The expected trend *K* provides one piece of information to predict the long term effectiveness of the plan. In the 1996-1997 dataset, the expected trend *K* of pH is positive for both gauges (see Table 4). This indicates the pH value was expected to increase although the plan was only partially implemented. However, in the 2002-2003 and 2006-2007 datasets, the expected trend *K* is negative. This indicates the pH value was expected to decrease thus increasing the acidity over the next few years.

The deterioration of long term effectiveness is predicted provided that the current trends are sustained. Thus, it is recommended that the installed components of the restoration plan should be inspected and restored.

The expected *M* represents the expected initial mean value of the evaluated time-series for a specific year. As shown in Table 4, the expected *M* of pH value is significantly increased at Site C3 when comparing the 1996-1997 and 2002-2003 datasets. After 2003, all the expected *M* for the pH values at Ravine are between 6 and 7, which indicates a sustained improvement within the acceptable range from 6 to 9 according to the Pennsylvania State stream water quality regulations.

All the values of the expected trend *K* for specific conductance (SC) are negative although some expected *M* did not decrease (see table 5). This indicates the plan has been successful in reducing the specific conductance in succeeding datasets for years 1996-1997, 2002-2003, and 2006-2007. The trend, however, was not sufficient to keep the similar mean value for the specific conductance in the following years.

ABSTRACT

It is quite difficult and risk-taking to directly measure velocity and discharge of the streams during rapidly changing floods under nasty weather. Traditionally, floating rod method as well as indirect method is used in this situation. Though safe, floating rod method is regarded as relatively less accurate. We developed a new floating rod equipped with an integrated module composed of a GPS receiver and a RF transceiver on the head, which can measure flood velocity by tracking its position. Furthermore, simultaneous deployment of up to fifteen floats provides longitudinal velocity of streamlines along which they pass. Discharge is instantaneously calculated by combination of measured velocities and pre-surveyed cross-section area data for every deployment of floating rods. Some application examples show measured velocity and a 2D flow vector plot, and discharges calculated with this floating rods system indicate fairly good agreement with reference discharges like dam release and rated discharge.

INTRODUCTION

Recently, large flood events occur more frequently either by intense and severe rainstorms which are caused by tropical storms like typhoon and hurricane, or by serious summer snow-melt related with global warming. In order to control these floods and prevent damages brought about by them, it is necessary to make accurate measurement of flood discharge.

It is quite difficult and sometimes highly risk-taking to make direct measurement on flood velocity and discharge since water level and flow are rapidly changing with nasty weather accompanied. In addition, in order to secure accuracy of flood discharge measurement, quick measurement is also necessary. For this condition, rod float method is widely used (WMO, 1994). In some countries, indirect slope-area computation is utilized to measure flood discharge.

Simple, safe and easy to measure, traditional rod float method have been widely used in some countries. However, since it assumes that rod floats move downstream along the straight-lines, inaccuracy may occur if the paths of flowing rod floats are not straight.

In the context, we developed a new floating rod system equipped with a GPS

receiver and a RF transceiver and named as Electronic float. It doesn't need assumption on straight-line flow path as is a shortcoming of traditional rod float method. In this paper, some application examples for measurement of velocity and discharge using this new method are presented with basic concepts and equipments introduced.

BASIC CONCEPTS AND EQUIPMENTS

Traditional rod-float method. Generally, a straight reach located downstream of either a bridge or a float throwing equipment is selected. Along the reach at least two cross-sections are surveyed before and after flood season. Up- and downstream cross-sections are divided into 10~15 subsections according to mid-section method. Spacing between each section is set to either 50 or 100 m considering flowing time of a rod float. When a measurement is made, a rod-float will be thrown at each sub-section and flowing time of it will be checked to compute water velocity. Here, a rod-float is assumed to move along the straight-line and velocity is equal to distance divided by time of travel between two sections. Finally, discharge is calculated by summing up of sub-section discharges which are computed by multiplying water velocity of each rod-float by mean of corresponding up- and downstream sub-section area. Concept of the rod-float method is summarized in Figure 1.

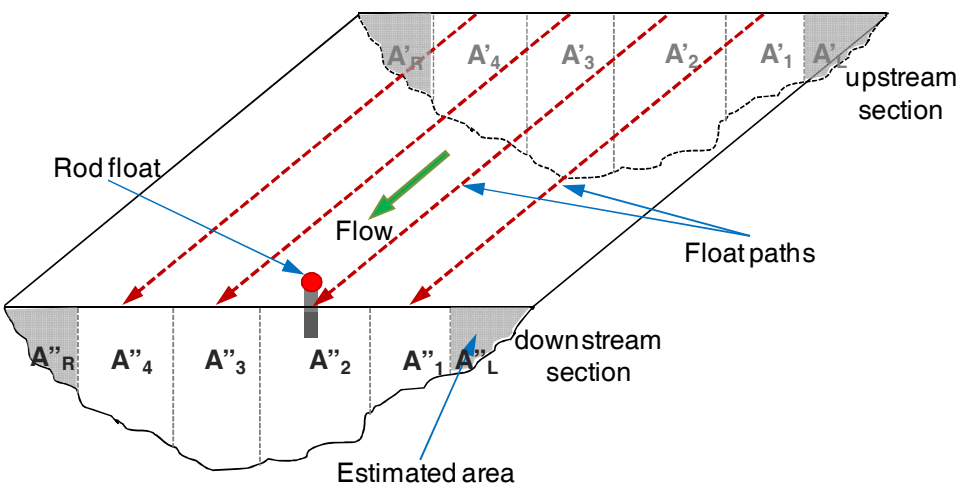

Figure 1. Basic concept of rod-float method (modified from ISO(1997))

The electronic float (EF). In the traditional rod-float method, position of a rod-float cannot be known. While, the electronic float receives GPS signal to determine its absolute position and is capable of tracking its path along the stream. Essentially, it does not need assumption on straight-line flow path and make velocity measurement more accurately.

