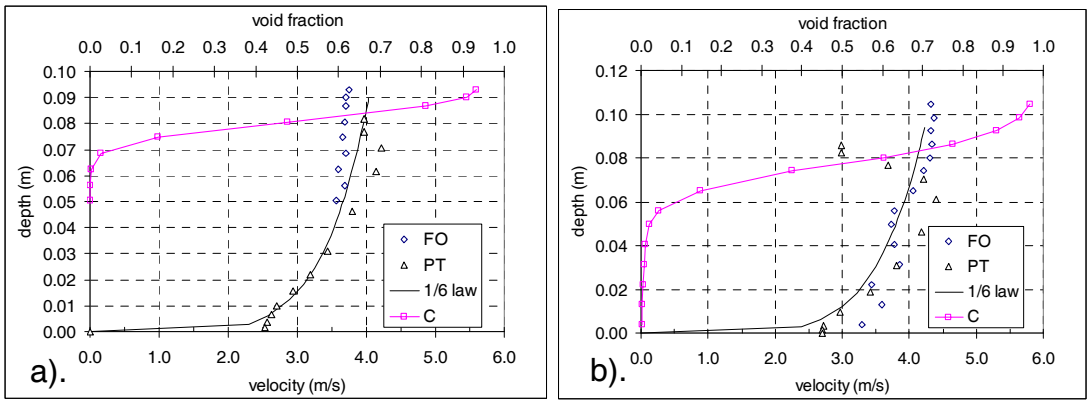

Figure 6. Depth-velocity and depth-void fraction (C) for a unit discharge of 0.28 $m^3/(s \cdot m)$ (3.0 cfs/ft) and a spillway step height of 38 mm (1.5 inches). a). Station 3.05 m (10 ft), b). Station 5.49 m (18 ft).

Figures 6a and 6b also illustrate depth-void fraction profiles. At each station, the void fraction increases in a logarithmic trend. The void fraction data was used to

determine the equivalent clear water depth, y_{cw}, for each station. For air-water flows, Chanson, et al. (2002) defines the equivalent clear water depth as

$$y_{cw} = \int_0^{y_{90}} (1-C) * dy \quad (1)$$

where y_{90} is characteristic depth (m) when the air concentration is 90% and C is air concentration, which is also known as void fraction. Upstream of the inception point, the depth is considered clear water depth because there is no presence of air in the flow. Downstream of the inception point, air is visibly present. Therefore, the equivalent clear water depth downstream of the inception point is the depth of flow with no air present. Figure 7 illustrates the equivalent clear water depth-velocity profile for station 5.49 m (18 ft). When Figure 7 is compared to Figure 6b, the clear water flow depth is less in Figure 7 as compared to the flow depth with air in Figure 6b. The clear water depth is needed to determine the average air concentration in the flow as well as the energy dissipation. As defined by Boes and Hager (2003a), the average air concentration, C_{avg}, in percent is

$$C_{avg} = 1 - \frac{y_{cw}}{y_{90}} * 100 \quad \text{for } \% \quad (2)$$

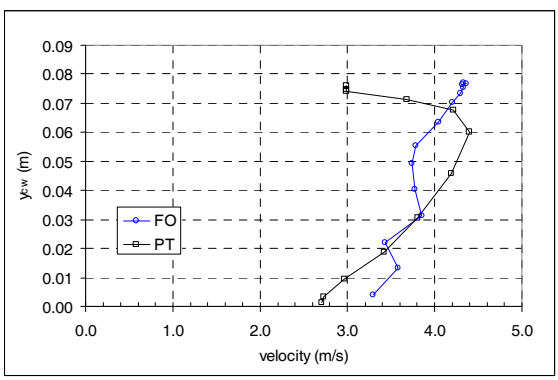

Figure 7. y_{cw}-velocity profiles at station 5.49 m (18 ft) for a q of 0.28 $m^3/(s \cdot m)$ (3.0 cfs/ft) and a stepped spillway with step height equal to 38 mm (1.5 inches).

The average velocity obtained from the velocity profiles was used to determine the relative energy loss on the spillway chute. The average velocity was based on the equivalent clear water depth, y_{cw}, as illustrated in a single example in Figure 7. With the average velocity at each station known, the total energy loss to a given step relative to the step of interest can be determined

$$\Delta H = H_o - H \quad (3)$$

where $H_o = y_o + \frac{V_o^2}{2g}$; $H = y_{cw}\cos\theta + \alpha\frac{V_{cw}^2}{2g}$, V_{cw} = clear water mean velocity; V_o = approach velocity; y_o = approach depth above datum, y_{cw} = clear water flow depth , θ = chute slope, g = gravitational acceleration, and α = energy coefficient. Figure 8 illustrates the energy loss parameters as they relate to the stepped spillway. In many open channel applications where the channel is of regular cross-section with fairly straight alignment, the energy coefficient, α, is assumed to equal one because the effect of nonuniform velocity distribution on the computed velocity head and

momentum is small (Chow, 1959). To determine the effect that the nonuniform velocity distribution has on the computed velocity head and momentum, Equation 4 was used to determine the energy coefficient.

$$\alpha = \frac{\int v^3 dA}{V_{cw}^3} \approx \frac{\sum v^3 \Delta A}{V_{cw}^3 A} \tag{4}$$

where v is the point velocity for an incremental area in the velocity profile, V_{cw} is the mean velocity of the of the equivalent y_{cw}-velocity profile, and A is the total area of the profile. Assuming two-dimensional flow that is uniform across the width, the area, A, is replaced by the equivalent y_{cw}. For both step heights, α ranged from 1.01 to 1.13. This α range is reasonable when compared to values of 1.05 to 1.1 reported by Boes (1999) for fully air entrained flows.

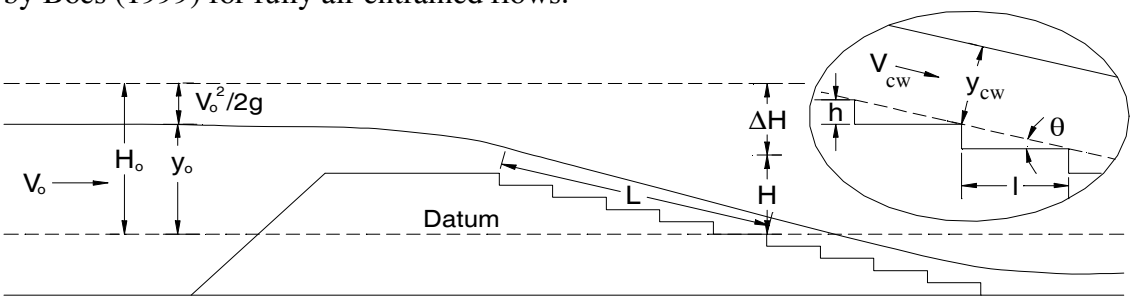

Figure 8. Energy loss parameters as they relate to the stepped spillway.

With the α determined, Equation 3 was used to determine the energy loss in the stepped spillway. Figures 9a and 9b illustrates a comparison of the energy loss for step heights of 38 mm (1.5 inches) and 76 mm (3.0 inches) and unit discharges of 0.11 $m^3/(s \cdot m)$ (1.2 cfs/ft) and 0.82 $m^3/(s \cdot m)$ (8.9 cfs/ft), with respect to horizontal stationing for the spillway. Energy loss increases as the flow descends the spillway chute. Additionally, Figures 9a and 9b illustrate that as the step height increases the energy loss also increases. Figure 9a also shows the inception point locations of 1.4 m (3.6 ft) and 1.1 m (4.6 ft) for the 38 mm (1.5 inch) and 76 mm (3.0 inch) step height chute configurations, respectively; indicating that as step height decreases the inception point moves further downstream for the given discharge. The inception points for Figure 9b are located in the stilling basin, so Figure 9b clearly shows the energy loss is greater for a step height of 76 mm (3.0 inch) upstream of the inception point while Figure 9a undoubtedly illustrates the energy loss is greater for the 76 mm (3.0 inch) steps downstream of the inception point.

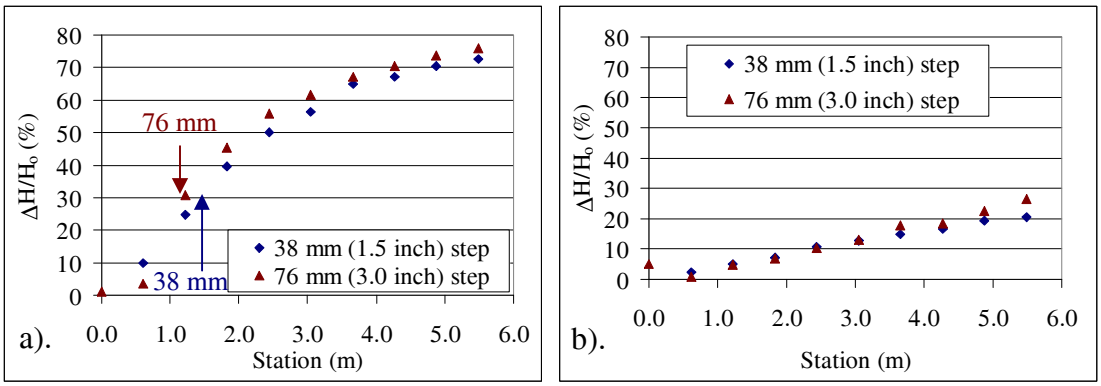

Figure 9. a). Energy loss for 38 mm (1.5 inch) and 76 mm (3.0 inch) step height for a unit discharge of 0.11 $m^3/(s \cdot m)$ (1.2 cfs/ft) versus horizontal stationing with the arrows defining inception point location with regards to step height b). Energy loss for 38 mm (1.5 inch) and 76 mm (3.0 inch) step height for a unit discharge of 0.83 $m^3/(s \cdot m)$ (8.9 cfs/ft) versus horizontal stationing.

Hunt and Kadavy (2008a) further compared the energy loss with respect to the inception point location and reported that the energy loss follows a linear trend upstream of the inception point for a 4(H):1(V) stepped chute with 38 mm (1.5 inch) high steps. The energy loss relationship upstream of the inception point provided by Hunt and Kadavy (2008a) is

$$\frac{\Delta H}{H_o} * 100 = 30 * \frac{L}{L_{i*}} \tag{5}$$

Downstream of the inception point in the same model, Hunt and Kadavy (2008b) reported that the energy loss follows a logarithmic trend, increasing from 30% energy loss at the inception point to approximately 73% for a value of L/L_{i*} of 3.5. Figure 10 illustrates these trends hold with the inclusion of the 76 mm (3.0 inch) step height data and the Salado data from the Rice and Kadavy (1996) study. The Salado data provides additional confirmation that this design information is also applicable for a chute slope of 2.5(H):1(V).

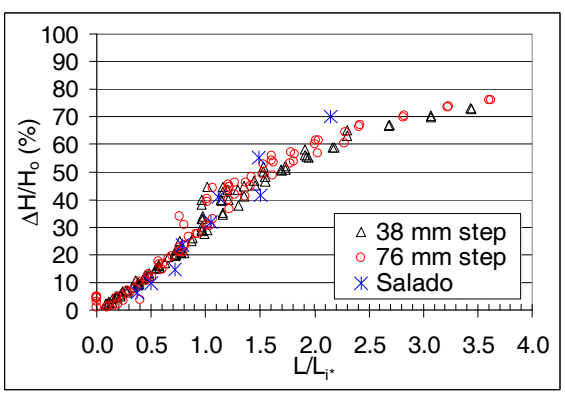

Figure 10. Energy loss versus the normalized length down the spillway chute.

CONCLUSIONS

RCC stepped spillways applied to embankment dams to increase spillway capacity create unique challenges for design engineers. These spillways typically

have flat slopes of 2(H):1(V) or flatter and are relatively short in length when compared to gravity dam stepped spillways. As a result, oftentimes the air entrainment is not fully developed within the spillway chute. Determining the energy loss in the spillway is valuable information for determining the dimensions of the stilling basin. Yet, most literature reports energy losses in the spillway downstream of the inception point where the flow is fully air entrained. In this study, the energy loss through the entire spillway chute is examined with regards to step height and inception point location. Findings show that with increasing step height, the energy losses at similar locations within the spillway chute also increase. Additionally, for a given unit discharge, the inception point location moves further downstream of the crest section as step height decreases. When the energy losses were compared to a normalized length, L/L_{i*}, the energy losses increased linearly from near zero at the spillway crest to 30% at the inception point for both spillway configurations. Downstream of the inception point, the two step height showed that the energy losses increased in a logarithmic trend from 30% at the inception point to approximately 73% when L/L_{i*} equals 3.5. This research is expected to assist engineers with the design of stepped spillways applied to embankment dams.

ABSTRACT

Run of the river low head dams provide an attractive nuisance since the relatively placid areas downstream of the dam entice people to either swim or canoe/raft/kayak into these areas. To address this public safety issue, the Illinois Department of Natural Resources, Office of Water Resources (IDNR) had been tasked to develop a hydraulic analysis or methodology to define the hydraulic characteristics at the Geneva Dam (on the Fox River near Geneva, IL) spillway and to develop the sizing of a temporary rock ramp on the downstream side of the existing run-of-river dam ogee spillway. The rock ramp was to minimize the existing submerged hydraulic jump "roller" at the site for flow conditions up to a 5-year frequency flow event. The rock ramp would also be stable for up to a 100-year frequency flow condition with a 20-year expected project life until a more permanent solution is developed and implemented.

A temporary rock ramp was proposed and sized to accomplish these criteria for the downstream side of the Geneva dam spillway. Several riprap methods that were applicable to steep slopes were analyzed. To facilitate the computations and to make direct comparisons of the results, a spreadsheet was developed that contained all of the methods and included warnings for applicability of the methods. This paper describes the thought processes, the applicability of single and multi-dimensional computational models for addressing the hydraulic roller problem, and the computations and the development of the steep ramp riprap design spreadsheet.

INTRODUCTION

Run of the river low head dams provide an attractive nuisance since this area, even under quiescent conditions, often contains a submerged hydraulic jump for energy dissipation, resulting in portions of the water traveling downstream, portions boiling to the surface, and other portions flowing back toward the dam. This phenomenon is called a reverse hydraulic roller and entraps people that enter the water, keeps them submerged and causes drowning.

To address this public safety issue, the Illinois Department of Natural Resources, Office of Water Resources (IDNR) had been tasked to develop a hydraulic analysis or methodology to define the hydraulic characteristics at the Geneva Dam (on the Fox River near Geneva, IL) spillway and to develop the sizing of a temporary rock ramp on the downstream side of the existing run-of-river dam ogee spillway. The rock ramp was to minimize the existing submerged hydraulic jump "roller" at the site for flow conditions up to a 5-year frequency flow event. The rock ramp would also be stable for up to a 100-year frequency flow condition with a 20-year expected project life until a more permanent solution is developed and implemented. The basic needs of IDNR to address these issues include:

- Determination of an hydraulic analysis or methodology to define the hydraulic characteristics at the Geneva dam spillway as well as be able to analyze alternatives that could be developed to minimize or alleviate the hydraulic roller problem. It must also be reasonably available (limited cost to purchase and run on existing IDNR office desktop computers) to the Office of Water Resources and reasonably used by Office of Water Resources staff with limited training. This hydraulic analysis or methodology may be applicable to other similar run-of-river dams on the Fox River.

- Development of a hydraulic analysis or methodology to define the hydraulic characteristics at the dam spillway and to support the sizing of a temporary rock ramp on the downstream side of the existing run-of-river dam ogee spillway on the Fox River in Geneva, Illinois.

Figure 1 shows the location of Geneva Dam. Figure 2 shows an aerial image of the area. Figure 3 shows a photo of the dam. Figure 4 shows an illustration of public safety concern related to the roller.

A temporary rock ramp was proposed and sized to accomplish these criteria for the downstream side of the Geneva dam spillway. Several riprap methods that were applicable to steep slopes were analyzed. The riprap methods examined were:

a. U.S. Army Corps of Engineers' (COE) method for steep slopes (from EM 1110-2-1601).
b. Isbash Method, high turbulence (from EM 1110-2-1601).
c. Frizell, Ruff and Mishra method for overtopping flows.

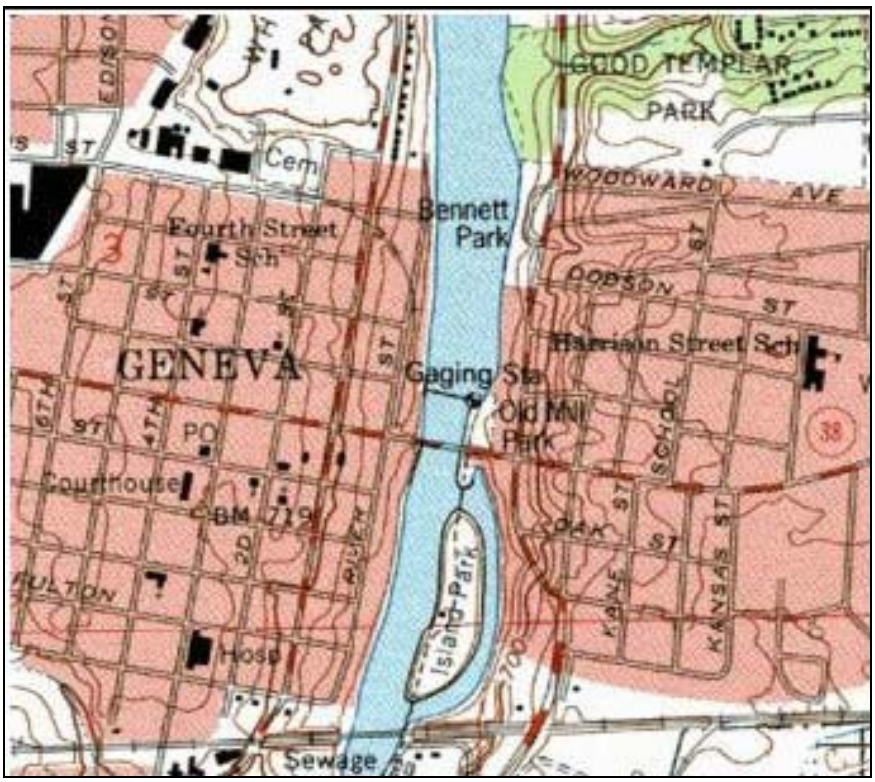

Figure 1. Location of Geneva Dam

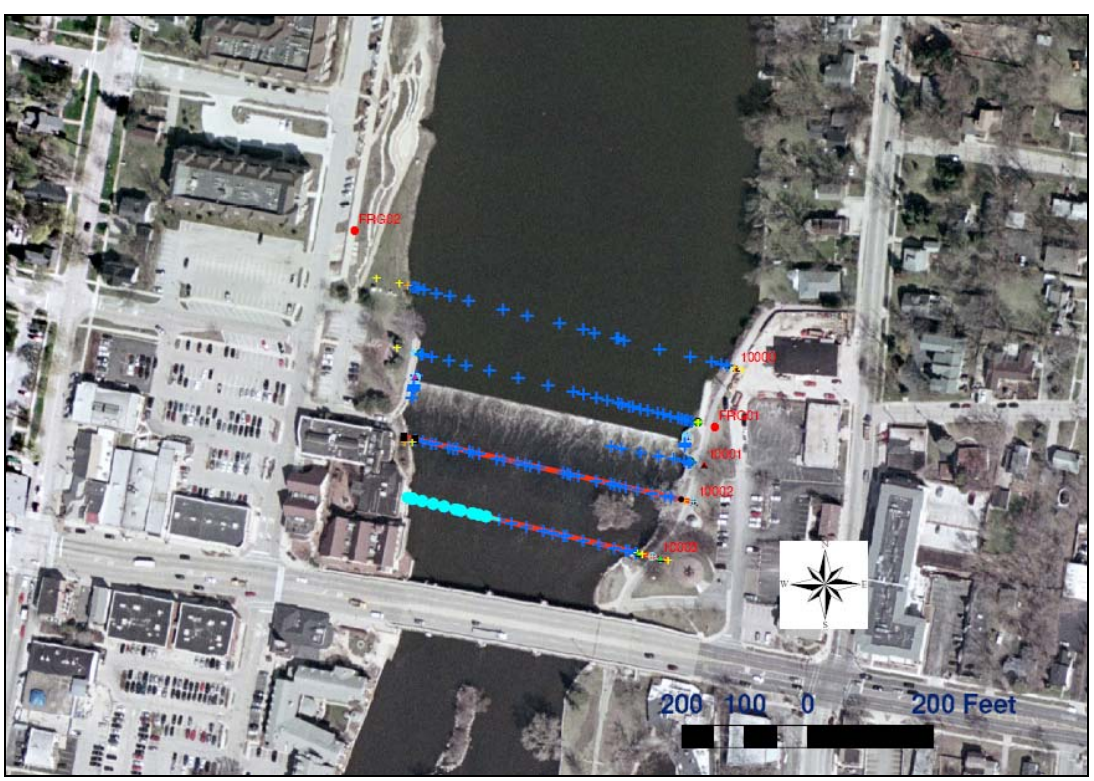

Figure 2. Aerial Image of Geneva Dam Area

Figure 3. Photo of Geneva Dam

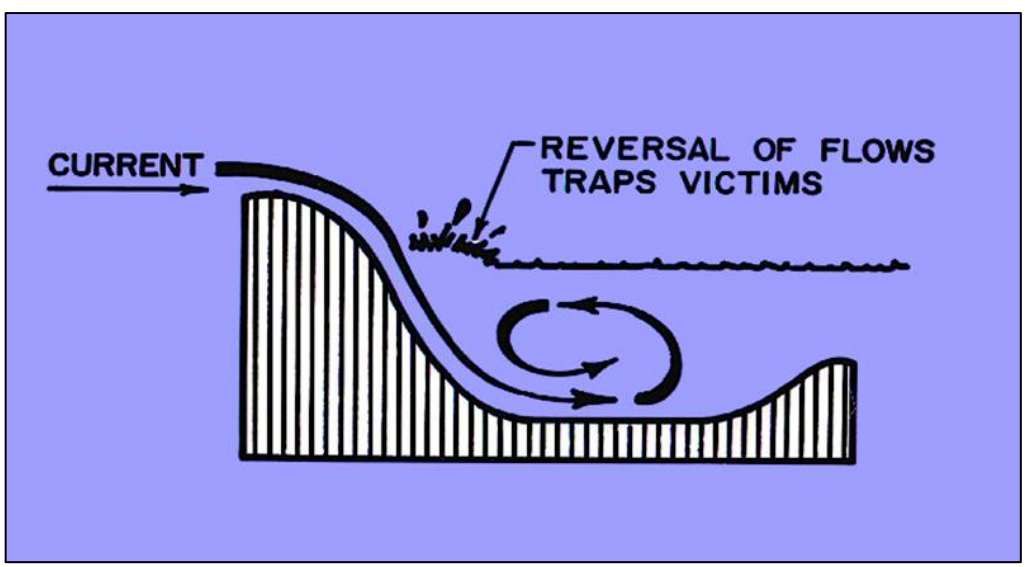

Figure 4. Public Safety Concern of Existing Dam Design

d. Hydraulic Engineering Circular 15, Design of Roadside, Channels with Flexible Linings (HEC-15, FHWA).

To facilitate the computations and to make direct comparisons of the results, a spreadsheet was developed that contained all of the methods and included warnings

for applicability of the methods. This paper describes the thought processes, the applicability of single and multi-dimensional computational models for addressing the hydraulic roller problem, and the computations and development of the steep ramp riprap design spreadsheets.

DATA COLLECTION AND REVIEW

Available data and information were provided by IDNR, including:

- Plan view of survey data available at Geneva Dam;
- Surveyed cross section (parallel to flow) of the Geneva Dam at each dam abutment;
- Four surveyed cross sections of the Fox River in the vicinity of the Geneva Dam (2 cross sections upstream and 2 cross sections downstream of the dam);
- Rating curve for the Geneva Dam;
- Flow frequency data for the Geneva Dam;
- HEC-2 input files for Geneva Dam;
- General description of the Geneva Dam; and
- Representative photos of the Geneva Dam.

Basic information of Geneva Dam includes:

- Type - ogee;
- Material - concrete;
- Weir Length – 134.4 meters (m) or 441 feet (ft);
- Height – 3.96 m (13 ft);
- Spillway elevation – 205.86 m (675.40 ft);
- Length of pool – 3.19 kilometers (km) or 1.98 miles; and
- Area of Pool – 0.36 km^2 (89 acres).

Based on the review of available data provided by IDNR, a technique was recommended to define the hydraulic characteristics at the Geneva dam spillway as well as evaluate possible alternatives to alleviate the hydraulic roller problem. The recommended technique was based upon consideration of availability (limited cost to purchase and run on existing office desktop computers) to IDNR, ability to address the hydraulic conditions for a full range of possible alternatives and use by IDNR engineering staff with limited training and specialized expertise. The technique must be able to, at a minimum, hydraulically (vertical dimension for roller analyses) simulate the following:

a. Structural modifications to the dam weir and apron
    1. Notches
    2. Steps
    3. Apron dimensions, etc.
b. Changes to the weir approach
c. Multiple bypass alternatives
    1. Fish bypass

2. Hydraulic bypass
3. Manual and automated operation of bypasses

Given the complexity of hydrodynamics immediately downstream of a dam and solutions that may include lateral bypasses, two- or even three-dimensional (2D or 3D) model are required to analyze the detailed water velocity distribution in the area. Potential 2D and 3D models that may be suitable for such analysis include: SOBEK, RMA2, FESWMS-FST2DH, HEM2D, HIVEL 2-D, TUFLOW, RMA10, ADCIRC, CH3D-WES, DELFT3D-FLOW, HEM3D, MIKE21/3, GLLVHT, FLUENT, and FLOW-3D. Although dendritic 1D models (such as HEC-RAS) can adequately model simplified bypass conditions, only 2D lateral (horizontal) model are applicable if approach conditions to the bypass are complicated or other multi-dimensional phenomena dominate.

For analysis of the hydraulic roller alone (near field analysis), the FLUENT and FLOW-3D models were recommended. For far field analysis only (for such alternative as bypasses), FESWMS-FST2DH is recommended for mixed flow conditions and if mixed flow is not an issue, RMA2 and FESWMS-FST2DH were recommended. For simulation of the hydraulic roller and far field analyses, a combination of FLUENT or FLOW-3D and RMA2 or FESWMS-FST2DH were recommended. These models do not pass the desktop PC or limited training constraints, so these methods are not recommended for this situation. If the far field conditions are hydraulically simplistic, that portion can be modeled using a 1D model such as HEC-RAS.

DEVELOPMENT OF HYDRAULIC MODEL FOR RIPRAP RAMP DESIGN

An HEC-2 model containing the geometry in the vicinity of Geneva Dam was obtained from IDNR. This geometry was converted to an HEC-RAS model and refinements made to the model. Most of the refinements to the model were made in the area at and near the dam spillway. The HEC-RAS model was then modified to simulate riprap ramp slopes of 5 and 10%. To bracket the possible Manning's n values for the riprap, which depends on its gradation, n values of 0.35 and 0.70 were used for each of the ramp slopes.

The hydrologic conditions include a 5-year frequency flow event for roller minimization, followed by the 10-year, 50-year and the 100-year frequency flow condition for the stability of the rock riprap ramp. Based on the data provided by IDNR, the 100-year flow is 346.88 cubic meters per second (cms) or 12,250 cubic feet per second (cfs). The 5-year flow was estimated to be 192.55 cms (6,800 cfs) by constructing a frequency plot shown in Figure 5 based upon other frequency discharges provided by IDNR.

The developed HEC-RAS model was executed for the following three physical conditions and four discharges:

a. Existing Conditions; 5-year, 10-year, 50-year and 100-year discharges

b. Proposed Riprap Ramp Slope = 0.05; 5-year, 10-year, 50-year and 100-year discharges
c. Proposed Riprap Ramp Slope = 0.10; 5-year, 10-year, 50-year and 100-year discharges

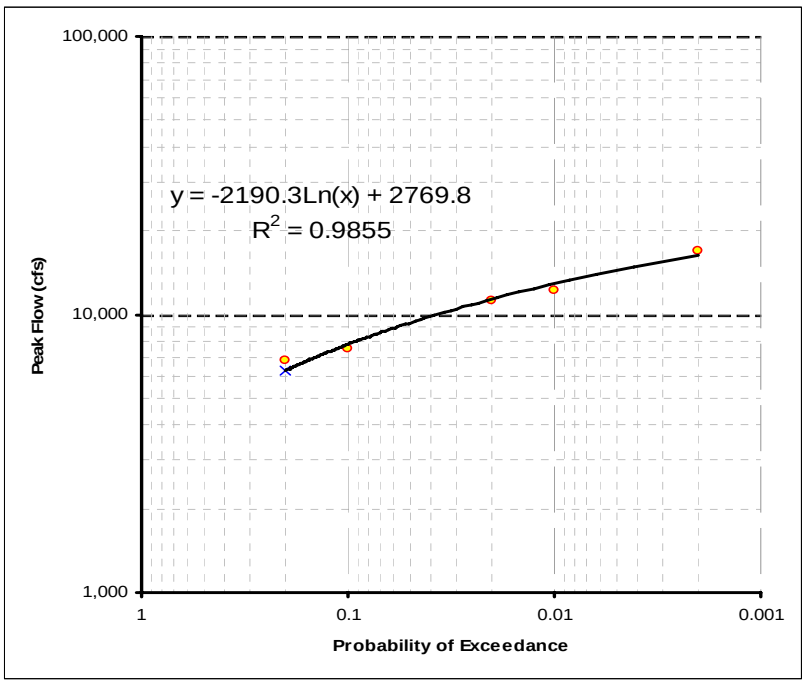

Figure 5. Flow Frequency Plot for Geneva Dam Location

SIZING OF ROCK RIPRAP RAMP

A temporary rock ramp was sized to eliminate, or minimize to a safe level, the existing submerged hydraulic jump "roller" at the site for the specified frequency flow events. The following riprap methods were examined:

a. U.S. Army Corps of Engineers' (COE, 1994) method for steep slopes (from EM 1110-2-1601).
b. Isbash Method, high turbulence (from EM 1110-2-1601).
c. Frizell, Ruff and Mishra method for overtopping flows (1998).
d. Hydraulic Engineering Circular 15, Design of Roadside, Channels with Flexible Linings (HEC-15, FHWA, 2005).

Note that the COE method for steep slopes gives D_{30} for the representative riprap size whereas the others give D_{50}. To make the methods comparable, the D_{30} result was converted to an equivalent D_{50} using the formula $D_{30} = D_{50} (D_{15} / D_{85})^{0.33}$, which is related to the COE gradation method (see EM1110-2-1601). The COE method assumes that the thickness is 1.5 times the D_{100} and the slope can range from 2 to 20%.

The HEC-15 was developed for riprap ramps that have riprap side slopes. Since the riprap design should be based upon the longitudinal slope and not the side slope, the weir side slopes was assumed to be relatively flat. For placement of the riprap on the downstream side of the weir crest, the riprap along the side should be anchored to the concrete sides of the dam. This can be done by extensive grouting or by anchoring large pieces of riprap with rebar that is attached to the concrete walls.

These methods were selected because they have a history of application to steep longitudinal slopes. The inputs to these methods were obtained from the flow data, the results of the HEC-RAS model, and user specified inputs such as the ramp slope. A Microsoft Corporation Excel spreadsheet was developed which included the computations for the four methods mentioned. This spreadsheet can be used for a variety of inputs. Figure 6 shows an illustration of an ogee dam cross section used for riprap volume calculations in the spreadsheet.

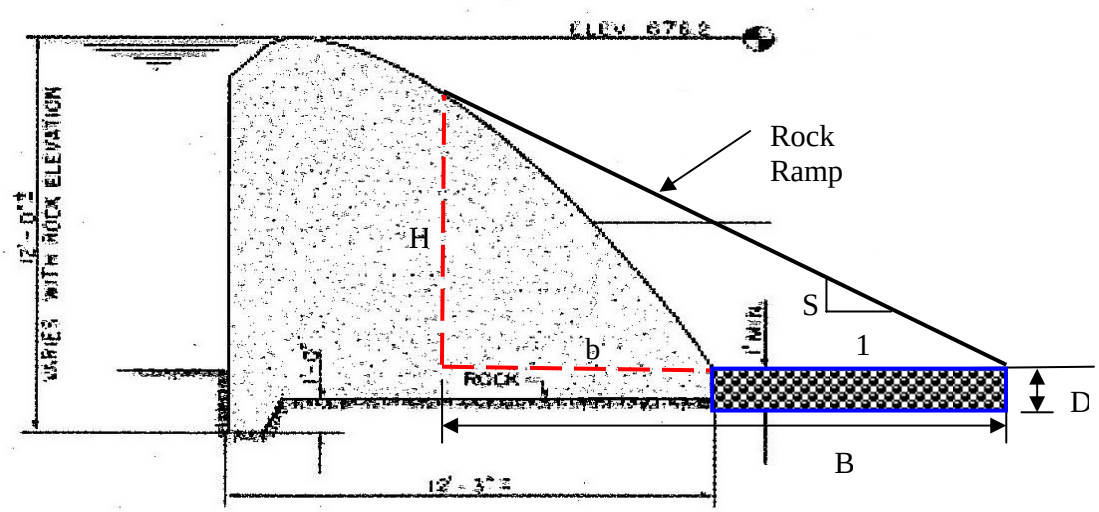

Figure 6. Illustration of Dam Section Used for Riprap Volume Calculations

Table 1 shows the results of the riprap design. The Isbach method results are much higher than the other 3 methods whereas those three methods give remarkably close results. Upon closely examining the Isbach method, it was found that the formula was developed for the construction of dams by depositing rock into running water. If the dumped rock did not slide or roll under that condition, the rock size was considered stable. Obviously this would result in very conservative answers. Because of this, the Isbach method was not recommended.

The next highest results (for a ramp slope of 10%) are from the HEC-15 method but this is not surprising since it uses a safety factor of 1.5. The Frizell et. al. method is the least conservative method for a slope of 10%. In the reference for this method, the unit discharge for the Geneva Dam exceeded those presented in the graph used in determining the D_{50} of the riprap. The COE method shows reasonable results for the full range of ramp slopes and discharges and therefore is recommended for design of the riprap for Geneva Dam.

Table 1. Results of Rock Ramp Design and Riprap Sizing

Return Period (years)	Channel Slope	Manning's n	Methodology				Average D_{50}* (m | ft)

50			0.448 | 1.47	0.710 | 2.33	0.326 | 1.07	0.661 | 2.17	0.561 | 1.84
100			0.475 | 1.56	0.722 | 2.37	0.354 | 1.16	0.716 | 2.35	0.591 | 1.94

*Averaging D_{50} includes the conversion of D_{30} to D_{50} using the USACE gradation of $D_{50} = D_{30}/0.82$.

The thickness and gradation of the riprap should be based upon the COE method, which is presented in EM 1110-2-1601, since the recommended method and the COE gradation method uses D_{30} as the basis for design.

Because of the high turbulence, vibration of the riprap would tear filter fabric; therefore, granular filter is recommended. The downstream end of the riprap, as projected from the weir at the design ramp slope, should be buried below the streambed and the burial depth equal to the thickness of the riprap and the filter material. The burial depth of the riprap at the downstream end should be projected horizontally upstream to the weir to define the lower limit of the riprap. Riprap volume can be determined by measuring the projected area of the proposed riprap (including granular filter) and multiplying it by the representative weir length. Note that the riprap immediately downstream of the crest (abutting the crest) can be from 1 to 2 feet below the crest. Cost is hard to estimate because it often depends on the availability of the particular size riprap and market conditions. However, estimates could be made using riprap bids from comparably located projects utilizing the computed riprap volume as described.

CONCLUSIONS

A study was conducted to evaluate and recommend hydraulic models or methodology for the analyses of the hydraulic roller problem at their run-of-the-river dams, in particular, Geneva Dam. A PC based hydraulic model was deemed not feasible to run in this scenario on IDNR desktop computers with limited training. Instead, four riprap methodologies were examined. The COE method for steep slopes was recommended since it did not have the deficiencies of the other methods and produced reasonable results for the full range of slope and discharge conditions. A recommendation using the chosen methodology was also made for the design of temporary riprap ramps to be placed just downstream of the weir crest of the run-of-the-river dams, in particular, Geneva Dam.

ABSTRACT

This paper summarizes research from separate studies of fish passage over weirs (Larson *et al*., 2004; Litvan, 2006; Litvan, *et al*., 2008a-c) and weir hydraulics (Papanicolaou and Dermisis, 2006; Papanicolaou and Dermisis, in press). Channel incision in the deep loess region of western Iowa has caused decreased biodiversity because streams have high sediment loads, altered flow regimes, lost habitat, and lost lateral connectivity with their former floodplains. In-stream grade control structures (GCS) are built to prevent further erosion, protect infrastructure, and reduce sediment loads. However, GCS can have a detrimental impact on fisheries abundance and migration, biodiversity, and longitudinal connectivity. Fish mark-recapture studies were performed on stretches of streams with and without GCS. GCS with vertical or 1:4 (rise/run) downstream slopes did not allow fish migration, but GCS with slopes ≤ 1:15 did. GCS sites were characterized by greater proportions of pool habitat, maximum depths, fish biomass, slightly higher index of biotic integrity (IBI) scores, and greater macroinvertebrate abundance and diversity than non-GCS sites. After modification of three GCS, IBI scores increased and fish species exhibiting truncated distributions before were found throughout the study area. Another study examined the hydraulic performance of GCS to facilitate unimpeded fish passage by determining the mean and turbulent flow characteristics in the vicinity of the GCS via detailed, non-intrusive field tests. Mean flow depth (Y) and velocity (V) atop the GCS were critical for evaluating GCS performance. Turbulent flow measurements illustrated that certain GCS designs cause sudden constrictions which form eddies large enough to disorient fish. GCS with slopes ≤ 1:15 best met the minimum requirements to allow catfish passage of a flow depth of ≥ 0.31 m and a mean flow velocity of ≤ 1.22 m/s.

INTRODUCTION

Channelization of streams and land use changes during the first half of the 20th century caused western Iowa stream channels to become unstable. Coupled with the highly erosive loess soils found in the deep loess region of western Iowa, the channels began to downcut and widen, causing an estimated $1.1 billion in damages to public and private infrastructure (by exposing buried bridge pilings, culvert outlets, utility lines, etc., and increasing their likelihood of failure), loss of farmland, and increased sediment loads (Baumel 1994). Streams that were once merely wetlands or shallow meandering streams are now deep, non-meandering, ditches nearly 9.1 m deep. Obviously, these streams have highly altered flow regimes (Hansen, 1971; Shields *et al*. 1994); channel roughness is lower and flow velocities and discharges are much higher than they once were. These scoured channels have lost much, if not all, of their original habitat; for example, many of these streams are devoid of riffle-pool sequences, except at very low baseflow. Prime fish habitat has been shown to be adversely affected by bed degradation in other studies (Shields *et al*. 1994; Raborn and Schramm 2003). Due to extreme downcutting, many channels have lost lateral connectivity with their former floodplains, except in the most extreme flow discharge events. Many streams are starting to establish a new, much thinner floodplain in the ditch bottom by widening of the channel due to bank failure. Extensive channel erosion has also caused dramatically increased sediment loads. The altered flow regimes, loss of habitat, loss of connectivity, and high sediment loads caused by channel incision has led to decreased biodiversity (Hansen, 1971; Shields *et al*., 1994; Bravard *et al*., 1997; Cooper *et al*., 1997; Shields *et al*., 1998; Raborn and Schramm 2003). Bunn & Arthington (2002) noted that in highly altered environments, invasive species may find it easier to out-compete native species in the new, altered environment. This may explain the abundance of invasive species such as carp in western Iowa streams. At a larger scale, what happens in western Iowa in terms of biodiversity and sediment loading will affect the Missouri and Mississippi Rivers (i.e., decreased dam storage due to siltation) and the Gulf of Mexico (i.e., hypoxia) due to longitudinal connectivity.

The most efficient and affordable way to prevent further channel incision and erosion, protect infrastructure, and reduce sediment loads is to build grade control structures. There are many types of grade control structures (GCS), but important fisheries are found in drainage areas > 7.8 km^2 which are most often controlled with weirs (Fig. 1A-D). Weirs are constructed with steel sheet pile, typically driven into the streambed 6.1 m, with a riprap and concrete grout slope immediately downstream, a riprap stilling basin downstream of the weir slope, and riprap covered banks. Only limestone bedrock is available in western Iowa, and it is found in relatively thin ledges (< 2.4-3.1 m), but due to bedding planes and stratification boulders greater than a 0.77 m^3 are very rare. Riprap also tends to fracture due to freeze/thaw processes and then move under higher flow conditions, so concrete grout is used to lock the riprap in place. Weirs are placed at regular intervals to locally decrease the stream slope and change the stream profile from an erosive steep incline to a stable stair-step pattern. Weirs allow a drop in stream elevation in a controlled setting, prevent further degradation, decrease sediment loads and turbidity, and increase water

quality. GCS have shown to be very economical, with every dollar invested in building a GCS, protecting more than $4.24 in property value and 889 kg of soil.

Figure 1. A) Sheet pile weir with loose riprap slope, originally built at 1:20 (rise/run), but note how rock has moved away from the sheet pile weir (black arrows). B) Sheet pile weir with 1:20 grouted riprap slope. C) Sheet pile weir with 1:4 grouted riprap slope. D) Sheet pile weir with 1:20 fish ladder and steel baffles.

Numerous government agencies affiliated with western Iowa have attempted to halt the process of channel degradation by constructing GCS over the last forty years; more than 750 GCS have been built already in western Iowa. A group of concerned government officials and private landowners formed the Hungry Canyons Alliance (HCA) to provide funding for some of these GCS. Despite these attempts at controlling streambed degradation, the problem is still widespread necessitating the construction of more GCS.

The subjects of streambed degradation, GCS, and the HCA is discussed in much greater detail in an accompanying paper in these proceedings entitled "Fish Passage and Abundance around Grade Control Structures on Incised Streams" by J. Thomas.

In-stream GCS may also increase habitat and flow diversity. The rock rip-rap used to construct GCS adds a unique substrate to the streams of western Iowa that are mostly dominated by silt and sand bottoms. GCS have been shown to affect flow characteristics within a stream, creating slower water above the structure and a scour pool below the structure (Shields *et al*. 1995). These changes in flow and habitat conditions may result in different fish and macroinvertebrate communities near and far away from these structures and increased biological diversity within the stream (Tiemann *et al*. 2004). The modification of local hydraulic conditions may actually

increase habitat for benthic macroinvertebrates during low flow conditions (Gore and Hamilton 1996). Artificial riffles have been shown to support macroinvertebrates at levels similar to natural riffles within the same stream (Ebrahimnezhad and Harper 1997). An increase of macroinvertebrates in stream segments altered by GCS would provide enhanced food resources for nearby fish communities, possibly resulting in improved growth and body condition of fish (Shields *et al*. 1995). Increased depth and substrate types found near GCS may increase diversity, growth, and reproduction potential of fish communities near GCS (Shields and Hoover 1991). Scour holes below GCS may be better fisheries resources than natural scour holes because of habitat stability (Cooper and Knight, 1987). However, some studies have shown that fish communities do not differ between un-altered stream reaches and reaches with GCS (Raborn and Schramm 2003).

Although large dams obviously present obstacles to fish movement, GCS in streams are more serious blockages to fish movement than originally believed (Ovidio & Philippart, 2002) and may limit the longitudinal connectivity of a stream. Streams in western Iowa with GCS tend to have a drainage area of less than 150 km^2. These are warm-water streams where the predominant fish species are channel catfish, flathead chub, creek chub, black bullhead, and yellow bullhead, all of which are not powerful swimmers. Preliminary sampling efforts and angler reports in western Iowa indicated a decline in channel catfish numbers, size and distribution, and species diversity. It is hypothesized that the downstream slope of GCS can be made gentle enough to allow for fish passage. However, the gentler the slope, the more money the GCS cost because of the additional rip-rap needed to create the longer downstream riffle. For example, the cost of a GCS with a 1:20 (rise/run) downstream slope is approximately $40,000 more than the same GCS with a 1:4 downstream slope. The Hungry Canyons Alliance (HCA) and Iowa Department of Natural Resources (DNR) commissioned research to determine the right balance between making GCS ecologically sound while making them inexpensive to build. The purpose of this paper is to review and disseminate the results of this research: two fish sampling studies (Larson *et al*., 2004; Litvan, 2006; Litvan, *et al*., 2008a-c) and one hydraulic (Papanicolaou and Dermisis, 2006; Papanicolaou and Dermisis, in press) study of the effects GCS have on fish passage and abundance. Nowhere in literature has the issue of fish passage been approached from both biologic (mark-recapture) and engineering (hydraulic analysis) viewpoints, making the combination of these studies unique.

METHODS

Fish Sampling Studies

The following methods and results sections dealing with fish sampling studies and GCS are discussed in more detail in Larson *et al*. (2004), Litvan (2006), and Litvan *et al*. (2008a-c). The Iowa Department of Natural Resources (DNR) and Iowa State University sampled fish on streams controlled by GCS through two different sampling studies, but because the methods were the same, they are not differentiated in this methods section. Fish sampling occurred at sites near GCS with different downstream slopes of 1:4, 1:10, 1:15, and 1:20 (rise/run) and at reference sites not near a GCS. Sites near GCS are defined as reaches that extend from the scour pool

below the GCS downstream to a point that is within 40 times the average summer wet width of the stream. Sites not near a GCS are defined as points more than 40 times the average summer wet width of the stream away from a GCS.

Passive gear (hoop nets baited with soy cakes and minnow traps) was used to collect fish for mark/recapture and community analyses during the summer at seven sites, five of which were near GCS. The fourteen hoop nets and fourteen minnow traps (two of each type at each of seven stations) were set for periods of twenty-four hours, four to five days a week. Captured channel catfish, flathead chub, creek chub, black bullhead, and yellow bullhead were measured for length and weight and given a site-specific tag or fin clip and released at the station of capture. All captured fish were inspected for previous fin clips or tags. Marked fish that were recaptured were measured for length and weight, the site of their recapture was noted, and they were given a site-specific fin clip indicating their site of recapture.

Electrofishing equipment was used to collect fish for community analyses and to increase the number of recaptures of marked fish during the fall and spring. A total of 10 sites (five GCS sites and five non-GCS sites which included the seven summer sampling sites) were sampled with a single pass of two backpack electrofishing units for a distance of 280 m (approximately 40 times the average summer wet width of the stream. A block net was placed at the upstream boundary of the electrofishing reach. Target fish species collected were identified, measured for length and weight and inspected for fin clips or tags. A combination of hook and line angling, casting nets, and bank electrofishing techniques were used to sample deep scour pools below GCS that were not accessible with hoop nets or backpack electrofishing methods. Fall and spring sampling periods were scheduled at times corresponding with seasonal migration movements of catfish in order to increase the chance of recapturing marked fish that had moved over GCS. Fish movement over a GCS was evident if a fish marked below a GCS is recaptured at an upstream sampling site or if a fish marked above a GCS is recaptured at a downstream sampling site. Physiochemical measurements including turbidity, dissolved oxygen, pH, canopy coverage, substrate, channel wet width, depth, flow, and water temperature were measured before each sampling event.

The slopes of all GCS were measured to verify that the intended design slope had not decayed due to high-flow events or age. Vertical distance was measured at the sheet pile across the width of the channel. Longitudinal slope was measured using a clinometer from the top of the sheet pile to the end of the GCS and at three shorter intervals within the GCS slope. These measurements were repeated during the spring, summer, and fall throughout the study.

During the summer, macroinvertebrate samples were collected from 20 sites: five sites were at a GCS, five were upstream of a GCS, five were downstream of a GCS, and five sites served as reference sites and more than 1 km away from any GCS. Macroinvertebrates were collected at two randomly chosen gird areas along a 10 m transect. Rocks lying within the predetermined grid spacing were scrubbed by hand, allowing dislodged organisms to flow downstream into a kick net. Washed rocks were placed outside of the sampling quadrant and the remaining substrate was disturbed with a 30 second kick. The two samples taken along the transect were combined and preserved. In the laboratory, macroinvertebrates were counted and

identified to the family level. Macroinvertebrate community structure from each site was evaluated by quantifying the number of taxa present, the number of individuals in each taxon, total macroinvertebrate biomass, and total macroinvertebrate abundance.

An index of biotic integrity (IBI) was used to help determine the status of fish community surveys. Twelve metrics were used to determine each communities IBI score: 1) number of native species; 2) number of sucker species; 3) number of sensitive species; 4) number of benthic invertivores; 5) percentage of total abundance of the top three species; 6) percentage of fish as benthic invertivores; 7) percentage of fish as omnivores; 8) percentage of fish as top carnivores; 9) percentage of fish as lithophilous spawners; 10) percentage of fish assemblage tolerance index; 11) adjusted catch per unit effort; and 12) adjustment for high percentages of deformities, erosions, lesions, and tumors..

Hydraulic Study

The following methods and results sections dealing with a hydraulic study of GCS are discussed in more detail in Papanicolaou and Dermisis (2006) and Papanicolaou and Dermisis (in press). The study was performed by IIHR-Hydroscience & Engineering, The University of Iowa. Twenty-two GCS were selected for determination of hydraulic characteristics: eight riprap weirs (Fig. 1A), ten grouted riprap weirs (Fig. 1B, C), and four fish ladder weirs (baffled and unbaffled) (Fig. 1D). A ground survey was performed for all of these weirs, from which weir slope was determined. The surveys were also used as background information for Acoustic Doppler Velocimeter (ADV) or Large-Scale Particle Image Velocimetry (LSPIV) measurements.

Time-averaged point measurements of mean flow characteristics (water depth and streamwise velocity) were performed during a low flow season for all 22 GCS and repeated during a high flow season for 8 representative GCS. Mean flow measurements of velocity at low flow were made upstream, atop, and downstream of each GCS using an Acoustic Doppler Velocimeter (ADV). An ADV uses a transducer that generates a narrow beam of sound at a known frequency (10MHz). This sound is reflected in all directions in the water. While receivers sample the reflected sound, the ADV measures the change in frequency between the transmitted and received signals which is proportional to the velocity along the bistatic axis of that receiver. Mean flow measurements of velocity at high flow were made upstream, atop, and downstream of each GCS using the Large Scale Particle Image Velocimetry (LSPIV) technique. LSPIV measurements use video equipment to capture the movements of small particles (mulch) as they float on the water surface over a GCS. Froude numbers were calculated to classify different reaches (pool, run, and riffle-glide).

Survey data were combined with the video in an LSPIV software package to calculate the two-dimensional (2-D) velocity field around GCS. Stream discharge was calculated from the combination of the 2D velocity LSPIV data with the 1D vertical velocity ADV data. The discharge was then used for developing stage-discharge equations.

For two GCS (a riprap weir and a baffled fish ladder weir), turbulent flow characteristics were measured at low flow with a high-frequency ADV to determine

instantaneous velocities, turbulent intensities, and Reynolds stresses in three dimensions.

RESULTS

Fish Sampling Studies

The first sampling study showed that the slope of a GCS can impact fish movement. Within a 3 year sampling period, between 10 and 28 percent of recaptured channel catfish and between 15 and 30 percent of recaptured flathead and creek chubs were able to move over GCS with a 1:20 downstream slope. However, within the same 3 year sampling period, no channel catfish and flathead and creek chubs were able to move over GCS with a 1:4 downstream slope. However, extremely low water conditions may have restricted migration behavior regardless of weir design. Species diversity was 1.57 times greater downstream of a 1:4 GCS than upstream.

The second sampling study reinforced the results of the first study. GCS with vertical or 1:4 (rise/run) downstream slopes did not allow fish migration, but GCS with slopes ≤ 1:15 did. GCS sites were characterized by greater proportions of pool habitat, maximum depths, fish biomass, and greater macroinvertebrate abundance and diversity than non-GCS sites. Fish community scores (IBI) were also slightly higher (5%) in stream reaches with GCS versus stream reaches without GCS. 98% of all fish movements over a GCS were in the upstream direction and occurred when streamflow was relatively high. Macroinvertebrate biomass, numerical densities, and diversity were greater in stream reaches with GCS versus stream reaches without GCS. Before modification, only 1% displayed movement over a GCS, but after modification 14.5% of all recaptured catfish, bullheads, and chub showed movement over GCS with 1:15 downstream slopes. After modification of three GCS, IBI scores increased at seven of nine sites and fish species, including channel catfish, which exhibited truncated distributions before modification were found throughout the study area afterwards.

Hydraulic Study

Performance of each GCS was described in terms of meeting the minimum requirements for catfish passage as determined by the Iowa DNR: a minimum flow depth of 0.31 m and a maximum velocity of 1.22 m/s. The best performing GCS had minimum flow depths greater than 0.31 m and maximum velocity requirement of less than 1.22 m/s. The worst performing GCS did not meet either requirement. Without considering drainage area, the best performance was exhibited by low gradient (≤ 1:16 slopes) grouted or riprap weirs and fish ladders with baffles. The worst performing GCS were the high gradient (≥ 1:6) grouted or riprap weirs and fish ladders without baffles.

The limiting factor for fish passage was different depending on GCS drainage area. When the drainage area is less than 51.8 km^2, the best GCS is the low gradient (≤ 1:16 slopes) weirs because flow depth is the limiting factor for fish passage, and low gradient weirs will provide deeper flows than high gradient weirs. When the drainage area is larger than 259 km^2, the best GCS is the low to medium gradient (1:10-1:16 slopes) weirs because maximum velocity is the limiting factor for fish

passage, and low-medium gradient weirs will have slower velocities than high gradient weirs. When the drainage area is between 51.8 and 259 km^2, the best GCS is either a low or medium gradient (≤ 1:10 slopes) weirs because flow depth or maximum velocity are the limiting factors for fish passage.

Measurements where ideal for evaluating the performance of structures at low flow due to the fact low flow conditions persisted throughout the study period; thus, recommendations concerning minimum flow depth requirements may be more accurate than recommendations of maximum velocity requirements because of the low flow conditions. Relations for stage-discharge measurements may not be good predictors for conditions exceeding a recurrence period of 1 year due to the low flow conditions.

Velocities atop GCS were about 10 times greater in magnitude than the upstream approach flow; thus, critical conditions occur over a GCS. Turbulence measurements showed that weirs had lower levels of turbulence compared to fish ladders with baffles; however, stresses on all GCS were ≤ 5.3 N/m^2, which is much less than 1,600 N/m^2 needed to cause fish mortality. Average catfish fork lengths are 0.3 m; turbulent flow measurements illustrated that fish ladders with baffles form eddies 30% larger than the average fork length, which is enough to disorient fish. Fish ladders were observed to often catch debris, probably due to the large quantity of vertical steel sheet pile exposed. Grouted riprap slopes were observed to degrade less quickly and were more resistant to large flow events than riprap slopes.

DISCUSSION AND CONCLUSIONS

These studies describe the effects of GCS have on fish migration and fish and macroinvertebrate abundance and biodiversity. This paper details the results of three studies commissioned to describe the effects of GCS on biota through field sampling (Larson *et al*., 2004; Litvan, 2006; Litvan, *et al*., 2008a-c) and through hydraulic characterization of GCS (Papanicolaou and Dermisis, 2006; Papanicolaou and Dermisis, in press). These studies showed that vertical to steeply sloping (>1:15) GCS will restrict fish migration, whereas gently sloping (<1:15) GCS will allow fish migration; however, extremely low water conditions can restrict migration behavior regardless of weir design. Following modification of weirs to <1:15 slopes, fish community scores (IBI) did not decrease longitudinally along the channel from downstream to upstream, indicating increased longitudinal connectivity. GCS can also have a positive effect on fish and macroinvertebrate communities with respect to increased biota abundance, habitat, and biodiversity compared to stream reaches without GCS. Fish migrating over a GCS will not die due to turbulent stresses because all GCS tested had low enough levels of turbulence. Because fish ladders often catch debris and riprap is not as strong or as resistant to high flows, future GCS should incorporate a grouted riprap slope. Weirs with 15:1 are now recommended for all GCS because they allow fish passage, but are less expensive than 1:20 GCS.

These studies were instrumental in creating design criteria for future GCS to be built in western Iowa that will control channel incision while allowing fish passage and increased longitudinal connectivity. They also showed that engineers and ecologists can cooperatively work together to design GCS that can not only protect streams from the affects of channel incision but can also allow for fish migration,

greater biodiversity, and better longitudinal connectivity of the stream systems in western Iowa.

ACKNOWLEDGEMENTS

Any GCS mentioned in this report were built using Hungry Canyons Alliance (HCA) or USDA Natural Resource Conservation Service (NRCS) Emergency Watershed Protection (EWP) funds. Funding for the Larson *et al*. (2004) study was provided by Iowa DNR Fisheries Bureau. The Litvan (2006) study was funded by the HCA (17%), Iowa DNR Fisheries Bureau (11%), US Geological Survey (22%), US Fish and Wildlife Service (15%), and Iowa State University (35%). The study by Papanicolaou and Dermisis (2006) was funded by the HCA (25%), Iowa DNR Fisheries Bureau (25%), and Iowa DOT Highway Research Board (50%).

Abstract

Design methods that account for the ability of fish to swim upstream through culverts are based on tests describing how fast and for how long different fish species can swim. These methods are based on an average water velocity but fail to recognize that fish can take advantage of resting places and non-uniform flow in culverts. Culverts that are designed using this average velocity are likely larger than is necessary. Current design methods could be greatly improved by accounting for the non-uniform velocity distributions in culverts, especially those with roughness elements.

In order to better quantify the benefits associated with in-culvert hydraulic refuge, fish tests have been performed in a laboratory flume. This project has focused on one species of fish native to Utah—longnose dace—and the ability to ascend the flume with and without roughness elements—cylinders—in place. Results suggest that the cylinders did allow fish to navigate upstream more successfully than fish attempting to ascend the flume without cylinders at nearly identical average velocities.

It is suggested that further testing be conducted by adapting this protocol to key variables affecting fish passage, producing probability distributions for fish performance applicable to culvert design.

Introduction

Problem Description

Many agencies enforce special design requirements that are meant to abet fish and other organisms attempting to move up or downstream through a culvert. Several categories of culvert design procedures have been defined (Hotchkiss et al. 2007) that account for fish passage.

Most culvert design procedures used when accounting for fish passage use the average velocity in the culvert as a governing design parameter. John T. Beebe points out that the use of the average fluid speed alone does not provide an accurate description of the real interaction between fish and their surroundings, instead suggesting that "the relationship between moving fluid and channel boundary is the most important in smaller streams that are used as habitat by fish (1996)."

Roughness elements, including fish baffles, oversized rock, or other strategically placed objects placed within a culvert drastically alter flow patterns in culverts. Due to a lack of experimental data, however, the effects of roughness elements on fish passage have not been quantified adequately. More testing may allow engineers to more fully understand the differences between the average velocity in a culvert and the local velocity which an individual fish chooses to actually overcome.

A publication by Theodore Castro-Santos (2004) describes an excellent experimental setup used to test fish passage rates and their relation to culvert length and average velocity, as well as valuable discussion of fish swimming behavior. This and similar tests nearly always ignore the effects of roughness elements within the flow.

Fish passage can be measured as the proportion of fish successfully traversing a culvert to those staging an attempt. Treating this proportion as the dependent variable, the number of independent variables affecting fish passage is quite large. The independent variables may be grouped into the following categories: characteristics of fish, characteristics of flow, characteristics of culvert, with a subcategory pertaining to the roughness elements, and characteristics of environment. Many of these are variables are listed below in Table 1.

Some of the variables in Table 1 are easily quantified while others are not. The variables which can be measured in terms of the elementary dimensions of length, mass, and time can be combined in order to reduce the amount of testing necessary to obtain relationships among the many independent parameters. These variables, along with their common symbols and elementary dimensions, are given in Table 2. The Buckingham Pi Theorem has been applied to combine variables into dimensionless ratios.

Table 1. Variables Likely Affecting Fish Passage

Variable	Supporting Source

Discharge	Q	L^3/T
Depth	y	L
Culvert Length	L_c	L
Element Diameter	D	L
Longitudinal Spacing	L_x	L
Lateral Spacing	L_y	L

Hypothesis

The tests described in this document are expected to show a positive effect of roughness elements on fish passage. Roughness elements placed in an open channel are expected to

correspond to an increase in the percentage of fish passing upstream over a defined distance. Individual fish will likely rest behind cylinders in areas of hydraulic refuge. The tests performed apply specifically to a single species, channel length, and roughness element configuration; however, they provide a better idea of the magnitude of the effects of roughness elements on fish passage, hopefully suggesting that similar tests be performed while altering appropriate variables.

Behavior versus Ability

Fish living in their native environment migrate for various reasons. They may be in search of food, shelter, safety, or a spawning location, among other things. While a laboratory setup may duplicate certain aspects of a natural stream setting, many differences cannot be eliminated. These differences are likely to change fish behavior. It is of paramount importance that results presented here not be applied directly to culvert design procedures without further investigation to the uncertainty due to this key assumption.

In order for a fish to travel upstream through a culvert, it must be physically capable of doing so and must have a motive strong enough for it to expend the necessary energy. These conditions have been described as swimming capacity and attempt rate. Figure 1 illustrates the idea.

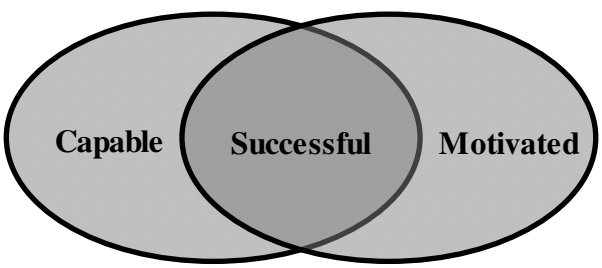

Figure 1. Capacity versus attempt rate.

While fish may be physiologically able to navigate upstream, the right motives for doing so may not be present. On the other hand, motives may be strong enough for a fish to "want" to swim upstream, but the fish may be too small or weak, or the culvert may be too long to allow successful passage. The results in this document do not attempt to differentiate between capacity and attempt rate.

Methods

Test Specimens

Thirty-six specimens of longnose dace were captured from their native stream habitat using an electrofishing device. Captured fish were kept in holding tanks for at least four days before testing began. During this time they were generally fed each day and their tanks were cleaned periodically as needed.

Longnose dace are benthic fish with a long, down-turned snout making them well adapted for life near the bottom of fast-flowing streams. The specimens tested were generally between 5 and 10-cm in total length. A longnose dace is shown in Figure 2 below.

Figure 2. Longnose dace (Helfrich et al. 2005).

Setup

Tests were performed in a rectangular flume with smooth Plexiglas on the bottom and sides. The flume is broken into five sections which were conveniently used as boundaries when monitoring fish movement. Figures 2 and 3 below are elevation and plan views of the flume. Figure 2 includes the locations of cylinders placed in the flume during the experimental setup.

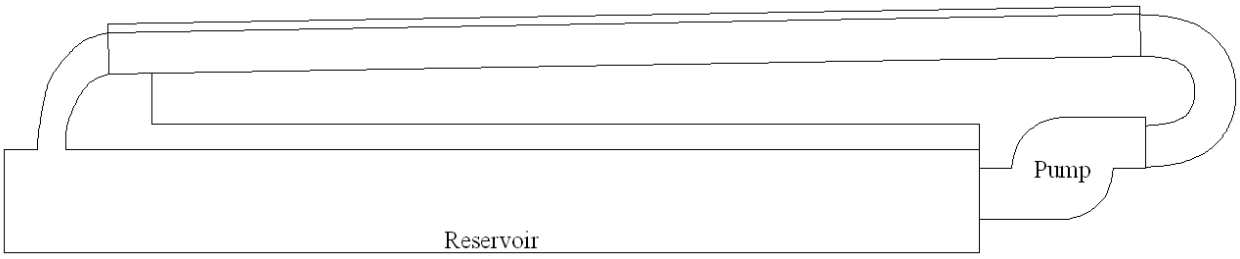

Figure 3. Flume in elevation view.

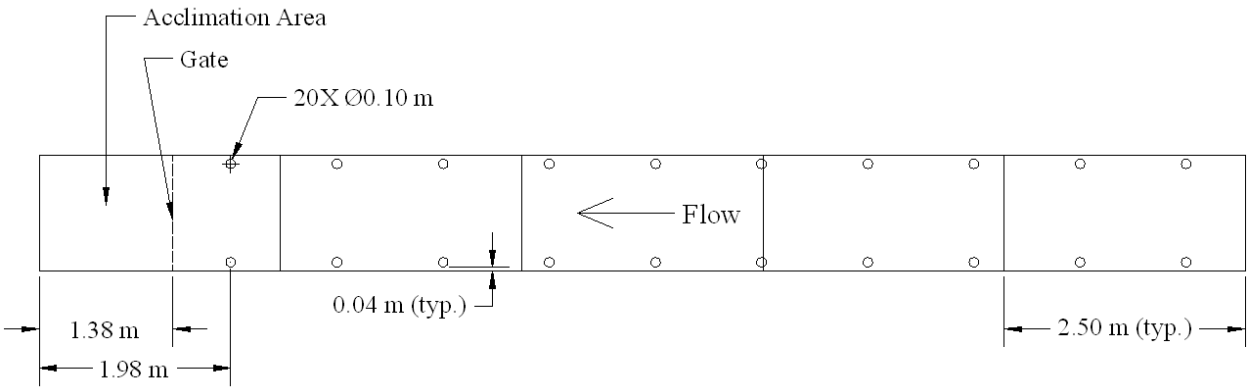

Figure 4. Flume in plan view with cylinders shown.

The acclimation area at the downstream end of the flume is 1.38-m and 1-m wide. The flume is divided into five 2.5-m sections. Within the flume, cylinders with a 10-cm diameter were placed 1-m apart and 5-cm from the flume wall. A boundary curtain was hung around the perimeter of the entire flume. Windows were cut in the curtain on both sides of the flume in order to enable the observer to collect data with minimal disturbance to the fish.

Testing Protocol

Testing included an acclimation period, a test run, and manual motivation. On the date of a test, 6 longnose dace were removed from the holding tank and moved in a bucket to the testing flume. Water from the flume was mixed with water from the holding tank carried in the bucket along with the fish, and the bucket was placed in the flume water for approximately 15 minutes to allow for initial acclimation to flume water conditions. After this 15 minute period, the fish were released into a caged area at the downstream end of the flume, where water speed was maintained such that the fish had little difficulty holding their positions while acclimating. The acclimation period lasted approximately one hour.

Testing and monitoring were performed during the next 80 minutes, during which all observers stayed outside of a boundary curtain to avoid human contact with the fish. The pump frequency and tailgate height were adjusted to attain the desired discharge and depth of flow. Next, the gate holding the fish in the acclimation area was raised, allowing the fish to begin their ascent. At intervals of approximately 10 minutes, fish were counted and their locations marked.

After official testing was completed, an observer entered the boundary curtain to perform an informal manual motivation to determine whether such motivation could stimulate the fish to move upstream. This was done with a small fish net and it was left to the observer to determine how much stimulation should be applied and how to describe any positive or negative affects on fish behavior.

Data forms were created to gather preliminary data. This data includes: type of setup (experimental or control), discharge, channel slope, water temperature, date, times for the beginning of acclimation, beginning of testing, and end of testing and finally, the number of fish tested. A sample data sheet and full protocol are provided in the appendix.

Assumptions

As mentioned in the introduction, native fish habitats are difficult to reproduce in a laboratory. None of the testing described in this report was intended to simulate a natural environment. Instead, any effect associated with differences between nature and the laboratory was assumed to be uniform. Similarly, time in captivity, time of year, time of day, and temperature differences between holding tanks and the flume were kept fairly constant, and any effects on fish behavior were assumed to be uniform.

Results

Data resulting from the tests are displayed below in the following graphs. Fish performance data were collected for groups of six or less individuals in either a control or experimental group. Eighteen fish were placed in the flume for each treatment. Figure 5 shows the relation between tested, attempted, and passed. The definition of these terms follows Figure 5.

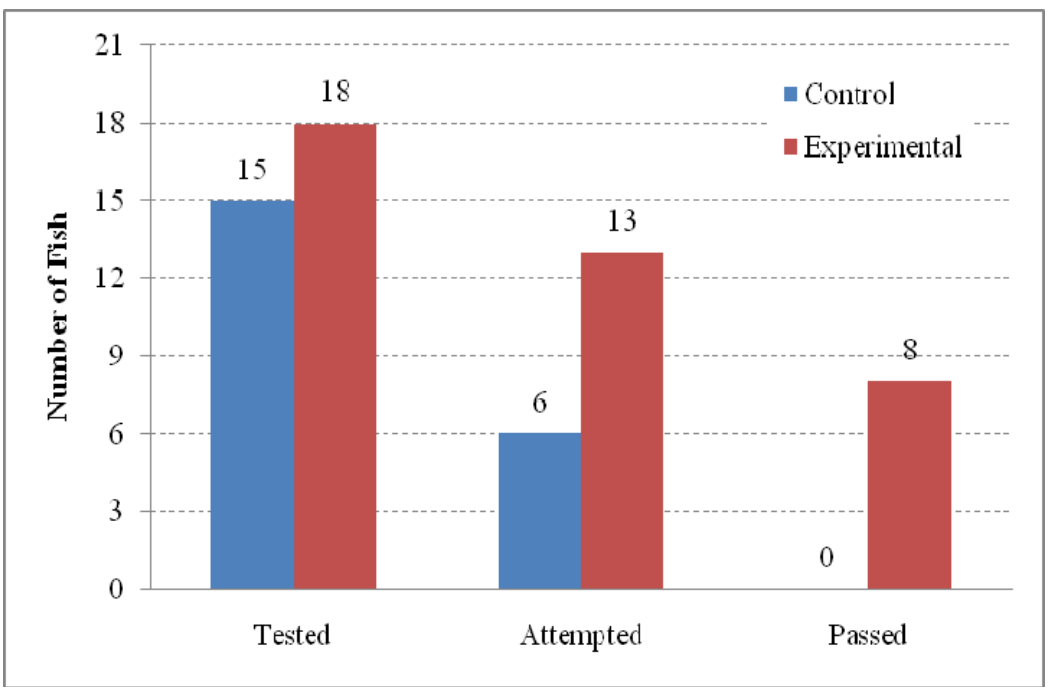

Figure 5. Number of Fish vs. Tested, Attempted, and Passed.

"Tested" is defined as the number of fish in the flume at the end of the acclimation period. "Attempted" is the number of fish that swam past the first section of the flume. "Passed" is the number of fish that made it into the most upstream (fifth) section of the flume. In the control group, 15 fish were tested because three fish failed before the end of the acclimation period. Of these, 6 attempted, and none passed. In the experimental group, 18 were tested, 13 attempted, and 8 passed.

Figure 6 shows the differences between the ratios of passed vs. attempted and passed vs. tested in each of treatment.

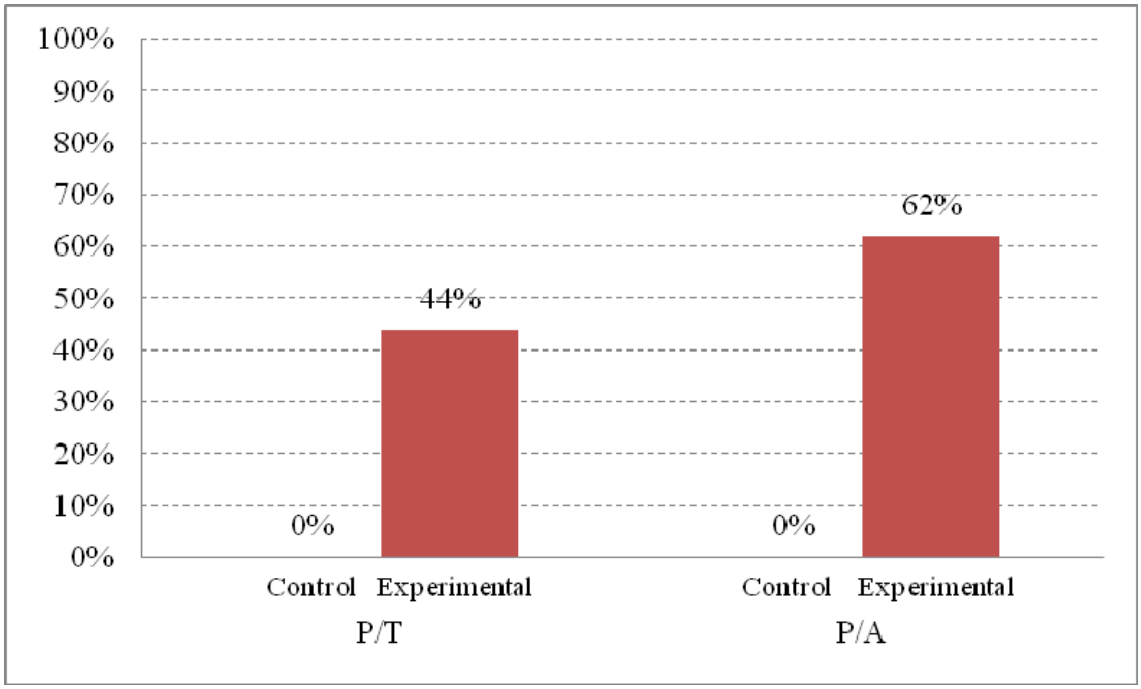

Figure 6. Percentage vs. P/T and P/A. Ratio of Passed vs. Tested and Passed vs. Attempted.

The percentage for each in the control group is 0%. The percentage for P/A in the experimental group is 62% and the percentage for P/T is 44%. In addition to these metrics, fish were observed at various time intervals. In this way, the progress of fish through the flume was observed. Figure 7 shows the number of fish in each section of the flume during given time intervals during the test for the control group. In the control group, none of the fish passed and only six attempted. Figure 8 shows the analogous results for the experimental group.

Eight fish passed in the experimental test and there is a general trend of fish moving towards section five. Only four fish are still in the first section during the last time interval (70-79 min).

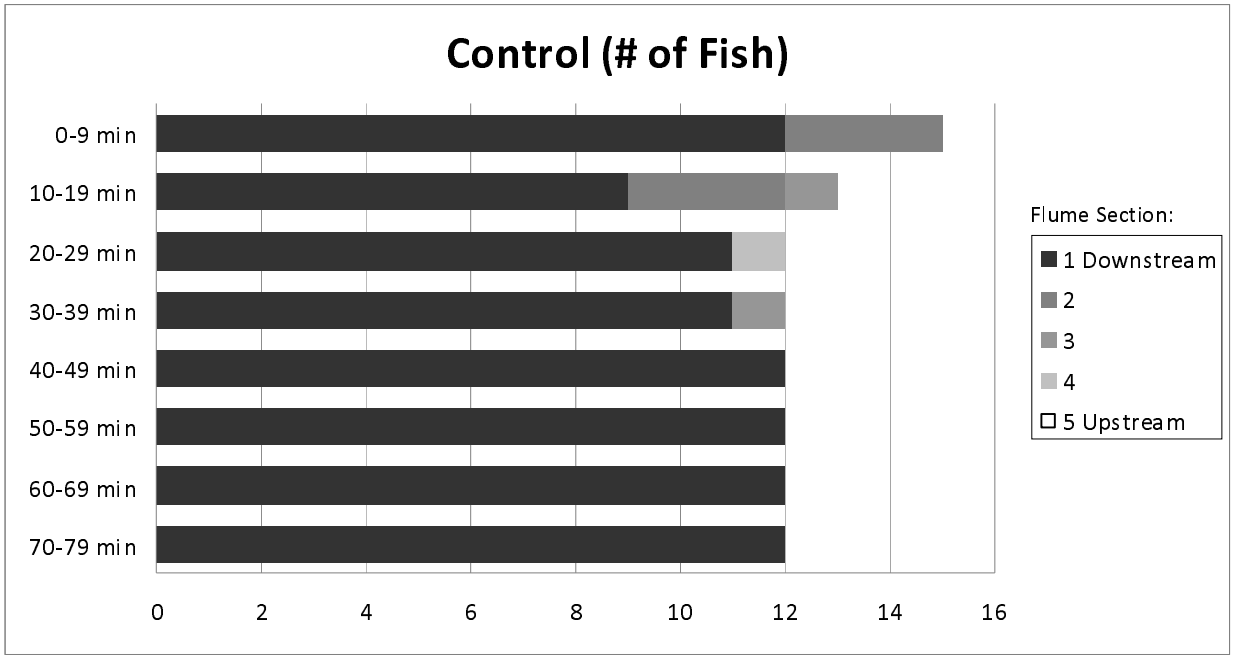

Figure 7. Control: Time vs. Section

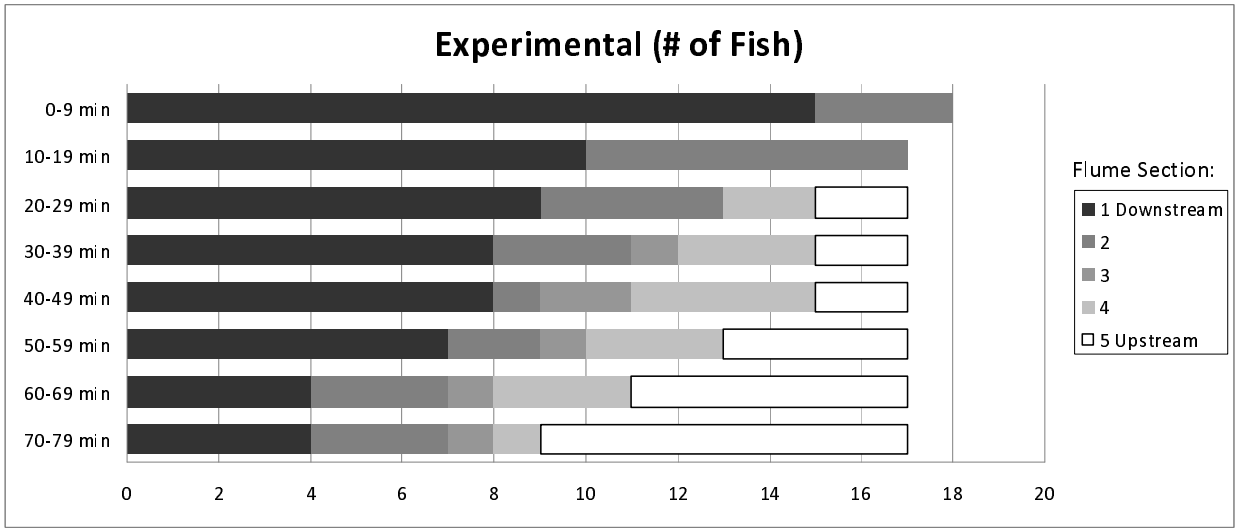

Figure 8. Experimental: Time vs. Section

Discussion

Expectations

As stated in the hypothesis, fish were expected to find refuge behind the cylinders and use this space for resting during their upstream attempt. However, fish were usually observed resting in front of the cylinders. This may be a natural tendency of the fish or it may be an indication that the experimental setup could be modified to increase fish success in navigating up the flume. The longitudinal spacing, lateral spacing, and diameter of the cylinder are variables that could be

changed. A change in the longitudinal spacing would influence the wake zone characteristics of the cylinders and perpetuate these differences downstream. Changing the lateral spacing would change the velocity and turbulence between the cylinder and the wall of the flume. Increasing the diameter of the cylinder would increase the wake zone so there would be a larger rest area behind the cylinder.

Confounding Variables

Time of year, or season, in which fish were captured and tested may be a confounding variable in the results. Informal tests used to determine the final protocol were performed during the summer. In these tests, dace were able to pass without cylinders when tested at 105-cm/s average velocity. However, dace were not able to pass at a similar velocity without cylinders in the fall, which may be due to metabolic changes in the fish between fall and summer. This suggests that fish swimming performance test results may not be representative of fish performance throughout all seasons.

The size of tested fish may be another confounding variable in these results. It was assumed that since the fish were randomly chosen, size would not affect the results. Thus, length and weight was not measured during tests. Nevertheless, bias may have been introduced into the experiment because swimming efficiency does generally increases with fish length (Webb et al. 1984) and the small sample size used in the experiment could have been insufficient to give a good representation of the species as a whole.

Possibly Invalid Assumptions

The following were assumed, but may have actually influenced the results:

- Fish would swim to their maximum capabilities: This may be erroneous since individual fish may not be motivated to swim upstream.
- Fish would all have the same capabilities: This is clearly false; however, it was assumed that by randomly selecting the fish in each group, their capabilities would average out.
- Each group had the same treatment: There is natural variation in each treatment due to human error. In addition, individual differences between the fish in each group may also affect the test results.

More caveats

These results cannot be applied to individuals because they were tested in groups. Social dynamics in fish behavior may result in fish reacting differently when tested individually. Larger test groups and more replications may also be necessary to achieve statistical significance.

Motivation

As discussed in the testing protocol, fish were motivated after the fish were given 80 minutes to swim up the flume. This indicated the existence of a difference between a fish's performance in

a test and its actual capabilities. After motivation, most fish in the test swam further up the flume than they had at any time during the initial 80 minutes. Because the motivation methods were not uniform, no numerical data was analyzed for the effects of physical motivation.

Conclusions

From these results, it can be concluded that cylinders aid in fish passage, when testing fish in groups. The percentage of fish that passed in the experimental tests was much higher than in the control tests. None of the tested fish passed in the control tests, while some fish passed in the control tests with motivation (see Discussion).

These conclusions cannot be applied without considering the difference between behavior and ability (see Introduction), as well as the numerous other elements that could have introduced confounding variables into the results. While common sense would dictate that roughness elements do help fish navigate through a current, the usable, numerical data supporting this is still lacking. A sure basis for revamping culvert construction protocol as suggested in the introduction rests on the gathering of this data.

Recommendations

As the field of research relating to fish passage is still relatively new, many factors affecting fish migration remain arbitrary hypotheses. The practical application of research following protocol similar to those used in this experiment is still in the distant future. In order to help researchers seeking to improve similar research protocol, the authors offer the following recommendations.

Motivation

Motivation of fish, as previously described, is a difficult question facing researchers who are trying to balance resources and results with the authenticity of the fish test environment. In order to show that many fish in the test were swimming well below their physiological capabilities, a step was added to the protocol where after the conclusion of the test period (80 minutes), the fish were encouraged to swim upstream by a small hand held net placed behind them. This was successful to a certain extent; many fish that remained at the starting section of the flume for the entire 80 minutes swam up the flume after the stimulus was applied repeatedly.

The protocol for applying the stimulus and the extent to which fish were encouraged to swim upstream was not standardized, however, rendering the results only useful for further postulating. If further researchers wish to implement a similar method of both volitional and motivated testing, it is recommended that motivation methods be standardized.

Wake region

Previous studies have shown trout using the vortices forming downstream of cylinders as a means of holding position with less energy expenditure (Liao et al. 2003). It was therefore expected that the longnose dace would also position themselves downstream of the cylinders. As discussed earlier, fish in this experiment actually preferred to hold position upstream of the cylinders. Video footage of the experiment suggests that the less turbulent, low velocity area downstream of the cylinders was too small for the fish to use. One fish in particular demonstrated this when it tried to take advantage of the small low velocity region, but it could only do so with its side pressed against the cylinder.

When it maneuvered into a more natural position, with its mouth facing the cylinder and body parallel to the flow, its tail entered the turbulent area of the wake region, and the fish was swept downstream. The authors suggest testing with larger cylinders or different shaped objects, thus enlarging the resting area usable by small fish. It is also recommended that data already gathered on cylinder hydraulics be applied to postulate sizes of cylinders and water velocities that might produce a wake region that would be beneficial to small fish.

Although trout have been shown to use the turbulent vortices (Liao et al. 2003), observations of dace in this experiment suggest that their smaller size may be more conducive to the low velocity area immediately downstream of cylinders.

Also, spacing cylinders more than 5-cm from the side of the flume is recommended because most of the fish had difficulty swimming between the cylinder and the wall of the flume, and some of the fish chose to swim between the cylinders. Increasing this spacing would result in a slower velocity between the cylinder and flume edge, potentially facilitating the fish's movement upstream.

Recommended future testing

Many potential lurking variables could be removed from fish tests using similar protocols. Some of the variables that could be tested and quantified are:

1. Time of day - research suggests that some fish species, even in captivity, tend to migrate at night (Pearson et al. 2005).
2. Time of year – fish behavior in informal testing performed in the summer compared with actual tests done in the fall suggests that longnose dace were far more willing and/or able to swim to the top of the flume in the summer.
3. Duration of captivity before testing – fish observed in captivity shortly after capture tended to regurgitate food and not eat anything for a few days, which could affect their ability and willingness to swim upstream in the flume.
4. Volitional or non-volitional entrance – due to the pre-constructed nature of the flume used in this experiment, an acclimation area inside of the flume was used.

This example of non-volitional entrance into the experimental water flow may introduce stress or other factors that could affect the percentage of fish "passing".

Volitional entrance into the experimental flow section where they are tested has been used in past experiments (Castro-Santos 2004), and could be a method of resolving this dilemma. A measured comparison of this option and the non-volitional method used in this experiment could be useful to future protocol and flume design. The two options are diagrammed below in Figure 10.

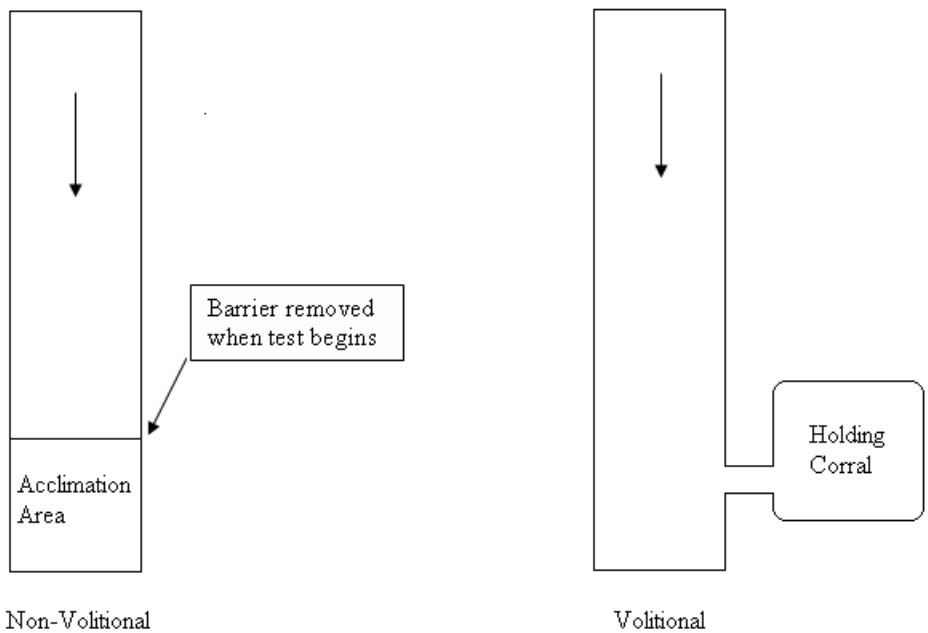

Figure 10. Comparison of acclimation options.

The volitional entrance configuration allows the fish to leave the holding corral and enter the test section at their own will. The non-volitional method keeps the fish in an enclosed partition in the test section until a pre-determined acclimation period is completed, whereupon the barrier holding the fish in is removed and the test begins.

Fish monitoring

Upon examination of the results, it was recognized that because this experimental setup did not allow for monitoring of individuals throughout the test limits the type of conclusions that may be drawn from the tests. Fish tracking systems using radio telemetry could remove this ambiguity, but if funding is an issue, less expensive elastomer tags could be used to identify individual fish by researchers.

Future testing

In order to better understand why the fish generally rested in front of cylinders, a detailed ADV analysis of turbulence and velocity gradients under testing conditions is planned. It is anticipated that these analyses will either demonstrate that: the region downstream of the cylinder was excessively turbulent; the area upstream of the cylinder was ideal for conserving energy; or that a combination of both was the underlying cause of refuge selection.

ABSTRACT

The hydrodynamics at two design discharges (85 and 15% exceedence on the flow duration curve) in the vicinity of the existing North Branch Dam are presented. A combination boat chute/fish passage is being designed for integration into the existing dam. The Dutch pool and orifice fishway has been selected for the fishway due to its relatively low flow requirement (on the order of 5 cfs for most operating heads), low velocities in the fishway, and relatively low turbulence in the fishway – all making it a reasonable option for passage of non-anadromous fish in a low-gradient waterway. The details of the hydrodynamics of this structure are being examined with a combination of a physical model study and through the performance Computational Fluid Dynamic (CFD) modeling.

1. CURRENT SCENARIO – CHICAGO NORTH BRANCH DAM

Prior to installing a potential boat chute design within the physical hydraulic model, several case scenarios of the boat chute design will be considered and tested, therefore optimizing its design. Prior to developing a CFD model at prototype scale for the North Branch Dam including any boat chute/fishway design, it is necessary to simulate the current (dam alone) flow structure in the vicinity of the dam to provide a background for future comparisons. Since the aim is to have the boat chute designed and tested to cover a wide range of flow discharges (30 – 223 cfs, corresponding to a flow exceedence of 85% and 15%, respectively), it is important to obtain CFD results for these two flow conditions. Hydrologic data upstream of the dam was obtained from a USGS gaging station 05536105 – North Branch of the Chicago River at Albany Avenue. Flow data for the North Shore Channel upstream of the confluence was obtained for the USGS gaging station 05536101 – North Shore Channel at Wilmette, IL and outfall data from the North Shore Waste Water Treatment Plant operated by MWRDGC.

A three-dimensional model (FLOW3D, Flow Science 2008) CFD models that solves the Navier-Stokes equations together with a model for turbulence (RNG, Yakhot and Smith, 1992), and an interface capturing method (VOF, Hirt and Nichols 1981) is applied to determine the flow

structure for the North Branch Chicago River Dam. The CFD model has been previously applied at several different projects associated with river restoration (Rodriguez et al, 2004; Abad and Garcia, 2005; Abad et al. 2008).

As observed in Figure 1, the computational domain has a reach that extends in the Upper North Branch Chicago River (UNBCR), a reach extending upstream into the North Shore Channel (NSC) and a reach downstream in Lower North Branch Chicago River (LNBCR); therefore suitable boundary conditions at these three boundaries are required. The upstream boundary condition for the UNBCR was determined from a 1-D HEC-RAS model of the upstream reach assuming critical depth at the dam. The HEC-RAS model was calibrated using the USGS gaging station at Albany Street. The Chicago River System downstream of the North Branch Dam is completely controlled by the operation of lock and dam structures located in Wilmette, the Chicago Harbor, and in Lockport and the stages are maintained relatively constant throughout the system. Therefore, a constant stage boundary condition has applied for the LNBCR independent of flow discharge. This stage was determined from the USGS gaging station 05536123 Chicago River at Columbus Drive at Chicago, IL.

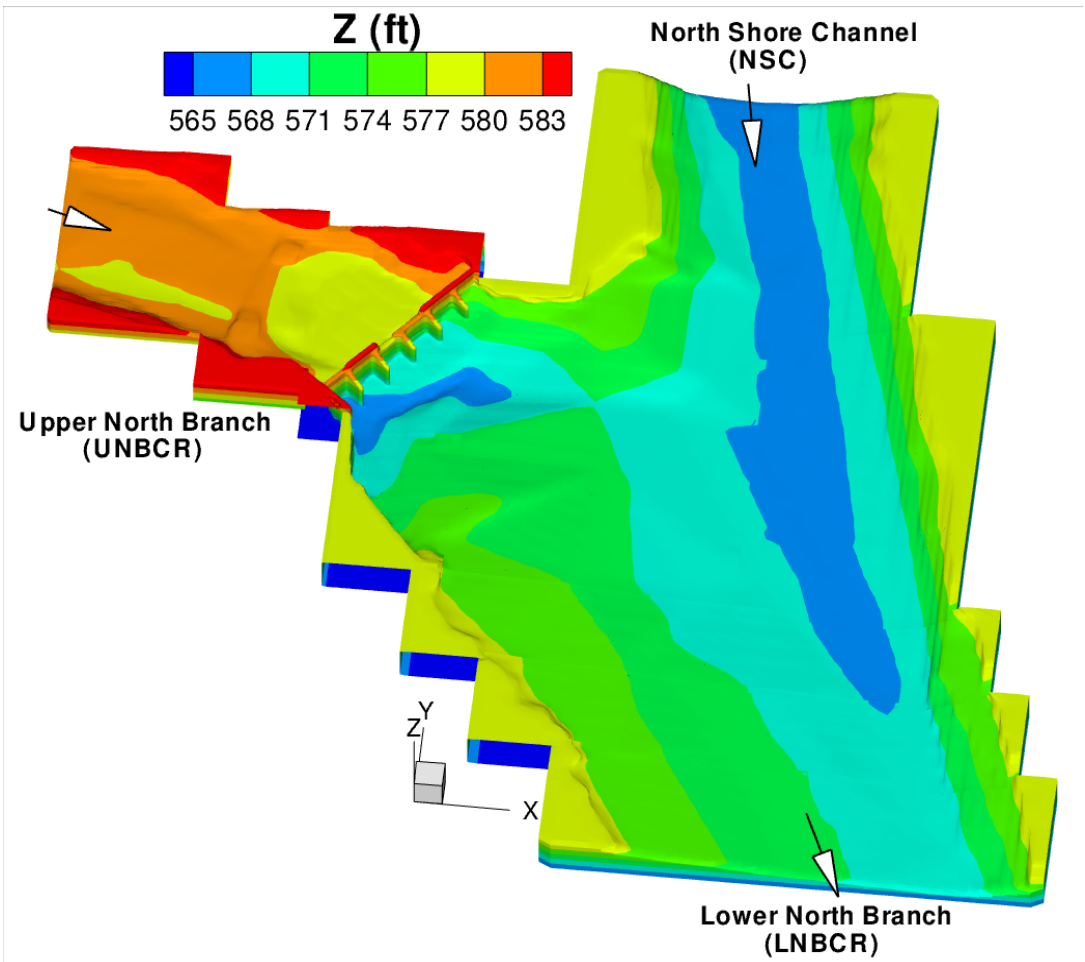

Figure 1. Bed elevation (in ft) of the entire computational domain (using 10 linked-type multiblocks)

Figure 2 shows the water surface elevation (wse) for both design discharges (85% and 15% exceedence). As observed the wse along the North Shore Channel (NSC and LNBCR) is almost constant for both conditions since it is a regulated channel. However, the wse at the UNBCR changes according to the backwater effects exerted by the dam. The control point (for backwater effects) for the 85% exceedence discharge is located upstream of the dam as observed in Figure 2(a), while the control point for the 15% exceedence discharge is given by the dam (Figure 2b).