The EF can also transmit its position information real-time to the hydrographic technician by radio-frequency (RF) communication. Three bands of low power RF are used: 424, 433, 447MHz. This system are provides up to 500 m

communication distance (may be increased by increasing power) and characterized as generality, low power consumption, relative communicative freedom from nasty weather and swell, and suitable to velocity and discharge measurement in streams. Consequently, once the EF is thrown to a river, its flowing path can be traced regardless of recollection of it. It is different from the previously developed GPS-based drogues (Hopping & Smith, 2002) in that they are not capable of real-time wireless communication so that they cannot be used for flood measurement condition in which it is unable to be recollected.

The system can use three frequencies mentioned above and five EFs can be supported in each frequency, so that maximum fifteen EFs can be operated simultaneously. The EF only picks out and transmits &GPRMC string among all the received GPS position information. Five EFs controlled in the same band conduct correspondence with one another and the base station collects their position information by time-sharing technique.

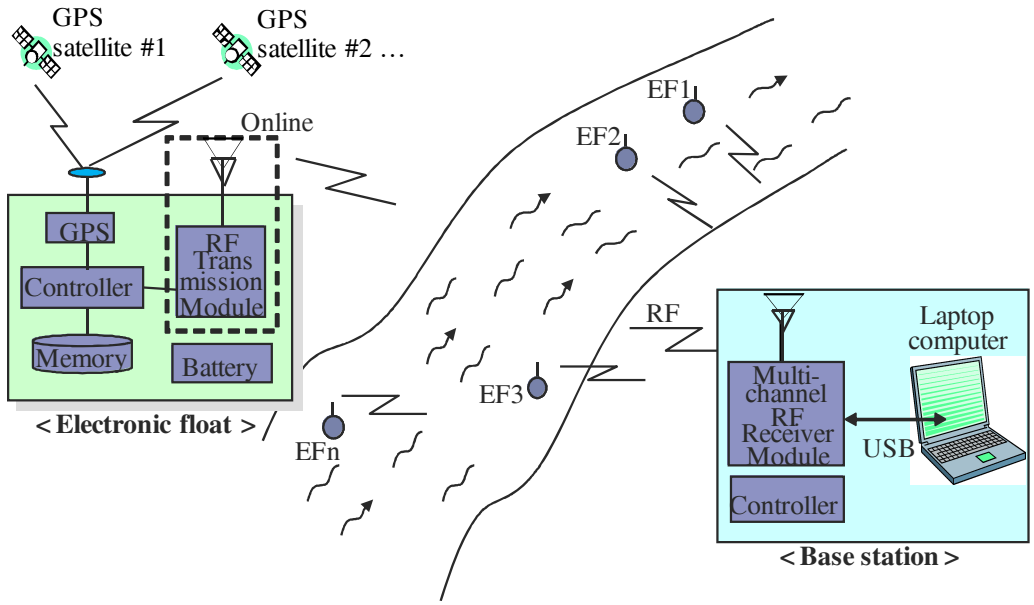

Figure 2. Concept of the electronic float system for flow measurement

FIELD APPLICATION

In order to test performance of the EF for measurement of velocity and discharge, field campaigns were made at five sites near official gauging stations in South Korea. Test sites are listed in Table 1. They are located at roughly straight river reaches. Three of them are located downstream of dams. Field campaigns at the Gumangyo and the Gangchon sites were made when the dam released for hydroelectric power generation in low flow season. At the other three sites, flood measurements were made. For each site, four cross-sections were surveyed for area calculation before either field campaign or flood season.

Table 1. General information on field campaigns

River	Site	Location	Date (yyyy.mm.dd)	Flow	Reference discharge
Dalcheon	Goesan	127-50-40, 36-45-51	2007.08.31	flood	dam release
North Han	Gangchon	127-38-08, 37-48-53	2008.04.15	flood	dam release
	Gumangyo	127-47-00, 38-07-00	2008.05.02 2008.05.16	low flow	dam release
South Han	Yeoju	127-38-58, 37-17-33	2008.07.24	flood	rated discharge
Imjin	Jeoksung	126-55-15, 37-58-56	2008.07.21	low flow	rated discharge

Figure 3 shows site locations with observed float tracks (left) and cross-sections (right). The EFs were thrown at the upstream bridge of each site. Four to ten EFs were used simultaneously at each site according to its measurement condition. For most sites, all the EFs moved straightly downstream. Cross-sections of the three sites (Goesan, Gumangyo, Jeoksung) are roughly symmetric and uniform, while the Gangchon site has rocky and rugged boundary and the Yeoju asymmetric cross-sections.