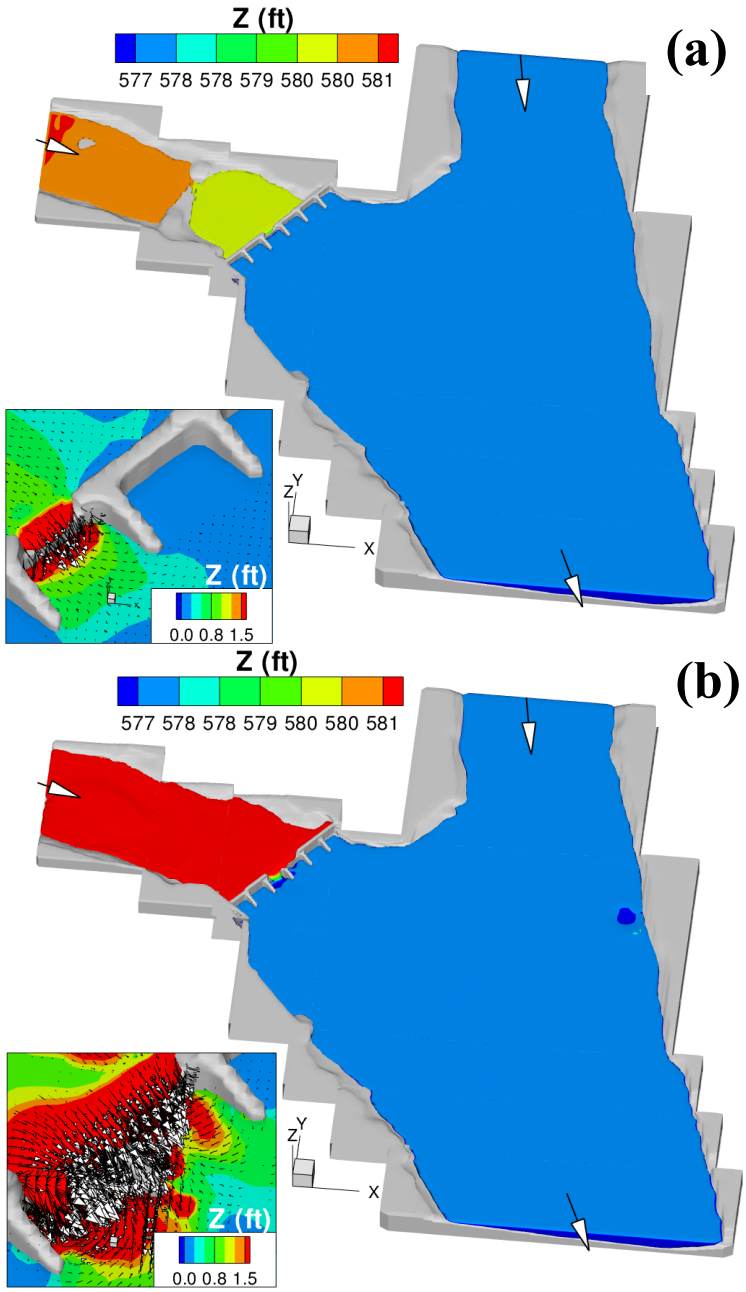

Figure 2. Water surface elevation (ft) for design discharges of (a) 85% exceedence and (b) 15% exceedence

Figure 3 shows the velocity distribution for both design discharges at different elevations (z=572.1 and 576.5 ft). Due to the interaction of NSC and UNBCR channels, there are regions of horizontal recirculation, especially near the downstream part of the dam. The junction serves as expansion for the NSC, therefore the velocities are reduced in this region for both design discharges. Downstream of the junction (around UNBCR), the velocities recover their magnitude as in NSC, demonstrating that the computational domain is good enough to reproduce the effects of the dam and of any future canoe/chute implementation.

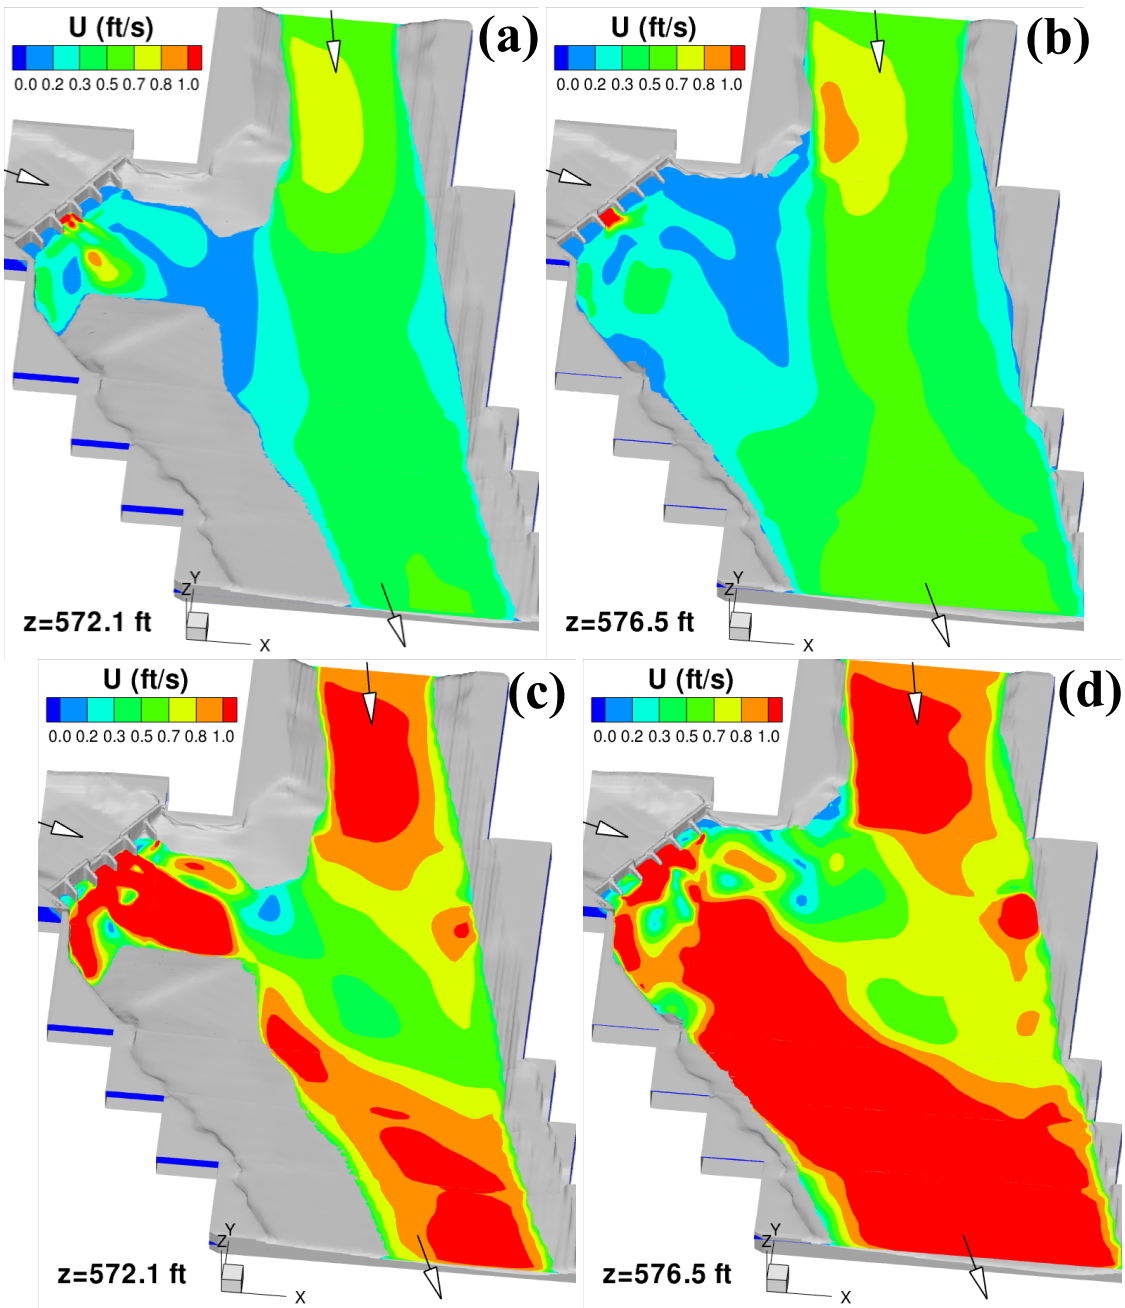

Figure 3. Velocity magnitude for both design discharges at different elevations (a) and (b)85% exceedence, (c) and (d) 15% exceedence

2. TESTING THE ALTERNATIVE: THE DUTCH POOL AND ORIFICE FISHWAY

Boiten and Dommerholt (2006) have presented a methodology (tested against experimental measurements) for the design of the Dutch pool and orifice fishway structure. Figure 4 shows the configuration of the Dutch pool and orifice fishway as used by Boiten and Dommerholt (2006). Herein the upstream and downstream channels are set to have 1.0E-5 of longitudinal slope, while the fishway channel has a longitudinal slope of 0.0625. The present case studies are design under uniform flow conditions, therefore, the upstream and downstream water depth are similar. Several discharges (from 0.057 m^3/s to 0.141 m^3/s) for a range of H=0.5m to H=1.0m are studied. The length and width of each pool are 0.80m and 1.20m respectively. The height and width of each orifice are 0.40m and 0.20m respectively. A total of 8 orifice fishway structures are placed into the channel, being the first orifice located near the right side wall. The design water drop (Δh) between consecutive pools is around 5cm.

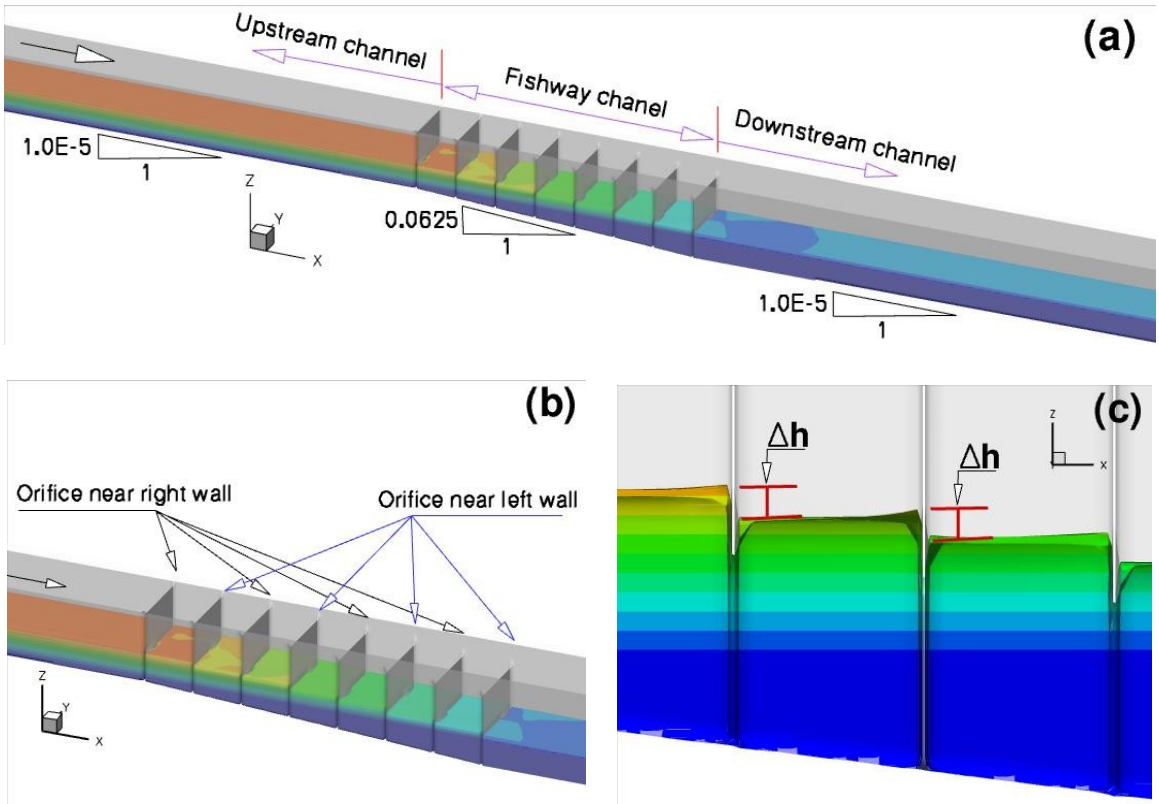

Figure 4. Dutch pool and orifice fishway configuration. (a) 3D view showing upstream, fishway and downstream channels, (b) 3D view showing alternate orifice fishway plates, and (c) Side view showing the difference in water surface elevation at two consecutive pools. The designed water drop elevation is set to 5cm.

Figure 5 shows the comparison of velocity magnitudes at orifice 5. While the agreement is not perfect, it reproduces the averaged velocity magnitude and its distribution. Higher velocities are found near the right lower corner as found in the experiments performed by Boiten and Dommerholt (2006). Currently more simulations are carried out finer meshes in order to improve the agreement and better describe the flow structure though the fishway structures.

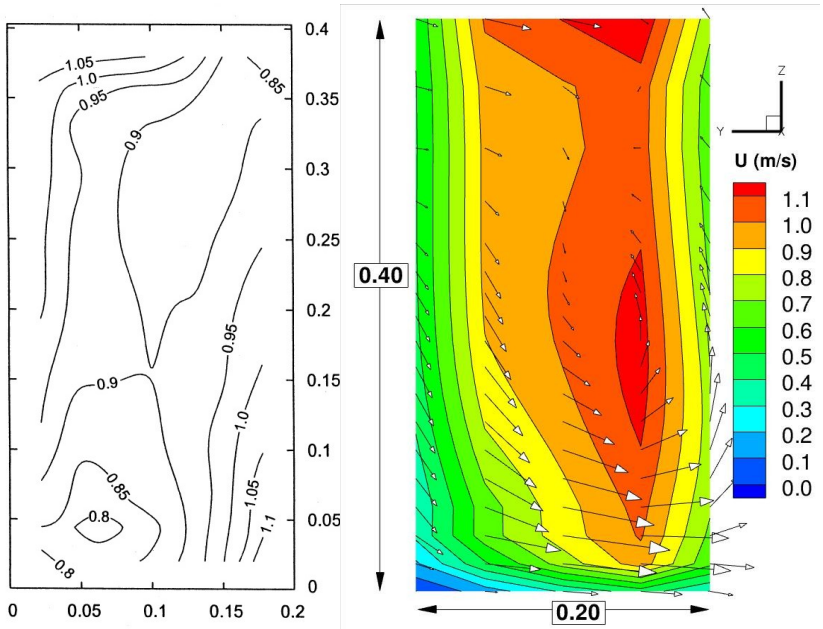

Figure 5. Comparison of measurements (Boiten and Dommerholt, 2006) and modeling results at orifice fishway 5. The water depth is H=1.0m.

Figures 6 and 7 show the plan view of velocity distribution at different elevations (z=0.62m, 0.77m, 0.96m, 1.12m, and 1.30m) for water depths H=0.5m and 0.9m respectively. As expected the velocity magnitudes are increased around the orifice fishway and recirculation cells are created along the pools. Since the orifice are located alternate at both sides, the core of higher velocity magnitude shifts from right to left and so on. The horizontal flow pattern at these different conditions is quite similar.

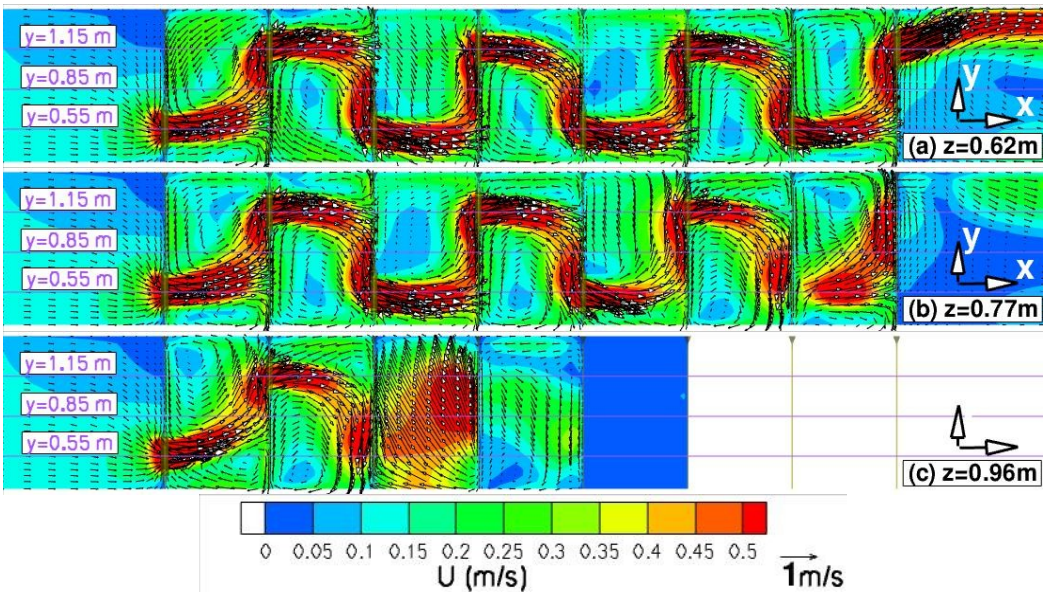

Figure 6. Velocity distribution at (a) z=0.62m, (b) z=0.77m, and (c) z=0.96m for a water depth of H=0.5 m.

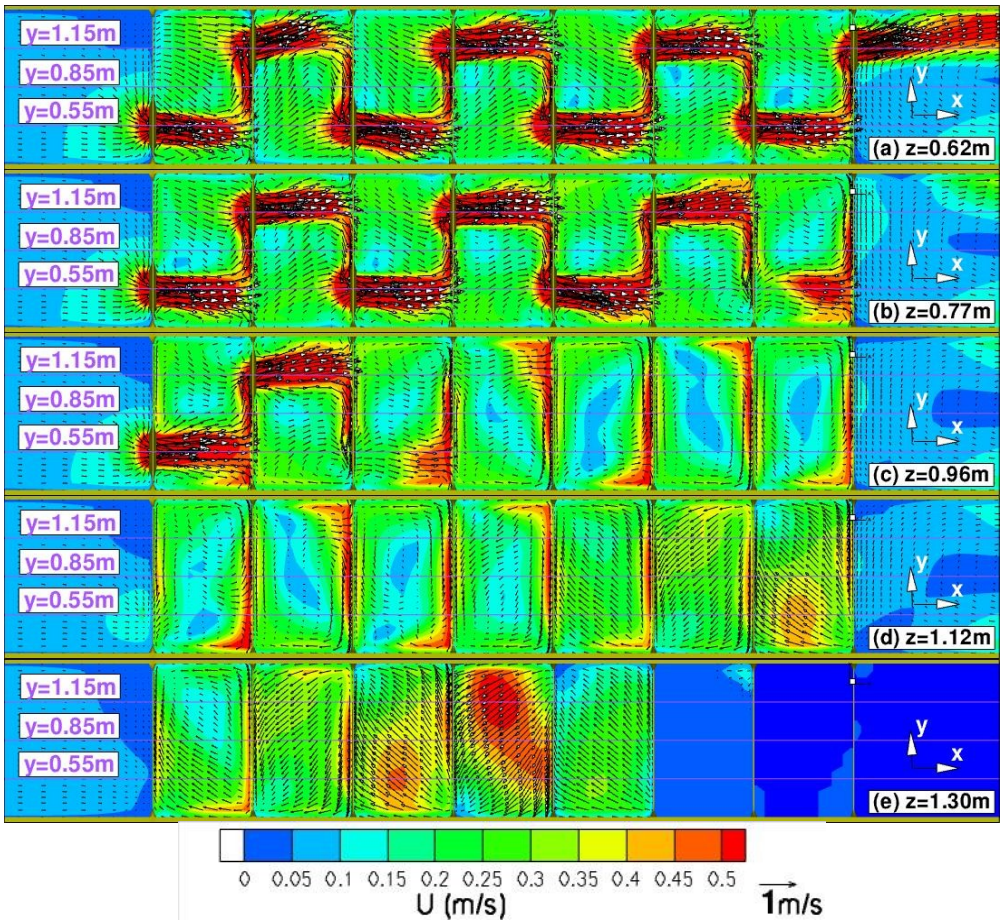

Figure 7. Velocity distribution at (a) z=0.62m, (b) z=0.77m, (c) z=0.96m, (d) z=1.12m, and (e) z=1.30m for a water depth of H=0.9 m.

Figures 8 and 9 show the side view of velocity distribution at different locations along the transversal coordinate (y=0.55m, 0.85m and 1.15m) for water depths H=0.5m and 0.9m respectively. The flow at y=0.85 represents the cross section at the center of the channel, therefore the velocity distribution is quite similar in all pools, while the other longitudinal cross sections (y=0.55m and y=1.15m) represent the location of the orifice, therefore, alternate pools present similar flow pattern. The higher the water depth, H, the higher the vertical velocities along the pools, since the disturbance flow coming out from the orifice is higher and it produces notorious recirculation cells. As designed, the water drop in consecutive pools is around 5cm, therefore, the CFD model was able to capture this macroscopic feature.

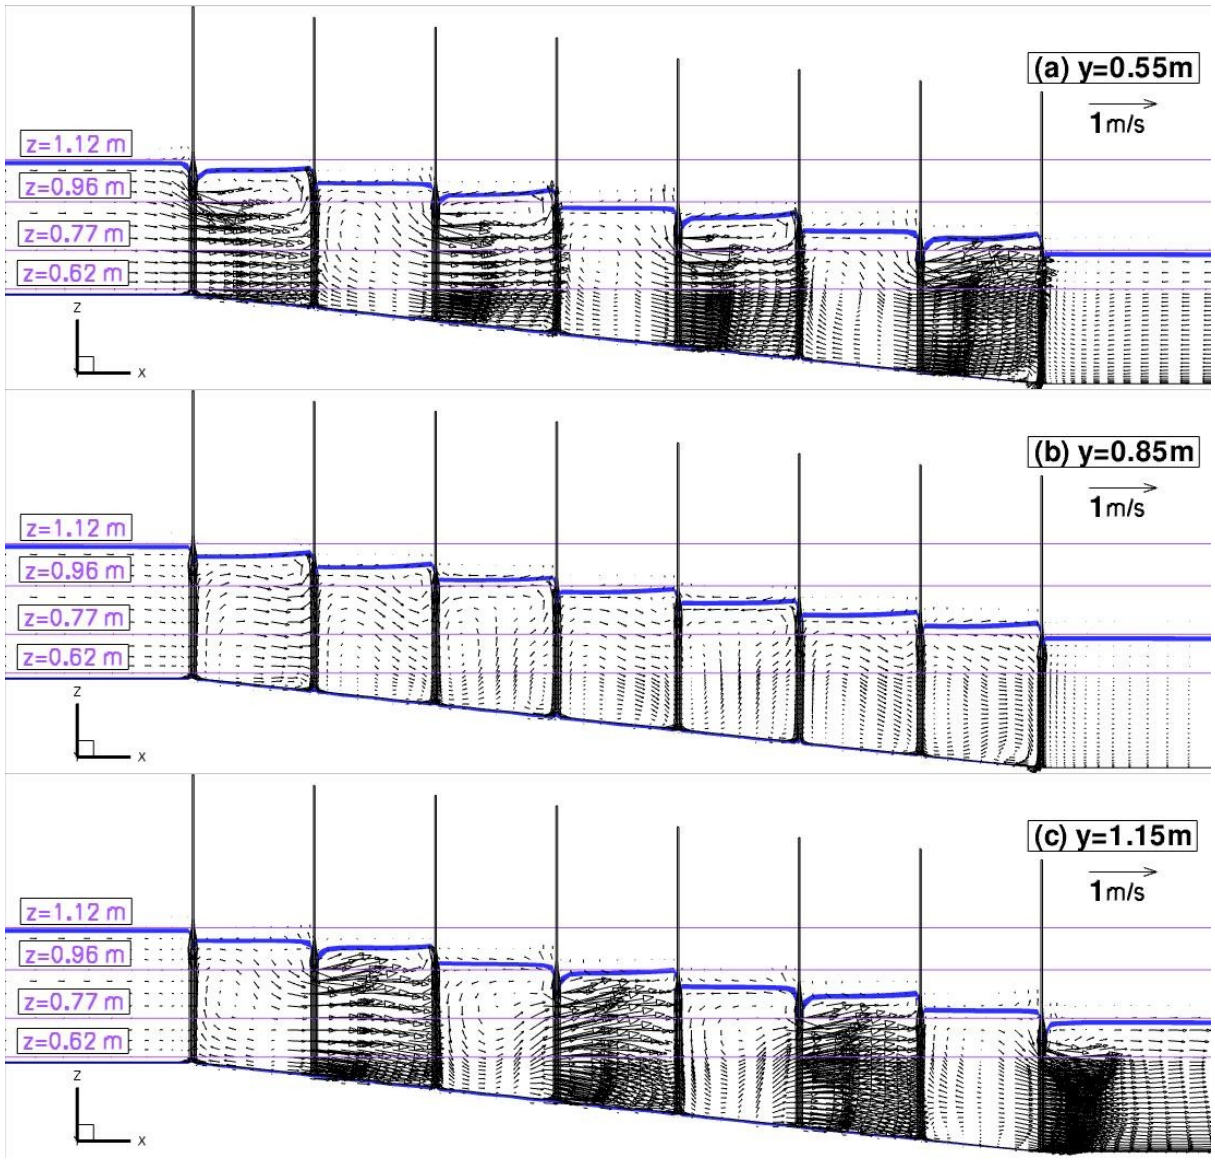

Figure 8. Side view. Velocity distribution at different cross sections along the transversal direction. (a) y=0.55m (orifice location), (b) y=0.85m (channel centerline), and (c) y=1.15 (orifice location). H=0.5 m.

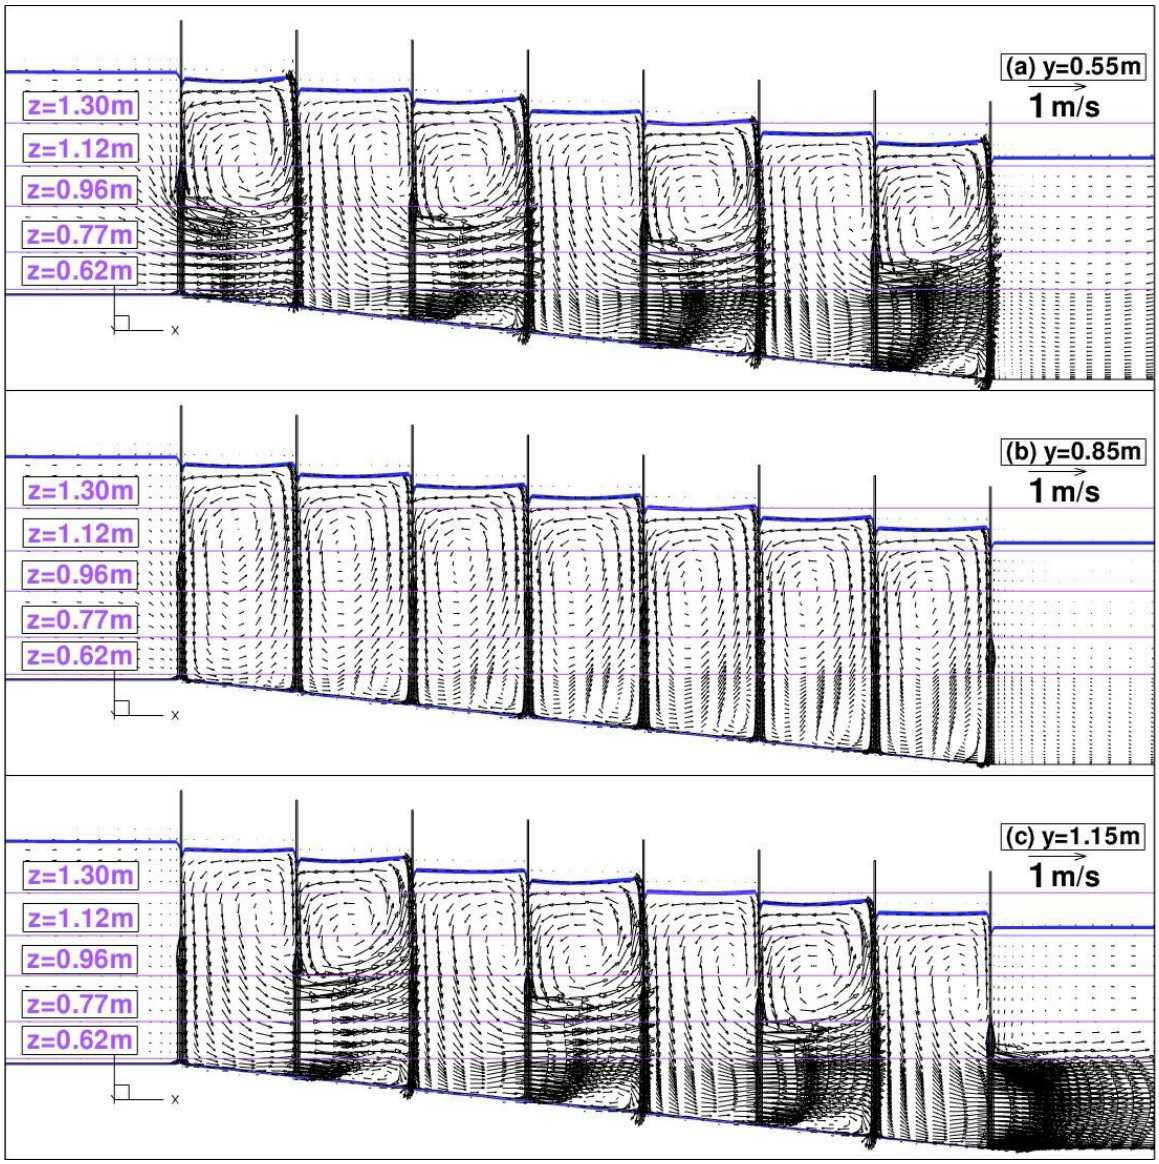

Figure 9.Side view. Velocity distribution at different cross sections along the transversal direction. (a) y=0.55m (orifice location), (b) y=0.85m (channel centerline), and (c) y=1.15 (orifice location). H=0.9 m.

3. PREDICTION OF DESIGNED SCENARIO – CHICAGO NORTH BRANCH DAM + DUTCH POOL AND ORIFICE FISHWAY

The previous sections described the CFD modeling of the current scenario (prototype scale) and the verification of the Dutch pool and orifice fishway. Herein, the objective is to incorporate a boat chute/fishway passage structure in the Chicago North Branch Dam (as shown in Figure 10). Several studies deal with the design of canoe chutes (e.g. Katapodis, C., 1992, Caisley et al. 1999, Caisley and Garcia, 1999, Odeh, 2003). Herein, Caisley et al. (1999) and Caisley and Garcia (1999) are used as designed guidelines.

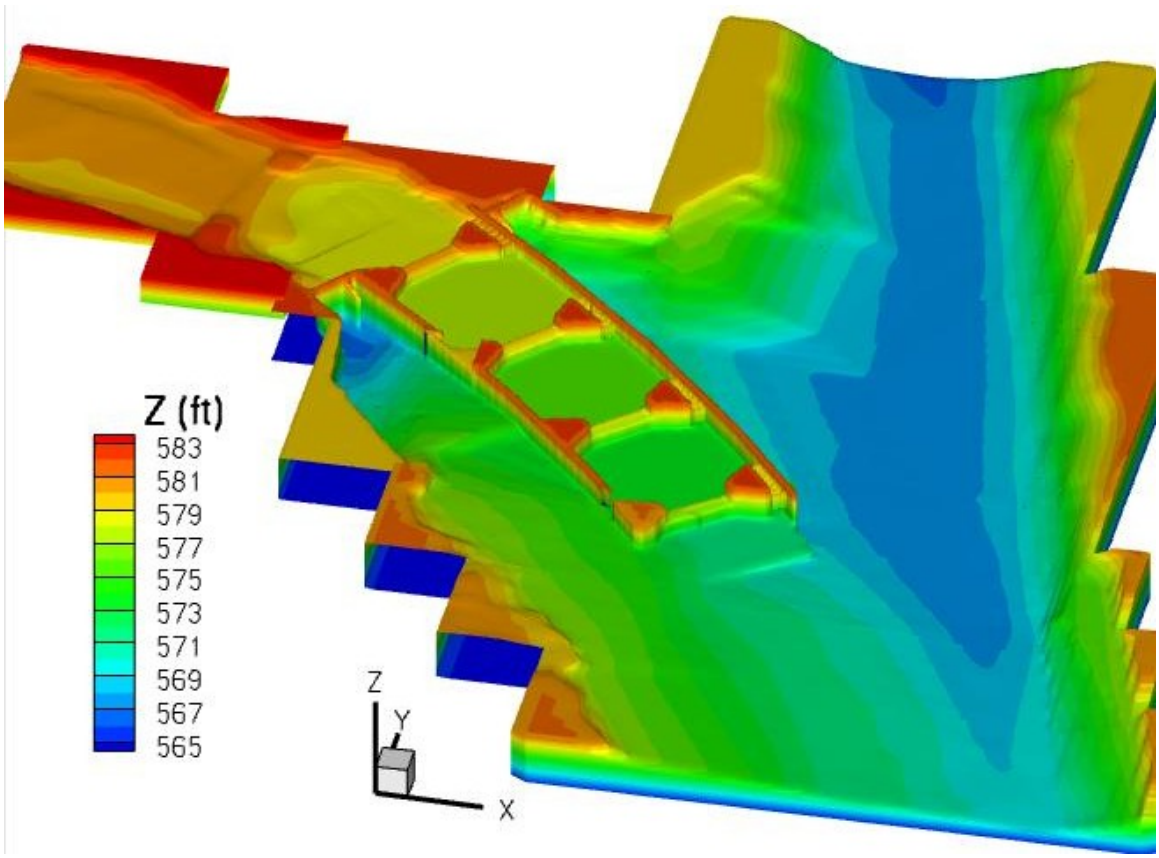

Figure 10.3D view of the computational domain including the Canoe chute and Dutch pool/orifice fishway structure. Colors define the bottom elevation.

Currently the above configuration is being simulated for both design discharges (85% and 15% exceedence) and studied experimentally.

Abstract

The variability in the effective discharge (Qeff) calculations was assessed and attributed to the flow frequency distribution (FFD) determination, the type of sediment data used in the analysis and the methodology used in the calculation. Improvements to the existing methods for Qeff determination included the use of a Log-Pearson Type III model to represent the FFD in an analytical approach and the use of density frequency distributions to avoid dependence on the class size of histograms, and to replace the concept of frequency of discrete events by frequencies of a continuous variable. A sensitivity analysis by using the analytical approach demonstrate that the use of the suspended sediment load data to infer the bedload transport rates is inappropriate and that FFD with less skew in the data tend to have low values of effective discharge. Qeff for three gravel rivers (*i.e.*, SF Salmon, SF Payette and Boise Rivers) were calculated. Methods used yield to similar results. Effective discharge is reached or exceeded about 6, 17 and 7 days per year for the SF Salmon, SF Payette and Boise River, respectively. The values of effective discharge and bankfull discharge are nearly identical for Boise and Payette River and the effective discharge is 1.2 times the bankfull discharge for Salmon River.This paper will emphasize understanding the basis of the formula or methodology for correct application. Numerical results are presented in comparative tables as well as conclusions.

Background

In this paper, the focus is on assessing the applicability of the effective discharge concept to three gravel bed streams in the Boise and Payette national forests: SF Salmon, SF Payette and Boise. Three different methods will be applied: 1) the traditional method based on the work of Wolman and Miller (1960), 2) the analytical approach of Nash (1994), but improved as it will be explained below and, 3) the method proposed by Emmett and Wolman (2001). The analytical approach of Nash (1994) will be improved by using a more appropriate statistical distribution besides the lognormal proposed by Nash. The methods and results will be compared and their advantages and disadvantages will be determined. Variables that can affect the results of the calculations of effective discharge will be assessed (i.e., number of class intervals/bin size when flow histograms are used, methods for the estimation of the sediment rating curve (Q_s vs. Q) and use of bedload/suspended load sediment data, among others).

Methods used for estimation of effective discharge

For many years, standard practice for effective discharge determination has been based on three main approaches. In the following sections the following notation will be used for each of the approaches to be used:

Method A: The traditional approach based on the flow frequency distribution and the sediment rating curve (Wolman, 1960).

Method B: The analytical approach based on representing the flow frequency distribution with a known statistical distribution and the sediment rating curve represented with a power function (Nash, 1994).

Method C: The approach based on finding the discharge that produces the maximum change in sediment load using the Andrews (1980) definition of effective discharge (Emmett and Wolman, 2001).

From the literature review it is evident that Method A is widely used. Method B is referenced in papers after 1995 but usually produces poor results or results not in good agreement with results of Method A or bankfull discharges. Since Method C is relatively new in comparison with the previous ones (Emmett and Wolman, 2001), no many papers were found that reference it. However, some similar approaches have been used after Andrews (1980) definition of effective discharge. Key references in this study to evaluate approaches used for effective discharge calculation were those published by Wolman and Miller (1960), Andrews (1980), Andrews and Nankervis (1985), Nash (1994), Emmett and Wolman (2001) and Biedenharn (et. al. 2001).

A few typical issues or problems referenced in the literature reviewed include the following:

If a significant proportion of the recorded discharges falls within the first-class interval of the flow distribution, the effective discharge could be significantly underestimated; for example, for streams that display a highly skewed distribution of flow events, like rivers in semi-arid environments, channelized streams, or incised channels (Watson, 2001).

Different criteria used in the selection of number of discharge classes used in the flow frequency distribution histogram (Biedenharn et. al., 2001).

Discontinuous flow frequency distribution histograms that generate an irregular bed material load histogram with outliers that reflect transport associated with individual flood events (Biedenharn et. al., 2001).

The gauging stations at which sediment data are available are located at sites where drainage basins have been impacted by human activities (*i.e.*, continuous changes in land uses) or whose flows are controlled or diverted upstream of the analysis site.

"Scatter pattern" observed in the sediment rating curves. Sediment discharge data not normally distributed and variance not constant with discharge cause differences in the sediment rating equations depending on the procedure used to estimate them (*i.e.*, transformation of data for a linear regression and correction factors to improve the results, non-linear regression estimation and the criteria used to select the model).

Sediment transport measurements taken infrequently and limited to the suspended portion. Suspended transport does not contain the bedload channel material and is more representative of watershed denudation.

Bimodal or multimodal effective discharge histogram. The effective discharge curve is not always a unimodal histogram as Wolman and Miller presented in 1960. Depending on the flow frequency distribution shape and the rating curve equation, the effective discharge curve can have more than one peak. If the multiple peaks are of similar magnitudes, an uncertainty in the selection of the peak (associated with the effective discharge value) is introduced.

In conclusion is that in general, there are three reasons for variability and uncertainty in the effective discharge calculations:

- The flow frequency distribution
- The sediment data used in the analysis
- The methodology used in the calculation

Case Study

Site Description

The study site is composed of three gauged gravel-bed rivers in west-central Idaho, whose drainage areas are within the Boise National Forest and the Payette National Forest. The site is on land administered by the Forest Service. The gage stations selected are:

1. South Fork Salmon River near Krassel Ranger Station, Idaho.
2. Boise River near Twin Springs, Idaho.
3. South Fork Payette River at Lowman, Idaho.

Information used in this report was collected by the USFS at Boise and the USGS (Idaho). The monitoring information was obtained because of the need to understand and describe the sediment-transport capabilities of the rivers to assist in land-use planning efforts of the USFS. Data collected under the direction of the USFS at the three sites include hydraulic geometry, bedload and suspended transport and bedload material characterization by pebble counting. Additional measurements include a survey of the stream reach and pebble counts of the surface substrate. Flows are continuously monitored by the automatic stations of the USGS. None of these site has upstream dams or significant diversions.

South Fork Salmon River near Krassel Ranger Station, ID

The South Fork Salmon River had extensive sedimentation in the early 1960's due to a combination of roads and timber harvesting coupled with very large storms (1955, 1962, 1964 and 1965). By 1965 the USDA Forest Service developed an integrated watershed restoration program concerned with the degradation of the river conditions. Since then this system has been in a recovery phase (Megahan et al. 1980; Platts and Megahan, 1975). A large storm around Jan 1, 1997 generated a lot of new sediment to the system.

In terms of river mechanics, since 1965 the sediment supply was reduced due to a restoration program. Energy available for sediment transport in the river was adequate to remove the excess of sediment in the system.

In 1978 a new Land Management was implemented. One of the challenges of this plan is monitoring to assure that goals are met. The monitoring was designed to be sensitive enough to detect potential problem situations. There were three periods in which sediment transport monitoring was developed, 1984-1986, 1995-1996, 1997. These data were used in the analysis of the effective discharge. Two representative periods (80's and 90's) will help to look at changes in time of streamflow versus sediment transport relationships that could affect the effective discharge estimation.

The study reach is at the Geological Survey (USGS) gage 13310700 (South Fork Salmon River near Krassel Ranger Station, Idaho) in the Payette National Forest. The stream gauging station is approximately 2.25 km downstream from the Krassel Ranger Station at an elevation of about 1,143 m. The drainage area upstream of this location is 852.9 km^2. Average annual streamflow for the period of record is 15.3 m^3/s and bankfull discharge is estimated at 65 m^3/s.

Bedload-transport rates were measured with a Helley-Smith bedload sampler. The three inches sampler was used for all of the SF Salmon River station samples. Suspended sediment was generally sampled at 10 verticals using a depth-integrating sampler. Samplers used included the DH-59, D-49, and D-74 models.

The sediment transport data include 130 measurements of bedload transport and 92 measurements of suspended sediment. Over the range of measured discharges, suspended transport accounts for the majority of the material in transport, with over an order of magnitude greater suspended transport at the lower range of sampled discharges to approximately equal amounts at the highest discharge.

South Fork Payette Station, ID

The study reach is at the Geological Survey (USGS) gage 13235000 (South Fork Payette River at Lowman, Idaho) in the Boise National Forest at an elevation of about1155 m. The drainage area upstream of this location is 1163.7 km^2.

Sediment transport measurements were made by USGS personnel during the spring flows of 1994 and 1995, and 1997. Average annual streamflow for the period of record is 24.4 m^3/s and bankfull discharge is estimated at 85.4 m^3/s.

Bedload-transport rates were measured with a Helley-Smith bedload sampler. The three inches sampler was used for most of the samples on the SF Payette River. The six inches sampler was used for the high flows in 1995. Suspended sediment was generally sampled at 10 verticals using a depth-integrating sampler. Samplers used included the models DH-48 and D-74.

Sediment transport measurements made in 1994 and 1997 include 72 measurements of bedload transport and 37 measurements of suspended sediment transport. Over the range of measured discharges, suspended transport typically accounts for the majority of the material in transport with over an order of magnitude greater suspended transport than bedload transport at the highest discharges and about similar rates between suspended and bedload transport at the lowest discharges during which sediment transport was measured.

Boise River Station, ID

The Boise River originates in the Sawtooth Mountains in Central Idaho as three separate forks that flow in a southwesterly direction. The North Fork and Middle Fork join near Twin Springs and the South Fork discharges into Boise River just above Arrow Rock Dam. The gauge station is located at the Geological Survey (USGS) gage 13185000 (Boise River near Twin Springs) in the Boise National Forest and at an elevation of about 992.4 m. The Boise river watershed to this site, is characterized by mixed forest, grass and brush vegetation in relatively good condition (Love and Benedict, 1948). There appears to be no direct evidence of any significant changes in stream beds in the vicinity of the gauge station.

The drainage area upstream of this location is 2153.8 km^2 and the stream gauging station is approximately 2.9 km upstream from the maximum flow line of Arrowrock Reservoir. The average gradient for the study reach is 0.0038.

Sediment transport measurements were made by USGS personnel predominantly during the spring of 1994, 1995 and 1996 and 1997. During this monitoring program a survey of the stream reach, pebble counts of the surface substrate, and core samples of the subsurface substrate material were carried out.

Bedload-transport rates were measured with a Helley-Smith bedload sampler. The three inches sampler was used for all of the Boise River samples. Suspended sediment was generally sampled at 10 verticals using a depth-integrating sampler. Samplers used for the Boise River were the models DH-59, D-49, D-74, and D-77.

Streamflow has been recorded since March 1911, although prior to October 1, 1965 the station was 0.48 km downstream of the present location. Average and bankfull discharge is estimated at 15.3 m^3/s and 165.2 m^3/s, respectively.

Analyisis and Results

Hydrology

Because the flow discharge patterns are important factors for the effective discharge, a break in the analysis of the Salmon River was done in 1990 to assess possible changes in the value of the effective discharge. However, the selection of the 1990 year to mark the break in the analysis is arbitrary and based on a combination of practical purposes. The mean levels change gradually (due to a cyclic effect) and there are no flow data during 1983-84 and 1987-1988 to analyze changes during the 80's. We can visualize the variation only after 1990. Because flow frequency distributions are critical for the calculation of effective discharge, frequency distributions before and after the adopted break in 1990 were calculated. There are no significant differences between the two periods except for flows lower than 3 m^3/s that are more frequent for the period after 1990.

Lognormal and Log-Pearson Type III models were tested to the data to assess their fits to the empirical frequency density curve. The Log-Pearson Type III models are preferred to fit the data of the Salmon, Payette and Boise Rivers.

Because of the significant skewness in the flow data and the variability of the daily flows, the number of class intervals necessary for an adequate histogram is very large. It would be impractical to use such an interval since scattered effective discharges will occur. As mentioned before, in this case, the use of histograms will ignore important information. A routine was used to analyze the best number of class intervals that could preserve the EFD shape. Because of the skewness of the data, a large number of class intervals is required to preserve the information of the low flows. However, information of the higher flows is missed since some intervals will have frequencies equal to zero. In gravel bed rivers it could be risky to discard information in this range of values since the "effective discharges" will probably be associated with infrequent flows. The number of class intervals selected ranged between 200 and 500 class intervals trying to avoid zero frequencies to analyze the effect of the use of histograms in the effective discharge calculation. Additionally, the approach using an empirical PDF or the relative frequencies obtained from the CDFs avoided the frequencies equal to zero when small width classes are used.

Sediment Transport

Although the sediment transport curves for the gauging stations studied indicate a good log-log relationship between stream discharge and suspended and bedload sediment discharge, there was a fair amount of scatter about the best fit regressions. Bias corrections were done and non-regression estimates were found to assess the sensitivity of the "best curve fit" on the effective discharge calculation.

It is important to notice that sediment rating curves obtained with linear and non linear regression methods have different *"a"* and *"b"* coefficients. It has been shown that the effective discharge is only dependent on the *"b"* coefficient, hence it is expected that different values of these coefficients will lead to different values of effective discharges. The magnitude of this change is evaluated in the effective discharge calculation.

Sediment rating curves for Salmon River data were calculated for the period before and after 1990. Sediment data collected before 1990 were used in combination with flow data collected before 1990 representing the first period of analysis (I). Sediment data collected after 1990

were used in combination with flow data collected after 1990 to represent the second period of analysis (II). In general, it was observed that for the same flows the first period of analysis was associated with greater bedload rates than the second period of analysis. However, the relationship between bedload rates in the first period and second period decreases as flow increases.

Rating curves for suspended sediment data were also estimated for the three sites of study. Where available information allowed separation of the fraction of sand size or larger of the suspended rates, additional curves were developed for these fractions of the suspended sediment. This comparison shows how different rating curve equations are obtained for bedload and suspended sediment, invalidating the suggestions made in past studies about the feasibility of using the sediment load transport information to infer the bedload transport rates or the coefficient *"b"* of the bedload rating curves for the calculation of the effective discharge. Nash (1994) pointed out that poor estimations of the transport function at the highest flows and the extrapolation of the rating curve to higher discharges than these measured can alter the classic form of the effective discharge curves. However, Withing (1999) mentioned that he did not believe these factors were important.

It was observed that the size fractions in motion in the channel were in general smaller than the fractions in the bed. In the three sites analyzed, the D_{50} of the material transported was finer than the D_{50} of the bed-load material. Even though the sediment particle size increases with increase in discharge, most of the bedload transported (caught with the Helly Smith) is sand size in Salmon River and an important portion in Boise and Payette River. Payette River shows a wider range of grain sizes moved from bed material.

The subsurface samples in SF Payette and Boise show that the subsurface layer contains finer material than the surface layer. Finer fractions will be present in the mixture as long as they are shielded by the stable coarser particles. Larger particles will move as soon as the shear stress exceeds the threshold of motion of coarse particles. The grain size distribution of a bar in Boise evidences similar characteristics to those of the grain size distributions of the surface and subsurface samples.

Using the traditional approach (Method A), the results obtained do not indicate a dependence on the "potential" number of class intervals (the ones that statistically can be used allowing a good representation of the EFD) used in the flow frequency distribution. The number of class intervals used was in the range of 200 to 500 for the three sites. However the smaller the number of class intervals the more information hidden in the frequencies and, as a consequence, the low values and high values tend to be under- or over-represented. In sediment load histograms like the one observed for Boise (where the peak is surrounded by other significant sediment loads), care should taken since variations either in the number of bins when method A is applied, or in the *"b"* coefficient, will produce variations in the peak that represent the effective discharge value. In such cases it will be advisable to do a sensitivity analysis to check for the potential "range of effective discharges."

The potential "range of effective discharges" in the effective discharge curves was visualized when the Empirical PDFs were used instead of histograms to represent the flow frequency distributions in the calculations. Although scattered graphs were obtained, by smoothing

these graphs the "competence of effective discharges" (range of potential effective discharges) could be observed. When histograms are used in selecting an arbitrary number of class intervals (*e.g.*, N=25), well defined peaks can be obtained in the effective discharge curve but the potential "range of effective discharges" is missed.

The smaller the discharge range, the more fluctuation in the effective discharge plot in the estimations with Method C. In spite of this pattern, the peak of the plot can be identified, and clear results were obtained when the whole discharge range was divided into 20 to 25 to select the "dQ" to use in the estimation of the slope of the relative accumulative sediment load curve for each historic datum under this range of flows. These results agree with Emmett and Wolman (2001) recommendations of 1/18 discharge range. Effective discharge values by using Method A and C are very similar and as a consequence, so are the recurrence intervals. The advantage of Method C is that we do not have to deal with choosing a good number of class intervals for the histogram.

Effective Discharge is reached or exceeded 6, 17 and 7 days per year for SF Salmon, SF Payette and Boise, respectively. SF Salmon analysis showed a "potential change" in the effective discharge values due to the changes in the availability of coarser material in the bed for transport. This potential change will change the frequency of exceedance from 6 to 4 days per year. These results were obtained based on the EFDs. The values of effective discharge and bankfull discharge are nearly identical for Boise and Payette River and the effective discharge is 1.2 times the bankfull discharge for Salmon River.

Effective discharge calculations were carried out for different *"b"* values obtained with the corrected Linear Regression (LR) and Non Linear Regression (NLR) estimation of the rating curve. It was found that the difference in the effective discharge value obtained was minimal, because the peak in the effective discharge curve (the effective discharge value) was well defined. Boise River did not have a "well defined peak" but a range of competitive effective discharges, so, a change in "*b*" can lead to a significant influence on the effective discharge value.

Results obtained using Method B were lower than those obtained by the other two methods. The reason is that the models, although good for the whole range of flows, did not represent very well the tails of the distribution (high flows). In gravel bed rivers this is important because this is the range of flows where the effective discharge is expected. The models underrepresented the frequencies in this range of flows, causing lower flows to be identified as effective discharges. These results do not invalidate the use of an analytical approach because models that are not "completely perfect" can be used for rivers where threshold conditions are not considerably high. Besides, those models must be used when the EFD is not available or, as in this report, to estimate patterns/sensitivity analysis, etc.

In order to check whether the effective discharge is really responsible for the changes and movement of bedload material, graphs with grain size distribution of bedload transported material (caught in the Helly Smith sampler) and bed material (determined by pebble count) were developed. Flows close to or larger than the bankfull and/or effective discharge contribute to a significant movement of the bed material. In all of the cases it was the sand size material that represented the bulk of the bedload transported.

The similarity in the values of effective and bankfull discharges for the Boise and Payette Rivers shows that the channel is adjusted to the range of discharges that transport the largest sediment load.

Conclusions

Using the analytical approach, a sensitivity analysis was performed to assess the variation of the effective discharge value with changes in the parameters that are involved in its quantification. Unless "a well defined effective discharge" is identified, the effective discharge can vary even with small changes in the parameters involved in the effective discharge calculation.

Sediment rating curves fitted for bedload generally have a larger degree of uncertainty than do curves for suspended sediment. The correlation coefficients are higher for suspended sediment rating curves than for bedload rating curves. For suspended sediment rating curves a logarithmic transformation of the data facilitated a linear regression between the transformed data that provided adequate rating curves (explaining more than 90% of the variability of the data).

Comparison of the bedload rating curves selected for the effective discharge calculation and rating curves obtained for suspended sediment transport showed the difference in the rating curve equations. This result invalidates the suggestions made in past studies (Nash, 1994) about the feasibility of using the suspended sediment load transport data to infer the bedload transport rates or the coefficient "*b*" of the bedload rating curves for the calculation of the effective discharge.

It was observed that the size fractions in motion in the channel were, in general, smaller than the fractions in the bed. In the three sites analyzed, the D_{50} of the material transported was finer than the D_{50} of the bed-load material.

The largest portion of the bedload transported in these gravel bed channels is not in the gravel size, but in the sand size. The sediment samples showed a rather straight cumulative curve (at the sand size) describing the bedload caught with the sampler and a markedly S-shape curve for bedload material. The armour and subarmour layer nearly always have a curve that lies under the bedload caught in the sampler.

In general, the particle size distribution of bedload sediment becomes proportionately coarser as stream discharge increases. Sand contributes (0.5 to 2.0 mm) the major volume of bedload in the three gravel-bed streams studied. However, the major morphological feature of gravel-bed streams is that they are composed of gravel, not the sand that makes up the bulk of the bedload. Records for the Boise and Payette streams showed different patterns from the records for the Salmon stream with respect to the ratios of bedload and suspended rates to discharges. These ratios increased with discharge for the Boise and Payette streams, but decreased with increasing discharge for the Salmon stream.

Using an adequate statistical approach for the selection of the class intervals (based on the EFD), the range of variation in the effective discharge as a function of the class interval size

became very narrow. However, it has been shown that for Method A it is much better to work with the original Empirical PDF or the relative frequencies derived from the empirical CDF than to use histograms. The potential "range of effective discharges" in the effective discharge curves is visualized in this way. Although scattered graphs were obtained, by smoothing these graphs the "competence of effective discharges" could be observed. Method C provided results nearly identical to those obtained with Method A. However, Method B provided results very different from those of Methods A and C. Thus, its use is recommended only when a well-defined flow frequency distribution is not available and/or "theoretical" conclusions need to be described by the proposed models. In fact, if a statistical distribution is good enough to represent the EFD, Method B provides good results.

Effective discharge is reached or exceeded about 6, 17 and 7 days per year for the SF Salmon, SF Payette and Boise, respectively. These results are in good agreement with previous results in the literature about periods of recurrence of effective discharges. The analysis for SF Salmon showed a "potential change" in the effective discharge values due to changes in the availability of coarser material in the bed for transport. This potential change will also change the frequency of occurrence.

Hydraulic geometry equations have been developed for gravel bed rivers and they give reasonable results when large rivers are involved. It has been noticed, however, that results of these equations do not reflect the observations for mountain rivers or steep streams (Chang, 1992). Mountain rivers tend to have flow frequency distributions (from hourly/daily data) that are markedly skewed (due to their characteristic flashy hydrographs). Thus, even though steep, mountain streams may have the same mean flow as streams of lower slopes, the effective discharges will be higher for the mountain rivers. In general, the "equivalence" between two-year floods, mean annual flows, bankfull flow and effective discharges, when applied to hydraulic geometry equations, will not be appropriate when it is known that hydrologic regimes in the sites of study are different from the ones whose source data were used to develop the equations. Hydraulic geometry equations do not take into account the flow regime and/or flow distribution and this may be one of the reasons of the variability between field observations and theoretical results.

Results obtained using the rating curves of the SF Salmon River show that streams similar to SF Salmon River can recover in time if sediment flows into the stream resulting from upland erosion are reduced to levels below the capacity of the stream to flush fines from the system. Because of that, the effective discharge tends to change to a stable value.

From the Analytical approach it is visualized that rivers with the same annual flow availability but with different regimes (*e.g.*, different flow frequency durations) will produce different effective discharges due to the difference in the skewness of the flow frequency distribution graph. The different flow frequency distributions could be associated to different climatic conditions or to different channel gradients.

ABSTRACT

Methods for filtering raw bathymetric field data are useful when developing multi-dimensional hydraulic models for river instream flow studies. Raw field data characterizing a submerged surface may include spikes or irregularities arising from instrument issues (e.g., signal loss, bubbles) or from actual objects (e.g., large woody debris) resting on or above the channel bottom. Identification and filtering of large woody debris (LWD) in single-beam echosounder data has been investigated by others and these concepts can be extended to other submerged objects. An improved application of a median filter approach is presented here that includes a method for varying the filter half-length to account for changes in boat speed.

With improvements to the identification method, typical raw datasets can be used to more effectively locate submerged objects according to size class. When developing a hydraulic model, locating filtered objects aids in identifying areas of bathymetric complexity and calibrating roughness coefficients.

BACKGROUND

Many recent instream flow studies have evaluated aquatic habitat using velocity and depth predictions generated from two-dimensional (2D) hydraulic models (Bowen et al. 2003; Osting et al. 2004; Hardy 2006; BIO-WEST 2008). Development of representative channel bathymetry is necessary for applying aquatic habitat prediction tools across a range of flow; therefore, identification and management of irregularities in inputs can reduce the level of uncertainty. Model bathymetry is potentially the largest source of uncertainty to these models, including uncertainty in the input depth and roughness data as well as uncertainty arising from predictions in areas with sharp vertical gradients (Osting and Hodges 2007).

Where large study sites or deep water prohibits measurement of in-channel bathymetry by conventional means (e.g., total station survey), a boat-mounted marine echosounder allows convenient measurement of depth over a large area. When the echosounder is synchronized with a Global Positioning System (GPS), a typical data set may be comprised of many depth readings per second measured and recorded along the boat path. The boat path, appearing as a line in Figure 1 because of extremely close proximity of each data dot, is designed to provide depth data to suitably characterize the channel bathymetry.

A typical characteristic of raw bathymetric data sets is the existence of irregularities in the data. Some irregularities are caused by erroneous echosounder

readings but others may represent accurate readings of submerged objects, including logs or Large Wood Debris (LWD). To utilize the bathymetric data during development of digital surfaces for modeling, it is desirable to filter the data to remove irregularities. Many filtering options exist, including manual editing, and some filtering methods have been used to both remove erroneous data and identify submerged LWD (White et al. 2006 and White and Hodges 2005).

FILTERING TOOLS

Use of a median filter allows for identification and removal of undesirable data irregularities, i.e. "spikes," that satisfy particular size requirements. Since the data is recorded sequentially in time along the boat track, the relationship between adjacent points can be utilized to aid in filtering. White and Hodges (2005) identify a filter half-length, *N*, based upon distance between adjacent points and upon the width, *L*, of objects to be filtered (see equation below). For each data point, a point subset is developed using *N* records preceding and *N* records following the data point; the depth of the original data point is replaced with the median depth from the subset (White and Hodges 2005).

$$N_{median} \geq \frac{L}{\overline{\Delta x} - \sigma}$$

Where, N_{median} = filter half-length
L = width of objects to filter
$\overline{\Delta x}$ = average distance between raw data points
σ = standard deviation of distance between raw data points

To filter objects with a width, *L*, of 1 meter, the filter half-length is determined from the average and standard deviation of the distance between raw data points. For a data set where the distance between points is normally distributed, a constant value of *N* may be suitable across the entire data set; however, a typical data set is more variable and σ is typically on the order of $\overline{\Delta x}$. Composed of many thousands (perhaps hundreds of thousands) of points measured under a range of conditions, the variability in distance between points arises from changing boat speed to avoid obstacles or during changes in heading.

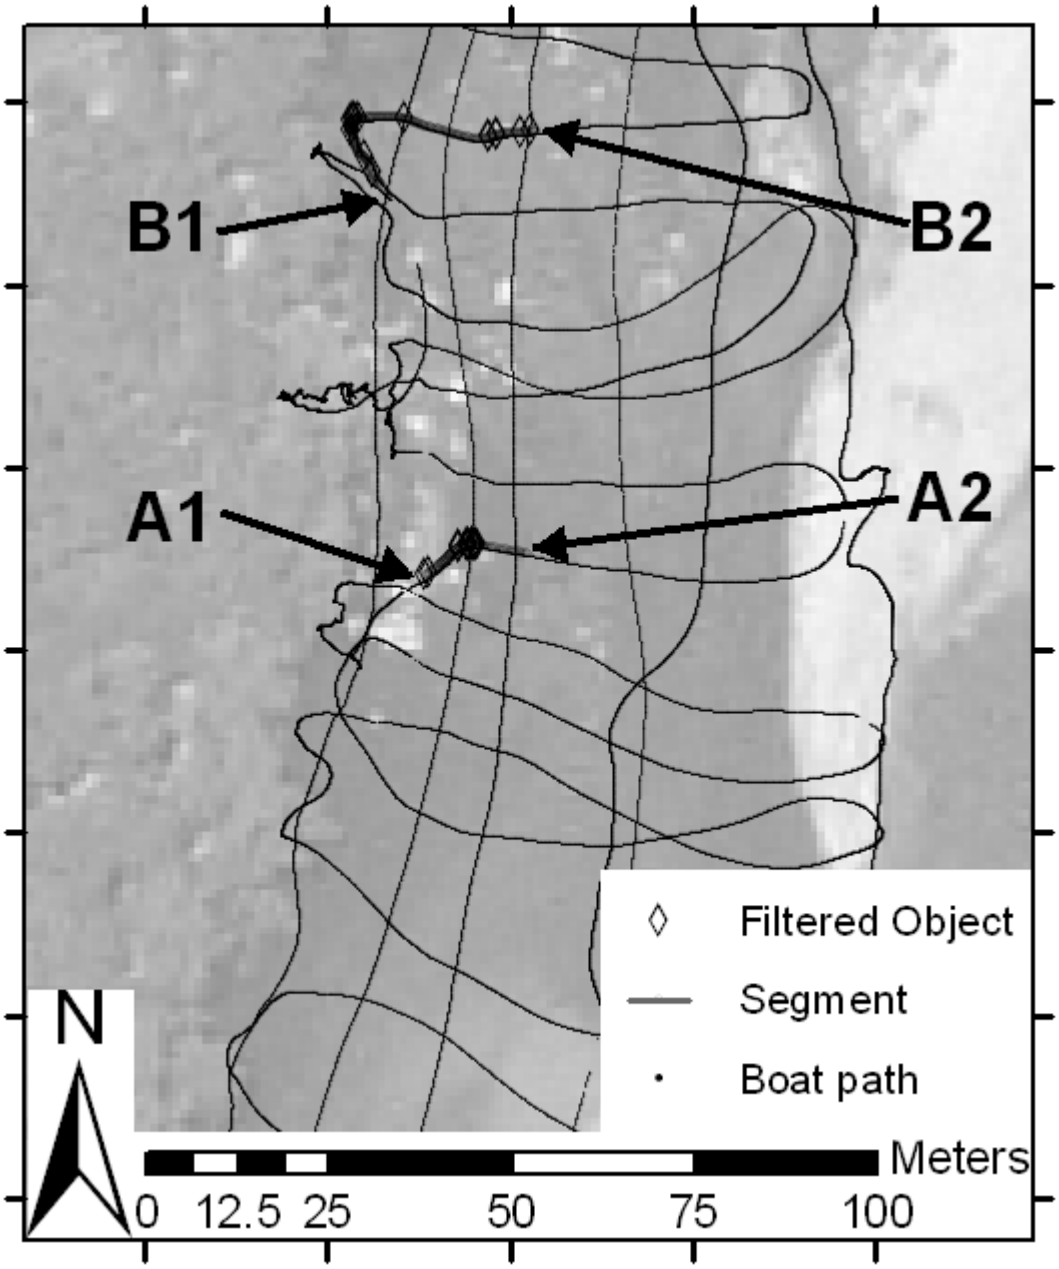

Figure 1 – Site map showing boat track, Segments A and B, and filtered objects.

APPLICATION

This paper presents application of the median filter to a large data set. Calculated across an entire raw data set of approximately 250,000 data points, the average distance between points, $\overline{\Delta x}$, is 0.105 meters and σ is 0.074. To filter objects having width, *L*, of 1 meter, the filter half-width, *N*, is 32.

For segments A1-A2 and B1-B2 (Figure 1), application of the data filtering is shown in Figure 2 (segment A1-A2) and Figure 3 (segment B1-B2). The small dots in Figures 2 and 3 represent the original raw data set. The filtered set developed using the constant half-width of 31 is shown as a light dotted line labeled "Filter 1." Near the distance stations of 29,042 and 29,049 meters, the Filter 1 line successfully filters spikes spanning less than 1 meter (Figure 3). However, the Filter 1 line is not representative of the raw data between stations 28,407 and 28,414 (Figure 2) and between stations 29,073 and 29,078 (Figure 3).

To expand the White and Hodges (2005) median filter method to account for varying distance between points, a varying half-length filter is applied. For the "Filter 2" set, the half-length is determined locally according to point spacing in the vicinity of each raw data point. Across the data set, the value of N ranges from 2 (where spacing between points is large because the boat is moving fast) to 1,141 (where spacing between points is extremely small); the mean value of N is 47.

The heavy solid lines labeled "Filter 2" on Figures 2 and 3 represent the filtered set developed from the locally-varying half-length. As with the Filter 1 set, the Filter 2 set successfully filters spikes spanning less than 1 meter (e.g., stations 29,042 and 29,049 on Figure 3). In addition, the Filter 2 line is representative of the raw data between stations 28,407 and 28,414 (Figure 2) and between stations 29,073 and 29,708 (Figure 3).

Objects filtered from the Filter 2 set that exceed 0.15 meter in height are identified as diamonds within each segment on Figure 1. The objects identified near the beginning and middle of Segment A1-A2 are consistent with raw data higher than the Filter 2 set (Figure 2). Similarly, the location of objects throughout segment B1-B2 (Figure 1) is consistent with the relationship of raw data to the Filter 2 set (Figure 3). Additionally, the location of filtered objects is consistent with location of instream boulders and near-bank debris depicted in the aerial photo (Figure 1).

CONCLUSION

Processing raw bathymetric data using a median filter is an effective means of smoothing spikes out of a raw data series of echosounder data. Analysis of the filtered data is also useful for evaluating roughness coefficients since locations where data is filtered represents locations with submerged objects (Osting et al. 2004).

Compared to the ordinary median filter method (Filter 1), the expanded method (Filter 2) results in a smooth processed data set more representative of the raw data. Consistent with the expanded method presented in this paper, the use of a median half-length calculated locally is recommended when the distance between raw data points varies.

ABSTRACT

Chemical spills in surface waters often occur in modern societies, which cause significant impact on water quality, eco-environment and drinking water safety. In this paper, chemical spill contamination in water resources is studied by using a depth-integrated computational model, CCHE2D, modified for predicting fate and transport processes of chemical contaminants in surface waters. The processes of volatilization, photolysis, hydrolysis, adsorption, desorption, degradation, etc. were included, and the interaction between sediment bed and water column were also considered. To simulate the fates and transport processes of chemicals using the developed chemical spill module, many parameters of the chemical materials are needed. A database was developed to provide information for involved chemical processes. Hypothetical chemical spill cases were simulated using the CCHE2D model and the developed chemical property database.

Keywords: Chemical spills, CCHE2D Model, Database, Chemical property,

INTRODUCTION

A large number and wide variety of chemicals are used in manufacturing facilities and transported near water bodies, raising potential dangers of chemical spill incidents. In recent years, the number of accidents by which large quantities of toxic chemicals are discharged into water bodies has increased. In March 1993, About 65,000 gallons of toluene spilled from a ruptured line into the Ohio River while being pumped from a barge into a factory (New York Times, 1993). This incident caused a

lot of potential environmental impacts on the Ohio River. In November 2005, an explosion at a chemical factory in China's Jilin Province released about 100 tons of highly toxic benzene into the Songhua River, a tributary of the Amur (Kim and Murphy, 2006). The blasts created a 80 km long toxic slick in the Songhua River. As the slick travelled downstream, dead fish washed up on the banks and many water supply facilities had to be shut down for a couple of days.

When a chemical accident occurs, it is imperative to know where the released chemical may go and what the chemical concentration in water is. Numerical model provides a useful tool for predicting the trajectory and fate of chemical spill in water body.

A two dimensional numerical model, CCHE2D, has been developed by the National Center for Computational Hydroscience and Engineering (NCCHE) to simulate the flow, sediment, pollutant transport, water quality, as well as chemical spills in natural water bodies. This model has been verified and validated rigorously using analytical methods, many sets of physical model data, and applied to many nature water cases (Jia and Wang 1999, Jia et al. 2002, Zhu 2006). In order to simulate the fate and trajectory of chemical spill in water body, the chemical properties are important parameters. In CCHE2D chemical module, the following parameters are required: Degradation rate in water, Degradation rate in soil, Organic-carbon partition coefficient, Molecular weight, and Henry's constant.

To provide those chemical properties, a database CHEMBASE was established using Microsoft ACCESS 2007, with objects such as table, query, report, form, macro, and module, etc. The CHEMBASE database can be used to provide the chemical property information for numerical simulation of chemical contamination. It also provides additional information for users to review so that the selected parameters can fit better to the conditions of the environment under investigation. For example, the ranges of the parameters Koc (organic-carbon partition coefficient), Degradation rate in water, and Degradation rate in soil, vary depending on the conditions, such as PH, temperature, etc. Measured values and the corresponding experimental conditions were provided by this database for users to review and select the reasonable values. The output parameters of the chemical database can be directly taken by the Graphical Users Interface of CCHE2D model as inputs (Zhang, 2008). Due to the fact that no field datasets with sufficient information has been found, two hypothetical chemical spill incidents in the Ross Barnett Reservoir, Mississippi, were simulated to demonstrate the capabilities of the developed CCHE2D model and CHEMBASE database

CCHE2D CHEMICAL MODULE DESCRIPTION

Governing Equations

CCHE2D chemical module has been developed and integrated into CCHE2D model to simulate the distributions of chemical concentrations in the water column as well as sediment layers (Zhu 2006). The processes of transportation, volatilization, sedimentation, adsorption, degradation, etc. were considered.

In the water column, the chemical concentrations can be described by the following mass transport equation:

$$\frac{\partial C}{\partial t} + u\frac{\partial C}{\partial x} + v\frac{\partial C}{\partial y} = \frac{\partial}{\partial x}(D_x \frac{\partial C}{\partial x}) + \frac{\partial}{\partial y}(D_y \frac{\partial C}{\partial y}) + \sum S_i \quad (1)$$

in which u and v = depth-averaged velocity components in x and y directions, respectively; C = depth-averaged chemical concentration in water column; D_x and D_y = dispersion coefficients; $\sum S_i$ = effective source terms, which include source terms due to external loading, volatilization, adsorption, desorption, degradation, and vertical diffusion at water-sediment interface.

In sediment layers, it is assumed that pore water may infiltrate in and out of those layers and thus induce additional chemical transfer. In the present module, a multiple-layer approach proposed by DiToro (2001) was used to simulate the chemical transport in sediment layers. The governing equations can be expressed as:

$$\frac{\partial h_j C_j}{\partial t} = \sum S_j \quad (2)$$

where C_j =concentration of chemical in sediment layers; h_j =depth of sediment layers; $\sum S_j$ is the effective source term. In the first sediment layer, $\sum S_j$ includes source terms due to external loading, vertical diffusion at water-sediment interface, degradation, and vertical diffusion between the first and second sediment layers. In other sediment layers, $\sum S_j$ includes source terms due to external loading, vertical diffusion between neighboring sediment layers, and degradation in sediment layers.

Chemical Fate Processes in the Chemical Module

In CCHE2D chemical module, some major chemical fate processes, including volatilization, adsorption, desorption, degradation, etc. were considered.

Volatilization is the movement of chemical across the air-water interface as the dissolved neutral concentration attempts to equilibrate with the gas phase concentration. The rate of exchange is proportional to the gradient between the dissolved concentration and the concentration in the overlying atmosphere and the conductivity across the interface of the two fluids. The conductivity is influenced by molecular weight, Henry's Law constant and environmental conditions at the air-water interface. In this model, a formula obtained from the "two-film" theory was used to calculate the volatilization rate (Wool et al. 2001).

The adsorption process occurs in the water column between dissolved chemical and particulate matter. Adsorption reactions are usually fast relative to other environmental processes, and equilibrium may be assumed. In the present model the processes of adsorption-desorption were assumed to reach equilibrium at each time step and a linear adsorption isotherm was applied to describe the kinetics of adsorption and desorption. The ratio between the concentrations of particulate and dissolved chemical was taken as a constant and defined as partition coefficient. Its value could be obtained from the experimental measurement or calculated based on the organic carbon partition coefficient (Karickhoff et al 1979).

Degradation encompasses the broad and complex processes of enzymatic attack by organisms on organic chemicals. In this model, a first order decay algorithm was used to simulate the degradation process of chemical, and constant decay rates were specified for chemical degradation in water and sediment systems. The degradation rate of a chemical in water or soil could be obtained based on the experimental measurements.

In this study, a chemical property database, CHEMBASE, was developed to provide the necessary parameters regarding chemical fate processes, such as Degradation rate in water, Degradation rate in soil, Koc (organic-carbon partition coefficient, Molecular weight, Henry's constant, etc.

Numerical Solution and Model Verification

Numerical Method

CCHE2D is a two dimensional depth-averaged computational model for simulating flow, sediment, pollutant transport, water quality, as well as chemical spills in natural water bodies. It was developed using the finite element method, and the structured conformal mesh was adopted in the model. The chemical spill module was decoupled with the CCHE2D free surface hydrodynamic model (Jia et al 2002). The unsteady flow equations were solved using the time marching scheme. A velocity correction method was applied to solve the dynamic pressure and enforce mass conservation. Provisional velocities were solved first without the pressure term, and the final solution of the velocity was obtained by correcting the provisional velocities with the pressure solution (Jia et al 2002). The system of the algebraic equations was solved using the Strongly Implicit Procedure method (SIP). Flow fields, including water elevation, horizontal and vertical velocity components, and eddy viscosity parameters were computed by CCHE2D hydrodynamic model and set as inputs for chemical simulations. The concentration distributions of chemical in the water column and sediment layers were simulated by solving mass transport Eq. (1) and (2) numerically.

Model Verification

To verify the chemical spill module, the numerical model was tested against an analytical solution for predicting concentrations of a non-conservative substance in a one-dimensional river flow with constant depth and velocity. At the middle of the river, there is a point source with constant concentration (Fig 1).

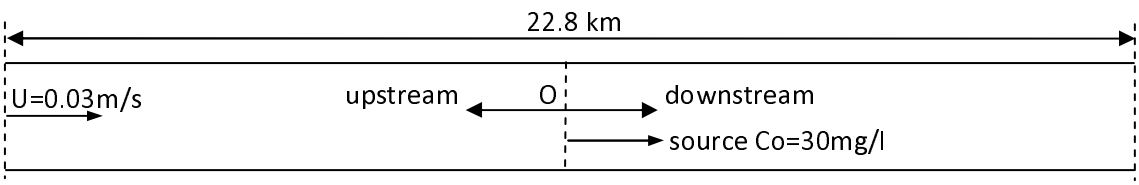

Fig. 1. Test river for model verification

Under this condition, the concentration of the substance throughout the river can be expressed as:

$$U\frac{\partial C}{\partial x} = D_x\frac{\partial^2 C}{\partial x^2} - KC \tag{3}$$

where U is the velocity; C is the substance concentration; D_x is the dispersion coefficient; x is the displacement from O point; and K is the decay rate. An analytical solution given by Thomann and Mueller (1988) is:

$$C(x) = C_0 \exp\left[\left(\frac{u+\sqrt{u^2+4KD_x}}{2D_x}\right)x\right] \quad \text{(upstream, } x \le 0\text{)} \tag{4}$$

$$C(x) = C_0 \exp\left[\left(\frac{u-\sqrt{u^2+4KD_x}}{2D_x}\right)x\right] \quad \text{(downstream, } x > 0\text{)} \tag{5}$$

where C_0 is the concentration at O point. In this test case, it was assumed, the water depth = 10 m and D_x=30 m^2/s, the values of K = 0, 1.0/day and 2.0/day, respectively, Fig. 2 shows the concentration distributions obtained by the numerical model and analytical solution. The maximum error between the numerical result and analytical solution is less than 2%.

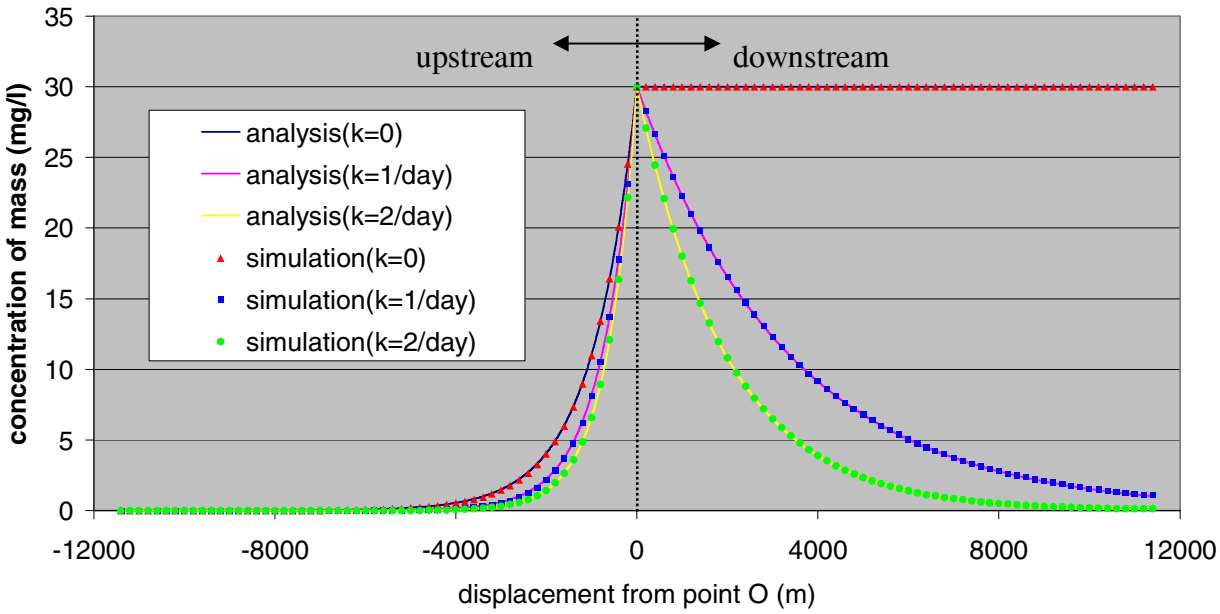

Fig. 2 The concentration distribution along the river

DEVELOPMENT OF CHEMICAL PROPERTY DATABASE

To provide necessary parameters for CCHE2D chemical module, a chemical property database, CHEMBASE, was developed using Microsoft Access 2007. The major objects in this database include table, query, report, form and macro.

Table

A table is used to store data in MS Access 2007. In the CHEMBASE database, all the parameters of physical-chemical properties were included in a table. For each chemical, the table contained more than 20 parameters for computing the processes of volatilization, photolysis, hydrolysis, adsorption, desorption, degradation, as well as the interaction between sediment bed and water column.

The parameters of physical-chemical properties in this table were collected from a few sources, including ChemFate (SRC 2008), and some other references (Mackay et al., 2006, Texas Register 2007). The database system allowed users to add new chemicals in the table and modify some parameters of physical-chemical properties for their specific needs.

Some parameters, such as Koc (organic-carbon partition coefficient), Degradation rate in water, and Degradation rate in soil, range widely. The minimum, maximum, and mean values were provided, and the mean values were set as defaults.

Query

A query is used to filter and retrieve data from the table. In order to provide required parameters of a chemical for numerical simulation, the database should allow the user to have the following operations:

(1) Identify a chemical based on the chemical name, CAS number, or chemical formula;
(2) Search the needed chemical parameters contained in the table.

Those operations can be accomplished using a parameter query. In order to select a chemical based on the Chemical name, CAS number or Chemical formula, the “Query by Form” technology was used to build a few criteria of the parameter query. The criteria of the parameter query were set as the name of combo boxes displayed on a form shown in Fig.3. For the current chemical spill module, the following physical-chemical property parameters are required:

(1) Degradation rate in water (mean)
(2) Degradation rate in soil (mean)
(3) Koc, organic-carbon partition coefficient (mean)
(4) Molecular weight
(5) Henry's constant

Report

A report is an object designed for summarizing the selected data. The recorded source of the report was the query. After choosing a chemical, the physical-chemical property parameters were displayed in the report.

Form (User Interface)

Form is an object designed primarily for data input or display or for a control of application execution. In this database, a form was built as a user interface, and it can be used to select a chemical. It can also be used to activate a few command buttons to show the report of physical-chemical properties, export data for CCHE2D model, and exit the database system. In this form, a button "Edit Parameters" was provided to active processes for reviewing and adjusting some parameters based on different experimental conditions (Fig.3).

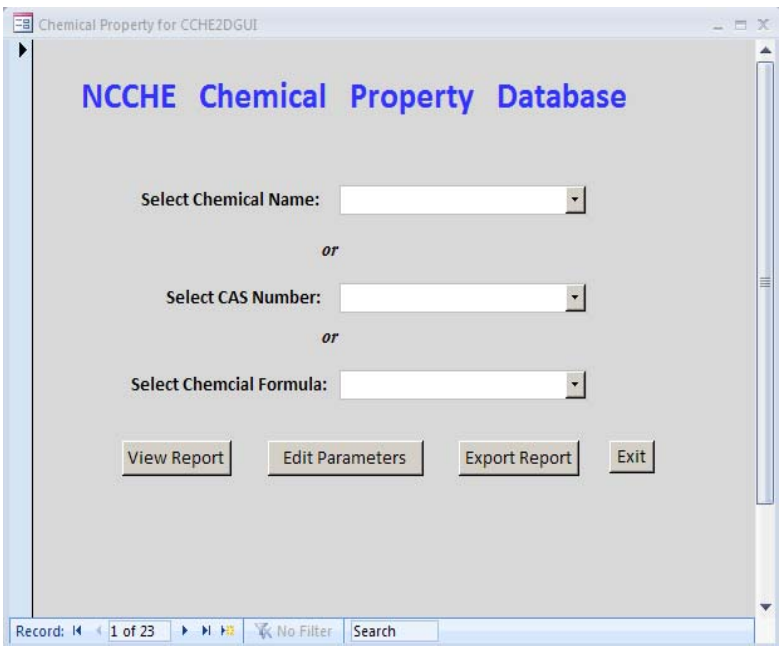

Fig.3 The form of CHEMBASE database

Adjust Chemical Parameters for more Reliable Results

Some parameters, such as Koc (organic-carbon partition coefficient), Degradation rates in water and soil range widely due to different conditions. In this database, the measured values and the corresponding experimental conditions were provided for users to review. Then the user may select a reasonable value based on the particular experimental conditions. In this developed database, the experimental information and related parameters were obtained from a public source: ChemFate (SRC 2008).

After load the data from ChemFate web (SRC 2008) based on CAS number, Formula or Chemical Name, a software "ChemFate Analyzer.exe", developed by NCCHE was applied to process those data. Two Microsoft access tables were generated to save the parameters and related experimental conditions for Koc and Degradation rates in soil and water.

In this database, a program was developed using the C# language to operate the "Edit Parameters" button for reviewing the measured values as well as experimental conditions and updating the output parameters in the report. This program provides a useful tool for the user to select reasonable values for his application based on experimental conditions.

LINK CHEMBASE DATABASE TO CCHE2D MODEL

After the values of chemical properties are finalized, the report can be exported as a ".txt" file by clicking "Export Report" button (Fig. 4). The CCHE2D model can load this text file automatically for model simulation (Fig. 5).

The chemical partition coefficient K_p in the model is calculated by

$$K_p = K_{oc} f_{oc} \tag{6}$$

in which K_p = partition coefficient; K_{oc} = organic/carbon partition coefficient, which can be obtained from the developed database; f_{oc}= organic carbon fraction of the solid and it is given by the CCHE2D model.

After loading all the data, the CCHE2D model can be applied to simulate the trajectory and fate of chemical spill in a water body.

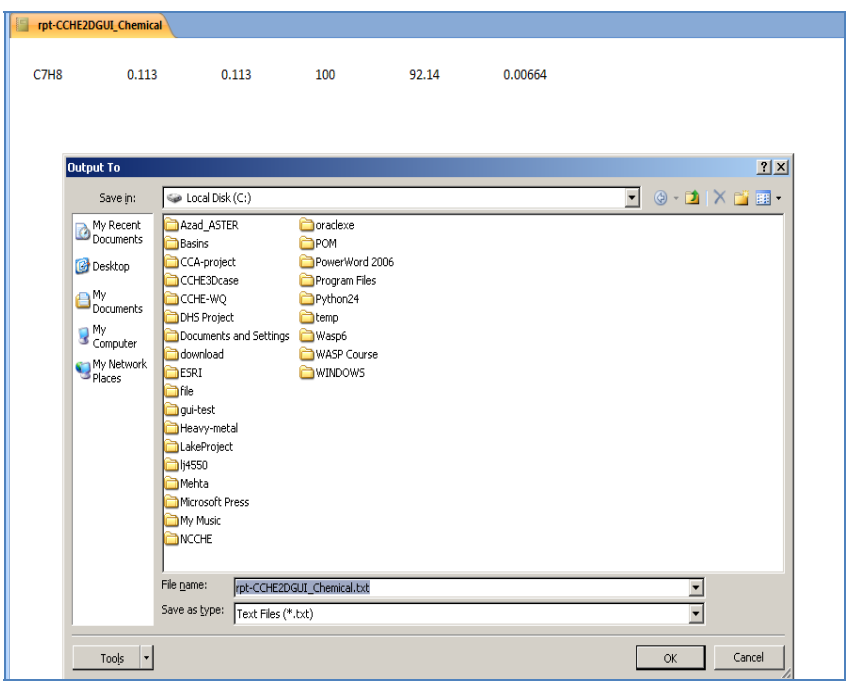

Fig.4 Export of chemical property parameters as a text file

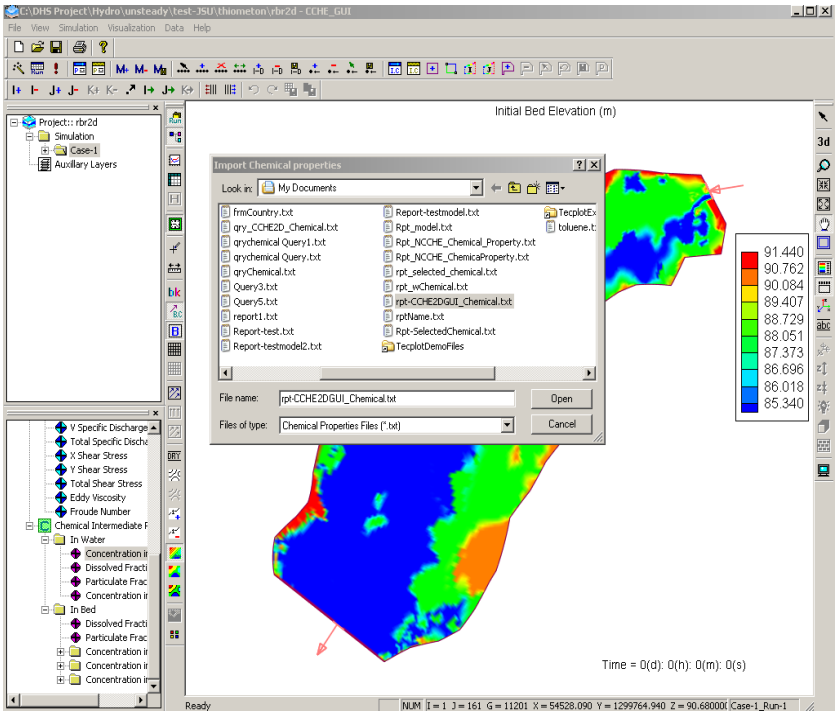

Fig.5 Import of the chemical property .txt file to CCHE2D Model

APPLICATION OF CHEMBASE DATABASE AND CCHE2D MODEL TO HYPOTHETICAL CHEMICAL SPILL CASES

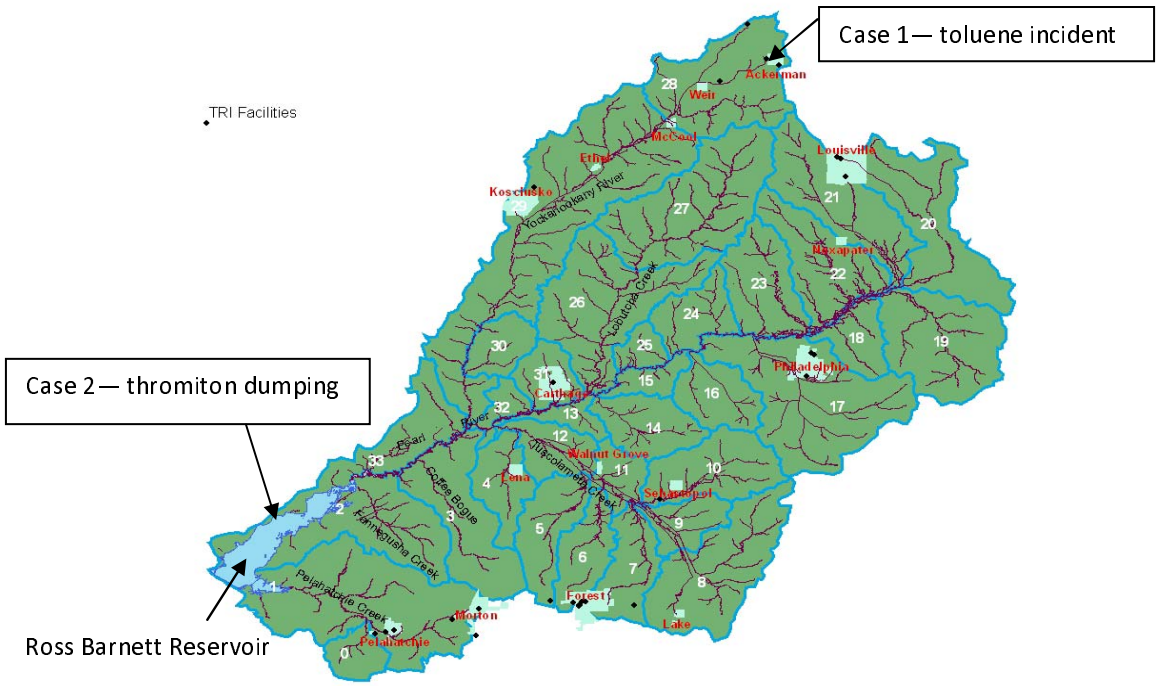
In order to test the capabilities of developed CHEMBASE database and CCHE2D model for simulating chemical spills in natural waters, two hypothetical chemical spill case occurred at Ross Barnett Reservoir in Mississippi were studied. This reservoir serves as the primary drinking water supply for the city of Jackson, and it also provides recreational opportunities in the forms of campgrounds, parks, boat launches, multi-purpose trails, etc.

It was assumed that 30 tons of toluene, one of toxic chemicals, was accidentally discharged into a river from a plant located 65 miles upstream of the reservoir, the chemical then flowed through a stream into the reservoir. When transporting in the river, about 1/3 of the toluene was lost due to evaporation, dissolution, decay, etc. It took 12 hours for the remaining 20 tons of toluene to completely discharge into the reservoir. In another case, it was assumed that 2000 kg of the toxic pesticide, thiometon, was dumped into the reservoir due to a traffic accident on a highway near the west shoreline. It took 12 hours for all the thiometon to release into water. Fig.6 shows the location of the two hypothetical incidents.

Flow Simulation

Wind stress and upstream discharge are the most important driving forces for flow currents in the reservoir. The period from Jan 1 to 31, 2005, was chosen for

model simulation. After obtained flow discharges at inlet, water surface levels at outlet, as well as wind speeds and directions during this period, CCHE2D model can be applied to simulate the flow fields in the reservoir. Fig. 7a and Fig. 7b show the velocity vectors at the first day and second day, respectively. The flow results were used for simulating the concentration of chemicals in the two hypothetical cases.



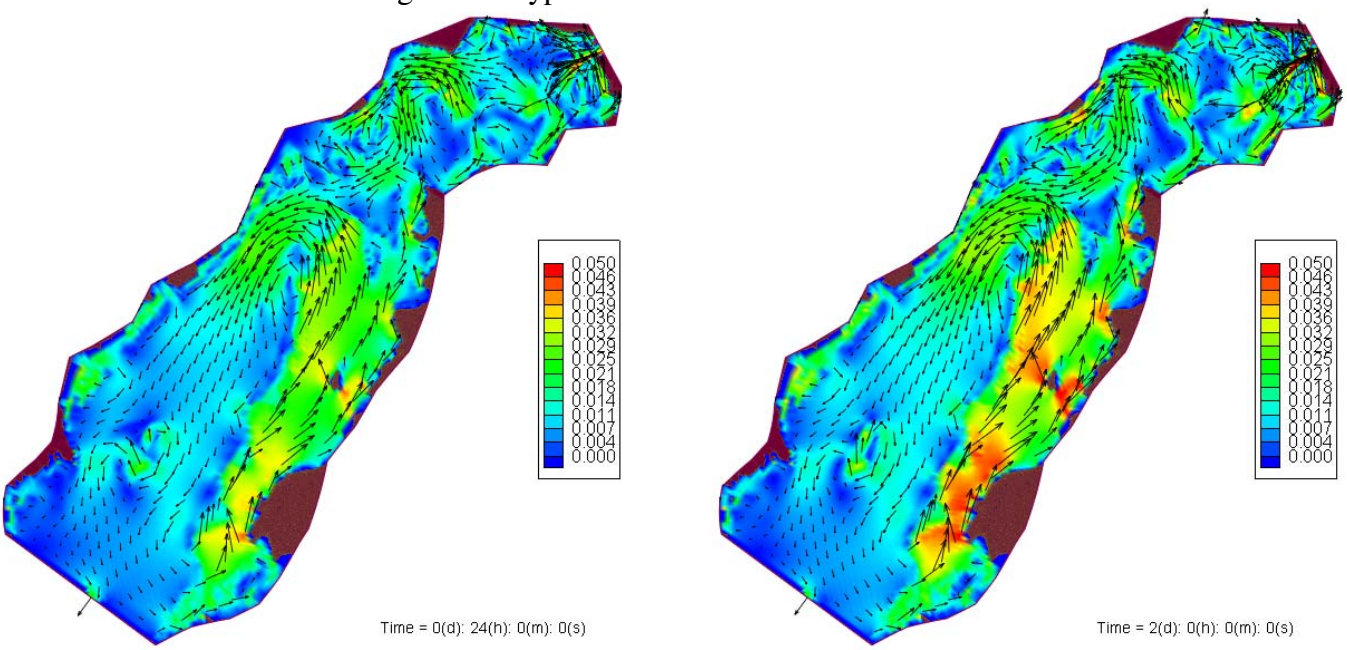


Fig.6 Two hypothetical chemical incident cases

a. At the first day b. At the second day

Fig.7 Numerical results of velocity vectors

Numerical Modeling of Two Hypothetical Chemical Spills Cases

Using CHEMBASE database, the physical-chemical parameters of toxic chemicals toluene and thiometon required by the model can be obtained (Fig. 4). These parameters can be loaded to CCHE2D model automatically, and used for model simulation (Figs. 5).

After all the parameters were set up correctly, CCHE2D model was used to simulate the fate and trajectory of chemical spills. Fig.8 shows the simulated concentration distributions of toluene at first day, third day and fourth day after toluene discharged into reservoir, respectively. It can be observed that during the first four days, the upstream of the reservoir is the major polluted area, and the concentration is greater than the 1ppm of the Maximum Contaminant Level (MCL) suggested by EPA. After four days, the concentration in the whole reservoir is less than the MCL. Fig. 9 shows the concentration distribution of thiometon at the 1st day, 10th day and 25th day after thiometon releasing into the reservoir. Without operating any decontamination processes, the concentration of thiometon would be greater than the 3 ppb of MCL for about 25 days. This chemical incident may cause huge impacts on the aquatic environment in the reservoir.

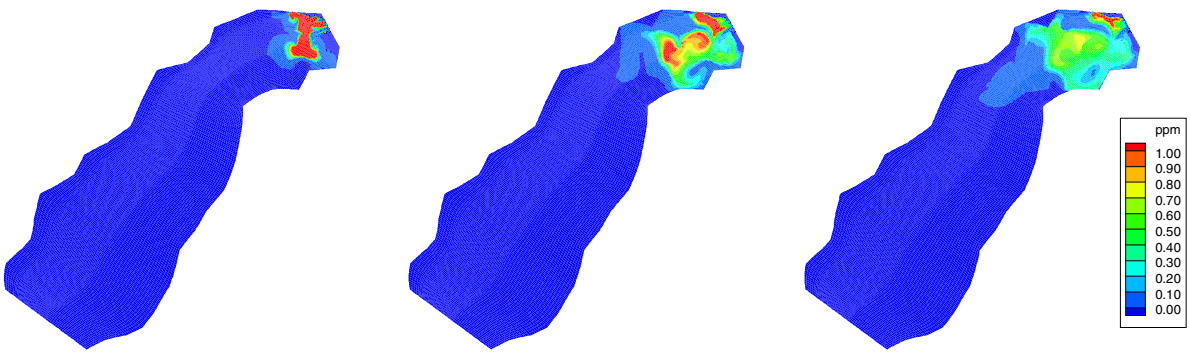

Fig. 8 Concentration distributions of toluene in the reservoir (ppm)

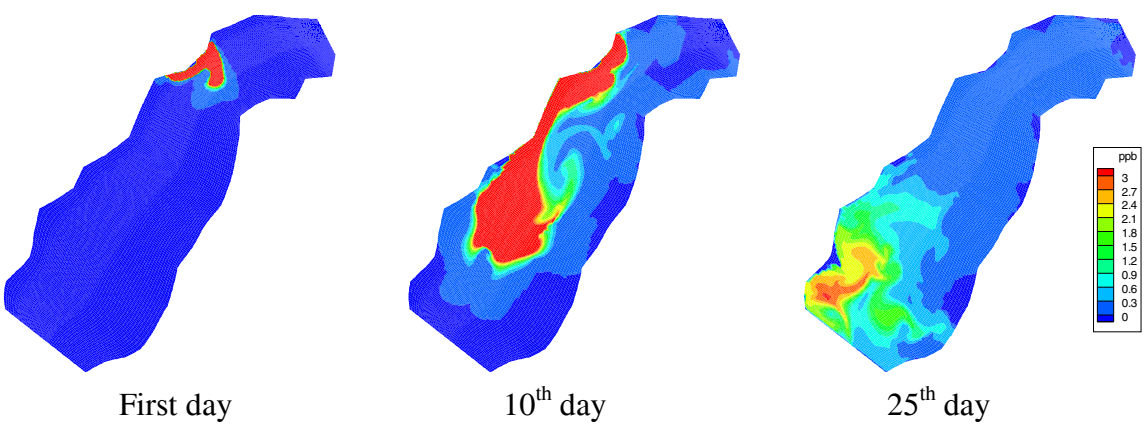

Fig. 9 Concentration distributions of thiometon in the reservoir (ppb)

These simulation results provide useful information to estimate the polluted area after a chemical incident occurs.

CONCLUSIONS

A depth-integrated computational model, CCHE2D, has been developed for predicting fate and transport processes of chemical contaminants in surface waters. A case with non-conservative substance in a one-dimensional river flow was used for model verification. To simulate the fates and transport processes of chemicals, some parameters of the chemical property are needed. A database, CHEMBASE, was developed using Microsoft Access 2007 for providing those parameters. In this database, the main table contained a number of physical-chemical properties for chemicals. This table can be expanded by simply adding more chemicals and their physical-chemical properties. The search of the chemical could be performed based on its name, CAS number, or chemical formula. A report was built to display the physical-chemical properties of the selected chemical. The user could review and adjust the parameters based on different experimental conditions. The parameters contained in the final report can be exported as a text file, and easily loaded by CCHE2D model for simulating the fate and trajectory of chemical spills. Two hypothetical chemical spill cases were simulated to demonstrate the capabilities of CCHE2D model and CHEMBASE database. This system provides useful tool for developing and implementing an emergency response plan, and it is also valuable for environmental impact assessment.

ABSTRACT

CCHE1D is a one-dimensional channel network model developed at the National Center for Computational Hydroscience and Engineering, the University of Mississippi. Recently, the CCHE1D has been enhanced to simulate water quality and aquatic ecosystems in streams. The numerical model computes stream water temperature by considering heat fluxes across the water surface. The aquatic ecosystem model considers a simple food-chain model of phytoplankton, zooplankton and fish. It simulates the changing concentrations of biotic organisms and couples with water quality parameters by considering processes of photosynthesis, respiration, mortality, decomposition and nutrient cycling. The integrated CCHE1D water quality and ecosystem model has been tested in the Tualatin River, Oregon. It well predicts the water temperature, phytoplankton biomass, zooplankton biomass and other water quality parameters along the simulation domain.

INTRODUCTION

During the past decades, many streams and rivers faced pollution problems that were directly relevant to human and environmental health. When a waterway is contaminated by chemical substances, aquatic organisms such as vertebrates and invertebrates are directly affected. Moreover, these aquatic organisms can be a source of human exposure to contaminants via food chain. Due to advanced computer technology and increased public health and environmental awareness, mathematical models have currently become an important tool in the study of complex systems. A variety of water quality and aquatic ecosystem software, such as WASP7 (Di Toro et al., 1983) and AQUATOX (Park and Clough, 2004), have been developed by various organizations with specific objectives. The newly integrated water quality and aquatic ecosystem model in the CCHE1D is focused on the simulation of water quality parameters and biotic and abiotic components in freshwater riverine ecosystems.

Because of the one-dimensional simulation, the model has a great advantage in computational speed and is suitable for long-term simulation.

CCHE1D WATER QUALITY AND AQUATIC ECOSYSTEM MODEL

The current CCHE1D version released in 2002 simulates unsteady open-channel flow by solving the St. Venant shallow water equations using the Preissmann implicit scheme, and computes non-uniform sediment transport using a non-equilibrium approach (Wu and Vieira, 2002). Recently, CCHE1D has been enhanced to simulate water quality and aquatic ecosystems in streams. The water temperature model describes heat transfer in the water column based on the first law of thermodynamics. The model computes the stream water temperature taking into account the combination of heat fluxes— short-wave solar radiation, long-wave radiation, latent heat flux and sensible heat flux (Wu, 2008). The aquatic ecosystem model considers a simple food-chain model of phytoplankton, zooplankton and fish; it simulates the changing concentrations of biotic organisms and water quality parameters including dissolved oxygen (DO), carbonaceous biological oxygen demand (CBOD), nitrogen (ammonia, nitrate, and organic nitrogen) and phosphorus (phosphate and organic phosphorus) by considering processes of photosynthesis, respiration, mortality, decomposition and nutrient cycling. The conceptual framework of the CCHE1D aquatic ecosystem model is illustrated in Figure 1.

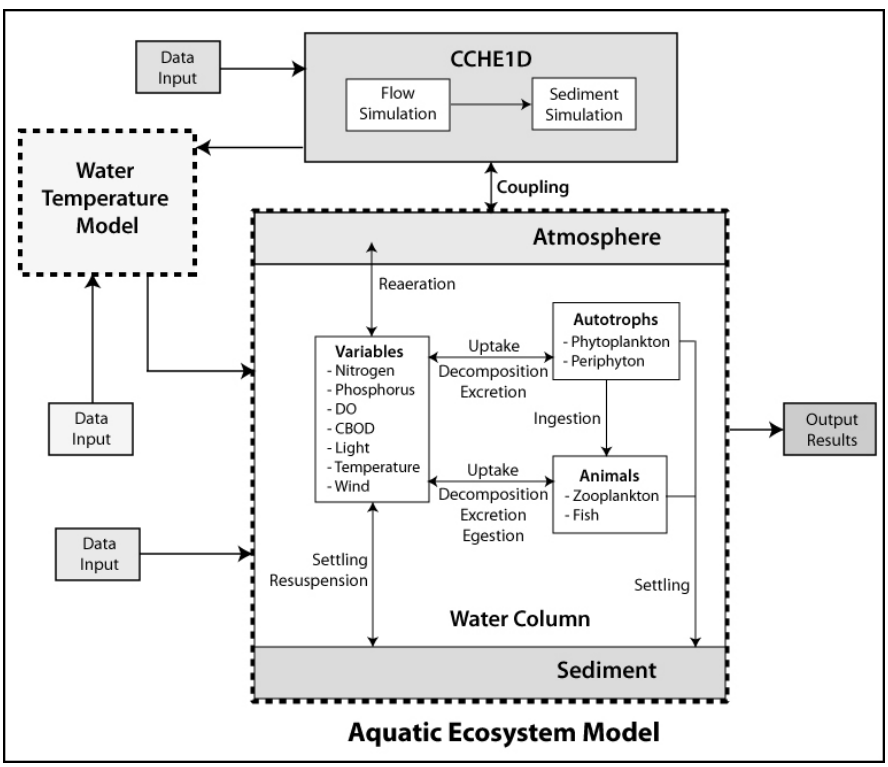

Figure 1. Conceptual framework of the aquatic ecosystem model.

The model simulates fate and transport of chemicals through drainage networks under steady or unsteady flow conditions. The transport equation is

described by the advection-dispersion equation based on the principle of conservation of mass and Fick's law:

$$\frac{\partial(AC)}{\partial t}+\frac{\partial(QC)}{\partial x}=\frac{\partial}{\partial x}\left(E_L A\frac{\partial C}{\partial x}\right)+S_c A \tag{1}$$

where x and t are the spatial and temporal axes; A is the cross-sectional flow area; Q is the flow discharge; C is the concentration of a constituent; E_L is the longitudinal effective diffusivity; and S_c is a net source term for each constituent due to biochemical and physical changes and/or due to lateral input to the channel by runoff. The rate of change for each source term is described as follows.

Phytoplankton. Source term for phytoplankton rate (S_a) is calculated by

$$S_a=\left(k_{ag}-k_{ar}-k_{ae}-k_{am}\right)C_a-k_{zg}\frac{C_a-\mu_z}{h_{zg}+C_a}C_z-\frac{\omega_a}{h}C_a \tag{2}$$

where C_a and C_z are biomass concentrations of phytoplankton and zooplankton, respectively; k_{ag} is the photosynthetic rate given in Eq. (3); k_{ar}, k_{ae}, k_{am} and k_{zg} are the maximum rates of phytoplankton respiration, excretion, non-predatory mortality and zooplankton grazing, respectively; μ_z and h_{zg} are the threshold and half-saturation phytoplankton concentrations for zooplankton grazing, respectively; h is the water depth; and ω_a is the settling velocity of phytoplankton.

The photosynthetic rate is calculated by

$$k_{ag}=k_{ag,\max}\frac{1}{\gamma h}\ln\left(\frac{h_L+I_0}{h_L+I_0e^{-\gamma h}}\right)\min\left(\frac{C_{PO4}}{h_P+C_{PO4}},\frac{C_{NH3}+C_{NO3}}{h_N+C_{NH3}+C_{NO3}}\right) \tag{3}$$

where $k_{ag,\max}$ is the maximum photosynthetic rate; γ is the total light extinction; I_0 is the average light intensity; h_L is the half-saturation light intensity for photosynthesis; C_{PO4}, C_{NH3} and C_{NO3} are phosphate, ammonia and nitrate nitrogen concentrations, respectively; and h_P and h_N are the half-saturation phosphorus and nitrogen concentrations for photosynthesis, respectively.

Zooplankton. The net source term for zooplankton rate (S_z) is described by

$$S_z=\left(e_{zg}k_{zg}\frac{C_a-\mu_z}{h_{zg}+C_a}-k_{zr}-k_{ze}-k_{zm}\right)C_z \tag{4}$$

where k_{zr}, k_{ze} and k_{zm} are the maximum rates of zooplankton respiration, excretion and mortality, respectively; and e_{zg} is the assimilation efficiency.

Dissolved Oxygen (DO). DO is affected by several factors such as atmospheric reaeration, photosynthesis, respiration, decomposition and nitrification. The DO source term (S_{DO}) is described by

$$S_{DO} = k_{re}\left(C'_{DO} - C_{DO}\right) + \left(\frac{32}{12} + \frac{48}{14}\alpha_{NC}\left(1 - p_{NH3}\right)\right)k_{ag}C_a - \frac{32}{12}\left(k_{ar}C_a + k_{zr}C_z\right) - k_{CBOD}\left(\frac{C_{DO}}{h_{CBOD} + C_{DO}}\right)C_{CBOD} - \frac{64}{14}k_{NH3}\left(\frac{C_{DO}}{h_{NH3} + C_{DO}}\right)C_{NH3} - \frac{s_{SOD}}{h} \quad (5)$$

where C_{DO} is the DO concentration; C'_{DO} is the saturation DO concentration; k_{re} is the reaeration rate; k_{CBOD} is the rate of deoxygenation; h_{CBOD} is the half-saturation DO concentration for deoxygenation; and s_{SOD} is the sediment oxygen demand.

Carbonaceous biological oxygen demand (CBOD). CBOD represents the oxygen demand by bacteria in the oxidation of organic material. The change rate in CBOD concentration (S_{CBOD}) can be determined by

$$S_{CBOD} = \frac{32}{12}\left(k_{am} + k_{ae}\right)C_a + \frac{32}{12}\left(k_{zm} + k_{ze}\right)C_z - \frac{5}{4}\frac{32}{14}k_{NO3}\left(\frac{h_{NO3}}{h_{NO3} + C_{DO}}\right)C_{NO3} + \frac{32}{12}\left(1 - e_{zg}\right)k_{zg}\frac{C_a - \mu_z}{h_{zg} + C_a}C_z - k_{CBOD}\left(\frac{C_{DO}}{h_{CBOD} + C_{DO}}\right)C_{CBOD} - \frac{\omega_{CBOD}}{h}f_{PCBOD}C_{CBOD} \quad (6)$$

where C_{CBOD} is the CBOD concentration; f_{PCBOD} is the fraction of particulate CBOD in the total CBOD; and ω_{CBOD} is the setting velocity of CBOD.

Nitrogen cycle. Three nitrogen compartments— ammonia (NH_3), nitrate (NO_3) and organic nitrogen (ON), are modeled in this study. The source terms for organic nitrogen (S_{ON}), ammonia (S_{NH3}) and nitrate (S_{NO3}) are expressed as

$$S_{ON} = f_{ON}\alpha_{NC}\left(k_{am}C_a + k_{zm}C_z\right) - k_{ON}\left(\frac{C_a}{h_{ON} + C_a}\right)C_{ON} - \frac{\omega_{ON}}{h}f_{PON}C_{ON} - \frac{s_{ON}}{h} \quad (7)$$

$$S_{NH3} = \left(1 - f_{ON}\right)\alpha_{NC}\left(k_{am}C_a + k_{zm}C_z\right) - k_{ag}p_{NH3}\alpha_{NC}C_a + \alpha_{NC}k_{ze}C_z + k_{ON}\left(\frac{C_a}{h_{ON} + C_a}\right)C_{ON} - k_{NH3}\left(\frac{C_{DO}}{h_{NH3} + C_{DO}}\right)C_{NH3} - \frac{s_{NH3}}{h} \quad (8)$$

$$S_{NO3} = k_{NH3}\left(\frac{C_{DO}}{h_{NH3} + C_{DO}}\right)C_{NH3} - k_{NO3}\left(\frac{C_{DO}}{h_{NO3} + C_{DO}}\right)C_{NO3} - k_{ag}\alpha_{NC}\left(1 - p_{NH3}\right)C_a - \frac{s_{NO3}}{h} \quad (9)$$

where C_{ON}, C_{NH3} and C_{NO3} are the concentrations of ON, ammonia and nitrate, respectively; α_{NC} is the nitrogen to carbon ratio; k_{ON}, k_{NH3} and k_{NO3} are the rates of mineralization, nitrification and denitrification, respectively; f_{ON} is the fraction of dead organic material to ON pool; f_{PON} is the fraction of particulate ON in total ON; h_{ON}, h_{NH3} and h_{NO3} are the half-saturation for mineralization, nitrification and denitrification, respectively; ω_{ON} is the settling velocity of ON; s_{ON}, s_{NH3} and s_{NO3}

are ON, ammonia and nitrate fluxes to the sediment bed, respectively; and p_{NH3} is the ammonia preference factor and can be estimated by

$$p_{NH3} = \frac{C_{NH3}C_{NO3}}{(h_N + C_{NH3})(h_N + C_{NO3})} + \frac{C_{NH3}h_N}{(C_{NH3} + C_{NO3})(h_N + C_{NO3})} \quad (10)$$

where h_N is the half-saturation constant for nitrogen uptake.

Phosphorus cycle. Phosphorus is divided into two groups: organic phosphorus (OP) and inorganic phosphorus (orthophosphate, PO_4). The source terms for organic phosphorus (S_{OP}) and phosphate (S_{PO4}) are expressed as

$$S_{OP} = f_{OP}\alpha_{PC}(k_{am}C_a + k_{zm}C_z) - k_{OP}\left(\frac{C_a}{h_{OP} + C_a}\right)C_{OP} - \frac{\omega_{OP}}{h}f_{POP}C_{OP} - \frac{s_{OP}}{h} \quad (11)$$

$$S_{PO4} = (1 - f_{OP})\alpha_{PC}(k_{am}C_a + k_{zm}C_z) - \alpha_{PC}k_{ag}C_a + \alpha_{PC}k_{ze}C_z + k_{OP}\left(\frac{C_a}{h_{OP} + C_a}\right)C_{OP} - \frac{s_{PO4}}{h} \quad (12)$$

where C_{OP} and C_{PO4} are the concentrations of OP and phosphate, respectively; α_{PC} is the phosphorus to carbon ratio; k_{OP} is the mineralization rate; h_{OP} is the half-saturation for mineralization; f_{OP} is the fraction of dead organic matters recycled to OP pool; f_{POP} is the fraction of particulate OP in total OP; ω_{OP} is the setting velocity of OP; and s_{OP} and s_{PO4} are the OP and phosphate fluxes to the sediment bed, respectively.

CASE STUDY

The Tualatin River is located on the west side of the Portland metropolitan area in northwestern Oregon. The river originates in the Coast Range and flows generally eastward before joining the Willamette River near West Linn. During summer, the river encountered water quality problems such as low dissolved oxygen level, high pH level and high phytoplankton concentrations.

The study domain for the main Tualatin River is approximately 50 km, from River Mile (RM)38.4 (Rood Bridge at Hillsboro) to RM5.5 (Stafford Road near Lake Oswego), shown as the CCHE1D interface (see Figure 2). The average bed slope is approximately 0.025%, and the average river width is 15 m. Flow discharge results mainly from precipitation. Within the study reach, the Tualatin River has two major tributaries (Rock Creek and Fanno Creek) and several minor creeks. The Rock Creek has both agricultural and urban influences while the Fanno Creek flows almost exclusively through an urban area. In addition to tributaries, two wastewater treatment plants (WWTPs–Rock Creek WWTP at RM38.1 and Durham WWTP at RM9.3) discharge treated effluent into the river. At several locations in the study domain, water is withdrawn for public water supply, irrigation, and power generation.

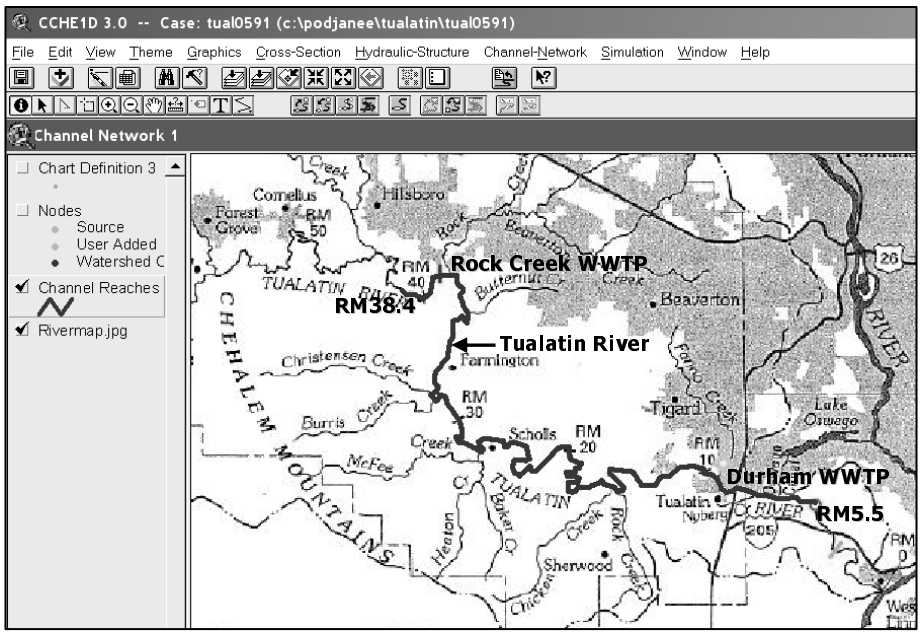

Figure 2. Simulation domain for the Tualatin River study.

The simulation period starts from May 01, 1991 to October 31, 1991. The simulation domain is represented by 132 cross-sections. Each cross-section is divided into 11 panels. Discharge hydrographs for the upstream boundary and the two major tributaries are obtained from the U.S. Geological Survey (USGS) site (http://waterdata.usgs.gov/or/nwis/). Irrigation withdrawal is documented by Rounds et al. (1999).

The unsteady flow from May 01 through Oct. 31 is simulated and compared to the field measurement (see Figure 3). The simulation result is in a good agreement in phase with the measurement, but the magnitude is slightly over-estimated. The differences between the simulated (RM5.5) and measured (RM1.8) rates are due to water's travel time and possible point and nonpoint discharges between two locations.

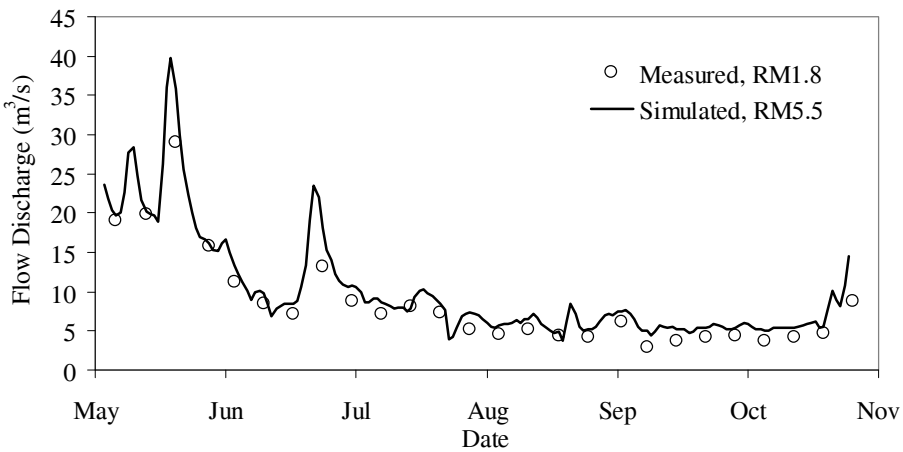

Figure 3. Comparison of measured and simulated flow discharges at the downstream of the Tualatin River.

Meteorological data at the Portland Airport weather station is used as input in the water temperature model. The transfer of intraregional data may contribute to some prediction errors, which, however, are assumed to be negligible in this study. Due to 1-D heat transport equation, the simulated water temperature is cross-sectionally averaged. The field data obtained from Doyle and Caldwell (1996) was mostly collected at the depth of 3 ft (approximately 0.9 m) below the water surface. Although both locations are possibly not at the exact depth, the phase and magnitude of both data is comparable (see Figure 4).

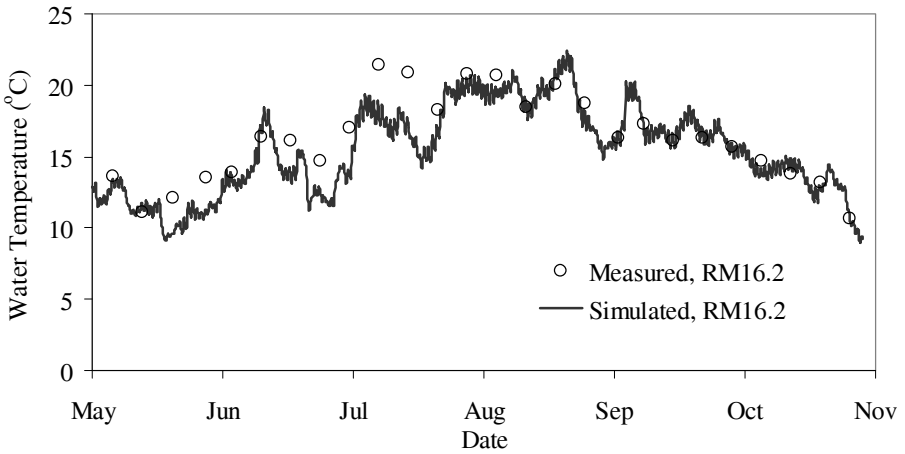

Figure 4. Comparison of measured and simulated water temperatures.

The phytoplankton and zooplankton concentrations and some water quality parameters are obtained from field study which was surveyed and documented by Doyle and Caldwell (1999). Most chemical and biological reaction rates used in this study are obtained from Rounds et al. (1999) and other literatures. The simulated phytoplankton biomass and the measurement data for a selected cross-section (see Figure 5) and the averaged phytoplankton concentrations over the simulation period (see Figure 6) are compared. The simulation results and the field data are in a good agreement in the upstream locations.

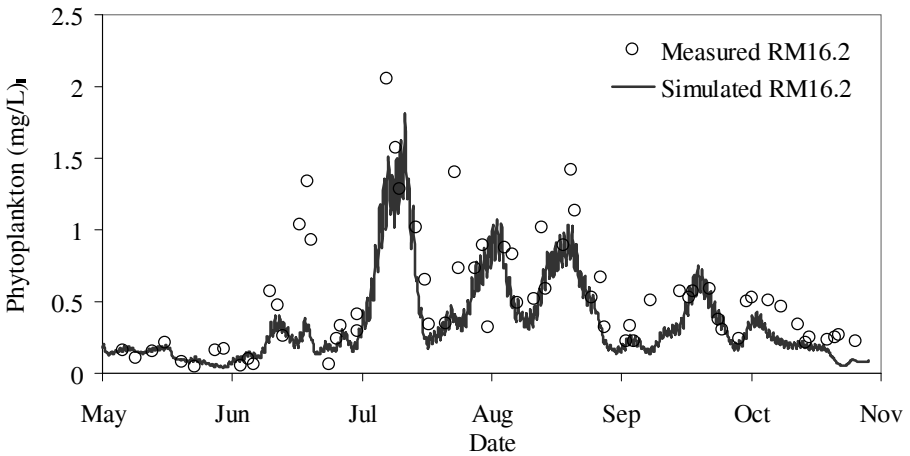

Figure 5. Simulated and measured phytoplankton biomasses at RM16.2.

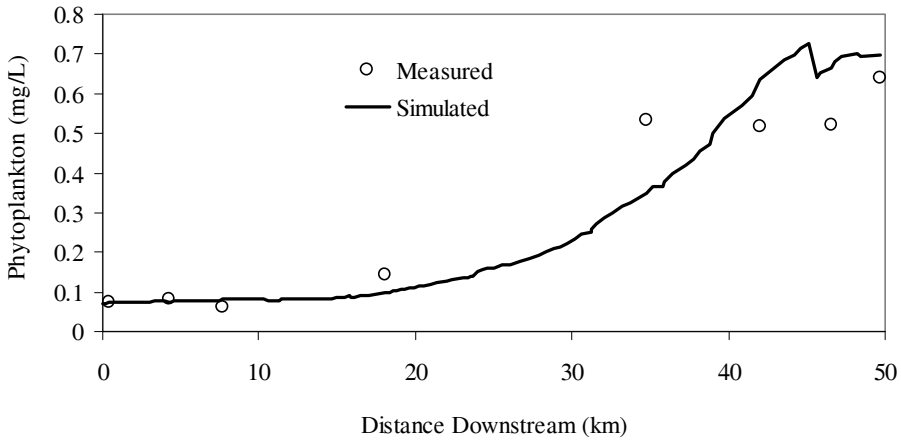

Figure 6. Comparison of the mean measured and simulated phytoplankton biomasses during May-October, 1991.

The comparison of simulated zooplankton concentration and measured data surveyed by Doyle and Caldwell (1996) is presented in Figure 7. The zooplankton abundances from the field data have been converted to the biomass concentrations by length-weight regression relations. These relationships have been taken from various literatures for calculating biomass of each zooplankton species at the specific life stage. Due to the limited zooplankton biomass at the upstream cross-section and the initial concentration of zooplankton biomass for some locations, the performance of the zooplankton dynamics model is rather undesirable. The simulated data is in the acceptable ranges for several times during the 5-month simulation period. The model will be further tested by studying its sensitivity.

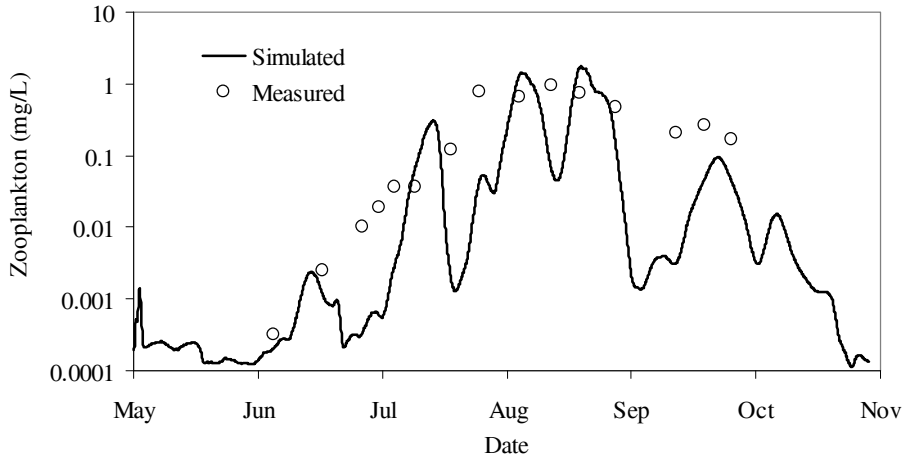

Figure 7. Simulated and measured zooplankton biomasses at RM5.5.

The simulated and measured ammonia and nitrate at the downstream cross-section (RM5.5) are compared in Figure 8. The model can well capture seasonal variations of nitrogen concentrations during the simulation period.

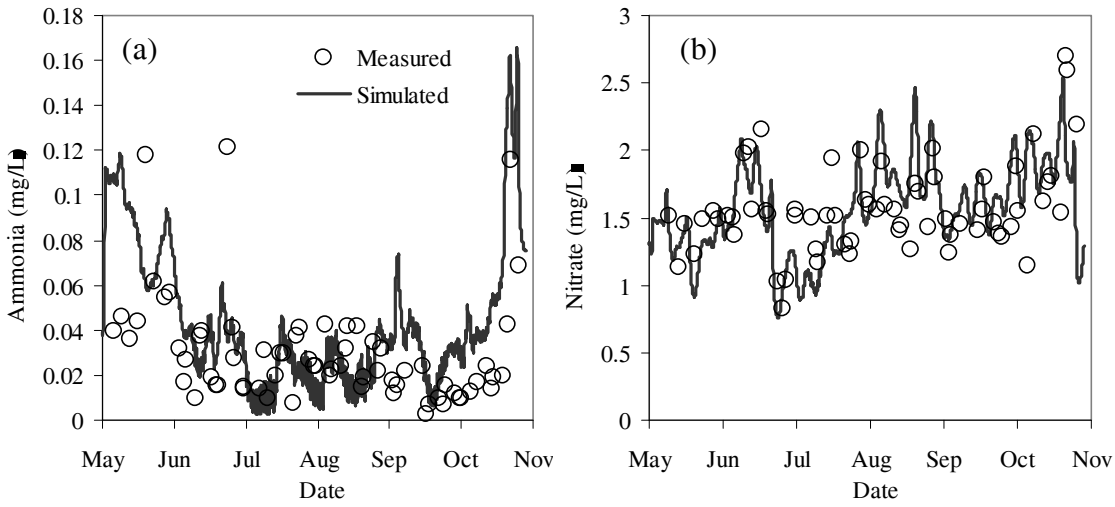

Figure 8. Comparison of the measured and simulated (a) ammonia and (b) nitrate concentrations at downstream cross-section.

Simulated DO and phosphate concentrations compared to the mean measurement data averaged over the simulation period are shown in Figure 9. Among various sources of DO, the photosynthesis process seems to be the most significant influence on DO in the Tualatin River. The overall profile of DO simulation and the field data are in a good agreement (see Figure 9a). Figure 9b presents a sudden change of phosphate concentration due to the effluents from the Durham WWTP. The overall trend of simulated phosphate concentration in the Tualatin River is comparable to the measured concentration; however the simulated concentration is slightly higher than the field data in some reaches.

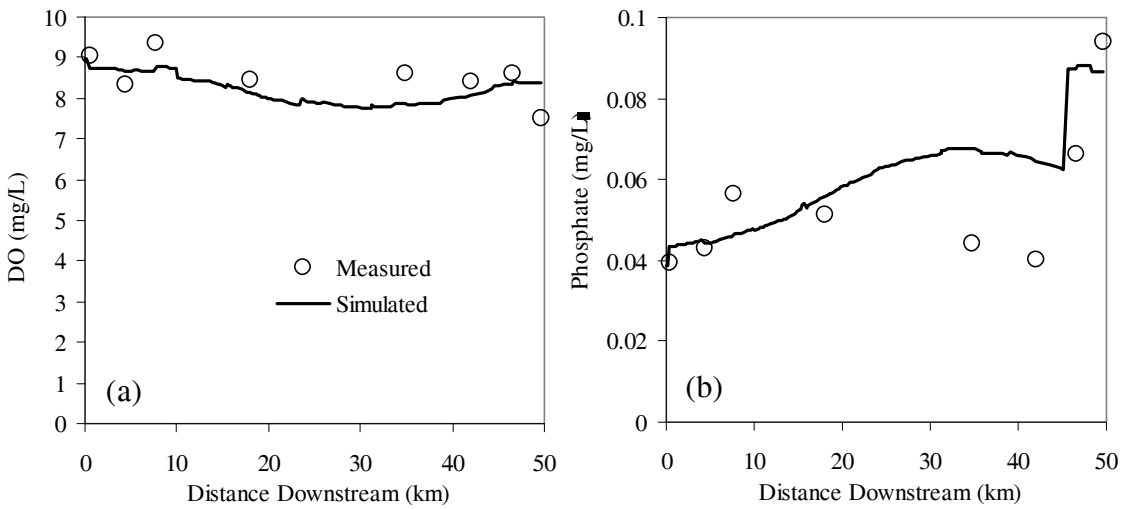

Figure 9. Comparison of the mean measured and simulated (a) DO and (b) phosphate concentrations along the Tualatin River during May-October, 1991.

CONCLUSION

The water temperature model and aquatic ecosystem model have been implemented in the CCHE1D package. The developed model is capable of simulating the heat transfer, transport and fate of chemicals, and concentrations of living organisms in channel networks under unsteady flow conditions. The model has been tested in computation of water temperature, water quality, and ecosystem components in the Tualatin River from May 01 until Oct. 31, 1991. Although the water temperatures simulated by the model are cross-sectionally averaged values and the field data are integrated samples measured at approximately 0.9 m below the water surface, both simulated and measured data are in a good agreement in both phase and magnitude. The model well predicts the time-series concentrations of the water quality parameters along the simulation domain. It has a good potential to simulate the concentration changes due to the lateral inputs from the wastewater treatment plants and the river's tributaries. The overall simulated biomass of phytoplankton is comparable to the measured data even though they are slightly different in some cross-sections. The model can roughly capture the trend of the zooplankton dynamics. The performance of the aquatic ecosystem model will be further validated in more cases.

ABSTRACT

Understanding the fish assemblage composition and assessing habitat preferences is an important requirement for ecological engineering practices for river restoration. This study collects fish and habitat data in the Tsengwen River Basin and Kaoping River Basin to provide criteria for fish habitat restoration projects. Fish samples were collected used prepositioned areal electrofishing devices designed for repeated grid sampling. The electrofishing data were used to identify habitat preferences and develop fish community-habitat models. A fuzzy rule-based model was used to characterize habitat units as deep pool, deep riffle, shallow riffle, and shallow pool based on measured depth and current velocity. The artificial neural networks then is used to model the connection between the autecology matrix analysis values and surveyed habitat unit compositions. The utility of the model was furthered using historical fisheries data in addition to the data collected as part of the study. The fish community-habitat model results provide a reference condition that can be used to guide stream restoration and ecological engineering decisions aimed at maintaining the natural ecological integrity and diversity of Taiwanese rivers.

INTRODUCTION

Management of water resources is highly developed in Taiwan due to the high density of people living on the island and the uneven spatial distribution of seasonal precipitation. Traditionally, water resources projects emphasized utility; flood defense projects including bank protection, erosion control, and dike construction have traditionally used concrete structures and designs with high safety factors to protect public safety and prevent economic losses from flooding. But recent projects have begun to incorporate additional principles of ecological engineering (Mitsch and Jorgensen, 2003). The Public Construction Commission began to promote ecological engineering approaches for river restoration in late 1990's. At present, environmentally-friendly and ecologically-appropriate engineering projects are being designed that shift the focus from river bank stabilization to instream structures such as riffles and pools (Kuo, 2006; Wu et al., 2006).

The physical habitat of rivers plays an important role in sustaining fish populations and maintaining biodiversity. The relationships between fish community and

physical habitat reveal repeatable ecological processes and are useful for river restoration and ecological engineering activities in rivers (Lamouroux and Cattaneo, 2006). But while it is known that many environmental factors are important to the presence and abundance of each fish species (Bovee, 1982; Jowett, 2002), the strong interrelation between factors makes it difficult to determine which of these factors play a dominant role in the maintenance of fish community structure (Lamouroux et al., 1999). The combinations of depth, velocity, and substrate have been used regularly as surrogates for an overall physical complexity and to describe the physical habitat for fish in rivers (Clifford et al., 2006). Physical habitat simulation models have been used for fish in river restoration projects worldwide (Bockelmann et al., 2004; Mouton et al., 2007). Physical habitat variables such as flow velocity, depth, and substrates can be related to the presence and abundance of a species to describe the species' preferred habitat. Habitat suitability curves based on these relationships can be used to determine the potential effects of hydraulic variation on fish species (Bovee, 1982). However, this type of analysis is limited in its application to multiple species; most physical habitat models are developed only for target or dominate species (Tomsic et al., 2007), and just a few of them are for fish communities rather than an individual species (Lamouroux and Souchon, 2002).

This paper aims to develop reference conditions based on historical fish community data for designing the instream structures in river restoration and ecological engineering projects. Fish data is collected using prepositioned areal electrofishing devices that allow identification of preferred habitat in an undisturbed environment; the physical variables of each habitat location are subsequently surveyed. Fish data then is analyzed using the fish autecology matrix to determine the environmental habitat requirements. Finally, an artificial neural network model is developed to connect the field work measurements to the fish autecology matrix analysis. This process provides a way that engineers can use the artificial neural networks models to analyze historical fish data and develop reference conditions for the design of ecologically-relevant instream structures.

Method

Sampling Design

This study focuses on an ecological analysis of fish habitat units mainly in mid- to upper-order streams. Fish were sampled using 1 meter-by-1 meter prepositioned areal electrofishing devices (PAEDs). Using this approach minimizes sampling method disturbance of fish position and provides a consistent method of sampling the same habitat over time (Schwartz and Herricks, 2004). The goal is to ensure all individuals are caught their most natural environment, and the physical environmental conditions of each location can be effectively measured and connected to habitat unit simulation models.

Artificial Neural Networks (ANNs)

Natural neural networks (the brains of animals) learn from experience and can perform difficult operations and recognize complex patterns, even if those patterns are noisy. The artificial neural networks research of recent years has attempted to mimic these networks to attain the advantages of their flexible and powerful calculating abilities. Although the concept of artificial neurons was first introduced by McCulloch and Pitts (1943), the major applications of ANNs have arisen only since the development of the back-propagation method of training by Rumelhart et al. (1986). ANN research following this development has resulted in successful solution of some complicated problems not easily solved by traditional modeling methods. The details of ANNs model operation are provided by Zurada (1992) and are not reported here.

Fish Autecology Matrix

The autecology matrix assembles information from scientific literature, reports, and field work observations into a database of habitats and life history requirements of fish species. The database provides easy access to ecological information in a form that can be readily and consistently used to support fish habitat and autecological analysis. In its present form, the autecology matrix divides factors into five sub-matrices: physical habitat, spawning requirements, ecological issues, water quality tolerance, and human values. Together, these five sub-matrixes include approximately 230 habitat and life history factors for each fish species. The matrix can be used in two primary ways: (1) to identify environmental requirements or ecological characteristics for a species by providing a summary of the expected habitat requirements or ecology and life history characteristics of the species, and (2) to identify a fish community that has specific environmental requirements or ecological characteristics by providing a list of species that share common habitat requirements (Suen and Herricks, 2006).

The autecology matrix can also be useful when emphasizing a limited set of factors that are important in providing both species and community information. In an analysis of the matrix for a community of organisms, it is possible to determine the proportion of species within the community with similar habitat preferences or life history requirements. Since these proportions are determined from a listing of species known to occur in a stream reach, it is possible to identify community habitat preferences or ecological characteristics based on a weight-of-evidence presented in matrix summaries (Suen and Herricks, 2006).

We have reviewed the literature and developed a Taiwan-specific freshwater fish autecology matrix that includes approximately 65 freshwater fish species and 230 environmental factors and ecological characteristics. Table 1 shows part of the matrix used in this study. In the matrix, a value of one (1) indicates that the environmental factor can be applied to the particular species, while a value of zero (0) indicates that the factor cannot be applied. These data for individual species can be used to analyze the environmental requirements of the fish community. For example, if the first five species of Table 1 are recorded in a sampling site, those five species

are considered the resident community. Because two of these species prefer deep pool locations, 40 % of this fish community's preferred location is deep pool. Similarly, three of the five species prefer gravel, so 60 % of this fish community's preferred substrate is gravel. The percentages of all of the 230 environmental factors can be easily calculated within the matrix.

The environmental preference percentages calculated in this way are used as input variables in the habitat ANNs models. In this research, the twelve environmental factors of deep pool, shallow pool, deep riffle, shallow riffle, no current, slow current, medium current, fast current, silt/sand substrate, gravel substrate, cobble substrate, and boulder substrate are used as independent variables in the habitat simulation ANNs models. These factors are generally physical habitat factors and are reasonable for habitat simulation models.

RESULTS AND DISCUSSION

Habitat-Specific Fish Collection

The study areas are the Tsengwen River and Kaoping River, located in southwestern Taiwan. Electrofishing sample sites were selected such that stream depth, velocity, and substrate could be related to the samples to develop an

understanding of fish habitat preference under existing environmental conditions. The sampling locations were identified as providing a wide variation of depth and velocity with relatively stable substrate conditions.

Fish were sampled at about one hundred habitat units within the four major sampling locations from 2007 to 2009 using the PAED technique. Ninety-eight units produced fish communities, while six of the units had no fish. A total of 1,035 individuals were obtained, including six genera and seventeen species. The dominant species were Pulin river loach (Sinogastromyzon puliensis), Freshwater minnow (Zacco pachycephalus), and two species of Goby (Rhinogobius giurinus and Rhinogobius rubromaculatus). The velocity at these habitat units varied from 0.01 to 1.58 m/s, and the depth varied from 3 to 160 cm.

The surveyed depth and velocity data of the same electric grid units were analyzed by the fuzzy rule-based model to identify habitat types (Suen and Su, 2009). Deep riffle (DR) is the most abundant habitat type, and the number of riffles is greater than the number of pools. This is likely because the study locations are within mid- to upper-order streams where riffle habitats and deeper water are more abundant than in low-order reaches. The habitat type results of the fuzzy rule-based model echo those of the field observations, but the fuzzy model classification procedure provides a quantitative way to define fish habitat types. It provides a clear, measurable procedure that is easier for engineers to apply.

Model Development

Historical fish sampling results usually show fish abundance or presence data in reach-scale sampling sites. Because this study uses PAEDs to sample fish in 1-by-1-meter habitat unit, the habitat scales between historical and recent data are different. To allow comparison between the datasets, 20 units were selected randomly from the habitat units. The habitat conditions of these units were used to mimic the habitat conditions at the historical reach-scale sampling sites. The combined fish data for the 20 units represented the fish abundance data for a reach-scale sampling site, and the compositions of the four types of habitat unit conditions of the 20 units represented the actual habitat condition at a sampling site. The fish data was then analyzed using the fish autecology matrix to determine the proportion of the communities that prefer each the of the twelve environmental factors (deep pool, shallow pool, deep riffle, shallow riffle, none current, slow current, medium current, fast current, silt/sand substrate, gravel substrate, cobble substrate, and boulder substrate). These percentages are used as input variables in the ANNs model. The percentages of each habitat type within the twenty units are used as output variables in the ANNs model. This process of randomly selecting twenty habitat units and calculating percentages is repeated twenty times, resulting in twenty sets of data to be used in developing the habitat ANNs model.

Table 2 shows the summary of habitat composition simulation models developed by the ANNs. The percentages of the 4 simulated habitat types may not sum to one, but

the percentages can still represent a relative comparison for engineering consideration. Most species sampled in riffle areas (e.g. Sinogastromyzon puliensis) only prefer riffle type habitats, but some species sampled in pool areas (e.g. Zacco pachycephalus and Rhinogobius giurinus) are habitat generalists which can also be caught in riffle type areas (Yu and Lee, 2005). This may cause the validation's r^2 value of the deep pool habitat unit model to be relatively low (0.508) and the validation's r^2 values of the two riffle habitat unit models to be relatively high (0.947 and 0.653). Improved sampling efficiency in deep pool areas and increased collection of guild species that use deep pool habitats (e.g. Hemiculter leucisculus) may increase the r^2 value of the deep pool habitat unit model.

Table 2 ANNs model results

	Training events			Validation events		
	RMSE	RMSE_P	r^2	RMSE	RMSE_P	r^2
Deep pool	0.0273	17.433	0.807	0.0370	24.657	0.508
Deep riffle	0.0208	4.599	0.944	0.0540	11.999	0.947
Shallow pool	0.0279	16.107	0.920	0.0748	39.382	0.543
Shallow riffle	0.0317	14.850	0.866	0.0598	27.172	0.653

While developing the regression models, autecology matrix analysis uses fish presence and absence data instead of abundance data. Although fish abundance data may provide more information, it is a snapshot-type result that reflects the antecedent environmental conditions. Besides that, the goal of the habitat simulation models is to reconstruct habitat unit compositions based on historical fish data; commonly, presence and absence data are all that can be found in the literature.

SUMMARY

This research develops a physical habitat simulation model by using historical fish data for river restoration and ecological engineering in mid- to upper-order streams in Taiwan. The simulated composition of four types of habitat units (deep pool, shallow pool, deep riffle, and shallow riffle) of a designed streamflow condition could guide the design of instream structures in creating pool-riffle systems with ecological reference. Although the compositions of habitat types in rivers may vary with streamflow variation, and the maintenance of instream structures for habitat composition is difficult, the habitat simulation model demonstrates how the design of an instream engineering structure can be guided by fish community information.

ABSTRACT

Between 2000 and 2012, nearly $180M in flood management and ecological improvements will be made in the lower seven miles of the Menomonee River and Underwood Creek in Milwaukee and Wauwatosa Wisconsin. When complete, these improvements will alter areas along at least one bank over nearly 70 percent of the river, resulting in more than 130 acres of riparian land conversion in that highly urban reach. These improvements were and will be undertaken by multiple parties for a variety of land development, flood management, and ecological restoration purposes.

To identify opportunities for providing multiple benefits from planned projects, the Milwaukee Metropolitan Sewerage District (MMSD) developed the Lower Menomonee River Watercourse Status Report. This report characterized the existing hydrologic, physical and ecological conditions of the river and its riparian area as it passes through a highly urbanized corridor. It summarized improvements made in the last seven years and identified remaining ecological and flood management concerns to be addressed by future projects. Additional projects are currently in various states of planning, and there is interest among various stakeholders to develop these projects in ways that provide additional environmental benefits beyond their primary flood management objectives.

Like many urban rivers, the Menomonee River is highly channelized. The status report identified four distinct reaches with varying degrees of channelization, natural substrate and riparian function. Prime opportunities for improvement include removing concrete sections that serve as fish barriers and providing additional riparian functionality in the mid-reach areas, both of which would help connect relatively high quality habitat upstream with Lake Michigan downstream. Several opportunities to enhance ecological function were identified associated with ongoing flood management projects and the report will serve as a basis for guiding additional efforts along the lower Menomonee River.

BACKGROUND

The Menomonee River is the second largest of three rivers that flow into Lake Michigan through the Milwaukee Harbor. Industrial development in the Menomonee River watershed began to occur rapidly following completion of the railroad connecting Chicago and Milwaukee in 1855 and the rate of urban growth along the lower Menomonee River peaked in the 1900s through 1920s. Industrial land use occurred

along the river, where water was used for both a resource and means of disposing of waste products. During this time, filling and dredging operations along the lower Menomonee River to satisfy industrial development interests resulted in a channelized river and filled floodplains.

Historically the Menomonee River, Milwaukee River Estuary and Lake Michigan supported a diverse and abundant fish and aquatic life community. The fishery included commercially and recreationally important cold, cool and warm water resident and potadromous species from Lake Michigan. The life requisites of many fish species were dependent, in whole or in part, on access to unique and seasonal habitats present in the lake, estuary and riverine environs.

Beginning with European settlement in the early 1800s, habitat for fish and aquatic life along the river and estuary was extensively modified or destroyed. The previously mentioned river channelization and filling of the floodplain resulted in the loss of over 10,000 acres of wetland habitat in the estuary and along the lower Menomonee River. A low-head dam, grade controls and concrete channel lining constructed in the lower Menomonee River acted as barriers to resident and potadromous fish movement. These structures also caused increases in water temperature, sedimentation and other impacts to water quality

Since the mid-1990's, a number of flood improvement and redevelopment projects in the area have resulted in significant changes to riparian land use (Table 1). Most of these projects have been implemented to improve flood flow conveyance for flood management. Some of these have had secondary benefits to improving the character of the river channel and riparian margins. A few have been implemented entirely for the purpose of improving the environmental characteristics of the river and the immediate riparian corridor.

While the loss of historical fish habitat is not fully reversible, some of the barriers to fish movement have been removed or abated. For example, the Falk Dam, formerly located at the Menomonee River estuary boundary, was removed in 2001. More significantly, in 2000 MMSD removed the six-foot high concrete grade control structure at N. 45th St. and 1,200 feet of concrete lining and replaced them with natural stone as the channel bed. The remaining 3,300-feet of concrete-lined channel remains a barrier to fish movement and an impediment to water quality goals. This section of the Menomonee River has not attained the State of Wisconsin’s assigned biological use for this reach.

Within this context the MMSD undertook the Lower Menomonee River Status Report. This report characterized the existing hydrologic, physical and ecological conditions of the river. With this information existing limitations to ecological function within the river corridor were evaluated, and the potential for planned or proposed projects to contribute to improved ecological function was explored.

Table 1. Completed Projects along the Lower Menomonee River.

Project	Status	River Mile	Date Built	Owner	Impact on River Corridor
Menomonee Valley Shops Redevelopment: Redeveloped 100-acre Shops site along 1,000 feet of north bank of the river	Complete	2.45 to 2.86	2006	City of Milwaukee	Increased floodplain area and improved riparian margin
Miller Park Riverbank Widening and Stabilization: Widened and stabilized 2,000 feet of riverbank; created trail and enhanced river access	Complete	3.06 to 3.56	2002	SWPBPD	Increased floodplain area and improved riparian margin
Valley Park Floodwall: Installed about 2,000 feet of floodwall to protect Valley Park	Complete	3.70 to 4.05	2001	MMSD	No impact on river channel
Wisconsin Avenue Viaduct Wetland: Created half acre wetland adjacent to the river	Complete	4.08 to 4.23	2000	City of Milwaukee	No impact on river channel
Drop Structure Removal: Removed impassible drop structure and 1,000 ft concrete and restored more natural gradient and bed	Complete	4.28 to 4.52	2000	MMSD	Provided fish passage
Hawley Road Bridge Removal: Removed Hawley Road Bridge and improved conveyance	Complete	5.13 to 5.14	2006	MMSD	No impact on river channel
Hart Park Project: Lowered 48 acres of floodplain, increased riparian corridor, expanded and stabilized riverbank, created trail	Complete	5.51 to 6.40	2006	MMSD	Increased floodplain area and improved riparian margin
Milwaukee County Grounds, Phases I and II: Creates a 960 acre-foot detention facility that will decrease flood flows in Hart Park by 3,000 cfs in a 100-yr event	Partially Complete	7.42 to 8.30	2008	MMSD	No impact on river channel
Hoyt Park Bank Stabilization: Stabilized 600 feet of riverbank and a headcut in the channel	Complete	7.51 to 7.62	2001	MMSD	Improved riparian margin

RIVER HYDROLOGY

While extreme peak flows are used to design flood management projects, base flows and frequent but minor flows tend to have a larger influence on ecological conditions in the river. Base flows occur in the periods between storm events and determine conditions experienced by aquatic biota during a large portion of the year. The typical daily flow in the lower Menomonee River is 44 cubic feet per second (cfs), and 70 percent of the time flow in the river is between 10 and 100 cfs. River flows show a clear seasonal pattern. The river exhibits a pronounced rise due to snowmelt in the spring, and then flows recede during the late summer and fall (Figure 1). During the spring melt, which generally occurs between February and April, the river experiences sustained 10-day or longer

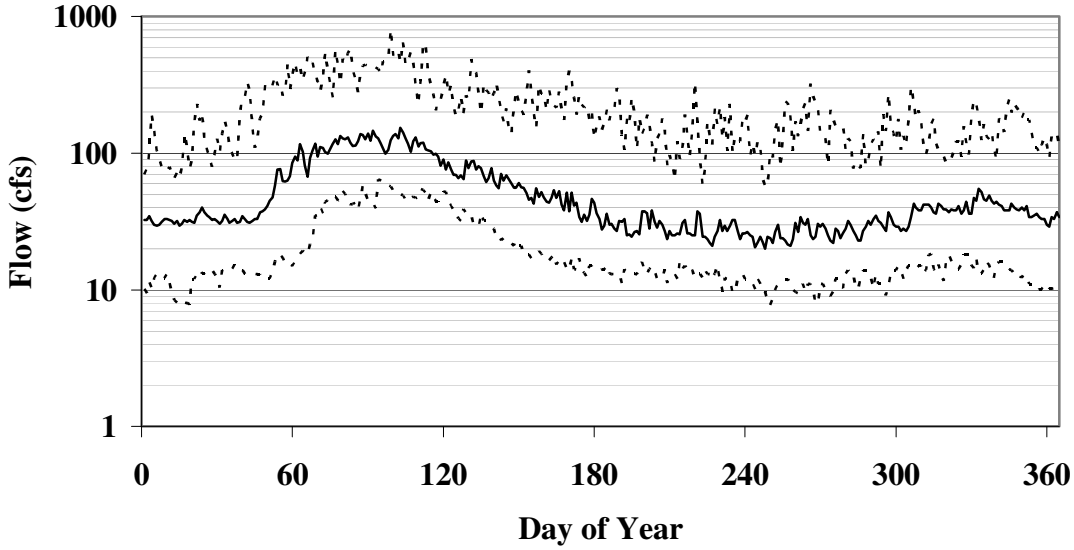

Figure 1. Median daily flow (solid line) and 10- and 90-percent limits (dashed lines) for Menomonee River at Wauwatosa (USGS Gage 04087120) based on Water Years 1962-1985 and 1987-2004.

periods of flow in the 150 to 400 cfs range, and often during that period there are one or two days with average flows of 1200-1500 cfs. Low flows during average years are around 20-30 cfs. High flow events can occur at any point throughout the year, and on almost any day there is at least a ten percent probability that flows in the river will exceed 100 cfs.

Character of high flows. On the lower Menomonee River larger flows (larger than the 50 percent annual probability, also known as the 2-year flow, equal to approximately 4,000 cfs) tend to occur quickly and last for a brief period. The peaks tend to be driven by a combination of two tributary inflows, Underwood Creek and Honey Creek, with contributions from upstream areas arriving after the highest flows have passed. Analysis of the 15-minute instantaneous flow records for the largest flows between 1986 and 2006 indicate two types of typical events. The first type is a "flashy" event, during which flows quickly rise and then steeply fall back. The second type is an "extended" event, during which flows fall back, but remain at an elevated level. The extended events occur at about the same frequency as flashy events, but the extended events tend to be larger and appear to reflect storms that fall over most of the watershed.

Ecological significance. Based on the preceding evaluation of the character of base flows and frequent higher flows, several flow thresholds of ecological significance were developed based on duration and frequency of occurrence. These include flows within the channel (300 cfs and less) and flows that inundate the stream banks and the immediate riparian margin (1,200 to 4,000 cfs). These flows, their duration and frequency are presented in Table 2.

Table 2. Qualitative threshold flows of ecological significance for the lower Menomonee River.

Flow (cfs)	Average Duration	Incidence	Seasonality
30	Months	Every year	Average daily flow during summer and fall
160	Weeks	Every year	Average sustained spring melt flow
300	Days	Nearly every year	Common peak daily flow during snow melt
1,200	8-24 Hours	Nearly every year, average daily flow that occurs twice a year on average	Can happen in any season
2,100	Few Hours	Nearly every year, average daily flow that occurs every other year on average	Generally in March through September
4,000	Minutes	Peak flow occurs approximately every other year	Usually in June through August

PHYSICAL AND ECOLOGICAL CONDITIONS

During the 1950s to 1980s, MMSD constructed concrete-lined channel waterways in an effort to improve conveyance and reduce the risk of flooding of structures and property within these floodplains. Nearly all of the approximately 26 miles of these concrete-lined channels are in need of repair or replacement. In some areas, the concrete-lined riverbed and banks are failing, and in many others, the concrete is nearing the end of its functional lifespan. These concrete-lined stream segments fragment and limit linear and lateral connectivity within the stream and their corridor habitat and ecosystems; limit or prevent fish and wildlife movement; increase water temperature; destroy fish, aquatic life and wildlife habitat; limit recreational use including those attendant to navigation, fishing and aesthetics; and may actually increase flooding and decrease public safety.

The conditions of the 6.3-mile long reach of the lower Menomonee River under study reflect these historic river and floodplain modifications. This section of the document presents a description of the physical and ecological condition of the streambed, banks and riparian margin within the study area.

Existing streambed and stream bank condition. The materials that comprise the streambed and stream banks of the Menomonee River were documented in 2000 as part of a geomorphic inventory of the entire watershed (Inter-Fluve 2001). The bed and banks of the lower Menomonee River consist of alluvial materials (gravels and cobbles), bedrock, riprap, concrete and WPA Walls.

WPA walls were constructed in the 1920s and 1930s as part of the Works Progress Administration to serve as flood management and river controlling structures. These walls consist of mortared limestone blocks and are up to 12 feet high. The WPA walls in the Menomonee River watershed range in condition from stable and functional to flanked, crumbling and non-functional. Throughout the study area, the WPA walls are functioning, although two segments exhibit degradation of the stone and mortar and are at risk for potential failure (Inter-Fluve 2000). Also, throughout the study area

approximately 17 percent of the bed and 50 percent of the banks consist of man-placed materials, indicating the extent of human-induced impacts along this section of river.

Inundation of riparian margins. The interaction of land and water at the riparian margin is one of the critical factors that influences riparian and channel quality and function. For this study, a HEC-RAS hydraulic model was used to characterize the aerial extent of inundation within the riparian margin along the lower Menomonee River study area. First, the modeled water surface elevations associated with the flows of ecological significance were determined. Then, using the bank line location and elevations, the floodplain topography, and the modeled water surface elevations, the areas of inundation for three different flows (600; 1,200; and 4,000 cfs) were determined. These inundation areas, as well as an average inundation width, were compiled for each reach. The inundation area and width are negligible in certain reaches because of the constrained channel geometry. The most upstream reach has the most functional floodplain, as this reach exhibits the largest inundation area and width at 4,000 cfs, but other reaches also provide important habitat because they contain pockets of habitat that inundate at the lower flows.

Fisheries. While many fish species are resident to the middle and headwater reaches of the Menomonee River, many others use—or could use—the lower river as a transitory corridor from the lake and estuary to access the habitat available in the river and tributaries. As one of its more integral fish habitat functions, the lower Menomonee River provides an important biological connection to the entire Menomonee River watershed. Additionally, the lower river also provides spawning, rearing and adult habitat to a variety of game and non-game fish, other aquatic life and wildlife.

Fish populations in the lower Menomonee River are less than optimal due to the impacted habitat conditions of the river. Factors responsible for the limited habitat include land use and resulting stormwater and pollutant loads; extreme flow conditions; and modifications to the original physical habitat along the river and its corridor. Habitat modifications include the 3,300-foot long reach of semi-impassible concrete channel lining, a lack of channel margin refuge caused by extended segments of smooth, vertical limestone block walls and reduced in-stream habitat diversity resulting from several causes, such as floodplain encroachment and a lack of woody material recruitment. Benefits from enhancements to river habitat could include fish access to historical upstream and newly created local habitats necessary for reproduction, development and other life requisites; enhanced genetic diversity; access to over wintering habitat; access to and increased production of food supplies; and enhanced water quality.

ECOLOGICAL LIMITATIONS

Local-scale ecological function is limited by the interrelated factors of channel bed condition, channel bank condition and the potential for fish passage, as well as the nature of the wetland or floodplain vegetative community. At the reach scale, the primary ecological limitation within the lower Menomonee River is a 3,300 length of concrete river bed which limits the connectivity of fisheries between the estuary and the rest of the river over all ranges of flow experienced by the river. The downstream areas of the river have very limited margin habitat, meaning that natural flow variations do not

inundate additional riparian land. Since the river banks are nearly all concrete wall, rip rap, other steep (3:1 and greater) slopes to the river, there are very limited floodplain wetlands and inundation of land during normal seasonal flow variations. The inundation of riparian margins during seasonal variations in flow is one of the key requirements for ecological function. Finally, the downstream portions of the river also have limited wooded riparian corridors, which provide shade and woody debris for the river.

POTENTIAL FOR IMPROVEMENT

This report evaluated the projects that may be constructed in the next several years from both a flood risk reduction perspective and from an ecosystem function benefit. Some projects such as the Western Milwaukee project and Phase 2 of Milwaukee County Grounds will be built primarily for flood management. Other projects such as the Airline Yards project will be more specifically focused on ecological restoration. Table 3 summarizes the improvements that will result from each of these projects. It was determined that, with proper design these projects could contribute to improvements in each of the areas of ecological limitation noted above.

CONCLUSIONS

- A key project for the entire system is completing Phase 2 of Milwaukee County Grounds. An undesired consequence of removing concrete in the Underwood Creek and Valley Park would be raising 100-year water surface elevations. The Milwaukee County Grounds project will lower the downstream100-year water surface elevation sufficiently to compensate for the increases caused by concrete removal. Without County Grounds, these projects would not be feasible due to unacceptable increases in the water surface elevation beyond existing elevations.

- The Western Milwaukee Floodwater Management Project will significantly improve conditions within Reaches 2 and 3 through creation of 1.5 acres of new floodplain wetlands, a day-lighted Schoonmacher Creek, and 31 acres of primarily wooded riparian corridor.

- Creation of a pilot channel in the Valley Park area is feasible without increasing the 100-year flood water surface elevations above existing elevations assuming that the County Grounds project is functional. The pilot channel would greatly improve the ecological connectivity throughout the entire watershed and allow fish to migrate from the estuary to the rest of the river.

- The feasibility for concrete side slope removal in the Valley Park area requires more study. Preliminary modeling suggests that in order to due this, additional land would need to be purchased to widen the channel so that 100-year water surface elevations would not be increased above the current conditions.

- Overall, the floodplain projects proposed by the MMSD will lower the 100-year water surface elevations and provide key ecological improvements in the lower river.

Table 3. Summary of Potential Ecological Improvements Along the Lower Menomonee River.

Project	Reach	Improved Condition				
		Channel Bed	Channel Bank	Fish Passage	Floodplain Wetland	Woody Riparian Vegetation
Phase 1 Western Milwaukee Flood Management	3	N/C	Converts 800 feet of WPA wall to riparian margin	N/C	Creates 0.5 acres	Creates 7 acres of tall grass prairie
Phase 2 Milwaukee County Grounds	4	Provides reduced flow conditions which allow channel bed improvement	Provides reduced flow conditions which allow bank improvement	N/C	N/C	N/C
Menomonee Valley – Airline Yards	1	N/C	Creates 2,500 feet of stabilized bank	N/C	Creates 1 acre	Creates 10 acres
Falk Corporation Floodwall	1	N/C	N/C	N/C	N/C	N/C
Phase 2 Western Milwaukee Flood Management	3	N/C	Converts 400 feet of WPA wall to riparian margin. Opens 500-feet of enclosed tributary creek	N/C	Creates about 1 acre	Creates 31 acres
Valley Park Concrete Removal –Pilot Channel Alternative	2	Replaces 3,900 feet of concrete bed with stone for fish passage	N/C	Provides fish passage	N/C	N/C
Valley Park Concrete Removal – Improve Bottom and One Side Alternative	2	Replaces 3,900 feet of concrete bed with stone for fish passage	Converts 400 feet of concrete bank to riparian margin	Provides fish passage	N/C	N/C

Abstract

Loss of biological integrity in streams due to excessive suspended sediment is a major cause of water quality impairment in the United States today. States monitor and assess streams for biotic integrity, and list streams as "impaired" according to §303(d) of the Clean Water Act for those that do not meet biological criteria. Biological criteria are set by states based on benthic macroinvertebrates or fish community metrics, developed as indices of biotic integrity (IBI) per Level IV ecoregions. In many cases, causes for biological impairment are not clear, and commonly states list causes as "siltation" and/or habitat alteration without strong evidence. A critical need exists to improve analytical tools to link loss of biological integrity with "siltation", and to estimate total maximum daily loads (TMDLs) for these impaired streams. This study tested an idea using autecological fish data and USGS suspended sediment concentration (SSC) data to better link causes of biological impairment to SSC metrics. The study was located in Northern Great Plains Level III Ecoregion, in which 77 USGS gauging stations with flow and suspended sediment data were co-located with fish data from federal and state agencies. Autecological data was summarized by fish species found in this ecoregion, including attributes on mesohabitat preferences, water quality tolerance, trophic structure, and feeding, diet, and spawning behaviors. An autecological data matrix was created using the species autecological information and site fish presence/ absence data, forming a matrix that included, per site, the number of occurrences an autecological attribute occurred for fish species present. Ecological analysis found significant differences for several autecological attributes between stable and unstable channels. Fish located at unstable sites tended to: 1) prefer open-water mesohabitat, 2) be dominated by herbivores with algae diet, and 3) exhibit non-guarding spawning behavior. Use of fish autecological data and the protocols applied in this study were found useful to improve "strength of evidence" approaches to link biological impairment to excessive SSC.

Introduction

Loss of biological integrity due to excessive erosion, transport, and deposition in rivers and streams is a major water quality (WQ) problem in the United States. The 2000 National WQ Inventory found that siltation was a leading cause of impairment, second to pathogens, representing 31% of the assessed and designated impaired rivers and streams. Siltation is generally defined as an impaired condition resulting from excessive fine sediments suspended in the water column, embedded in course bed sediments, and/or deposited in the active channel degrading habitat (USEPA, 2006). Siltation-impaired

streams on state §303(d) lists require states to development and implement sediment total maximum daily loads (TMDLs) (USEPA, 1999a). A TMDL represents a pollutant load allocation that meets a pollutant WQ standard (USEPA, 1999b). However for suspended sediment, no state to date has adopted a WQ standard although Minnesota has adopted a 25 NTU turbidity standard as a surrogate for suspended sediment. Most state WQ assessments rely on indices of biotic integrity (IBI) to designate biologically-impaired streams, and if no identifiable chemical degradation causes are identified, siltation is generally inferred in human-dominated watersheds. A critical need exists for a TMDL linkage analysis that can relate excessive fine sediments with loss of ecological function, so that sediment load reduction targets can be set in impaired watersheds.

In order to implement sediment TMDL targets that can potentially achieve a positive ecological response in degraded watersheds, targets must be ecologically-based. Stream ecosystems can be impacted by increased levels of suspended sediment in various ways including a reduction of primary production and macroinvertbrate abundance, which in turn can limit food availability for fish (Waters, 1995; Henley *et al*., 2000). Particularly with clear-water fishes, excessive suspended sediment over prolonged periods of time can cause mortality, depress growth, reproduction and recruitment, and elicit avoidance behavior inducing out migration from impacted reaches (Newcombe and MacDonald, 1991; Servizi and Martens, 1992; Newcombe, 2003). Although ecological responses can be complex, loss of ecological function can be observed by changes in fish community structure (Lamouroux *et al.*, 2002; Walters *et al.*, 2003).

Quantifying impacts on fish community structure from excessive suspended sediment has been problematic because of the episodic nature of elevated suspended sediment levels, and species-specific responses to sediment dose, and their regional differences (Newcombe, 2003; Schwartz *et al*., 2008). Simon *et al*. (2004) found significant differences of suspended sediment concentrations at the 1.5-year recurrence frequency ($Q_{1.5}$) among ecoregions in the United States, in which the $Q_{1.5}$ represents the effective sediment discharge. Effective discharge is defined as a discharge or range of discharges that over the long term transports the largest proportion of annual suspended sediment load (Wolman and Miller, 1960). Utilizing the $Q_{1.5}$ and a field-based geomorphic assessment technique to distinguish stable and unstable conditions, annual sediment yields ($T/yr/km^2$) was computed for watersheds and condition, providing a means to set a sediment TMDL allocation (Simon *et al*., 2004). This methodology reasonably assumes sediment loads estimated for unstable conditions were at levels that can induce biological impairment. However no linkage analysis has been attempted to test this hypothesis.

It is important as one of the outcomes of a TMDL linkage analysis is identifying what ecological functions have been lost due to elevated suspended-sediment levels (USEPA, 2006). Reliance on species data can introduce undue variance into the linkage analysis, and fails to identify what ecological functions have been lost. Ecological function can be expressed by species traits or autecological attributes, e.g. for fish, feeding and spawning behavior, mesohabitat preferences, microhabitat availability for predation avoidance and flood refugia (Schwartz, 2002). Use of autecological data in a linkage analysis may provide a means to identify specific losses of these ecological functions, which then sediment TMDLs can specifically target corrections through best management practices.

The objective of the study was to explore whether fish autecological data can be used in a linkage analysis relating biological impairment to suspended sediment metrics. A change in fish community structure, parameterized by autecological data based on species traits information, and related to channel stability may provide a useful methodology to link biological impairment to stream siltation.

Methods

Study Design: The study area was the Northwestern Great Plains Ecoregion (ER43), which includes western North and South Dakota, eastern Montana, and northeastern Wyoming (Fig. 1). Study sites included watersheds having United States Geological Survey (USGS) gauging stations with instantaneous discharge data and 15 or more suspended sediment collections. Suspended sediment collections contained wash load clays and silts, and suspended load sands. Basin drainage areas and elevations above MSL were also obtained from the USGS database for each site. Overall, a "strength of evidence" interpretive approach was to test an idea whether fish autecological data could be used to identify biologically impaired streams due to "siltation" by correlating autecological data to suspended sediment metrics. Fish data were obtained from federal and state agencies co-located at the USGS gauging station sites with flow and suspended sediment data, in which 77 sites were found. This "strength of evidence" is recommended for watershed-scale ecological analysis by USEPA (2000) guidance document on stressor identification.

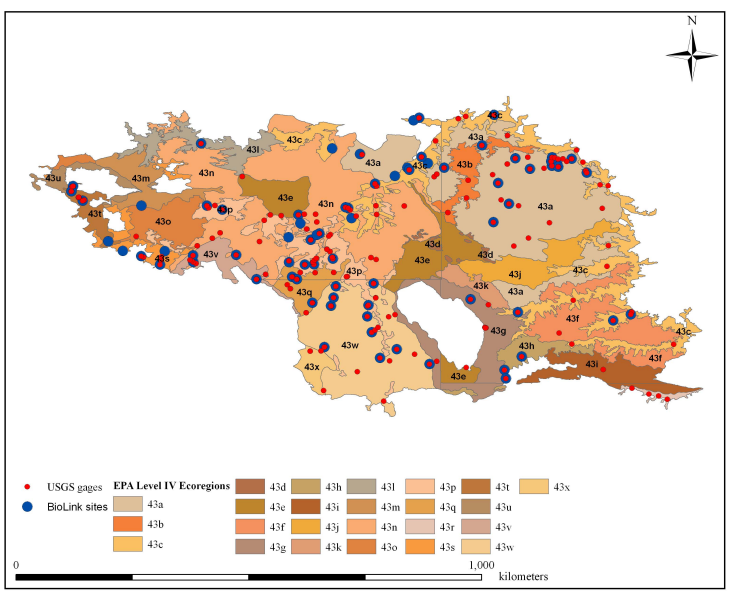

Figure 1. Location map of study sites in the NW Great Plains Ecoregion (43), showing USGS gauging stations and fish data sites.

Suspended Sediment Loads at the $Q_{1.5}$ for Stable and Unstable Channels: The $Q_{1.5}$ was computed by a log-Pearson Type III distribution using the annual-maximum peak-flow series for each of the sites with available data (Simon *et al*., 2004; 2008). Suspended-sediment yield at the $Q_{1.5}$ was obtained by using the sediment-transport relation developed for the site, substituting the $Q_{1.5}$ into the relation and solving for suspended sediment load. As part of the analytic procedure, the maximum sampled discharge is compared at the $Q_{1.5}$ to make sure that it falls within the flow range sampled. If the $Q_{1.5}$

exceeds the maximum sampled discharge by 50%, the site is not used in further analysis. This is because considerable error can occur in calculating loads high flows, particularly if the sediment-transport relation is extended beyond the measured bounds of the data. To normalize data for watersheds of different size, sediment load was divided by drainage area, providing calculations of sediment yield ($T/d/km^2$) and presented by quartile measures to describe data ranges and central tendencies.

Channel stability at each site was determined by a rapid geomorphic assessment (RGA), a field-based technique using nine metrics to infer dominant processes and magnitude of instabilities (Simon *et al*., 2004, 2008). The RGA was created based on geomorphic concepts from the channel evolution model, in which disturbance to an alluvial channel initiates a systematic response of downcutting followed by channel widening (Simon and Hupp, 1989; Simon, 1989; Simon and Darby, 1999). The RGA provides a quick assessment of channel stability providing an index score based on nine metrics consisting of: 1) primary bed material; 2) bed/bank protection; 3) degree of incision; 4) degree of constriction; 5) stream bank erosion; 6) stream bank instability; 7) established riparian woody-vegetative cover on banks; 8) occurrence of bank accretion; and 9) stage of channel evolution. ER43 field assessments were conducted in 2007 (Simon *et al*., 2008). Unfortunately, it is not uncommon suspended-sediment sampling was carried out over decades earlier, and measured suspended sediment loads do not represent current channel stability conditions. This issue was addressed by establishing stability condition during the sampling periods for suspended sediment using available USGS data and the following techniques: 1) examination of stage-discharge relationships and cross-sectional data noting whether bed elevation changed over time; and 2) analysis of long-term suspended-sediment data computing rating curve relationships by decade, and observing for changes in rating curve power function coefficients and exponents. Changes in rating relations imply channel adjustments with time, and possible unstable conditions. Study sites were designated as stable or unstable for current conditions based on the field RGA, and measured suspended sediment loads were used for matched conditions (Simon *et al*., 2008).

Autecological Data: Fish data were obtained from federal and state agencies, in which fish were sampled between the 1997 and 2006, with the majority of samples occurring between 2000 and 2003. Data sources included: 1) USEPA Region VIII EMAP and REMAP datasets; 2) North Dakota Division of Health (NDDH); 3) USGS Coop Unit at South Dakota State University, Dr. Charles Berry; and 4) Montana Department of Fish, Wildlife and Parks, online Fisheries Information System database (http://maps2.nris.state.mt.us/scripts/esrimap.dll?name =MFISH&Cmd=Main&Pc) accessed March 2, 2008. Fish data sites were co-located with USGS gauging station locations by latitude and longitude coordinates, in which a total of 77 sites were found. Per site, species presence and absence data were compiled from these four key data sources. Presence and absence data were used because: 1) analysis of this data type alleviates issues associated with differences in sampling gear and effort, important when abundance data are used, and 2) this study's focus on attributes of ecological function based on species traits, and essentially grouped as guilds. A summary list of fish species found within the final fish presence/absence dataset, and the number of occurrences per stable and unstable sites can be found in Table 1.

Table 1. Fish species with ordination codes, and the number of each species found within the dataset, at stable and unstable sites.

Autecological data are species trait information for this study included: rearing mesohabitat preference (open water, pool, riffle), water quality tolerance, trophic structure, feeding location (bottom, pelagic, surface), feeding behavior (grazing, sorting, stalking, pursuit), diet (algae, crustaceans, insects, fish, etc.), and spawning behavior (guarding, nest builder type, egg dispersion/laying type) (Table not shown due to space limitations). Data were compiled for each species from the following references: Smith (1979); Etnier and Starnes (1993); Barbour *et al*. (1999); Coker *et al*. (2001); and on-line Search FishBase (www.fishbase.org) accessed February 18, 2008. Compiled data consisted of a spreadsheet matrix with fish species by rows and autecological attribute by columns, and when the attribute applied it was given a value of "1", and when it did not apply it was given a "0" value (Table not shown due to space limitations). A second spreadsheet matrix was generated that consisted of study site by autecological attribute, in which the number of occurrences an autecological attribute occurred for that site based on fish species presence were enumerated (Table not shown due to space limitations).

The approach to this ecological analysis was to first use ordination statistics to: 1) examine whether patterns of fish presence and absence correlated in ordination space with channel stability, accounting for the potential effects of basin attributes drainage area and elevation, and 2) through ordination statistics, examine what autecological attributes correlate with channel stability, which can be interpreted as to the potential losses of various ecological functions. Parametric statistics were then used to examine whether autecological attributes, summed by the number of occurrences by fish species per site, differed between stable and unstable sites. These statistics were used to support the qualitative findings observed by the ordination statistics.

Statistical Analysis: Ordination techniques included principal components analysis (PCA) and canonical correspondence analysis (CCA). PC-ORD (version 5.0) was used to perform these analyses (McCune and Mefford, 1999; McCune and Grace, 2002).

Typically for the CCA, site x fish species +/- data was used as the main data matrix, and site x physical variables was used as the secondary matrix. For the autecological analysis, "site x autoecological attributes" was used as the secondary data matrix. A t-test for unequal variances was used to test the statistical hypothesis that the means for an autecological attribute was significantly different between stable and unstable sites (Excel™ Data Analysis Tool). Each autecological attribute was tested separately and significance levels reported.

Results and Discussion

Fish distribution has been shown to be strongly influenced by site drainage area and elevation (Schwartz, 1991; Newall and Magnuson, 1999), particularly in this ecoregion (Rahel and Hubert, 1991; Kral and Berry, 2005; Hoagstrom *et al*., 2006). Therefore, a preliminary analysis tested whether channel stability was equal or greater in importance as drainage area and elevation influencing fish distribution. This analysis was necessary to provide evidence that the stability attribute could be effectively used in the analysis of fish autecological attributes. Site drainage area, elevation, and channel stability were found to be equally important as influencing basin-scale fish distribution for some species as observed by the CCA ordination (Fig. 2). In Figure 2, the channel stability eigenvector appeared to be slightly less dominant compared to drainage area and elevation plotted by axes 1 and 2, however, a better orientation of three basin attributes was observed by axes 2 and 3. A fish assemblage that clustered dominantly with stable sites included: brook stickleback, johnny darter, walleye, black crappie, pumpkinseed, yellow bullhead, brown trout, lake chub, mountain whitefish, and plains killifish (Fig. 2b). In this CCA ordination, the Pearson's correlation coefficients (*r*) for drainage area were -0.59, -0.59, and -0.26, elevation were -0.76, 0.77, and 0.22, and channel stability were -0.28, 0.41, and 0.86 (axes 1, 2, and 3, respectively).

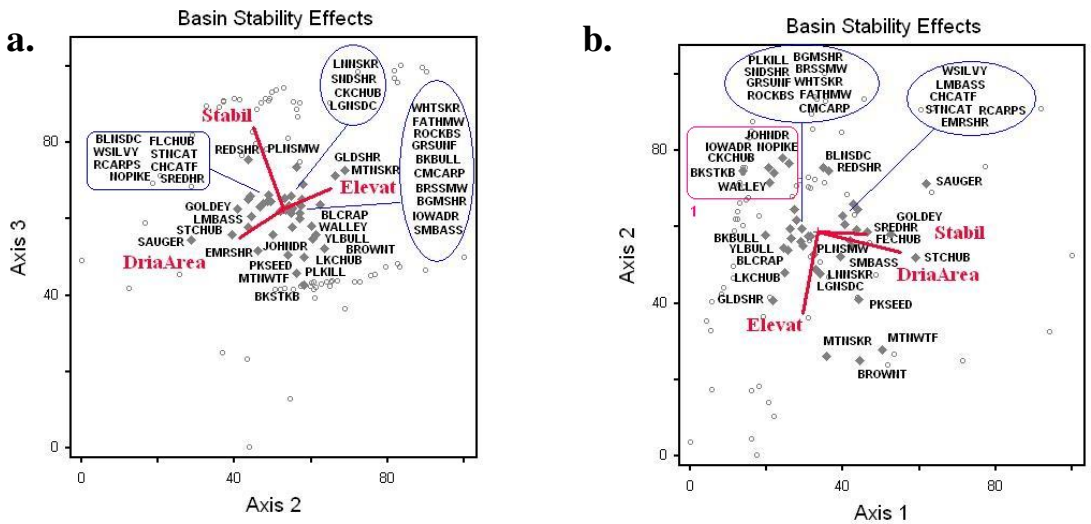

Fig. 2. CCA ordination of fish species by site, with secondary environmental attributes accounting for effects of site drainage area (DraiArea), elevation (Elevat), and channel stability (Stabil). Ordination plot shows a) axis 1 and 2; and b) axes 2 and 3. Ordination codes for fish species can be found in Table 1.

PCA ordination was used to examine the orientation of eigenvectors relative to site channel stability and various sets of autecological attributes. Fish with pool and riffle mesohabitat preferences strongly orientated with stable sites, whereas fish with open channel habitat preference and water-quality tolerant fish oriented more with unstable sites (axes 1 and 2 accounted for 72.8% of the variance). Ordination figures are not shown due to proceedings space limitations. By definition, unstable sites generally lack bed substrate suggesting channels for these sites would characteristically have more open channel, glide-type mesohabitat. The PCA examining site relationships of fish trophic structure and channel stability found unstable sites aligning strongly with herbivores (axes 1 and 2 accounted for 56.6% of the variance). Other trophic levels, e.g., insectivores and piscivores, did not orientate near clusters of stable or unstable sites. This relationship between unstable sites and herbivores is interesting considering that fish with open channel mesohabitat preference orientated with unstable site too. Herbivores tend to occupy shallow-water, glide habitat (Schwartz and Herricks, 2008).

The PCA examining site relationships of fish feeding behavior and channel stability was weak, but showed a slight tendency for stalking and pursuit behaviors to align with the stability eigenvector and unstable sites. In general, stable and unstable sites did not cluster in ordination space. Axes 1 and 2 in this PCA ordination with feeding behavior accounted for 64.2% of the variance. The PCA examining site relationships of fish diet and channel stability found unstable conditions aligning strongly with algae (axes 1 and 2 accounted for 73.1% of the variance). This result was consistent with findings where the herbivore eigenvector aligned with the stability eigenvector. It is possible watersheds with unstable channels tended to have nutrient rich waters from human and agricultural waste promoting algae growth, however this is only speculative without further analysis. Also, fish diets consisting of annelids, crustaceans and molluscs tended to orientate towards stable sites. The fact these secondary trophic prey oriented with stable sites is interesting from an ecosystem perspective, possibly inferring a broader food web structure in stable sites in contrast with unstable sites.

The PCA examining site relationships of fish spawning behavior and channel stability found unstable sites aligning strongly with egg non-guarders, egg deposition submerged open water and substrate, and egg adhered to substrate (axes 1 and 2 accounted for 51.1% of the variance). In contrast, stable sites aligned to some degree with egg guarders and nest builders. This result suggests that non-guarders that disperse eggs into the water column or on substrate do not require stable channel morphology, but guarders need adequate substrate to build nests, therefore their annual recruitment is dependent of stable bed morphology.

Statistical comparisons of site occurrences of autecological attributes, using a t-test to compare the attribute means between stable and unstable channels, resulted in 14 significant differences. Of the mesohabitat preference attributes, open water preference occurred more in unstable channels than stable channels ($p = 0.04$). Of the trophic level attributes, herbivores and piscivores species occurred more in unstable channels than stable channels ($p = 0.0021$, 0.09, respectively). Pelagic feeders and pursuit behavior occurred more often in unstable channels than stable channels ($p = 0.01$, 0.03, respectively). Grazing feeders and fish that prefer an algae diet were found more often in unstable channel than stable channels ($p = 0.10$, < 0.01, respectively). Of the spawning

behavior attributes, non-guarders, and egg dispersion into open water/substrate and on substrate occurred more often in unstable channels than stable channels ($p = 0.028$, 0.001, 0.068, respectively). Spawners that build nests were found more often in stable channels than unstable channels ($p = 0.01$). Also, fish that that prefer an annelid diet were found more often in stable channel than unstable channels ($p = 0.07$). Findings from this statistical analysis follow similarly the ordination statistics, in which the significant autecological attributes included: open water mesohabitat preference, herbivores, pursuit feeding behavior, algae diet, egg non-guarders, egg dispersion into open water/substrate and on substrate, and egg nest builders.

Conclusion

Sufficient evidence was found in the ecological analysis to support the utility of RGA determinations of stable-unstable reaches, and subsequent sediment transport differences summarized by suspended-sediment yield and dose (Simon *et al*., 2008). Whether the ecological consequences are from direct or indirect stressors, fish species that preferred open water channels occurred more often at unstable sites. In addition, herbivores with algae diet, pelagic piscivores with stalking and pursuit feeding behaviors, and fish with non-guarding spawning behavior that disperse eggs into the water column or adhere to loose substrate tended to occur more often in unstable channels. Fish that preferred pool-riffle habitat structure and had guarding spawning behavior occurred more often at stable sites. Ecologically, a "strength of evidence" interpretation suggests mesohabitat structure is degraded at some sites by sedimentation forming channels with open water, glide-pool habitat that appears to promote algae growth, and creates bed material dominated by sands which appears to promote fish recruitment by non-guarding spawners. In addition, non-guarding spawners that disperse eggs would benefit from more frequency events with high suspended sediment, increasing more days with higher turbidity. Findings from this study suggest the general approach to assess channel stability, and analyze for autecological differences between stable-unstable determinations hold promise as a linkage analysis protocol for sediment TMDLs. Autecological results, as described above, provide a means to guide development of additional studies focusing monitoring parameters. In addition, outcomes can support watershed corrective actions plans to meet required TMDL targets for sediment load reductions.

Acknowledgements

The study was funded by the USEPA Region VIII, Ecosystems Protection and Monitoring Program through a cooperative agreement with the USDA National Sedimentation Laboratory (Project # 6408-13000-017-31). We would like to thank Kris Jensen, USEPA Team Leader, and Tom Johnson and Tina Laidlaw for EMAP data support. Additional assistance with compiling fish data included: Mike Ell and Joe Gross with the North Dakota Department of Health, Division of Water Quality; Dr. Charles Berry with the South Dakota USGS Cooperative Unit at South Dakota State University, and Ann Harrie with the Montana Department of Environmental Quality. USDA NSL staff assisting in field work included Brian Bell, Danny Klimetz, and Mark Griffith**.** Danny Klimetz and Wendy Disckerson provided GIS and database support.

Abstract

Hydrological processes impact the functioning of ecosystems and influence fish population dynamics. In the Great Smoky Mountains National Park (GRSM), native brook trout (*Salvelinus fontinalis*) and rainbow trout (*Oncorhynchus mykiss*) populations have declined in some watersheds over the past two decades. Since 1986, 69 streams (369 sites) are routinely sampled by GRSM fisheries biologists, in which detailed data have been collected on fish condition (length, weight), abundance, year class strength, and biomass. To evaluate the impact of floods and droughts on trout, indicators of hydrologic alteration (IHA) were computed for 127 fish sampling sites between 1990 and 2007. The Hydrological Simulation Program - FORTRAN was used to model flows at each ungaged fish-sampling stream site. Outlets were defined for each site, and flow was calculated for the period of record. The model was calibrated by adjusting parameters including storage, infiltration, runoff, and ground water for three elevation classes (low < 800 m ≤ medium < 1200 m ≤ high) to fit flow output from model with two USGS gaging stations and one NPS gaging station. The ecohydrologic regimes, characterized using the IHA method, were compared with trout abundance and biomass at each site. Results indicated the abundance of young-of-the-year brook and rainbow trout significantly declined after extreme floods and droughts. In particular, low-flows during droughts significantly reduced recruitment for both brook and rainbow trout, which is likely due to decreased spawning habitat. Brook trout populations in larger low-elevation streams showed more stability compared to smaller headwater streams.

Key Words: drought, Great Smoky Mountains, flood, HSPF, IHA, trout

Introduction

The flow regime of a stream affects the structure, composition, and productivity of fish communities by regulating abiotic habitat conditions and biotic processes (Poff et al. 1997; Richter et al. 1996). In the Great Smoky Mountains National Park (GRSM), native brook trout (*Salvelinus fontinalis*) and rainbow trout (*Oncorhynchus mykiss*) populations have declined in some watersheds over the past two decades. Although it is believed that trout have primarily been impacted by episodic acidification, the effect of natural hydrological extremes or disturbances on brook trout populations in GRSM streams is examined in this research.