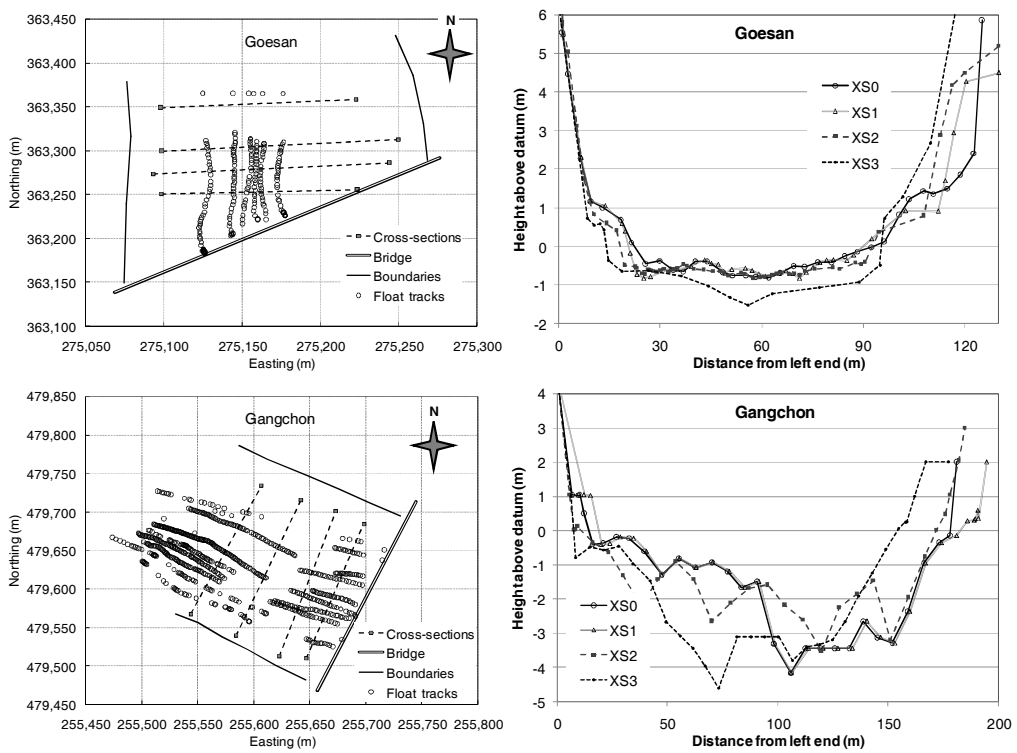

Figure 3. Site location with observed float tracks (left) and cross-sections (right)

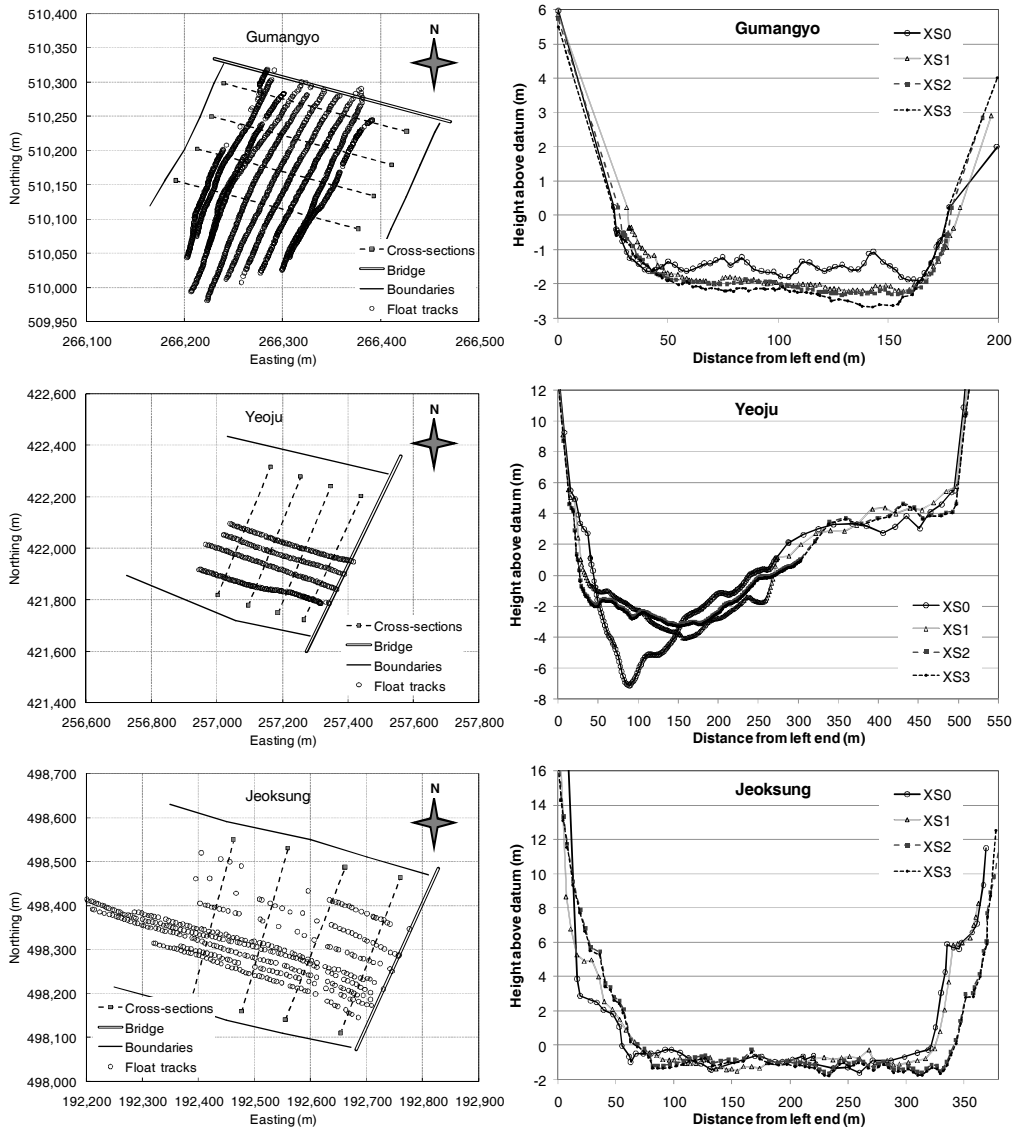

Figure 3. (continued)