Floods and droughts are the major forms of natural hydrologic disturbances that regulate riverine biological communities (Cattaneo et al. 2002). The natural flow regime of a river plays a critical role in determining the distribution, diversity, and abundance of riverine species. A river's flow regime can affect abiotic characteristics such as flow depth and velocity, temperature, oxygen content, turbidity, streambed substrate, and morphology (Richter et al. 1997), and biotic processes in the riverine community (Poff et al. 1997). The timing, frequency, duration, and magnitude of a disturbance may dictate the success or failure of populations in stream ecosystems (Lake 2000). The severity of the hydrologic event to biota is dependent on the timing of the event relative to the fish developmental stage. Mountain headwater streams, such as those in the GRSM, are more sensitive to variations in streamflow which affects the availability of habitat for communities to grow, forage, and reproduce (Elwood and Waters 1969).

High-elevation stream communities are especially prone to large disturbances caused by floods (Roghair et al. 2002; Swanson et al. 1998). Floods may cause rapid effects on fish populations primarily from high in-stream velocities and debris flow, which may cause death, displacement, or reduce effective habitat (Elwood and Waters 1969). Harvey (1987) concluded that the ability of fish to maintain their position in-stream under high flows increased rapidly with size because larger fish are stronger and have better swimming abilities. Extreme high flows can destroy or damage fish eggs or larvae in redds (Carline and McCullough 2003) or increase sedimentation of fine material on spawning gravel decreasing oxygen availability to developing embryos and physically trapping emerging alevins (Jensen and Johnsen 1999). Additionally, fish can be stranded in isolated pools from the main channel once a flood flow has receded. Severe flooding in salmonid streams commonly destroys the year class of fish that are still incubating or have recently emerged and can take two to three years to recolonize (Carline and McCullough 2003). Timing is important as winter flooding can destroy redds of fall-spawning brook trout and spring floods can destroy redds of spring-spawning rainbow trout.

Droughts can affect the fish communities by physically decreasing the surface area and volume of the water body, and by altering the water quality, particularly temperature and oxygen (Closs and Lake 1996; Cowx et al. 1984; Matthews and Marsh-Matthews 2003). Drought reduces habitat leading to increased fish density, causing increased biotic interactions including predation and competition for diminishing food. Low water levels may prevent aquatic species access to spawning grounds leading to possible loss of a year class (Lake 2003; Richter et al. 1996).

Severe drought may reduce groundwater flow into streams thereby negatively affecting spawning grounds for fish species that utilize discharging groundwater to regulate temperature, chemistry, and hydrology within redds (Curry et al., 1995). Low flow can cause brook trout eggs to become infected with the fungus *Saprolegnia* reducing the recruitment class (Hakala and Hartman 2004). Lack of food abundance has been attributed to a loss of benthic macroinvertebrate populations, reduction in surface area available to catch falling terrestrial insects, and diminished invertebrate drift, the principal food source for salmonids (Canton et al. 1984; Hakala and Hartman 2004).

The objective of the current study was to evaluate the impact of floods and droughts on trout populations for 127 fish sampling sites in the GRSM between 1990 and 2007. The Hydrological Simulation Program - FORTRAN (HSPF) was used to model flows at each ungaged fish-sampling stream site. The ecohydrologic regimes, characterized using the indicators of hydrologic alteration (IHA) method, were statistically correlated with trout population data to evaluate the influence of hydrological disturbances to trout populations in the GRSM.

Methods

Study Area

The GRSM lies in the Blue Ridge physiographic region, located in the Southern Appalachians in eastern Tennessee and western North Carolina. The physiographic region is characterized by rugged topography, heavily forested slopes, and steep mountain streams. Streambeds are dominated by boulder and cobble, and gradients of the stream channels increase with elevation (Larson and Moore 1985). The climate of the GRSM can be described perhumid mesothermal with seasonal temperature variation and precipitation distributed throughout the year.

The average annual rainfall varies significantly throughout the park with lower elevations generally receiving near 127 cm and some higher elevation sites more than 215 cm (NCDC 2008). Most summer rainfall occurs during thunderstorms and an occasional tropical storm. Winter precipitation is associated with large-scale frontal systems. Summer and early spring generally have the most abundant precipitation, with rainfall averages of 12.7 cm and 20.3 cm per month in lower and upper elevations, respectively. Autumn is the driest season due to slow-moving high pressure systems, with rainfall averages around 7.6 cm and 12.7 cm per month in lower and upper elevations, respectively.

Brook trout is the only salmonid species indigenous to the southern Appalachian Mountains. Rainbow trout were introduced into GRSM streams in the early 1900's and often live sympatrically with the native brook trout (Larson and Moore 1985). Rainbow trout usually dominate lower elevation streams, whereas brook trout are predominantly found in headwater streams.

GRSM fishery biologists have surveyed brook and rainbow trout populations at 369 sites in 69 different streams since 1990 (Moore and Kulp 2007). Trout samples are collected in the summer and early fall (May to October) using backpack electroshocking units. Most sites are surveyed every 3-5 years; approximately 25 sites are surveyed annually. Trout are collected from a 100 m representative section of stream by a standard three-pass removal technique (Reynolds 1996). Trout are

separated into two age groups, young of year (YOY) and adults, and are measured for total length (mm) and weight (g). Trout less than 100 mm in length are classified as YOY. Using a maximum likelihood estimator, population estimates are generated based on the number of trout sampled from a section of stream. Trout densities are calculated as population per unit area of stream (number of trout/100 m^2). Trout biomass is reported as kilograms of trout per hectare (kg/ha).

The current study evaluates trout survey data for the period 1990-2007. We assumed trout sites within a 700 m reach did not have significantly different hydrology, and combined sites within this distance when confluences and physical barriers did not separate them. Trout data was averaged for combined sites.

Hydrology Model

HSPF, developed through the U.S. Environmental Protection Agency (USEPA), was used to model flows at the 127 ungaged fish-sampling stream sites. Watersheds for each of the study sites were delineated using a Digital Elevation Model (DEM; cell size = 9.13 m^2) in ArcMap 9.2 and brought into Better Assessment Science Integrating Point and Nonpoint Sources (BASINS). Watersheds were characterized using manual delineation to represent the topography (DEM), streams (National Hydrologic Dataset), and ArcMap created subbasin boundaries. BASINS used these three layers to create the map layers required for setting up the HSPF model, including defining and physically characterizing the stream network, calculating subbasin slopes and areas, and defining outlets. Additionally, a landuse layer was created, characterized as forest or field, and incorporated into the model.

Three gaged watersheds were used to define and calibrate hydrologic parameters in HSPF. This included two USGS gages (Stations 03497300 and 03460000) and a high-elevation H-flume at Noland Divide (Cai and Schwartz 2008). A three-tier hydrologic parameter band was used assuming the major change in the hydrologic parameters was primarily due to elevation differences. Subwatersheds were associated with outlets a) above 1200 m with the Noland Divide high-elevation parameters, b) between 800 m and 1200 m with Station 03460000 middle-elevation parameters, and c) below 800 m with Station 03497300 low-elevation parameters.

Time series data including hourly potential evapotranspiration (calculated from daily high and low temperatures and latitude) and hourly precipitation were required to simulate hydrology in HSPF. Hourly rainfall and daily temperature data were acquired for 16 stations from sources including the Tennessee Valley Authority, the National Oceanic and Atmospheric Administration through the National Climatic Data Center (NCDC), and the National Park Service (NPS). Seven different climate layers containing a unique combination of the weather stations were used to simulate the study watersheds throughout the GRSM. Weather data was segregated into high- and low-elevation classes, defined at 1000 m.

The model was calibrated by adjusting hydrologic parameters including storage, infiltration, runoff, and groundwater for three elevation classes (low<800 m $\leq$ middle $\leq$ 1,200 m < high) to observed flows from the aforementioned gaging stations. The calibration period for both USGS stations (03497300 and 03460000) was approximately 10 years. First, the annual water volume balance and parameters controlling groundwater and evapotranspiration losses were adjusted. Monthly

volumes and baseflows were examined by adjusting parameters including infiltration, monthly evapotranspiration rates, and storage capacities. To fine-tune the peak of the hydrograph and the recession rate, the hydrograph shape, and interflow and upper zone storage parameters were adjusted. Yearly and monthly volumes were examined during calibration. During model calibration, annual volume differences less than 15% were deemed acceptable (Donigian et al. 1983). Models with a coefficient above 0.6 were considered to perform satisfactorily (BASINS 2007). Additionally, the Nash and Sutcliffe (1970) coefficient of efficiency (NSE) was used to evaluate model performance, with NSE values greater than 0.36 considered acceptable (Kim et al. 2007). After the model was calibrated and met the visual and goodness-of-fit criteria, Station 03460000 was modeled for a five-year validation period. Finally, the hydrology of each of the 127 trout sites were simulated for the period between January 1, 1990 and December 31, 2007 corresponding to the years the GRSM has surveyed trout populations.

Indicators of Hydrologic Alteration

Hydrologic regimes were assessed using a method proposed by Richter et al. (1996) referred to as the IHA method. Once hydrology simulations of the trout sites were completed, daily flows for each site were characterized into ecologically relevant parameters using IHA software developed by the Nature Conservancy. The IHA program calculated 32 parameters organized into five hydrological groups to statistically characterize hydrologic variation in the flow regime, including ecologically-significant flow parameters of magnitude, timing, frequency, duration, and rate of change. Additionally, environmental flow components (EFCs) were calculated to include five components important to river ecosystem health; including extreme low flows, low flows, high-flow pulses, small floods, and large floods. The IHA and EFC parameters were calculated using non-parametric (median and percentile) statistics because of the non-normal nature of the hydrology data.

Statistical Analyses

The relationship between trout populations and hydrology patterns over the entire study period was examined. The 67 IHA hydrology parameters were statistically compared to brook and rainbow trout metrics including density (YOY and adult), total biomass, and ratio of brook adult density to rainbow adult density for each site. The means of IHA variables were normalized among sites by taking IHA variables with units of flow and dividing them by the mean flow (average of the monthly medians). Nonparametric multivariate analyses were performed to define significant correlations between the trout metrics and normalized IHA variables. Relationships between each IHA hydrology variable and trout metric were examined using the Spearman's Rho. A relationship among trout and predictor variables was considered significant if the p-value was less than 0.05.

The relationship between trends in trout populations and hydrology were also evaluated. We defined a trend as a discernable decrease or increase in a trout metric for three or more consecutive years with a correlation coefficient above 0.70. YOY trout were excluded from this analysis because of high variability in the data. Once trends were identified, a linear regression was performed; the slope of the regression

was used to characterize the trend. The IHA hydrology variables during the periods of the identified trout population trends were characterized. Nonparametric multivariate analysis of trends of trout metrics and corresponding IHA parameters were used to identify significant correlations between trout population trends and hydrology. An additional variable, trout watershed area (in thousandths of hectares – same order of magnitude), was incorporated in this analysis as well. The criteria set for examining significant results was $p < 0.01$ for brook trout and $p < 0.05$ for rainbow trout.

To evaluate the relationship between hydrological extremes and trout abundance, three IHA variables were chosen to represent hydrological extremes including the 10-year flood, the two most extreme 90-day minimum flows, and the two largest 2-year floods. The 90-day minimum was used because it characterized an extended dry period which has been shown to significantly affect aquatic communities (Lake 2003). Trout populations were examined for a four-year period during these extreme hydrologic events. Adult brook and rainbow densities, and total biomass were examined before, during, after, and two years following the floods and droughts. The affects of the floods and droughts on the YOY brook and rainbow trout population densities were evaluated by comparing the mean YOY population and the post-drought population. Over 50 data points were used for each year in both the flood and drought analyses. Means were compared using Student's t pairwise comparison test and considered significant at the $\alpha = 0.05$ level. Outliers, determined by standardized residuals by finding the residual and sample standard deviation, were omitted. A least squares difference matrix and ordered difference report were used to examine the results of the means comparison.

Results

The visualization plots and goodness of fit measures for calibration and validation indicated the HSPF hydrology model was able to adequately represent the hydrological processes in GRSM and were aligned with USEPA recommendations (USEPA 2000). Output from the calibrated models of the two USGS gaging sites indicated better than satisfactory model performance and met simulation objectives. The hydrologic modeling results from Station 03460000 during the validation period verified the performance of the model and also met stipulated criteria. Calibration and validation results by month showed the model generally met the 15% volume difference, but consistently overestimated fall flow rates, although the majority of R^2 values and Sutcliffe values were within the acceptable range.

Brook trout were more abundant in streams with larger fall flows as evidenced by positive correlations with mean stream flows in September, October, and November. Additionally, brook trout were also positively correlated with high and low pulse lengths. Brook trout were less abundant when streams had larger spring flows as indicated by the negative relationships with mean stream flows in February, March, April, and May. Brook trout were also negatively correlated with the fall rate and reversals. A higher ratio of brook trout adult densities were found in streams with higher mean monthly flows in the fall; alternatively, lower density ratios corresponded to higher mean monthly flows in the spring. Rainbow trout were more abundant in streams with larger mean spring flows indicated by positive correlations

with stream flows in March, April, and May. Rainbow trout were also positively correlated with reversals. Rainbow trout were less abundant in streams with longer high and low pulse lengths.

Brook trout in smaller watersheds have greater increases and decreases in population such that larger streams have less steep trends than headwater streams. Brook trout increases in abundance positively correlated with increases in high and low pulse lengths. A decrease in the ratio of brook trout adult density to rainbow trout adult density was correlated with decreases in February and March mean flows.

YOY brook and rainbow trout populations decreased in following droughts and floods. Adult brook trout densities and total brook trout biomass significantly increased two years following droughts. Adult rainbow trout densities and rainbow trout total biomass significantly decreased following droughts and recovered the following year. Adult brook densities were not significantly affected by larger floods. Adult rainbow densities did not significantly decline a year following floods, but significantly decreased two years following the extreme hydrologic event.

Discussion

Brook trout were found to be more abundant in streams with larger mean flows in autumn which corresponds to spawning (Etnier and Starnes 1993; Moore and Kulp 2008). Lower mean flows during these critical months were found to harm recruitment especially after severe droughts occurring in late summer and early fall. Low flows associated with a severe drought may have influenced brook recruitment in several ways: 1) adult brook trout surviving the drought months likely had diminished body fat reserves leading to reduced egg deposition (Canton et al. 1984); 2) low water levels during autumn months would expose more streambed and decrease available spawning habitat (Hakala and Hartman 2004); and 3) lower flows may have enabled sediment to deposit on redds, possibly reducing oxygen for the embryos (Reice et al. 1990). Hydrograph fall rates were also seen to be negatively correlated with brook trout abundance and may have impacted recruitment by exposing eggs and thereby causing desiccation of redds. Adult brook trout were found to be more resistant to severe drought than YOY trout. YOY trout may be less tolerant than older trout of increased temperatures and decreased oxygen content associated with lower flows (Closs and Lake 1996). Decreased riffle habitat may have also led to the increased mortality of YOY trout (Cowx et al. 1984). Similar to brook trout, rainbow trout were found more abundant in streams with a larger mean flows when spawning occurs. Rainbow trout spawn from late winter to early summer, and would similarly have better recruitment with better habitat conditions influenced by hydrology.

The strong influence severe droughts have on rainbow trout abundance was apparent from the results. Similar to brook trout YOY, rainbow YOY densities declined significantly after major droughts. Unlike adult brook trout, adult rainbow densities and total rainbow biomass significantly declined after severe droughts. These declines could possibly be attributed to: 1) adult rainbow trout being significantly larger than brook trout and having a harder time finding refugia (Moore and Kulp 2008); 2) diminishing habitat and food both of which would cause increased competition during drought conditions (Canton et al. 1984); and 3) rainbow trout are

not native and would not have evolved survival traits specific to streams of the Southern Appalachians (Moore and Kulp 2008). Adult rainbow abundance did show a strong recovery the second year after the drought to near pre-drought levels, which indicated the resilience of the species.

Brook trout were found less abundant in streams with larger mean spring flows and this may be due to smaller yearly recruitments associated with loss of redds, or displacement of recently hatched YOY by stronger currents (Harvey 1987). Large flood events also usually occurred in late winter or early spring, corresponding to incubation and emergence of the brook trout year class. There were significantly fewer YOY brook trout after large flood events. This may be attributed to incubating eggs and YOY trout not being able to maintain their position under strong currents and being swept downstream against debris and substrate. Seegrist and Gard (1972) and Carline (2003) both found similar results and concluded winter floods destroyed incubating or recently emerged year classes. Adult brook densities, however, did not change significantly after large flood events. This is likely due to their strong swimming ability and ability to find refugia in complex habitat morphology. Like brook trout, rainbow YOY densities sharply declined after larger floods, where as adult densities did not.

The reason smaller streams have steeper shifts in brook trout populations may be attributed to increased frequency of extreme hydrological events and less habitat and refugia to take shelter in during large disturbances (Elwood and Waters 1969). Larger streams may be more diverse and would be able to provide more refugia such as deep pools which would be utilized under extreme hydrological events (Pearsons et al. 1992). Smaller streams would also have smaller numbers of trout and be limited in their total production, and thereby would be more vulnerable to larger shifts in abundance caused by extreme hydrological events.

Characterizing stream ecosystems and evaluating the ecohydrology relationships was better utilized when the species traits were examined. Mathews and Richter (2007) suggested looking at ecohydrology relationships utilizing IHA metrics in stages corresponding to important life cycles of the aquatic species of interest. Their proposed IHA methodology was successfully demonstrated in this study. By identifying the important life cycles of both brook and rainbow trout, such as spawning and emergence, and splitting the trout populations into two separate age-groups, the ecohydrology relationships were identified and useful conclusions were made on how hydrological patterns influence the population dynamics of brook and rainbow trout in the GRSM.

Stream hydrological patterns do play an important role in determining the abundance of brook and rainbow trout in the GRSM. The magnitude and timing of extreme hydrological events, such as droughts and floods, was shown to be a major regulator of trout assemblages. The mean magnitude of monthly water conditions demonstrated dominant controls in the distribution and abundance of rainbow and brook trout. Trout spawning success was also strongly dependent on hydrology with the strength of yearly recruitments shown to correspond to certain hydrological patterns. In addition, the IHA software was shown to adequately characterize the flow regime into manageable ecohydrology parameters that could be statistically compared to brook and rainbow trout abundance. The conclusions of this study helps

GRSM fisheries biologist understand how certain hydrology patterns and extremes influence the brook and rainbow trout populations, allowing them to more effectively manage valuable GRSM resources.

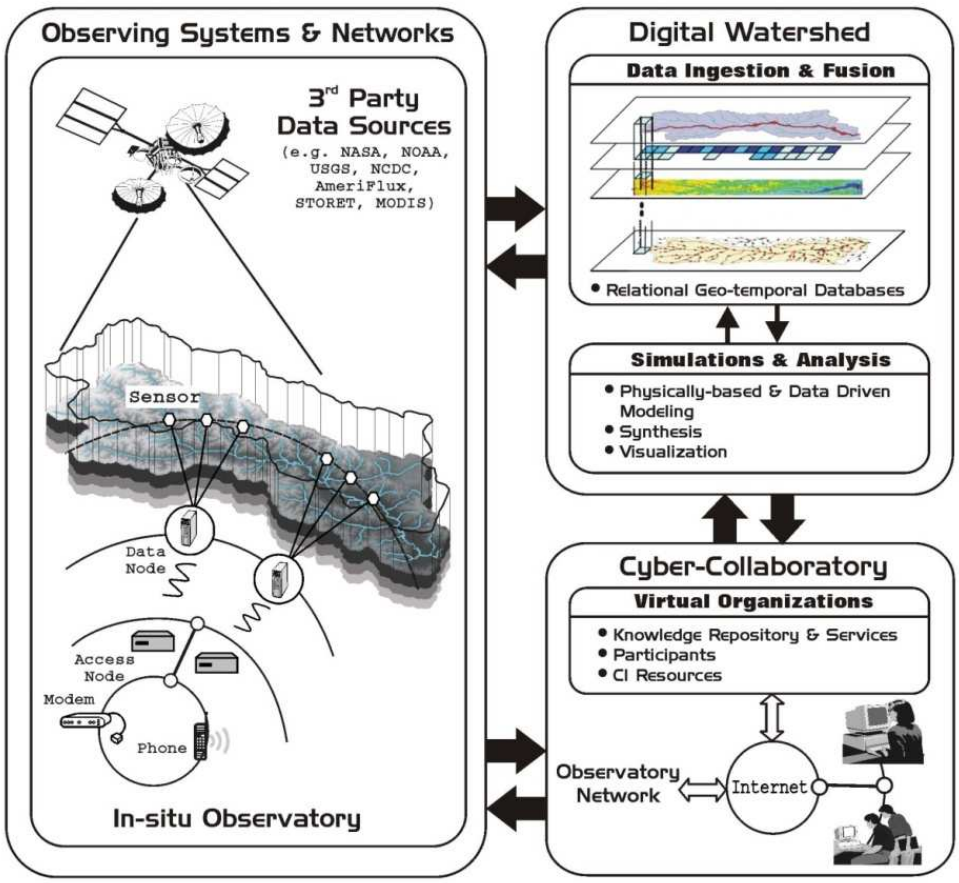
Abstract

The University of Iowa's IIHR - Hydroscience & Engineering is creating an *envirohydrologic* observatory on Pool 16 of the Upper Mississippi River. Centered at the Lucille A. Carver Mississippi Riverside Environmental Research Station (LACMRERS), the observatory's sensor network will collect highly time resolved data to support modeling efforts for water quality and watershed process studies. Coupling sensor data with models will enable testing of existing hypotheses and will generate new hypotheses focused on water quality, nutrient, and sediment fluxes as they relate to food webs containing freshwater mussels and microbes. One hypothesis currently under investigation is that intense deposition of particulate organic matter from extreme flooding alters these food webs through physical and chemical means.

1. Introduction

Society's current water use practices have caused much concern for diversity and health of water-cycle systems at local and regional scales. Natural processes within watersheds can often be significantly altered by human activity. Studying these human-water dynamics has proven to be quite difficult due to complexity of the processes involved. However, the environmental engineering and hydroscience communities have developed a new investigative approach which considers all water cycle components and their interactions with the ecological, biogeochemical, and human systems at the watershed-scale (Muste et al. 2009). The new approach responds to the challenges of the human-water dynamics by creating *envirohydrologic* observatories, utilizing digitally-based remote and in-situ observation and communication technologies integrated with relational geospatial databases and high-performance computing.

The creation of these observatories is being led by two relatively new National Science Foundation (NSF) communities: the Consortium of Universities for the Advancement of Hydrologic Science, Inc. (CUAHSI) and the Water and Environmental Research Systems Network (WATERS Network). These two organizations have been promoting the development and implementation of the cyberinfrastructure (CI)-based environmental observatories for the investigation of watershed processes. The observatories facilitate full-scale hypothesis testing and verification of pilot-study findings through the observations made at large scales in comparable settings (Muste et al. 2009). The observatories enable the cross-disciplinary process discovery and understanding through observation, simulation, analysis, and knowledge synthesis using components and connections similar to those illustrated in Figure 1.



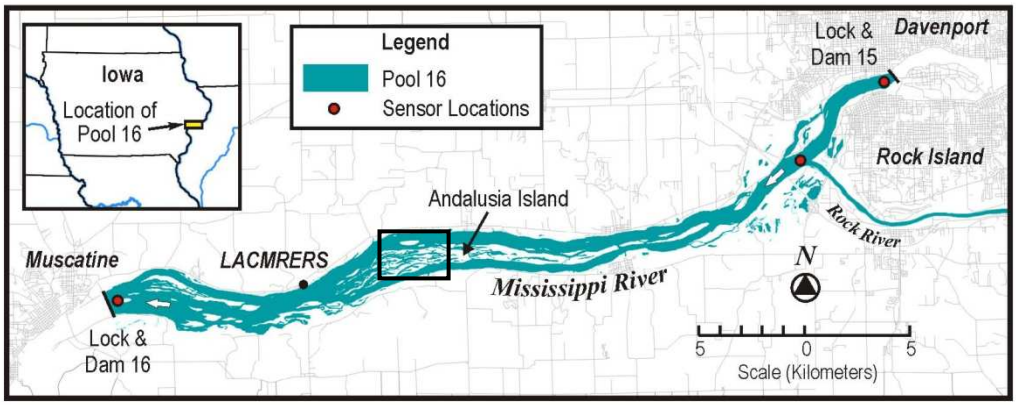


Figure 1: Conceptual configuration of the CI-based environmental observatory (Muste et al. 2009).

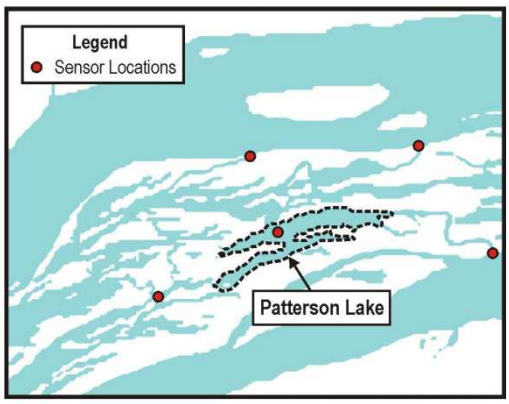

Figure 1 illustrates integration of the in-situ observatory, compiled digital watershed, and collaboration of virtual organizations for the Clear Creek watershed, located near Iowa City, Iowa. With the successful creation of an observatory at this small local scale, the investigators seek to implement an observatory along a segment of the Mississippi River near Muscatine, Iowa.

2. Observatory Location

The University of Iowa's IIHR - Hydroscience & Engineering (IIHR) is in the process of creating an Environmental - Hydrologic Observatory on Pool 16 of the Upper Mississippi River Basin (UMRB). Pool 16 of the UMRB extends 41 kilometers from Mississippi Lock and Dam 15 near Rock Island, Illinois to Lock and Dam 16 near Muscatine, Iowa (see Figure 2a). The only major tributary to Pool 16, the Rock River, enters just south of Rock Island. The Andalusia Island Complex dominates a significant stretch of the pool (see Figure 2b). IIHR's Lucille A. Carver Mississippi Riverside Environmental Research Station (LACMRERS) is located adjacent to Pool 16 in Fairport, Iowa. This project will provide proof of concept in acquisition and application of highly time resolved data to accurately predict the movement of water, nutrients, or sediments over broad geospatial and temporal scales.

(a)

(b)

Figure 2: (a) Navigation Pool 16 on the UMRB with locations for primary monitoring stations. (b) Five stations will be used to monitor primary inlets and outlets to Patterson Lake and within the lake in the Andalusia Island Complex.

High-frequency observations at different scales will allow conservation and transport equations for water, nutrients, and sediment to be parameterized, optimized, and solved. This will enable accurate analyses of water quantity and quality subject

to changing climate, nonpoint sources of nutrients causing coastal hypoxia, and total dissolved and suspended solids. Sensors deployed within Clear Creek watershed have proved dependable for measuring water constituents.

Past studies of nutrient levels in the Mississippi River generally focused on data from single locations, which was then used to upscale nutrient loads for entire pools. Concurrent data from multiple locations will enable more accurate modeling of nutrients along a defined stretch of the river due to major events (from major floods, to isolated events along a tributary, to agricultural trends), seasonal fluctuations, and role of nutrient processing within the pool.

State-of-the-art sensors featuring the latest remote communication technologies are placed at the entrance and exit of Pool 16 at the mouth of the Rock River and within the Andalusia Island Complex for long-term study of:

1) Water Balance: Continuous information on the volume of water entering Pool 16 via the main Mississippi channel, tributaries, and precipitation, and the volume of water exiting Pool 16 over several years will enable more accurate modeling of river response to climatic events and very accurate modeling of the mass of transported sediment and nutrients.

2) Nutrient Load: Continuous monitoring of nutrient transport at the inlet and outlet of Pool 16, the Rock River, and other locations within the Pool will allow the researchers to track changes over time and space. Results from this study may create a more complete understanding of nutrient transport in the Mississippi River from its upper reaches to the Gulf, and have significant implications on our understanding of hypoxia.

3) Sediment Load: Like nutrient load, sediments entering and exiting Pool 16 will be closely monitored to quantify sediment load in the Pool and to establish temporal and geospatial trends. Sediment transport within the river channel, erosion/deposition trends along the banks, sediment composition, sediment provenance, and other parameters will be examined.

3. Sensor Network

Each sensor cluster in Pool 16 (currently at various levels of completion) is data logging and telemetry-enabled via a Campbell Scientific CR1000 datalogger, an AirLink Communications Raven CDMA cellular modem, two NP12 rechargeable batteries and charge controllers, and two BP SX20U solar panels (see Figure 3).

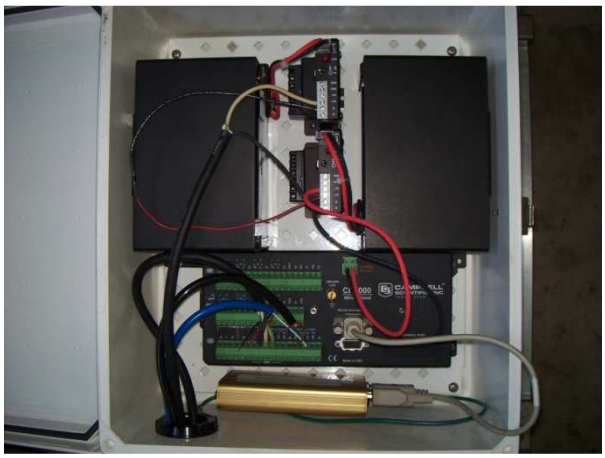

Figure 3: Components of sensor cluster including datalogger, cellular modem, batteries and charge controllers.

The networking equipment has been coupled with a Hach DS5X water quality sonde, a Forestry Technology Systems DTS-12 turbidity probe, and a Hach Nitratax UV sc plus nitrate sensor (see Figure 4). Real-time parameters measured at these sites include: dissolved oxygen, pH, conductivity, temperature, turbidity, and nitrate-N.

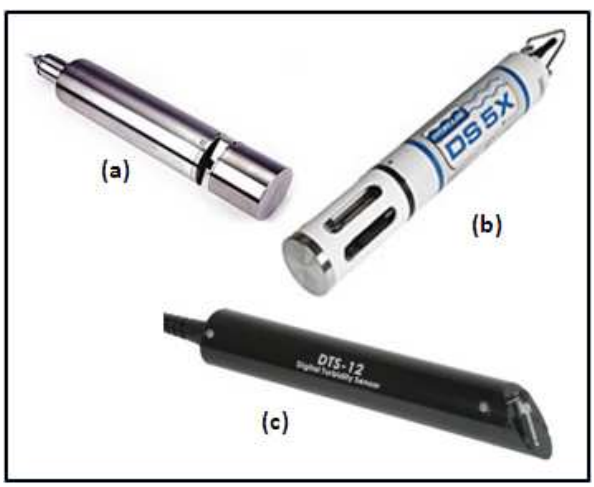

Figure 4: Sensors used to measure water quality include (a) a Hach Nitratax UV sc plus nitrate sensor, (b) a Hach DS5X water quality sonde, and (c) a Forestry Technology Systems DTS-12 turbidity probe.

For field deployment, each of the three sensors is individually housed in constructed PVC pipe units and placed in the selected location. The housing units provide protection for the sensors. Holes drilled in the PVC pipes allow water parameters to be measured (see Figure 5a). Sensor cables are attached to a log chain and submerged. The cable ends are attached to the networking equipment located at the top of a 14-foot ladder (see Figure 5b).

(a) **(b)**

Figure 5: (a) Sensor housing unit placed in water connected to (b) the networking and logging equipment placed on top of ladder.

Ladders (secured to nearby trees) were utilized to maximize the modem's antenna signal, as well as to insure the networking equipment would not be inundated during floods. Locating the network equipment well above the normal pool level will prevent damage caused by devastating floods such as those which occurred in Eastern Iowa and nearly the entire UMRB during May-July 2008. In Pool 16, waters abruptly rose from a highly managed stage of approximately 10 feet to 20 feet and then to nearly 24 feet from May-June 2008 (see Figure 6).

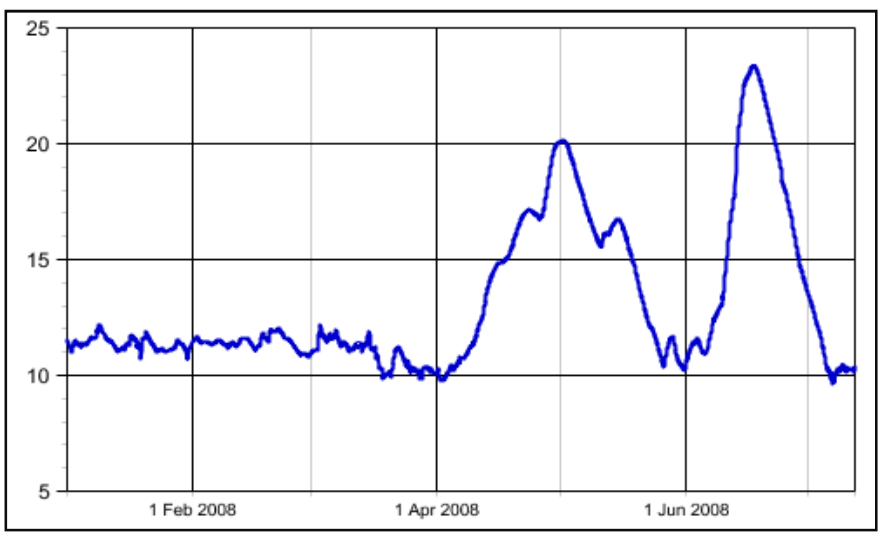

Figure 6: A hydrograph showing Pool 16 stage (in feet) versus time during 2008 (derived from USGS data).

Sensors in the envirohydrologic observatory have collected concurrent data at 15-minute intervals (e.g. dissolved oxygen, turbidity, nitrate, pH, temperature) from multiple locations to enable the modeling of diurnal phenomena and processes

associated with extreme events. As more data are collected over time, measurements will enable the study of seasonal fluctuations and will help to better determine Pool 16's nutrient processing dynamics.

4. Impact of Extreme Events on Mussels and Nutrient Processing

Data collected using the Pool 16 envirohydrologic observatory is currently being used to investigate the influence of extreme flood events on freshwater mussels and nutrient processing. Freshwater mussels and bacteria play a major role in nutrient processing in large river ecosystems by further cycling nutrients taken up by phytoplankton and zooplankton. Under typical ecosystem conditions, mussels appear to process nitrogen more rapidly than denitrifying bacteria (Gardner et al. 1995). Substantial deposition of carbon-rich sediment resulting from extreme flooding may increase nitrogen cycling rates by bacteria and thus alter overall denitrification rates.

It is also known that mussels and bacteria play a major role in nutrient cycling in the broad food web containing phytoplankton, zooplankton, micro-zooplankton, dissolved and particulate organic matter, and benthos (see Figure 7).

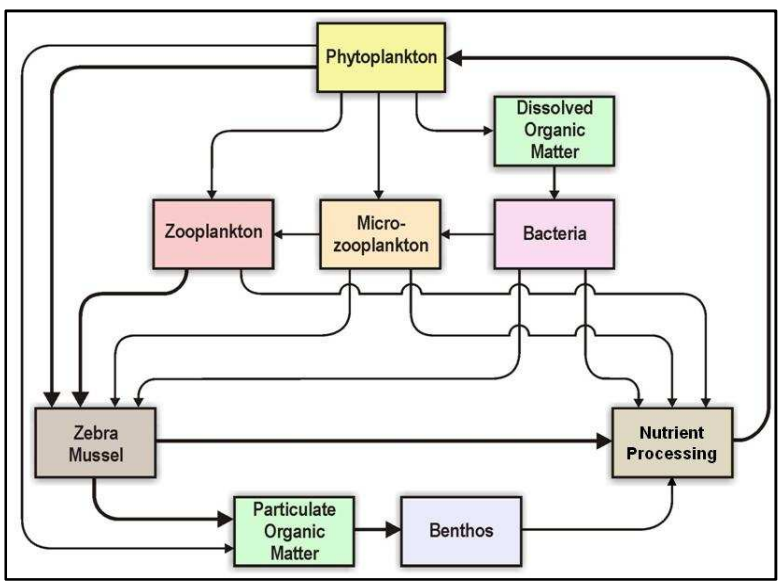

Figure 7: Nutrient cycling during quiescent conditions. Bold lines indicate more significant processing pathways.

Currently, researchers have been focusing on a well characterized Pool 16 mussel bed near Buffalo, Iowa. A substantial number of adult and juvenile mussels, including the federally endangered Higgins Eye mussels, were observed at the site in October 2003 (Helms 2003) and again by the investigators in October 2008. Physical features of the mussel habitat will be characterized using multibeam sonar, and will be compared with bathymetric data collected in 2005 to quantify sediment deposition (Young 2006). Sediment cores will be obtained throughout the bed to determine particulate deposition characteristics from the 2008 flood.

In addition, flow data from USGS and US Army Corps of Engineers gauging stations in Pool 16 will be used in conjunction with nutrient data collected from

municipal drinking water treatment plants and the USGS National Water-Quality Assessment Program (NAWQA) to estimate nutrient mass fluxes before, during, and after the flood. Data from these existing sources will complement data compiled from several post-flood installed sensors located in Pool 16. Data analysis will determine how the mussels' ability to process nutrients may have been affected by the flood event.

Lab experiments are being conducted to explore the effect of intense organic matter deposition on mussels. Using intact sediment cores from the mussel bed in Pool 16, the researchers will use two sets of pseudo-sterilized habitats, one with microbes only and one with a microbial-mussel co-habitated system (Lavrentyev, Gardner and Yang 2000). Mussels to be introduced to the microbial-mussel systems have been collected from the Pool 16 habitat.

One set of the microbes only and microbial-mussel lab systems will contain sediment cores of carbon-rich, flood deposited sediment while another set will contain cores containing older sediments. River water will be continuously pumped through each of the systems at a flow rate of 1 mL min^{-1}. To measure nitrogen processing rates for the bacteria and mussels, the stable isotope ^{15}N-ammonium will be fed into the systems. Microbial denitrification rates will be measured through acetylene blockage techniques. Initial studies on nitrate transformation capacity revealed that bacteria in the organic rich sediments from the mussel bed were capable of completely removing nitrate within 72 hours, compared to no removal in the mildly organic sediments (see Figure 8).

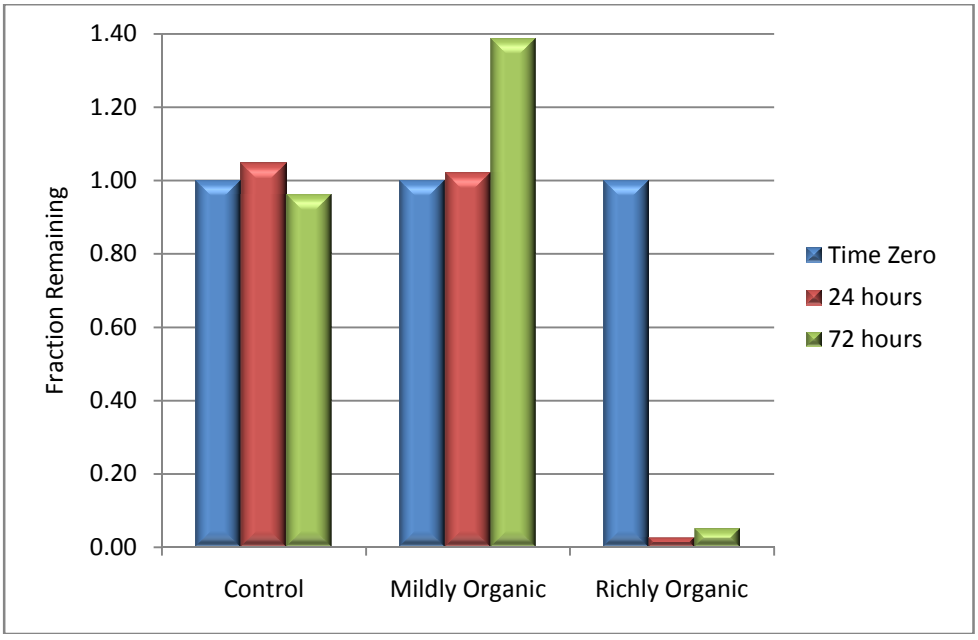

Figure 8: Initial studies on nitrate transformation capacities in mussel bed sediments.

Also, most probable number techniques will be used to quantify total heterotroph and total denitrifying populations. Finally, the researchers will use molecular methods to measure reductase enzyme activities in the microcosms.

5. Scaling Research

Scientific understanding of water related processes is currently limited by an inability to describe how heterogeneous processes interact at different scales to produce the variability witnessed in the water environment (Butcher and Covington 1995). For example, Figure 9 displays dissolved oxygen (D.O.) measurements for the Clear Creek headwaters, mid-point, and tailwaters.

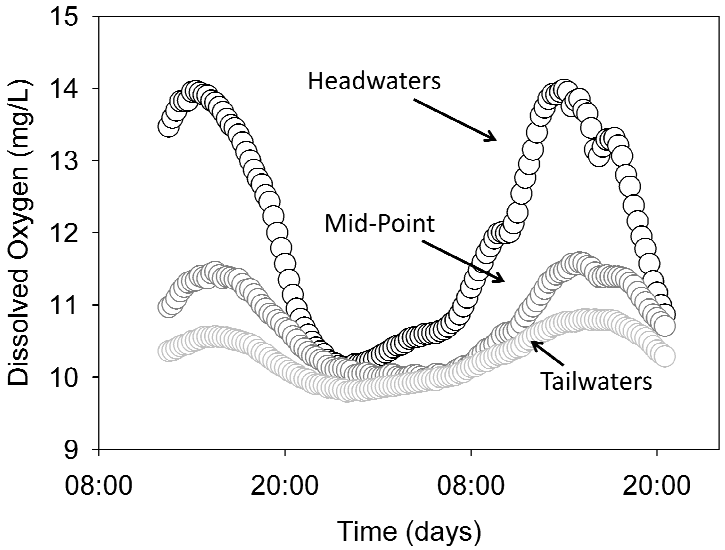

Figure 9: Dissolved oxygen (DO) data collected at three sensing stations located in the Clear Creek Watershed. The largest changes in concentration occurred at the headwaters, and the smallest changes occurred at the tailwaters.

The magnitude of the diurnal cycle for D.O. (in Figure 9) is greatest at the headwaters of Clear Creek then decreases with distance downstream. This provides evidence to support the concept of scaling phenomena in water chemistry processes from small to larger watershed drainage areas. The investigators hypothesize evidence of these scaling phenomena will continue to be observed as research is expanded to the Iowa River and the Upper Mississippi River Basins.

6. Conclusions

Recent historic floods in the Midwest present unique, and short-lived, opportunities to test scientific hypotheses related to a highly perturbed, large river ecosystem. The Pool 16 ecosystem of braided channels and natural backwaters is just one of many Mississippi River subsystems that inadequately process nutrients that contribute to Gulf of Mexico hypoxia. Extreme, flood-related sediment deposition almost certainly impacts the nutrient processing cycle in the short and long term.

This research will expand our limited scientific knowledge of how aquatic environments are affected by increasing human and climate induced changes by using freshwater mussels as a sentinel species. Freshwater mussels have been likened to the "canary in a coal mine" in that their presence in a waterbody is generally indicative of

good sediment and water quality. In addition, mussels provide an integrated record of water quality and current day nutrient dynamics. Understanding how mussels process nutrients in this large river ecosystem is important for engineering, managing, and setting policy to improve and sustain the health of this valuable societal resource. Additionally, the creation of the envirohydrologic observatories will assist in the comprehension of the processes that govern watershed environmental systems, which will in turn aid in watershed management, restoration, and resource optimization.

A COMPARISON OF FORMED SUCTION INLETS FOR FLOOD CONTROL APPLICATIONS

By

David Werth[1], Mark Allen[2] and Brent W. Nicholas[3]

Formed suction inlets (FSI) are commonly used with large vertical pumps in flood control applications. The US Army Corps of Engineers Type 10 FSI is used extensively throughout the southeastern United States. However, variations of this inlet have been utilized with increasing frequency for a variety of reasons including cost, flexibility of use in existing intakes and smaller foot prints.

Type 10 formed suction inlets have a proven record of success in a wide variety of approach flow conditions including high cross flow applications and with less than ideal vertical or horizontal transitions. Published guidelines and extensive field experience provide reliable design guidance for this type of inlet. While design guidance has been published on alternative inlets there is very little information or data available providing a direct comparison of effectiveness between a Type 10 with an alternative FSI.

This paper presents the results of a physical model study which was conducted with the specific goal of comparing the Army Corps of Engineer Type 10 FSI with an alternative "shoe box" version. The model was used to identify surface vortex activity for both types of inlets as well as a comparison of flow straightening and vortex suppression abilities. A side by side comparison of the two different formed suction inlet designs is presented which is useful when evaluating various station and equipment alternatives in flood control applications.

Background

Formed suction inlets (FSI) are very common in flood control applications and have often been used to replace the typical pump bell for a variety of reasons. A discussion by Werth and Zheng (2008) outlined a number of advantages including insensitivity to high cross flow conditions, an ability to eliminate sub-surface vortex activity, and the potential to reduce the required minimum pump submergence to minimize surface

vortex activity. Numerous configurations of formed inlets exist with the most familiar of these designs developed by the U.S. Army Corps of Engineers and referred to as the Type 10 FSI. Design guidelines for the minimum size of the inlet were published by the Corps (Fletcher and Oswald, 1992) and distributed widely in the 1998 Hydraulic Institute Standards (ANSI, 1998). Photo 1 shows a typical Type 10 FSI.

Photo 1 Typical Type 10 Formed Suction Inlets (attaches to pump column)

While the Type 10 FSI is relatively well known there are several other variations of formed inlets, scoops or elbows. Werth and Cheek (2004) presented guidelines for an Alternative FSI which was intended for use under existing pumps with suction bells already installed. The internal geometry of the Alternative FSI varies from the Type 10 FSI in that most surfaces are flat rather than curved but both inlet functions in much the same way. The most significant variation between the two is that the Type 10 FSI attaches directly to the pump column and replaces the pump bell and the Alternative FSI attaches to the floor directly below the pump bell. Photo 2 shows the Alternative FSI.

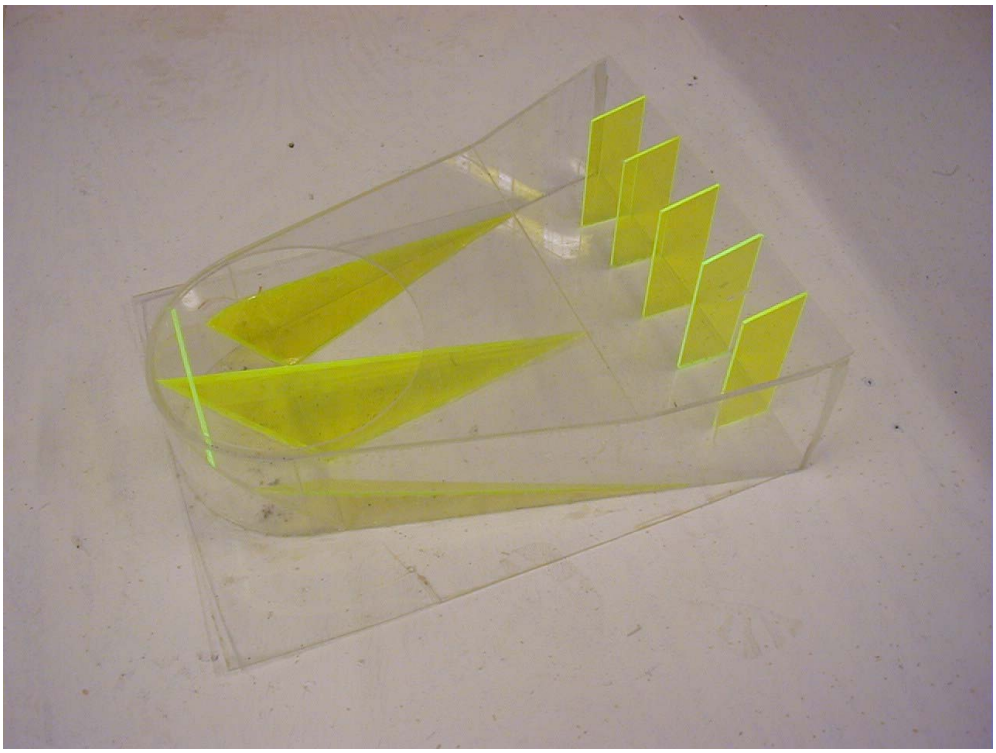

Photo 2 Alternative Formed Suction Inlet (sits under pump bell)

Project Background

Clemson Engineering Hydraulics, Inc. conducted a physical hydraulic model study of the Henderson Bayou Levee, Floodgate and Storm Water Pumping Station for Camp, Dresser, & McKee Inc. (CDM). The intake structure, designed by CDM, will be located in Ascension Parish on the Henderson Bayou and will serve as a flood control pump station. The intake will house a total of three (3) lift pumps, each with a rated capacity of 500-cfs. The pumps will serve as lift pumps by passing flow from the bayou protected side of the pump station to a higher discharge elevation on the opposite side. The primary purpose of the pump station is to protect the Henderson Bayou Watershed from a combined storm event coupled with a high backwater elevation from the Amite River.

The model was used to evaluate the hydraulic conditions within the intake structure and directly compare the Type 10 and "Alternative FSIs. The model was also use to develop recommended modifications as needed to remediate any adverse hydraulic phenomena which could impact pump performance as well as to evaluate the potential for debris accumulation.

Model Configuration

The Henderson Bayou intake will be located within an existing channel that will also house run-of-river sluice gates and a navigation channel. During a coincident storm event and high Amite River backwater event, the sluice gates and navigation channel

gate will be closed and the pump station will operate. Flow transitions from the invert of the channel and station entrance to the invert of the sump via a sloped ramp. The full width of the channel, including the floor topography of the channel entering into the lift station and the floor topography of the navigation channel were included in the model. The entire geometry of the pump station, including the individual bays housing the trash screens, as well as the sloped transition was simulated in detail in the model. Photo 3 shows a model overview.

Photo 3 Model Overview

The Henderson Bayou model was constructed at a 1:12 scale and operated according to Froude scaled flow rates. At this scale the model Reynolds number at the entrance to each inlet (based on an equivalent diameter) was on the order of 1.5×10^5, which is well above the value of 1.0×10^5 recommended by the Hydraulic Institute (1998) for modeling closed conduit pump approach flows.

The individual model pump flow rates, as well as the total model flow rate were determined with an ASME standard orifice meter with an accuracy of +/- 2 percent or better. The water levels in the pump sump were recorded with a staff gauge referenced to the sump floor with an accuracy of 3-mm (0.01-ft) or better Dye was used to visually evaluate hydraulic phenomena including vortex formations. Velocity fluctuations and turbulence levels were measured just upstream of the pump impeller location using a miniature rotor velocity meter. A swirl meter was installed in each pump at the prototype impeller location to measure the level of pre-swirl of flow

entering the pump. Each swirl meter consists of 4 straight vanes mounted on a shaft with low friction bearings. Photo 4 shows the model Type 10 (left and center) and Alternative Inlets (right side) in place in the model.

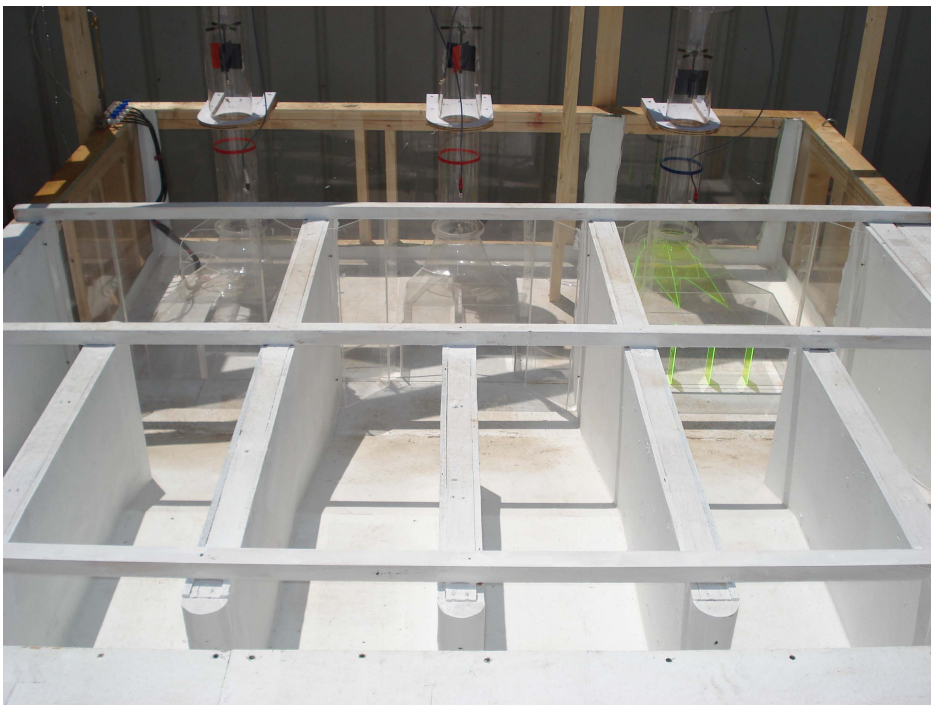

Photo 4 Type 10 FSI (left side) and Alternative FSI (right side)

The Type 10 FSIs were fabricated per the US Army Corps of Engineer Guidelines. The Alternative FSI was fabricated according to Werth and Cheek (2004) as shown below in Figures 1 and 2.

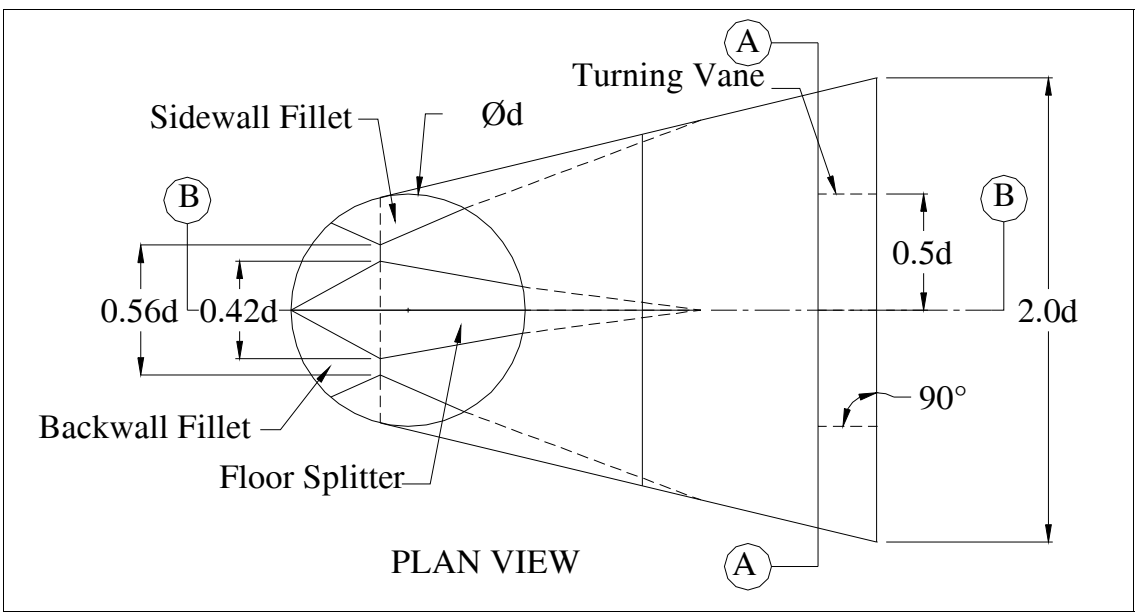

Figure 1 Alternative FSI – Plan View

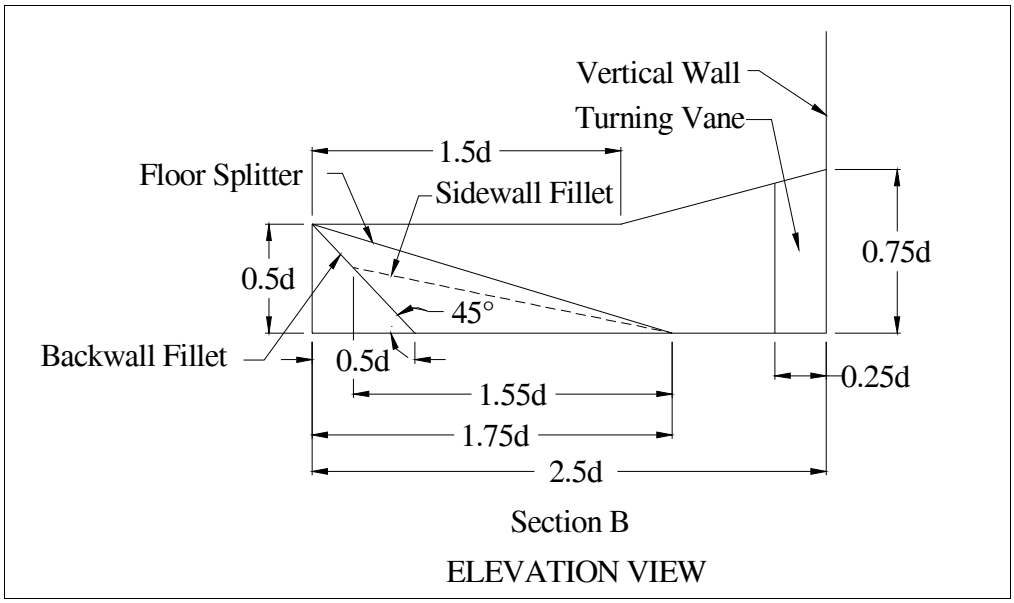

Figure 2 Alternative FSI – Elevation View

Test Results

The intention of the original study was to evaluate the overall performance of the intake structure, including the run-of-river gates and overall approach flow conditions. The intention of this paper is to provide a direct comparison between the Type 10 and Alternative FSI designs in the same intake with nearly identical approach flow conditions. While the project report contains considerable detail this paper presents only conditions observed within the inlets. Flow rates and water levels were the same for both types of inlets allowing for a direct comparison of the results.

The data collected in each type of inlet included velocity measurements around the pump throat location, flow pre-swirl entering the pumps, and vortex activity and overall flow conditions within the intake. Because the intake housed a total of three pumps a Type 10 FSI and an Alternative FSI were installed in the outside pump bays. A slightly modified Type 10 was installed in the center bay but is not part of this comparison. Acceptance criteria was established per the 1998 HI guidelines and included velocity data presented as the maximum individual point deviation from the overall average and should be less than +/- 10%. Turbulence is defined as the standard deviation of the approximately 15,000 velocity samples taken at a single point over a 30-second period divided by the average of those velocity readings. Turbulence should be less than 10%. Pre-swirl should be less than 5-degrees for a traditional pump bell but experience has shown that most FSIs have pre-swirl values less than 2.5-degrees. No organized vortex activity should reach the pump throat.

Ten different pump combinations and water levels were investigated during the baseline portion of the study. While several issues were identified for improvement with the overall structure related to the run-of-river gates and screen chambers the conditions were generally uniform and stable within the inlets.

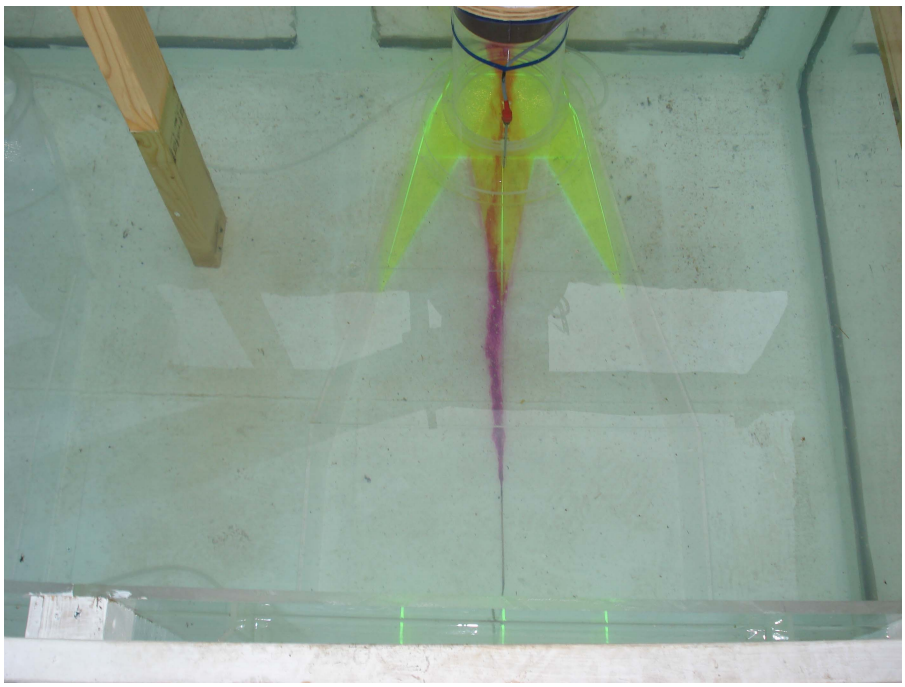

Photo 5 Uniform Flow Inside Alternative FSI

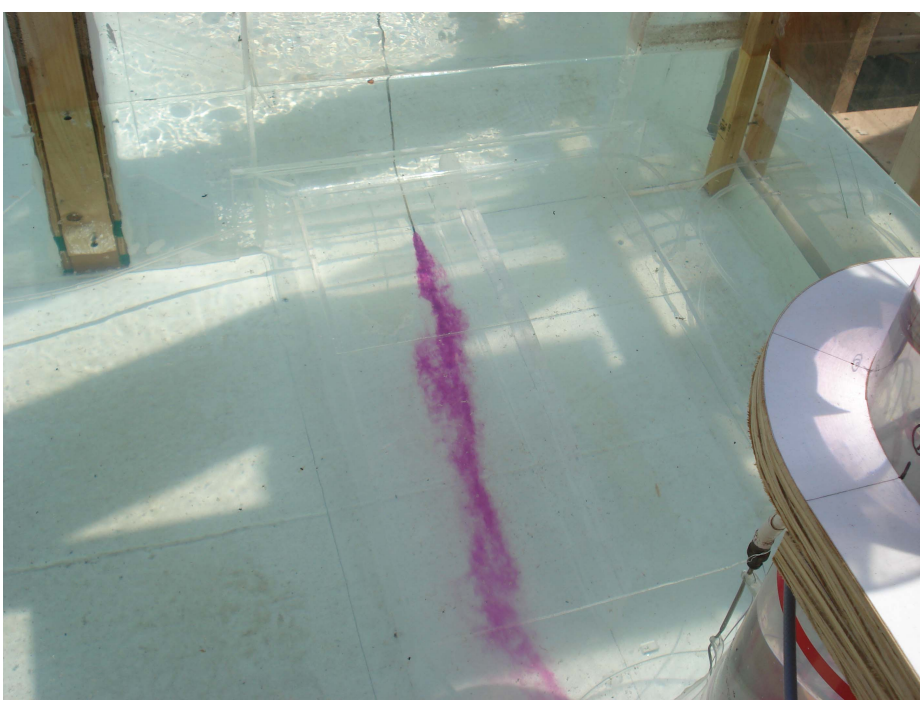

Photo 6 Uniform Flow Inside Type 10 FSI

During all baseline tests the pre-swirl values were less than 1.0-degree in both the Type 10 and Alternative FSI configurations. Velocity and turbulence readings were also within criteria.

Surface vortex activity was present and entered both the Type 10 and Alternative FSIs. Surface vortex suppression beams were installed upstream of each inlet and dissipated this vortex activity. A previous paper by Werth and Zheng (2007) investigated submergence requirements of formed suction inlets and the reader is encouraged to refer to this for additional details regarding submergence requirements.

Conclusions

In any discussion regarding a comparison of different types of pump intakes it is important to note that very few intake structures have identical approach flow conditions, site constraints and operational characteristics. This makes a direct comparison of different types of modifications or inlet alternatives from different studies difficult.

The purpose of this paper was not to determine whether one FSI was better than the other. The purpose was determine whether the two types of formed suction inlets were equally effective in providing pump approach flows within acceptable criteria. Each of the two inlets investigated have advantages and disadvantages and specific project requirements or constraints may dictate a preferred configuration.

The results of this study indicate that both the Type 10 FSI and the Alternative FSI are equally effective at providing acceptable flow conditions at the entrance to the pump impeller. Previous experience has shown both FSI designs to be effective over a wide range of intake configurations but little information existed to determine if they were equally effective under similar approach flow conditions. Both FSI configurations resulted in a similar reduction of pre-swirl, an equal ability to suppress sub-surface vortex activity, an equal tendency for surface vortex formation and both resulted in pre-swirl and turbulence readings that were within established guidelines.

This suggests that design engineers have an additional alternative when evaluating formed suction inlets. In cases where the pump can be readily attached to the inlet a Type 10 FSI may be feasible. In other cases, such as an existing sump, where a pump bell already exists or where a narrower pump bay is desired then the Alternative FSI may be more practical.

Again, the intent of this paper is not to suggest one type of formed inlet is more effective than the other but rather to provide the results of a relatively rare study involving the direct comparison of the two under nearly identical approach flow conditions. These results suggest that both are equally effective at improving the approach flow and resulting in conditions which are well within the established HI

Guidelines. The actual model study is ongoing and no final selections had been made at the time of publication.

CASE STUDY: IMPACT OF VARYING MITERED SUCTION ELBOWS ON LARGE WASTEWATER PUMPS

By

David Werth[1] and Ted Stolinski[2]

Mitered elbows are commonly used for suction inlets on large vertical raw waste water pumps. While information exists regarding the appropriate number of miters or maximum angles to prevent flow separation, little information is available in regards to the impacts on the approach flow conditions into the impeller when used in pump suction piping.

Pump manufacturers commonly use mitered elbows in dry-pit and occasionally in wet pit pump applications. Each manufacturer has a "typical" design with a specific number of miters that is used across a wide range of elbow sizes and turning radii. Experience has shown that in some applications, an insufficient miter design can lead to severe instability of the approach flow into the impeller. Limited design guidance is available to evaluate the impact of mitered elbow design for varying flow rates and suction sizes. The Hydraulic Institute Standard does not address mitered suction elbows mounted directly on a pump suction.

This paper presents the results of a physical model study which was conducted to evaluate an existing raw wastewater pumps station housing five large (40,000 gpm) pumps. The existing station has exhibited a number of issues over the years and when a sixth pump was added, a model study was conducted to evaluate the approach flow conditions. Testing indicated that the mitered suction inlets were causing excessive flow separation and significant velocity variations at the pump inlet. Test results are presented which outline the impact of varying the miter design on pump inlet conditions.

Background

Black & Veatch Corp. is currently overseeing an upgrade to the existing MSD Lemay waste water treatment plant pump station. Currently the station houses five (5) 40,000 gallon per minute (gpm) raw sewage pumps but has an existing suction pipe already in place for a sixth pump. Black & Veatch Corp. is planning to install the sixth pump, also rated at 40,000 gpm in the available pump location. Given a history of

[1] David Werth, Ph.D., P.E. Principal, Clemson Engineering Hydraulics, Inc. Anderson, SC 29625, e-mail: dwerth@ceh-lab.com, Ph. 864-231-9585

[2] Ted Stolinski P.E., Black & Veatch Corp., Kansas City, MO, e-mail: stolinskit@bv.com, Ph. 913-458-3448

accelerated impeller and wearing ring wear Clemson Engineering Hydraulics was commissioned to conduct a physical hydraulic model study of the intake to evaluate the existing and future conditions within the wet-well and suction piping.

Existing Intake

Flow is introduced into the circular structure which is divided into two symmetrical halves, via a common influent channel. After entering the intake flow splits into one of the two halves, each housing up to three pumps. Currently three pumps are installed in one half and two in the other. A series of three (3) 60-inch diameter suction lines withdraw flow from each side of the intake for a total of six (6) pumps. The existing five pumps utilize mitered elbows which transition from the 60-inch suction lines to a 42-inch elbow discharge and then a 36-inch pump suction. The new pump was proposed to utilize a nearly identical mitered elbow but transitions from the 60-inch pipe directly to a 36-inch elbow discharge.

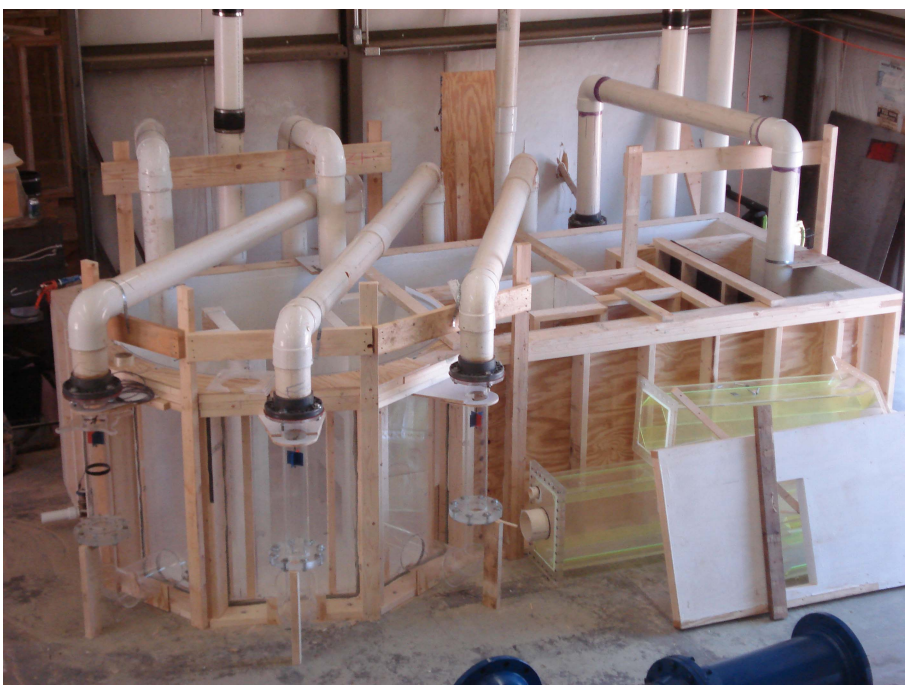

Photo 1 Overview of Pump Station Model

The station currently has the 60-inch suction line for the new pump installed but does not have the mitered elbow in place. The only constraints on the new elbow design was that it be attached to the existing 60-inch suction line and maintained the same pump centerline and discharge location as the existing pumps. The pump manufacturer was responsible for the suction elbow design and utilized a design very similar to the existing elbows. Photo 2 shows a close-up view of the original mitered elbow.

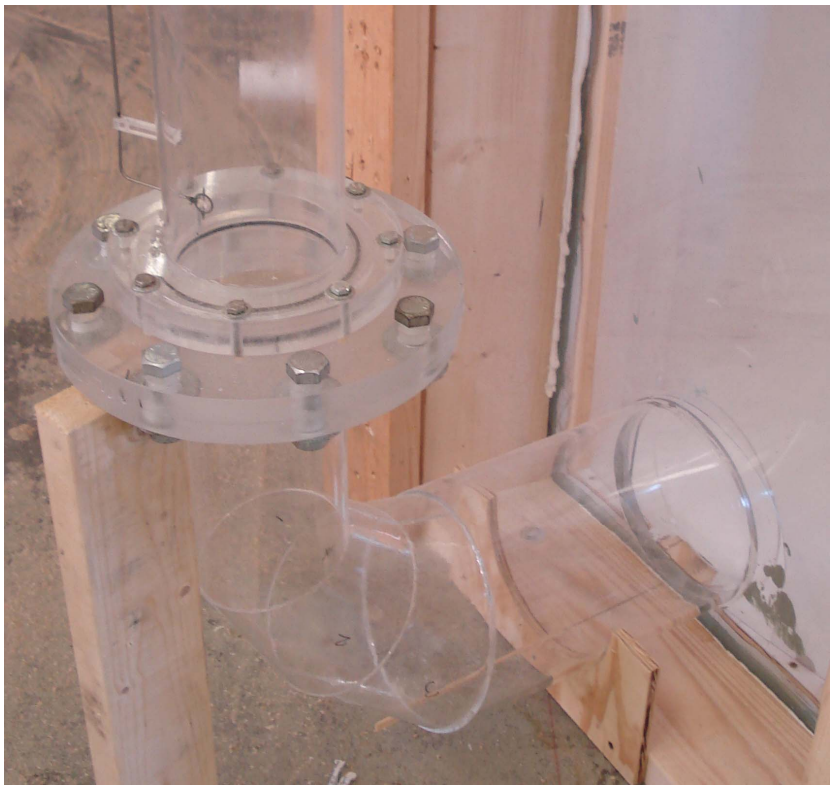

Photo 2 Original Three-Miter Model Elbow

Model Configuration

The Lemay model was constructed at a 1:8.0 scale. The resulting Reynolds number will be on the order of 1.0×10^5 at the 60-inch suction piping and 1.7×10^5 in the suction piping at the pump. The resulting Weber number was approximately 620.

The individual model pump flow rates, as well as the total model flow rate were determined with an ASME standard orifice meter with an accuracy of +/- 2 percent or better. The water levels in the pump sump were recorded with a staff gauge referenced to the sump floor with an accuracy of 3-mm (0.01-ft) or better). Vortex formation was visually observed. Dye was used to aid in the visualization of vortex formation.

Velocity fluctuations and turbulence levels were measured in just upstream of the pump impeller location. A free spinning miniature propeller was used to measure the velocities. A swirl meter was installed in each pump at the prototype impeller location to measure the level of pre-swirl of flow entering the pump. Each swirl meter consists of 4 straight vanes mounted on a shaft with low friction bearings. A lab pump was used to re-circulate flow from the wet well, through the model elbows and back to the model head box.

The original miter elbow proposed for the new pump application was very similar to the existing elbows with the exception of the elbow discharge diameter. The existing

elbows terminate at 42-inches and then utilized a reducer to transition to 36-inches. The new elbow transitioned from 60-inches directly to 36-inches. Figure 1 shows the initial elbow design.

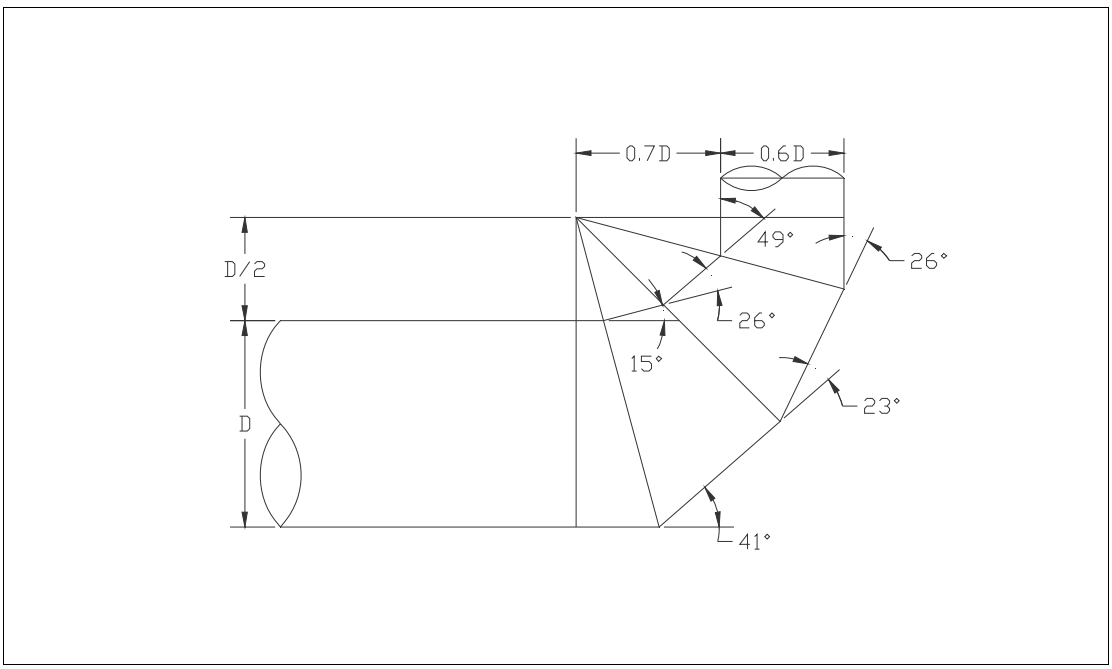

Figure 1 Original Miter Elbow Design

As shown on Figure 2, the drawing the initial design included diverging angles which varied from 15-degrees to 49-degrees. Most design guidelines suggest keeping diverging angles to 10-degrees or less.

Test Results

The intention of the original study was to evaluate the overall performance of the intake structure, including the overall approach flow conditions. The intention of this paper is to provide a comparison between varying mitered elbow designs as part of the overall design. While the project report contains considerable detail this paper presents only conditions observed within the actual mitered elbows. Flow rates and water levels are the same for both types of elbows allowing for a direct comparison.

The data collected in each type of inlet included velocity measurements around the pump throat location, pre-swirl, vortex activity and overall flow conditions. Velocity data is presented as the maximum individual point deviation from the overall average and should be less than +/- 10%. Turbulence is defined as the standard deviation of the velocity samples taken at a single point over a 30-second period divided by the average of those velocity readings. Turbulence should be less than 10%. Pre-swirl

should be less than 5-degrees for a traditional pump bell but pre-swirl values less than 2.5-degrees is preferred. No organized vortex activity should reach the pump throat.

Numerous different pump combinations and water levels were investigated during the baseline portion of the study. During all tests there were significant variations in the velocity profile around the pump throats. Testing revealed a significant region of low velocity on the upstream (short radius) side of the mitered elbow. Velocity readings indicated that velocities on the upstream side were in excess of 30-percent lower than the sides and back of the elbow. The flow rates were adjusted to simulate the velocities going through the existing 40-inch discharge elbows and testing revealed very similar results even with the lower elbow velocities. Photo 3 shows a large region of dye which indicates the low velocity separation zone.

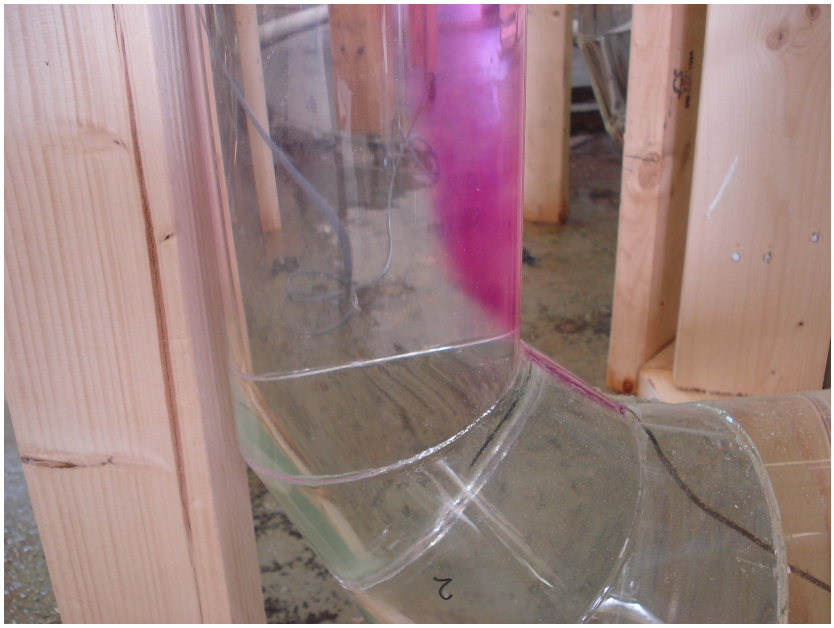

Photo 3 Separation on Upstream Side of Elbow

Numerous turning vane arrangements were investigated but because this is a raw sewage station the design needed to be “open vane” to minimize the potential for debris accumulation. As a result they had limited effectiveness.

Given that the elbow was not yet fabricated for the new pump it was decided to vary the miter design. The elbow was changed from a 3-miter to a 5-miter design. This decreased the maximum diverging angle from 49-degrees to 33-degrees as shown in Figure 2.

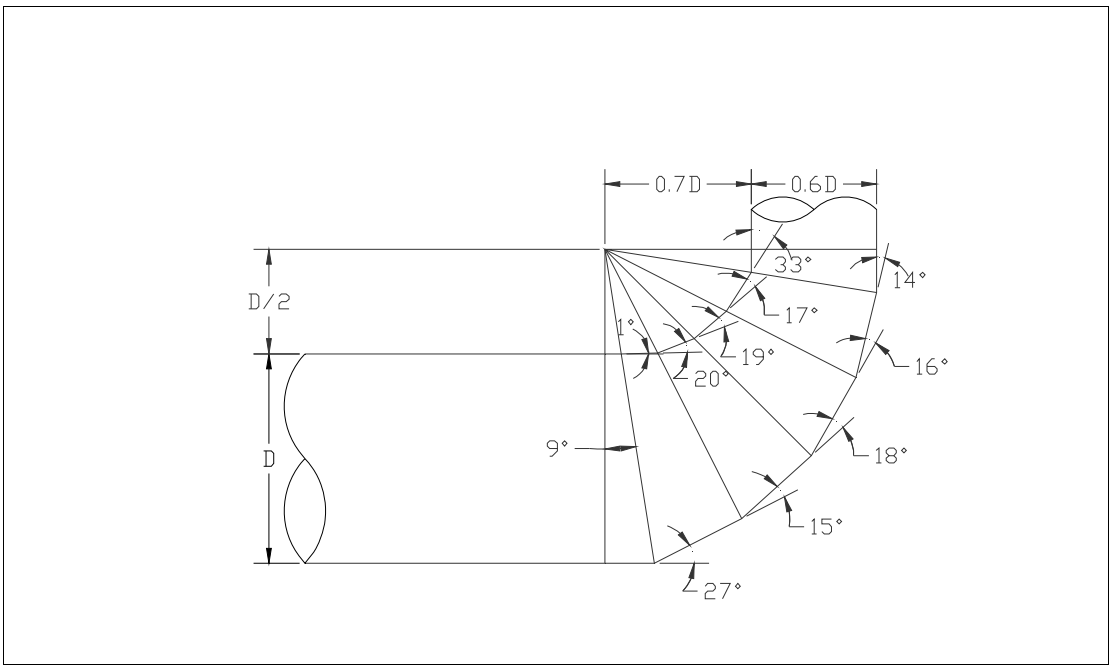

Figure 2 Revised Miter Elbow Design

Photo 4 shows the revised model elbow.

Photo 4 Uniform Flow Inside Type 10 FSI

The model was operated with the revised elbow in place and observations indicated that the separation zone was significantly reduced. Velocity variations decreased from

in excess of 30-percent with the original design to less than 8-percent with the revised elbow design. Virtually no separation was observed on the upstream (short radius) side of the elbow.

Conclusions

The results of the model study show that relatively small variations in mitered elbow design can have a significant impact on conditions within the elbow. In this application a maximum divergence angle of 49-degrees resulted in significant flow separation and a large region of low velocities at the pump impeller location. Revising the elbow to reduce the maximum divergence angle to 33-degrees significantly improved impeller entrance flow conditions and virtually eliminated the separation on the short radius side of the elbow.

However, it should be noted that flow separation in elbows is also related to the flow velocity. Additional studies would prove useful in attempting to quantify a maximum angle versus elbow velocity. A sufficient amount of test data is not yet available to determine a maximum miter angle as a function of velocity.

In this application the maximum elbow velocity was just over 12-ft/sec and testing indicated that a miter angle of 33-degrees was acceptable. Based on this data it is likely that future design could utilize miter angles up to 30-degrees on inlets with velocities of 12-ft/sec or less. Additional work could determine if this angle, or another, would be acceptable at higher and lower velocities.

Abstract

Culverts throughout the country are approaching or are past their original design lives. These 'baby boomer' culverts will need to be repaired, rehabilitated, or replaced. Because entire culvert replacement is so expensive and intrusive, alternate measures to extend the culvert project life are growing increasingly popular. One such method is slip lining, where a 'sleeve' is installed within an existing culvert barrel and stabilized. Plastic pipe sleeves are very popular for slip lining primarily because the plastic material's lower Manning's roughness values allow for the culvert capacity to be maintained despite a reduction in culvert size.

Unfortunately, the reduced friction within the barrel can create a barrier to fish passage due to increased water velocities. The increased velocities also cause greater outlet scour which can result in further obstacles to fish passage. These new fish barriers can greatly affect aquatic ecosystems by limiting the access that fish have to smaller tributaries used for spawning and rearing—access that is critical to the life-cycles of many fish, including stream salmonid populations.

It is suggested that mitigation of the increased velocities should go hand-in-hand with slip lined culvert design projects where fish passage (present or future) is to be considered. Can the demand for hydraulic capacity as well as the demand for fish passage be satisfied?

A literature review and survey of all U.S. state Departments of Transportation as well as state Fish and Wildlife Departments has shown that there has been very limited experience in providing for fish passage through slip lined culverts. Site visits have been made to the few states with this experience to assess developing technologies and record successful and unsuccessful installations. Additional hydraulic analysis using current software is also underway to determine ranges of flows and sizes of culverts where slip lined retrofits can adequately serve as fish corridors.

Introduction

The vast majority of pipe culverts in the United States were built over 40 years ago, during a massive transportation infrastructure upgrade; our culverts are reaching a kind of middle age. A Transportation Research Board Research Needs Statement explains that the highway infrastructure is characterized by a huge inventory of damaged and decaying culverts. Because entire culvert replacement is so expensive and intrusive, alternate measures to extend 'baby boomer' culvert life are growing increasingly popular. One such method is slip lining, where a 'sleeve'—usually plastic—is installed, or slipped, within the existing culvert barrel and stabilized. The sleeve's lower roughness value allows for the smaller pipe to convey the same capacity. This slip lining method is attractive because it does not require any excavation of the existing pipe and roadway fill, providing an opportunity for culvert replacement without the undesired disruption to highway traffic, not to mention the advantage of rehabilitating the culvert without less right of way concerns. Culvert and pipe fabricators have begun to design and manufacture product conducive to this new technology (TRB 2007).

The huge inventory of aging culverts was designed solely on the basis of peak design flows, and likely did not take into account fish passage. Many of these culverts have turned out to be significant barriers for fish. In 1973 the United States Government signed into law the Endangered Species Act (ESA). Once a species is listed as threatened or endangered, the ESA requires that 'critical habitat' be designated for that species, including areas necessary to recover the species. Federal agencies are forbidden from authorizing, funding, or carrying out any action which "destroys or adversely modifies" critical habitat (USC 1973). Unfortunately, the increased velocities due to slip lined culvert retrofit can result in further obstacles to fish passage. These new fish barriers can greatly affect aquatic ecosystems by limiting the access that fish have to smaller tributaries used for spawning and rearing—access that is critical to the life-cycles of many fish, including stream salmonid populations.

It is suggested that mitigation of the increased velocities should go hand-in-hand with slip lined culvert design projects where fish passage (present or future) is to be considered. Can the demand for hydraulic capacity as well as the demand for fish passage be satisfied? To this point, there has been very limited experience in providing for fish passage through slip lined culverts. The objective of this paper is to introduce slip lining as an option for culvert retrofit and discuss fish passage implications associated with this method. Additionally, this paper contains a review of the currently available literature on mitigation techniques, a survey of transportation and fisheries agencies who have utilized mitigation techniques, and reports on visits to various project locations to identify successful implementation of slip lined culvert retrofits. The scope and objectives of an ongoing Utah Department of Transportation research project relating to mitigation techniques to allow fish passage in slip lined culvert retrofits is also included.

Slip Lining and Fish Passage

Slip lining involves three major steps. First, the existing culvert must be inspected and prepared for lining. This process includes flushing or cleaning the existing culvert to eliminate obstructions. Second, a smooth plastic (generally) pipe end is placed into the culvert and pushed through the culvert. Finally, the culvert ends are capped and the annular spaces between the existing culvert and the new liner are grouted to fix the liner in place and provide additional structural support (Campbell 1995). These culvert lining techniques often reduce construction costs by 50-75% (DeMarco 1993, Campbell 1995). Additionally, slip lined retrofits often take half the time as regular culvert replacement, often with only very minor to no traffic impedance (DeMarco 1993).

The 1973 ESA requires that critical habitat be designated for all listed species and that federal agencies are forbidden from authorizing, funding, or carrying out any action which "destroys or adversely modifies" this critical habitat. All listed aquatic organisms are therefore a concern when considering both culvert design and culvert retrofit. While all aquatic organisms are of concern, this report focuses solely on fish passage. There are at least seven reasons that a culvert is considered a barrier to fish passage. These barriers and possible effects were summarized in the following table, found in the recent Federal Highway Administration document "Design for Fish Passage at Roadway-Stream Crossings: Synthesis Report" (FHWA 2007).

Table 2. Description of Barriers to Fish Passage and Possible Effects (from FHWA 2007)

Barrier Type	*Description*	*Impact*
Drop	Drop at outlet exceeds fish jumping ability, or jump pool is insufficient to generate sufficient thrust.	Fish cannot enter structure, can be injured, or will expend too much energy entering the structure to traverse other obstacles.
Velocity	High velocity exceeds fish swimming	Fish tire before passing the crossing.
Turbulence	Turbulence within culvert prevents fish from entering, or confuses sense of	Fish do not enter culvert, or are unable to successfully navigate the waterway.
Length		Fish may not enter structure due to darkness. Fish may fatigue before traversing the structure.
Depth	Low flow depth causes fish not to be fully submerged.	Fish will be unable to swim efficiently or unable pass the structure.
Debris	Caught within a culvert, debris can block flow, or portions of flow.	Fish may not be able to pass by debris, or constricted flow may create a velocity or turbulence barrier within the culvert.
Cumulative	Series of culverts, each of which stresses fish during passage.	Group of culverts, each marginally passable, may be a combined barrier.

Although slip lined culvert retrofits may be extremely appealing when considering cost, time, and culvert discharge capacity, this method is fraught with fish passage issues, and therefore, basic slip lined retrofits are not terribly conducive to the ESA. The same hydraulic characteristic that makes slip line retrofit possible—increased velocities due to low roughness—can be a barrier to fish passage, not to mention the cause of several other barriers. The decreased roughness can cause increased

scouring at the outlet of the culvert, causing it to be perched. This increase in velocity can also create a steep velocity gradient between channel and culvert velocities. Many of the baby boomer culverts are already significant barriers to fish. A simple hypothetical example shows how culvert outlet velocities can be increased by 20% after slip lined retrofit (Webb 2008). This example of a change in velocity is used to highlight the fact that slip-lining methods can make a bad fish passage issue even worse without proper consideration of mitigation techniques.

Survey of Current Practices

There are several mitigation techniques available for application when culverts represent velocity barriers. The majority of the literature on this topic centers on baffles and weirs both inside and outside of a barrier culvert. The concept and function of the baffled culvert is similar to most fishways in that the baffles create a series of short high velocity runs between the baffles and a series of low velocity backwater areas behind the baffles. These areas allow the fish to swim in short bursts and then rest (Bryant 1981). A second prevalent idea is to place tailwater control weirs near the outlet of retrofitted culverts. This causes water to slow down and back up into the culvert itself, providing favorable depth and reduced velocities within the culvert.

A nation-wide survey of all U.S. state Departments of Transportation as well as state Fish and Wildlife Departments has shown that there has been very limited experience in providing for fish passage through slip lined culverts. The Oregon Department of Fish and Wildlife requires that a structure is completely backwatered throughout the entire migration period at all discharges. In order to provide this condition, baffles, weirs, bedload retention grids, tailwater control weirs, and over-steepened channel reconstruction are utilized. The California Department of Transportation has little experience with liners where fish passage is a concern, and warns that attaching baffles to HDPE liners can be difficult and may be prone to getting torn out during heavy storms. Another study suggests that baffled culverts may create a barrier to the downstream passage of juvenile Chinook salmon smolt, as the smolt avoided the structural complexity provided by baffles and selected a control channel over a baffled channel (Kemp 2008). The Ohio Department of Transportation often buries the invert of slip lined culverts to decrease culvert velocity. The Connecticut Department of Transportation has completed several slip lined retrofits on culverts 1.8-m (6-ft) in diameter or larger. The Maine Department of Transportation discourages considering slip lined culvert retrofits which will result in a culvert less than 1.2-m (4-ft) in diameter. Smaller retrofits can cause too great of a velocity change, as well as create maintenance issues due to the increased possibility debris impaction. Maine also suggests that careful attention be paid to the increased elevation of culvert inverts due to slip lined retrofitting, which can cause outlet pool degradation.

The Vermont Agency of Transportation rarely slip lines culverts, but also mentions that they “have had success only in those instances where backwater through the full

length of the barrel could be achieved." Vermont has been very creative in their mitigation techniques.

> "In large multi plate systems where the problem is confined to the invert area of the structure, where deformation has not progressed, where the danger appears to be loss of fines from around the pipe, we have installed up to a foot of concrete in the invert. Rebar is placed on a 12 x 12in grid and tack welded where possible. This type of repair can be used with a roughened surface, baffles, or random placement of embedded stone. In these cases, the goal is to simulate velocity and depth in the adjacent stream reach. Well placed stone clusters may recruit sediment and debris that could facilitate passage. Bottom characteristics will change yearly based on timing and distribution of large storm events that may scour the concrete surface."

The following photos from a visit to Vermont show many of these mitigation techniques used in non-lined culvert retrofits.

Figure 1, 2, 3. Various techniques for velocity mitigation in stream crossings.

Unfortunately, as is true with much advancement in engineering practice, the survey has also shown that many of the treatments for velocity mitigation remain unproven. Several respondents suggested that finding funding for post-construction monitoring is often difficult to obtain. This leaves the hydraulic engineer or biologist with untested conduits and without feedback necessary for design development and adaptive management in culvert rehabilitation. In order to further the science and continue creative developments in culvert treatments, both pre- and post-construction monitoring must be a priority. Following are four case studies which have undergone some type of pre-construction assessment, and post-construction monitoring.