VELOCITY CALCULATION

Calculation of flow velocity. Generally, in the rod-float method, depth-averaged flow velocity in a vertical can be expressed as follows:

$$v = k\frac{l}{t}$$

where, v is depth-averaged flow velocity, k calibration factor concerning the draft of the rod-float, l length of the path, and t travel time. The EF calculates l and t using GPS position information. For calculation of instantaneous velocity at every point during the travel, the EF uses following equation:

$$v_i = k\frac{l_i}{\Delta t} = k\frac{\sqrt{(x_i - x_{i-1})^2 + (y_i - y_{i-1})^2}}{t_i - t_{i-1}}$$

where, v_i is instantaneous velocity at time i, l_i is displacement from a point (x_{i-1}, y_{i-1}) to another point (x_i, y_i), Δt is time span, and x and y are positions in the earth coordinates. For calculation of discharge, velocity for travel time of a rod-float passing through two successive cross-sections is to be considered with angle calibration as expressed in the following equation.

$$v_{j,j+1} = k\cos\theta\frac{L_{j,j+1}}{\Sigma\Delta t}$$

where, $v_{j,j+1}$ is velocity for travel between successive cross-sections j and $j+1$, θ is angle difference between real direction and perpendicular direction to cross-section, $L_{j,j+1}$ is line distance between up- and downstream intersection points.

Results. Figure 4 shows velocity vectors of the Gumangyo site. Though calculated velocity using the EFs were not yet directly verified with velocity obtained by other instruments like conventional current meters, it displays well flow patterns in the straight reach of a stream which cannot be easily measured with other methods.

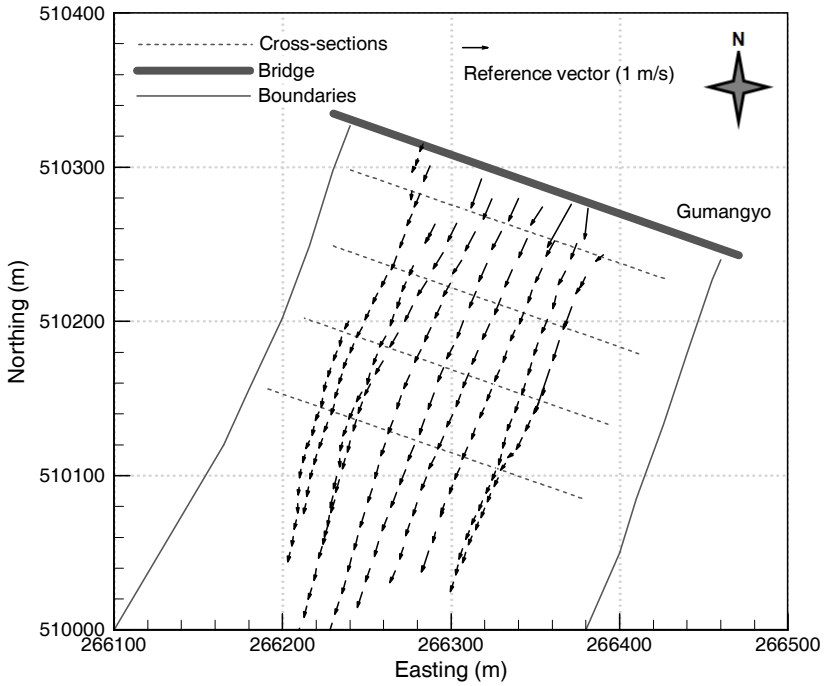

Figure 4. Velocity vectors calculated using the EFs for the Gumangyo site

Figure 5 indicates lateral velocity distributions of selected sections at four sites. Though measured velocity by the EFs is not compared with velocity by other

methods, lateral velocity distributions except the Gangchon data represent similarity with generally accepted forms.

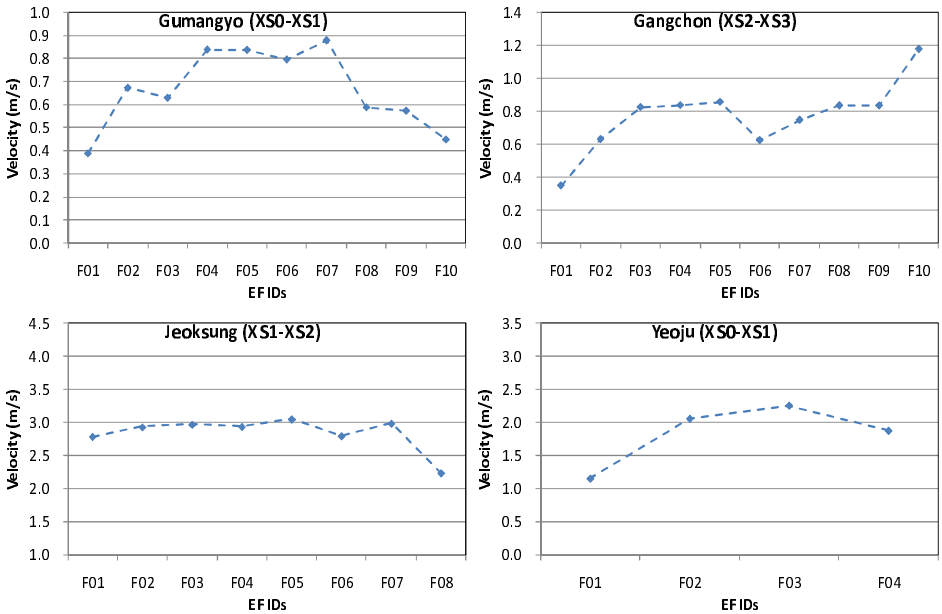

Figure 5. Lateral velocity distributions of the four sites

DISCHARGE CALCULATION

Cross-section area measurement. In order to compute discharge, cross-section areas should be calculated. In the rod-float method, a sub-section area for each rod-float is calculated averaging corresponding up- and downstream sub-sections areas based on the cross-section survey data using mid-section method (Figure 1). Since each EF has position information where it intersects with pre-established cross-sections, a sub-section area for computation of sub-section discharge is delineated by two neighboring EFs. Finally, remnant sub-section areas near both banks are delineated by the position of either the first or the last EF (Figure 6).

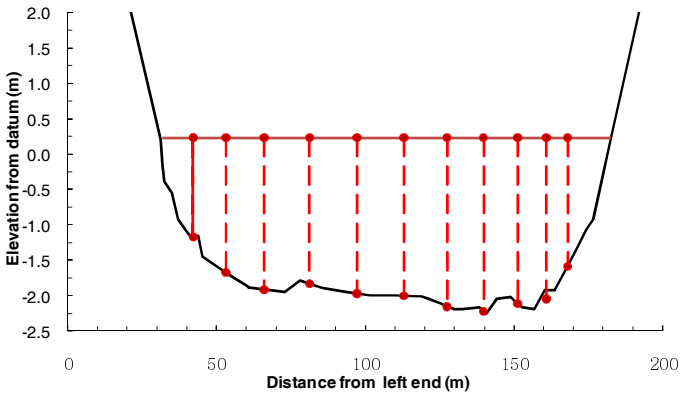

Figure 6. Sub-section delineation by the EFs

Discharge calculation. Discharge for each site is calculated by summing up of all sub-section discharge which is a product of flow velocity and sub-section area (Table 2). The Yeoju site is excluded because entire channel width of it cannot be sufficiently covered with only four EFs. Discharge for near-bank zone is calculated according to following equation presented by Simpson (2001).

$$Q_{L(R)} = 0.707 V_{1(n)} \frac{A'_{L(R)} + A''_{L(R)}}{2}$$

For three sites which have roughly symmetric and homogeneous cross-sections in the straight reach, measured discharge is very close to reference discharge. Measured discharge of the Gangchon site shows rather large difference with reference discharge. It seems related to irregular cross-section characteristics. Though the tests are preliminary and application is to be made for various sites, this result indicates that the EF system can be used as a good method for discharge measurement as well as velocity. Especially, it will be very useful for hazardous flow condition.

Table 2. Measured discharge values compared with reference ones

Date (yyyy-mm-dd)	Site	Measured discharge (m^3/s)	Reference discharge (m^3/s)	Difference (%)	Remarks
2007.08.31.	Goesan	64.8	63.0	2.86	Dam release
2008.04.15.	Gangchon	317.8	276.1	15.10	Dam release
2008.05.03.	Gumangyo	155.1	154.0	0.71	Dam release
2008.07.21.	Jeoksung	2,702.6	2,656.0	1.76	Rated discharge

CONCLUSION

In this study, the electronic float (EF) system which is developed based on GPS and RF technology, is briefly introduced and field application results of the EF system are presented. Velocity and discharge are well measured with the EF. Though it is necessary to test the EF for various sites, it is expected to be a useful tool for measurement of velocity and discharge for risky flow condition.

Abstract

Non-point source nitrate loading to stream water can be affected by land use, soil type, slope of discharging watershed, water flow rate, and storm events. This study considers the effects of land use type, water flow rate and seasonal and regional variation in order to understand and predict transport of nitrate in stream water discharging from watersheds along Virginia's Eastern Shore. A simple regression analysis was performed to check the relationship between nitrate concentration and land use type. Fertilized land was found to be the strongest contributor to nitrate concentration in stream water. Developed land was also a contributor but with a lower weighting factor. Forested land acted as a significant inhibitor. A predictive model was generated using multiple regression analysis. Besides land use type, nitrate concentration was also significantly influenced by stream flow rate. Other variables, including sampled area, seasonal and regional variation, may be treated as background information, in which they may have some effect on nitrate concentration, but not significantly enough to be included in the predictive model. Therefore, stream nitrate concentration levels can be predicted along the Eastern Shore of Virginia based on land use type and stream flow rate. Predictions may be improved by incorporating other geomorphic or hydrologic information.

1. Introduction

Nitrogen inputs to stream water have increased considerably over the past several decades. Human activities and products, including agricultural fertilizers, livestock ranch runoff, sewage discharge and fossil fuel combustion elevate natural nitrogen concentrations (Monti 2003). Approximately one third of the net anthropogenic input of nitrogen is discharged to streams and rivers (Jordan 1997a).

Stream water quality is influenced by a variety of parameters and mechanisms. The effects of these parameters during biogeochemical processes are confounded in the natural environment. Land use plays a very important role in determining the nitrogen loading level in stream water. Other factors, including stream flow rate, and seasonal and regional variation, which may indicate different levels of water-rock, microbial, and dilution processes, may influence base flow biogeochemistry, the pathways of water, and nutrient transformation.

Recent studies indicate a strong relationship between agricultural activities and nitrogen concentration in streams and rivers (Judith 2004; Monaghan 2007; Pieterse 2005). Low-end values of nutrient loading are based on estimated nutrient exports from forested watersheds, which can intercept and store precipitation-borne nutrients and are treated as one possible nitrogen sink (Jordan 1997a). Developed areas have the potential to generate large amounts of wastewater or sewage, which is associated with high concentrations of nitrogen (Jordan 1996; Monti 2003). Urbanization has a great impact on stream flow and ground water. Other specific indicators that warrant further consideration include housing, road and population densities, and the presence or absence of wastewater treatment facilities (Wayland 2003).