Site Visits

As a result of information provided by survey respondents, site visits have been made a few states with this experience to assess developing technologies and record successful and unsuccessful installations. Visits were made to slip lined culvert retrofits in northern California, Maine, Vermont and Connecticut. These culvert tours included discussions on design considerations, post-construction observations, and general recommendations from those familiar with the installations. Brief case studies of four of these improved crossings follow.

Mendocino County Retrofit

The California Fish and Game approved a slip lined retrofit of a culvert in Mendocino County. In this case, a 0.91-m (3-ft) corrugated metal pipe culvert was lined with a 2.5-ft steel pipe with corner baffles, and was enhanced with three tailwater controls with removable notches, as shown in Figure 4

Figure 4. Outlet of slip lined culvert retrofit in Mendocino County, CA, showing corner baffles and one of three tailwater control barriers.

This culvert is on an intermittent, flashy and highly degrading stream. The stream bottom is at least 6-m (20-ft) below the road level and is adjacent to upstream private property. Because the stream is intermittent and because of a fish barrier upstream, this retrofit was installed as a case study, to learn more about the effects of corner baffles and tailwater controls. Study has shown that the baffles don't change the water surface profile or the overall culvert capacity significantly. However, the baffles have significantly increased sediment loading, which is flushed out only in high flows.

Cape Elizabeth Retrofit

The first stream crossing in Maine to be discussed is located near Cape Elizabeth, Maine. The 2.13-m (7-ft) CMP culvert at the Cape Elizabeth site is replaced by a 1.8-m (6-ft) Weholite pipe. The aquatic organisms of interest in this case are the American Eel and Alewife, which come inland in the spring as adults to spawn, and whose elvers return in the following spring. These animals are strong swimmers, but exhibit no leaping ability; therefore, it was expedient that water be backed up into and through the culvert during spring flows. A HDPE weir, costing approximately $3000 was placed downstream of the culvert and creates a subcritical condition to within roughly 1.5 to 2-m (5 to 6.5-ft) of the culvert inlet. Figure 5 shows the retrofitted culvert with the tailwater weir submerged.

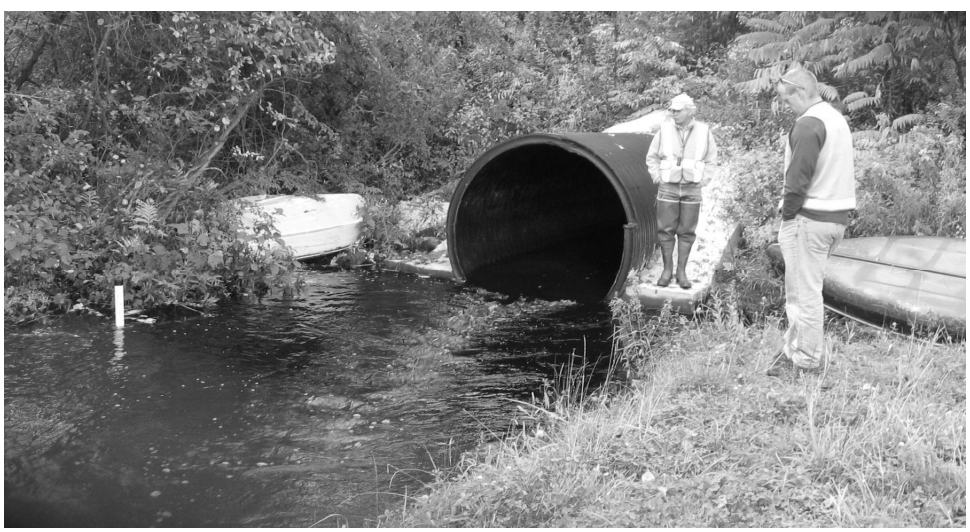

Figure 5. Culvert retrofit near Cape Elizabeth, ME. Tailwater weir is submerged.

Since construction, alewives have been found upstream and within the retrofitted culvert. It is suggested that observational, as well as formal post-construction monitoring is essential to determining the viability of such retrofits under similar conditions.

Belfast Retrofit

State Highway 1 runs along the Atlantic coast of Maine. This highway is the only road which connects the quaint coastal villages on the east coast of Maine which are so important to the tourism industry of the state. Given that the seasonal construction window coincides with the peak of the tourist season, full replacement of this culvert

would create a dramatic disruption. This culvert is only about 60-m (200-ft) from the ocean, and is a thermal refuge for juvenile brook trout. As a conduit for juvenile brook trout, the retrofit was designed for low flows. Roughly 16-18 baffles are inside the 1.8-m (6-ft) culvert. These weirs are 7.7-cm (3-in) tall with 5-cm (2-in) notches. Readily available jersey barriers were used for tailwater control weirs, and are designed to back the water into the culvert at a depth of 7.7-cm (3-in) over each baffle at the design flow. Figures 6 and 7 show the culvert outlet, as well as an image of the baffles within the HDPE pipe.

Figure 6. Culvert retrofit outside Belfast, ME, showing tailwater control weir.

Figure 7. Baffles within Belfast culvert retrofit.

Prior to the retrofit of this culvert, the roughly 60-m (200-ft) of stream above the culvert had no juvenile brook trout. A study after the retrofit found 80 juvenile brook trout in the same reach. Further observation has revealed that rocks tend to pile up below the downstream weirs, and between larger flows, rocks and sediment build up

next to the baffles. In all, the Department of Transportation was able to retrofit this culvert for fish passage without closing the road for long periods of time and saved more than $100,000 dollars.

Falmouth Retrofit

An interesting case study is the retrofit of a stream crossing near Falmouth, Maine. The Town of Falmouth applied to the Maine Department of Environmental Protection to lengthen a culvert using slip lined techniques, which were favored due to steep ravines which would cause entire culvert replacement to be extremely costly. The Maine Department of Inland Fisheries and Wildlife (MDIFW) reviewed the application and were concerned that this improvement might prevent or limit the passage of juvenile wild brook trout which persist in the stream system. Calculations performed by MDIFW resulted in the suggestion that corrugated metal pipe be used for the retrofit, in conjunction with a tailwater control at the outlet pool in order to back water into the pipe. "The Town really wanted to try plastic pipe . . . (and because of) an existing manmade barrier to passage was located a short distance downstream, it was decided to proceed with (the) project on an experimental basis" with the Town agreeing to provide a grade control structure downstream and that further modifications would take place if fish were unable to pass the retrofitted pipe. The outlet of the pipe is shown in Figure 8.

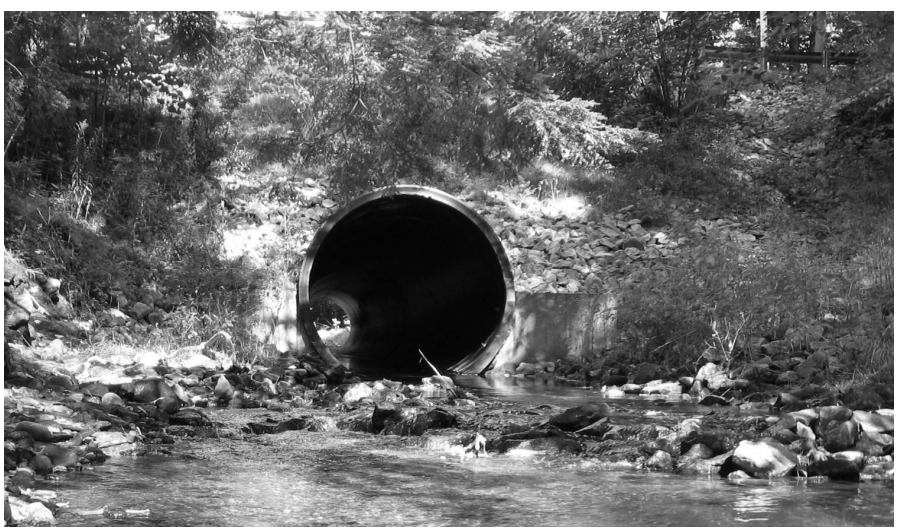

Figure 8. Outlet of Falmouth slip lined culvert retrofit. Rock tailwater grade control also shown.

In order to verify the success of the project, 60 marked hatchery farmed brook trout were introduced just downstream from the culvert, with nets downstream from the outlet pool and 112 m upstream from the inlet. After 24 hours, the site was revisited and fish were caught using an electrofishing unit. The study found 62% of the fish within the pipe, 28% of the fish upstream of the culvert and 10% unaccounted for. The retrofit was deemed a success, and no further construction was done on the site.

It has been shown that many states have begun utilizing slip lined culvert retrofit technology. Some agencies refuse to use slip lining when fish passage is an issue,

while others have chosen to modify retrofit designs to provide for passability. These have been done using varying techniques and have been met with varying degrees of success. This paper has shown four such cases. It is almost certain that there are more slip lined culvert retrofit success stories throughout the country, as well as more failures. Unfortunately, many of these retrofits have not been documented, and have not included pre-construction assessment and post-construction monitoring. It is suggested that increased documentation of design methods and monitoring results is essential to identifying conditions where slip lined retrofits are favorable, as well as evaluating the plethora of structural improvement methods that can be applied to the retrofitting process.

Current Work

The Utah Department of Transportation, in cooperation with Brigham Young University (BYU) and Utah State University (USU), intends to identify measures that can be used to mitigate the increased velocities associated with lined culverts. This is a two-Phase project. The project will provide broad guidelines, as well as some specific alternatives, for potential implementation of slip lined culvert retrofits that are passable to fish. Phase I includes the following objectives:

1. Determine what fish passage measures are currently being used to provide for fish passage in slip lined culverts.

2. Visit a limited number of sites to inspect and measure flow characteristics in slip lined culverts retrofitted for fish passage.

3. Perform analyses (no lab work) to establish ranges of hydraulic characteristics of flow that may be expected in slip lined culverts retrofitted for fish passage.

4. Determine the range of fish species for which passage may be feasible when retrofitting slip lined culverts for fish passage.

5. Prepare for Phase II of the study.

A survey of current design methods, along with culvert site visits, is complete. Hydraulic analysis currently being performed on this culvert data to determine ranges of flow characteristics possible in slip lined culverts retrofitted for fish passage. Much of this analysis has employed HY-8, a culvert hydraulics software package developed by the Federal Highway Administration. This analysis will provide information for task 4, which is to determine the ranges of fish species in Utah for which retrofitting slip lined culverts may be feasible. The final steps to Phase I of the research is to address constructability, durability, sedimentation retention and maintenance issues. After Phase I, several potential design alternatives will have been identified and examined using general hydraulic principles.

Phase II will be completed by Utah State University. Phase II will involve installing several of the potential alternatives in the field and testing them in detail in the laboratory. The lab tests will provide information on the propensity for retrofit designs to retain or evacuate sediments. The field tests will be tested for actual fish passage. At the end of Phase II, specific design procedures for retrofit and installation will be available based upon both field and lab tests.

Summary

The highway infrastructure of America includes a huge inventory of damaged and decaying culverts. Entire culvert replacement is so expensive and intrusive that alternate measures to extend culvert life are growing in popularity. One method of culvert retrofit that doesn't require any excavation or disruption to traffic is slip lining, where a 'sleeve' is installed within an existing culvert barrel and stabilized. Sleeves are typically made of plastic because the plastic material's lower roughness value allows for culvert capacity to be maintained despite a reduction in culvert size.

Unfortunately, the same hydraulic characteristic that makes slip line retrofit possible—increased velocities due to low roughness—can create barriers to fish passage. Since the ESA of 1973 requires that federal agencies are forbidden from authorizing, funding, or carrying out any action which "destroys or adversely modifies" this critical habitat, it is imperative that mitigation of the increased velocities accompany the inevitable culvert inventory upgrade where fish passage is to be considered.

There has been very limited experience in providing for fish passage through slip lined culverts. The relatively sparse amount of literature on this subject centers on baffles and weirs both inside and outside of a barrier culvert, which create a series of short high velocity runs between the baffles and a series of low velocity backwater areas behind the baffles. These areas allow the fish to swim in short bursts and then rest. A key concept put forth in the literature is that a very wide range of baffle sizes can be effective.

A survey of various transportation and fish and game agencies has shown that many forms and combinations of these ideas have been creatively put into practice with varying degrees of success. Visits to several sites have shown a range of solutions which have had positive results. Post-construction monitoring has proven essential in these cases to make determinations toward the viability of various approaches. A Utah Department of Transportation (with BYU and USU) project involving research and a review of current methods, as well as development of new design methods is currently in progress.

Field evaluation of engineered large woody debris for structure performance and habitat value

Kendra Russell[1] and Elaina Holburn[1]

[1]Technical Service Center, Bureau of Reclamation, Denver Federal Center Bldg 67 (86-68240), Denver CO 80225-007; PH (303) 445-2552; FAX (303) 445-6351; email: krussell@do.usbr.gov

ABSTRACT

Engineered large woody debris (LWD) structures are frequently used for habitat restoration and enhancement, bank protection and stabilization, and to alter flow within a channel. This paper discusses current LWD guidelines as well as ongoing field investigations on constructed LWD structures in the Middle Fork John Day River near John Day, OR. Low altitude balloon photogrammetry was completed for seventeen structures on the Middle Fork John Day to complete a stability and effectiveness assessment of the LWD structures. A habitat evaluation of the structures was also completed. The structures have experienced just over a 2-year peak discharge since constructed and are still in place. Preliminary findings show that the structures are generally acting as intended by altering channel morphology through locally narrowing the channel, adding pools, forming bars, and providing cover for fish habitat. The next step for the field analysis is to look at the stability of each LWD structure and perform quantitative comparisons.

INTRODUCTION

Many forested river ecosystems with minimal anthropogenic impacts commonly have the presence of large woody debris (LWD). Much of the natural LWD in channels was removed during the 20th century. However, replacement efforts are becoming widespread due to increased understanding of the many varied benefits of LWD. Engineered LWD structures are frequently used for habitat restoration and enhancement, bank protection and stabilization, and to alter flow within a channel. One major ecological benefit of LWD within rivers is the improvement to floodplain connectivity and creation of habitat through hydraulic complexity and cover (holding and rearing refuge habitats) for important fish species.

The Bureau of Reclamation (Reclamation) is using engineered LWD structures in habitat restoration efforts to provide short-term benefits to supplement long-term riparian vegetation recovery. To maximize the success of these structures, as measured through stability and habitat value, an increased understanding of the linkages between design parameters, structural stability, and resultant habitat is needed. To achieve this, Reclamation is involved in an ongoing research effort to evaluate LWD designs through field investigations and physical modeling in a laboratory setting. This paper discusses a few important habitat benefits and design guidelines identified through a literature review and presents an example of a field investigation of constructed LWD structures in the Middle Fork John Day River. This information will be used as the foundation for determining structure configurations in future physical modeling of LWD structures.

Short-term habitat benefits related to the presence of LWD within channels has been well documented. Previous studies have shown that more wood in rivers causes greater numbers and complexity of textural grain size patches (Buffington and Montgomery 1999). The addition of wood has led to increased habitat heterogeneity and overall macroinvertebrate richness and density (Lester et al. 2007). Based on these studies' findings, when used appropriately, LWD can enhance habitat for certain important fish species. Benefits of these structures have been monitored and evaluated. Among those monitored and published, Cederholm et al. (1997) and Shields et al. (2003) recorded marked biological responses. Cederholm et al. (1997) measured a 20-fold increase in the population of coho salmon during winter months at engineered LWD sites in a tributary to the Chehalis River, Washington. Within a 2 kilometer stretch of the Little Topashaw Creek in Mississippi, Shields et al. (2003) identified an increase in the average number of species, the number of fish, and the size of the fish following installation of 72 structures. However, the long-term ecological recovery in the latter study was doubtful due in part to the instability of most of the structures.

Important analysis steps and design considerations were identified through a literature review. An understanding of river processes within the system proposed for LWD installations is imperative so as to understand the historical presence of LWD, how recruitment and input of LWD has changed over time, and how well the current river processes coalesce with the installations of LWD. This type of assessment is needed to determine if a LWD structure is appropriate and if so, the type of structure that would be successful based on the geomorphology, hydrology, hydraulics, and human features (Abbe et al. 2005). Another important step is to identify the physical and biological objectives of the structure(s), such as additional cover and slow water rearing habitat for juveniles, scour pool development for adult holding, spawning gravel depositional zones, or hiding or resting locations from predators.

Following completion of analyses to determine that LWD structures can effectively be used as part of a habitat restoration effort and identification of structure objectives, several design parameters need consideration. Objectives should be consistent with the proposed stability of the structure, design life, and potential downstream risks. Parameters such as drag, scour, spacing, angle, burial, wood characteristics, and backwater effects all require examination and quantification. Key design variables that can be directly linked to increased success in meeting habitat goals include structure orientation with respect to flow and structure spacing. Results of research performed by Cherry and Besctha (1989) provided evidence that the vertical and horizontal orientation of wood affects channel scour and stability. In their flume study, pieces of wood lying on the bottom of the bed produced the greatest scour surface area. This information can be expanded to LWD complexes and points to having an understanding of what range of angles from the bank produces the greatest stability and scour pool volume.

Multiple LWD structures in series may increase the success of meeting structural objectives. Structures should be spaced closely enough that fish can rest between consecutive structures. However, structures spaced too closely may limit the maximum development of scour holes and area of spawning gravel deposition between the structures. Montgomery et al. 1995 developed a relationship between pool formation and natural LWD loading across multiple channel types. This relationship can be used to compare naturally effective LWD loading with constructed LWD loading. Alternatively, a relationship may be developed specifically within a river of interest based on the availability of historical data documenting the presence of LWD (e.g. pre-disturbance aerial photography).

Many other studies have been conducted documenting useful guidance and important considerations for the design of engineered LWD. By combining documented relationships in published literature with findings in the field, we can begin to compare how closely engineered structures fit published data, evaluate the performance of the structures in achieving their intended habitat goals, identify successful designs as well as those that could be improved, and ultimately recognize where data gaps exist that can be further examined in a physical laboratory setting.

EXAMPLE FIELD INVESTIGATION

The field investigation in the Middle Fork John Day River is part of a comprehensive program to use field investigations and physical modeling to determine stable LWD configurations, placement, and sizing to create habitat through depositional and scouring mechanisms. Information from the field investigations will assist designers, resource managers, and stakeholders understand how habitat characteristics and structure stability vary based on the location of the LWD structure within the channel and design the most stable structures with the highest habitat value. Upon completion of data processing from the field investigations, key design parameters from the literature review will be compared with the structures along the Middle Fork to determine if the designs fit with previously conducted studies.

LWD structures were installed on the Middle Fork John Day River near John Day, OR in July–August, 2007 and July-August, 2008 (MWH 2006). Seventeen total structures were installed; seven were designed as collector v-logs, four were designed as scouring v-logs, and six were designed as deflector v-logs. The structures are split into two groups separated by approximately one mile: the upstream section has ten structures and the downstream section has seven structures. Figures 1 and 2 show the locations of the LWD structures. Scouring v-logs were intended to provide salmonid resting habitat and depth cover as well as physical cover and shade. Deflector v-logs were meant to create friction within the structure and cause the river flow to go around the structure, resulting in narrowing and deepening of the channel. Instream cover and habitat diversity was anticipated to be created by these structures. Collector v-logs were designed to collect woody debris in the channel and create cover, resting, and hiding refuge for adult and juvenile fish. The scouring v-logs have a pre-excavated pool unlike the deflector or collector v-logs. Based on design drawings, the collector v-log and scouring v-log have 4 key log members; the deflector v-log has 5

key log members. All log members of the structures are bolted together. The collector v-log was designed with a root wad at the structure apex that extends into the river; the deflector v-log did not incorporate this feature. All structures are similar in size spanning approximately 35 feet along the river bank and extending roughly 20 feet into the river.

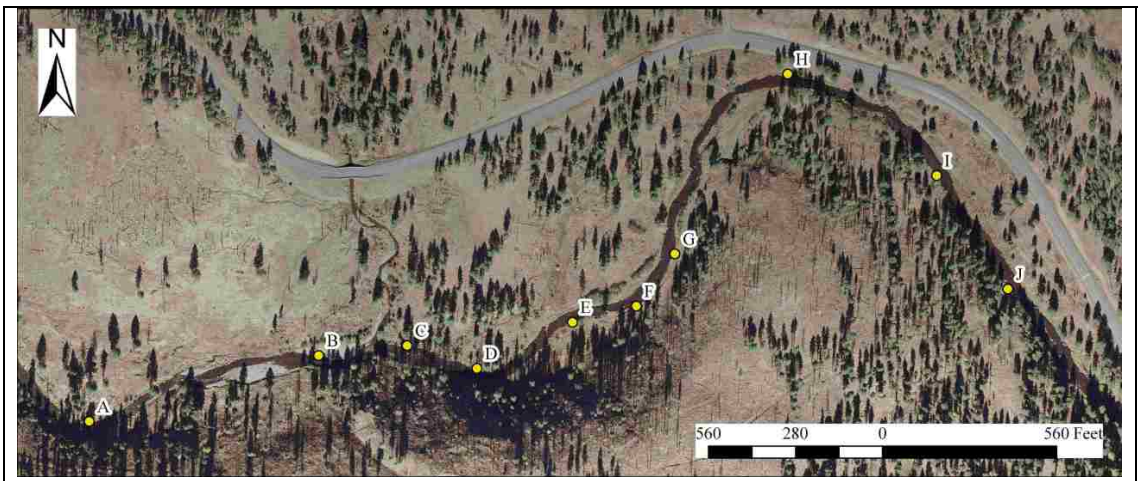

Figure 1. Overview of upstream portion of LWD structures on the Middle Fork John Day River. Structures are labeled A through J. Flow is from right to left.

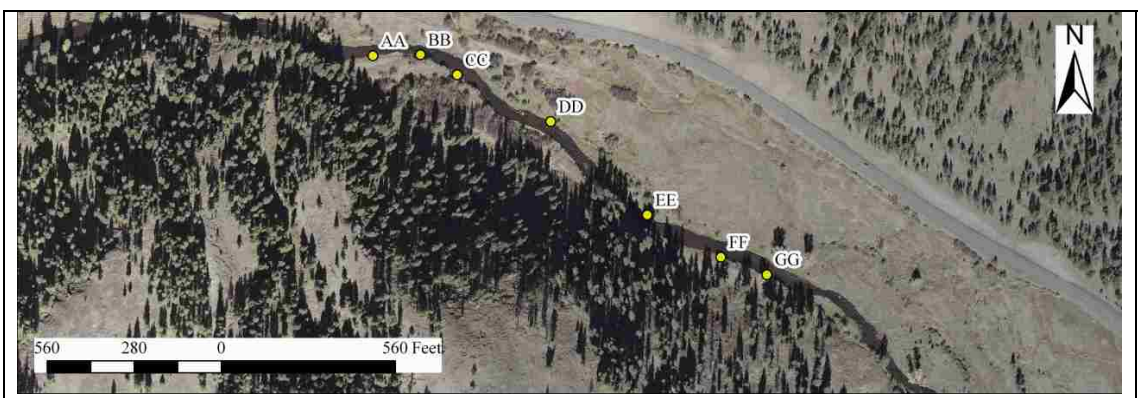

Figure 2. Overview of the downstream portion of LWD structures on the Middle Fork John Day River. Structures are labeled AA through GG. Flow is from right to left.

A site visit to these structures was conducted in November, 2008. The largest peak flow the 2007 structures have experienced to date was approximately 1,200 to 1,500 cubic feet per second (cfs) based on 2,300 cfs measured 30 miles downstream from the structures (recorded at USGS 14044000 Middle Fork John Day River at Ritter, OR). This flow is between a 2-year and 5-year event for the Middle Fork John Day based on a recent hydrologic analysis (Reclamation, 2008). The 2008 structures had only experienced base flow conditions (less than 100 cfs) between the time of their installation and the site visit.

Since the goal of the field investigation is to compare the structural stability and habitat value of the LWD structures to determine the most efficient configuration for future designs, detailed surveys are needed to measure previously identified key parameters. This information will help determine which parameters have the most influence on stability and habitat. The quantity of structures, time allotted for the field investigation, and poor satellite coverage made a detailed topographic survey with a total station or GPS equipment at each structure not feasible. Therefore, low altitude balloon photogrammetry was used.

Low altitude balloon photogrammetry is an emerging technology. Originally photogrammetry was limited to professionals with the required training, equipment, and software. However, with the development of high quality digital cameras, Adam technology developed a "system that retains all of the rigor of a state-of-the art photogrammetric system but with a degree of performance and automation that make it accessible to anybody who can capture a photographic image (Birch 2006)." The Adam technology has been used by Reclamation to map vertical rock faces and seemed appropriate to test in collecting topographic information within rivers.

Reclamation has been working to expand the areas in which small scale photogrammetry is applicable. To acquire photographs for mapping ground surfaces and in-channel features, the digital camera was attached to an 8-foot diameter helium balloon. The balloon was tethered to the ground and manually moved to the location of concern. Pan and tilt camera movements were remotely controlled using a control unit designed for flying small airplanes and helicopters. The live image from the camera was transmitted to a receiver on the ground, enabling the operator to see directly through the camera lens and remotely trigger the camera at specific overlapping intervals for development of accurate terrain models. In the field investigation of the Middle Fork John Day River, the balloon was approximately 100 to 150 feet above the ground for the photographs. Figure 3a and 3b show the balloon and camera used to take photographs of the LWD structures.

The low altitude balloon digital photogrammetry provides high resolution spatial information in a fraction of the time it would take to survey the same number of points using traditional methods. Ground survey control was established by placing small targets along the channel corridor and using GPS equipment to obtain spatial information for each target. In addition to the target survey points, GPS survey was completed on top of and adjacent to the log structures to compare with the photogrammetry results. Qualitative information about the structures and the river were also collected including: planform location, bed material size, vegetation on the banks, bank material, and structure burial.

Figure 3a. Helium balloon used to carry digital camera. The balloon can carry approximately 12 pounds.

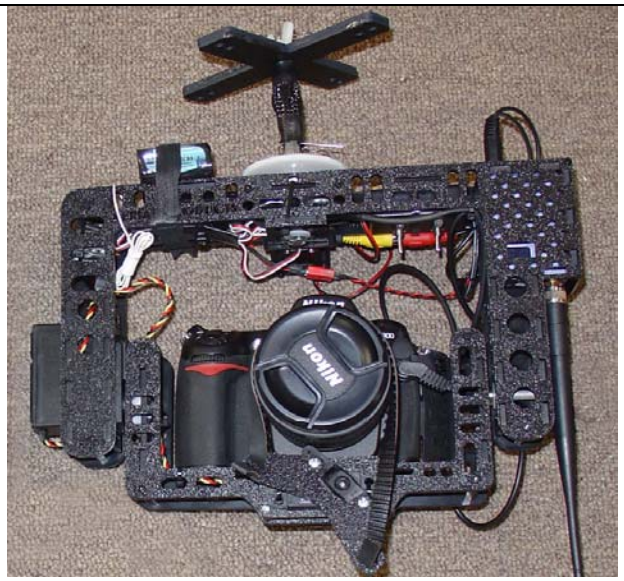

Figure 3b. D300 Nikon camera mounted to frame with pan (360° rotation) and tilt (from horizontal to straight down) servo motors to control orientation.

Qualitative habitat evaluations of the structures were completed by a local biologist (Wilson personal communication, 2008), who examined each structure trying to determine whether structures were providing micro or macro habitat, how they differed from one another, and potential ideas for improvement. For this habitat evaluation, micro habitat features generally provided areas for cover and hiding. Macro habitat generally referred to structures with scour pools or larger channel morphology changes occurring. Snorkel surveys were completed on the Middle Fork John Day River prior to construction. However, to date not enough post-construction data has been collected to quantitatively evaluate the structures.

PHOTOGRAMMETRIC PROCESSING

Photographs acquired from the helium balloon were imported into Adam Technology's 3DM Analyst Mine Mapping Suite. An example photograph is shown in Figure 4. Using the software, images were paired, and common points were generated between the images. The software experienced difficulty finding common points within the river channel, and therefore, multiple points were added manually to accurately match the images. Control points and associated GPS information were added to the targets in the images to orient the photos spatially.

Figure 4. View of an engineered LWD structure in the Middle Fork John Day River as seen from a helium balloon about 120 feet above the ground (flow is from left to right).

The software needs a least three control points with known locations to form an absolute orientation (Birch 2006). Four targets were placed at each structure, and overlapping images were taken from one structure to the next to orient the entire project in the State Plane coordinate system. Figure 5 shows a pair of images in the Adam Technology software with labeled common and control points.

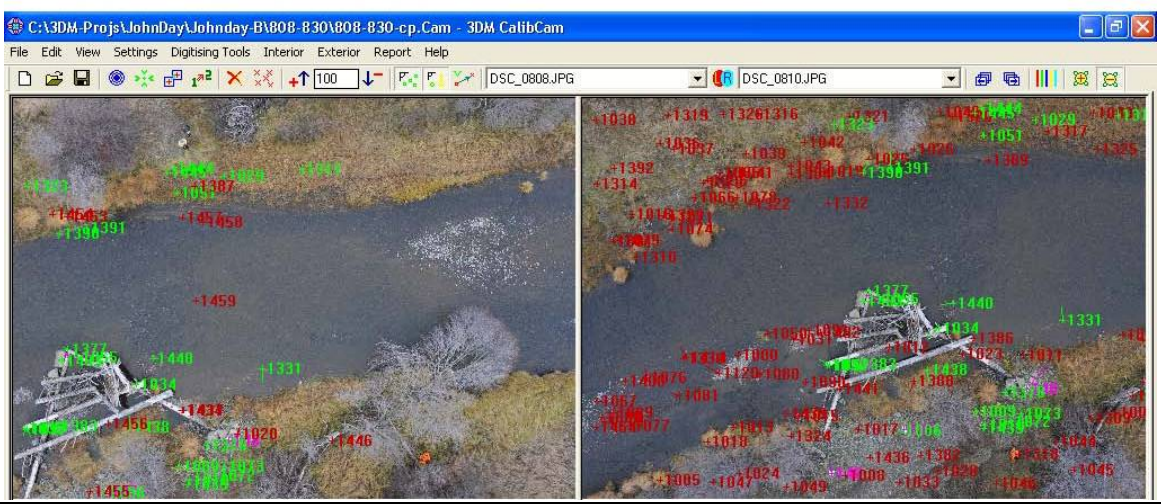

Figure 5. Common points are either automatically generated by the Adam Technology software or entered manually. Control points from the surveyed targets are also input into the program to create a digital terrain model (DTM) from the photographs.

The digital terrain model (DTM) generator within the Adam Technology software was used to create spatial points with elevation and orthophotographs. The accuracy of the DTM points varied within each photo-image pair; the total residual ranged

from 0.04 to 0.19 feet for 36 of the control points. Figure 6a shows the orthophotograph for LWD structure CC. Figure 6b shows the same structure with the DTM points overlaid. There are over 50,000 points generated for the one photograph. As seen from the DTM points, the software had difficulty in generating elevation points across the water surface and also in locations with trees.

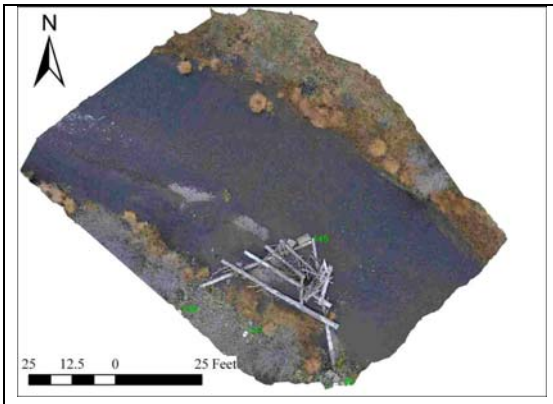

Figure 6a. Orthophotograph generated by Adam Technology software for LWD structure CC on the Middle Fork John Day River.

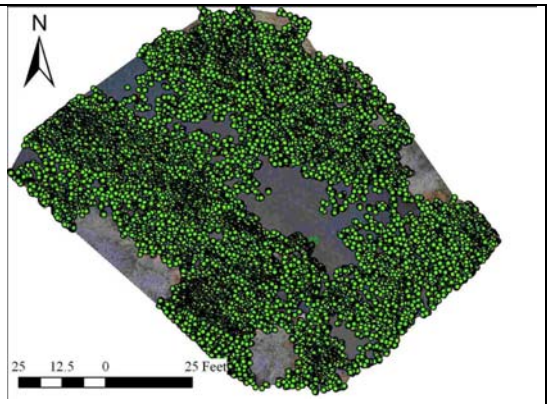

Figure 6b. Orthophotograph of LWD structure CC with elevation points from Adam Technology software processing overlaid.

Since there were multiple structures in series the orthophotographs were merged to create a continuous image. Three of the downstream site structures (AA, BB, and CC) are shown in Figure 7. Continuous images can be used to evaluate changes in morphology upstream and downstream of the structure as well as the interaction between the structures. For example, bars are beginning to form between the structures illustrated in Figure 7,

Figure 7. Ten merged orthophotographs generated from Adam Technology software that cover a portion of the downstream site from LWD structure AA to CC. Flow is from right to left.

HABITAT EVALUATION

Fourteen of the seventeen LWD structures were visited in November, 2008 with a local biologist. Key limiting factors for salmonid species on this section of the Middle Fork John Day River include high summer temperatures, a lack of large wood debris structure for shade and hiding, and a lack of mature trees in the riparian for shade and food production (Wilson 2008). Many species use the LWD structures including bull trout, spring Chinook, summer steelhead, and long nose dais. Table 1 lists each of the structures, their type, and the habitat they provide based on the qualitative evaluation performed by the local biologist.

Table 1. Summary of habitat evaluation completed in November, 2008.

Structure ID	Type	Pre-dug scour	Macro-habitat	Habitat Functionality	Physical Changes
B	Scouring	X	X	Spawning, Rearing, Thermal refuge, Cover, Hiding	Pool
C	Deflector			Hiding	
D	Deflector			Cover, Hiding	
E	Deflector			Cover, Hiding	Scour on opposite bank
F	Collector			Cover, Hiding	Deeper channel
G	Collector			Cover, Hiding	Deeper channel
H	Scouring	X	X	Adult Holding	Pool, divided run in channel
AA	Collector			Cover, Hiding	Channel narrowing, scour
BB	Deflector		X	Spawning, Cover, Hiding	Bar formation, gravel deposition, scour
CC	Deflector			Cover, Hiding	Bar formation
DD	Collector			Little cover, Hiding	Channel narrowing, scour
EE	Scouring	X	X	Thermal refuge, Spawning, Adult holding, Juveniles	Pool, channel narrowing, gravel deposition
FF	Deflector				Bar formation, scour, channel narrowing
GG	Collector			Juvenile rearing	Bar formation, deeper channel, gravel deposition, channel narrowing

Based on the field evaluation by the biologist, all structures did provide habitat value to the system. However, the downstream portion (Structures AA-GG) seems to be outperforming the upstream section in creating habitat complexity, locally narrowing the channel, and changing the river morphology. In particular, structure EE is working to narrow the channel and add complexity through an approximately 50 foot river segment. Also, structure B is providing thermal refugia and was one of two places fish lived during the 2007 fish kill due to high water temperatures (Wilson 2008). Some of the recognized benefits may relate to localized morphologic conditions, such as bed rock outcrops, in addition to variations in structure configurations.

PRELIMINARY RESULTS AND DISCUSSION

At the time of this report, field data from the Middle Fork John Day are being processed. A qualitative examination of the habitat evaluation results suggests that

structures are generally performing as intended. All scouring structures have maintained some scour pool, although comparisons with the pre-excavated scour pool volume have not been examined. Deflector structures, such as E or FF, are deflecting flows against the opposite bank creating a scouring mechanism and narrowing localized flow conveyance. Finally, collector structures appear to be providing cover and hiding for fish (Wilson, personal communication, 2008). In addition, several structures are providing habitat benefits that were not considered in the design. For example, although structure GG was designed as a collector, it is creating greater channel complexity by causing bar formation and channel narrowing. Next steps for the field component of the research include finishing data processing and measuring structure attributes, such as flow constriction, spacing, and key member lengths. Quantitative information from the field investigation will then be compared to the habitat evaluation and the existing design guidelines and coupled with results from the physical modeling to best understand the relationships between geometric variables of the structure, structure stability, and habitat benefits.

ABSTRACT

River spanning rock structures are being constructed for water delivery as well as to enable fish passage at barriers and provide or improve the aquatic habitat for endangered fish species. Current design methods are based upon anecdotal information applicable to a narrow range of channel conditions. The complex flow patterns and performance of rock weirs is not well understood. Without accurate understanding of their hydraulics, designers cannot address the failure mechanisms of these structures. Flow characteristics such as jets, near bed velocities, recirculation, eddies, and plunging flow govern scour pool development. These detailed flow patterns can be replicated using a 3D numerical model. Numerical studies inexpensively simulate a large number of cases resulting in an increased range of applicability in order to develop design tools and predictive capability for analysis and design.

The numerical model U^2RANS is used to investigate how variations in structure geometry affect local hydraulics, scour hole development, and overall structure performance. An automatic mesh generator was developed to expedite the process of generating 30 structure geometries in a simulated straight trapezoidal channel. Variations in structure geometry include: arm angle, arm slope, drop height, and throat width. Various combinations of each of these parameters are modeled at 3 flow rates: 1/3 bankfull discharge, 2/3 bankfull discharge and bankfull discharge. The numerical modeling focuses on how variations in structure geometry affect local flow patterns and scour development. Numerical modeling results duplicated both field observations and lab results by quantifying high shear zones near field and lab scour areas and low shear zones near field and lab depositional areas.

The analysis and results of the numerical modeling, laboratory modeling, and field data provide a process-based method for understanding how structure geometry affects flow characteristics, scour development, fish passage, water delivery, and overall structure stability. Results of the numerical modeling allow designers to utilize results of the analysis to determine the appropriate geometry for generating desirable flow parameters. The end product of this research will develop tools and guidelines for more robust structure design or retrofits based upon predictable engineering and hydraulic performance criteria.

1 INTRODUCTION

River spanning rock structures provide sufficient head for irrigation diversion, permit fish passage over barriers, protect banks, stabilize degrading channels, activate side channels, reconnect floodplains, and create in-channel habitat. Vertical drop height, lateral constriction, size of rock material, and construction methods are common design considerations for these structures. The use of in-stream structures for habitat and stream restoration dates back to the early 1900s; however, the design, effectiveness, and performance of these types of structures have not been well documented. A review of international literature on grade control structure design by Nagato (1998) found that no official standard guidelines for designing

low-head drop structures exist. The review found that design guidelines were relatively tentative or provisional and site specific in nature. While recently there have been a large number of laboratory experiments and empirical relationships developed from field data, efforts to link these relationships with field engineering practices are lacking.

Monitoring of in-stream restoration projects has focused primarily on whether structures produce the desired physical response rather than understanding the physical processes that cause the physical response and how that response might change with differing structure configurations. While general monitoring of in-stream restoration projects provides some information pertaining to success and failure rates, it usually does not provide enough detailed quantitative information to determine the physical processes associated with the success or failure of a given structure geometry. As a result, current design methods are based upon anecdotal information applicable to narrow ranges of channel conditions. Complex flow patterns and performance of rock weirs are not understood, and methods and standards based upon predictable engineering and hydraulic performance criteria currently do not exist. Without accurate hydraulics, designers cannot address the failure mechanisms of structures.

In 2005, the Bureau of Reclamation (Reclamation) initiated a program to evaluate the performance of these structures and develop design guidelines using a multi-faceted approach that consists of field reconnaissance, physical modeling, and numerical modeling. Integration of field, lab, and numerical data sets provides a scientific basis for predicting structure performance under various river conditions and for developing the most-effective design criteria. This paper focuses on the numerical modeling of rock weirs and the effects that variations in the structure geometry have on local hydraulics. A design matrix consisting of approximately 30 different structure configurations along with a field validation case are presented. The following section takes a closer look as to why lower order (1D and 2D) models are not suitable for simulating the complex flow patterns associated with rock weirs.

2 PRELIMINARY COMPARISON OF NUMERICAL MODELING OF ROCK WEIR FLOW PATTERNS

Numerical modeling provides an opportunity to test design parameters over large ranges. A numerical model must capture significant flow patterns and replicate the important dominant physical processes. One-dimensional (1D) numerical simulations model downstream changes in hydraulics while neglecting vertical and lateral variation. Two-dimensional (2D) models incorporate lateral differences in velocity and water surface elevation, but neglect flow patterns that are not parallel to the stream bed. Three-dimensional (3D) modeling simulates the motion of water in all directions and most accurately captures flow patterns. Estimating structure performance with lower dimensional methods requires understanding the impact of representing a feature with methods farther divorced from real world processes. The limited understanding of the complex flow patterns around rock weirs require 3D simulations.

Flow characteristics such as jets, near bed velocities, recirculation, and plunging flow govern scour pool development. 3D numerical models capture these patterns without requiring prior and possibly incorrect assumptions typically required when using lower order models. Figure 1 shows a U-Weir in the field and the corresponding water surface and velocity output from the 3D numerical model U^2RANS (Lai et al, 2003). In the photograph, entrained air reveals areas of high velocity and turbulence. The 3D model captured flow features including the draw down curve, hydraulic jump, and variations in velocity. Dry areas in the photograph, such as the protruding rocks in the upper left corner match the 3D model water surface. Figure 1 demonstrates the capability of three-dimensional numerical modeling to match field conditions.

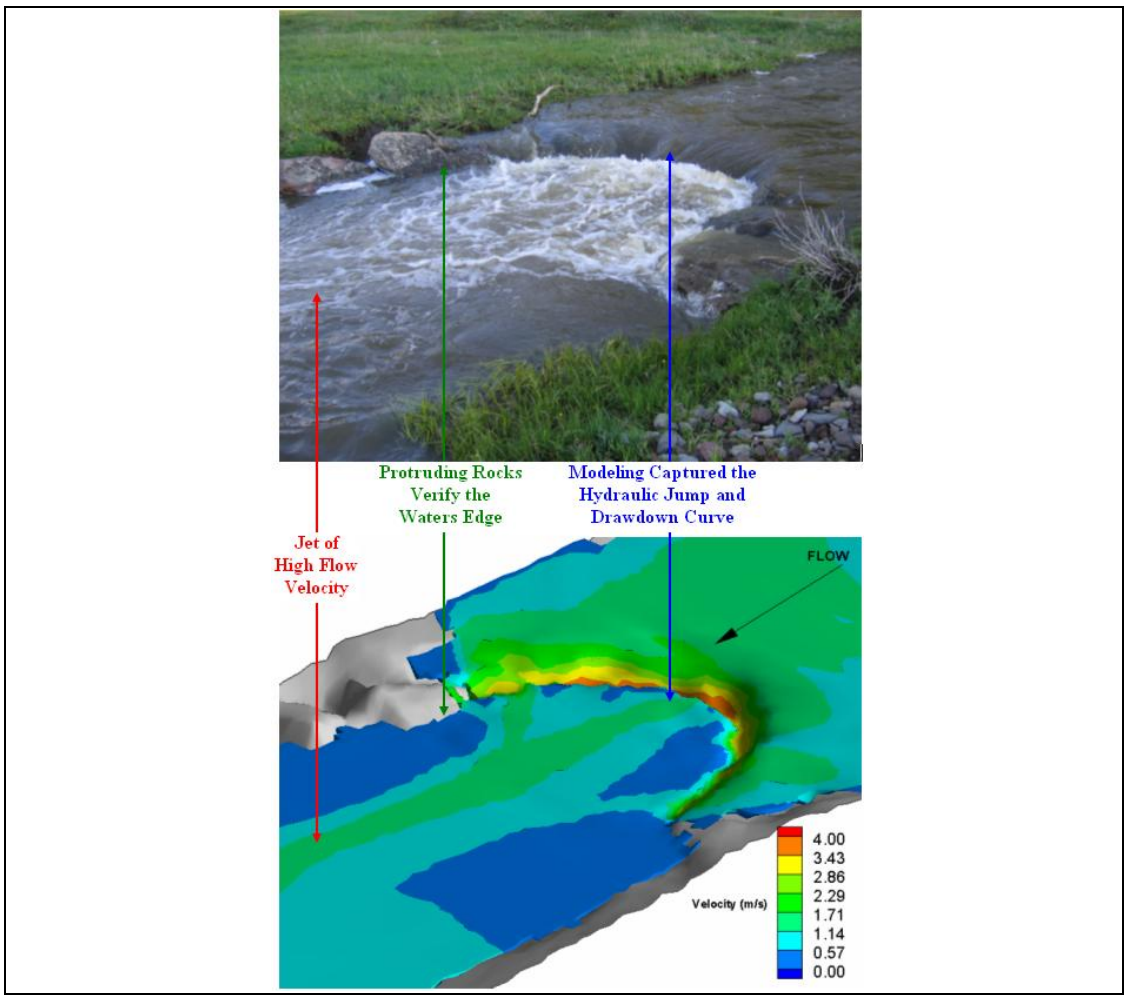

Figure 1. Field Photo and Corresponding Numerical Modeling Results

Figure 2 shows a plan view with water surface elevation contours. The areas upstream and downstream of the structure show little lateral variation. The water surface drops rapidly over the structure and follows the weir crest topology. 1D modeling assumes gradually varied flow and constant water surface elevation across a transect. Methods to meet 1D water surface requirements include constructing cross sections tracing water surface elevation contours or coding multiple cross section perpendicular to the thalweg.

Figure 3 shows surface velocity vectors. In the channel upstream and downstream of the structure water generally flows parallel to the banks. Over the weir, the flow paths rapidly converge and then slowly expand. A jet through the center of the channel creates abrupt lateral changes in velocity. 1D modeling requires cross section lines perpendicular to the velocity vectors and therefore must accommodate lateral variability through bending the cross section.

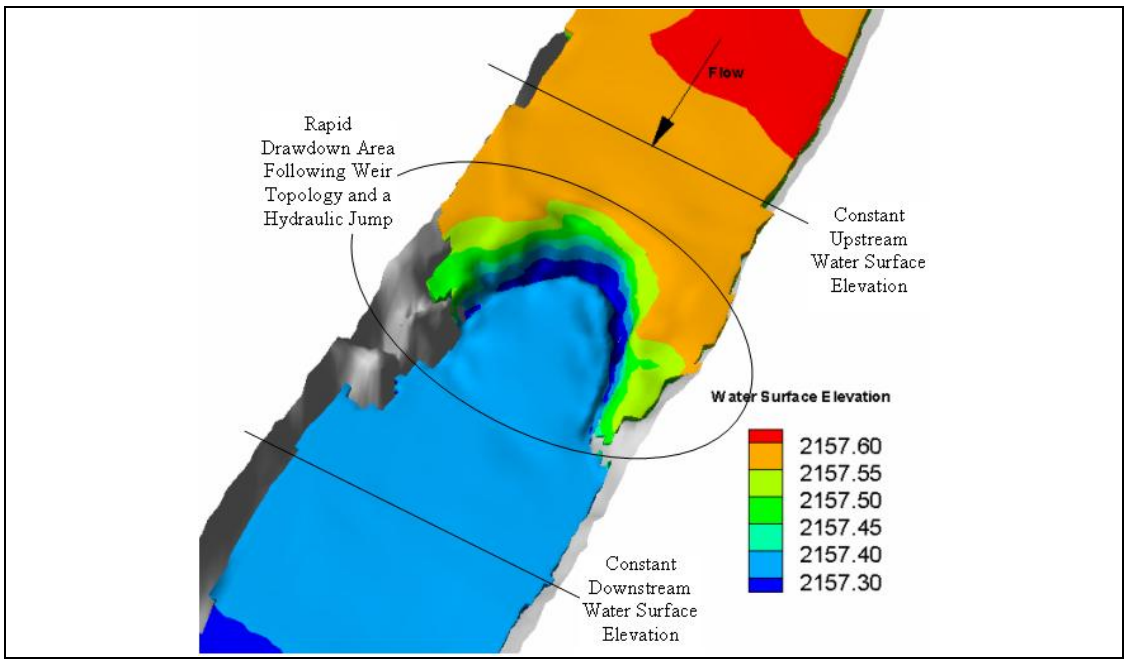

Figure 2. Modeled Water Surface Elevation (Z-Axis Scaled Factor of 5)

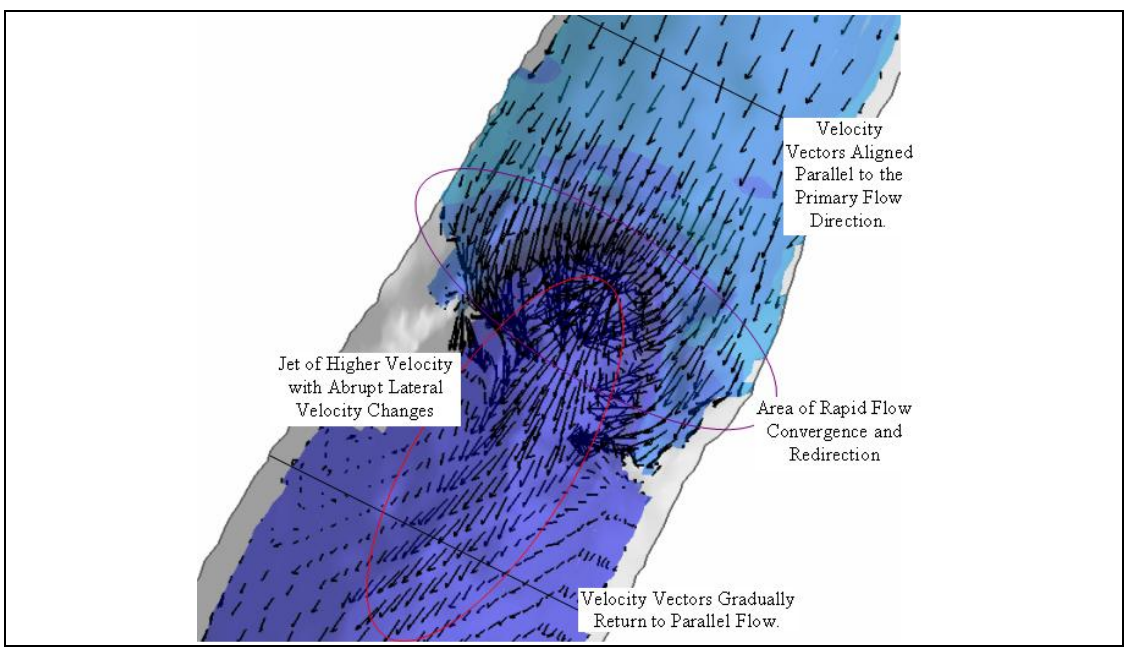

Figure 3. Plan View Velocity Vectors and Wetted Area

Figure 4 shows a vertical profile view for velocities along a longitudinal section of the thalweg. Water flows parallel to the bed upstream and downstream of the structure. The stream lines rapidly converge and diverge vertically through the structure. The velocity profile contains a jet midway through the water column rather than the logarithmic profile of a typical river section. Vertical velocity components in the scour pool show plunging flow. 2D modeling requires velocity vectors perpendicular to a vertical plane while 1D modeling requires perpendicular velocity vectors in both vertical and lateral planes. As a result, these lower order models are not able to properly represent the flow patterns associated with these types of structures.

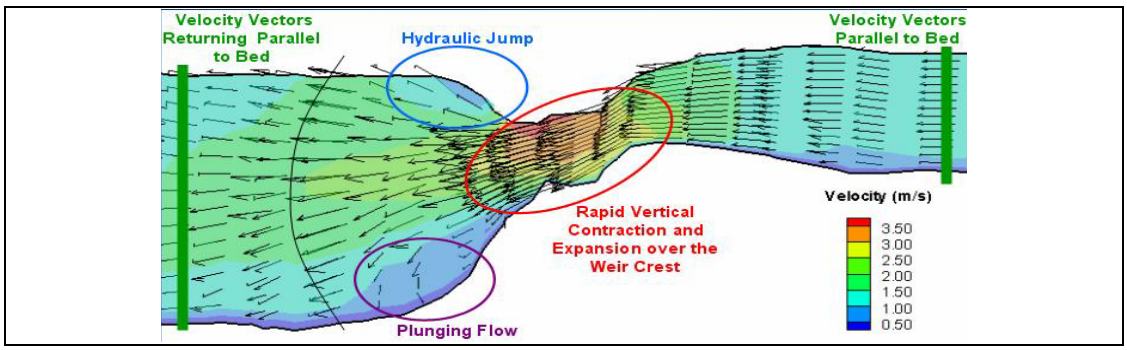

Figure 4. Thalweg Profile View and Velocity Magnitude

Figure 5 illustrates attempts to reconcile the cross sectional 1D requirement with observed field conditions. A cross section model can meet either water surface requirements or velocity requirements, but not both. Figure 5 demonstrates why 1D models require adjustments for multi-dimensional effects. HEC-RAS contains placeholders, but the magnitude of the adjustment is unknown for rock weirs. The adjustment will depend on the throat width, profile and plan arm angle, drop height, and more. After understanding the 3D processes, developing 1D and 2D adjustment parameters may be possible.

In addition to the field data comparison, with the recent completion of the rock weir laboratory testing, measured water surface elevations, velocities, and bed topography are currently being analyzed and compared to results from the 3D numerical model in order to develop rating curves and scour prediction equations for various rock weir configurations.

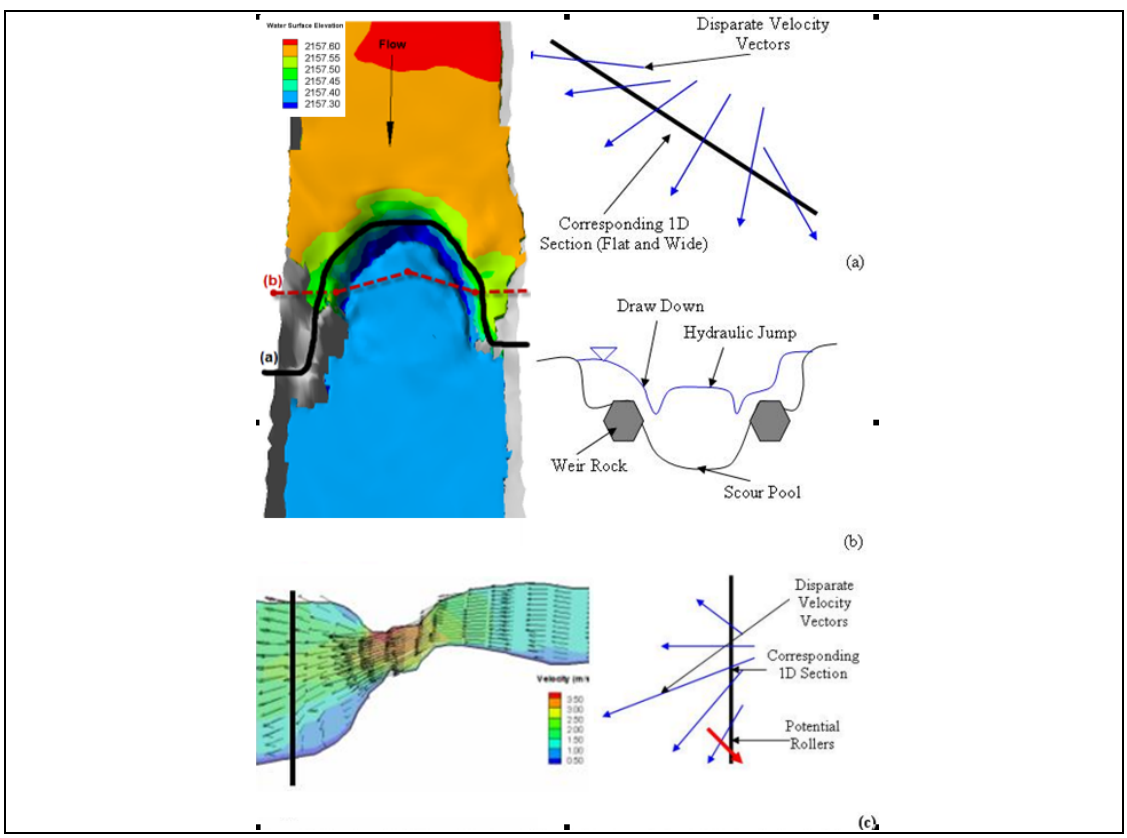

Figure 5. Meeting 1D Water Surface Criteria Fails to Meet Velocity Criteria (a) and vice versa (b). No Method captures jumps or plunging flow (c).

3 3D MODEL SETUP AND DESIGN

The numerical model U^2RANS (Lai et al, 2003) is used to investigate how variations in structure geometry affect local hydraulics, scour hole development, and overall structure performance. An automatic mesh generator was developed to expedite the process of generating 30 different structure geometries in a simulated straight trapezoidal channel. Variations in structure geometry include: arm angle, arm slope, drop height, and throat width. The following sections describe how the design matrix was generated.

3.1 Included Variables

The following variables were included in compiling the final design matrix:

- Bed Material
- Channel Slope
- Throat Width
- Drop Height (fish passage criteria per WDFW 2003)
- Arm Length (Planform Angle and Profile Angle)

3.2 Excluded Variables

The following variables were considered but not included in the final design matrix:

- Bank Height: Water depths will not exceed weir depth. All model runs are at bank full or less, no superbank discharge.
- Bank Angle (Side Slope): 0.75:1 (H:V) Assuming wide-rectangular is adequate.
- Top Width: set by hydraulic geometry equations.
- Bankfull Design Discharge: set by hydraulic geometry equations.
- Asymmetric Geometries: This is a limitation of the study scope.
- Radius of Curvature: This is a limitation of the study scope.

3.3 Matrix Configuration

3.3.1 Bed material

Grain sizes were selected to match field conditions in which river spanning rock structures are most commonly used (ie. gravel bed rivers). The distributions for the D84 and D16 were set to plus and minus one phi class. Three D50 grain diameters were selected using the geometric mean of the AGU classification system, a log base 2 scale:

- Coarse Gravel: D50 = 22.63 mm, D84 = 45.25 mm, D16 = 11.31 mm
- Small Cobble: D50 = 90.51 mm, D84 = 181.0 mm, D16 = 45.25 mm
- Large Cobble: D50 = 181 mm, D84 = 256 mm, D16 = 90.51 mm

3.3.2 Bankfull Channel Geomerty

Previous research has shown that it is possible to define a ‘‘bankfull channel geometry’’ [Leopold and Maddock, 1953; Leopold et al., 1964] in terms of a bankfull width B_{bf}, bankfull depth H_{bf} and down-channel bed slope S. More recently, Parker et al. (2007) used a baseline data set consisting of four differing stream reaches from Canada, USA, and Britain to determine bankfull hydraulic relations for alluvial, single-thread gravel bed streams with definable channels and floodplains. Their results (eqns, 1-3 below) show a considerable degree of universality and the exponents of Q_{bf} in these equations are similar to those found by other authors (e.g., Millar, 2005).

$$S \cong 0.101 \cdot \left(\frac{Q_{bf}}{\sqrt{gD_{s50}} D_{s50}^2} \right)^{-0.344} \quad \text{Equation 1}$$

$$W_{bf} \cong \frac{4.63}{g^{1/5}} Q_{bf}^{0.4} \left(\frac{Q_{bf}}{\sqrt{gD_{s50}} D_{s50}^2} \right)^{0.0667} \quad \text{Equation 2}$$

$$H_{bf} \cong \frac{0.382}{g^{1/5}} Q^{2/5} \quad \text{Equation 3}$$

Where,

S = bed slope;

Q_{bf} = bankfull discharge (m^3/s);

D_{s50} = median particle diameter, (m);

W_{bf} = bankfull width (m);

H_{bf} = bankfull depth (m).

Because of the degree of universality and ease of use of the hydraulic geometry equations presented by Parker et al., they were selected for determining the bankfull hydraulic geometry used in this study. Given the bed material grain sizes listed above and a range of representative channel slopes (0.001, 0.004, and 0.01), Equations 1, 2, and 3 were used to compute central width, depth, and discharge tendency in the design matrix. In order to analyze each structure configuration and its effects on the local flow patterns, the discharge for each structure configuration was varied to include 1/3, 2/3, and bankfull discharges.

3.3.3 Throat width

Initial structure throat width was set to 1/3 the bankfull width as specified in Rosgen (2001) and following observed field applications. To study how flow patterns are affected by changes in structure throat width, the throat width was varied from 1/4, 1/3, and 1/2 the calculated bankfull width for each of the three grain sizes and corresponding channel geometry.

3.3.4 Drop height

Drop height was set to 0.8ft as prescribed by the WDFW (2003) for the maximum drop height allowed for fish passage. In order to study how the drop height over the structure effects flow patterns, this parameter was varied by 0.5 and 1.5 times the value prescribed by WDFW (2003). This results in a range of drops heights of 0.4, 0.8, and 1.2ft.

3.3.5 Arm length

Initial structure arm lengths were designed to approach as close as possible the midpoint of the design ranges specified in Rosgen (2001). Rosgen's recommended plan angles were between 20 to 30 degrees and profile angles range from 2 to 7 percent. Target angles were 25 degrees for plan angles and 4.5 percent for profile angles. The solver function in Microsoft Excel® was then used to calculate the weir arm length that minimized the relative distances on the planform and profile angles of the weir arms. This minimized solution was then used to calculate the arm length ranges that would be used in the numerical modeling in two ways;

multiplying the minimized values by ½ and 2. This provided a wide range of planform (10.31 to 48.35 degrees) and profile angles (1.47 to 10.11 percent) to be tested (Figure 6).

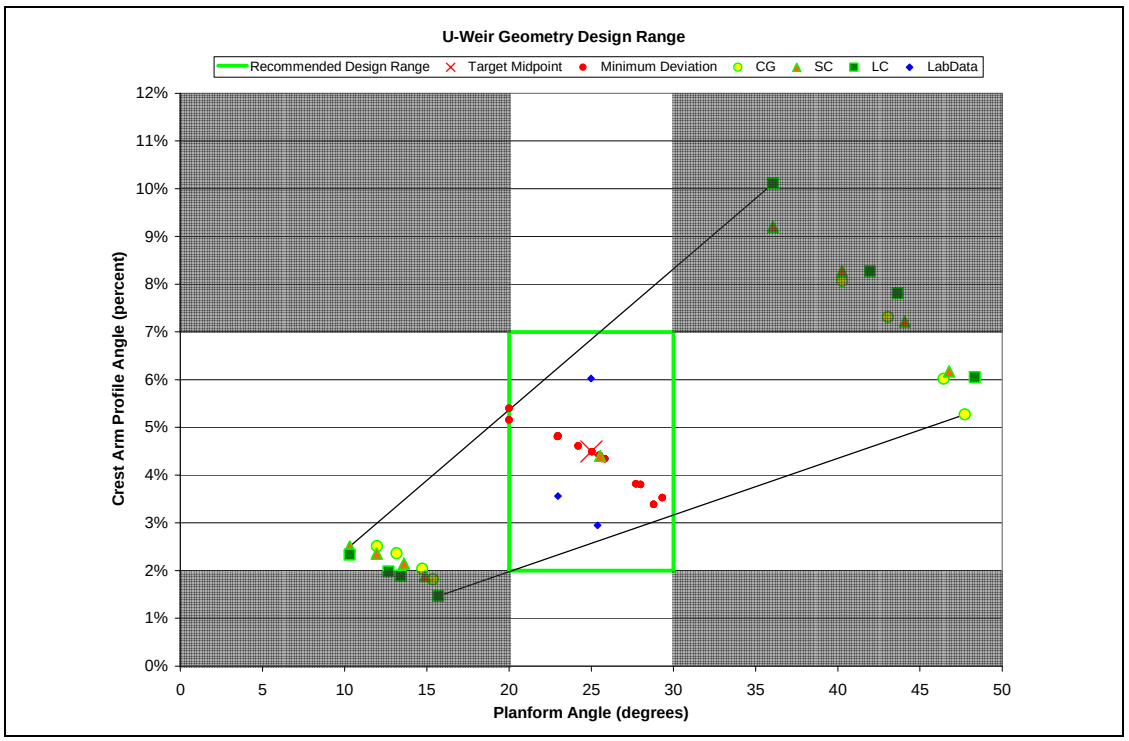

Figure 6. Plot of variation in structure parameters used in design matrix.

3.4 Mesh Generator

The automesh generator simplifies the process of 3D numerical modeling by allowing the generation of multiple structure geometries in a quick and cost effective manner. Five lateral definition lines describe a structure in the 3D mesh generator: upstream bed, upstream header, downstream header, downstream footer, and downstream bed. Overbank, top of bank, and toe lines describe the channel. Each line consists of eight definition points. Combinations of river left or river right, toe, top of bank or overbank, upstream or downstream, bed, header or footer, and pool uniquely identify each definition point. Dashed lines show the intersection of the structure with the channel bank. Each point can be uniquely identified through selecting one from each column in Table 1. Figure 7 shows the conceptualized structure with definition lines and definition points.

Table 1. Structure Definition Point Identification

Flow-Wise	Bank-Wise	Structure-Wise	Laterally
Upstream	Left	Bed	Throat
Downstream	Right	Header	Toe
		Footer	Top bank
		Pool	Overbank

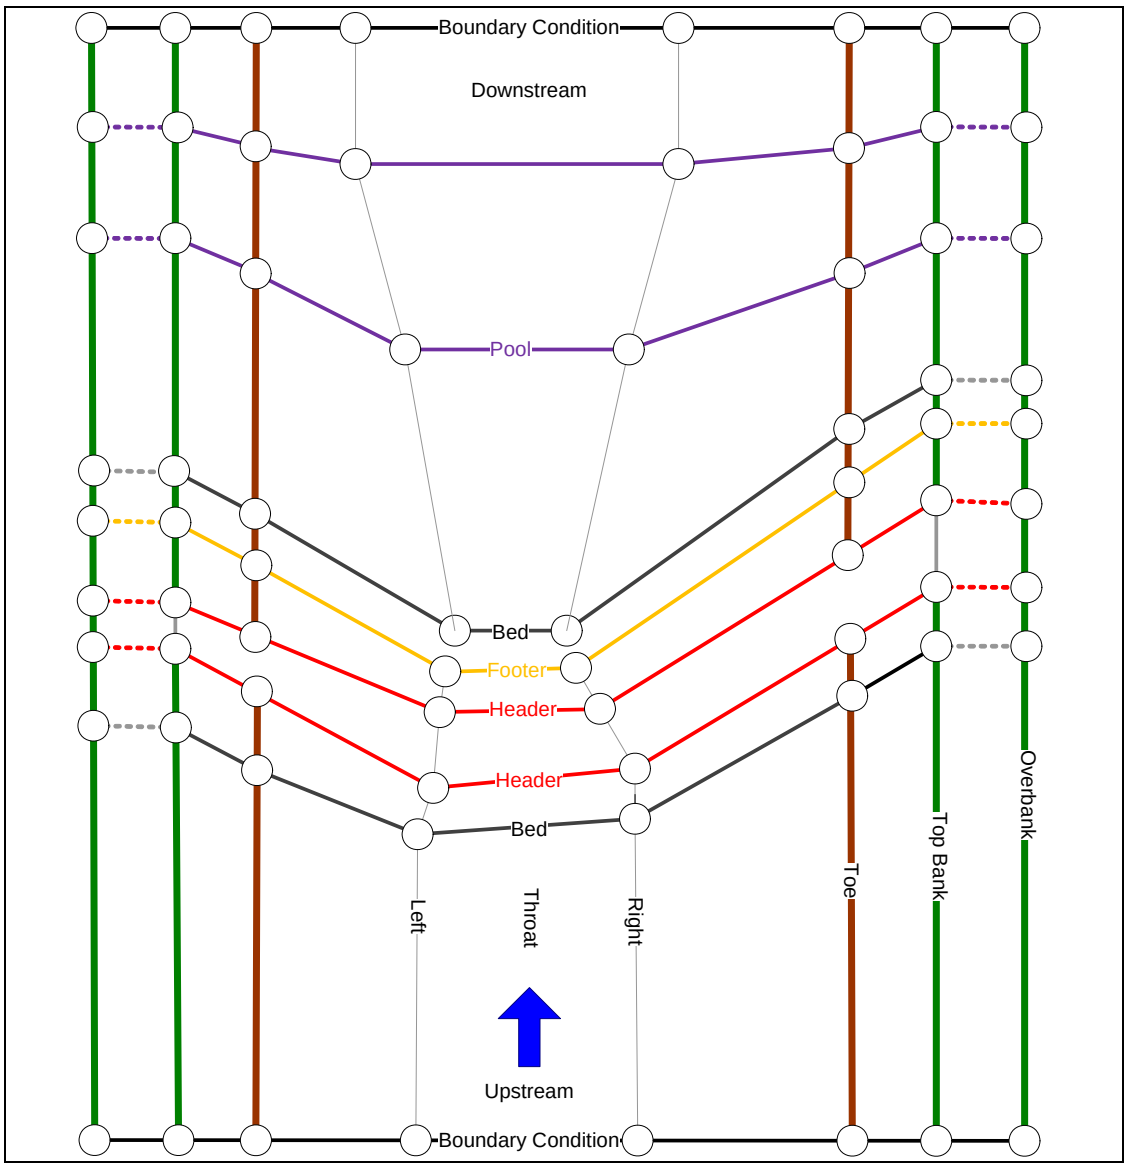

Figure 7. Profile of 3D Structure Line and Point Definition

The definition lines can be identified by the endpoints. For example, the line from the downstream right footer toe to the downstream right footer top of bank identifies where the downstream face of the structure intersects the bank on river right (looking downstream). Definition lines create structure faces that can be identified as left arm, throat, and right arm.

4 PRELIMINARY ANALYSIS OF STRUCTURE CONFIGURATION AND RESULTING HYDRAULICS

Analysis of the effects that variations in rock weir arm length (arm angle and slope), throat width, and drop height have on local hydraulics is currently underway. The following are being analyzed to determine how variations in structure geometry affect local hydraulics: velocity field, bed shear stress, conveyance or flow constriction, energy dissipation, eddies and flow re-direction, and near bank velocities and shear stresses. Figure 8 and Figure 9 show how the velocity field and bed shear stresses are altered for various structure configurations.

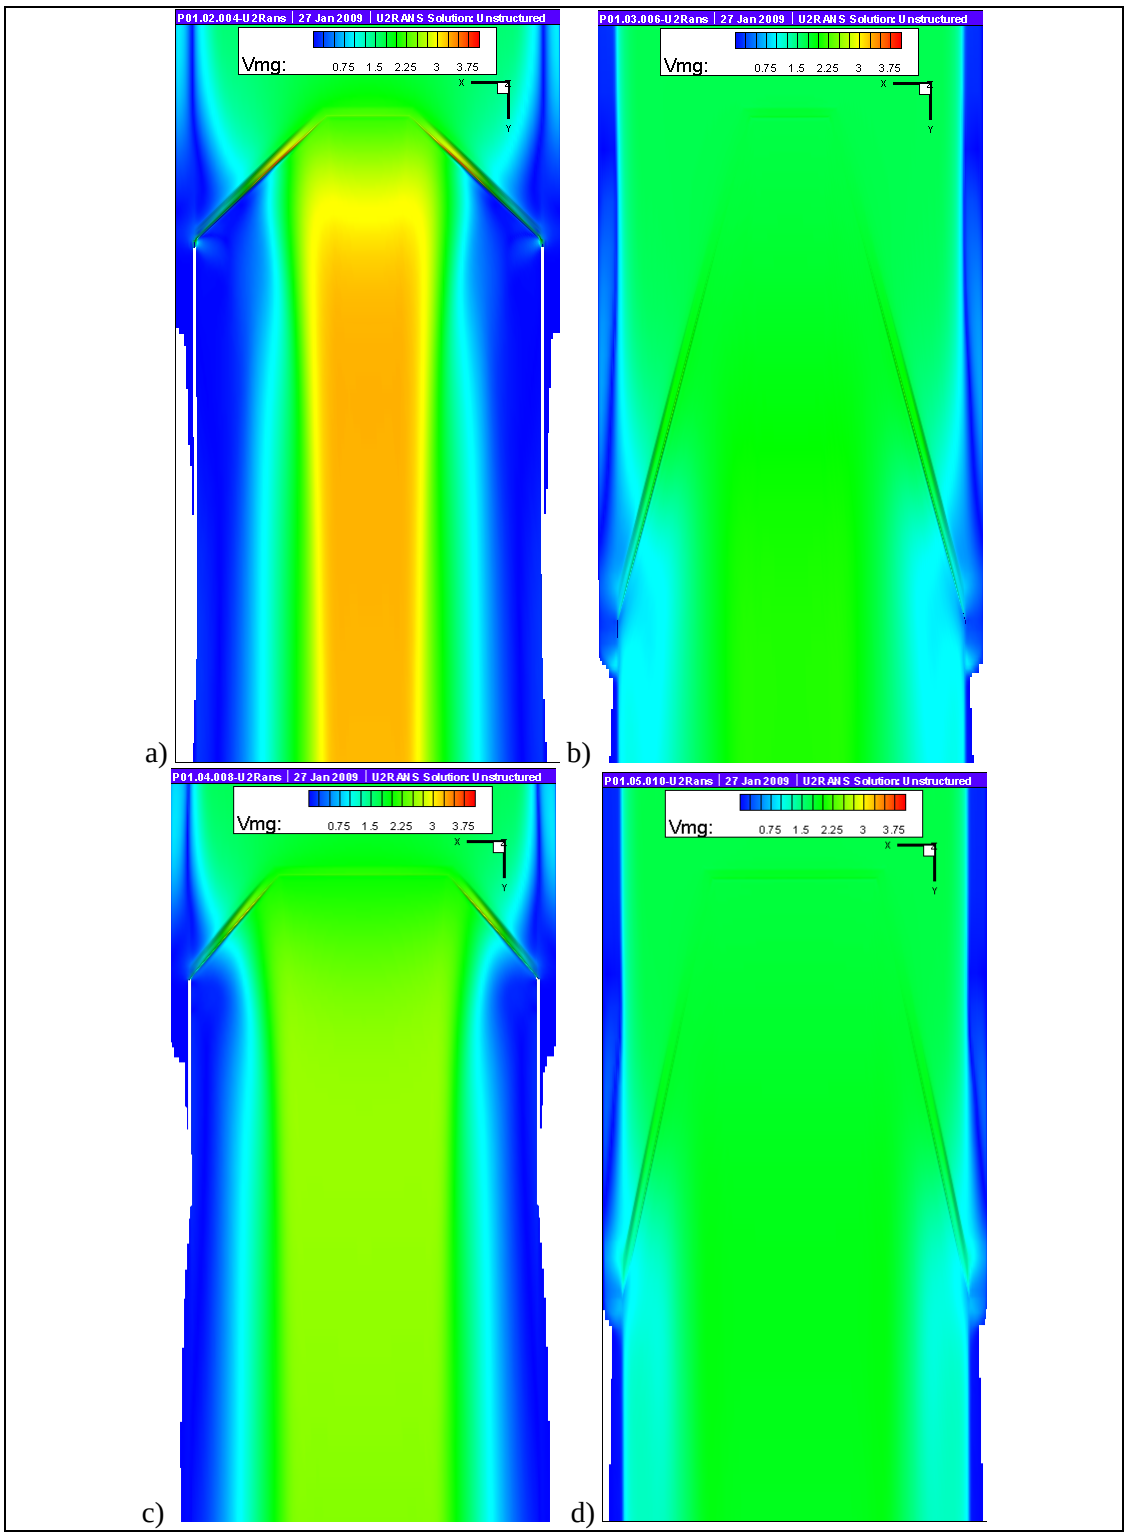

Figure 8. Change in surface velocity for various structure configurations: a) .25Width-.5Arm Length, b) .25Width-2Arm Length, c) .5Width-.5Arm Length, d) .5Width-2Arm Length.

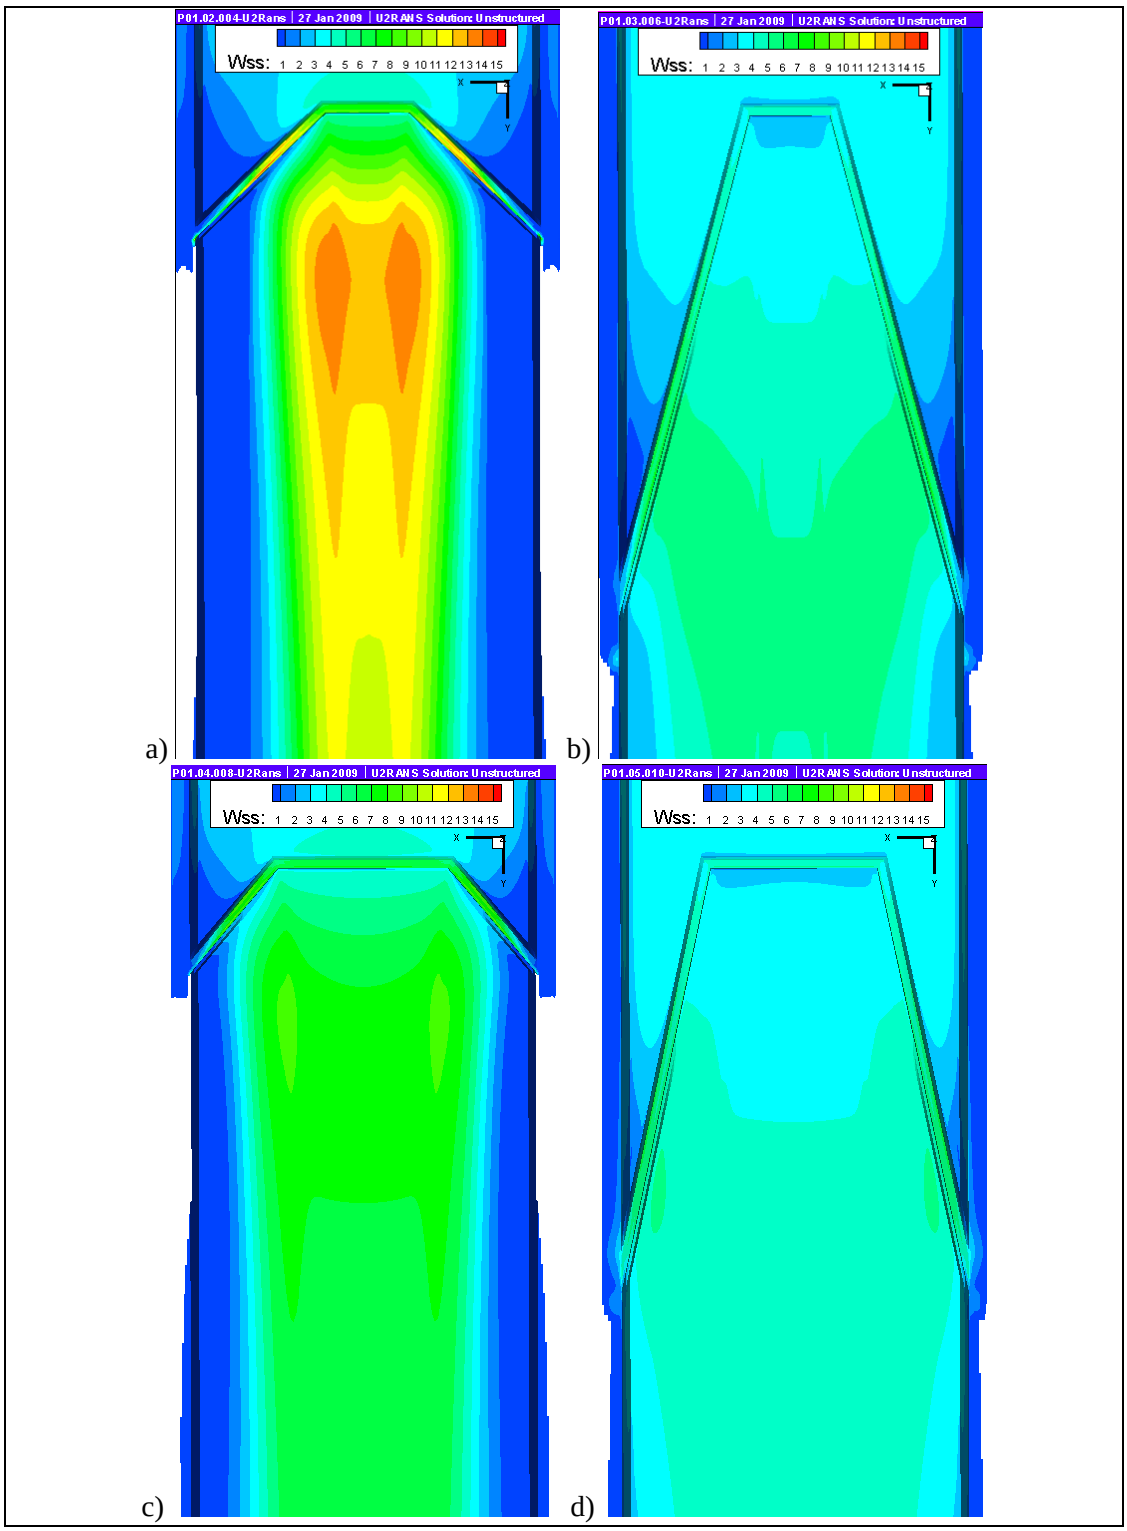

Figure 9. Change in bed shear stress for various structure configurations: a) .25Width-.5Arm Length, b) .25Width-2Arm Length, c) .5Width-.5Arm Length, d) .5Width-2Arm Length.

5 CONCLUSIONS

The numerical modeling focuses on how variations in structure geometry influence local flow patterns and scour development. Current numerical modeling results have duplicated both field observations and laboratory results by quantifying high shear zones near field and lab scour areas and low shear zones near field and lab depositional areas. Results of the numerical modeling allow designers to determine the appropriate geometry for generating desirable flow parameters. The results may also be coupled with the results of the physical model to develop a method to predict critical variables, such as bed shear stress and scour depths, using a 1D model.

The analysis and results of the numerical modeling, laboratory modeling, and field data provide a process-based method for understanding how structure geometry affects flow characteristics, scour development, fish passage, water delivery, and overall structure stability. The end product will develop tools and guidelines for more robust structure design or retrofits based upon predictable engineering and hydraulic performance criteria.

Quantitative Evaluation of Rock Weir Field Performance

David Varyu, Kendra Russell, Elaina Holburn,

Hydraulic Engineers, Sedimentation and River Hydraulics Group, Technical Service Center, Bureau of Reclamation, Denver, CO (dvaryu@do.usbr.gov)

Abstract

River spanning loose-rock structures are used in channels for a variety of purposes ranging from grade control to habitat complexity. Despite the use of in-channel rock weirs for a myriad of purposes, there is a lack of widely applicable guidelines for the design of the structures. Integration of field, laboratory, and numerical data sets will provide a scientific basis for predicting structure performance under various river conditions and for developing the most-effective design criteria. Investigation of surveyed structures in the field identified several important relationships between structure parameters and the degree of failure. The most notable include the relationships with throat width, open angle of the structure, profile arm angle, and distance to next upstream or downstream rock structure. In general, structures with wider throats relative to the channel width failed less frequently than those with smaller throats. Structures characterized by wider open angles and greater arm slopes tended to fail more frequently than those with narrower open angles and milder slopes. Structures placed in close sequence tended to fail less frequently than those with wide distances between structures. Additional field data continues to be collected and their inclusion in the field data set will further refine observable trends between structure parameters and degree of failure. The quantitative analysis performed in this study must be coupled with the results from the laboratory and numerical modeling components to best understand the relationships between geometric variables of the structure and structure stability.

1. Introduction

River spanning loose-rock structures are used in channels for a variety of purposes ranging from grade control to habitat complexity. The most common objectives in implementing these structures in rivers are to provide sufficient head for diversion without creating migration barriers for fish, to increase channel and bank stability, and to improve habitat features for endangered fish species. Due to the wide range in their application, designs of the structures and determinations of structure functionality are highly variable. However, common performance objectives of most river spanning rock structures include the ability to withstand high flow events and preserve their intended functions over a range of flow conditions.

Despite the use of in-channel rock weirs for a myriad of purposes over the last 50 to 100 years, a literature review of available information on river spanning rock structures identified a lack of widely applicable guidelines for the design of the structures (Mooney et al, 2007). The review found that methods and standards for designing rock weirs based upon predictable engineering and hydraulic performance criteria currently do not exist. As such, Reclamation initiated a multi-faceted research effort to improve design criteria for river spanning rock structures. Ongoing research consists of three primary components:

1. Field investigations of river spanning rock structure performance,
2. Physical modeling in a laboratory setting, and
3. Numerical modeling of hydraulics resulting from the presence of river spanning rock structures.

Integration of field, laboratory, and numerical data sets will provide a scientific basis for predicting structure performance under various river conditions and for developing the most-effective design criteria. This paper focuses on the results of field investigations and the correlation between failure mechanisms and physical design parameters.

Field investigations identified structure performance and hypothesized failure mechanisms at each structure (Mooney et al., 2007). Of the 127 structures evaluated, over 70% were determined to have at least partially failed based on the definition used to define failure, which was predominantly related to structural stability of constituent rocks. The most common failure mechanism was the growth of the scour pool and subsequent slumping of the footer rocks. Field observations suggest that most structures were comprised of rocks adequately sized to prevent failure by sliding and rolling through incipient motion. Qualitative investigations also identified a need for a greater understanding of system processes (e.g. sediment loads and channel migration rates) and recognized structure tie-in to the bank and depth of foundations as critical components of structure designs.

The purpose of this report is to utilize field measurements and topographic surveys collected during field investigations to correlate specific design parameters and to identify possible failure mechanisms. River spanning rock structures evaluated for this report include rock weirs comprised of loose rocks that extend across the width of the channel. Results from the quantitative evaluation of field performance will inform other aspects of the research effort and assist engineers, planners, and manager in improving rock weir designs through increased focus on critical design parameters.

2. Methods

2.1. Data Collection and Processing

Of the 127 structures evaluated, topographic surveys were performed on 76 river-spanning loose rock structures between June, 2005 and November, 2007. Fifty-four of these structures are included in the quantitative analysis. The remainder of the original 127 structures either were non-river spanning, not rock structures, too newly constructed (minimal flows experienced), or were not surveyed sufficiently to quantify structure dimensions. Structures surveyed include A-weirs, U-weirs, Asymmetrical U-weirs, W-weirs, and VW-weirs (Figure 1). To maintain consistency for comparing parameters (i.e. arms and angles) across multiple structures, a consistent method of identifying arms and angles was developed. The most commonly surveyed structures were U-weirs and A-weirs. Examples of both are included in this section.

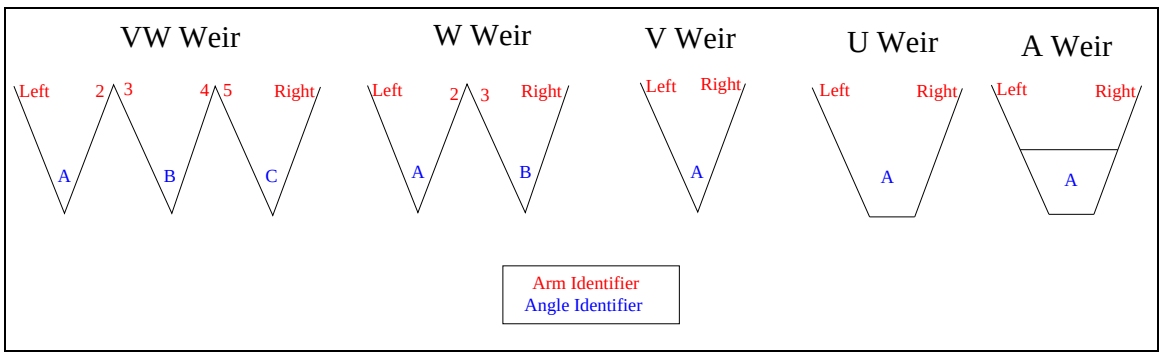

Figure 1. Arm and Angle Identifiers for surveyed structure types.

Following collection of river and structure topography, data were imported into ArcMap (ESRI Version 9.2). Structure planforms were digitized within ArcMap, along with other site characteristics such as bank line locations, structure opening, location of maximum scour depth, etc. Digitized lines were used to calculate parameters such as arm lengths, throat widths, cross arm lengths, bankline and structure angles, and distance from the location of maximum scour to specified points on the structure crest. Figure 2 displays some of the common structure parameters considered during analysis.

All structure parameters were gathered into a single database to determine ranges of different elements of constructed rock structures and to develop any statistical correlations that could be used to direct the design of future structures to prevent or minimize the observed failure mechanisms.

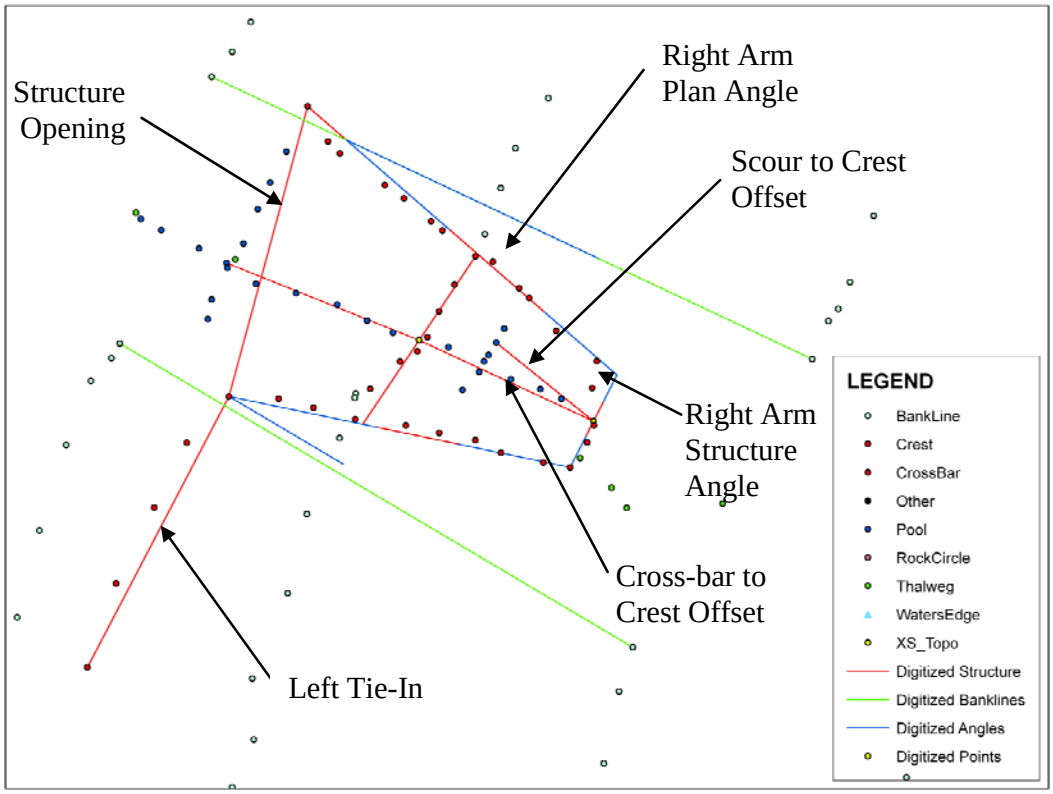

Figure 2. A-weir structure K at Rio Blanco site with some parameters identified.

3. Results

3.1. Distribution of each structure by type and whether failure, partial failure, or success.

In the qualitative investigation of in-channel structures (Mooney et al., 2007), a total of 127 structures were evaluated to evaluate structure performance and identify potential failure mechanisms. This quantitative report focuses on river spanning rock structures. Because the type and amount of data collected at each structure varied greatly, a total of 54 structures were suitable for quantitative analysis (river spanning and with sufficient survey data). Table 1 presents the river spanning rock structures that are considered in the results section, broken down by degree of failure.

One W weir and one VW weir were surveyed during the qualitative evaluation. Due to the small number of each of these structures, no quantitative comparison could be conducted across the individual structure types to determine which parameters are important to structure success. Note that both the W-weir and the VW-weir failed. In addition to these 52 structures (54 less one W-weir and one VW-weir), eight structures on Red Hill Creek in Canada were surveyed. These eight Red Hill Creek structures were surveyed shortly after there installation and had not experienced any substantial flows; therefore, identifying a degree of failure and failure mechanisms for these structures was not possible.

Table 1. Usable structures considered by degree of failure

Structure Type	Count	Usable	NoFail	PartialFail	Fail	Unknown
V-weir	13	5	0	0	5	0
U-weir	37	22	7	8	6	1
A-weir	11	8	0	6	2	0
Asymmetric U-weir	22	17	3	8	5	1
VW-weir	1	1	0	0	1	0
W-weir	3	1	0	0	1	0
Total	**87**	**54**	**10**	**22**	**20**	**2**

Some structures are installed in series along a river, sometimes with structure types varying from structure to structure. Distances to upstream and to downstream structures were identified for those structures that were not stand-alone structures. Also, if the next structure (upstream or downstream) was not a river spanning rock structure, then the distance to the next river spanning rock structure was measured. Table 2 presents the number of structures that did have upstream and downstream structures, whether river spanning or not.

Table 2. Structures with upstream and downstream structures.

Structure Type	Usable	US structure	US RSRS	DS structure	DS RSRS
V-weir	5	3	3	2	2
U-weir	22	21	20	21	21
A-weir	8	5	5	7	7
Asymmetric U-weir	17	17	16	16	16
VW-weir	1	0	0	1	1
W-weir	1	1	1	1	0

Some parameter values common to U-weirs, V-weirs, A-weirs, and asymmetrical U-weirs are presented in Table 3, along with maximum, minimum, and mean values, delineated by degree of failure. Table 4 presents additional data relevant to A-weirs in terms of cross bars. Note that one A-weir consisted of dual cross bars (a double drop). Also note that all of the A-weirs considered were categorized as partial failures or full failures. Due to a lack of A-weirs that did not fail, and because only two A-weirs were full failures, trends between degree of failure and various parameters can not be substantiated by the structures surveyed in this analysis alone.