Base flow rate also has a strong influence on stream water quality, especially nitrate concentration. Greater infiltration and ground water flows are likely to promote discharge of nitrate, since nitrate has a high solubility in water and is more prone to leaching from soil (Jordan 1997c).

Other factors contributing to varying nitrate concentration levels include seasonal and regional variation. The highest stream flows generally occur in the winter and spring, when the water table is high, groundwater discharge to streams is greatest, and evaporation is lowest, compared to summer and fall (Judith 2004). Lower chemical reactions and biological activity further this difference (Monti 2003). Another seasonal factor is that agricultural applications of fertilizer generally occur in the spring. There is also a relationship between nitrate loading and hydrogeomorphic region. It is seen that there is more serious groundwater nitrate contamination in areas with well-drained soils compared to areas with poorly drained soils(Bachman 1998; Jordan 1997c). One possible explanation for this phenomenon is that anoxic conditions associated with saturated soils may favor denitrification, which decreases the nitrogen concentration in groundwater (Groffman 1993).

In this study, the effects of land use, water flow rate, and seasonal and regional variation are analyzed in order to understand and predict the fate and transport of nitrate in stream water discharging from watersheds along the Eastern Shore of Virginia. It was

expected that nitrate discharge to streams increases as the anthropogenic input of nitrogen to the watersheds increases. Factor analysis was conducted to determine significant variables impacting nitrate concentration. Next, multiple regression analysis was used to generate a predictive model of nitrate concentration in stream water using the selected variables. As a result of this model, nutrient concentrations can be predicted based on land use type and a regional dummy variable. Other geomorphic or hydrologic information may add to the accuracy of the model.

2. Methods

2.1 Description of study site

Virginia's Eastern Shore, bounded by the Atlantic Ocean to the east and the Chesapeake Bay to the west, contains most of Delaware and parts of Maryland and Virginia. The eastern shore area is a rural region with agriculture and forest as the dominant land use types, with scattered industrial and developed areas around the existing towns. The catchment area of this study site is located between latitude 37°10'-37°46'N and longitude 75°36'-75°58'W. The study area was a mixed land-use site, with 54.08% fertilized land (including crop land and fertilized grassland), 39.18% forested land (including deciduous forest, evergreen forest, mixed forest, and palustrine forest), 3.49% developed land (including high intensity and low intensity), and 3.22% mixed shrub.

There are many studies on the water quality of streams in the Chesapeake drainage basin (Jordan 1997a; Jordan 1997b; Jordan 1997c; Lindsey 1998; Miller 1997; Puckett 1992), most of which are based on large watersheds, which have a complex combination of different land cover and geomorphic, hydrologic, and biological processes. The watersheds in this study are mostly small (from 36.25 ha to 712.35, with a median area of 197.7 ha). There is relatively little climate variation or point-source input. Because of this, it is easier to test the impacts of land cover and other factors, which would be confounded in larger watersheds.

2.2 Sample collection

Thirteen watersheds were selected for nutrient sampling and discharge measurements, ranging in size from 36 ha to 712 ha. Individual sampled watersheds varied in size and land-use distribution, and are characterized in Table 1.

Eight synoptic surveys were performed, between April, 2005 and October, 2006, measuring $N0_3^-$ concentration and discharge at stream locations downgradient in the watershed but uninfluenced by tidal effects. Stream 1 is on the southern-most part of the study site, and stream 13 is furthest north. Grab samples were analyzed for nitrate concentration using ion chromatography.

2.3 Sample analyses

2.3.1 Stream discharge measurements

Stream velocity measurements were made using a Marsh-McBirney, Inc. Model 2000 Flow-Mate portable flowmeter. Cross-sectional reaches of the sampled streams were divided into several segments and an average velocity for each segment was recorded

Table 1 Percentage of land use types for study watersheds

Sample ID	Creek name	Total area (ha)	Land-use Type (%)			Mean NO_3^- (mg/L)
			Forest	Developed	Fertilized	
1	Tommy's Ditch	97.92	16.14	8.85	74.47	5.42
2	Mill Creek S	201.40	25.14	3.90	70.32	4.79
3	Pt Rocks	173.40	21.24	4.17	71.50	6.69
4	Narrow	223.20	28.68	0.08	68.52	2.95
5	Taylor	135.86	20.19	3.28	75.67	2.86
6	Mill Creek N	225.25	59.98	2.39	36.11	0.57
7	Red Bank	36.25	15.09	0.50	84.16	5.93
8	Green's	231.13	62.61	4.02	25.89	1.69
9	Coal Kiln	197.70	42.35	1.89	52.39	1.92
10	Frogstool Branch	712.35	49.52	4.67	41.14	1.21
11	Ross Branch	211.78	40.98	1.04	53.93	2.43
12	Parker's	146.31	21.74	2.23	74.16	1.47
13	Bundick	115.14	22.45	7.57	68.67	2.67

using the portable flowmeter. Stream discharge was calculated by determining the cross-sectional area of each segment, and adding the contributing water flow from all segments.

2.3.2 Chemical analysis

Triplicate stream-water samples were collected at each sampling site using 150-mL sampling bottles, and stored in a cooler. Upon returning to the laboratory, samples were refrigerated and filtered through 0.2-m disposable filters. Stream-water samples were analyzed for nitrate, chloride and sulfate using a Dionex® ion chromatograph equipped with a Gilson® 234 autoinjector and a Dionex IonPac AS4A® 4 x 250 mm analytical column.

2.4 Statistical analyses

2.4.1 Single factor analysis: One-way ANOVA

SPSS for Windows (SPSS Inc. 2007) was used to perform one-way ANOVA analysis to observe the effects of seven factors (stream flow rate, sampled area, percentages of agricultural, developed and forested land, seasonal variation and regional variation) on nitrate concentration in stream water. The null hypothesis (H_0) assumes that all mean nitrate concentrations are equal:

$$H_0 : \mu_1 = \mu_2 = \mu_3 = ... = \mu_C \quad (1)$$

All mean nitrate concentrations are equal

$$H_1 : \mu_1 \neq \mu_2 \neq \mu_3 ... \neq \mu_C \quad (2)$$

At least one mean nitrate is different: the null hypothesis is not true

The F statistic, which is the ratio of the among estimate of variance and the within estimate of variance (F=MSA/MSW), was used to interpret the results of the one-way

ANOVA. The decision rule is to reject H_0 if $F>F_U$ (F_U is the critical F-value at the level of significance at 0.05), otherwise not to reject H_0.

2.4.2 Simple regression analysis

Microsoft Office Excel 2007 (Microsoft Corporation) and its add-in software PHStat (Prentice Hall, Inc.) were used to perform a simple regression analysis, in order to check the relationship between nitrate concentrations and land use.

2.4.3 Multiple regression analysis

Microsoft Office Excel 2007 (Microsoft Corporation) and its add-in software PHStat (Prentice Hall, Inc.) were used to perform multiple regression analyses in order to predict stream nitrate concentration based on the land use type or other known geomorphic or hydrologic information.

The hypotheses are:

$$H_0 : \beta_1 = \beta_2 = \beta_3 = ... = \beta_k = 0 \quad (3)$$

No linear relationship between X_j and Y

$$H_1 : At_least_one_\beta_i \neq 0 \quad (4)$$

Linear relationship does exist between X_j and Y

The F-test statistic mentioned before was used to test for overall significance of the multiple regression models. Then residual analysis was performed to check the regression assumptions: independence of errors, normality of error, and equal variance. The heteroscedasticity-consistent standard errors (HCSEs) procedure was used to check if unequal variances in different observations existed. A stepwise regression was performed to check if there was a better model to complete the prediction.

A full model was constructed (Equation 5) including seven factors: log (flow rate), log (sampled area), fraction of forested land, fraction of developed land, fraction of fertilized land, and dummy variables for seasonal and regional variation.

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_4 X_4 + \beta_5 X_5 + \beta_6 X_6 + \beta_7 X_7 \quad (5)$$

where Y - log (nitrate concentration); X_1 - log (sampled area); X_2 - log (flow rate); X_3 - fraction of forested land; X_4 - fraction of developed land; X_5 - fraction of fertilized land; X_6 - seasonal dummy variable, 1 for data between Dec and May, and 0 otherwise; X_7 - regional dummy variable, 1 for southern group (sample ID 1-7), and 0 otherwise.

A reduced model (Equation 6) was assumed, dependent only on flow rate and land-use characteristics.

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 \quad (6)$$

where Y-log (nitrate concentration); X_1-log (flow rate); X_2-fraction of forested land.

3. Results

3.1 Relationships between nitrate concentration and individual variables

Effects of individual variables, including regional and seasonal variation, sampled area and land use, on nitrate stream concentration were tested and are presented below. Table 2 shows results of one-way ANOVA data analysis.

It was observed that northern streams had lower nitrate concentrations than southern streams. Averaged nitrate concentrations over the entire sampling period for the southern and northern stream groups were 4.08 mg/L and 1.85 mg/L, respectively. This regional difference may be due to the different levels of forested land and fertilized land, so it was not treated as an independent variable in our model. Forested land accounts for less than half of the total area of the southern and northern groups (30.67% and 44.95%, respectively). Fertilized land accounts for 64.59% of the total area for the southern group, compared with 46.97% for the northern group. Stream 7, with the highest fraction of fertilized land (84.16%) and the lowest fraction of forested land (15.09%) had a stream nitrate concentration much higher than the overall trend. It most likely receives the largest quantity of fertilizer or net imports of nitrogen-fixing crops (Charmbers 2005; Jain 2007; Jordan 1996), and there is only minimal forested land to intercept and store these nitrogen nutrients (Jordan 1997a; Jordan 1997c).

Nitrate concentrations in stream water samples displayed seasonal fluctuations during the sampling period, although there was no statistically significant correlation between nitrate concentration and season. The lowest nitrate values were observed during summer and highest values during winter. The two lowest mean values of nitrate concentration were 2.10 mg/L (August 28th, 2005) and 2.08 mg/L (May 12th, 2006), and the highest was 3.65 mg/L (January 28th, 2006). This effect can be explained by low groundwater discharge to streams, and high chemical reactions and biological activity during the summer time (Judith 2004; Monti 2003). However, there were two high nitrate concentrations measured on April 12th, 2005 (3.98 mg/L) and May 8th, 2005 (3.72 mg/L), which made the pattern of nitrate concentration less clear.

Sampled area size was a statistically significant factor for nitrate concentration in stream water, but it was not included in the final model because the effect of sampled area was accounted for by flow rate, which was significantly correlated with sampled area.

Strong correlations were observed between nitrate concentration and both fertilized and forested land fractions (Figures 1, Table 3). The fraction of developed land also affected stream nitrate concentration, although the effect was not as strong as the other two land-use types (Figure 1, Table 3).