3.2. Observable Trends of Degree of Failure with Structure Parameters

A comparison of parameters across all structures was presented in Table 3. A further comparison of parameters by degree of failure for each structure type was performed. U-weirs and V-weirs were combined, with V-weirs being described as U-weirs with throats of zero-width. For analysis of trends, U-weirs and V-weirs are combined into the category U,V weirs. Ranges of selected structure parameters were compared across the degree of structure failure to determine the presence of trends and identify where strong relationships exist between specific design parameters and degrees of failure.

Scour depth relative to foundation depth was expected to be an important factor in the success of a structure's stability due to the fact that the most prevalent mode of failure observed was the growth of scour pool and subsequent slumping of the header and footer rocks (Mooney et al. 2007). The data indicate no trend relating the scour depth to the degree of failure. However, the lack of a trend may be due to the fact that scour depth was not evaluated as a ratio to foundation depth. Evaluating scour depth as a ratio to footer depth is expected to be the most useful way to non-dimensionalize this parameter. Foundation depths were not surveyed in the original data collection plan. Therefore, attempts were made to non-dimensionalize scour depth to parameters that showed significant correlations to scour depth, including arm length, throat width, and structure opening. However, these ratios involving scour depth did not show improved trends with degree of failure. Attempts were also made to non-dimensionalize scour depth to the relative size of the channel, such as structure/channel width. Again, no improved trends with degree of failure were realized. Future analyses that incorporate footer depths as a surrogate for foundation depths may display improved trends with the degree of failure.

Certain trends were observed in considering degree of failure relative to various parameters. These trends were not necessarily observed in all structure types, however. For instance, Figure 3 presents structure open angle for U,V-weirs and Figure 4 shows the same parameter for asymmetrical U-weirs. U,V-weirs tended to fail when the open angle exceeded 45 degrees, and asymmetrical U weirs experienced a full failure when the open angle exceeded 60 degrees.

Proximity of structures to the next upstream or downstream structure showed a trend with the degree of failure for U,V-weirs. No trends were present for structure spacing of asymmetrical U-weirs. U,V-weirs with structures (regardless of type) of closer proximity to other structures, either the upstream or downstream direction, were less likely to fail than widely spaced structures.

Another parameter that suggested some correlation with the degree of failure included throat width. To compare throat width across varying river conditions, throat width was non-dimensionalized through the use of the ratio of throat width to channel width. Throat width relative to channel width shows trends with degree of failure for U,V-weirs, asymmetrical U-weirs, and even A-weirs. Data suggest that the more of the channel width that is blocked by the throat (as opposed to arms), the likelihood for failure decreases.

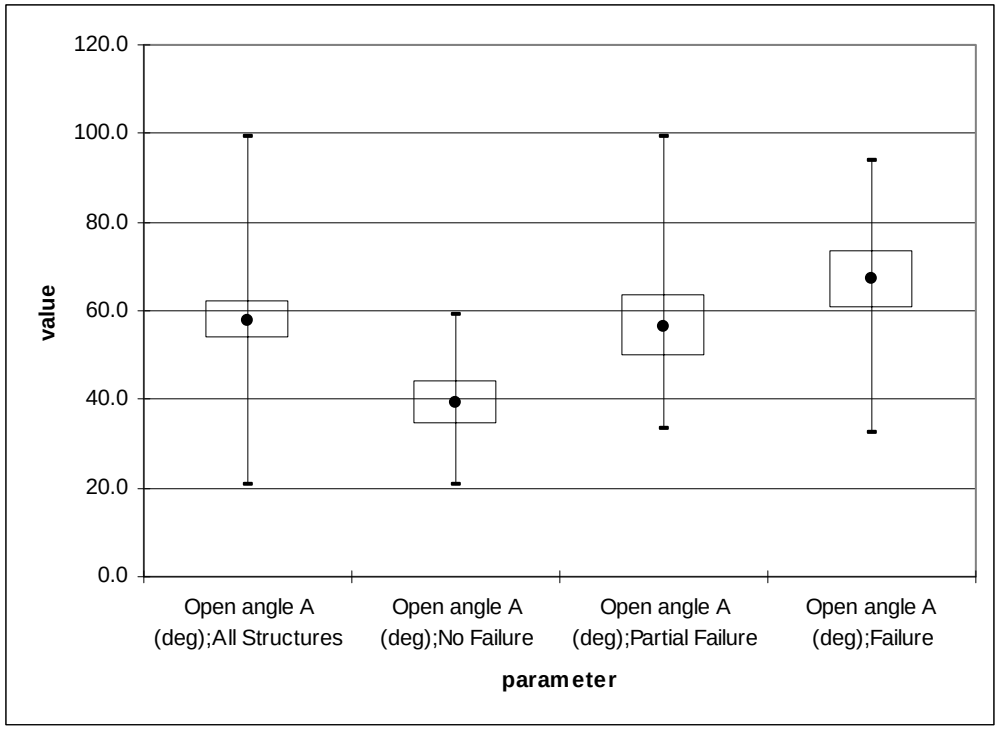

Figure 3. Degree of failure compared to open angle; U,V-weirs

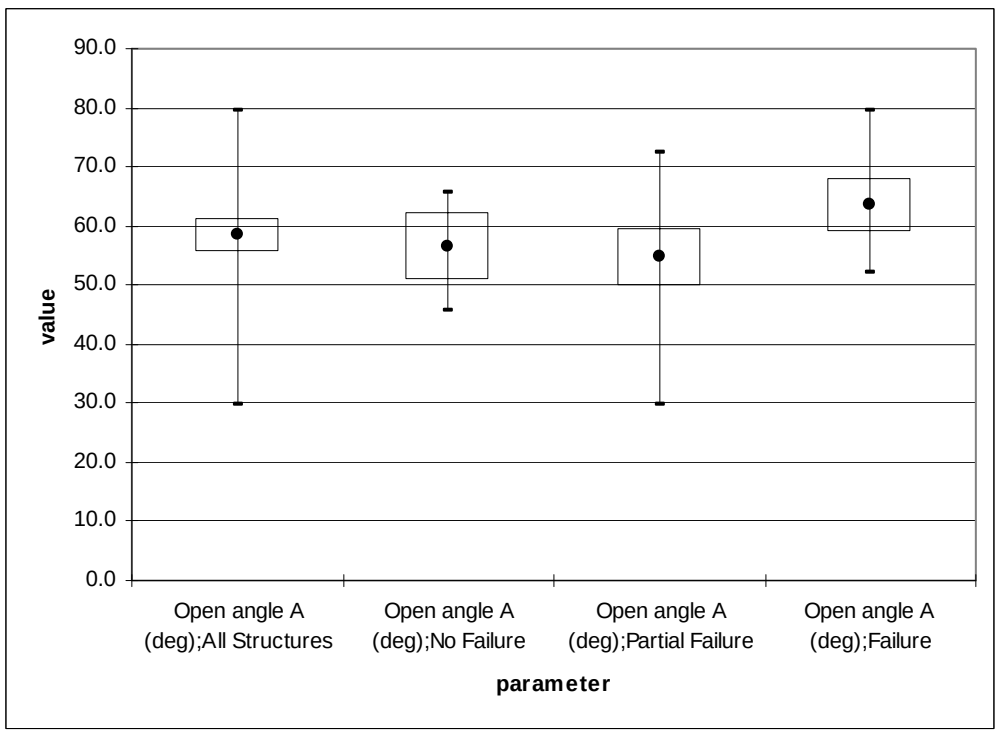

Figure 4. Degree of failure compared to open angle; asymmetrical U weirs

.

Observable trends were categorized as increasing or decreasing, depending on if the likelihood of failure was observed to increase with an increase or decrease of the parameter value. For instance, open angle was determined to have an increasing relationship with the degree of failure since the greater the value, the more likely the structure was to have experienced some degree of failure. Throat width divided by structure width was determined to have a decreasing relationship with the degree of failure since the lower the value, the more likely the structure was to have experienced some degree of failure. Scour depth can be described as not showing a trend. Table 5 presents whether select parameters show an increasing or decreasing trend. These trends are strictly observations and are not described based on their statistical significance. Since all A-weir structures were observed to have partially or fully failed, the relationships presented only indicate whether there is a tendency for the structure parameter to have experienced a greater degree of failure with a variation in the parameter value. Incorporating fully functioning A-weirs that have never required maintenance could change the presented relationships.

Table 5. Observations of trends by structure type for select parameters.

Parameter	U,V weir	Asymmetrical U weir	A weir

4. Discussion and Conclusions

Within the context of this report, quantitative analyses were performed on 54 structures that contained adequate survey information for development of a consistent data base of information. Surveys collected were processed and digitized in ArcGIS and Microsft Excel to quantify up to 80 geometric parameters at each site. Each site, however, varied in the number of quantifiable parameters based on the topographic surveys. The parameters were used as predictor variables to understand the relationships between the individual variables and the degree of failure associated with each structure type. While hydraulic processes can partially explain the relationships between the parameters and failure, some limitations are recognized by the sample size of each of the parameters. Each parameter was evaluated based on its individual relationship with structural

integrity. However, multiple parameters are interacting to produce a specific outcome of structural stability. By separating out relationships between the structure and individual parameters, the analysis is lacking the ability to incorporate all potential interactions between the predictor variables. Using the current data that were collected in the field across a relatively small sample size, these relationships represent a first attempt to correlate specific parameters with degrees of failure. A more robust analysis could be performed if the response variables were described with discrete quantitative values as opposed to categories of degree of failure or failure mechanisms. Based on field findings, quantification of each of the response variables requires additional data. Therefore, multiple regression analyses were not conducted on this initial set of data, but may be evaluated in the future.

The investigation identified several important relationships between structure parameters and the degree of failure. The most notable include the relationships with throat width, open angle of the structure, profile arm angle, and distance to next upstream or downstream rock structure. In general, structures with wider throats relative to the channel width failed less frequently than those with smaller or no throats (V-weirs). Structures characterized by wider open angles and greater arm slopes tended to fail more frequently than those with narrower open angles and milder slopes. Structures placed in close sequence tended to fail less frequently than those with wide distances between structures. However, the installation of multiple structures should consider the project objectives and the hydraulics to determine adequate spacing so as not to limit pool development or impact structure submergence at lower than design flows.

Two parameters that were evaluated as part of this analysis but did not illustrate notable trends included scour depth and the structure location relative to lateral channel morphology. The scour depths surveyed did not represent the maximum scour experienced by the structure prior to failure, as scour pools may fill at lower flows and on receding limbs of hydrographs while maximum scour depths will be experienced during significant storms. The location of the structure with respect to meander pattern did not illustrate a trend with the degree of failure. This may be in part related to the small sample size evaluated, system interactions such as lateral channel migration, or to flow path realignments associated with the structure geometry.

The parameters included in this analysis did not address system wide processes that would need to be evaluated on a larger scale to evaluate potential impacts to structure stability. Lateral channel migration, sediment transport throughout the system, changes in slope through the system, and root strength present along the channel banks, among many other system-wide processes, may all play a role in how well a structure performs in a given location. One substantial finding of this analysis is that an understanding of the fluvial geomorphic processes must be gained prior to installing these structures to best recognize their potential for success in reaching a specific project objective and to realize the level of maintenance required at each site.

The quantitative analysis performed in this study must be coupled with the results from the laboratory and numerical modeling components to best understand the relationships between geometric variables of the structure and structure stability. The variability across structure performance as identified in this field investigation portion of the research was based on a small sample size of structures surveyed with large ranges in geometric

parameters. Numerous landowners perform undocumented “maintenance” on the structures, which convolutes the ability of the field data alone to quantify structure performance. Modification to one variable while maintaining the values of all other parameters would be necessary to isolate how changes to the parameter impact the structure performance. Interactions between the variables add further complexity to the ability to evaluate an individual variable. An evaluation of the interactions of multiple variables is more suitable to numerical and physical modeling than to the field investigations. However, the relationships identified through the field investigation help inform inputs to the numerical and physical modeling and can be used to assess ranges of specific parameters that drive structure stability. Furthermore, the information from the field investigations can be used to determine how well relationships developed from the physical and numerical modeling translate to the field.

5. Planned Additional Tasks

A large amount of topographic information was collected during the site evaluations. During the analysis, several parameters were identified that were not collected but could be used to further the statistical analysis and might be strongly correlated to the degree of structure failure and possibly the mechanism for failure. The parameters include: sediment size upstream of the structure, sediment size in structure scour pools, sediment size downstream of the structure, size of rock material used in structure, elevations of structure foundation rocks, distance of the spacing or voids between the rocks used in the structure, and throat and cross-bar drop heights from the original bed elevation.

In addition, during the analysis, two parameters were identified that were not consistently collected throughout the first stage of site evaluations. These were the dimensions of the scour pool and delineation of the river banks near the structures. Some parameters still need to be calculated, including channel slope and bank lines for some sites. The channel slope based on the thalweg needs to be calculated at all sites.

Multiple sites are missing a few key topographic survey measurements needed to include them in our dataset. During the completion of this quantitative analysis, several sites were revisited during October, 2008, including the East Fork Salmon River, Bear Creek, Catherine Creek, and the Entiat River. Data from these sites need to be digitized and added to the quantitative analysis to increase the population size for statistical analysis and to perform more detailed evaluations on several parameters that were not previously collected.

ABSTRACT

This paper discusses the use of a digital camera setup developed for the in-situ measurement of floc size distributions as a function of time in a turbulent field. The camera assembly consists of a CCD camera fitted with a 2X objective lens coupled with an LED spotlight and a strobe controller. The setup allows for the measurement of a wide spectrum of particle sizes, ranging in size from 5 micron to a few millimeters, in a single image. The system was tested for accuracy using suspensions of known particle sizes (Coulter Counter standard particles) and compared to. The camera system is then used to measure floc particle size distributions of kaolin clay in fresh and salt water suspensions.

1. INTRODUCTION

The evolution of flocculated particle size distributions is a fundamental component in the transport and deposition processes of fine muddy sediments in estuaries, lakes, and oceans. Floc particle size distributions can change as a function of the local turbulent stress field and the biological/chemical properties of the sediment-water mixture. Important for the development and testing of analytic floc population dynamic models is the accurate measurement of floc grain size distribution as a function of the driving turbulent fluid motion. This type of data can be quite difficult to obtain since flocs are both fragile and dynamic, meaning that an accurate measurement requires nonintrusive in-situ measurements of the size distribution as a function of time. Digital cameras have proven to be one of the best technologies for accomplishing this (Ridd and Alessandra (2006); Mikkelson et al. (2005); Esima and Kalf (1996)).

The camera setup is a nonintrusive, automated assembly which provides a direct mechanism to measure the floc size distribution without disturbing the original floc structure. The camera assembly consists of a data acquisition system which is controlled by a current source controller (regulating the current pulses for illumination and trigger signals), a data logger (recording data) and the storage unit (storage of the data). The major focus of this paper is on the validation of the camera setup developed at the University of Houston for the in-situ measurement of floc size distributions. Section 2 describes the camera assembly. Section 3 elaborates the camera method and the steps involved in the validation process of the camera technique. Section 4 presents the application of the camera setup. Section 5 presents the concluding thoughts on the camera technique to measure floc size distribution.

2. CAMERA ASSEMBLY

The camera assembly consists of a 1392 X 1040 AVT Firewire progressive scan, monochrome CCD camera fitted with a 2X primary magnification objective lens coupled with an LED spotlight. The spotlight is attached to a strobe controller which can be triggered or run in continuous mode. The camera can capture single images using an external trigger or can capture images at a speed of up to 17 fps. The camera shutter speed, gain, brightness, gamma, resolution (camera settings) are set to particular values in order to achieve a desirable image as per the test sample conditions. The camera captures images of flocs which are then processed using an image analysis tool (Image J).

The lens system consists of the front objective and a rear assembly, the Modular Magnification System kit R200 plus Objective 9 from Edmunds Optics. The lens has a magnification of 2X with a field of view of 3.2 mm X 3.2 mm and has a working distance of 91 mm. The in-line system of the objective lens is equipped with a C-Mount. The C-Mount is inserted between the rear assembly and the front objective and then threaded to a tripod. The adjustable screw on the side of the front objective is used to regulate the amount of light to pass through the aperture of lens assembly. The LED spotlight acts as a source of illumination for the camera and is connected to the strobe source which allows to vary the light intensity on the LED spotlight as per requirement.

The S4000 Advanced Illumination Strobe source runs on three different modes - continuous, test and trigger. The continuous mode is used for very slow moving or static fluid flow conditions. However for rapidly moving turbulent flow fields, it becomes difficult to capture clear floc images with the continuous mode. This problem is resolved by strobing the light, which makes it possible to freeze the motion of fast moving flocs. The strobing of the light is achieved by simultaneously triggering the camera and the strobe source to achieve minimum blurred and clear images. Trigger lines from the camera and the strobe controller are connected to the Data Acquisition device (NI-DAQ) which is controlled through LabView (8.7.1) National Instruments. Figure 1 is a pictorial representation of the test setup. Figure 2 shows an example of fast moving microspheres in water. Microspheres are polystyrene particles (Large Polymers BB03N –Bangs Lab) with particle size less than 90 µm.

3. VALIDATION OF THE CAMERA METHOD

In order to validate the camera technique, tests were performed on suspensions of standardized particle sizes, used in calibrating Coulter Counter. The goal was to validate the results given by the imaging system. The camera and lens specifications yield a pixel size of 2.2 µm/pixel and allow for the measurement of a wide spectrum of particle sizes ranging from approximately 5-10 µm to a few millimeters in size, in a single image. The Coulter Counter solution consists of standard Polystyrene Latex particles (L10, L20, L30) with nominal size of 10 µm, 20 µm and 30 µm. Images of Coulter Counter particles (10 µm, 20 µm and 30 µm) were captured using the camera system (Figures 3, 4 and 5). The back lit images were then processed to obtain the imaged particle size distribution. The

imaged samples of Coulter Counter particles were tested in a Coulter Counter particle size analyzer to compare the results with the camera method.

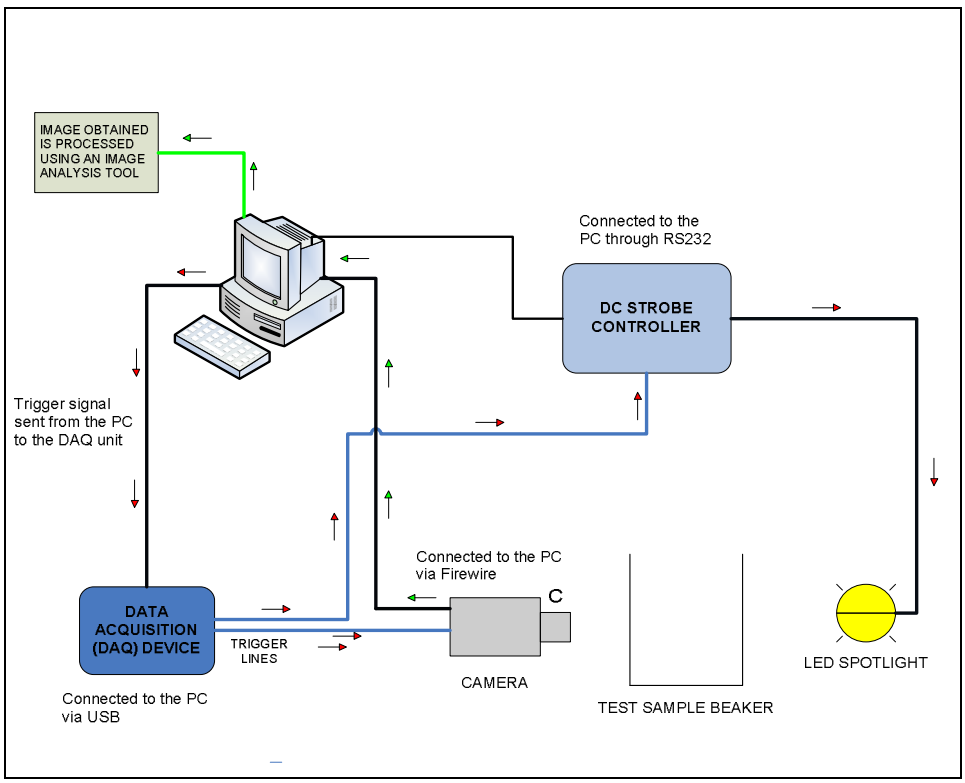

Figure 1 - Camera Assembly Network

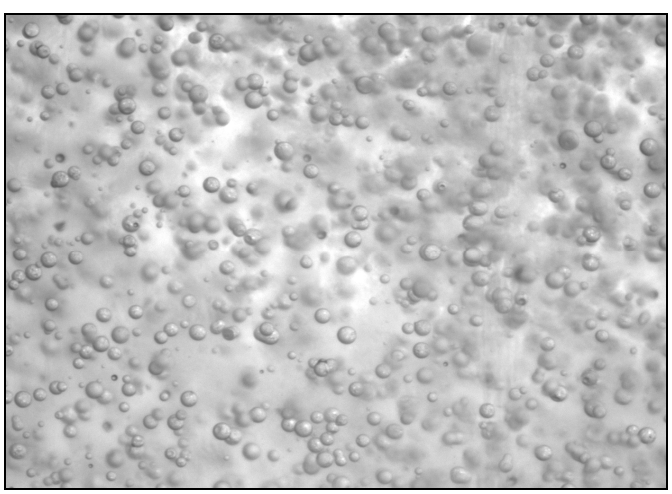

Figure 2 - Image of Microspheres with size < 90 µm taken in the camera setup

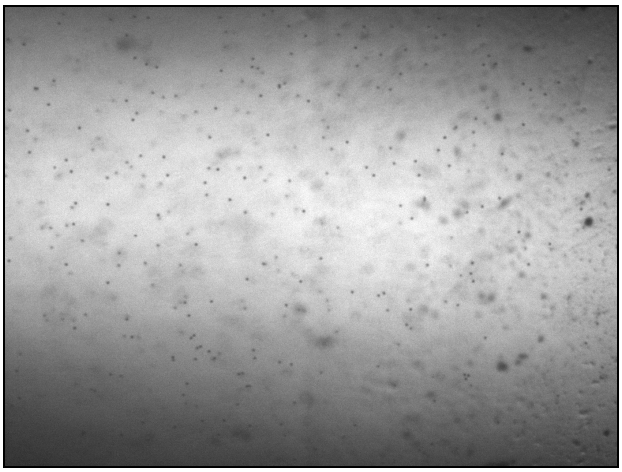

Figure 3 - L10 Coulter Counter standard solution 10 µm particles taken in the camera setup

Figure 4 - L20 Coulter Counter Standard Solution 20 µm particles taken in the camera setup

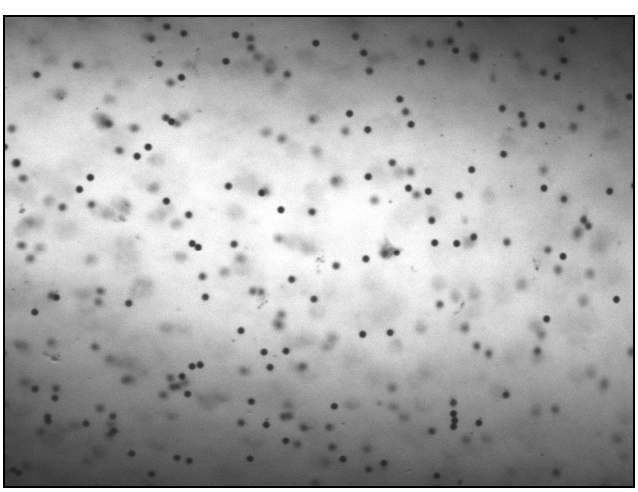

Figure 5 - L30 Coulter Counter Standard Solution 30 µm particles taken in the camera setup

The images of the Coulter Counter particles were processed using the image analysis tool (ImageJ). The results were then compared with that obtained from the Coulter Counter (Tables 1 and 2). The average particle size measured by the camera setup varied from the values obtained from the Coulter Counter in the order of 3 - 4 µm.

Table 1- Mean and Standard Deviation for L20

L20	COULTER COUNTER	CAMERA SETUP
Mean	20.32µm	17.51µm
Standard Deviation	1.76µm	2.79µm

Table 2- Mean and Standard Deviation for L30

L30	COULTER COUNTER	CAMERA SETUP
Mean	32.19µm	27.49µm
Standard Deviation	0.99µm	3.36µm

The results showed that the camera under estimated the particle sizes. This could be due to over exposure of light, which could have made the flocs look smaller in size. There is this possibility of an error in the calibration of the camera, which could have lead to the underestimation of the particle sizes.

4. APPLICATION OF THE CAMERA METHOD

The camera method is used to measure the floc size distribution of kaolin clay. Figure 6a shows an image of kaolin flocs. The image is then processed using an image analysis procedure for automated grain size measurement (Strom et al. 2007) (Figure 6). The camera method can also be applied to measure the fall velocity of flocs and to study the time evolution of flocs.

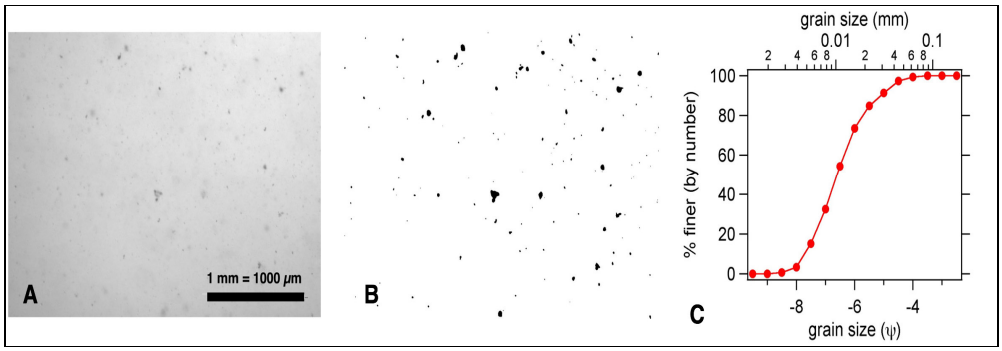

Figure 6 - Application of camera setup for floc measurement. (A) imaged flocs, (B) threshold image for automated grain sizing, and (C) resulting grain size distribution.

5. CONCLUSIONS

The floc camera assembly is capable of providing comprehensive information on the floc size, structure, floc formation, and the temporal evolution of flocs. This enables the study and characterization of flocs and their various parameters such as settling velocity, fractal dimension, and excess density. Collecting quality images for analysis are, however, non-trivial; since the camera setup is dependent on several parameters such as the sediment concentration, the amount of lighting, the speed at which the particle moves, and the camera specifications. The validation process results suggest that the particle sizes estimated for the standard size particles (L20 and L30) by the camera and Coulter Counter are reasonably close. An offset of 2-3 microns in the average particle size is observed between the camera measured distributions and the standardized sizes. The camera method did yield greater spread in the measured particles comparatively to the Coulter Counter results. This may be due in part to over exposure of the particles, having particles at varying depths of field, or other measurement errors.

Multi-Criteria Assessment of Pallid Sturgeon Habitat Restoration for the Missouri River

John Stansbury[1], PhD, PE, M.ASCE; Jennifer Gitt[2], EI, S.M.ASCE; and Istvan Bogardi[3], PhD

The U.S. Army Corps of Engineers (USACE) in cooperation with other agencies such as the U.S. Fish and Wildlife Service is currently planning, designing, and constructing projects designed to restore habitat for the endangered pallid sturgeon (Scaphirhynchus Albus) and associated species in and along the Missouri River. Management and restoration of habitat is a complex process with many and often conflicting priorities, and habitat restoration success is difficult to measure, in part because there is often a significant lag time between the restoration activity and the biological response by the target species. This project develops a multi-criteria assessment tool to help the USACE and cooperators assess the status and the progress of the habitat restoration efforts on the Missouri River. The multi-criteria assessment method uses composite programming which assesses the overall condition of the habitat based on multiple indicators (e.g., water velocity, depth, substrate). Indicator values were determined at different locations and times, and weights were assigned to the indicators to represent their relative importance. The result obtained from the assessment is a river bend-scale value that characterizes the overall quality and quantity of habitat at different points in time for that bend. Conversely, the method can be used to characterize conditions before and after a habitat restoration project or to compare the effectiveness of different habitat restoration methods on different bends within the river reach. The assessment method will also be used to identify data gaps and deficient habitat components that require further restoration.

INTRODUCTION

The U.S. Army Corps of Engineers (USACE) in cooperation with other agencies including the U.S. Fish and Wildlife Service (FWS) is currently planning, designing, and constructing projects designed to restore habitat for the endangered pallid sturgeon (Scaphirhynchus Albus) and associated species in and along the Missouri River. Management and restoration of habitat is a complex process with many and often conflicting criteria, and habitat restoration success is difficult to measure, in part because there is often a significant lag time between the restoration activity and the biological response by the target species. This need for habitat assessment using a diverse set of components may be fulfilled by the multi-criteria habitat assessment (MCHA) tool presented in this paper. The multi-criteria assessment method uses composite programming which assesses the overall condition of the habitat based on multiple indicators (e.g., water velocity, depth, substrate). The focus of the assessment is for the habitat required by pallid sturgeon fry and juveniles, age 0 to 1 year.

Missouri River History and Problems

The Missouri River flows 3734 km (2321 mi) from the Rocky Mountains near Three Forks, Montana to its confluence with the Mississippi River near St. Louis, MO. The river's basin drains all of Nebraska, and parts of Colorado, Iowa, Kansas, Minnesota, Missouri, Montana, North Dakota, South Dakota and Wyoming. Figure 1 shows the Missouri River drainage basin.

Figure 1: Missouri River, source USACE

As recently as 1923, the Missouri River was a predominantly meandering stream with channel widths ranging from 457 to 1893 m (1500 to 6500 ft) (USFWS, 2000). Six Missouri River main stem dams, built between 1933 and 1964, have inundated approximately 36 percent of the river length and associated riverine habitat creating a lacustrine environment behind each dam and altering the natural downstream temperature, hydrograph, and sediment loads, as well as creating fish migration barriers. In addition, 40 percent of the Missouri River has been channelized (from Sioux City, IA to its confluence with the Mississippi River near St. Louis, MO) as part of the Bank Stabilization and Navigation Project. This reach of the river has been narrowed into a stable, self-scouring channel maintained at widths of 180 to 270 m (600 to 900 ft) containing a 90 m (300 ft) navigation channel maintained at a minimum depth of 2.7 m (9 ft). The channelization greatly reduced the meander belt habitat, including riparian timber,

sandbars, and shallow water habitat. Additionally, the dams and channelization have reduced substrate diversity and bottom structure (USFWS, 2000).

Habitat and Ecological Issues for the Pallid Sturgeon

Pallid sturgeons are native to the Mississippi and Missouri Rivers and their major tributaries including the Yellowstone and Platte Rivers. The pallid sturgeon was listed as an endangered species on October 9, 1990. The reasons for listing are habitat modification, apparent lack of reproduction, commercial harvest, and hybridization (USFWS, 2000). In 2000, the FWS issued a jeopardy opinion for the pallid sturgeon (Korschgen, 2007). Habitat modification is listed as the most significant cause for the species decline. Pallid sturgeon can travel long distances to find suitable habitat with an average home range of 78.6 km (48.8 mi). The maximum recorded migration distance is 319.7 km (198.6 mi), and they have been reported to travel 20.9 km per day (13 mi/day) (USFWS, 2000). However, dams restrict movement in the upper Missouri River, possibly preventing sturgeon from reaching spawning habitat and preventing fry from reaching recruiting grounds. In addition, habitat homogenization by channelization in the middle and lower reaches has reduced available habitat by decreasing channel variability with the loss of islands, sand bars, and scour holes.

In the upper reaches of the Missouri River, pallid sturgeon have been found to reach lengths of 1.8 m (6 ft), weigh up to 36 kg (80 lbs), and live in excess of 60 years. They are benthic fish having a streamlined body with a flat rostrum and large pectoral fins allowing them to exploit river bottoms as current refugia (USFWS, 2000). Gut analyses indicate pallid sturgeon diet consists of benthic macro-invertebrates, and as the sturgeon grows, the diet includes an increasing proportion of fish (USFWS, 2000).

Spawning cues are thought to be the combination of rising stream flow and temperature, which historically occurred between late April and July (USFWS, 2000). There have been reports of recent spawning activity by the pallid sturgeon; however, a lack of young-of-the-year pallid sturgeons found in the River indicates a problem with recruiting the young fish to adulthood. The population is currently being sustained by efforts to breed and stock the fish throughout its historical range. This study is focused on the early life-stage, age zero to one, to address the needs of the juvenile pallid sturgeon at the recruitment bottle-neck that is suspected to be hindering the survival of the species.

Current Habitat Restoration Efforts

Historically, the Missouri River was a wide meandering stream with 98 percent of the main channel less than 3 m (10 ft) deep and with velocities generally between 0.3 to 0.75 m/s (1 and 2.5 fps) during the late summer and fall (USFWS, 2000). Shallow water habitat (SWH) was found to be lacking in the modified Missouri River and was defined to fill the gap between historically available habitats and those which are found in the river today. SWH is defined as area having water velocities less than 0.6 m/s (2.0 ft/s) at depths less than 1.5 m (5.0 ft) at the effective discharge (50 percent exceedance discharge from August flow duration curves) (USACE, 2007). The habitat restoration goal, as set forth by the FWS in the 2000

Biological Opinion is to create 12.4 to 18.6 ac/km (20 to 30 ac/mi) of shallow water habitat (SWH). According to the USACE SWH program interoffice management plan, dated August 2003, the long-term goal is to convert an average of 61 m (200 ft) of the top width, about 24 acres per river mile, to SWH while maintaining all authorized project purposes. Habitat restoration efforts on the channelized portion of the Missouri River include notching dikes and building in-stream chevrons, which create scour holes, sand bars, promote bank erosion, and catch passing woody debris. In addition, historic side chutes are being reopened to create backwaters and channels with low velocities.

Multi-Criteria Habitat Assessment Process

The multi-criteria habitat assessment (MCHA) tool is similar to other habitat assessment methods, for example the US Environmental Protection Agency's Rapid Bioassessment Protocols. The MCHA is designed to help evaluate the status and progress of the habitat restoration efforts on the Missouri River using composite programming. The overall condition of the habitat in a river bend is assessed using multiple indicators resulting in a value that characterizes the overall habitat quality and quantity at a single point in time. The resulting value may be used to evaluate changes through time or to compare habitats in multiple locations. The assessments will be used to assess restoration progress and effectiveness.

The indicators are the habitat components in the river system that significantly affect the pallid sturgeon. Each indicator is given a weight, w, that reflects the importance of the indicator. Each indicator has a normalized value, c, that places the measured condition (e.g., velocity magnitude) within the range of the best and worst case values. Normalization scales the indicator condition values between zero and one using Equation 1. A normalization value of one represents the best case and zero is the worst case.

$$c_i = (\text{Measured Value} - \text{Worst}) / (\text{Best} - \text{Worst}) \quad (1)$$

The normalized indicators are then compiled into groups of increasingly less specific categories as shown in Figure 2. The indicators in each group are traded off using Equation 2:

$$c_T = [(w_1 * c_1)^p + (w_2 * c_2)^p + (w_3 * c_3)^p + \ldots]^{(1/p)} \quad (2)$$

where

c_i = normalized condition for criterion i,

c_T = composite condition value for a criteria group,

p = balancing factor, usually 1-3, which removes bias and emphasizes outstanding criteria,

w_i = weight for criterion i, (sum of weights in criteria group must equal one).

This equation is iterated through all the indicator groups until a single value for the overall habitat condition is reached (see Figure 2). The result obtained from the assessment is a river bend-scale value that characterizes the overall quality and quantity of habitat for that bend.

Habitat management and restoration is a complex process with many and often conflicting criteria making MCHA a fitting tool for monitoring the progress and effectiveness of the restoration efforts. The process of data collection to support the assessment can help managers evaluate their data collection priorities and to fill data gaps. The structure may also be used to evaluate impaired bends to identify conditions that need improvement by finding the categories and indicators with the lowest values.

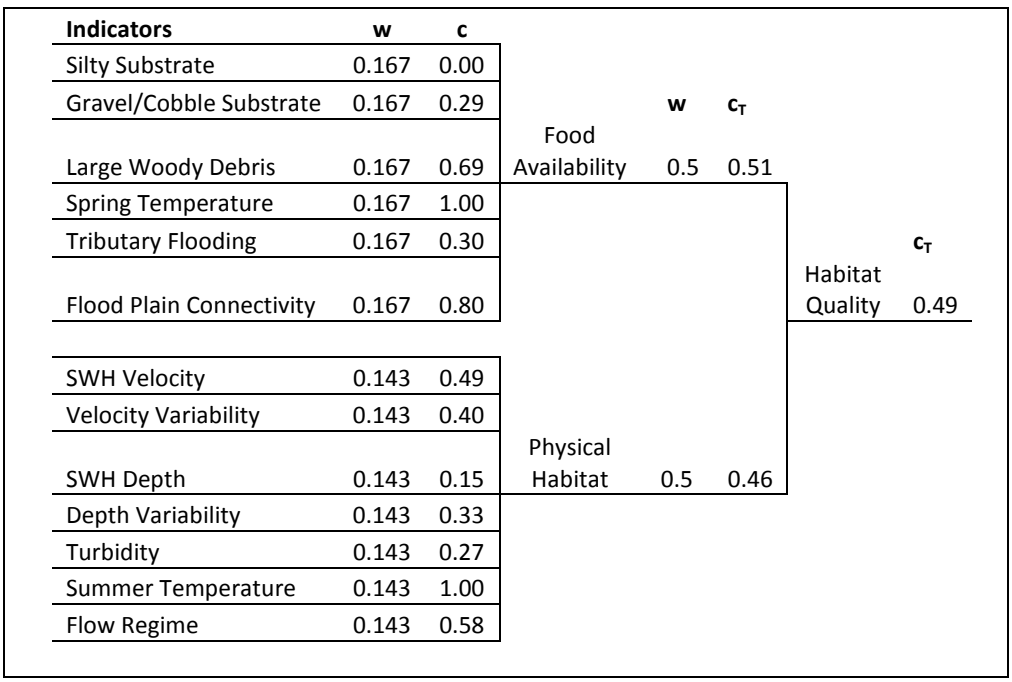

Figure 2: The MCHA Structure for Age 0-1 Pallid Sturgeon in the Missouri River. Note that this figure shows a balanced weighting scheme; other weighting schemes can be used as discussed below. A balancing factor (p) of 1 is used for this figure. Criterion values (c) are for Lower Little Sioux Bend 2006.

MCHA Challenges

The primary difficulty of using the MCHA for pallid sturgeon habitat is gathering sufficient data for each indicator and linking the indicators to specific ecological functions. For example, studies have been implemented to locate pallid sturgeon and track their movements, and those studies can be overlaid by physical data, such as substrate. However, it is unknown whether the fish are in that particular location because they prefer that type of substrate, the substrate supports a food source, or that the substrate is all that is available. The lack of clear links between habitat conditions and ecological function limits the ability to definitively assess habitat conditions.

The data required to use the MCHA tool for pallid sturgeon on the Missouri River are extensive, and data collection can require a great deal of time and money. Because of limited available data, estimates have been required for some of the indicator values for this analysis. This will be a problem for applying the MCHA

method until data collection is done specifically to meet the needs of the MCHA process.

METHODS

Develop Goals and Uses of the MCHA Tool

The MCHA method can be used to characterize conditions through time (e.g., before and after a habitat restoration project) or to compare the effectiveness of different habitat restoration methods on different bends within the river reach. The assessment method could also be used to identify data gaps and deficient habitat components that require further restoration. Habitat restoration success is difficult to measure, in part because there is often a significant lag time between the restoration activity and the biological response by the target species. The MCHA tool can assist resource managers by helping them identify the best locations and methods for restoration, the types of habitat monitoring and data collection to focus on, as well as to assess the status and the progress of the habitat restoration efforts.

Selection of Composite Programming

Composite programming was selected for use in the MCHA tool because it allows for the comparison of multiple indicators within common groupings as shown in Figure 2 (e.g., Food Availability), and these broader categories are then traded off for the overall condition. Dividing criteria into smaller groups decreases the number of criteria in each group and helps maintain the relative importance of each criterion within a group. Conversely, multi-criteria assessment tools such as compromise programming multiattribute utility theory allows all criteria to be traded off together, the larger number of criteria traded off together may allow a fatally flawed criterion to pass through undetected in an otherwise outstanding habitat and mislead improvement efforts.

Selection of Habitat Assessment Sites

The Habitat Assessment and Monitoring Program (HAMP) collects data from 20 river bends from Ponca, NE to Rulo, NE in the USACE's Omaha District, providing a wealth of physical and biological data. Three habitat assessment sites were selected from the HAMP bends in the channelized portion of the Missouri River based on data availability. The three bends including Lower Little Sioux bend, downstream of Decatur, NE at river mile (RM) 672.8 to RM 670.5, Upper Civil bend at RM 574.8 to RM 572.8, and Nebraska bend at RM 562.9 to RM 560.4, the latter two are near Nebraska City, NE. The results presented in this paper are from the Lower Little Sioux Bend, data for the other two bends are still being developed.

Identify Criteria

The value of the overall Habitat Quality, the final indicator, is defined by two second-level indicator categories, Food Availability and Physical Habitat, which are each composites of first-level indicators. The composite structure is made up of 13 first-level indicators, described in detail below. Each indicator was selected because it represents an important component in the habitat of the juvenile pallid sturgeon.

Identify Best and Worst Values for Each Criterion

The best and worst values define the potential range of values of each criterion. For this study, these values are developed from literature sources and from expert

opinion (e.g., from fisheries biologists studying the pallid sturgeon). There have been numerous studies of pallid sturgeon habitat and behavior; however, little data were collected before construction of the main stem dams, limiting the availability of historical data such as unrestricted population size and habitat preferences. As noted above, the modern habitat studies can only identify preferences for what is available under current conditions which, in many cases, are strikingly different from the historic river. The values for the worst case condition are based on conditions that would likely not support pallid sturgeon survival. The best values could be defined by one of two sets of conditions, these include: the "reasonable and prudent" conditions detailed by the 2000 Biological Opinion, or the untouched natural conditions of the river Lewis and Clark experienced in 1804 to which the pallid sturgeon are adapted. The "reasonable and prudent" version of the best values is the choice for the MCHA structure for two reasons: first it is the selected goal of the managing agencies overseeing the restoration of the sturgeon habitat, and second it is likely impossible to return to predevelopment conditions.

The choice of the values of the best and worst conditions affects the trade-off results. For example, as the best condition increases (i.e., moves farther away from the actual condition), the value of the trade-off result will be lower (i.e., farther from the best). For some applications of multi-criteria analysis, this phenomenon must be carefully evaluated. However, for this study, the trade-off results will be used as relative values for comparing the condition of a site through time or comparing the conditions of different sites. Since all of the analyses will use the same "best" and "worst" values, the selection of these values will not materially affect the comparisons.

Determine Values of the Criteria under Each Treatment

1. Silty Substrate

Juvenile pallid sturgeon diets consist mainly of invertebrates. Silty substrates provide a higher density of invertebrates than sand substrates due to the instability and tight packing of sand grains which reduces the ability of the substrate to trap detritus and may limit available oxygen (Allen, 2007). However, high silt levels can reduce heterogeneity by filling interstitial spaces and coat consumers and food resources, so a mix of sand in the silty substrate is desired (Allen, 2007). Substrate data are collected at the end of each HAMP fish collection trawl as a grab sample and with the USACE's physical survey around a small selection of channel structures in each HAMP bend. These data do not provide a good representation of the entire width of the channel, but are reflective of what is likely occurring in the shallow fringe. Ideally, this indicator would be represented by the area, in acres/mile, of silty substrate, defined by the Unified Soil Classification System as grain sizes less than 0.075mm in a sieve analysis (Das, 2006). However, due to the current lack of substrate data points to compile realistic areas, a preliminary data model was developed using the fraction of samples out of the total number collected that fall into this substrate classification. The best indicator value is up to 20 percent of the total number of samples collected, and the worst is zero.

2. Gravel/Cobble Substrate

Gravel and cobble substrates are important for the incubation of the pallid sturgeon eggs because they require an adequate supply of oxygenated water circulating through the coarse substrate; the embryos will suffocate in an overly silty substrate. The gravel also protects the eggs from predators and sweeping currents (Allen, 2007). This indicator is also represented by a preliminary model using the fraction of samples out of the total number collected that fall into the gravel/cobble substrate classification for the same reasons noted above. With a more complete dataset, this indicator would be represented by the area, in acres/mile, of gravel or cobble substrate defined by the Unified Soil Classification System as grain sizes 76.2 to 4.75mm in a sieve analysis (Das, 2006). The best indicator value is up to 20 percent of the total number of samples collected, and the worst is zero. Substrate data for this indicator is the same data used in the Silty Substrate indicator.

3. Large Woody Debris and Rocky Substrate

Large woody debris (LWD) is a minor energy source itself because few invertebrates feed on it directly; however, it does provide food and habitat for a number of species serving as an important substrate for biofilm development. LWD traps organic material and leaves and creates a depositional area, where sediments and organic matter settle and decompose, providing nourishment through primary production for the inhabitants of the microhabitat (Allen, 2007). Large wood and rock structures or boulders in a river are thought to be mostly interchangeable as suitable substrates for biofilms and as flow obstructions for organic material retention. This indicator is represented by the area, in acres per mile, of LWD and rock structures. The best indicator value is one acre per mile of LWD and rock structures, and the worst value is zero.

4. Spring Temperature

Temperature has a strong influence on secondary production in a river system by limiting the availability of food at several levels of the food chain. Temperature affects the organic matter decomposition rate, the accrual and loss rate of benthic algae, and determines metabolic rates of organisms (Allan, 2007). The main stem dams release cold water from the bottom of the reservoirs keeping the downstream river water colder than the natural system. Certain insect species have lifecycles requiring exposure to near freezing followed by rapidly warming temperatures to break egg diapauses. This temperature cue cannot occur in the cold waters below dams until late in the season if at all (Allen, 2007). If insects do not hatch, there could be a shortage of food in these river reaches for insectivores, which include juvenile pallid sturgeon.

This indicator is represented by the number of degrees below 17°C (62°F) for the average May temperature as recorded by the USGS stream gage nearest to the given river bend. The best indicator value is zero, signifying that the average May temperature has warmed to at least 17°C, and the worst value is ≥5, meaning the temperature did not exceed 11°C (51°F).

5. Tributary Flooding

Tributary flooding is an important ecological function because it brings organic matter into the river. This organic matter in turn provides the base of the food chain for the pallid sturgeon. Since much of the natural flooding for the river has been eliminated through dams and levees, tributary flooding is now likely a major source of organic matter for the system. This indicator is represented by the number of tributary floods within 50 miles upstream of the bend within the last 10 years as found on USGS stream gage data for the major tributaries. Flooding is defined as out of bank events. The best value is 10, an average of one flood per year, and the worst value is zero.

6. Flood Plain Connectivity

The importance of a flood plain to a river ecosystem is substantial, as production by aquatic and terrestrial macrophytes in the flood plain along with inputs from flooded forest make up approximately 90 percent of carbon production (Allen, 2007). A connectivity model was developed for the Missouri River Master Water Control Manual Revised Draft Environmental Impact Statement (RDEIS) in 2001 to measure inundation of low-lying lands along the channelized portion of the river. The model outputs the number of acres inundated vs. the percent of years flooded for a minimum of two days. The best value is 4000 acres inundated at a 33 percent frequency, meaning 4000 acres will be flooded approximately every three years, the same frequency as the FWS's requirement in their Biological Opinion (2000) for Gavin's Point Dam to release an artificial spring rise. The worst value is zero.

7. Shallow Water Habitat Velocity

Shallow water habitat for the pallid sturgeon recovery is defined as areas in the river with velocities less than or equal to 0.6 m/s (2.0 ft/s) and depths less than or equal to 1.5 m (5.0 ft). Low velocity is important to provide refugia for fish (especially juveniles) and to provide other ecological functions (e.g., macro-invertebrate production) associated with low velocity. Since much of this type of habitat has been eliminated due to dams and channelization, the presence of this habitat attribute is important to the recovery of the sturgeon. The indicator SWH Velocity accounts for the presence of the shallow water habitat velocity component in the river bend. The total area, in acres per mile, with velocity magnitude less than or equal to 0.6 m/s (2.0 ft/s) is the indicator value. The best indicator value is the upper limit of the USACE goal of 18.6 ac/km (30 ac/mi), and the worst value is zero.

The USACE collected in-channel velocity data in the selected HAMP bends using an Acoustic Doppler Current Profiler (ADCP) concurrently with hydrographic data and recorded the data as depth averaged velocity magnitude and direction (USACE, 2007). The ADCP data were recorded at low flows; therefore, the depth averaged velocities are not representative of effective discharge (USACE, 2007). The ADCP data were fit to run a 2D model to delineate SWH at various flow exceedances, including the effective discharge. The 2D model output is the data used in this study which allows for a detailed set of data around all structures at the effective discharge. The data used for this research is true to the 2D model but is not a perfect representation of what is occurring in the river. The GIS environment

ArcMap was used to calculate areas of given velocity classes, such as the SWH component 0 to 0.6 m/s (0 to 2 ft/s), by generating a triangulated irregular network (TIN) surface for each bend representative of the velocity magnitudes using the velocity data.

8. Velocity Variability

Velocity variability is a measure of the complexity of the habitat conditions which can be considered an indication of the ecological complexity and stability. A frequency distribution of the areas in the river with various measured classes of velocity represents the in-channel variability for the indicator, Velocity Variability. The velocity variability model normalizes the number of acres in each velocity class to the total number of submerged acres in the bend to get the frequency, f, at the effective discharge. The sum of all frequencies should equal one. The data were compiled into six velocity classes in feet per second, see Table 1. The number of frequencies equal to or greater than 0.10, representing 10 percent of the total bend area, is the indicator value. The greater the number of classes where $f \geq 0.10$, the higher the variability in the bend and better the indicator value. The best indicator value is six, which is the total number of defined velocity classes; and the worst value is one, representing no variability in the bend. The data used for this indicator is the same as for the SWH Velocity indicator.

Table 1: Frequency Distribution Model for Velocity Variability

Velocity Range, fps	Acres in Velocity Range	Frequency, f	$f \geq 0.1$
0 - 1	17.66	0.080	0
1 - 2	18.93	0.086	0
2 - 3	27.08	0.123	1
3 - 4	78.85	0.358	1
4 - 5	77.75	0.353	1
5 - 12	0.01	0.000	0
Total	220.27	1.000	3
# Velocity Classes $f \geq 0.1$ =			**3**

9. Shallow Water Habitat Depth

The indicator SWH Depth accounts for the presence of the shallow water habitat depth component in the river bend. The total area, in acres per mile, with depth less than or equal to 1.5 m (5.0 ft) is the indicator value. The best indicator value is the upper limit of the USACE goal of 30 acres per mile, and the worst value is zero. The USACE measured and recorded the in-channel depths in the selected HAMP bends, with cross sections every 15.2 m (50 ft), concurrently with the velocity data previously described. Backwaters and chutes were not included (USACE, 2007).

10. Depth Variability

A frequency distribution of the areas within measured depth classes characterizes the indicator, Depth Variability. The depth variability model is the same as the method used for Velocity Variability. The data were compiled by the

USACE into four depth classes in feet; see Table 2 and Figure 3. The classes are divided into uneven increments about the desired SWH criteria including a two foot fringe class above and below the SWH criteria; however, only the inundated areas during effective discharge are considered for this model. The best indicator value is four classes with a frequency of at least 0.1, indicating good depth variability, and the worst value is one.

Table 2: Frequency Distribution Model for Depth Variability

Depth Range, feet	Acres in Depth Range	Frequency, f	f ≥ 0.10
12+	135.53	0.678	1
7 to 12	45.53	0.228	1
5 to 7	7.45	0.037	0
0 to 5	11.3	0.057	0
Total	199.81	1.000	2
# Depth Classes f ≥ 0.10 =			**2**

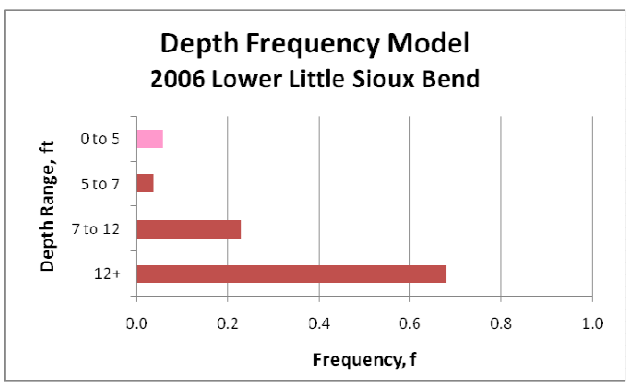

Figure 3: Depth Variability Frequency Chart

11. Turbidity

Turbidity is caused by suspended sediments, including algae and colloidal matter, restricting light transmission through the water providing the sturgeon with cover for protection from predators as well as for feeding on unsuspecting invertebrates and fish (Allen, 2007). The suspended sediment load has decreased by 69 to 99 percent from historic conditions, depending on downstream distance from the nearest dam, due to sediment trapping behind dams (USFWS, 2000). A decrease in turbidity allows sight-feeding species to increase in abundance which in turn could increase predation, competition, and reduce food availability (Allen, 2007).The Turbidity indicator is represented by the average Nephelometric Turbidity Units (NTU) as sampled by the HAMP data collection teams during the summer months. The best value is 100 NTUs, and the worst value is zero. The pallid sturgeons avoid areas without turbidity and current and are even suspected to be photophobic (USFWS, 2000).

12. Summer Temperature

Temperatures on the Missouri and Mississippi Rivers typically range from 0°C to 30°C (32°F to 86°F), and pallid sturgeons are found within the entire range (USFWS, 2000). There are point sources of heat pollution along the length of the Missouri River, for example the discharge of industrial cooling water, that have the potential to increase the nearby water temperature to the point that it is uninhabitable by most aquatic species. This indicator is represented by the number of degrees above 30°C for the average July temperature as recorded by the USGS stream gage nearest to the given river bend. The best indicator value is zero, signifying the average July temperature did not exceed 30°C, and the worst is ≥5, meaning the temperature exceed 35°C (95°F).

13. Flow Regime

A seasonally varied discharge is important to a river ecosystem because high flows entrain organic matter from stream banks, side channels, and other depositional areas unavailable during base flow (Allen, 2007). Many individual species have specific adaptations associated with particular flow regimes that cue various life history stages, for example high flows in spring cue spawning in some species including the pallid sturgeon, these adaptations may also allow them to exploit historical cycles of floods and drought (Allen, 2007). The indicator, Flow Regime, is a qualitative analysis of how closely the hydrograph follows historical seasonal variations, for example spring rise and summer low flows. The indicator value is determined by the number of months with 10-year average flows that fit within ±142 cubic meters per second (± 5000 cfs) of the proposed GP2021 hydrograph, defined in the RDEIS, using the USGS stream gage data monthly mean discharge. The best value is 12, representing a strongly correlated hydrograph where each month's 10-year mean discharge is within the hydrograph envelope, and the worst value is zero.

Determine the Weighting for the Criteria

The weight given to each indicator is based on the perceived importance of the criterion to the pallid sturgeon. There are a number of weighting techniques commonly used in multi-criteria assessment and decision modeling, these include: fixed point, which splits a total value among all indicators; rating, where each indicator is placed on a scale 1-10 and then the values are normalized; and paired comparisons, where each indicator is compared to all the others in pairs most popularly done using Saaty's analytic hierarchy process calculating eigenvalues to represent weights (Hajkowicz et al., 2000). The fixed point method was used for this study to demonstrate the effect of weights on the final outcome. This will be discussed in the results section. Saaty's method of paired comparisons is planned for use in further research when a select group of pallid sturgeon and habitat experts aid in the ranking of the indicators presented in this paper.

Application of CP Method

Once the indicators have been determined, weighted, and measured they may be placed into the structure for calculation. The final composite value is telling of the conditions in the assessed bend, and comparison of the value to other

temporally, spatially, or structurally varied assessment values will show improvement or deterioration over time, or reveal the most effective habitat types.

Uncertainty

There is considerable uncertainty in this assessment. Two primary sources of uncertainty are: lack of knowledge of the links between habitat conditions and ecological function related to juvenile sturgeon, and lack of measurement data regarding conditions in the river (e.g., extents of substrate types). Assessment of these uncertainties is critical to the proper use of the MCHA. For some of the data (e.g., flow frequencies) statistical analyses can be done to assess uncertainty. In cases where statistical analysis is not possible (i.e., where distributions are not known), fuzzy set theory may be used. In the cases where uncertainty is associated with lack of knowledge (e.g., ecological links), a more qualitative analysis based on expert opinion may be needed. Unfortunately, at this time, these analyses have not been completed. A proposed approach will be to conduct the trade-off analysis while directly incorporating uncertainties using fuzzy set methods.

RESULTS

Trade-off values

The trade-off of the criteria including the normalized values of the first-level indicators, the trade-off values for the second-level indicators, and the overall habitat quality value for the Lower Little Sioux study bend is shown in Figure 2.

The trade-off values provide relative estimates of the overall habitat quality of the bend at a particular point in time. It is important to note that the trade-off values are relative values indicating the quality of the overall habitat relative to worst-case and best-case conditions. While each trade-off value can be use to gain improved understanding of how a site compares to “best” and “worst”, the most reliable use of the tool is to compare how a site changes with time or how different sites compare. This is because consistent analyses will provide consistent comparisons.

From Figure 2, it can be seen that the condition of the Silty Substrate criterion is the worst possible, while the Spring and Summer Temperature criteria are the best possible. The overall Food Availability criterion trade-off value is 0.51, indicating that the condition is about half way between the best and worst. The overall trade-off value, Habitat Quality, is also half way to the best mark. Note that several of the data, as mentioned above, are preliminary and the results should only be considered for method demonstration purposes. However, once the complete data sets are available, these results will be useful for habitat managers because with this information, they can see where more effort is needed and where efforts have provided the most improvement. They can also see which types of remediation efforts have led to the greatest overall habitat improvements, or how a site has changed with time. Note that at this time, data are available for only one year, so the year-to-year comparison is not yet available.

In addition to the overall habitat quality (final trade-off value), important information can be found from the lower-level trade-offs and from the values of the indicators themselves. While managers may be more interested in the overall

habitat quality comparisons, scientists may be more interested in the more specific information found in the lower-level trade-offs. For example, to gain a better understanding of how food production/availability might compare between two bends (or two remedial treatments), a comparison of the trade-off values from the upper bracket in Figure 2 could be made.

Analysis of Criteria Weighting

The weighting of the criteria is developed by the habitat experts. Either the experts can develop a consensus of the weighting system, or each expert can assign weights according to his beliefs. The first case will provide a single final trade-off result that reflects the consensus weighting. The second case will result in a different final trade-off value for each expert. The second case method can be instructive as it will show the range of results reflected by the range in expert judgments. In both cases it is important to conduct sensitivity analyses of the weighting systems to understand how the weights affect the final trade-off values. For the study to-date, the expert judgments on the weights have not been solicited. Therefore, several possible weighting schemes (which are likely similar to schemes that will be proposed by the experts) have been assumed by the authors. These weighting schemes are shown in Table 3. The final trade-off values for each given weighting scheme are also shown in Table 3. Weighting scheme 1 makes all weights within a trade-off group equal; weighting scheme 2 emphasizes the importance of substrates over flow regime, shallow water habitat over turbidity/temperature/flow, and food production over physical habitat; weighting scheme 3 is the opposite of scheme 2.

Table 3: Weighting Schemes and the overall Habitat Values

Indicators/Criteria	Weight 1	Weight 2	Weight 3	Ideal	Worst	Value
Food Availability	**0.500**	**0.700**	**0.300**			
Silty Substrate	0.167	0.250	0.080	20	0	0
Gravel/Cobble Substrate	0.167	0.250	0.080	20	0	20
Large Woody Debris	0.167	0.250	0.090	1	0	0.69
Spring Temperature	0.167	0.090	0.250	0	5	0
Tributary Flooding	0.167	0.080	0.250	10	0	3
Flood Plain Connectivity	0.167	0.080	0.250	4000	0	3200
Physical Habitat	**0.500**	**0.300**	**0.700**			
SWH Velocity	0.143	0.250	0.063	30	0	14.6
Velocity Variability	0.143	0.250	0.063	6	1	3
SWH Depth	0.143	0.250	0.063	30	0	4.6
Depth Variability	0.143	0.063	0.063	4	1	2
Turbidity	0.143	0.063	0.250	100	0	27.3
Summer Temperature	0.143	0.063	0.250	0	5	0
Flow Regime	0.143	0.063	0.250	12	0	7
Habitat Quality Value	**0.49**	**0.41**	**0.57**			

CONCLUSIONS

Several conclusions can be drawn from this preliminary study of multi-criteria habitat assessment that may help guide further study, they include:

- A multi-criteria habitat assessment tool was successfully developed to assess habitat quality for pallid sturgeon on the Missouri River
- A great deal more research is needed to develop a scientific understanding of the links between habitat attributes and ecological functions related to pallid sturgeon
- The MCHA can be used to compare changes in habitat quality for a site over time or to compare habitat quality at different sites and across remedial treatments
- More data collection (e.g., mapping substrates and flood plain) is needed to fully support the MCHA
- The MCHA tool can help managers identify data gaps and direct data collection efforts
- The MCHA tool can be useful in forcing managers to consider the entire range of pertinent habitat attributes
- The MCHA tool and data collection efforts need to be coordinated so data collection supports tool and the tool supports decision-making

Need for further research

Considerable research is needed to support the efforts to restore the pallid sturgeon habitat in the Missouri River. Much research is needed in the basic sciences to better establish the links between habitat conditions and ecological functions related to the sturgeon. For example, it is generally assumed that pallid sturgeon eat macro-invertebrates. However, the actual invertebrate species that are preferred and needed by the sturgeon at various life stages are not known. As a consequence, it is not known what types of substrates are needed to support these macro-invertebrates.

Further research directly related to the MCHA tool includes developing species diversity indices both for macro-invertebrates and for fish species. These indices would be good indicators of not only the physical habitat attributes but also of the ecological functions working in the habitat. Another area of further research for the MCHA tool is to develop the method to directly assess uncertainties using fuzzy set theory methods. Understanding uncertainties is critical for decision-makers, and it is easy to overlook or misinterpret the effects of uncertainty if they are not directly incorporated into the assessment, so the incorporation of fuzzy set methods into the MCHA tool would be a very useful improvement.

ACKNOWLEDGEMENTS

The authors would like to thank the US Army Corps of Engineers – Omaha District for providing funding, technical support and data for this research. We would also like to gratefully acknowledge the biologists and engineers from the Habitat Assessment and Monitoring Program, the Nebraska Game and Parks Commission, the Shallow Water Adaptive Management Team, the US Fish and Wildlife Service, the US Geological Survey, and the US Army Corps of Engineers for providing their time and knowledge.

ABSTRACT

Description of physical aquatic habitat often includes data describing distributions of water depth, velocity and bed material type. Water depth and velocity in streams deeper than about 1 m may be continuously mapped using an acoustic Doppler current profiler from a moving boat. Herein we examine the potential of using the echo signal strength from the bed as an indicator of bed material type. Mean signal strength from soft, muddy beds was consistently 10 to 20 dB lower than mean signal strength from noncohesive (gravel or sand) beds. Sand beds tended to have complex signatures with large variances.

INTRODUCTION

Restoration or rehabilitation of degraded stream and river habitats requires definition of a target condition and preferably post-implementation monitoring to measure progress toward the target. A physical habitat condition, rather than some state of biotic populations, is often selected as a target because biotic conditions are more difficult to sample and describe and often exhibit great variation driven by variables outside the stream ecosystem (e.g., climate or ocean events). Stream physical aquatic habitat has been described as the joint distribution of water depth, water velocity, bed type and sometimes cover (e.g., Gorman and Karr 1978, Shields et al. 1994). Practically, stream habitat has been characterized by computing statistics based on measurements of water depth and velocity at each point of a horizontal grid. In many cases stream bed type and cover, both qualitatively assessed, were included as additional grid variables. Resultant statistics describing the central tendency, variability and spatial distribution of these three or four variables and their combinations have been used to explain key differences between more- and less-degraded streams and to infer biotic responses. Usually the required data are collected by wading observers.

Collection of water depth and velocity information may be automated across a wide range of stream sizes using an acoustic Doppler profiler (ADCP). Here we suggest that ADCP data may also be used to infer bed hardness and thus bed sediment type. Acoustic seabed classification for mapping habitats and other marine features is a rapidly expanding field (Anderson et al. 2008). Many workers have advanced methods for using specialized equipment and software to acoustically explore or classify underwater sediments (Chivers et al. 1990, MacDougall and Black 1999, Preston et al. 2000, Cholwek et al. 2000 and 2005, Wienberg and Bartholoma 2005); here we propose use of off-the-shelf technology to simply map the distribution of bottom types based on sediment at the bed surface. Bottom types (hardness and surface roughness) may be determined by extracting the return signal strength from

the bottom track echo and using this information to compute the echo intensity at the bed. Bed echo intensity is a function of the sediment bulk density, the amount of gas in voids near the bed surface, the amount and type of submersed vegetation (if any), and the geometric uniformity (flatness) of the bed. All of these qualities are related directly or indirectly to sediment grain size and bed shear stress. The discussion below is based on use of a Teledyne RDI 1200 kHz Workhorse Rio Grande ADCP in streams, rivers and lakes with depths ranging from 1 to 7 m and velocities ranging from 0 to 2.5 m s^{-1}.

COMPUTATIONS

The echo intensity detected by the instrument is given by (Gordon 1996):

$$EI = SL + SV + K - 20\log(R) - 2\alpha R \tag{1}$$

where

EI = echo intensity recorded by the instrument (dB),

SL = source level or transmitted power (dB),

SV = bottom backscattering strength (dB),

K = transducer-specific constant based on the relationship between pressure at the transducer face and the measured signal strength

R = distance from the transducer to the bottom measured along the beam (m) = $r/\cos\theta$, where r = vertical distance from the transducer to the bottom (m) and θ = beam angle (20^o), and.

α = sound absorption coefficient (dB/m).

The last two terms account for signal strength decay due to beam spreading and absorption of acoustic energy, respectively. Solving for *SV*,

$$SV - K = EI - SL + 20\log(R) + 2\alpha R \tag{2}$$

Below we compute *SV- K* for various river and lake bottom types and compare results. We use *dB** as a symbol for *SV – K*.

EI, the echo intensity was determined by converting the RSSI (return signal strength indicator) recorded by the ADCP in "counts" to units of dB by multiplying RSSI by the echo intensity scale factor supplied by the manufacturer (RD Instruments 1999)

$$scale_factor = \frac{127.3}{(273 + T_e)} \tag{3}$$

where T_e is the temperature of the instrument in degrees C, assumed equal to the water temperature .

Source level, *SL*, is given by the equation

$$SL = 10\log\left(\frac{P}{P_0}\right) \tag{4}$$

where

P_0 = reference pressure (1 μPa) and

P = pressure of the signal propagated by the ADCP, given by

$$P = \sqrt{\rho c I} \tag{5}$$

where

ρ = density of the medium (kg m^{-3}),

c = speed of sound (assumed to be constant = 1450 m s^{-1}), and

I = power density (W m^{-2}).

Power density, I, was computed by assuming the transmitted power is spread out over a surface area equal to the area of a circle with a diameter equal to one beamwidth 1 m from the transducer.

$$I = \frac{4 A_{rms} V_{rms} P_F E}{\pi d^2} \tag{6}$$

where

A_{rms} = rms current for transmitted signal(amp),

V_{rms} = rms voltage for transmitted signal (volts),

P_F = power factor (assumed = 0.5),

E = efficiency (assumed = 0.5), and

d = beam diameter (m).

The transmit voltage and current were obtained from the binary output file (RDI 2001, p. 122) and converted from counts to amps and volts as follows:

A_{rms} = 0.011451 * ADC_Counts, and

V_{rms} = 0.253765* ADC_Counts

For the 1200 kHz Workhorse Rio Grande, the far field beam is conical with a side angle of 1.4° (RDI Instruments 1996). Therefore, the beam diameter, d, at a distance of 1 m from the transducer would be

d = 2 tan 0.7 = 0.0244 m (RD Instruments 1999, personal communication, Kent Deines).

Transducer constants, *K,* were unknown, but it was assumed that each of the four transducers on a given ADCP would have different constant values. We adjusted dB* values from transducers 2, 3 and 4 to a common reference based on regression against dB* values measured simultaneously by transducer 1.

Because the sound beam is approximately cylindrical in the near field and then spreads as a cone in the far field, the expression for beam spreading, $20\log(R)$, is valid only for R in excess of a near-zone distance. The near-zone distance is specified by the ADCP manufacturer as R = 2.1 m (RD Instruments 1999). For computation, the value of R in the term $20\log(R)$ was replaced by an expression proposed by Libicki et al. (1989) and used by Thorne et al. (1991) whenever $0.4 < R \leq 2.1$ m. Values with $R < 0.4$ m were discarded.

$$R \times \left[\frac{2 + \frac{\varepsilon r_n}{R}}{3} \right] \tag{7}$$

where $\varepsilon = 1$ and $r_n = 2.1$ m.

The sound absorption coefficient, α, is dependent on water temperature, salinity, and suspended sediment concentration. However, variation over the range of water temperatures observed in this study is slight, and no information was available regarding suspended sediment concentrations. Therefore a constant value of 0.35dB m^{-1} was assumed based on the work of Francois and Garrison (1982a and b) for the (http://resource.npl.co.uk/acoustics/techguides/seaabsorption/) given an assumed temperature of 19 C^o, 1228.28 kHz frequency in freshwater. The assumption of a constant α likely introduced error for sites with sand in suspension.

DATA COLLECTION

Bottom track data were collected using a 1228.28 Teledyne RDI Rio Grande Workhorse ADCP from an aluminum boat anchored in a range of fluvial environments as shown in Table 1. Stations were selected to represent a range of bed types, and samples of bed material were collected at each station with either a BM60 bed material sampler or a petite Ponar dredge. Qualitative, visual descriptions were recorded for each bed sample, and sediments were returned to the lab and subjected to standard analysis for grain size distributions. Additional ADCP data were collected from river reaches encompassing the points where bed samples had been collected.

ANALYSIS

Values for $SV - K$ (also referred to here as dB^*) were computed using the procedure outlined above. Initial analysis focused on ensembles with good data for all four beams. Beams 1 and 3 (which point port and forward, respectively) produced dB^* site means within 1-5% of each other while beams 2 and 4 (pointing starboard

and aft, respectively) produced site means within 2-22% of each other. Beams 2, 3, and 4 were corrected to the same relative magnitude as Beam 1 using regression formulas based on data ensembles with good values for all four beams (Figure 1). After correction, correlation coefficients and coefficients of determination were computed between *dB** and each term in equation 1. Mean *dB** values were computed for the four beams in each ensemble, and frequency distributions were computed for each site and for each major sediment type and hydraulic environment.

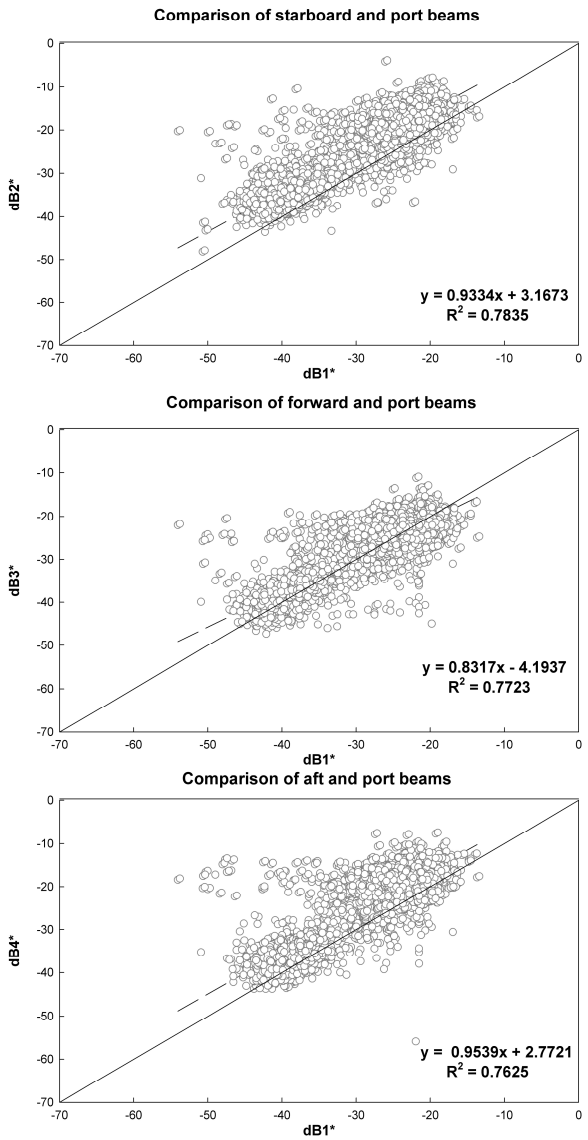

Figure 1. Comparison of simultaneous measurements of bottom backscattering strength using different transducers on the same ADCP.

An entire meander bend of the Little Tallahatchie River in Mississippi was acoustically scanned on the same day that point samples of sediment and bottom

backscatter strength were obtained. Resulting data were used to generate contour maps of bottom backscatter strength, water depth, and current velocity in order to create a synoptic view of physical aquatic habitat.

RESULTS

From 59% to 68% of the variation in *dB** was due to variation in *EI*, the bottom echo intensity for a database comprised of more than 7500 measurements. Power level varied little within our data set, and r^2 values between *dB** values for each beam and *SL* ranged from 1 to 3%. The variation in terms in equation 2 representing losses due to beam spreading and sound absorption in the water column accounted for 3% to 8% and 7% to 13% of the variation in *dB**, respectively.

Table 1. General characteristics of sites sampled for bottom signal strength

Water body	Environment	Bed type	Water Depth, m	Mean current velocity, m/s
Big Sunflower River	Channelized river	Silt and clay	1 to 5	0.02 – 0.03
Deep Hollow Lake	Natural oxbow	Silt and clay	1.0	nil
Little Tallahatchie River	Meandering river	Sand and gravel	1 to 4	0.3 – 0.7
Luxapalila Creek	Channelized river	Fine gravel and sand	1 to 4	.06 – 0.14
Sylamore Creek	Meandering river	Gravel	2.9	0.02
White River	Meandering river	Sand	2.6	11.14
		Gravel	2.5 – 2.8	0.6 – 0.7

Initial exploration of data focused on well-sorted (narrowly graded) sediments from quiescent environments (lakes or low-velocity rivers). Frequency distributions associated with each major sediment type are provided in Figure 2a and summary statistics are shown in Table 2. Cohesive and noncohesive bed material had distinct signatures. Gravel beds produced backscatter strengths about 10 to 20 dB greater than for soft muddy, bottoms. Sandy bottoms had backscatter strengths intermediate to mud and gravel, and sand produced a much wider range of *dB** than other bed types (Figure 2a), likely due to the range of sediment transport and bedform regimes at the sand bed sites. Addition of data from similar well-sorted beds located in higher energy environments indicated that sands and gravels produce similar average backscatter strengths, but that sand again had much higher variance (Figure 2b), perhaps due to sand transport or bedforms. The higher mean *dB** for sand from the White River sand bottom site relative to the Little Tallahatchie sites (Table 3) may be related to bed roughness. Bathymetric data from the ADCP indicated that the White River sand site had a plane bed while the Little Tallahatchie sites (Table 3) exhibited dunes.

Table 2. Mean bottom backscattering strength, *dB, for low-energy sites.**

Water Body	Bed Type	% by weight				No. of values	Mean *dB**	Std dev
		Gravel	Sand	Silt	Clay			
Deep Hollow Lake	Soft mud	D_{50} = 0.012 mm, Mean = 0.043 mm, Std dev = 0.063 mm				388	-43	1.3
Big Sunflower River	Soft mud	0	3	40	56	319	-38	1.5
		0	8	38	55	435	-42	1.0
Luxapalila Creek	Sand	8	91	1	0	150	-30	3.4
		4	96	1	0	152	-23	1.3
	Gravel	86	14	0	0	151	-22	1.0
Sylamore Creek	Gravel	96	4	0	0	1523	-23	1.2

Table 3. Mean bottom backscattering strength, *dB, for high-energy sites.**

Water Body	Bed Type	% by weight			No. of values	Mean *dB**	Std dev
		Gravel	Sand	Fines			
Little Tallahatchie River	Sand	0	98	1	210	-27	1.4
		0	100	0	95	-24	0.9
		1	99	0	44	-23	0.7
		0	100	0	39	-26	0.9
		1	99	0	57	-24	0.9
		0	100	0	61	-27	0.8
White River	Sand	0	89	11	165	-19	1.0
	Gravel	99	1	0	344	-20	1.1
		93	6	1	346	-22	3.1

Contour maps of *dB**, water depth and current velocity for a large, complex bend of the Little Tallahatchie River are presented in Figure 3. "Ground truth" for the *dB** measurements was obtained by sampling bed sediments and bottom

backscatter strength simultaneously as described above at the points shown as red crosses in Figure 3b. The three numbers adjacent to the crosses indicate the composition of bed samples as gravel, sand and fines in percent by weight Bottom habitats were complex, exhibiting the influence of bend flow hydraulics and inflows of coarse sediments from a tributary mouth on the downstream left descending bank. A large area of finer sediments on the upstream left descending bank was associated with a slackwater overflow channel.

CONCLUSION

Synoptic maps of three of the major components of riverine physical aquatic habitat, current velocity, water depth, and bottom type can be made using commercially available boat-mounted ADCP. However, conversion of signal strength values recorded by the instrument to bottom hardness requires use of instrument-specific coeffiecients that must be obtained by ground-truthing each ADCP using bed sediment samples and ADCP data collected simultaneously. Furthermore, the return signal strength for sandy bottoms varies widely based on bedforms and sediment bulk density.

ABSTRACT

Dredging has historically been important for keeping the nation's waterways navigable, mining, and more recently for the removal of contaminants and restoring natural habitat. The placement of dredged material, re-suspension of sediments, and contaminated dredged material could all result in adverse environmental impacts. These impacts have all been, and are being, studied extensively. What has not been investigated, however, are the air emissions resulting from dredging operations. The incorporation of air emissions into management decisions such as the selection of dredging technology is needed and would allow decisions based on environmental impacts and not solely on cost. This analysis lends itself to a limited life cycle and ecoefficiency analysis.

IMPORTANCE OF DREDGING

Dredging is the underwater excavation of accumulated sediments. The removal of sediment from a water body can be done for several reasons. The primary purposes are: navigation, mining, ecosystem restoration, and the removal of contaminants. Once sediment has been removed from the channel it is referred to as dredged material. In fiscal year (FY) 2006 the U. S. Army Corps of Engineers (USACE) dredged a total of 204.2 million cubic yards (CY) of sediment (NDC 2007). Navigation maintenance dredging accounted for 137.8 million CY or 67.5% of this total. Two types of dredging equipment performed 66.6% of the total dredging completed in FY 2006. Cutterhead pipeline dredges removed 118.6 million CY of material or 58.1% and mechanical dredges removed 17.4 million CY or 8.5% of the total material dredged in 2006.

Navigation maintenance dredging is an integral and necessary operational component of our waterborne transportation system. Waterborne commerce in the United States totaled 2,588 million short tons in 2006 (IWR 2006). Of that total 702.1 million short tons were transported within the Mississippi River System with 490.6 million short tons being classified as internal traffic. Internal traffic is defined as "vessel movements (origin and destination) which take place solely on inland waterways. An inland waterway is one geographically located within the boundaries of the contiguous 48 states or within the boundaries of the State of Alaska" (IWR 2006). Nearly 25% or 120.4 million short tons of the Mississippi River System internal traffic were transported on the Illinois Waterway. The waterborne transportation system would be crippled if navigation maintenance dredging was not performed in a regular and timely manor.

TYPES OF DREDGES

There are numerous types of dredges used for the various purposes including: cutterhead pipeline (CPD), mechanical bucket or clamshell (MBD), hopper, sidecaster,

and dustpan dredges. Each type of dredge is well suited for different site conditions (both dredge cut and placement site), sediment characteristics, quantities of sediment to be dredged, production rates, and distance that the material must be transported to a placement site (USACE 1983).

COMPARISON OF DREDGING METHODS

The type of equipment included in this analysis will be limited to that which is commonly used for navigation channel maintenance dredging on the Illinois Waterway (IWW) and Upper Mississippi River (UMR) within the U. S. Army Corps of Engineers, Rock Island District. The equipment selected was used by Rock Island District for navigation channel maintenance dredging on the IWW during the 2005 dredging season. It included a 16-inch cutterhead pipeline dredge owned and operated by an independent contractor and a mechanical bucket dredge owned and operated by Rock Island District (Graham 2007/08).

Cutterhead pipeline dredges are capable of pumping dredged material approximately 5,000 to 12,000 feet with just the pump on the dredge itself, depending on the size dredge, elevation change to the placement site, and sediment characteristics. In order to transport dredged material over longer distances, additional inline booster pumps must be added. Typically, only two booster pumps can be efficiently added to the dredging process, increasing the transport distance by 1,000 to 3,000 feet per booster pump. If the distance between the dredge cut and placement site exceeds the total distance with booster pumps then an intermediate placement site within the water body must be identified and approved. The sediment would be dredged to this intermediate placement site then the dredge would be moved from the original dredge cut to the intermediate placement site and the material would be dredged a second time and transported to the final placement site, commonly referred to as re-handling or double handling the dredged material. This process significantly increases the environmental impacts and the cost per CY which usually makes a cutterhead pipeline dredge unsuitable for dredging and transporting dredged material distances greater than that reachable with two booster pumps. The transport distances for the 16-inch contractor-owned dredge used by Rock Island District for the 2005 dredging season are 8,000 feet for the dredge alone, with each booster pump capable of increasing the transport distance by 2,000 feet. Once a cutterhead pipeline dredge has been mobilized and set up at a dredge cut it is capable of nearly continuous dredging with few interruptions except for routine maintenance for the equipment, movement of the discharge pipeline to minimize delays to navigation, and relocation of the pipeline within one or to another placement site. This results in relatively high production rates. Cutterhead pipeline dredges generate a considerable quantity of water that must be managed at the placement site to meet water quality standards.

Mechanical bucket dredges are well suited when the dredge material must be transported distances greater than 12,000 feet. Once the material has been dredged and loaded onto a barge it can be transported long distances without requiring re-handling. Another situation where mechanical bucket dredges are well suited is for small quantities of material to be dredged from one location, because they are relatively quick and inexpensive, compared to cutterhead pipeline dredges, to mobilize and demobilize. Another consideration for dredging equipment is the distance from the river channel to

the placement site. Either an excavator or a dozer would be used to transfer the dredged material from the barge to the placement site as long as the site is adjacent to the river channel. If the placement site is not immediately adjacent to the channel, material dredged by a mechanical bucket dredge would need to be transferred from the barge to a truck for transport overland to the placement site. This would add expense, negative environmental impacts, and reduce production rates over a cutterhead pipeline dredge. A cutterhead pipeline dredge could extend the discharge pipeline over land to the placement site as long as the total transport distance doesn't exceed the maximum distance for that dredge.

Each type of dredge has distinct advantages and disadvantages that contribute to the decision-making process (USACE 1983). Mechanical bucket dredges are quicker and more economical to mobilize, are capable of transporting dredged material over long distances, require less supporting equipment, and have relatively low production rates. Cutterhead pipeline dredges are more difficult and costly to mobilize, are limited in the distance they can transport dredged material, require more support equipment, and have relatively high production rates. In general terms this means that mechanical bucket dredges are better suited to small quantities of material to be dredged at a given location and/or long (greater than 12,000 feet) transport distances while cutterhead pipeline dredges are better suited to large quantities and shorter transport distances (less than 12,000 feet).

Typically, dredging decision makers utilize multiple criteria for selection of dredging equipment and placement site for each dredge cut(s) (USACE 2003-A). These criteria are used to identify and implement the most suitable combination of equipment and placement site(s) for navigation channel maintenance dredging over a 20 to 40 year planning horizon.

DREDGED MATERIAL PLACEMENT SITES

Dredged material placement sites used in Rock Island District fall into five broad categories including: thalweg, bankline, near shore, upland, and confined. The thalweg is the deepest part of a river channel cross section which usually has the highest flow rates. A bankline placement site would be within the flood plane and immediately adjacent to the river channel. Beach nourishment would be one example of a bankline placement site. Near shore placement sites would also be located within the flood plane but further away from the river channel than a bankline placement site. Upland placement sites are located outside of the flood plane, frequently behind a levee. Confined disposal placement sites are engineered facilities that contain dredged material within a specified footprint.

Thalweg Dredged Material Placement Sites

Thalweg placement of dredged material could be done using either a cutterhead pipeline or mechanical bucket dredge. The site would be located in a reach of river that is particularly deep, usually 20 to 30 feet in depth or more, this compares to the navigation channel mandated minimum depth of nine feet. Not all reaches of the UMR or IWW have thalweg conditions that are suitable for dredged material placement. This is not a particularly desirable option since it does not remove the sediment from the river channel and could result in additional environmental impacts. There are some

advantages to thalweg placement that must be taken into account before eliminating this type of placement site from consideration. Thalweg placement is economical as long as the distance between the dredge cut and placement site are within the dredges transport distance capabilities. Also, there is no return water to manage when using a cutterhead pipeline dredge.

Bankline Dredged Material Placement Sites

Bankline placement could be done using either a cutterhead pipeline or mechanical bucket dredge. The dredged material is placed on the river shore or bankline for habitat restoration, beach replenishment or nourishment, or erosion protection. A bankline placement site for habitat restoration could be to stabilize tree root systems that have been exposed due to erosion, increase the land surface elevation in areas to provide safe havens for wildlife to use during flood events, and create or enhance islands. Recreational facilities along the river are highly desirable to state and local governments along with the public. Dredged material can be used to nourish beaches and enhance the recreational experiences for boaters and swimmers. On occasion dredged material can be placed on banklines for erosion protection of cultural and historic sites that are not easily accessible for more traditional erosion protection systems such as riprap. In addition, dredged material can be used as short-term erosion protection or as fill to restore a bankline in preparation for riprap or some other erosion protection system.

Near Shore Dredged Material Placement Sites

Near shore placement sites would include those sites that are within the floodplain but beyond the bankline. These placement sites can be used for habitat restoration similar to bankline sites or as long-term placement sites. The preferential option for long-term placement sites is typically to locate them outside of the floodplain to avoid adverse impacts to flood water surface elevations and the risk of re-suspension of the sediment and transport back into the river channel during high water events. However there are locations where the floodplain extends beyond practical and economical limits of transporting dredged material so near shore sites must be considered.

Upland Dredged Material Placement Sites

Upland sites are located outside the floodplain and are typically the preference of resource and regulatory agencies since they will have no impact on flood water surface elevations and they eliminate the potential for transport back into the river channel during floods. Upland sites could include: placement on the landside of levees (as long as the level of flood protection is not increased); placement on existing agricultural fields; beneficial use stockpiles; and for habitat restoration.

Confined Dredged Material Placement Sites

Confined dredged material placement facilities (CDF) are engineered and constructed sites that will retain the dredged material within a specified footprint. CDFs can be used for island creation, long-term dredged material placement sites, commercial and recreational site development, and for contaminated dredged material to ensure contaminates do not migrate off-site.

DREDGING EQUIPMENT EMISSIONS TO THE ATMOSPHERE

Navigation channel maintenance dredging equipment used on the IWW and UMR, as with most locations, needs to be mobile and capable of operation without an external power source, making diesel fuel the predominate choice. All of the equipment included in this study is diesel powered. The combustion of diesel fuel releases pollutants into the atmosphere that can be quantified and compared between dredging crews to determine the lowest adverse environmental impacts for each type of equipment and scenario. These contaminants impact air quality and may add to global climate change considerations.

CURRENT KNOWLEDGE

The U.S. Army Corps of Engineers (USACE) was first tasked with maintaining and improving a waterborne navigations system in 1824. Deepening and clearing out rivers and harbors was added to the USACE responsibilities in 1826 (USACE 2007) and remains an integral part of the USACE mission. Typical types of equipment and placement sites utilized for navigation channel maintenance dredging are outlined in the "Types of Dredges" and "Dredged Material Placement Sites" sections respectively. USACE, both independently and in collaboration with the U. S. Environmental Protection Agency (USEPA), have developed several manuals for dredging operations, including dredged material placement sites, and environmental impacts from dredging.

Even though navigation maintenance dredging has been done for hundreds of years the environmental effects are fairly recent considerations. Environmental impacts of dredging have been studied and documented with most of the information having been developed over the past 10 to 15 years (Bridges 2008). The areas of primary focus have been the identification and implementation of beneficial uses for dredged material, environmental dredging, emissions to air from the placement and/or re-suspension of contaminated dredged material, and the regulation of emissions to the air from marine engines. Though environmental impacts of dredging have been studied, no efforts have been applied to the evaluation of air emissions from comparable types of dredging equipment, as in this study.

Beneficial Use of Dredged Material

Beneficial use of dredged material is it's productive use as a resource material. Some possible uses include construction materials, aquaculture, topsoil, beach nourishment, berm creation, capping, land creation, land improvement, fill, shore erosion protection, habitat enhancement, and wetland restoration.

The Great Lakes Commission, responding to the findings of the Great Lakes Beneficial Use Task Force, has identified the beneficial use of dredged material as a "priority management option" and has adopted a resolution for increasing federal funding, research, and USACE authority for beneficial use (Pebbles 2002). The emphasis on identifying and implementing beneficial uses for Great Lakes dredged material will help to minimize environmental impacts from dredging but does not address the air emissions from dredging equipment.

The loss of Louisiana coastal wetlands is being addressed through the beneficial use of dredged material. USACE, New Orleans District has utilized approximately 27 million CY of the 90 million CY of sediment dredged from federal navigation channels

for coastal wetlands restoration projects. This has resulted in the restoration of approximately 10,000 acres of wetlands (Creef and Mathies 2002).

The Illinois River, a major segment of the Illinois Waterway, is part of a large flyway for North American migratory birds. Extensive sedimentation in the backwaters has severely degraded this habitat. The restoration of this migratory flyway will require the removal and placement of a considerable volume of sediment (Marlin and Darmody 2002). Beneficial use applications for this dredged material are being investigated including: island creation and enhancement, topsoil, fill, and urban renewal (Marlin and Darmody 2002).

USACE, Rock Island District has been actively involved in identifying and implementing beneficial uses for navigation channel maintenance dredged material. Examples of beneficial uses for dredged material from the IWW and UMR are levee repair, island creation, fill/construction materials, beach nourishment, and habitat enhancement.

Environmental Dredging

Environmental dredging can be defined as "dredging performed specifically for the removal of contaminated sediments for the purpose of remediating environmental risks" (Bridges 2008). An environmental dredging workshop sponsored by the U.S. Army Corps of Engineers (USACE) and U.S. Environmental Protection Agency (USEPA) focused on re-suspension of sediments, release of contaminants from in-situ and suspended sediments, residual contaminated sediments, and environmental risks (Bridges 2008). None of these focus areas included the air emissions from dredging operations.

According to W. D. Rokosch and N. J. Berg, selection of the best dredging technique for a particular project should be based on several criteria including: dredging location conditions such as water depth, extent of dredge cut, navigation, structural obstructions, sediment characteristics, potential for debris, and underwater structures; environmental regulations; cost considerations; and the positive and negative effects of the dredging operations (Rokosch and Berg 2002). None of the considerations for selection of dredging techniques are air emissions from the dredging equipment.

Several stakeholders from four European countries, France, the United Kingdom, Belgium, and the Netherlands, developed New!Delta, a project to promote the sustainable development of ports and port related activities. One of New!Delta's strategies is sustainable dredging defined as "a strategy in which management of dredging operations is a part of an integrated estuary management that strikes a balance between environmental, economic, social and technical aspects while respecting the legal requirements" (NEW!Delta 2007). The focus of their sustainable dredging strategy is on the potential changes to the physical and sedimentary processes, ecology and habitats, and the existing and future use of the estuary. The primary effects of dredging and dredged material disposal, as outlined in their report, include changes to the hydromorphology, loss of habitat, sedimentation, suspended sediment and turbidity, dispersion of contaminated sediment, reduction in oxygen levels, and disturbances such as noise, light, and movement (New!Delta 2007). Again, there is no consideration for the air emissions from the dredging equipment included in their sustainable dredging strategy.

A rating system similar to that used with Leadership in Energy and Environmental Design (LEED) could be utilized to promote sustainable port development and operation (Abood 2007). The LEED system includes the following six categories: "1.) sustainable sites, 2.) water efficiency, 3.) energy and atmosphere, 4.) materials and resources, 5.) indoor environmental quality, and 6.) innovation and design process". A total of 69 points can be awarded within these categories. According to Abood LEED Categories 4, Materials and Resources, and 6, Innovation, would be the primary sources for dredging and dredged material placement to achieve points (Abood 2007). These points could be received for beneficial use of dredged material, enhancement of aquatic life, and minimizing the loss of habitat. In addition, LEED Categories 2, Water Efficiency, and 5, Indoor Environmental Quality could achieve points for dredged material treatment and reductions in dredging equipment air emissions (Abood 2007). Specifically, Abood identifies the reduction in emissions from ships through the use of alternative fuels, retrofitting engines, addition of emission reduction devices such as catalysts, and reductions in light loading and tidal delays by deepening channels. Interestingly, the deepening of channels would require additional dredging that could increase rather than reduce air emissions. This study addresses reductions in air emissions but does not look at selecting the dredging equipment that would reduce emissions while maintaining navigation channel dredging.

The U.S. Environmental Protection Agency (USEPA) and USACE have collaborated in the development of a document titled "Evaluating the Environmental Effects of Dredged Material Management Alternatives – A Technical Framework" (USEPA, 2004). This framework provides overall guidance for the application of detailed testing manuals developed by USACE and USEPA. These technical testing and design manuals address aquatic and terrestrial impacts from the dredging and placement operations, including the potential for volatization of contaminants into the atmosphere. None, however, consider the air emissions from the dredging equipment in the design and equipment selection process.

Dredged Material Emissions to the Atmosphere

Emissions to the atmosphere from dredging operations include the volatization of chemicals from contaminated dredged material within both the placement site and re-suspended in the water column and emissions from marine engines used to power dredging equipment. The rate at which specific chemicals volatize from dredged material has been studied using various models. Volatization rates for hydrophobic organic compounds from four different locations were modeled to tentatively rank the magnitude of emission rates. The four locations were the dredging location or cut, the exposed placement site location, the ponded placement site location, and the placement site location with vegetated cover (Valsaraj 1995). The results indicated that the greatest emissions resulted from the exposed placement site followed by the dredge cut location with high levels of suspended solids (Valsaraj 1995). Air quality impacts from odorous or toxic compounds in dredged material and effects on inhabitants near dredging operations can be costly to control (Zimmer 2004). Multiple models were tested with differing operational and remediation alternatives. The results were evaluated against acute air quality standards and odor threshold (Zimmer 2004). Neither of these studies considered the air emissions from dredging equipment.

Regulation of Air Emissions From Marine Engines

Air emissions such as Nitrogen Oxides (NOx) from marine engines are being regulated under both the USEPA's "Control of Emissions of Air pollution from New Marine Compression Ignition Engines at or Above 37 kW" and Individual State Implementation Plans (SIP) (Gore 2002). Actions taken to comply with these standards include using shore power instead of marine power when tied up to pier, voluntarily reducing speed when in port to below normal, and potentially limiting industrial equipment operations to a specified number of hours each day (Gore 2002). These standards address air emissions but do not examine the dredging equipment selection process as a source for reducing emissions to the atmosphere.

The significance of United States port air quality concerns are increasing. In response, the USEPA generated the transportation and general conformity rules (Rhoads 2004). These rules require project sponsors to include air quality analysis in their planning process. An approach has been developed based on emission reduction plans that allow projects to maintain general conformity status. Cost estimates are developed that include the type and size of equipment to be used, production rates, hours of operation, and labor requirements that meet existing standards without supplementary air emission control considerations (Rhoads 2004). This approach utilizes a similar approach to that done in this study for quantifying air emissions from diesel equipment but does not use the results for selection of equipment. Nor does it focus on navigation maintenance dredging but considers all equipment required for unspecified projects.

SUMMARY

Considerable effort has been put forth to identify and reduce environmental impacts from dredging operations. Reductions in adverse impacts have been achieved through the identification and implementation of beneficial uses for dredged material, development of environmental dredging techniques, minimization of the volatization of compounds from contaminated dredged material, and striving toward compliance with air quality standards. The reuse of dredged material for construction materials, aquaculture, topsoil, beach nourishment, berm creation, capping, land creation, land improvement, fill, shore erosion protection, habitat enhancement, and wetland restoration has minimized the need for long-term placement sites and the resulting impacts to both aquatic and terrestrial environments. Removal of contaminated sediments minimizes the risk of contaminants migrating into the water column or biota. Identifying solutions that minimize volatization of contaminates from dredged material either from a placement site or when re-suspended in the water column help to reduce environmental impacts. In addition, the adaptation of air quality standards for marine engines reduces adverse impacts to the environment. All of these efforts significantly improve the sustainability of dredging operations and reduce environmental impacts. One potential area for reducing adverse environmental impacts that is conspicuously missing from this list is the quantification and selection of comparable dredging equipment based on the air emissions. By identifying the type of dredging equipment with the lowest air emissions, when cost, site conditions, and equipment availability are comparable, environmental impacts can be minimized without compromising the dredging project.

ABSTRACT

The Trinity River Corridor Project in Dallas, Texas will realign and naturalize eight miles of the Trinity River channel and create a wide variety of recreational and habitat features on the floodplain within the boundaries of the Dallas floodway. Major flood control projects in the 1920s and 1950s relocated, straightened, and channelized the river, and regular mowing on the floodplain has maintained homogenous conditions with limited habitat value. Primary river naturalization elements of the project include restoration of channel meanders, creation of more natural channel geometry, integration of natural geologic controls into the channel profile, and creation of an oxbow lake. Floodplain improvements include creation of wetlands, lakes, recreational features such as trails and playing fields, and establishment of more natural vegetation assemblages. This suite of channel and floodplain improvements will create more complex hydraulics and sediment transport characteristics that will strongly influence the operation and maintenance of the Project area, and therefore the overall sustainability of the Project. Therefore, the design of channel and floodplain features has been guided by detailed analysis of historical geomorphology of the Project site and the region, and two-dimensional hydraulic and sediment transport modeling of the proposed channel and floodplain design. We present results from the integrated fluvial geomorphology and two-dimensional hydraulic and sediment transport modeling based design process introduced in Tompkins et al (2008) and describe how these results, which included velocity and shear stress distribution and sediment deposition patterns, were used to develop and refine channel alignment, geometry, and bank treatment designs as well as configuration and design of floodplain features.

INTRODUCTION

The Balanced Vision Plan (BVP) for the Trinity River (City of Dallas 2003) struck a balance between the following diverse and potentially conflicting goals for the Trinity River Corridor:

1) Provide undiminished flood protection for the full length of the corridor in a way that supports the achievement of environmental, recreational, mobility, and economic goals;
2) Complete bold initiatives of environmental responsibility, restoration, and proper management in the midst of an intensely urban setting;
3) Create a magnificent recreation and urban open space amenity while co-existing successfully with flows of vehicular traffic as well as periodic floodwaters;
4) Meet stated regional transportation goals in a way that supports economic development, air quality improvement, and appreciation for the park; and
5) Create critically important community and economic opportunities for the neighborhoods bordering the Trinity River, for downtown, and as the centerpiece of a major urban region.

One of the primary motivations for the development of the BVP is the current degraded condition of the largely single-purpose Trinity River floodway in the City of Dallas. The Trinity River in Dallas has experienced dramatic change over the past century, with the most rapid and extensive changes occurring during the construction of the original Dallas Floodway project in the late-1920s and the US Army Corps of Engineers (USACE) reconstruction of the floodway in the mid-1950s. These projects relocated, straightened, and channelized the Trinity River in the vicinity of Dallas (Figure 1), creating a homogenous river corridor with limited habitat and aesthetic value.

Furlong et al (2003) describe in detail the changes that have occurred to the Trinity River in Dallas since the mid-1800s. While some change has continued to occur since the USACE project was completed (e.g. the Dallas Floodway improvements in 1990), the channel realignment portion conceptualized in the BVP and designed as part of the ongoing Trinity River Corridor Project (Project) will result in perhaps the most significant change to the Trinity River since the 1920s-era Dallas Floodway project.

The Trinity River channel is a central feature of the BVP, as it influences the design and sustainability of nearly all of the other proposed features for the floodway. The BVP describes significant physical changes to the channel and floodway including restoration of channel meanders, creation of a mid-channel island, alterations to channel geometry, and construction of two lakes in the floodway adjacent to the channel. This paper summarizes hydrologic and geomorphic assessments conducted to document and quantify historical and ongoing channel and floodway change, and presents a design process that combines these historical analyses with approaches from landscape architecture and state-of-the art hydraulic and sediment transport modeling to translate the Balanced Vision for the Trinity Lakes project into the most sustainable detailed design possible for the site.

Figure 1: Oblique aerial photograph of the Trinity River near Dallas in 1929. Note the straightened channel under construction in the center of the photo and the vegetated, meandering natural channel to the right of the new channel. Downtown Dallas is on the right side of the photograph. Flow direction is from top to bottom.

HYDROLOGY ASSESSMENTS

The hydrology of the Trinity River watershed (Figure 2) has been a critical consideration in the channel realignment design process as it will govern not only flow magnitude, frequency, duration, and timing that Project features will be exposed to, but construction scheduling and post-project operation and maintenance requirements as well. We assessed all available hydrology data and reports to characterize river stage-discharge relationships, daily streamflow characteristics, flood frequency, influence of reservoir regulation, and seasonality and inter-annual variability. The Project reach of the Trinity River has a drainage area of 6,100 square miles and includes approximately 8 miles between the confluence of the Elm and West Forks and the Dallas Area Rapid Transit (DART) Bridge downstream. The climate in this part of the watershed is humid subtropical with hot summers and mild winters. Average annual rainfall in the watershed is between 30 and 40 inches. Most of the annual precipitation occurs during thunderstorms, with occasional very heavy rainfall occurring over short time periods. Thunderstorms can occur throughout the year, but are more frequent in the late spring and early summer.

River Stage – Discharge Relationships

The relationship between river stage (i.e. depth of flow above a datum) and discharge is an important consideration in channel design as rapid changes in stage can lead to bank failure due to increased pore water pressure that develops as high flows recede from the floodplain back into the river channel. Flow and stage in the Trinity River near Dallas change rapidly in response to rainfall in the watershed. This is due in large part to urbanization that has increased impervious watershed area and decreased travel time of runoff entering the Trinity River and tributaries. The estimated stage-

discharge rating curve (Figure 3) illustrates that river stage increases approximately 40 feet between 200 cfs and 80,000 cfs. Flow and stage increases of this magnitude frequently occur over short periods of time, often less than twenty four hours.

Figure 2: Trinity River watershed. Project reach is in the Dallas Metro Area.

Daily Streamflow

Daily streamflow characteristics are important to consider in channel design as they largely dictate the day-to-day flow conditions that will be experienced by people accessing and recreating in the Project area and by the river corridor ecosystem. The United States Geological Survey (USGS) maintains a streamflow gauge (#0805700) in the Project reach that began recording in 1903. Mean daily flows in the Trinity River during the period of record range from a low of approximately 10 cfs (which has occurred less than 0.3% of the time) to a high of 152,000 cfs on June 26, 1908. The average daily flow is approximately 1,700 cfs, and "base" flow is between 500 and 600 cfs.

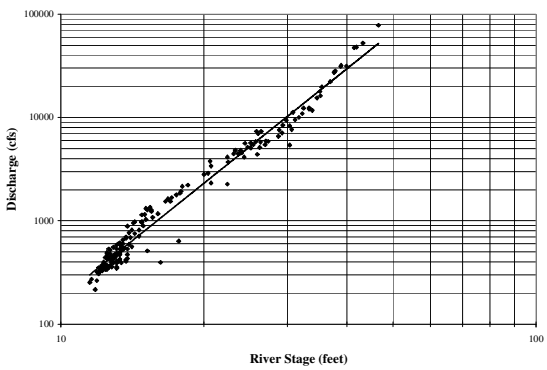

Figure 3: Estimated stage-discharge rating curve from observed data (1982-2007) at USGS Gage #08057000 (Trinity River at Dallas)

Flood Frequency

The frequency and magnitude of peak floods at the Project site will influence many facets of the final channel realignment design, including erosion control measures, riparian vegetation planting schemes, recreational features, and operation and maintenance. While high magnitude, low frequency floods are not the primary focus of the channel realignment design, an understanding of extreme event hydrology is crucial as it will inform assessments of sustainability of Project elements and development of long-term operation and maintenance procedures. Annual peak floods in the Trinity River range from 4,540 cfs (05/28/1978) to 184,000 cfs (flood of record on 05/26/1908). The Flood of Record occurred after 10 to 15 inches of precipitation in the watershed over a three day period, when the stage and discharge at the Dallas gage were 52.6 feet and 184,000 cfs, respectively, and the river was over two miles wide between West Dallas and downtown Dallas (Furlong et al. 2003). The average annual flood is approximately 30,000 cfs and the median flood is 21,400 cfs.

Influence of Reservoir Regulation

Reservoir regulation at the Project site is an important consideration for channel design because the reservoirs in the watershed have altered the historical frequency and magnitude of floods that will be experienced by Project design elements. Further, because the large storage reservoirs were constructed around the middle of the period of record for the USGS Dallas gage, the changes they have caused influenced selection of hydrology to consider for design (i.e. pre- vs. post-reservoir hydrology). Upstream of Dallas, the Trinity River watershed is regulated by 15 reservoirs and lakes with total storage capacity of over 5.5 million acre feet (Bureau of Economic Geology 1997). By 1960 seven large reservoirs had been constructed with a combined maximum observed storage volume of almost 2.4 million acre-feet. Two additional reservoirs were constructed in the 1980's with a combined maximum observed storage volume of almost 1.5 million acre-feet. Peak flows have been reduced significantly post-1960, except relatively frequent floods (i.e. up to the 1.10 year flood) which have increased slightly since 1960. It is unclear whether this increase is a result of reservoir regulation, changes in the watershed, or some combination of the two.

Hydrologic Seasonality and Interannual Variability

The timing of flows in the Project area is important because it will influence construction scheduling as well as operation and maintenance of the Project. The temporal distribution of flows in the Trinity River near Dallas is relatively constant throughout the year. Median monthly streamflow (calculated using the entire period of record) ranges from 300 to 500 cfs for all months except April, May, and June, when median monthly streamflow increases to between 700 and 1,100 cfs. Large precipitation events typically occur during the months of April, May, and June, which explains the rise in median flow values as well as the increase in peak flows during these months. Reservoir regulation has not changed these patterns significantly;

however it has altered the magnitude of difference between streamflows during different seasons. Prior to dam construction, median monthly streamflow varied over a wider range throughout the year and maximum monthly streamflows were higher. In addition to seasonal variability, flows in the Trinity River vary from year to year as hydrologic conditions change. Interannual differences in flow are important to consider in the design of the Trinity River channel because conditions in the channel and floodway will vary from year to year and will influence potential uses of the channel as well as maintenance requirements. While low flows are similar across water year types, the duration of periods with high flows (and the magnitude of those high flows) varies significantly. For example, in 1978 (an extremely dry year) daily average discharge was approximately 200 cfs for most of the year, with brief peaks of 4,000 cfs or less, while in 1989 (an extremely wet year), peaks between February and June kept daily average discharges above 5000 cfs for much of the year and as high as 43,000 cfs during large storms. The final channel design will consider differences between water year types of this scale.

TRANSLATING HYDROLOGY AND CHANNEL GEOMORPHOLOGY INTO DESIGN

A variety of fluvial geomorphic assessments were conducted in the Trinity River Corridor Project area (Tompkins et al 2008) to develop a template for the preliminary alignment, geometry, and profile design for the realigned channel that would satisfy the project's multiple objectives. Table 1 summarizes the process by which the hydrologic, hydraulic, and geomorphic characteristics described above were translated into the initial channel design. The initial design alignment, geometry, and profile was evaluated and refined in an iterative application of two-dimensional hydraulic (RMA) and sediment transport (SED-2D) models to identify and minimize potential problem areas, thereby producing a final schematic design that incorporated a thorough understanding of hydrology and fluvial geomorphology and maximizes sustainability through natural processes.

TABLE 1: CHANNEL CONDITIONS AND RELATED DESIGN GUIDANCE

River Corridor Characteristic	Conditions in Trinity River at Dallas Floodway	Related Channel Realignment Design Guidance
Stage – Discharge Relationship	Rapid changes in stage with changes in flow	To minimize the erosive effects of these rapid changes and maintain better recreational access and aquatic and riparian habitat, channel geometry should be designed with flatter slopes than the 1:1 slope used in the 1955 USACE channel design
Flood Frequency	Frequent (every 1.4 years on average) bankfull flows of approximately 13,000 cfs, and flows above 13,000 inundate the floodway	Consider expanding cross-sectional area to increase conveyance and protect future floodway developments; Design geometry that is relatively stable during flows of at least 13,000 cfs
Hydrologic Seasonality and Interannual Variability	Periods of extended low and high flow conditions that vary seasonally and with water year type	Create features (e.g. terraces, floodplain benches, etc.) that are appropriately situated in relation to low, high, and intermediate flow stage
Riparian Vegetation	Narrow band of riparian vegetation along channel margins reduces extent of bank erosion and imparts roughness to in-channel flow.	Create channel geometry that facilitates growth of desired riparian vegetation and achieves aesthetic and recreational objectives

TABLE 1: CHANNEL CONDITIONS AND RELATED DESIGN GUIDANCE

River Corridor Characteristic	Conditions in Trinity River at Dallas Floodway	Related Channel Realignment Design Guidance
Channel Geometry	Relatively stable since initial adjustment to USACE channel improvements (8 – 20 feet of widening); Extensive local bank erosion "repaired" by sediment deposition and revegetation	Maintain at least 50 foot bottom width from USACE improvement design and sideslopes flatter than 1:1 to reduce extent of bank erosion; Increase top-of-bank width to minimize channel widening immediately after implementation; Armor banks in close proximity to sensitive floodway developments
Channel Profile	Stable reach slope with undulations in channel invert profile that vary in location and magnitude	Minimize alterations to existing profile slope; Incorporate gradient control or plan for channel dredging where slope must be changed significantly
Channel Alignment	Stable channel centerline alignment, even in large meanders with strong eddy currents; channel width varies between 120 and 200 feet within Project area	Incorporate a 120 to 200 foot-wide buffer area between channel margins and no-encroachment area boundaries so that channel adjustments will not threaten critical areas; Where corridor is not wide enough to accommodate buffer, armor channel banks (or install sub-surface "cut-off wall") to protect sensitive floodway developments

Figure 4 shows the model grid developed to represent the proposed conditions for both the channel and floodway elements of the project. Note the varied channel geometry shown in different colors in the oblique view in Figure 4. Given the complex nature of both in-channel and overbank hydraulics expected with the proposed conditions, this two-dimensional representation was critical in adequately describing and gaming both channel and floodplain design features.

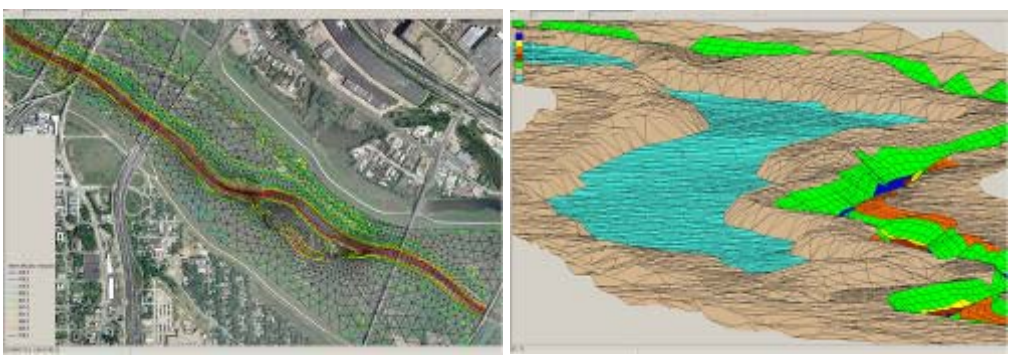

Figure 4: Plan view (left) and oblique 3-D view of the RMA-2 two dimensional model grid developed to represent the proposed Trinity river channel and floodplain conditions.

Figure 5 shows the RMA-2 model output for an overbank model run of approximately 38,000 cfs. The velocity and shear stress magnitudes and locations were used to develop design criteria for bank treatments and in-channel habitat features, and to design complex park features on the floodplain such as the weirs that control flow into and out of the floodplain lakes and the outfall channel that connects the lakes to the channel.

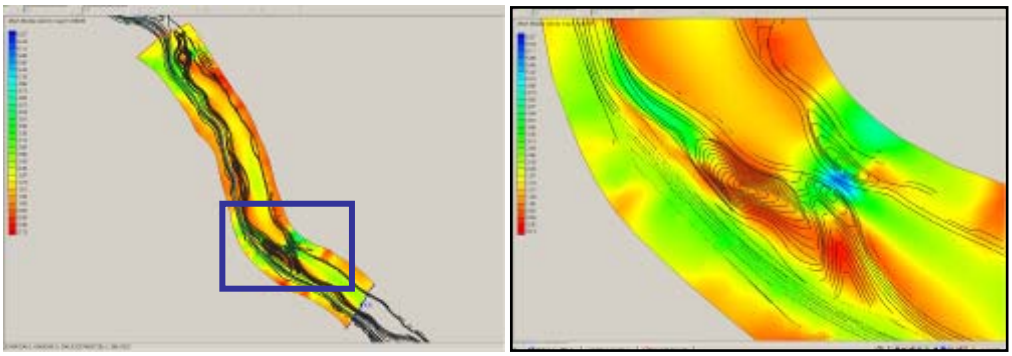

Figure 5: 2-D velocity contours showing channel and floodplain hydraulics for a flow of approximately 38,000 cfs. Blue areas are high velocity and red areas are low velocity.

Figure 6 shows the SED-2D model output that was used to further refine channel and floodplain designs, and to guide development of operation and maintenance requirements and costs. Because the floodplain will become a heavily used park in the City of Dallas, a detailed understanding of likely sedimentation patterns was essential throughout the design process.

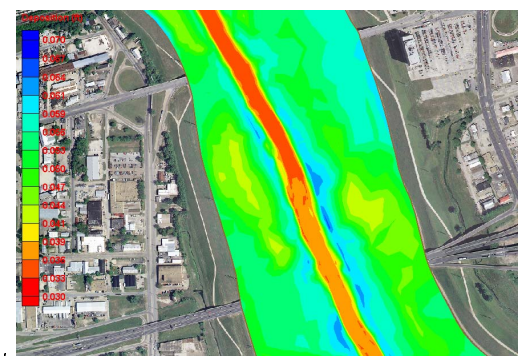

Figure 6: 2-D elevation contours showing depths and locations of expected erosion and deposition in the channel and on the floodplain.

While two-dimensional hydraulic and sediment transport modeling tools are not necessary on every channel realignment or restoration project, they have proved to be an extremely useful on the highly complex Trinity River Corridor Program where major changes are proposed to both the channel and floodplain. They provided meaningful design feedback with respect to hydraulics and sediment transport and helped identify areas where small-scale design modifications could significantly improve conditions in ways that would not have been possible using traditional one-dimensional tools.

Abstract

Along the Middle Rio Grande near Bernalillo, New Mexico, sediment loads and flood peaks have been reduced, and the river channel is incising and has converted from a low flow braided sand-bedded channel to a single thread gravel-controlled bed channel (often bi-modal sediment transport conditions), with a slightly sinuous planform. As a result, the river has migrated laterally, and before the project, was closer to the levee that provides flood protection for the adjacent developed areas. A project has been implemented to prevent levee failure, safely pass peak flows, re-establish some measure of floodplain connectivity, and improve habitat conditions for two endangered species. Project features include a new channel relocated away from the levee, bendway weirs, a low floodplain surface along the outside of the new river bend, a secondary channel, rootwads, and native vegetation plantings. The new low floodplain surface is intended to provide a new riparian zone near the existing riparian zone that has become decadent as a result of channel incision and reduced flood peaks. Data include post project cross sections showing the re-connected floodplain and the initial riparian zone re-establishment, and main channel and near bank vertical velocity profiles. Initial channel response is qualitatively evaluated.

Background

During most of the 20th century the Middle Rio Grande in the vicinity of Bernalillo, New Mexico, has been a low-flow braided, relatively straight or slightly sinuous aggrading channel with a shifting sand substrate and low banks, with high floodplain connectivity. Since the 1950's, upstream reservoirs and channelization works have been constructed to reduce sediment supply and flood peaks, increase sediment transport capacity, and protect riverside facilities and infrastructure. During this period there have been extended periods of drought and high flows affecting the channel. The altered flow and sediment regimes, largely from upstream dam and channelization construction, have affected channel conditions. The post-Cochiti Dam and channelized river in this area is a gravel-controlled bed which is mostly single thread with a slightly sinuous planform. Sediment transport is bi-modal during gravel mobilizing events. The channel changes (Reclamation, 2007) include

- Channel bed incision began after dam construction and continued through the 1990's. Historical floodplains have been abandoned and are now terraces with bank heights larger than 6 ft (Massong et. al., 2006).
- The reduced supply of sand size sediment material since dam construction, together with the availability of coarser sediments, has resulted in the bed material size changing to gravel and cobble size material.
- Planform conversion occurred in the 1990's. The channel is now predominantly a single thread, deep thalweg, with side channels becoming inundated only during high flow events (the 2-year flow or greater).
- Medial bars or islands were transient prior to planform conversion and are now relatively stable channel features with partial vegetation. These medial bars or islands now act as high-flow floodplain surfaces narrowing the active channel and in many cases have become attached to the banks.
- A series of migrating bends is developing as a result of planform conversion, narrowing, incision, and bed coarsening.
- The channel bank height, at present, is mostly tall enough that the thalweg elevation intersects the bankline beneath the root zone of the riparian vegetation on the abandoned terraces.
- Small patches of riparian vegetation are growing on the new smaller floodplain surfaces being created by the migrating incised channel, while the historical floodplain is becoming increasingly isolated from the main channel and 2-year return period peak flows.

The channel incision and narrowing have degraded native aquatic and terrestrial habitats, including that of two endangered species, the Rio Grande silvery minnow (*Hybognathus amarus*) (RGSM) and the Southwestern willow flycatcher (*Empidonax traillii extimus*) (SWFL). Habitat needs for the RGSM include low velocity, low depth, silt/sand substrate habitats, inundated floodplains and inlets to side channels (Dudley and Platania, 1997; SWCA, 2007; Reclamation, 2007). The SWFL habitat needs are dense growth of trees and shrubs, about 13 to 15 feet tall, located in riparian ecosystems associated with wetlands, and other areas near rivers and lakes (Reclamation, 2007). An incised channel with coarse substrate, tall banks, and small patches of floodplain connectivity does not generally provide suitable habitat for these two endangered species.

The river rehabilitation project near Bernalillo, New Mexico, was initiated to address bed and bank erosion threatening river side facilities and the degradation and loss of native habitat in this reach. The protection of river side facilities, rehabilitation of riverine habitat to one more favorable to the RGSM, and the development of a riparian zone connected to the river's hydrology are the primary objectives of the project.

Project Description

Near the town of Bernalillo, New Mexico, the river channel has moved close to the levee on the east side, and the angle of the upstream bend directed flows at this bank. Based upon a time sequence of visual observation, there was concern that, at moderately high flows of 3,000 to 5,000 cfs, the bank could erode, causing the levee to fail and the river to

flow into the Bernalillo Riverside Drain and flood an extensive area east of the river, with both residential and agricultural uses (Sixta and Nemeth, 2005). The site is located on the east side of the Rio Grande, approximately 3,300 feet south of the U.S. Highway 550 Bridge in Bernalillo, New Mexico (Figure 1).

To protect the levee from future damage, the main channel of the Rio Grande was realigned slightly to the west, bendway weirs were installed, a low floodplain surface along the outside of the bend was created, and a secondary channel was constructed (Figure 1). The low floodplain surface and secondary channel are intended to reduce erosion potential on the east bank and create more favorable habitat. The project was designed by Bio-West, Inc. (Bio-West, 2005), under contract with the Bureau of Reclamation, and construction was performed by a Reclamation crew from August 2006 to March 2007.

To reduce the energy directed at the east bank, the main channel was realigned as shown in Figure 1. This realignment decreases the bend angle and also increases the distance from the river channel to the levee. A low floodplain surface was established by placing alluvial fill in the old main channel with a sloping and multi elevation surface. The alluvial fill volume was about 42,000 cubic yards, and was taken from the new channel alignment and the secondary channel. The secondary channel was excavated to the west of the existing main channel (Sixta and Nemeth, 2005).

Re-establishing the terrestrial-aquatic connectivity in river rehabilitation and inundation of the floodplain is essential for ecosystem health (Brookes, 1996). The new riparian zone is about 120 ft wide (Figure 2) and varies in width throughout the project area (Figure 1) with a total land area of 2.4 acres. Various levels of floodplain surfaces were established with some being inundated with about 1 to 1.5 feet of water depth at about 5,000 cfs (Sixta and Nemeth, 2005). These varied flow depths are intended to encourage natural recruitment of native riparian forest species at different flow rates on the multiple levels of the low floodplain surfaces (Figure 2). Planting of native willow and cottonwood on the new low floodplain surfaces also encourages establishment of a riparian forest. Finally, numerous rootwads and woody debris piles were included to provide short term habitat enhancement (Figure 1).

The 13 bendway weirs were constructed on the outside of the bend along the east bank of the river to prevent bank erosion. Bendway weirs are upstream angled stone sills, submerged at high flows, and placed along the outer banks that are designed to control and redirect currents through the bend (Derrick, 1997). A new thalweg location develops at the tips of the bendway weirs. Bendway weirs are typically constructed with a top width of two to three times the maximum diameter of the rock used to construct the weir, and typical heights range from one half to one times the bendway weir top width (McCullah and Gray, 2005). The bendway weirs at the Bernalillo site were constructed of 12 inch nominal diameter riprap, with an approximate width of four feet, and a length projecting 25 feet into the flow. To prevent flanking by possible future lateral migration, an additional length of riprap extends into the bank, and is typically about 75 feet. The weirs are approximately four feet high at the bank and taper to three feet high at the tip.

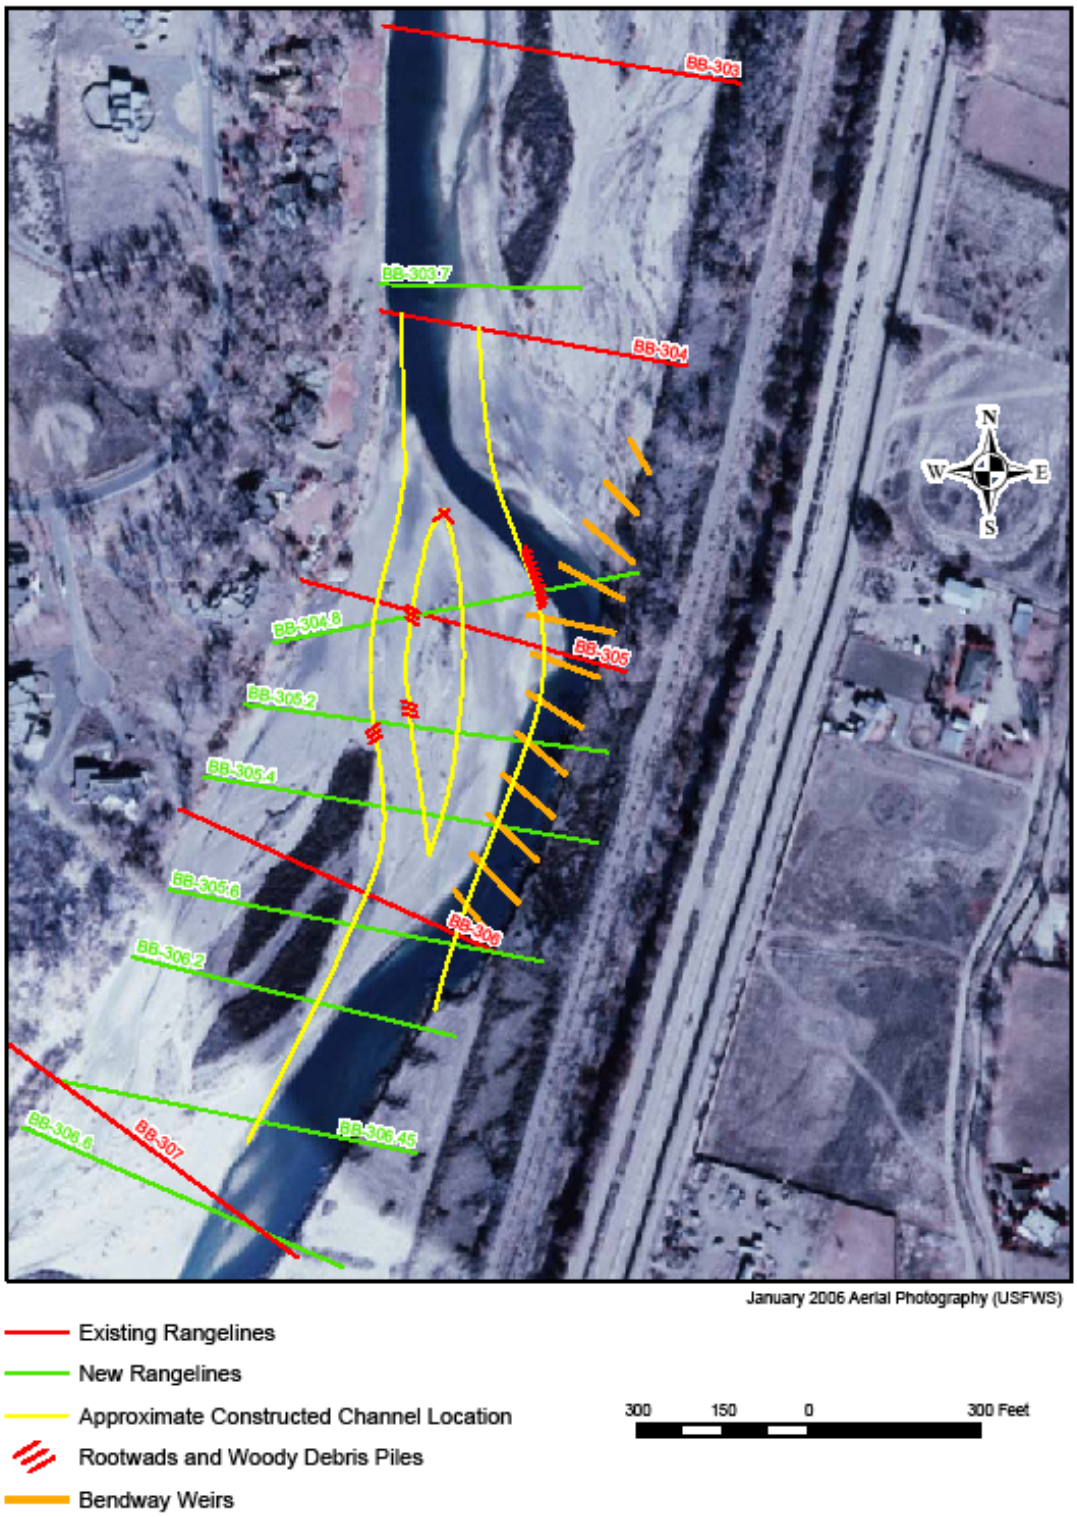

Figure 1. Bernalillo Project plan view showing relocated channel, secondary channel, bendway weirs, and range line locations.

The four foot height corresponds to the 500 cfs water surface elevation at the bank, and to slightly less than half of the modeled 5,000 cfs water surface elevation. These flows correspond to a typical low and high flow, respectively. The weirs were constructed at a spacing of 75 feet and oriented 20 degrees upstream of a perpendicular line extending from the bank (Sixta and Nemeth, 2005).

Since it is difficult to precisely estimate potential project outcomes for river rehabilitation, adaptive management is included in the project. Adaptive management consists of post project data collection and observation, evaluation, and modifications to the project to meet project goals. Adaptive management for the project (Sixta and Nemeth, 2005) includes 1) replanting vegetation if initial survival rate is low, 2) additional earthwork to maintain the new channel alignment until the new bankline is stabilized by vegetation and the bendway weirs, 3) earthwork to adjust the elevation of the constructed low surface floodplain to improve establishment of a new riparian zone, 4) additional rock to replace rock which may erode from the bendway weir tips or for field weir modifications, and 5) replacing dislodged rootwads and debris piles.

Post Project Assessment

The objective of the post project assessment plan is to determine the overall effectiveness of the project features and channel response to provide for improved future project function. Specifically, the post project assessment includes the following: 1) determine initial and longer term channel response to project construction in terms of channel plan view, hydraulic geometry, and channel profile; 2) measure the velocity and estimate shear stress in the main channel and along the bankline between weirs; 3) determine the actual frequency of overbank flows in the excavated floodplain, 4) estimate sediment transport rates through the project area, 5) observe and document the stability of the bendway weirs and the constructed bank line.

The initial channel cross section changes, velocity, and shear stress (in both the main channel and along the bankline between weirs), and discharge measurements are reported in this paper.

Data Collection, Analysis, and Results

Cross sections were collected in May 2007 and May 2008. A discharge measurement was made during May 2008 to determine the flow split between the main channel and the secondary channel. A series of point velocity and vertical velocity profiles were measured to estimate velocity and bed shear stress in the main channel and along the bankline between the bendway weirs during May 2008. Comparative cross sections, for section 304.8 are shown in Figures 2 and 3. The pre project (August 2004) cross section is 305 (Figure 2). The location was slightly changed after the project was constructed so the cross section would be oriented perpendicular to the new channel alignment. The thalweg elevation is higher and the main channel flow depth is reduced post construction (Figure 2). This is attributed to increasing the local centerline bend radius, and the new secondary channel (Figure 2) which, at high flows, conveys a significant portion of the

flow. In the pre-construction cross section, there was an abandoned channel from about station 340 to about station 575, which was not a secondary channel. The secondary channel (measured in May 2007) is much wider and conveys more flow than originally designed. During construction a small secondary channel was excavated. The new main channel was blocked and all river flows were directed down the secondary channel. A larger than anticipated flow event occurred during construction, enlarging the secondary channel beyond the design dimensions (May 2007 in Figure 2).

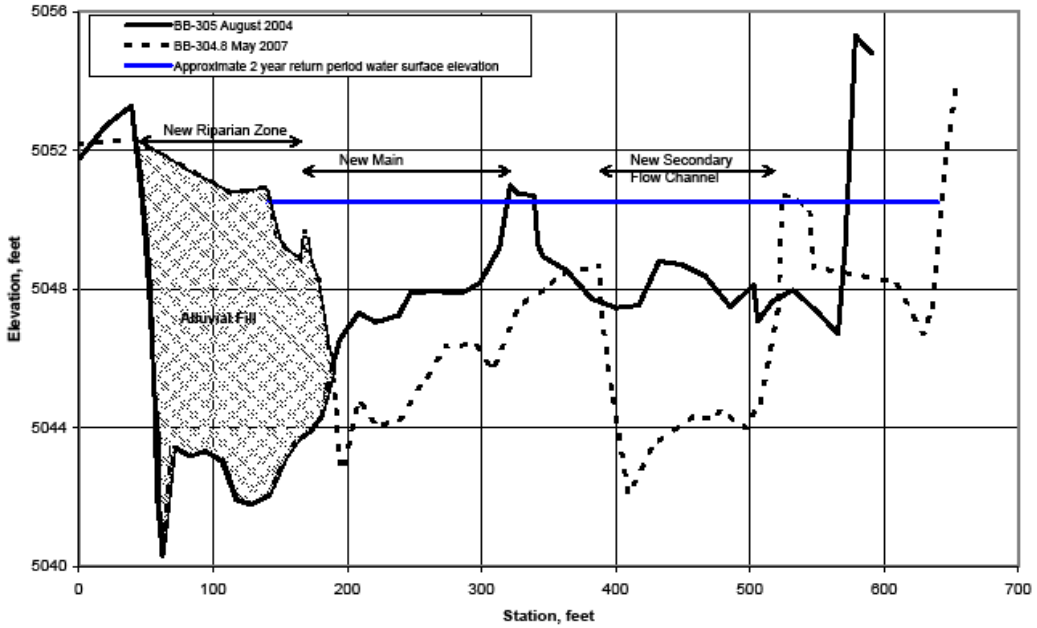

Figure 2. Rangeline comparison before and after construction, showing the alluvial fill for the new riparian zone, and the new main and secondary channel locations.

Between May 2007 and May 2008, there was scour in the main channel between station 200 and about 300 (Figure 3). There was scour in the secondary channel between stations 310 and 400, and fill between stations 395 to about 510. During the May 2008 discharge measurement there was 1970 cfs flowing between stations 180 to 310 in the main channel, and about 1660 cfs flowing in the secondary channels between stations 310 to 520. During May 2008, a series of velocity measurements were made near the bendway weirs. Velocity measurements consisted of instantaneous measurements made using an ADV manufactured by SonTek/Ysi in San Diego, California. A sampling rate of 25 Hz for 60 seconds was made with the ADV mounted to a standard 50 lb USGS

weight. The effectiveness and limitations of the weight mounted ADV are described by Baird (2004).

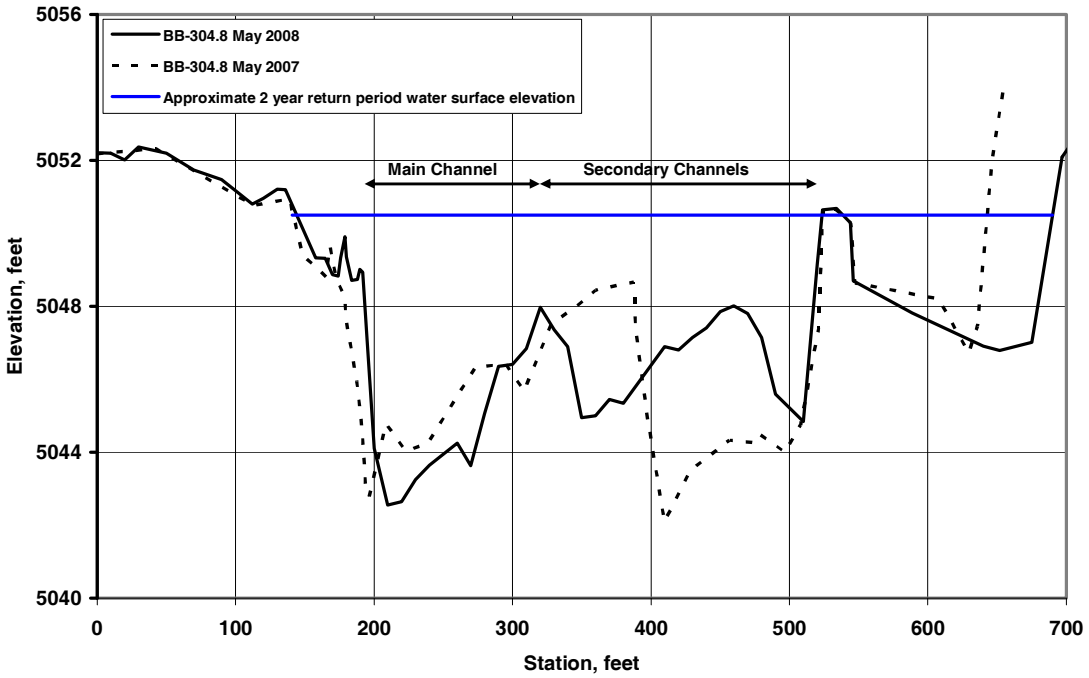

Figure 3. Same rangeline as Figure 2, comparing May 2007 and May 2008 data and showing some main channel scour, and secondary channel scour and filling.

At some locations, 3-point velocity measurements were made in the vertical at 0.2, 0.6, and 0.8 *y*/*d*. At other locations, a series of 19 point velocities were made to develop a vertical velocity profile. The purpose of the vertical velocity profile is to estimate bed shear velocity (u_*) and bed shear stress (τ_o) in the main channel and along the bankline between bendway weirs. The velocity profile also was collected for the purpose of gaining an understanding of this part of the flow field and thus erosion patterns around the bendway weirs. The main channel velocity, velocity profile, and shear stress were collected and estimated to compare with same variables along the bankline between bendway weirs. The difference between the main channel and bank line velocity and shear stress is the reduction as a result of the bend way weirs. The bank line vertically averaged bank line velocity and shear stress will be compared with published bank stability criteria based upon bank material soil types and sizes. Estimating u_* from the velocity profile relies upon the logarithmic velocity profile law being valid. Whether a logarithmic zone existed near the bank between the bendway weirs was an unknown at the time of data collection. Assuming a logarithmic zone exists its thickness was also an unknown. To aid in these purposes the measured vertical velocity profile was also compared to the log wake flow law given by Nikora and Goring (2000) using estimated values of shear velocity zero velocity roughness height, and the Coles (1956) wake flow parameter:

$$\frac{\bar{u}}{u_*} = \frac{1}{\kappa}\ln\left(\frac{y}{y_o}\right) + \frac{2\Pi}{\kappa}\sin^2\left(\frac{\pi y}{2d}\right) \quad (1)$$

where u_* is the shear velocity in ft/s, κ is the von Karman constant equal to 0.4, y_o is the zero velocity roughness height in ft, and Π is the dimensionless Coles wake flow parameter. For the flow region from the bed to about 0.2 y/d (inner region), a logarithmic profile exists (Figures 4 and 5). This is sufficient thickness to estimate u_*. For the flow region about y/d > 0.2 (outer region) the flow deviates from the logarithmic law. Secondary currents have also been shown to cause this departure (Baird, 2004).

The main channel shear velocity was 0.585 ft/s, compared to 0.159 ft/s twelve feet downstream of the sixth bendway weir from the upstream end (bendway weir 6). Using the relationship $\tau_o = \rho u_*^2$ bed shear stress was estimated (Table 1). The value of the Coles wake flow parameter was -0.16 for the main channel, and -0.05 for the bankline downstream of bendway weir 6. A negative Cole's wake flow parameter is caused by flow retardation from secondary currents. The main channel flow velocity profile (Figure 4) is in good agreement with the profile of the log-wake law with a logarithmic zone in the inner region, and some deviation near the top of the water column. The bankline line velocity profile (Figure 5) has a logarithmic zone in the inner region, and deviates significantly from the log-wake law in the outer region, attributed to bank line (side wall) effects. Main channel vertical mean velocity (average of 0.2, and 0.8 y/d values) was 4.00 ft/s, the bankline 12 feet upstream of each weir measured was 2.85 ft/s, the bankline 12 feet downstream of each weir measure was 2.96 ft/s, and the bankline halfway (35 feet) between each weir was 3.21 ft/s. The bank line would remain stable under these shear stress and velocity conditions for particle sizes larger than 0.3 to 0.6 inches in diameter (Table 1). During data collection the banks were not actively eroding and are comprised of sand and gravel sizes.

Initial Post Project River Response

Post project visual observations show few naturally-seeded cottonwoods that have grown beyond several inches, even though the newly established floodplain was inundated after spring runoff of 2006. Willows and cottonwoods planted as part of the project have experienced some mortality, and some continued growth. Those closest to the water surface have experienced mortality attributed to extended periods of inundation. Further up the bankline plantings are generally more successful. The bendway weirs have remained stable and variable depth and velocity flow conditions have been established as a result of scour at their tips and downstream eddies. However, the downstream eddies were only observed during low flow conditions. Data from May 2008 showed that no eddies existed downstream of the weirs along the bankline. Between the time the project was constructed and the May 2008 data collection period, no bank erosion had occurred between the bendway weirs. Post runoff observations indicate that there is some bank erosion along the outside of the realigned meander bend between the bendway weirs.

Measurements made at 3,900 cfs, in May 2008, show that the near bank shear velocity and depth averaged velocity were reduced (Table 1).

Table 1 Material Sizes Which are Stable for the Measured Velocity and Shear Stress. Sizes are from Fischenich (2001).

Location	Vertically Averaged Velocity (ft/s)	Stable Boundary Type for the Measured Velocity	Local Shear Stress (lb/sq ft)	Stable Boundary Type for the Measured Velocity
Main Channel	4.0	Graded Loam to cobbles and 6 inch gravel	0.661	Graded silts to cobbles and 1-2 inch gravel
Near the Bank Line between Bendway weirs	2.85 to 3.21	1-2 inch gravel	0.159	Fine loam 0.6 to 1.3 inch gravels

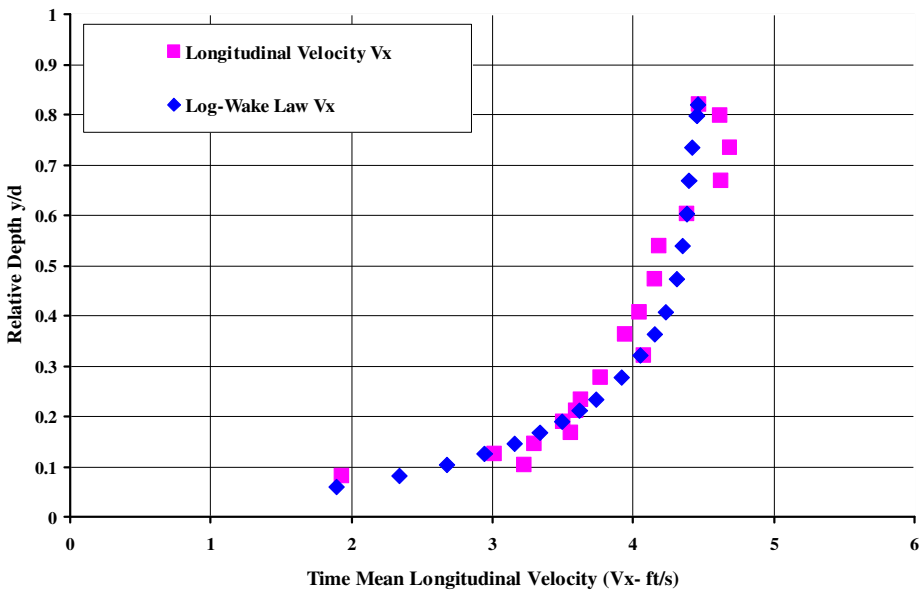

Figure 4. Main channel vertical velocity profile 12 ft. from the tip of weir 6.

For the flow rate in May 2008 (3,900 cfs), the near bank shear velocity 12 feet downstream of bendway weir 6 was 27.2% of the main channel shear velocity, the near bank depth averaged velocity either 12 feet or upstream or downstream of the bendway weirs was 72.6% of the main channel depth averaged velocity, and the near bank depth averaged velocity at the midpoint between two bendway weirs was 80.3% of the main channel depth averaged velocity. The large secondary channel conveyed a significant

portion of the flow. Post-runoff observations indicate that it is filling with sediment, while the main channel appears to be scouring. Additional data collection is planned to confirm these post runoff observations. The low floodplain surface area between about

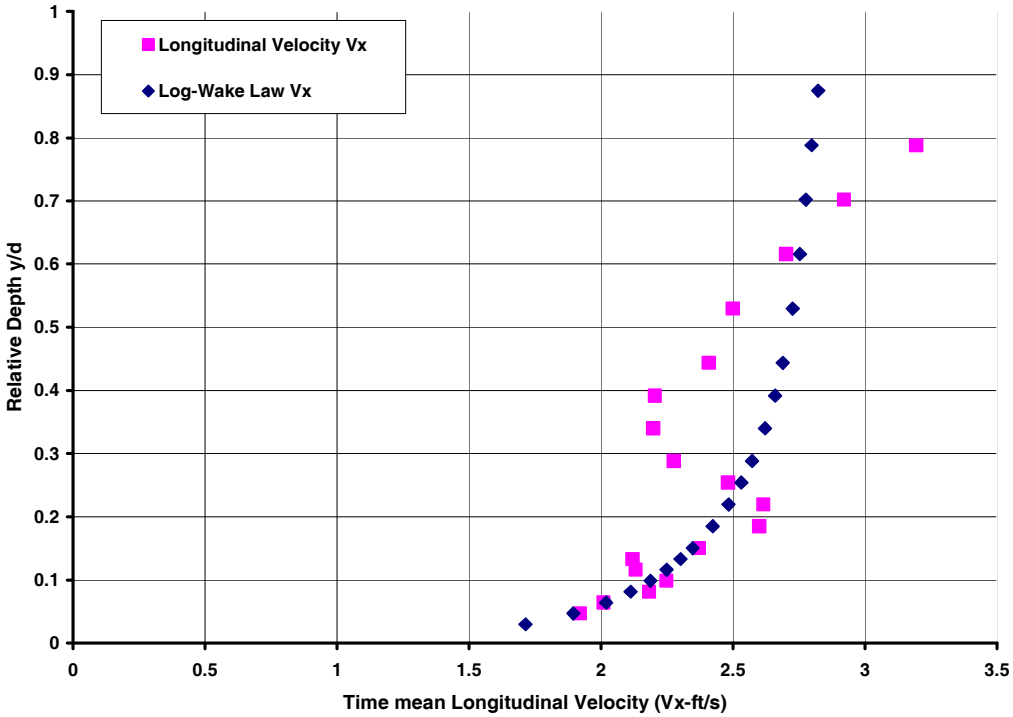

Figure 5. Main Channel vertical velocity profile along the bankline 12 ft. downstream of weir 5.

station 40 and station 120 was constructed with a slope for habitat and revegetation purposes. The bankline velocity and shear stress have also been reduced. For the time period up to the May 2008 data set, the bankline remained intact without scalloping or bank erosion between groins, indicating sufficient near bank velocity reduction to maintain bank stability. The peak of the 2008 runoff occurred later in May and was 5,150 cfs. After the recession of the hydrograph it was observed that the large secondary channel had filled significantly with sediment, and that bank scalloping between bendway weirs occurred. .

Conclusions and Recommendations

Successful rehabilitation of incised, narrowed river channels can include re-establishing connectivity between the main channel and floodplain by either raising the riverbed or lowering the banks or terraces. In some cases, smaller inset floodplains will establish within the abandoned terraces as the channel migrates laterally. Floodplains may need to be re-established by excavation when incision prevents floodplain connectivity, and raising the river bed is not possible. In other cases where channel incision is mild or doesn't exist, removal of barriers can create floodplain connectivity. These could be spoil berms from channel excavation, or longitudinal dikes which are no longer needed.

For this project, a new low floodplain surface was created by relocating the river and placing alluvial fill material in the previous main channel. At the Bernalillo project site, the initial response shows that a riparian zone is not developing naturally and additional plantings may be needed to ensure long term establishment of a riparian zone. At present the riverside infrastructure is adequately protected, and the bendway weirs are stable, although scallops have developed between weirs. If scour in the main channel and sediment deposition in the secondary channel continue, the weirs may erode away and the main channel could migrate laterally.

Large river rehabilitation and floodplain connectivity may require a great deal of earth work, depending upon the local topography and geomorphology. This project illustrates the challenge of achieving multiple, diverse goals in a highly managed natural system. Goals such as maintaining flood conveyance and protecting riverside infrastructure may require a different approach than creating or improving habitat for endangered species. Habitat restoration projects generally attempt to mimic conditions that evolved before the system was managed. The initial response at this site indicates that the project may require adaptive management and additional post project maintenance. This is a work in progress, and, with additional data, findings and conclusions may be added or altered based on future observations.

It is recommended that additional data be collected and evaluated to understand and document post project channel processes affecting the flood conveyance, protection of riverside facilities, floodplain connectivity, bank stability near the bendway weirs, and the variable depth and velocity conditions found near the bendway weirs. Additionally, longer reach river response assessment would be useful to determine any channel changes as a result of the project.

USACE River Ecosystem Restoration Planning: Lessons Learned From the Illinois River Study

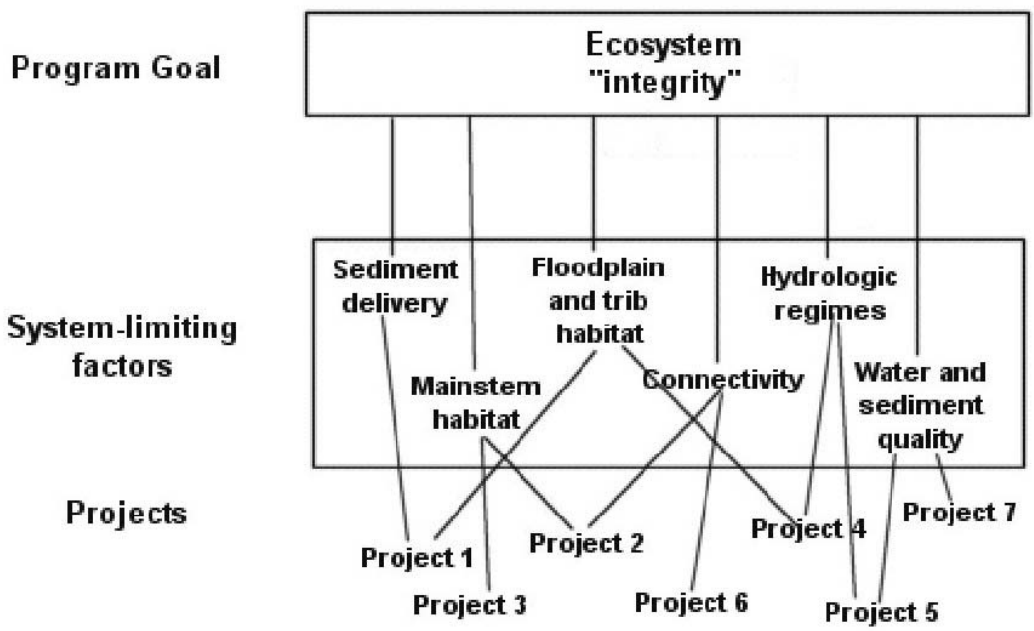
ABSTRACT

Planning undertaken by the U.S. Army Corps of Engineers for the Illinois River (IL) Basin Restoration Study utilized formulation techniques that could be adapted for other river ecosystem restoration planning efforts. The USACE planning process requires quantification of benefits in order to evaluate the relative merit of alternative approaches. Historically, these benefits have often been quantified in terms of "acres of habitat created or improved". However, when altered abiotic processes or biotic interactions limit ecosystem function to a larger degree than habitat limitation it is necessary to incorporate both spatial and functional considerations to develop meaningful measures of restoration benefit.

In the Illinois River system, ecosystem function is generally considered to be limited by a combination of abiotic processes (including sediment transport, water level and water quality), biotic interactions (including lost connectivity and exotic species), and habitat limitation (including deep waters, connected backwaters and floodplains). For the Illinois River Basin Restoration study, developed by the USACE in partnership with the State of Illinois seven overall restoration goals were developed, each addressing one of the identified limiting factors. Each objective was quantified using individually specific criteria, such as tons of sediment delivered to the river, degree of water level fluctuation, miles of connected tributary mainstem and acres of connected backwater multiplied by a depth distribution function. Alternatives were then developed based on differential attainment of the various criteria relative to the level necessary to reach full functionality.



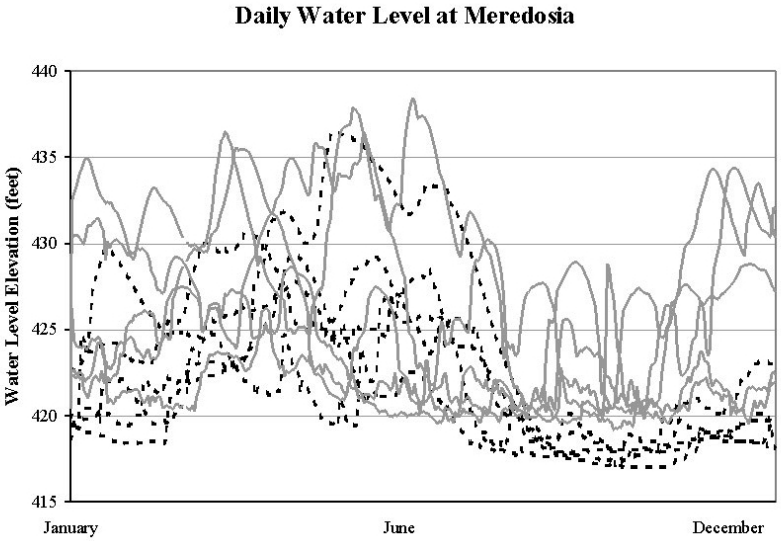
Sophisticated hydrologic and hydraulic modeling, supplemented with GIS analyses, were used to quantify tributary-, basin- and reach-level effects of alternative implementation. HSPF was used to evaluate hydrologic and sediment transport benefits within tributaries from implementation of different levels of infiltration and storage practices. UNET hydraulic modeling was used to estimate the reduction of water level fluctuation due to tributary improvements and reconnection of floodplain areas. The relationships between level of implementation and modeled effect were used to determine the level of effort (or number of individual projects) required along the river or throughout the watershed to reach the desired criterion levels for each particular alternative.

The ecological function of impacted rivers, wetlands and their watersheds tends to be degraded by factors above and beyond habitat loss. Identifying the relevant factors and formulating plans that adequately address each is crucial to developing successful

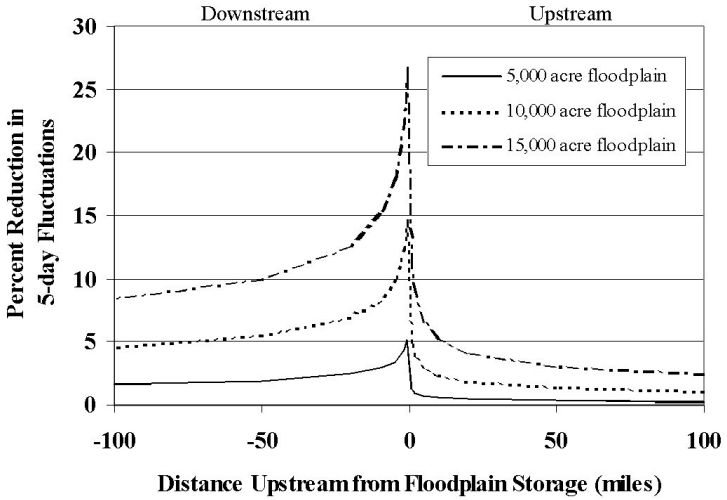
restoration projects. Combining sophisticated models of physical processes with the input of ecologists with extensive local knowledge allows the development of ecologically meaningful planning and design criteria for these projects.

INTRODUCTION

The Illinois River Basin Restoration Program is a joint Federal-State effort to restore ecosystem function to the Illinois River. In the Illinois River system, ecosystem function is generally considered to be limited by a combination of abiotic processes (including sediment transport, water level and water quality), biotic interactions (including lost connectivity and exotic species), and habitat limitation (including deep waters, connected backwaters and floodplains). The project team, led by the USACE and the Illinois DNR established an overarching goal: "Restore and maintain ecological integrity, including habitats, communities and populations of native species, and the processes that sustain them.". To reach the overarching goal, the team developed seven overall restoration goals, each addressing one of the identified limiting factors and associated with specific measurable criteria. Projects will be developed to address one or more goals and the level of effort and focus of the restoration determines the number and types of projects implemented.

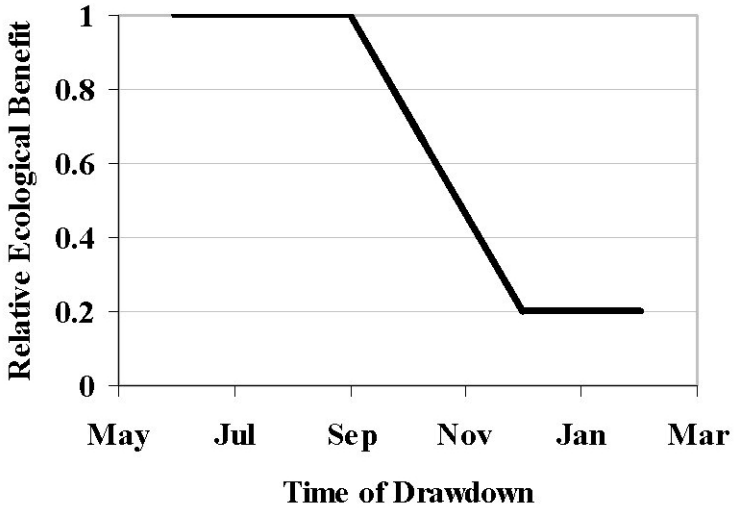


Illinois River Basin Overall Restoration Goals



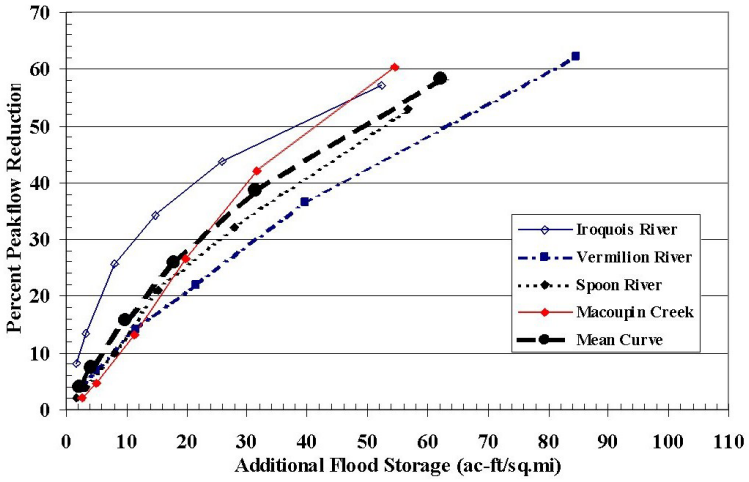
Goal	Measures of Success
Reduce sediment delivery to the Illinois River from upland areas and tributary channels with the aim of eliminating excessive sediment load	– Reduced tons of sediment delivered to the River – Reduced tons of sediment delivered to high-value habitat areas
Restore aquatic habitat diversity of side channels and backwaters, including Peoria Lakes, to provide adequate volume and depth for sustaining native fish and wildlife communities	– Acres of diverse backwaters – Acres of side channel and island habitats – Maintained connections between backwaters and main channel – Improved substrate conditions for plants and animals (compaction)
Improve floodplain, riparian and aquatic habitats and functions	– Acres of mainstem floodplains – Acres of tributary floodplains – Miles of riparian habitat
Restore aquatic connectivity (fish passage) on the Illinois River and its tributaries, where appropriate, to restore or maintain healthy populations of native species	– Passage at dams
Naturalize Illinois River and tributary hydrologic regimes and conditions to restore aquatic and riparian habitat	– Reduced low water fluctuations along mainstem – Reduced tributary peak flows – Increased tributary base flow – Pool drawdowns for 30 days at least once every 5 years
Improve water and sediment quality in the Illinois River and its watershed	– Achieving full use support (first for aquatic life, later for all uses) – Encouraging remediation – Achieving nutrient standards – Maintaining existing full use waters

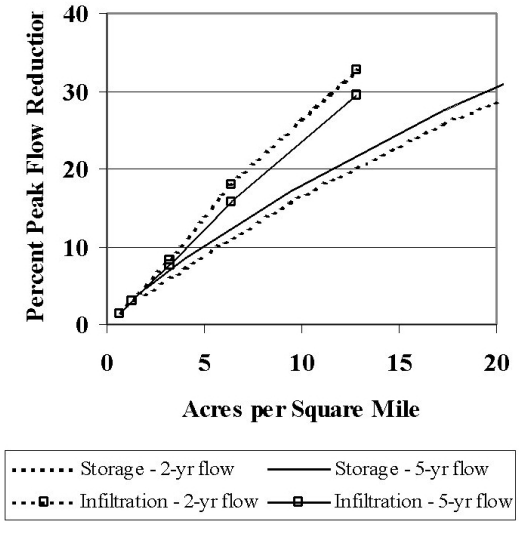
HYDROLOGIC RESTORATION ANALYSIS



A number of modifications within the basin, notably extensive land use change, has led to flashier hydrologic regimes in tributaries and increased water level stability in the mainstem Illinois River. Since tributary hydrology and mainstem water levels are often linked, the effects of restoration had to be evaluated holistically. Watershed restoration effects were modeled using HSPF using long-term (30-year) rainfall inputs and river water levels were modeled using a UNET model of the river, also using long-term inputs and run at two hour timesteps. For example, the effects of adding various quantities of floodplain storage along the river was hydraulically modeled; it was determined that such storage could smooth water level regime locally and for a short distance downstream but would have little effect upstream.

(Dashed lines are pre-1900 river levels, solid lines are from 1990-2000)



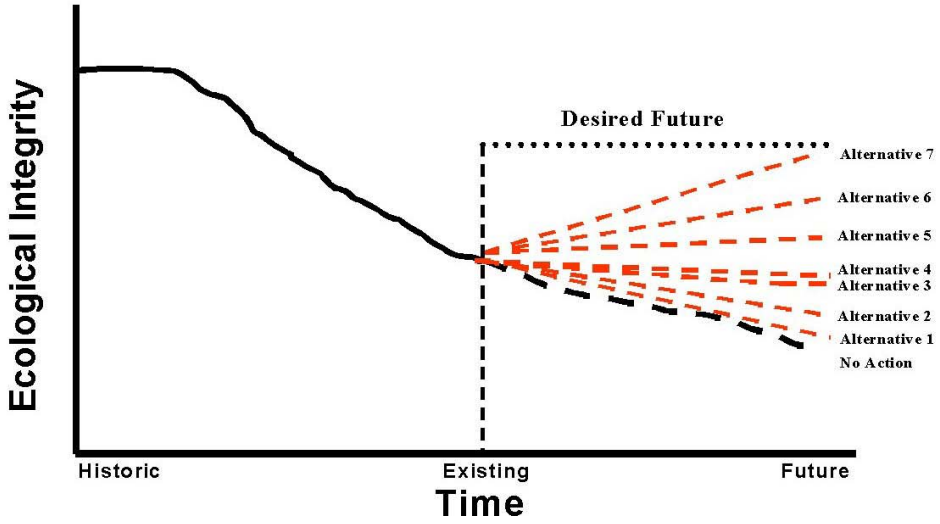


The UNET model was also used to evaluate potential drawdown opportunities. The model was run using long term flows to probability of maintaining extended exposure upstream of the Peoria and La Grange dams if drawdowns were attempted at different times of the year. The figure below shows the assumed ecological benefits from drawdowns at various times of the year, and by combining the relative benefit with the probability of success the expected benefit of different strategies can be determined. Although summer drawdowns have the highest potential benefits, they were found to have a low likelihood of success due to the incidence of storms that would flood exposed areas. Later drawdowns are more likely to succeed and despite the lower benefits during that time of year, the average expected benefit per attempt is highest for drawdowns beginning in August.

Starting Date		Jun 1	Jul 1	Aug 1	Sep 1	Oct 1	Nov 1	Dec 1
Suitability (30-day)		1.0	1.0	1.0	0.8	0.6	0.4	0.2
Suitability (70-day)		1.0	0.97	0.86	0.66	0.46	0.29	0.2
30-day attempt	Full success rate	0.15	0.3	0.6	0.65	0.65	0.55	0.4
	Expected benefit (per	**4.5**	**9**	**18**	**15.6**	**11.7**	**6.6**	**2.4**
70-day attempt	Full success rate	0.1	0.2	0.45	0.45	0.4	0.3	0.2
	Expected benefit (per	**7**	**13.6**	**27.1**	**20.8**	**12.9**	**6.1**	**2.8**
	30-day but not 70-day rate	0.4	0.6	0.4	0.4	0.4	0.4	0.55
	Expected benefit (per	**12**	**18**	**12**	**9.6**	**7.2**	**4.8**	**3.3**

Watershed and tributary benefits were quantified using HSPF simulations of four tributaries that are considered to represent the range of conditions present in the basin. Various implementation levels of restoration techniques were modeled and the benefit curves for the four tributaries were used to generate a mean curve that was used to represent basinwide implementation. The output from these simulations was also used as input to the river UNET model to evaluate the effects on mainstem water level fluctuations and other downstream benefits.

PLAN FORMULATION



After determining the benefits of individual restoration measures, plans to address the hydrologic restoration goal were developed by combining various levels of implementation of these measures. Costs were then estimated for each of these plans. Selected plans for each individual goal were assembled to create alternatives with different ecological integrity endpoints.

	Initial Cost ($M)			Tributaries		Reduced Main Stem Fluctuations

Overarching Goal – Ecological Integrity will be addressed by the other goals through prioritization and specifications on restoration measures.
Goal 1 - Sediment delivery benefits are expressed in percentage reductions in tributary delivery resulting from in-channel stabilization and upland practices.
Goal 2 - Backwater (BW) Benefits are expressed in acres dredged, but will benefit larger reaches. Side Channel benefits associated with increased structure and some dredging.
Goal 3 - Main stem (MS) floodplain and riparian (trib) areas are expressed as acreages. Aquatic areas are expressed in stream miles.
Goal 4 - Connectivity (Fish Passage) lists reaches to be addressed. Main stem passage is at Starved Rock, Marseilles, and Dresden Island.
Goal 5 - TPF and TBF are tributary peak flow and base flow, respectively. MSF is the change in the main stem fluctuation regime, representing an average of 5-day windows in the lower river fluctuations over the course of the average growing season. Auto gates allow increased management to smooth flow releases and are included in Alternatives 6 and 7. Wicket dam replacements are considered for the Peoria and La Grange pools in Alternative 7.
Goal 6 - Water quality issues will be addressed through other goals. Greatest benefits likely associated with Goals 1 and 3.
Only rough benefits estimations are included in table; see writeup for additional details.

CONCLUSIONS

At this point, the field of large-scale river restoration necessarily includes many non-quantitative elements. Overall goals of ecosystem integrity can rarely be assigned specific measurable values, the restoration measures necessary to reach such goals are not usually understood with precision and available large-scale monitoring data is often inadequate to evaluate trends over relatively short time scales. But there are certain aspects that are sufficiently understood that processes can be simulated and restoration alternatives can be quantitatively compared. By incorporating such information into the planning process, more meaningful evaluations of project benefits can be developed where "acres of habitat" is not a sufficient indicator.

ACKNOWLEDGEMENTS

ABSTRACT

A depth-averaged 2-D model has been developed to simulate the breach processes of non-cohesive dams and levees caused by overtopping flows. It solves the 2-D flow and sediment transport equations using an explicit finite volume method on a rectangular grid, with the HLL approximate Riemann solver to handle the mixed-regime flows near the breach. It considers interactions among transient flow, strong sediment transport and rapid bed change by including bed change and variable flow density in the continuity and momentum equations of flow. The model adopts the non-equilibrium approach for total-load sediment transport, and specifies different repose angles for the sediments below and above the water surface when handling the non-cohesive embankment slope avalanching. It uses a varying time step length that satisfies both the CFL condition and the limitation that the bed change is less than about ten percent of the local flow depth at each time step. The test using laboratory experiments shows the developed model predicts well the breach dimensions and flow characteristics.

INTRODUCTION

Thousands of dams and levees have been built around the world for flood defense, water supply, navigation, power generation, etc. Failure of any dam or levee poses significant risks to people and property nearby and the services provided by the structure. Examples of such incidents include the failure of the Tenton dam in 1976 and the levee failures in the Mississippi River in 1993 and in the Yangtze River in 1998. Therefore, understanding and prediction of dam/levee failure processes is crucial for decision making for safety and maintenance of dams and levees. The most common reasons for dam failures are surface erosion due to overtopping flow and internal erosion due to downstream seepage and piping. In the last decades, many embankment breach models have been developed. Singh (1996) introduced and

evaluated several analytical and empirical earthen dam breach models available in that time, whereas Mohamed et al. (2005) reviewed many existing dam/levee breach models. In most of these models, the breach section is simplified as a rectangle, trapezoid or triangle, the flow at the breach is estimated using the broad-crested weir relation, and the erosion is estimated using different simplified models. Uncertainties in predicted breach parameters and flood hydrograph exist due to significant model simplifications (Mohamed et al. 2005).

Unlike the above simplified breach models, 1-D and 2-D numerical models can simulate the flow and morphodynamic processes due to dam/levee breach more realistically (Wu and Wang, 2008; Faeh, 2007). Because dam breach flows are usually in mixed flow regimes and with discontinuities, the often used numerical schemes are the shock-capture schemes, such as approximate Riemann solvers and TVD (Total Variation Diminishing) schemes. Many of these methods have been verified and successfully applied in the simulation of dam-breach flow over fixed beds (Toro, 2001). However, the simulation over movable beds is much more challenging and encounters additional difficulties due to high sediment concentration and rapid bed change that might significantly affect the flow. The depth-averaged 2-D model of Faeh (2007) decouples the governing equations of flow and sediment transport and thus ignores the effect between them. Wu and Wang's (2008) model considers the effect of sediment concentration and bed change on the flow, so that it is extended herein to the depth-averaged 2-D case. The governing equations, numerical methods and validation of the developed 2-D model are presented in this paper.

GOVERNING EQUATIONS

For dam breach due to overtopping flows, the interaction of flow, sediment transport and channel bed becomes significant. The generalized 2-D shallow water equations considering this interaction are (Wu, 2007)

$$\frac{\partial(\rho h)}{\partial t}+\frac{\partial(\rho uh)}{\partial x}+\frac{\partial(\rho vh)}{\partial y}+\rho_b\frac{\partial z_b}{\partial t}=0 \tag{1}$$

$$\frac{\partial}{\partial t}(\rho uh)+\frac{\partial}{\partial x}\left(\rho u^2h\right)+\frac{\partial}{\partial y}(\rho uvh)+\rho gh\frac{\partial z_s}{\partial x}+\frac{1}{2}gh^2\frac{\partial \rho}{\partial x}+\rho g\frac{n^2m_buU}{h^{1/3}}=0 \tag{2}$$

$$\frac{\partial}{\partial t}(\rho vh)+\frac{\partial}{\partial x}(\rho uvh)+\frac{\partial}{\partial y}\left(\rho v^2h\right)+\rho gh\frac{\partial z_s}{\partial y}+\frac{1}{2}gh^2\frac{\partial \rho}{\partial y}+\rho g\frac{n^2m_bvU}{h^{1/3}}=0 \tag{3}$$

where t is the time, x and y are the longitudinal and lateral coordinates, h is the flow depth, u and v are the flow velocities in x and y directions, $U=\sqrt{u^2+v^2}$, $\partial z_b/\partial t$ denotes the rate of change in bed surface elevation, z_b is the bed surface elevation above a reference datum, z_s is the water level, n is the Manning roughness coefficient, g is the gravitational acceleration, ρ is the density of the water and

sediment mixture in the water column determined by $\rho = \rho_w(1-C_t)+\rho_s C_t$ with C_t being the volumetric concentration of total-load sediment, ρ_b is the density of the water and sediment mixture in the bed surface layer determined by $\rho_b = \rho_w p'_m + \rho_s(1-p'_m)$ with p'_m being the porosity of the surface-layer bed material, ρ_w and ρ_s are the water and sediment densities, and $m_b = \sqrt{1+(\partial z_b/\partial x)^2+(\partial z_b/\partial y)^2}$ considering the bed slope.

Simulation of the fluvial processes under dam breach flow can be achieved by computing bed load and suspended load separately or the total load directly in the case of non-cohesive sediments. Here, the latter approach is used, so that the sediment transport equation is (Wu, 2007)

$$\frac{\partial(hC_t)}{\partial t}+\frac{\partial(huC_t)}{\partial x}+\frac{\partial(hvC_t)}{\partial y}=-\frac{1}{L}(UhC_t-m_b q_{t*}) \tag{4}$$

where C_t is the actual total-load sediment concentration, q_{t*} is the total-load sediment transport capacity or the so-called equilibrium transport rate per unit channel width, and L is the non-equilibrium adaptation length of sediment transport. Note that the coefficient m_b introduced in Eq. (4) considers the lateral erosion along the side slope.

The bed deformation is determined with

$$(1-p'_m)\frac{\partial z_b}{\partial t}=\frac{1}{L}(UhC_t-m_b q_{t*}) \tag{5}$$

The sediment transport capacity is determined using the formula of Wu et al. (2000), with the modification suggested by Wu (2004) to consider the effect of gravity on sediment transport over steep slope. In addition, to consider the effect of sediment concentration, the settling velocity ω_s used in Wu et al. (2000) formula is determined by Richardson and Zaki's (1954) method: $\omega_s = \omega_{s0}(1-C_t)^m$, with m≈4.0 and ω_{s0} being the settling velocity of single sediment particles in quiescent, distilled water.

NUMERICAL METHODS

To establish an explicit algorithm, Eqs. (1)–(3) are reformulated by eliminating the flow density on their left-hand sides using the relation of $\rho = \rho_w(1-C_t)+\rho_s C_t$ and Eq. (4). The new continuity and momentum equations are

$$\frac{\partial h}{\partial t}+\frac{\partial(uh)}{\partial x}+\frac{\partial(vh)}{\partial y}=-\frac{1}{1-p'_m}\frac{UhC_t-m_b q_{t*}}{L} \tag{6}$$

$$\frac{\partial(uh)}{\partial t}+\frac{\partial(u^2h)}{\partial x}+\frac{\partial(uvh)}{\partial y}=-gh\frac{\partial z_s}{\partial x}-\frac{1}{2}gh^2\frac{1}{\rho}\frac{\partial\rho}{\partial x}-g\frac{n^2m_buU}{h^{1/3}} + u\frac{\rho_s-\rho_w}{\rho}\left(1-\frac{C_t}{1-p'_m}\right)\frac{UhC_t-m_bq_{t*}}{L} \tag{7}$$

$$\frac{\partial(vh)}{\partial t}+\frac{\partial(uvh)}{\partial x}+\frac{\partial(v^2h)}{\partial y}=-gh\frac{\partial z_s}{\partial y}-\frac{1}{2}gh^2\frac{1}{\rho}\frac{\partial\rho}{\partial y}-g\frac{n^2m_bvU}{h^{1/3}} + v\frac{\rho_s-\rho_w}{\rho}\left(1-\frac{C_t}{1-p'_m}\right)\frac{UhC_t-m_bq_{t*}}{L} \tag{8}$$

Eqs. (6)–(8) and (4) are written in the following compact form:

$$\frac{\partial\mathbf{\Phi}}{\partial t}+\frac{\partial\mathbf{F}(\mathbf{\Phi})}{\partial x}+\frac{\partial\mathbf{G}(\mathbf{\Phi})}{\partial y}=\mathbf{S}(\mathbf{\Phi}) \tag{9}$$

where $\mathbf{\Phi}$, $\mathbf{F}(\mathbf{\Phi})$, and $\mathbf{G}(\mathbf{\Phi})$ represent the vectors of unknown variables and fluxes

$$\mathbf{\Phi}=\begin{bmatrix}h\\uh\\vh\\hC_t\end{bmatrix},\quad \mathbf{F}(\mathbf{\Phi})=\begin{bmatrix}uh\\u^2h\\uvh\\huC_t\end{bmatrix},\quad \mathbf{G}(\mathbf{\Phi})=\begin{bmatrix}vh\\uvh\\v^2h\\hvC_t\end{bmatrix} \tag{10}$$

and $\mathbf{S}(\mathbf{\Phi})$ includes the remaining terms in each equation.

Consider the finite-volume mesh shown in Figure 1. Each control volume (cell) is embraced by four faces. Non-staggered (collocated) grid system is used here. The primary variables h, u, v and C_t are defined at cell centers and represent the average values over each cell, while the fluxes are calculated at cell faces.

Integrating Eq. (9) over the (i, j) control volume, applying the Green theorem, and using the Euler scheme for the time derivative, one can derive the following discretized equation:

$$\mathbf{\Phi}_{i,j}^{n+1}=\mathbf{\Phi}_{i,j}^{n}-\frac{\Delta t}{\Delta x_{i,j}}\left(\mathbf{F}_{i+1/2,j}^{n}-\mathbf{F}_{i-1/2,j}^{n}\right)-\frac{\Delta t}{\Delta y_{i,j}}\left(\mathbf{G}_{i,j+1/2}^{n}-\mathbf{G}_{i,j-1/2}^{n}\right)+\Delta t\,\mathbf{S}_{i,j} \tag{11}$$

where Δt is the time step length, $\Delta x_{i,j}$ and $\Delta y_{i,j}$ are the cell lengths in x and y directions, $\mathbf{F}_{i+1/2,j}^{n}$ is the flux at face $(i+1/2, j)$, and $\mathbf{G}_{i,j+1/2}^{n}$ is the flux at face $(i, j+1/2)$.

The HLL approximate Riemann solver (Harten et al., 1983) is used to determine the fluxes at cell faces. The terms on the right-hand side of Eq. (6) and the last three terms on the right-hand side of Eqs. (7) and (8) are evaluated using the values at cell centers and the central difference scheme at time level n. The water

surface gradient term is discretized using the backward difference when the velocity is positive and the forward difference scheme when the velocity is negative. The numerical method has the first-order accuracy in both time and space.

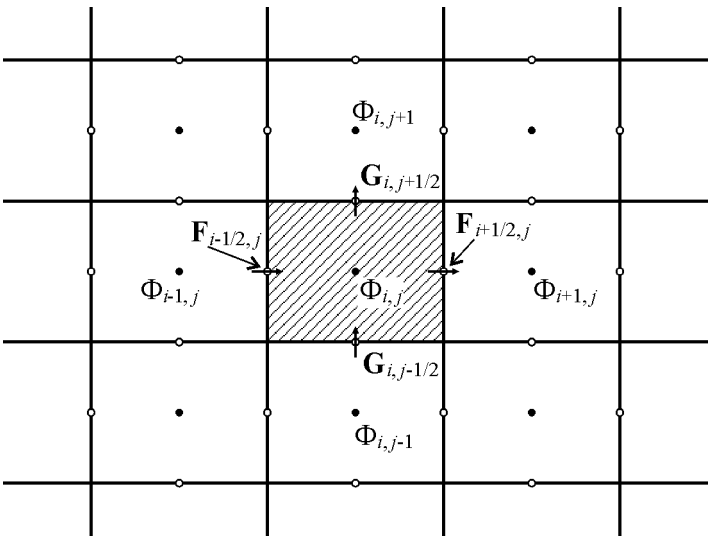

Figure 1. 2-D finite-volume mesh

The bed deformation equation (5) is discretized as

$$\Delta z_b = \frac{\Delta t}{1-p'_m}\frac{UhC_t - q_{t*}}{L} \tag{12}$$

Because the above solution procedure is explicit, the computational time step should be limited by numerical stability conditions, such as the Courant-Friedrichs-Lewy (CFL) condition for flow computation and additional conditions for sediment transport and bed change computations. By trial and error, it has been found that to obtain a stable solution, the bed change at each time step should be less than about 10% of the local flow depth. This, in addition to the CFL condition, limits the time step length.

Considering nearly vertical side walls of the breach observed in laboratory and field experiment even for non-cohesive dam/levee materials, a specially designed avalanching algorithm is adopted here. The non-cohesive slope avalanching algorithm presented by Wu (2007, pp. 278-279) is modified by specifying two different repose angles for the submerged materials and the dry materials above the water surface. The submerged repose angle is about 33 degrees as normally used, while the dry repose angle is about 79 degree for the test case present in the following case.

MODEL TEST

The present model has been validated quantitatively using the laboratory experiments carried out by HR Wallingford, UK (Morris et al., 2005). The experimental flume was about 50 m long and about 10 m wide, schematically shown in Figure 2. A series

of experimental runs were conducted under different flow and sediment conditions. The experimental test case #2 is selected here to validate the present numerical model. The model dam was located at about 36 m downstream of the flume entrance. It was 0.5 m high and had a crest of 0.2 m in width. Its upstream and downstream slopes were 1V:1.7H. The dam materials were non-cohesive. A wide grading and a narrow grading sediment mixture were tested; however, both had the same median diameter of 0.25 mm.

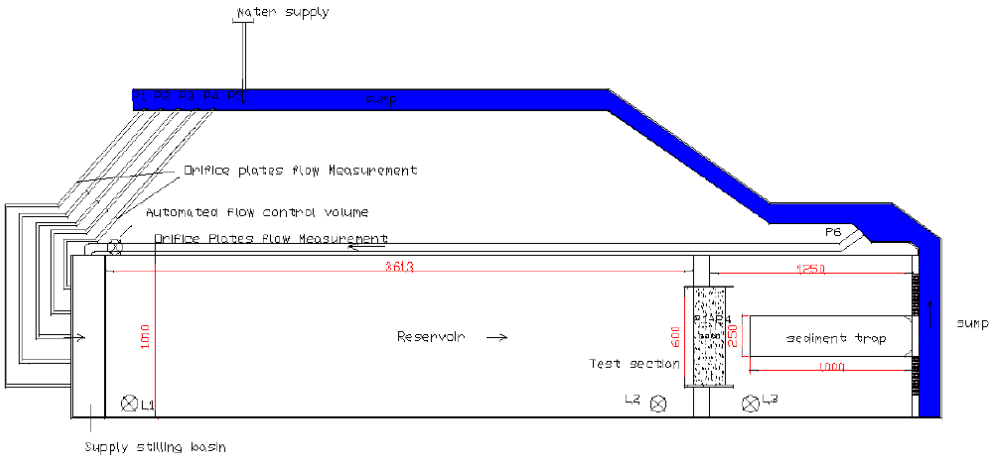

Figure 2. Schematic plan of the experimental flume at HR Wallingford (Morris et al., 2005)

The experiment started from pumping water into the reservoir. When the reservoir water level rose to the bottom of the pilot channel, the flow overtopped the dam. Water eroded the downstream slope first, so the downstream slope became milder and the dam crest retreated and eroded downward. No headcutting was observed in this test case because the non-cohesive sediment was used. Once the material was nearly eroded to the base, the material below the water level is eroded. This undermined the slopes and leaded to block failure. These processes continued until there was not enough water to erode more material. In the meantime, the upstream slope was also eroded leading to a curved "bell mouth" entrance to the breach. This "bell mouth" weir controlled the flow through the breach. Slumping was also observed on the upstream face due to this erosion (Morris et al., 2005).

A uniform mesh consisting of 1000×200 nodes in longitudinal and lateral directions is used in the simulation. The dam material porosity is estimated as 0.36, and the Manning roughness coefficient n is estimated as 0.018. The sediment adaptation length is set as 0.05 m, which is close to the longitudinal grid spacing as suggested by Wu (2007) and Wu and Wang (2008) to avoid the appearance of anti-dunes in the simulation. The time step length is determined by setting a Courant number of 0.5 but limiting the ratio of bed change to flow depth to be less than 0.1. This means that the time step length varies in different time steps. The initial pilot channel is 0.02 m deep and 0.2 m wide. The bed material repose angle is set to be 33^o in the submerged condition and about 79^o in the emergent condition. The inflow

discharge of 0.07 m^3/s is specified at the flume entrance, while a free overfall flow condition (Froude number =1) is applied at the end of the flume.

Figure 3 shows the simulated bed topography and Figure 4 shows the simulated water surface profile and flow pattern at the peak breach flow. A breach of 2.83 m in width forms at the time of peak flow. The water surface exhibits a shape of "bell mouth" weir flow, which agrees with the observation in the experiment. At the downstream of the breach the flow spreads laterally and a hydraulic jump exists.

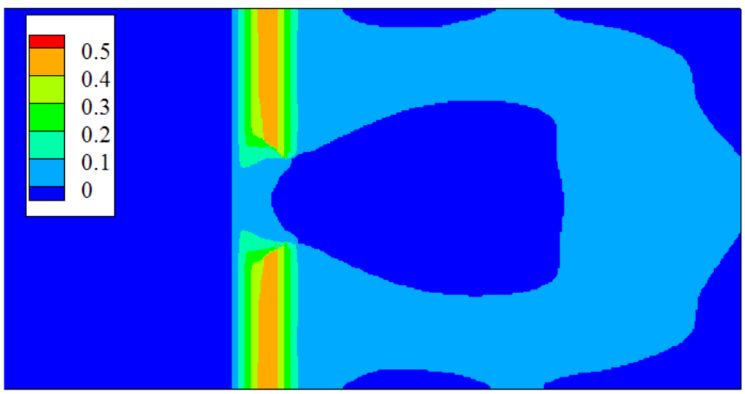

Figure 3. Simulated bed topography at the peak breach flow (contour levels in meter)

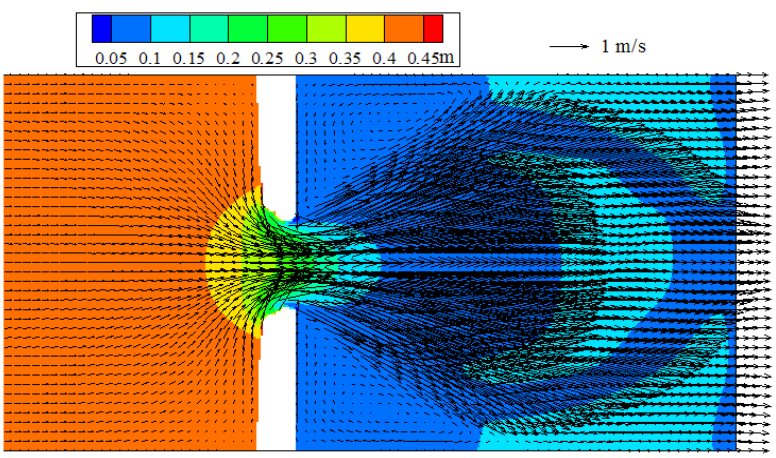

Figure 4. Simulated flow pattern and water surface at the peak breach flow

Figure 5 compares the measured and simulated breach flow discharges varying with time, and Figure 6 compares the measured and simulated breach widths. The measured data were obtained using both wide and narrow grading materials. Because the numerical simulation uses only a uniform sediment size and does not consider the gradation of sediment mixture, only one set of simulation results is obtained. The simulated breach flow hydrograph has a steeper rising limb than the

measured ones, as shown in Figure 5, while Figure 6 also shows a faster widening process in the simulation than in the experiments. However, the simulation results agree generally well with the measured data; in particular, the peak breach flow discharge and the final breach width are well predicted by the model.

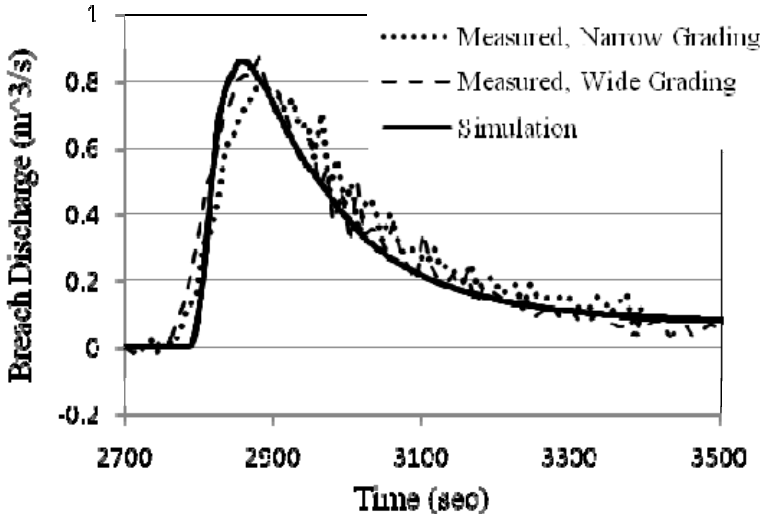

Figure 5. Measured and simulated breach flow discharges

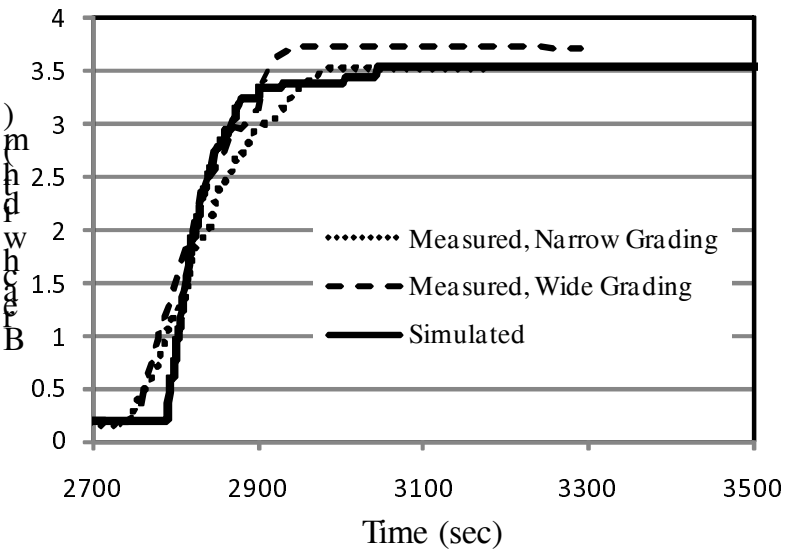

Figure 6. Measured and simulated breach widths

CONCLUSIONS

A depth-averaged 2-D finite-volume model has been established to simulate the earthen dam/levee breach processes due to overtopping flows. The effects of sediment concentration and bed change on the flow are considered in the continuity and

momentum equations. The sediment transport model simulates the non-equilibrium transport of total load. An explicit algorithm based on the finite volume method is adopted to solve flow, sediment transport and bed change equations. The model adopts the HLL approximate Riemann solver to handle the mixed-regime flows near the breach and the wetting-drying problem efficiently. A specially designed avalanching algorithm is adopted in this model, to consider different repose angles for the submerged materials and the dry materials above the water surface. To enhance the performance of the model, a varying time step is used that satisfies the CFL condition and ensures the bed change at each time step is less than ten percent of the local flow depth.

The developed model has been tested using the laboratory experiments conducted at HR Wallingford. The model predicts generally well the breach width, the flow pattern near the breach, and the breach flow hydrograph.

ACKNOWLEDGEMENT

This study is part of the research project sponsored by the USDA-ARS Specific Research Agreement No. 58-6408-7-236 (monitored by the USDA-ARS National Sedimentation Laboratory) and the University of Mississippi.

A Lattice Boltzmann Model for Dam Break Flows

H. Liu, J. G. Zhou, R. Burrows and Y. Peng

Department of Engineering, University of Liverpool, Liverpool L69 3GQ, UK
Haifei.Liu@Liverpool.ac.uk

Abstract

A two-dimensional lattice Boltzmann model (LBM) for dam break flows is developed. Shallow water equations coupled with the large eddy simulation model is numerically simulated by the lattice Boltzmann method, so that the turbulence can be taken into account and modeled efficiently. The model is verified and applied to two cases: (a) partial dam break flow; (b) circular dam break flow. The objectives of this study are to validate the two-dimensional LBM in transient flow simulation and analyze the detailed transient processes in open channel flows.

Key words: dam break flow, lattice Boltzmann method, large eddy simulation, shallow water equations, LABSWE

1 Introduction

Catastrophic flash flooding occurs when a dam fails and the impounded water escapes through the breach into the downstream valley. The suddenness and disastrousness of the shock wave make the dam break flow attract many interests from both engineers and academicians. The dam break flow has two-dimensional characteristics and is usually turbulent. This phenomenon is mathematically described by the set of two-dimensional nonlinear shallow water equations, the solutions of which can be obtained only by numerical integration, except some simplified cases. There are many numerical schemes that can be used to solve the SWE, such as finite difference and finite volume methods. However, a good solution to the SWE for the transient flows depends on the accuracy, the efficiency and sometimes the shock-capturing ability. During recent decades, the lattice Boltzmann method has developed into an alternative method for simulating surface water flow (Chen and Doolen, 1998). It is derived firstly to avoid the drawbacks of lattice-gas cellular automata in late 1980s. In the early 1990s, the

Navier-Stokes equations were recovered by the LBM with the Bhatnagar- Gross-Krook (BGK) model (Chen et al., 1992; Qian et al., 1992; Sukop and Thorne, 2006). Later, Zhou (2001, 2002a) proposed improved theories on the lattice Boltzmann methods for nonlinear shallow water equations (LABSWE), which introduced the LBM into river and coastal engineering. Compared with traditional methods, the LABSWE is a simple and efficient model with easy treatment of boundary conditions (Zhou, 2007), and so is adopted in this study. In order to accelerate the computing speed with-out loss of the accuracy, the multi-block algorithm with acceleration technique proposed by Dupuis and Chopard (2003) is incorporated in the LABSWE.

The present study aims to develop an efficient two-dimensional numerical model using the lattice Boltzmann method for dam break flows. Providing the depth-averaged features, the nonlinear shallow water equations with the large eddy model embedded in are selected as the governing equations. The model is verified and applied to two cases: (a) partial dam break flow; (b) circular dam break flow.

2 Theoretical Backgrounds

2.1 Governing Equations

The shallow water equations describe the evolution of a hydrostatic, incompressible flow with comparatively large ratio of the horizontal scale to vertical scale. The general two-dimensional governing equations for shallow water flows can be derived from the Navier-Stokes equations. The nonlinear shallow water equations can be written in a tensor form as (Zhou, 2004):

$$\frac{\partial h}{\partial t}+\frac{\partial (hu_j)}{\partial x_j}=0 \tag{1}$$

$$\frac{\partial (hu_i)}{\partial t}+\frac{\partial (hu_iu_j)}{\partial x_j}=-\frac{g}{2}\frac{\partial h^2}{\partial x_i}+\nu_k\frac{\partial^2 (hu_i)}{\partial x_j\partial x_j}+F_i \tag{2}$$

where the Cartesian coordinate system and the Einstein summation convention over Latin indices are used; h is water depth; x_j and u_j are the distance and instantaneous velocity components in the j direction respectively, i.e. for $j = 1$, $x_j = x$ and $u_j = u$; for $j = 2$, $x_j = y$ and $u_j = v$. x and y are defined as longitudinal and lateral directions of the channel; v_k is the kinematic viscosity; $g = 9.81 m/s^2$ is gravitational acceleration; t is time. In addition, F_i is the force term and is defined as:

$$F_i=-\frac{\tau_{bi}}{\rho}-gh\frac{\partial z_b}{\partial x_i} \tag{3}$$

Where z_b is bed elevation above datum. The bed shear stress τ_{bi} in the i direction is given by the depth-averaged velocities,

$$\tau_{bi} = \rho C_b u_i \sqrt{u_j u_j} \tag{4}$$

In which C_b is the bed friction coeffcient.

In natural water, turbulence is a quite common phenomenon. Generally, introducing the Reynolds equations and turbulent stress as in the $k-\varepsilon$ model is the usual way to model the turbulence, giving the time-averaged properties. However, this type of method cannot provide the detailed structure of the turbulence. Large eddy simulation, using space-filtered governing equations with subgird-scale stress model for the unresolved scale stress, can efficiently simulate vorticity larger than a prescribed scale, but needs only moderate computational effort (Tutar and Hold, 2001), so is used in this paper.

If u_j is regarded as the velocity component after being space-filtered, it can be defined by

$$u_j(x, y, z, t) = \int_{\Delta V} u_j^b G(x, y, z, x', y', z') dV \tag{5}$$

With a spatial filter function G and u_j^b is the velocity component before being space-filtered; $\Delta V = \Delta x' \Delta y' \Delta z'$; x', y' and z' are the coordinates of the space chosen for velocity filter; v_t is the total viscosity ($=v_k + v_e$), replacing v_k in Eq. (2); v_e is the eddy viscosity, defined by

$$v_e = (C_s l_s)^2 \sqrt{S_{ij} S_{ij}} \tag{6}$$

Where C_s is the Smagorinsky constant, l_s is the characteristic length scale ($l_s = \Delta x$ in the present study) and S_{ij} is the magnitude of the large scale strain-rate tensor,

$$S_{ij} = \frac{1}{2h}\left[\frac{\partial(hu_i)}{\partial x_j} + \frac{\partial(hu_j)}{\partial x_i}\right] \tag{7}$$

The depth-averaged subgrid-scale stress τ_{ij} with eddy viscosity is calculated by

$$\tau_{ij} = 2hS_{ij} \tag{8}$$

2.2 Lattice Boltzmann Model

The lattice Boltzmann model for nonlinear shallow water equations with turbulence (LABSWE^{TM}) has been presented by Zhou (2002b). After incorporating the subgrid-scale model, for motion in the i direction within a collision step, the lattice Boltzmann equation with 9-speed square lattice and force term is

$$f_a(x+e_a\Delta t,t+\Delta t)=f_a(x,t)-\frac{1}{\tau_t}\left[f_a(x,t)-f_a^{eq}(x,t)\right]+\frac{\Delta t}{N_a e^2}e_{ai}F_i \tag{9}$$

Where f_a is the particle distribution function; e=Δx /Δt; Δx is the lattice size; F_i is the force term calculated by Eq. (3); Δt is the time step; N_a is a constant, decided by the lattice pattern.

$$N_a=\frac{1}{e^2}\sum_a e_{ax}e_{ax}=\frac{1}{e^2}\sum_a e_{ay}e_{ay} \tag{10}$$

$\tau_t=\tau+\tau_e$ is the total relaxation time, wherein τ is the single relaxation time and τ_e is the eddy relaxation time with respect to the eddy viscosity which can be calculated (Hou et al., 1996)

$$\tau_e=\frac{-\tau+\sqrt{\tau^2+18C_s^2/(e^2h)\sqrt{\prod ij\prod ij}}}{2} \tag{11}$$

Where

$$\prod ij=\sum_a e_{ai}e_{aj}(f_a-f_a^{eq}) \tag{12}$$

e_{ai} is the particle velocity vector in the i spatial coordinate. For the two-dimensional 9-speed square lattice the velocity vector of particles is defined by

$$e_a=\begin{cases}(0,0), & a=0\\ e\left[\cos\dfrac{(a-1)\pi}{4},\sin\dfrac{(a-1)\pi}{4}\right], & a=1,3,5,7\\ \sqrt{2}e\left[\cos\dfrac{(a-1)\pi}{4},\sin\dfrac{(a-1)\pi}{4}\right], & a=2,4,6,8\end{cases} \tag{13}$$

One can obtain N_a = 6, if substitute Eq. (13) into Eq. (10). The local equilibrium distribution function is expressed as

$$f_a^{eq}=\begin{cases}h-\dfrac{5gh^2}{6e^2}-\dfrac{2h}{3e^2}u_iu_i, & a=0\\ \dfrac{gh^2}{6e^2}+\dfrac{h}{3e^2}e_{ai}u_i+\dfrac{h}{2e^4}e_{ai}e_{aj}u_iu_j-\dfrac{h}{6e^2}u_iu_i, & a=1,3,5,7\\ \dfrac{gh^2}{24e^2}+\dfrac{h}{12e^2}e_{ai}u_i+\dfrac{h}{8e^4}e_{ai}e_{aj}u_iu_j-\dfrac{h}{24e^2}u_iu_i, & a=2,4,6,8\end{cases} \tag{14}$$

From the distribution function, the water depth h and flow velocity u_i can be calculated through:

$$h = \sum_a f_a , \qquad u_i = \frac{1}{h} \sum_a e_{ai} f_a \tag{15}$$

2.3 Boundary Conditions

The discrete particle distribution must satisfy imposed constraints for water depth and momentum along the boundaries of the lattice. Several schemes that can be used for solid boundaries, such as bounce-back scheme of no-slip boundary conditions and elastic-collision scheme of slip boundary conditions; periodic and zero-gradient conditions for inflow and outflow boundaries, etc.

3 Numerical Tests

3.1 Partial Dam Break Flow

A benchmark test of partial dam break, initially used by Fennema and Chaudhry (1990), is investigated using the multi-block LABSWE. A dam is located in the central line of a 200m × 200m square reservoir with still upstream and downstream water depths being 10m and 5m, respectively. The dam fails at time t = 0s with a 75m break, as depicted in Fig. 1. The generated bore wave propagates downstream and in the mean time, a depression wave moves upstream. A uniform coarse grid of 100 × 100 is applied to the computational domain, and a fine block of Δx_f = $0.5\Delta x_c$
(I.e. m = 2) covers the adjacent area of the dam (x = 25 ~175m shown in Fig.1). The time step is 0.01s and the single relaxation time τ is 0.52. The Smagorinsky constant C_s is 0.3.

The contours of the water depth based on simulation results of the partial dam break flow at t = 2s, t = 4s and t = 7.2s have been plotted at the left column in Fig. 2. They agree well with previous results from the adaptive Q-tree Godunov scheme by Rogers et al. (2001). Additionally, the corresponding plots obtained from the simulation with only coarse grid have been presented at the right column in Fig. 2. As shown in the figure, the coarse gird models provide rough and inaccurate results.
Compared with the simulation results of the multi-block model and the previous researches (Rogers et al., 2001; Anastasiou and Chan, 1997), the dam break wave obtained by coarse grid model influences farther distances, indicating that the model may suffer from numerical dispersion when only coarse grid is used.

3.2 Circular Dam Break Flow

Another popular test examines the wave propagation of a circular dam break (Mingham and Causon, 1998). A uniform 200 × 200 grid is used to cover a 2000m × 2000m square frictionless domain, where the bed slope is zero. The time step is 0.1s and the single relaxation time τ is 0.506. The Smagorinsky constant C_s is 0. The initial condition in Eq. (16) is discontinuous and flow velocity is zero, when the circular dam is suddenly removed.

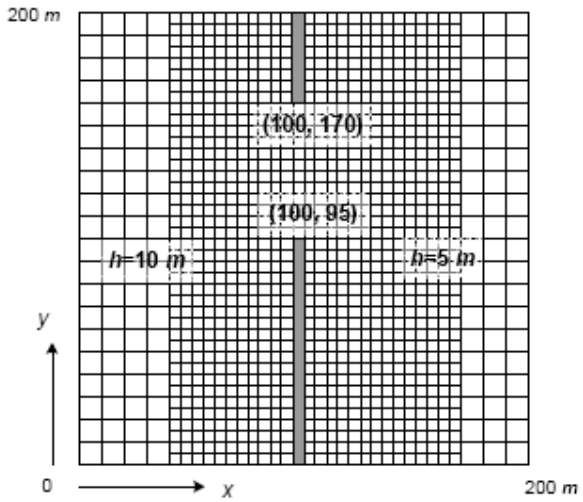

Fig. 1. Indicative Grid Layout and Channel Size for Two-dimensional Dam Break

The water depth evolutionary process along a radial up to 50 seconds has been presented in Fig. 3. Figure 4 shows the three-dimensional plots of the water depth at t = 20s and t = 50s. A uniform finer grid with lattice ratio m = 2 is also used to test the grid convergence, based on which the fractional error is only 0.82%. It illustrates that the model with the prior grid has produced the solution of acceptable accuracy. These results can be compared with those from other high resolution schemes (Murillo et al., 2006), giving the excellent agreements.

$$h(r) = \begin{cases} 10, & r < 800m \\ 5, & r \geq 800m \end{cases} \tag{16}$$

4 Conclusions

In this study, a two-dimensional lattice Boltzmann model for dam break flows has been developed and validated, in which the large eddy simulation model is coupled with nonlinear shallow water equations (LABSWE^{TM}) for turbulence modeling.

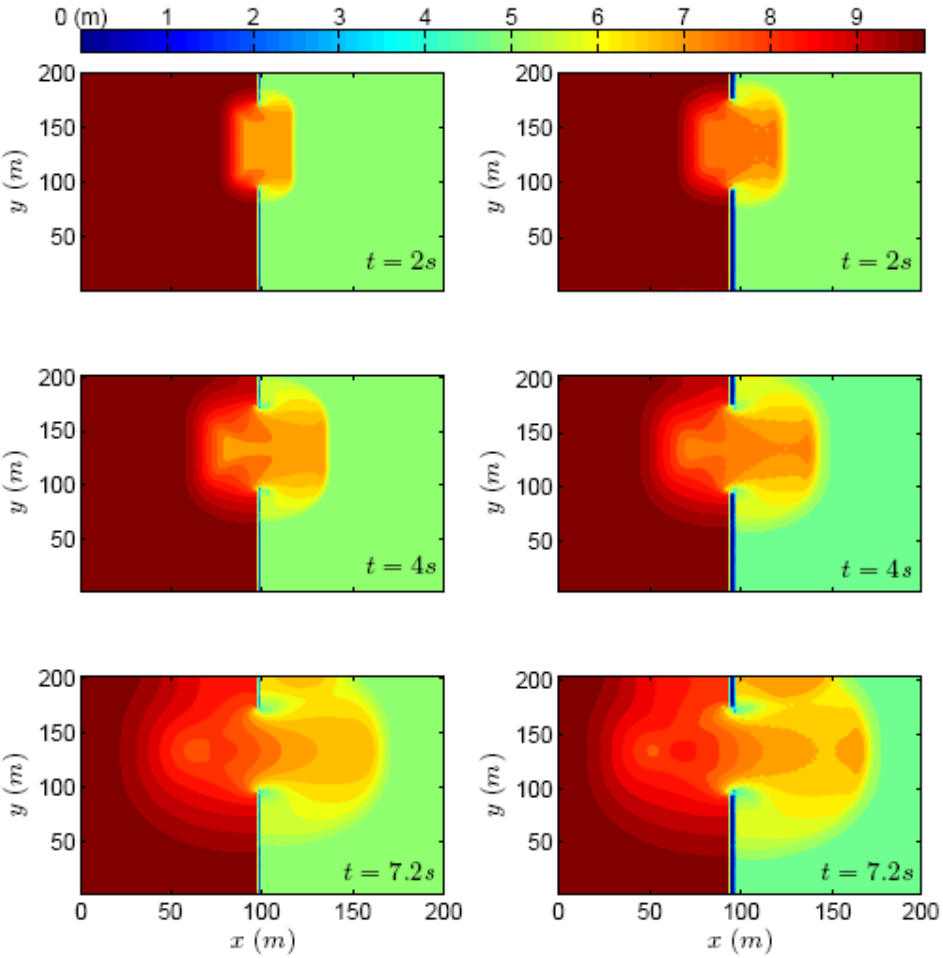

Fig.2.Contours of Water Depth at Different Time Using Multi-block (Left Column) and Coarse Grid (Right Column)

Numerical simulations have been verified by two tests and the detailed flow processes in unsteady state have been presented. Overall, it is found that the two-dimensional multi-block model is efficient and capable of producing depth-averaged hydrodynamic characteristics of dam break flows.

Comparison of Dam Breach Parameter Estimators

D. Michael Gee[1]

[1] Senior Hydraulic Engineer, Corps of Engineers Hydrologic Engineering Center, 609 2nd St., Davis, CA 95616; email: michael.gee@usace.army.mil.

ABSTRACT

Analytical techniques for the estimation of dam breach parameters were evaluated and compared. The development of potential flooding from a dam failure requires several elements; the hydrologic scenario, the possible dam failure modes, breach parameters that are associated with the failure modes, and the routing and mapping of the consequent discharge hydrograph. This paper presents recent research into the use and application of several dam breach parameter estimators to describe the physical characteristics of a dam breach, use of those parameters within the unsteady flow routing model HEC-RAS, and the computation and display of the resulting downstream impacts. The breach parameter estimators that were used include both empirical and embankment erosion process models.

INTRODUCTION

Many agencies are reviewing and updating dam safety and risk studies. The Corps of Engineers is performing a portfolio risk analysis of their projects. Included in that study is the updating of probable maximum flood inflow hydrographs and routing of potential dam break floods to ascertain downstream consequences. The estimation of possible breach dimensions and development times is necessary in any assessment of dam safety. The breach parameters will directly and substantially affect the estimate of the flows, inundated areas and warning times at downstream locations. The breach location, size, and formation time are often the most uncertain pieces of information in a dam failure analysis. Application of several commonly used analysis techniques to several projects is described in this paper.

The geometric description of a dam breach must be estimated to simulate the resultant flood wave and downstream consequences. Some readily available models that can be used for performing dam breach outflow hydrograph computation and downstream routing are HEC-RAS (HEC, 2006a), HEC-HMS (HEC, 2006b), NWS-DAMBRK (Fread, 1988b), NWS-FLDWAV (Fread, 2000), and a few others. These models require that the potential breach characteristics be estimated outside of the model. Several "process" models are also available, or being developed, that attempt to simulate the progression of a dam breach using sediment transport equations to estimate erosion rates and soil mechanics relations to predict mass slope failures. One process model that is discussed herein is the NWS-BREACH model (Fread, 1988a).

Breach dimensions and time of development must be estimated for various failure scenarios. This requirement includes different failure modes as well as different hydrologic events. The breach parameters associated with a hydrologic event of the scale of the probable maximum flood may differ from those for a sunny day failure triggered, perhaps, by a seismic event. Therefore, a set of breach parameters needs to be developed for each combination of antecedent pool elevation (hydrologic event) and failure scenario.

The breach characteristics can be estimated in several ways; including: comparative analysis (comparing the study project to historical failures of dams of similar size, materials, and water volume); regression equations (equations developed from historical dam failures in order to predict peak outflow or breach size and development time); and physically based computer models (computer programs that attempt to model the physical breaching process by using sediment transport/erosion equations, soil mechanics, and principles of hydraulics). All of these methods are viable techniques for estimating breach characteristics.

Reasonable values for the breach size and development time are needed to make a reliable estimate of the outflow hydrographs and resulting downstream inundation, flood travel times, water velocities, etc. These parameters describing the breach have large uncertainty. The HEC-RAS and HEC-HMS software require the following information to describe a dam breach:

Failure Location

The breach failure location depends on many factors, such as; type and shape of dam, failure mode, and structural elements of the dam. All factors concerning the dam, particularly any historical records of seepage and foundation problems, should be considered in order to place the breach in the most probable location for each failure mode. If a most probable location cannot be identified, then the centerline of the breach should be set to the centerline of the downstream main channel

Failure Mode

The hydraulic algorithms in HEC-RAS and HEC-HMS are designed to simulate the hydraulics of overtopping and piping failures. The failure mode is the mechanism for starting and growing the breach. Overtopping failures start at the top of the dam and grow to maximum extents, while a piping failure can start at any elevation/location and grow to the maximum extents. The ultimate breach size and breach development time are much more critical in the estimation of the outflow hydrograph than the actual failure mode.

Breach Development Time

Both HEC-RAS and HEC-HMS require as input data a breach development time. That time is described as follows:

Overtopping Failure: The time, from when the breach has eroded back to the upstream side of the top of the dam, to when the breach is fully formed (ie., significant erosion has stopped, not the time until the reservoir pool is emptied).

Piping Failure: The time from when a significant amount of flow and material are moving through the piping failure to when the breach is fully formed

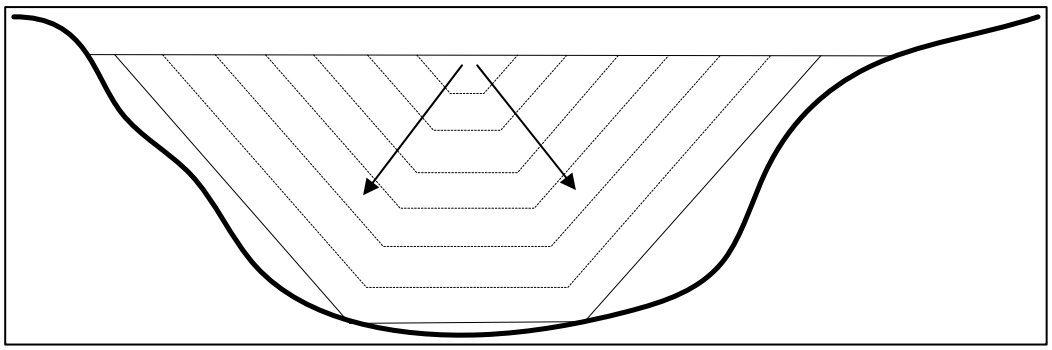

Figure 1. Generalized Trapezoidal Breach Progression

(significant erosion has stopped, not the time until the reservoir pool is emptied).This paper focuses on the description and hydraulics of overtopping breaches. The ultimate size of the breach must be described. This is the size expected when breach has stopped growing. The breach may stop growing because the entire dam has eroded or because the reservoir has drained and there is no more water available to erode the dam. The ultimate bottom elevation is the point at which erosion stops; usually either bedrock or the bottom of the reservoir pool. The breach size is described by a bottom width and side slopes. The conceptual development of a generalized trapezoidal overtopping breach is shown on Fig. 1.

It is necessary to define the circumstances of breach initiation (trigger mechanism) and how long it takes for the breach to progress to the ultimate size. The development time is the elapsed time from significant flow through the breach to the time at which ultimate size is reached. For overtopping failures the breach parameters should describe the initiation and progress of the hydraulic control (weir) that governs the release of water from storage.

Several options are available for identifying the breach initiation time. One option is to specify the duration that the pool elevation exceeds some threshold. This information may be the result of a geotechnical investigation. A second option is to specify a pool elevation; the breach begins to form as soon as that elevation is reached. The final option is a specific time during the simulation regardless of the pool elevation. This is useful for "sunny day" type failures that are not associated with a hydrologic event.

The breach shape develops in time from initiation to its ultimate configuration. The simplest development rate is linear; that is, the breach dimensions grow at a uniform rate. Options are available to simulate a breach that initially grows very quickly then slows down towards the end of the development time. Information for defining these growth rate parameters could be obtained from geotechnical information or from use of a process model such as NWS-BREACH (Fread, 1988a).

REVIEW OF GUIDANCE FOR BREACH PARAMETERS

Federal Agency Guidelines

Many federal agencies have published guidelines in the form of possible ranges of values for breach width, side slopes, and development time. Shown in Table 1 is a summary of guidance to date (USACE, 1980: USACE, 2007).

Table 1. Ranges of Possible Values for Breach Characteristics

Dam Type	Average Breach Width B_{ave}	Horizontal Component of Breach Side Slope (H) H:1V	Failure Time t_f (hrs)	Agency
Earthen/ Rockfill	(0.5 to 3.0) x HD (0.5 to 5.0) x HD (1.0 to 5.0) x HD (2.0 to 5.0) x HD	0 to 1.0 0 to 1.0 0 to 1.0 0 to 1.0 (slightly larger)	0.5 to 4.0 0.1 to 4.0* 0.1 to 1.0 0.1 to 1.0	USACE (1980) USACE (2007) FERC (1988) NWS (Fread, 2006)
Concrete Gravity	Multiple Monoliths Usually ≤ 0.5 L Usually ≤ 0.5 L	Vertical Vertical Vertical	0.1 to 0.5 0.1 to 0.3 0.1 to 0.2	USACE (2007) FERC NWS
Concrete Arch	Entire Dam (0.8 x L) to L Entire Dam (0.8 x L) to L	Valley wall slope 0 to valley walls 0 to valley walls 0 to valley walls	≤ 0.1 ≤0.1 ≤ 0.1 ≤ 0.1	USACE (1980) USACE (2007) FERC NWS
Slag/ Refuse	(0.8 x L) to L (0.8 x L) to L	1.0 to 2.0	0.1 to 0.3 ≤ 0.1	FERC NWS

Where: HD = Height of the dam.
L = Length of the dam crest.

* Note: Dams that have very large volumes of water, and have long dam crest lengths, will continue to erode for long durations (i.e. as long as a significant amount of water is flowing through the breach), and may therefore have wider breach widths and longer times than what is shown.

Determining the size and growth rate for breaches is not a precise exercise. Therefore, simulation models such as HEC-RAS allow for the user to quickly evaluate the impacts of a range of parameters on the results. The Bureau of Reclamation (Wahl, 1988) offers an excellent literature review of this subject.

Regression Equations

The following regression equations have been used for several dam safety studies found in the literature and are being considered for inclusion in guidance for the Corps of Engineers Portfolio Risk Assessment study:

- Froehlich (1987,1995a,1995b)
- MacDonald and Langridge-Monopolis (MacDonald, 1984)
- Von Thun and Gillette (1990)

Froehlich utilized 63 earthen, zoned earthen, earthen with a core wall (i.e. clay), and rockfill data sets to develop a set of equations to estimate average breach width, side slopes, and failure time. In the application of these equations reported herein, the height of the breach is calculated by assuming that the breach goes from the top of the dam to the natural ground elevation at the centerline of the breach location.

MacDonald and Langridge-Monopolis (MacDonald, 1984):

MacDonald and Langridge-Monopolis utilized 42 data sets (predominantly earthfill, earthfill with a clay core, and rockfill) to develop a relationship for the "Breach Formation Factor." The Breach Formation Factor is a product of the volume of water released from the dam (V_{out}) and the height of water above the dam. They then related the breach formation factor to the volume of material eroded from the dam's embankment. The V_{out} parameter is not exactly known before performing the

breach analysis as it is the volume of water that passes through the breach (not including flow from gates, spillways, and overtopping of the dam away from the breach area). A good first estimate, however, is the volume of water in the reservoir at the time that the breach initiates. Once a set of parameters are estimated and a breach analysis is performed, a better estimate of the actual volume of water that passes through the breach can be made. Then the parameters can be recalculated using that volume. The recalculation of the volume makes the method iterative in these situations. The resulting ultimate breach dimensions are a function of the volume eroded and the embankment geometry. The MacDonald and Langridge-Monopolis paper states that the breach should be trapezoidal with side slopes of 0.5H:1V. The breach size is computed by assuming that the breach erodes vertically to the bottom of the dam and then erodes horizontally until the maximum amount of material has been eroded or the abutments of the dam have been reached. The base width of the breach can be computed from the dam geometry with the an equation given in (Washington, 1992). Note that the MacDonald and Langridge-Monopolis paper states that the equation for the breach formation time is an envelope of the data from earthfill dams. An envelope equation implies that the equation will tend to give high estimates of the actual breach time (for homogenous earthfill dams).

Von Thun and Gillette (Von Thun, 1990):

Von Thun and Gillette used 57 dams from both the Froehlich (1987) and MacDonald and Langridge-Monopolis (1984) papers to develop their methodology. The method suggests the use of breach side slopes of 1.0H:1.0V; except for dams with cohesive soils, where side slopes should be on the order of 0.5H:1V to 0.33H:1V. Von Thun and Gillette developed two different sets of equations for the breach development time depending upon the embankment material.

NWS-BREACH (Fread, 1988a):

The NWS-BREACH model is a "process" model in that it uses sediment mechanics and transport relationships to simulate the breach development. The model uses sediment transport equations to compute the rate of erosion and size of a breach given information regarding the soil characteristics of the dam material, the inflow hydrograph, etc. Enlargement of the breach over time is computed by sediment transport equations, sudden collapse due to excess hydrostatic pressure and width expansion by slope stability. Sediment transport equations are available for either cohesive or noncohesive materials.

Other process models such as SIMBA (Hanson, et al., 2005; Temple, et al., 2005) and HR-BREACH (Mohamed, 2002) are currently under development. At this time these models are undergoing testing with various field data and are not yet available for general use.

DAM BREACH FLOW SIMULATION USING HEC-RAS

The implementation of these breach parameters in the HEC-RAS modeling system is depicted on Fig. 2.

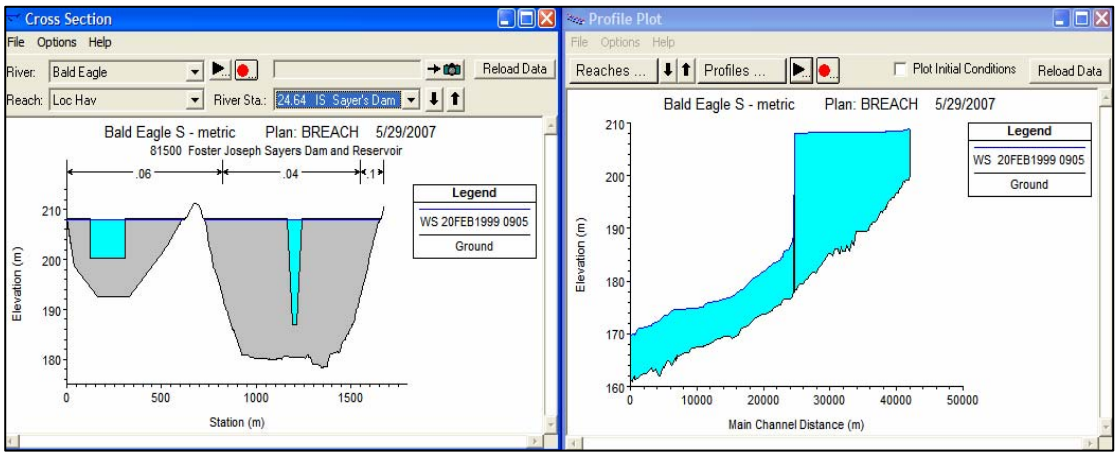

Figure 2. HEC-RAS Dam Breach Model

The graphical depiction of the breach size, location and progression associated with the computed upstream and downstream water surface profiles provides useful information for the analyst as well as the clients of the study. HEC-RAS uses dam breach parameters developed externally (using the techniques outlined above or any others deemed appropriate) to compute the temporal progression of a breach in an inline structure (dam). The flows through that structure are computed considering breach flow, overtopping flow, spillway discharges, gated flow, and submergence effects due to downstream backwater. Those several flow components are used as an internal boundary condition for unsteady flow modeling of the pool and the downstream reach. The pool may be analyzed using either simple level pool routing or as an unsteady flow reach using cross sections. Differences in breach outflow hydrographs due to different breach parameters will decrease as the floodwave is routed through the downstream reach.

SOME COMPARISONS

At this time, the breach parameter estimation methods described above have been applied to five situations. Two are hypothetical failures at actual projects. One of these has measured cross sections in the pool and the downstream reach so that the effects of in-pool and downstream routing can be examined. Three actual historic failures are also reproduced; one of which was a planned experiment. All of the cases discussed here are overtopping failures. In all cases the breach development was assumed to be linear in time. The hypothetical cases were assumed to start breaching when the overtopping was about 0.3 m; the reported beginning time of failure was used for the historic cases. Only the applications to the two historic failures are presented here due to space limitations; complete results can be found in (Gee and Brunner, 2007).

APPLICATIONS TO SOME HISTORIC OVERTOPPING FAILURES

Oros Dam

Oros dam (Brazil) was under construction when it failed by overtopping in

March of 1960 (CEATI). The dam height was about 35.5m. It was composed of a clay core with sand and rock shoulders. The empirical methods of MacDonald, Froehlich and VonThun were applied to this structure along with the BREACH process model. The volume of water released was estimated to be $660*10^6$ m^3 (1). Table 2 summarizes the resulting breach parameters computed by these methods.

Table 2. Breach Parameters for Oros Dam

Oros	Parameter			
Method	W_b (m)	Side Slopes (h:v)	t_f (hrs)	Vol eroded (m^3)
MacDonald	900	0.5	3.7	$2.38*10^6$
Froehlich	305	1.4	4.8	
VonThun	132	0.33	1	
BREACH	284	0.6	7.3	
Reported	200	0	6.5 to 12	$0.87*10^6$

The breach outflow hydrographs computed using these parameters are shown on Fig. 3 with the estimated outflow hydrograph. The outflow hydrograph was deduced from the record of water level during the event (CEATI).

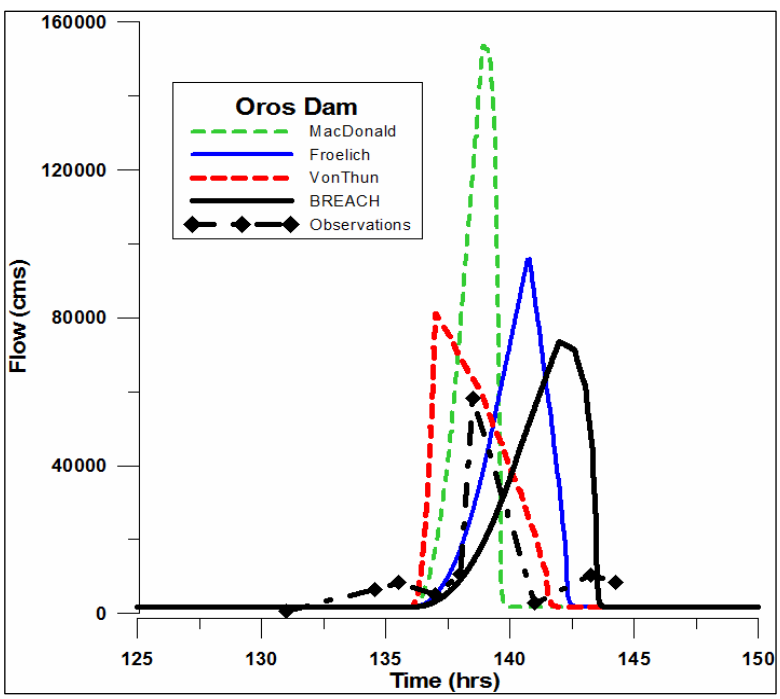

Figure 3. Breach Hydrographs for Oros Dam

Banqiao Dam (China)

Banqiao Dam failed by overtopping from a large storm in 1975 (CEATI). The dam was constructed of a clay core containing shale. The upstream and downstream fill was homogeneous earth. It can be assumed that, due to construction methods (primarily non-mechanized), that the core was poorly compacted. The dam

was about 24.5 meters high with a crest elevation at 116.34m. Crest width was 6m and length 2020m. The upstream slope was 3H:1V and downstream 2.5H:1V. The design capacity for the spillway and outlet works was 1742 m^3/sec; the estimated peak inflow was about 13,000 m^3/sec when breaching occurred. The estimated breach parameters are shown in Table 3.

The breach outflow hydrographs computed using these parameters are shown on Fig. 4. Field observations for this event consist of the pool elevation time history. These observations can be compared with the pool drawdown computed using HEC-RAS with the estimated breach parameters as shown on Fig. 5.

Table 3. Breach Parameters for Banqiao Dam

Banqiao	Parameter			
Method	W_b (m)	Side Slopes (h:v)	t_f (hrs)	Vol eroded (m^3)
MacDonald	1037	0.5	3.4	$1.85*10^6$
Froehlich	281	1.4	7	
VonThun	108	0.33	0.7	
BREACH	641	0.6	3.6	
Reported	210	0	1.5	$0.6*10^6$

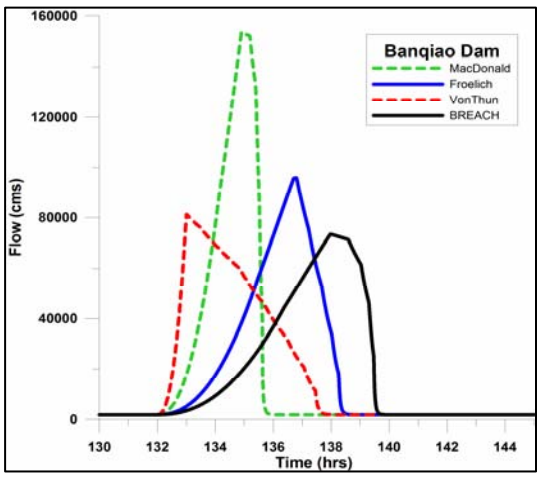

Figure 4. Breach Hydrographs for Banqiao Dam

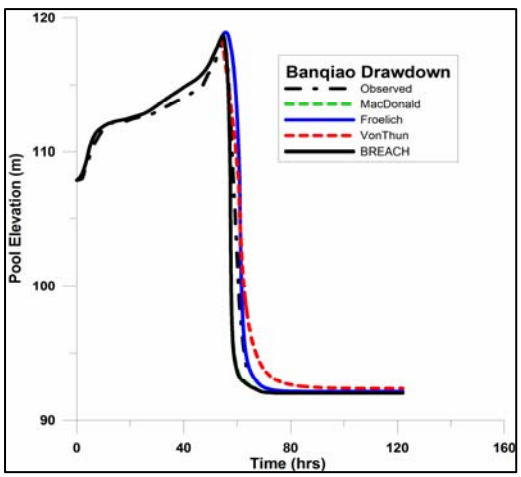

Figure 5. Pool Drawdown for Banqiao Dam

CONCLUSIONS AND OBSERVATIONS

Several techniques are available for estimating the breach parameters resulting from dam overtopping and subsequent failure. These techniques are predominately empirical, based on fitting relationships between key parameters such as water depth behind the dam and historic observations. One process model, NWS-BREACH, was also applied for comparison.

Estimation of dam breach parameters is a necessary first step in performing the analysis of the downstream consequences of possible dam failures. These parameters are used to compute breach outflow hydrographs using estimated inflow hydrographs, reservoir elevation-capacity data, and spillway and gate hydraulic capacities. Techniques are being developed to interpret and utilize the breach parameters estimated by application of these methods in an unsteady flow model; HEC-RAS. The methods predict a wide range of breach parameters and therefore, a large difference in outflow hydrographs. The MacDonald method routinely produced the largest peak outflows. The only comparison to an estimated historic outflow hydrograph (Oros) showed that all of the methods produced flows larger than those observed. For the case in which the pool drawdown data were available, all of the methods, when used in the HEC-RAS simulation model, produced comparable results.

The methods tested suggest use of flatter breach side slopes than are typically observed. The bases for development of the empirical techniques must be kept in mind. The breach configuration used in developing the regression equations was typically the ultimate shape that was observed at the after the event. What is needed for computing outflow hydrographs is the progression of the hydraulic control; be it a weir flow in the case of overtopping or an orifice flow in the case of piping. The hydraulic computations done in HEC-RAS assume that the hydraulic control progresses based on a failure time estimated from the method applied. Downstream submergence of the control is possible and is included in the outflow computation.

Process models are currently being developed and tested (Wahl, et al., 2008). The expected advantage of this type of model will be the ability to relate breach parameters to the materials and construction of the structure of interest. Tracking of the progression of the hydraulic control during breaching should be improved as well.

ABSTRACT

Highly transient floods resulting from the failure of dams and levees can lead to loss of life and property damage. Two-dimensional (2D) numerical simulations that use modern shock-capturing schemes are particularly suited to simulate these mixed-regime floods for flood mapping, consequence analysis and emergency management planning. The Digital Elevation Models (DEM) are often used as a regular computational mesh. Unfortunately, linear terrain features, such as road and railroad embankments and dikes, which may influence flood patterns, are not adequately captured in DEMs. This study describes a two-sided cut-cell boundary method for representing linear terrain features on a regular Cartesian mesh. The proposed method is briefly described and some test simulations are presented.

INTRODUCTION

Dams and levees are one of the eighteen critical infrastructures/key- resource sectors that require protective actions to prepare for, or to mitigate against, a terrorist attack or other hazards. Their failure leads to highly transient flows that can cause loss-of-life, property damage and cascading failures in other critical sectors.

US National Inventory of Dams (NID, 2008) currently lists about 79,000 dams in the USA, including those in Guam and Puerto Rico. Only about 5% of these dams are owned by the federal government. The majority of the remaining dams are privately owned and they are under the responsibility of the states. Out of the 79,000 existing dams, 11,243 are classified as high hazard and 12,656 as significant hazard dams. All high hazard dams are required to have an Emergency Action Plan (EAP) identifying potential emergency conditions at a dam and specifying preplanned actions to be followed to minimize property damage and loss of life. The EAP also contains inundation maps and the procedures and information to assist the dam owner/operator in issuing early warning and notification messages to responsible downstream emergency management authorities. Unfortunately, 5,035 high hazard dams and 6,013 significant hazard dams do not yet have an EAP. Among these, 1,858 high-hazard dams and 2,533 significant hazard dams were built before 1940.

Two-dimensional (2D) numerical models based on modern conservative shock-capturing schemes can provide a cost effective way to prepare EAPs for all high-hazard and significant-hazard dams. The 2D numerical models can directly use Digital Elevation Maps (DEM), which are readily available from federal and state owned geospatial data clearinghouses. This greatly facilitates input data preparation. The 2D simulation captures the highly dynamic nature of these floods and provides reliable results even in flat areas without channelized flow. Moreover, simulation results can be readily imported into a GIS platform, as raster or shape files, to be used for map creation, risk and vulnerability analyses, and flood emergency management and decision support.

Using a DEM directly as computational mesh, however, presents certain drawbacks. For typical DEM resolutions of 30m to 100m used in dam-break studies, the DEMs do not adequately capture linear terrain features, such as road and railroad embankments, which may constitute obstacles and influence the flood propagation and inundation limits. Increasing the resolution or using a locally refined unstructured triangular mesh is not always desirable as it may lead to longer computational times due to CFL (Courant-Friedrichs-Lewy) condition.

The present paper discusses the implementation of a two-sided cut-cell boundary method (or immersed boundary method) in a 2D numerical model in order to represent linear terrain features on a regular Cartesian mesh without penalizing the time step. A few test cases are also presented.

DESCRIPTION OF THE NUMERICAL MODEL CCHE2D-FLOOD

Consider the two-dimensional shallow water flow depicted in Figure 1. Two-dimensional unsteady shallow water equations governing the flood flow can be written in the following vector form:

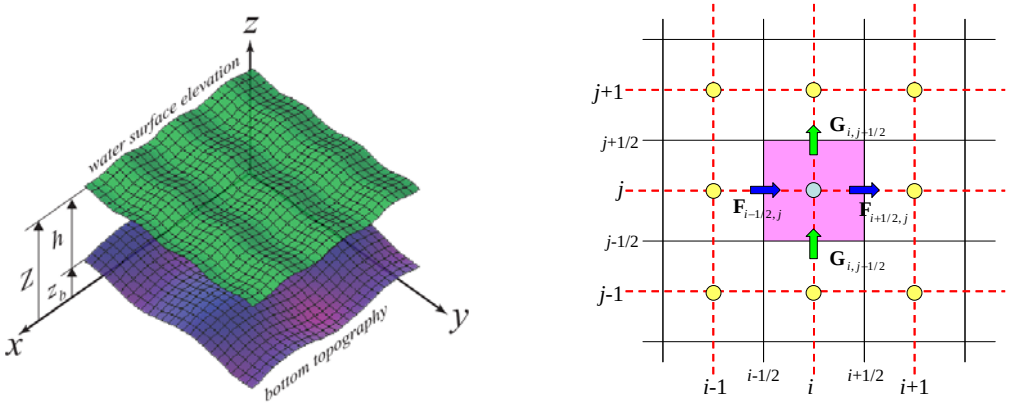

Figure 1. Left: Definition sketch for a two-dimensional shallow water flow; Right: Regular Cartesian computational grid.

$$\frac{\partial \mathbf{U}}{\partial t}+\frac{\partial \mathbf{F}(\mathbf{U})}{\partial x}+\frac{\partial \mathbf{G}(\mathbf{U})}{\partial y}=\mathbf{S}(\mathbf{U}) \tag{1}$$

where $\mathbf{U}$ is the vector of conserved variables; $\mathbf{F}(\mathbf{U})$ and $\mathbf{G}(\mathbf{U})$ are the flux vectors in horizontal x and y directions:

$$\mathbf{U}=\begin{bmatrix} h \\ hu \\ hv \end{bmatrix}=\begin{bmatrix} h \\ Q_x \\ Q_y \end{bmatrix} \quad ; \quad \mathbf{F}=\begin{bmatrix} Q_x \\ Q_x^2/h \\ Q_xQ_y/h \end{bmatrix} \quad ; \quad \mathbf{G}=\begin{bmatrix} Q_y \\ Q_yQ_x/h \\ Q_y^2/h \end{bmatrix} \tag{2}$$

In the above equations, h is the water depth, u and v are the components of horizontal velocity vector in x and y directions. The components of volume flux (discharge) in x and y directions are represented by Q_x and Q_y. The vector of source terms $\mathbf{S}(\mathbf{U})$ is given by:

$$\mathbf{S}=\begin{bmatrix} q_v \\ -gh(\partial Z/\partial x)-g\left(u\sqrt{u^2+v^2}/C^2\right) \\ -gh(\partial Z/\partial y)-g\left(v\sqrt{u^2+v^2}/C^2\right) \end{bmatrix} \tag{3}$$

where q_v is a volume source or sink located in the cell, Z is the water surface elevation with respect to the reference plane and C the Chezy friction coefficient.

Referring to the computational grid represented in Figure 1, cell-centered finite-volume discretization of Eq. 1 over a rectangular control volume leads to the following explicit scheme:

$$U_{ij}^{n+1}=U_{ij}^{n}-\frac{\Delta t}{\Delta x_i}\left(F_{i+1/2,j}-F_{i-1/2,j}\right)-\frac{\Delta t}{\Delta y_j}\left(G_{i,j+1/2}-G_{i,j-1/2}\right)+\Delta t\, S_{ij} \tag{4}$$

where Δx and Δy represent the cell dimensions in x and y directions, and Δt is the time step. The terms $F_{i+1/2,j}$, $F_{i-1/2,j}$, $G_{i,j+1/2}$ and $G_{i,j-1/2}$ represent the *intercell*

fluxes along the four cell edges. The two-dimensional (2D) numerical model CCHE2D-FLOOD, which was developed at the National Center for Computational Hydroscience and Engineering of the University of Mississippi, uses the first order upwinding method to compute the intercell fluxes:

$$\mathbf{F}_{i+1/2\,j} = \begin{bmatrix} Q_x \\ Q_x^2 / h \\ Q_x Q_y / h \end{bmatrix}_{i+k} \quad k = \begin{cases} 0 & Q_x \geq 0 \\ 1 & Q_x \leq 0 \end{cases}; \quad \mathbf{G}_{ij+1/2} = \begin{bmatrix} Q_y \\ Q_y Q_x / h \\ Q_y^2 / h \end{bmatrix}_{j+m} \quad m = \begin{cases} 0 & Q_y \geq 0 \\ 1 & Q_y \leq 0 \end{cases} \tag{5}$$

The above upwinding relationships for intercell fluxes are supplemented by additional relationships to take into account special conditions, such as wet and dry cell interactions, converging flows, very steep ground elevations, etc. The source terms are discretized in the following manner:

$$\mathbf{S} = \begin{bmatrix} q_v \\ -gh_{ij}^{n+1}\left[\left(\partial Z / \partial x\right)\right] - g\left(u_{ij}\sqrt{u_{ij}^{\,2} + v_{ij}^{\,2}} \Big/ \left(h_{ij}^{1/6}/n\right)^2\right) \\ -gh_{ij}^{n+1}\left[\left(\partial Z / \partial y\right)\right] - g\left(v_{ij}\sqrt{u_{ij}^{\,2} + v_{ij}^{\,2}} \Big/ \left(h_{ij}^{1/6}/n\right)^2\right) \end{bmatrix} \quad \text{with} \quad C = \frac{h_{ij}^{1/6}}{n} \tag{6}$$

where n represents the Manning's roughness coefficient.

The CCHE2D-FLOOD model handles dry-bed condition by maintaining a very small water depth, which is chosen sufficiently small not to cause any noticeable change in the propagation speed of the wet/dry front. When a wet cell and dry cell share a common edge, only the mass flux is allowed into the dry cell (momentum flux is set to zero) during that particular time step.

The numerical code resulting from this discretization is stable, robust and oscillation-free near discontinuities. It has been shown to rigorously conserve mass and momentum. No special entropy fixes are needed to ensure physically plausible solutions. CCHE2D-FLOOD has been verified and validated using analytical solutions as well as data from laboratory experiments, model tests, and past dam break events (see Ying et al., 2003a and b; Ying and Wang, 2004; and Ying et al., 2004).

Different types of boundary conditions are implemented in CCHE2D-FLOOD: 1) fully reflecting impervious solid boundary; 2) open boundary (which allows the flow to exit the computational domain freely); 3) stage-time boundary (which allows to specify the water surface elevation at the boundary as a function of time); 4) inlet boundary (which allows definition of a discharge hydrograph entering or leaving through the boundary).

CCHE2D-FLOOD uses an explicit scheme to solve the shallow water equations. It is, therefore, subjected to the Courant-Friedrichs-Lewy (CFL) condition for stability and convergence. Given a mesh size, $\Delta x \times \Delta y$, the CFL condition places an upper bound on the time step as follows:

$$N_{CFL} = \text{Max}\left[\frac{\Delta t}{\Delta x}(|u| + \sqrt{gh}), \frac{\Delta t}{\Delta y}(|v| + \sqrt{gh})\right] \le 1 \quad (7)$$

The time step can be either automatically selected by the program based on the consideration of the CFL condition or directly specified by the user.

CUT-CELL BOUNDARY METHOD AND LINEAR TERRAIN FEATURES

A two-sided cut-cell boundary (or immersed boundary) method was implemented in CCHE2D-FLOOD to represent linear terrain features on a regular rectangular Cartesian mesh. Referring to Figure 2, the linear terrain feature to be represented in the 2D model is projected onto the DEM from a GIS shape layer by imposing the following rules: 1) a cell can only be cut by a single straight line; 2) The line joining the centers of two adjacent cells can only be cut by a single straight cut-line, 3) When two adjacent cells are both cut by a line, the cut lines should meet at the same point on the common edge. The projected line cuts through computational cells and divides them into two irregular-shaped parts. Some of the irregular-shaped cells can be very small. The main challenge resides in developing a scheme that does not require smaller time steps to meet the CFL condition for stability. The oscillation-free shock-capturing property of the scheme must also be preserved.

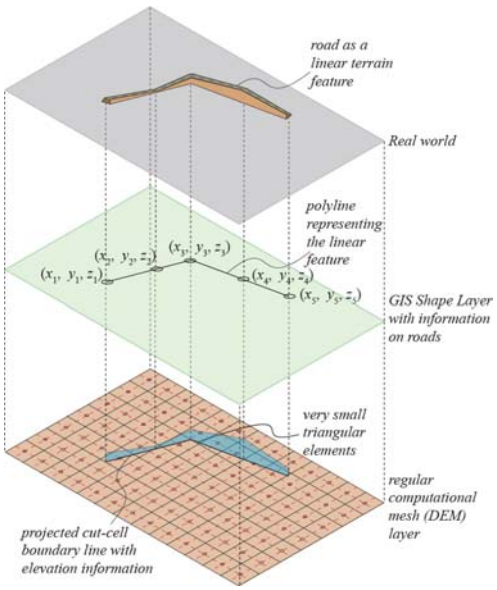

Figure 2. Projection of a linear terrain feature on the regular Cartesian Mesh.

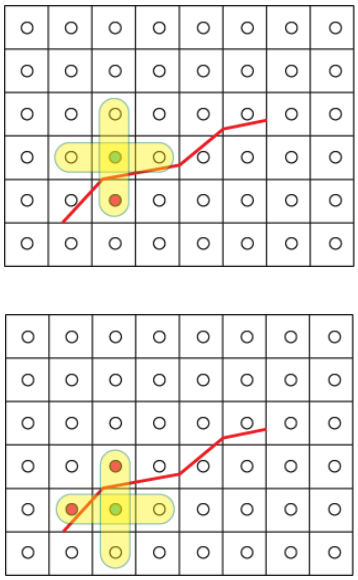

Figure 3. Computational stencils in the presence of a cut-cell boundary.

Several methods have been proposed to deal with cut-cells in two and three-dimensional meshes. Causon et al. (2000) combines cut-cells with adjoining regular cells to avoid small time steps. The h-box method (Helzel et al., 2005) use a rotated control volume for calculating the flux through the cut-cell boundary. The present study has adopted the Ghost Fluid Method (GFM) (Ghias et al., 2007), which is a special form of a class of techniques called Immersed Boundary Method (IBM) (Mittal and Iaccarino, 2005). The two-sided version of GFM implemented in CCHE2D-FLOOD is described in Miglio et al. (2008). Here only a brief presentation of the method will be given and some test cases will be presented.

Figure 3 shows the computational stencil in the presence of a cut-cell boundary. In the upper figure, the computed point (shaded green) is located in the upper side of the cut line representing the linear terrain feature. The cell below (shaded red) lies on the other side of the boundary; thus, the variables at the cell center are not available for applying the stencil. When calculating the cell below the cut line, the values of variables for cells above and on the left are not available for applying the stencil. The missing cells of the computational stencil are said to be *ghost cells* (GP) with respect to the cell being computed. The idea behind the GFM method is to use specially computed values for the variables in ghost cells in such a way that the following boundary conditions are enforced along the cut-line:

$$Q_n = q, \qquad \frac{dQ_t}{dn} = 0, \qquad \frac{dZ}{dn} = 0, \tag{8}$$

where Q_n and Q_t are the normal and the tangential components of the discharge, Z the water surface elevation, $\mathbf{n} = \lfloor n_x, n_y \rfloor$ the vector normal to the immersed boundary and q represents the overtopping discharge, if any, which can be calculated using an appropriate weir equation, for example.

The computational procedure to determine the values of the variables in ghost cells will be explained referring to Figure 4. In both left and right cases, the cell (i, j) is being computed. In the left hand side configuration, the cell $(i, j-1)$ is a ghost point (GP) with respect to the computed cell (i, j). To compute the flux across the lower edge, the values of the unknown must be defined at GP in such a way that the boundary conditions along the immersed boundary are correctly represented. To find the unknown values at GP, the point GP is first reflected onto the other side of the immersed boundary to find the *reflected point* RP. Note that the line segments $GP - B_{34}$ and $B_{34} - RP$ have the same length. The value at RP can be calculated by bilinear interpolation using the known values of the variables at the surrounding cells.

The values at GP are then linearly extrapolated from RP using the boundary conditions at B (Eq. 8). Once the values to be used at GP are determined, the computational stencil can be directly applied to compute the next step values for the cell (i, j). This was the simplest situation where all the four corner nodes of the

interpolation cell are on the same side of the cut-cell boundary as the computed cell. A different situation arises when all the corners of the interpolation cell are not on the same side as the computed cell. Such a case is depicted on the right hand side of Figure 4. The corner 1 of the interpolation cell is on the opposite side of the cut-cell boundary and, thus, its value is not defined. The fix in such cases is to replace the missing corner by the boundary condition; in this case condition at B_{34}. The rest of the procedure basically remains the same. Details of the method and derivation of the equations for different situations are presented in detail in Miglio et al. (2000).

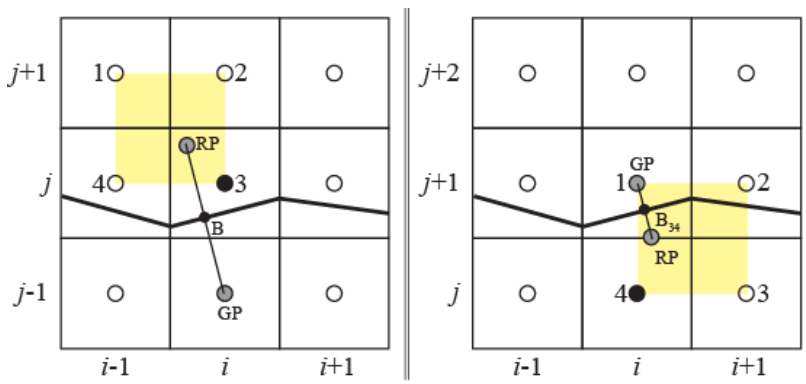

Figure 4. Procedure for determining the values of the variables in a ghost cell.

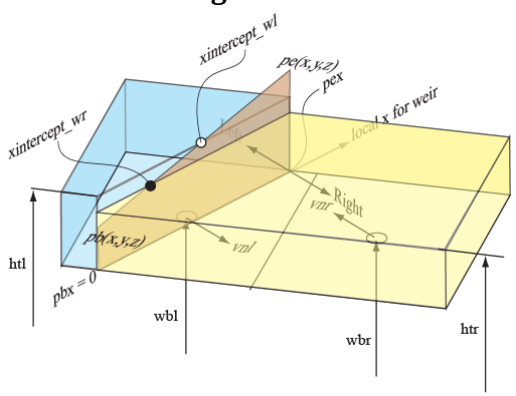

Figure 5. Definition sketch of a cut-cell boundary reach with overtopping.

Depending on the height of the cut-cell boundary and the water surface elevation on both sides, an overtopping discharge of q may be flowing from one side to the other. Figure 5 shows a cut-cell boundary reach with regions of unsubmerged flow, submerged flow and no flow. In order to be able to take into account all possible flow situations, the reach is divided into a number of equal-length sub-reaches. Using the ogee weir equation, the incremental overtopping discharge, Δq_j is separately calculated for each sub reach based on the elevation of the weir at the sub-reach center and the water depths on both sides. These incremental discharges are then summed up to determine the total discharge passing over the reach, q.

VALIDATION OF CUT-CELL BOUNDARY METHOD AND TEST CASES

Circular dam break in a closed square domain

The case of a 4m-diameter circular dam in a 15×15m close rectangular domain filled with 1m-deep still water is used to validate the cut-cell boundary method. Referring to Figure 6, the square domain for the reference case is defined along the grid lines by imposing a fully reflecting wall boundary condition. In the test case, the 15×15m square domain is defined inside a 25×25m domain by using cut-cell boundaries making an angle of 45° with the gridlines of the computational mesh. In both cases the computations are carried out with $\Delta x = \Delta y = 0.5m$ and $\Delta t = 0.1s$.

Computed water surface contours for both solutions are shown in Figure 7 for the first 5 seconds. The test-case solution is rotated 45° counter clockwise to facilitate comparison with the reference solution. The color-bar range is varied with time for better readability. However at each time, the test solution and the reference solution use the same color-bar range. As it can be seen, the water depth patterns obtained with cut-cell boundary method are almost identical to those of the reference solution.

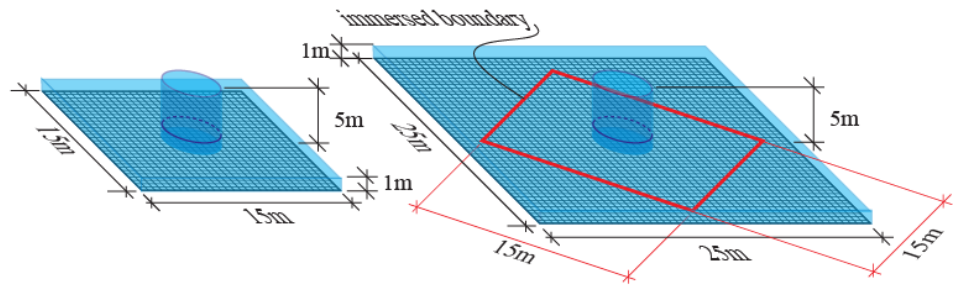

Figure 6. Set-up for circular dam break case with and without cut-cell boundary capability.

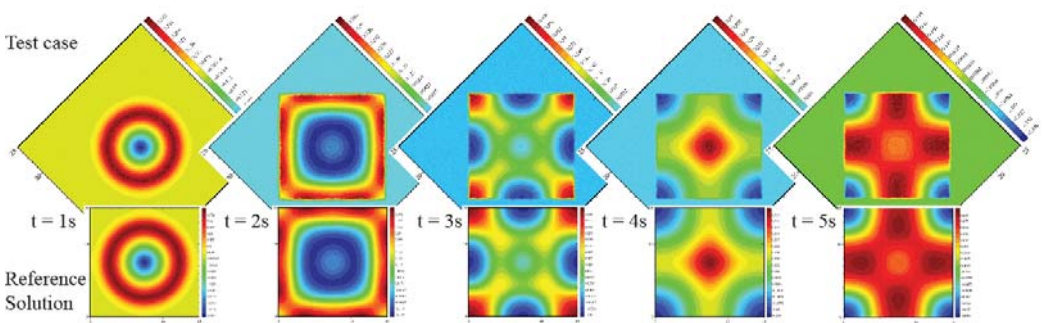

Figure 7. Circular dam break simulation with and without cut-cell boundary.

Dam-break flood over a variable height cut-cell boundary

Figure 8 shows the experimental set-up for this test case. The wedge shaped cut-cell boundary has a very low height near the apex. The height of the cut-cell

boundary increases towards both extremities. The dam located along the upper boundary of the computational domain breaks at the beginning of the simulation. Everywhere else there is still water with a depth of 0.5m.

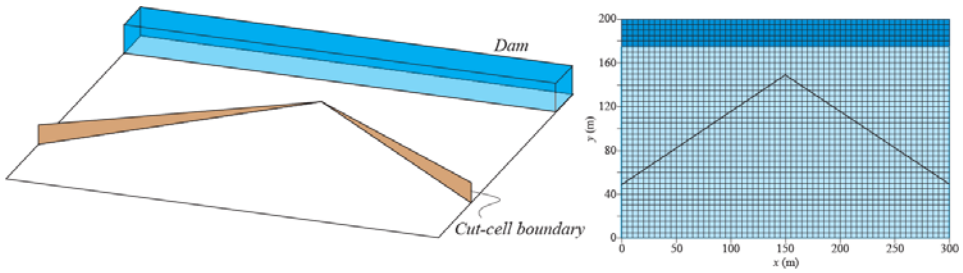

Figure 8. Set-up for dam-break flood over a variable-height cut-cell boundary.

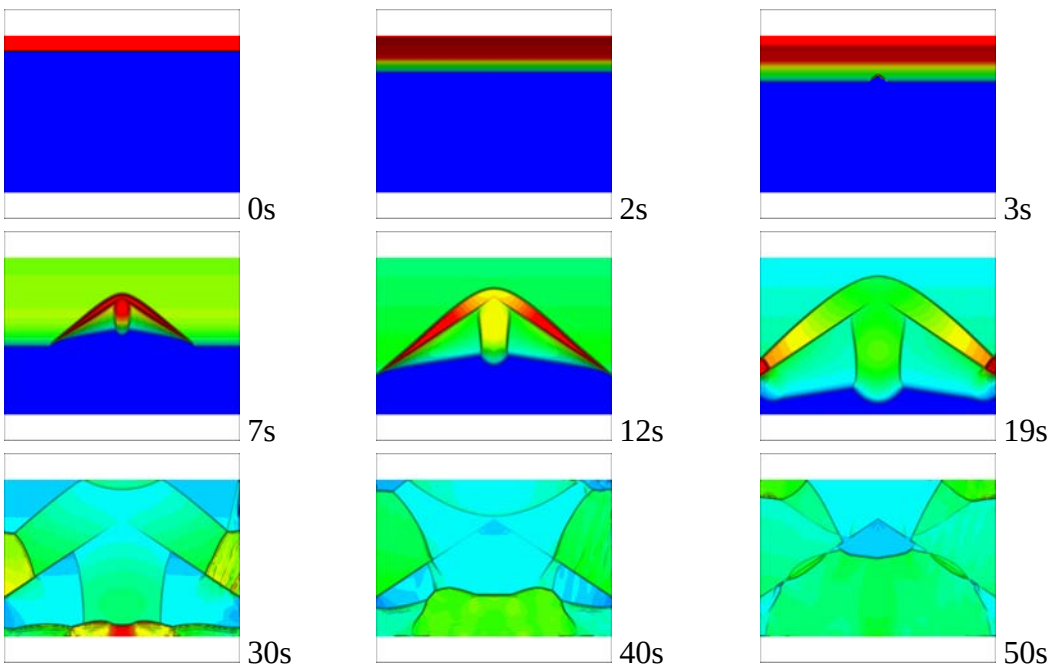

Figure 9. Water surface contours for dam-break flood over a variable-height cut-cell boundary. Numbers below the frames represent time in seconds.

Computed water-surface elevations are plotted in Figure 9 at different times after the dam break. When the dam-break flood reaches the cut-cell boundary, the flow partly overtops boundary (in the middle part); partly it is reflected, leading to the formation of a moving hydraulic jump. As more water arrives toward the cut-cell boundary, eventually the overtopping takes place over its entire length. The following images show the interaction of various wave fronts resulting from this complex configuration. Since four sides of the computational domain are declared as a fully reflecting wall boundary, mass conservation can be easily verified. Loss of mass at the end of several hundred seconds of simulation is found to be less than 1%.

CONCLUSIONS

The paper described the implementation of a two-sided cut-cell boundary method in the numerical model CCHE2D-FLOOD, which uses a first order upwinding finite-volume scheme to solve 2D shallow water equations on complex topography defined by a DEM. This two-sided cut-cell boundary method allows representing the linear terrain features on a Cartesian regular mesh, which cannot be adequately captured in a DEM. The implemented method allows overtopping of the cut-cell boundary. The results of two selected test cases demonstrate the effectiveness of the method.

ABSTRACT

For over two decades, the U.S. Army Corps of Engineers (USACE) has required that all of their planning processes address the Nation's water resources needs in a systems context. Corps policy also requires that all flood damage reduction studies adopt risk analysis. While the USACE has these requirements, there is little guidance and few tools to support them. For this reason, the USACE Institute for Water Resources (IWR) sponsored investigations into the development of a new tool to analyze complex riverine systems while implementing the current flood risk analysis and systems requirements. This new tool, currently called HEC-FRM or Flood Risk Management, is the next generation of the Hydrologic Engineering Center's Flood Damage Analysis (HEC-FDA) model. This paper will present the model development for this tool which will be used for levee certification and assessment, planning and design studies, and advance the Corps modeling approach for risk analysis.

Introduction

A primary mission of the U.S. Army Corps of Engineers is to provide flood protection for communities and rural areas throughout the United States. During flood episodes the Corps operates flood control projects and conducts emergency management activities. At the direction of Congress, the Corps studies and implements flood risk management measures and over the years the Corps Flood Risk Management programs have significantly reduced flood risks by implementing many structural and non-structural flood damage reduction measures such as dams, levees and floodplain management initiatives. The Corps Hydrologic Engineering Center continues to develop new procedures and programs to meet the changing needs of the country and utilize new science & technology. These new programs need to be aligned with current Federal policies. One such policy that has regained significant interest is performing systems studies with risk analysis.

For this reason, the U.S. Army Corps of Engineers (USACE) Institute for Water Resources (IWR) sponsored investigations into the development of a new tool to analyze complex riverine systems while implementing current flood risk analysis and systems requirements. This new tool, currently called HEC-FRM or Flood Risk Management, is the next generation of the Hydrologic Engineering Center's Flood Damage Analysis (HEC-FDA) model. It will include a systems approach, event-based sampling, the ability to do scenario analysis, and structure-by-structure, cost, non-structural, loss-of-life, and agricultural damage analysis. The tool will accommodate many, if not all, of the recommendations that the Corps agreed with from the National Research Council report on the Corps' implementation of risk analysis for flood damage reduction (NRC, 2000). It will also aide in implementing the Chief of Engineers' Actions for Change.

This paper will present the HEC-FRM model development including sampling and solution techniques, uncertainty definitions, and system-wide component fragility and performance interactions/relationships for these complex riverine systems. The paper will describe the capabilities as detailed in the recently written software design document, "Flood Damage & Risk Analysis of Complex Riverine Systems" which proposes significant advancements to the USACE modeling approach for risk analysis. The new tool would be used nationwide for levee certification, levee assessment and planning and design studies.

Need for Systems Approaches and Risk Analysis

The U.S. Army Corps of Engineers Engineer Regulation ER 1105-2-100, Planning Guidance Notebook has required that the Corps planning processes address the Nation's water resources needs in a systems context. However, Corps policy does not provide guidance on how to perform system-wide analyzes. Also, Corps policy, ER 1105-2-101, Risk Analysis for Flood Damage Reduction Studies requires "All flood damage reduction studies will adopt risk analysis…" While EM 1110-2-1619, Risk Analysis for Flood Damage Reduction Studies, provides procedures on how to conduct risk analysis for local projects, it provides little support for risk analysis in a systems context. Therefore, while the Corps has requirements for systems approaches using risk analysis, there is little guidance and few tools to support these requirements.

Problem with Current Approaches

In spite of the fact that few tools are available for using risk analysis with system studies, risk analyses have occurred. These studies are being performed using the tool HEC-FDA or Flood Damage Reduction Analysis. HEC-FDA is a plan evaluation and plan formulation tool that helps to answer the question, "Which proposed flood damage reduction plan is the best from an economic standpoint?" It provides the capabilities to evaluate the with and without project plans and compares the plans using expected damage and damage reduction benefits. It also develops project performance metrics for comparison of alternatives and levee certification and since 1996 has included the capabilities to perform risk analyses.

However, even with these advanced capabilities, HEC-FDA still looks at a system of projects as a number of independent projects. This issue and others raised by the National Research Council, current users of HEC-FDA and HEC have clearly shown that HEC-FDA needs to include explicit systems analysis capabilities. Other needs identified to improve HEC-FDA include: re-plumbing FDA's Monte Carlo sampling to address a combination of damage reaches; include providing risk and uncertainty capabilities about non-structural measures, adding agricultural damage and project costs; providing correlated sampling of dependent relationships (e.g. rating curve versus the reservoir inflow/outflow curve); adding additional failure modes and features; analyzing impacts of project failure for residual risk requirements (e.g. loss-of-life); and addressing additional H&H support of risk analysis (e.g. realistic physical limits on frequency analysis and update the equivalent record length procedures).

Another problem the Corps faces when trying to conduct comprehensive watershed studies is the requirement to identify a local sponsor. Since the1986 Water Resources Development Act became law, water resources development and research to support it has been accomplished project-by-project because of the need for a local sponsor. Therefore, we are in a catch 22. Current policy requires a systems context but current legislation still requires the identification and support of a local sponsor. Is the sponsor willing to participate in a comprehensive study or only their local project?

Corps' Actions for Change

Nowhere has the need for a systems approach been more apparent than in New Orleans. The city is protected from flooding by a series of levees. During Hurricane Katrina some of the levees failed demonstrating that no matter how strong some of the levees were, if all of the levees are not robust, catastrophic flooding can still occur.

Because of the unacceptable systems performance of the New Orleans hurricane protection system, the Corps developed the Corps' Actions for Change (AFC). The goal of these actions is to improve public safety and the Nation's water resources infrastructure. Several actions were identified such as shifting decision making from individual, isolated projects to that of an interdependent system and communicating risk in simple and clear terms. In addition, a complete Theme was created to focus on employing risk analysis concepts with the goal to address many of the needs identified in the section above.

One of the first products addressing the systems approach is Engineer Circular (EC) 1110-2-6067. This circular requires that the Corps use risk analysis and a systems approach when performing levee certifications. This process evaluates components as an interconnected system necessary to insure protection of the associated floodplain. These items can include the levee, floodwall, closure structures, pumping stations, culverts and interior drainage works.

White Paper for the Development of HEC-FRM

Another product addressing the AFC was the development of a White Paper titled "Risk-Based Flood Damage Analysis: Software Design Document, Model Design for Flood Damage and Risk Analysis of Complex Riverine Systems." Written by Dr. David W. Watkins, Ph.D. while on a temporary assignment at HEC as the Roy Beard Visiting Scholar, the paper proposed an initial design for the new tool that will perform risk analyses for complex river systems. The goal of the proposed new tool, HEC-FRM, is to perform systems approaches for assessing risks in complex, interdependent systems. It will incorporate social and environmental consequences and include capabilities to perform levee assessments and certifications. It will also assist in effectively communicating risk. To accomplish these tasks, HEC-FRM will have to incorporate new computational methodologies. He conducted a thorough literature review where he uncovered previous efforts including the Sacramento and San Joaquin River Basins Comprehensive Study, the recommendations of the Interagency Performance Evaluation Team, the software used for estimating coastal storm damage (Beach-fx), the Corps dam and levee safety programs and several European projects. Each provided valuable lessons and insights on how to conduct a systems approach including risk analysis.

The White Paper became the basis for HEC-FRM's Project Management Plan and defined the domain of the new tool as that dealing with riverine systems with floodplain consequence areas. The tool would include a linear system representation of the components including levees, floodwalls, closure gates and loading and resistance assumed uniform for a specific reach. Both structural and non-structural measures were to be addressed.

A suggested computational flow starts with each project alternative, a single scenario of the project life cycle (e.g. 50 years), being simulated by sampling the annual maximum flood events over the duration of the life cycle. Of course, if agricultural damage is to be considered, seasons within a year will have to be sampled as well. The system performance and flood characteristics will determine when and if breaches occur to the various projects. If breaches do occur, the impacts will be calculated based on flood inundation and related consequences. The consequences shall include economic, social, environmental and loss-of-life. Life cycle modeling will include rehabilitation, repair and flood recovery when necessary. So, if the damage is substantial the characteristics of the consequence area may be altered prior to the next flood event. This process would then be repeated for the next scenario.

Several key issues were identified. A primary issue is how to generate the flood events themselves, i.e., should HEC-FRM use frequency curves like HEC-FDA or use synthetic events. Other problems include how to automate thousands of hydrodynamic simulations, model multiple failure modes, evaluate consequences and; reduce the computational burden necessitated by the comprehensive systems approach. One way to reduce the computational burden is to examine the trade off between detailed modeling and important sources of uncertainty. If only a few sources of uncertainty

are examined, then the burden could be significantly reduced. Regardless of how these issues are addressed, it is clear that flexibility or varying levels of fidelity will be key to the success of the software.

Software Design Concepts

In a parallel effort, HEC is developing the Watershed Analysis Tool (HEC-WAT) to help the Corps and its study partners conduct watershed and water resources management studies with risk analysis. Funding for the development of HEC-WAT (WAT) is being provided through the System-wide Water Resources Program and the Flood and Coastal Storm Damage Reduction Research and Development program. The R&D program is also contributing toward the development of HEC-FRM.

WAT modeling teams benefit because they develop their models in a closely coordinated manner, track progress of other models, and automatically retrieve results from previous model runs thus assuring more efficient and coordinated results. The team benefits by using a common interface to track project status through each modeling component and displaying results during public and project status meetings.

The WAT streamlines and integrates the analytical process using software commonly applied by multi-disciplinary teams (HEC-HMS, HEC-RAS, HEC-ResSim, and HEC-FIA, etc.). The integration of the software is accomplished through the use of a concept called a "plug-in" as shown in Figure 1. The "plug-in" concept allows the WAT to know little about individual software, but provides an analysis framework for the software. A "plug-in" can provide the ability to access and edit software parameters, and view results available from the software through the WAT framework.

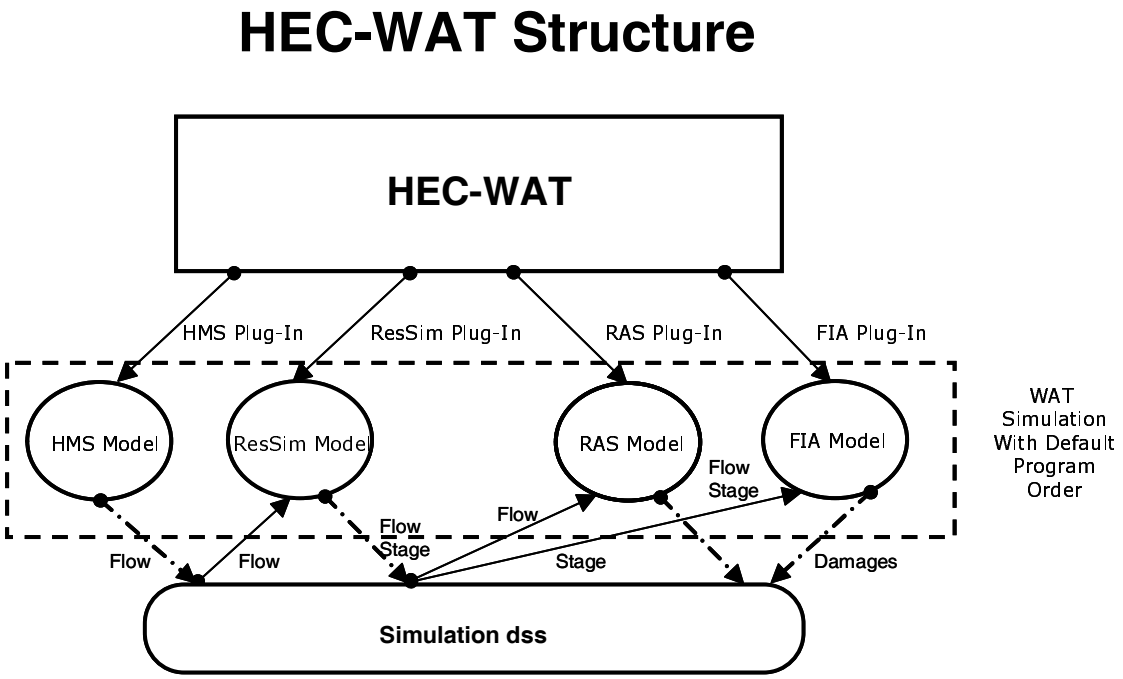

Figure 1. HEC-WAT Structure

HEC-FRM Framework

The HEC-FRM framework starts from the organization and structure of the WAT. FRM will operate within the WAT as a computational option if the user chooses to perform plan formulation or system performance analyses. The basic FRM organizational structure is shown in Figure 2. FRM will have the capability to sample from a pre-defined flow-frequency with associated inflow hydrographs as shown in Figure 2, or utilize the HEC-HMS (Hydrologic Modeling System) and HEC-ResSim (Reservoir Simulation) models in the WAT to generate inflows to the system (not depicted in Figure 2). A fragility sampler plug-in will set failure elevations to be used in HEC-RAS (River Analysis System) which would then route the inflow hydrographs down the system. Where failures occur breach hydrographs will be made available to a spreading model to delineate inundation areas and compute depths, velocities and duration in the consequence area of interest. Once the inundation and gridded hydraulics data is determined, that data is made available for HEC-FIA (Flood Impact Analysis) to compute consequences. The FRM process will apply the Monte Carlo simulation, a numerical-analysis procedure that computes the expected value of consequences ($ damage, loss-of-life, etc) while explicitly accounting for the uncertainty in the parameters used to determine those flood inundation consequences. FRM will be configured to allow for a life-cycle type computation of consequences and associated performance indices.

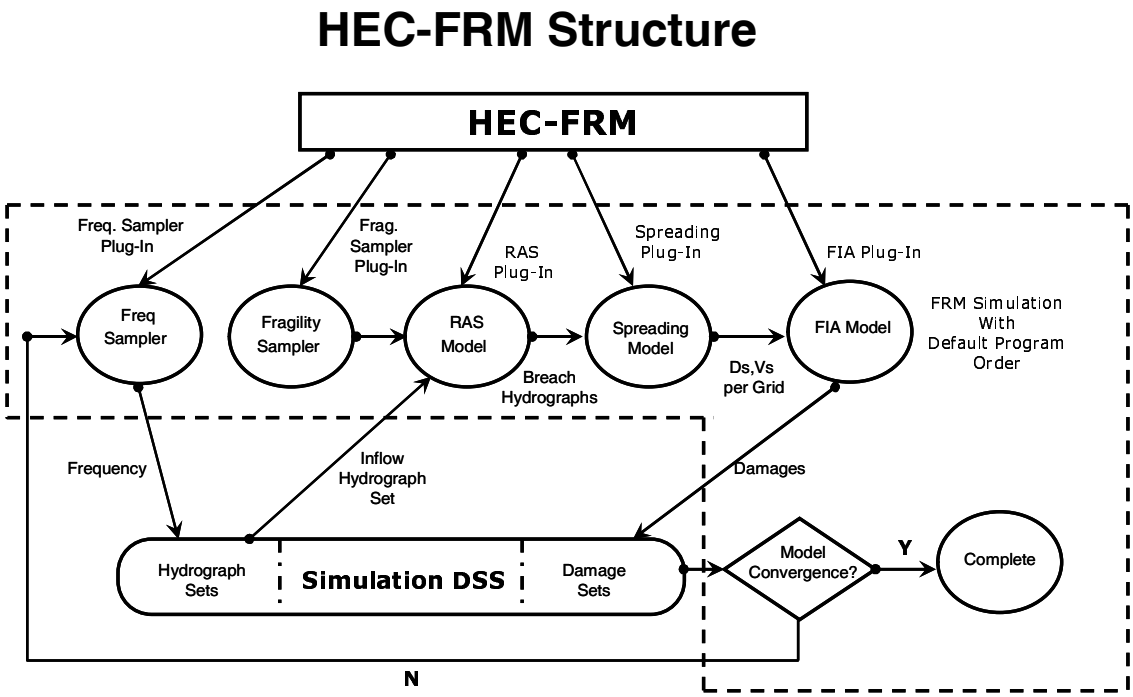

Figure 2. HEC-FRM Structure

Hydrologic Definition and Sampling

The hydrologic inputs to develop system loadings can be defined in FRM in two ways. Two distinct methods were discussed. First, FRM could use HMS and ResSim with sampling of key parameters for each simulation to capture uncertainties and to

generate loading hydrographs. This method would use all models in the WAT and allows for explicit evaluation of alternatives having upstream storage features as shown in Figure 3. The second method uses pre-defined flow-frequency functions with uncertainties and associated hydrographs defined for each frequency. This is the method depicted in Figure 2. From either of these methods, sets of 50 year sequences would be developed; each set representing one realization of a project life-cycle. The 50 year sequences would allow for inclusion of asset management activities, system degradation, etc.

System Load Distribution

System loadings would involve the application of HEC-RAS routing of the inflow hydrographs, $Q_{i,}$ to be tested against fragility functions at pre-defined locations in the system (see Figure 3). These pre-defined locations, or index locations, are representative of a levee reach (shown as segments around a consequence area in Figure 3) or of other system components such as gates, floodwalls, etc. As the system components fail, reduced flows are subsequently delivered to the downstream extents of the system, Q_o. Flows leaving the system via a failed system component produce a breach inflow hydrograph, depicted by $Q_{b.}$

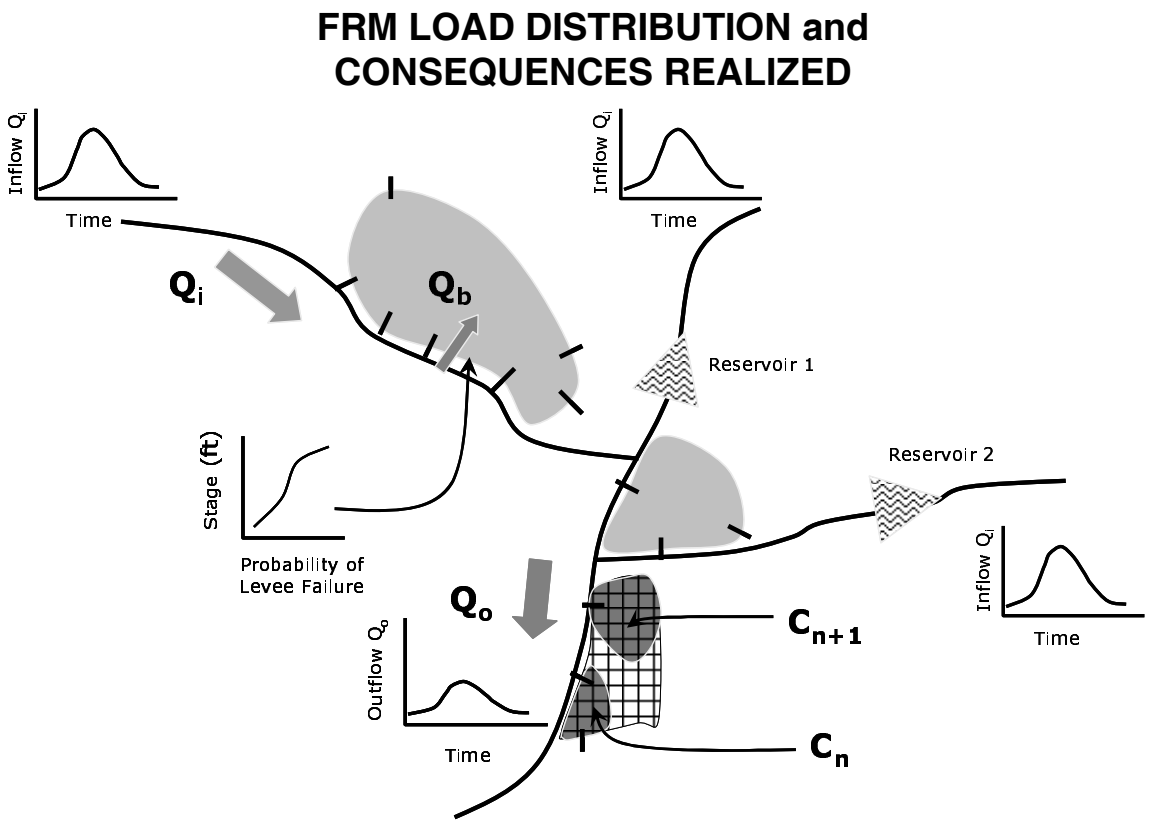

Figure 3. HEC-FRM Load Distribution and Consequence Realized

Sampling of Fragility Curves

As described above, the fragility curves will be sampled at each location for each routing/loading simulation. A random sampling between 0.0 and 1.0 will set the elevation of failure which in turn is set in HEC-RAS for testing against hydrologic loadings. The traditional way of interpreting a levee fragility curve (stage vs. probability of failure) is that when water reaches a given stage on the levee, there is a certain chance of the levee failing. For example, at a stage of 7 feet, the fragility curve shown below in Figure 4 shows a 29% change of failing, and a 71% chance of not failing. At 8 feet, the same curve shows an 88% chance of failing, and so a 12% chance of not failing. From a simulation standpoint, if water level reaches 7 feet, we actualize the chance of failure by drawing a uniform random number between 0 and 1 and choose failure if it is less than 0.29.

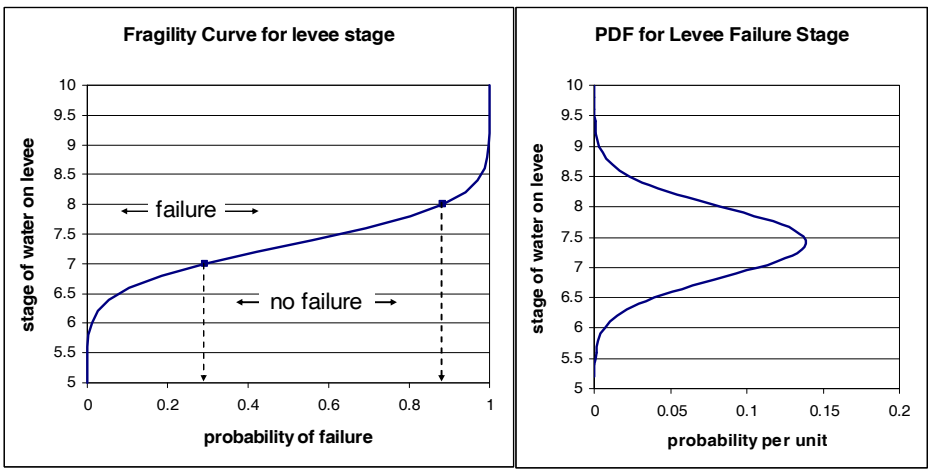

Figure 4. Fragility Curve

Another way to look at the fragility curve is to recognize that it is a non-decreasing function that spans probability from 0 to 1. The curve can be considered a cumulative distribution function (CDF) of the stage at which failure occurs. This also allows us to infer a PDF (probability density function) or bell curve of the failure distribution, in the figure above right. With this interpretation, with the CDF we'd say that there is a 29% chance that the failure stage is less than or equal to 7 feet, and there is an 88% chance that the failure stage is less than or equal to 8 feet. We're using the same information, but instead of a yes or no outcome at a given stage, we have linked failure stage to a "non-exceedance" probability. Using the second method of interpreting the fragility curve allows us to actualize the random element with a single random number (choosing levee failure stage for that realization) rather than needing to query a random number at every time step to say "at this stage, does it fail or not?" Once the levee failure stage is chosen, randomness is gone, and it remains only to route the hydrograph to determine if and when stage reaches the failure stage.

In a systems context with multiple failure modes/locations, sampling of those fragility curves, including uncertainty, is required for each realization of a FRM simulation. The fragility sampling plug-in would generate for each realization a set of random numbers between 0 and 1 for each index location and then determine failure stages from each fragility curve. These stages are then exported to RAS for use in that simulation. After a large number of simulations, this would result in the evaluation of the full range of failure possibilities over the entire system. This sampling and failure routine would define the system load distributions as well as inundation delineations in the consequence areas of interest.

Inflow Spreading

As failures occur in the consequence area, RAS computes the inflow/failure hydrograph shown as Q_b in Figure 3 and is then distributed with a "spreading" or inundation model. FRM will have options for the spreading model plug-in and could be accomplished with a simple or complexly linked ponding area option in RAS, ERDC's SMS or other 2D models depending on topography and inundation hydraulic characteristics. Whichever technique is used to generate inundation parameters, the information will be cast into a gridded format using the same grid definition as FIA. This gridded data will then be made available for computation of consequences in FIA.

Consequence Modelling

Consequences will be computed using FIA including economic damages and Loss-of-Life estimates. Depth, duration and velocity gridded data would be passed from the spreading model to FIA for those computations. FIA is also used to determine flood damage reduction benefits attributed to individual flood control projects (reservoirs, levees and diversions) and for real-time response activities as part of the Corps Water Management System. For a specified event or for each of 50 yr life cycle sequences, HEC-FIA can compute urban and agricultural flood damage, area inundated, number of structures inundated, and population at risk. Damage analysis of crops involves a complex series of factors and considerations. Among these are the type of crop, season of the year, cropping patterns, duration and magnitude of flooding, and much more. Monetary damage values are determined from investment losses, mature-crop price values, harvest costs, and may include secondary business losses. The new version the software, FIA will include a graphical user interface with GIS capabilities from either FIA itself or through the WAT structure.

Computational Challenges

The major issue that confronts this effort is the computational demand inherent in this type of methodology. Areas of focus will be on sequencing and "stacking" of multiple RAS simulations using multi-processors, hot-start techniques and various forms of "importance" or "intelligence" sampling for minimizing simulations. Of all of the technical aspects of this proposed modelling approach for computation of risk assessment parameters, reduction of the computational burden is the largest challenge.

Conclusion