Stream water from primarily forested watersheds (with a forested land fraction larger than 50%) had lower average nitrate concentrations (0.57 mg/L in stream 6, 1.69 mg/L in stream 8, and 2.43 mg/L in stream 11) than the mean value of 3.12 mg/L. Stream 6, with 59.98% forested land, had the lowest average nitrate concentration during the sampling period (0.57 mg/L) of all 13 streams. Nitrate concentrations decreased with larger fractions of forested land, possibly because forested land can intercept and store

Table 2 One-way ANOVA for each individual variable

variables	F value	Critical F value	Decision made from F-test	Included in model or not
Regional variation	28.79	3.94	Significant	No
Seasonal variation	1.47	3.94	Not significant	No
Sampled area	10.60	3.94	Significant	No
Land use	5.40	4.84	Significant	Yes

Table 3 Regression equations for exponential relationship between average nitrate concentration and fraction of fertilized land, forested land, and developed land

	Nitrate concentration and fertilized land fraction	Nitrate concentration and forest land fraction	Nitrate concentration and developed land fraction
R-squared values (R^2)	0.542	0.548	0.031
C_1 constant	0.420	7.037	2.148

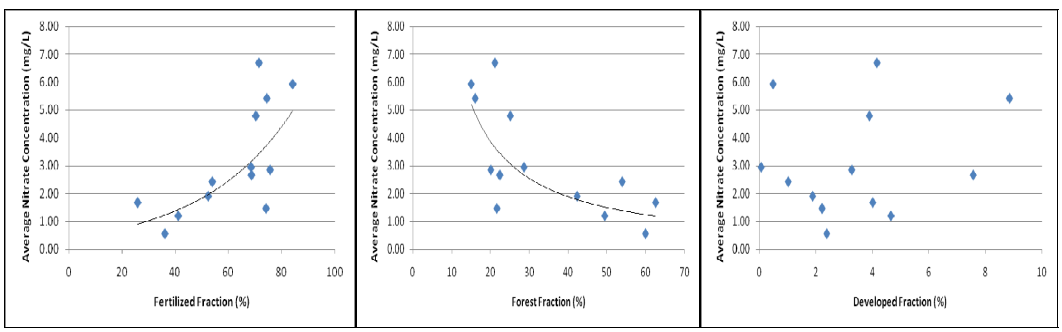

Figure 1 Nitrate concentrations in stream water averaged over the sampling period varied with fertilized, forested and developed fraction of watershed

nutrients, resulting in effective nitrate removal (Jordan 1997a; Jordan 1997c). It is attributed not only to plant uptake, but also to soil type in the forested area, which is suitable for removal of nitrate through denitrification (Speiran 1996).

The fraction of fertilized land had an inverse impact on nitrate concentration. Streams discharging from highly fertilized land areas produced high nitrate concentrations. The nitrate concentrations for stream 7 with 84.16% fertilized land, and stream 1 with fertilized land fraction of 74.47 % were 5.93 mg/L and 5.42 mg/L, respectively, approximately twice as high as the mean nitrate concentration for all streams. The reason would be higher fertilizer application and cultivation of nitrogen-fixing crops (Charmbers 2005; Jain 2007; Jordan 1997a; Jordan 1996).

It was found that the fraction of developed land also affected stream nitrate concentration, although the effect was not as strong as the other two land-use types.

Stream 1 discharging from land with the highest fraction of developed area (8.85%) had nitrate concentrations as high as 5.42 mg/L. The same level of nitrate was also found in stream 7 (5.93 mg/L), although only 0.5 % of the drainage area was developed land. Developed land may be affected by human activity, which produces larger volumes of runoff from storm-sewer systems (Scorca 2001). It may be associated with deteriorated water quality, and with subtle impacts on stream nitrate concentrations.

Based on the scatter plots of nitrate concentration versus land use, we checked the fitness of both exponential and power relationships between stream nitrate concentrations and fertilized, forested and developed land fraction through simple regression analysis (Table 3). Exponential relationship fit data better, but still near 0 between nitrate concentration and developed land fraction. Nitrate concentration predictions based solely on individual land-use type were very poor. Therefore a multiple regression, including all land-use type components and other factors, was assumed to describe the trend of nitrate concentration.

3.2 Multiple regression analysis

According to the multiple regression analysis, there was overall significance for the full model, with an F-value of 20.62 and R^2 of 0.6266 (Table 4). The variables for sampled area, fraction of developed land, seasonal and regional variation did not contribute as much as the other three variables of flow rate, fractions of forested land, and fertilized land to nitrate concentration. Since fraction of fertilized land was highly correlated with fraction of forested land (with R square of 0.9729), forested land was treated as the representative land-use variable in the reduced model (Equation 6). Flow rate is another significant variable. The overall significance of this reduced model increased to an F-value of 49.1, with a slightly decreased R^2 of 0.5190 (Table 5). Both of the two variables in the reduced model had significant effects on nitrate concentration (all p-values less than 1E-5), so the reduced model had advantages in describing nitrate concentration over the original full model. It was also verified from the stepwise regression that there was no significant relationship between the predicted nitrate concentration and the deleted variables (i.e. stream flow rate, sample area, fraction of developed land, seasonal and regional dummy-variable).

4. Conclusions

This study has shown that fertilized land was the strongest contributor to elevated nitrate concentrations in stream water. Developed land was also a contributor but with a lower weighting factor. Forested land acted as a significant inhibitor. Nitrate concentrations were also influenced by increased stream flow rate, which confirms that the major source of non-point pollution in stream water is from discharged ground water and surface runoff from watersheds. Other variables, including sampled area, and regional and seasonal variation, may be treated as background information. A predictive model correlating land use type and stream flow rate with stream nitrate concentration was constructed.

Table 4 Multiple regression results for full model

Adjusted R^2=0.5084	% forested	-4.215	0.4254	3.963E-16

The statistical approach applied in this work can help us to determine the relative impact of different land use types on nitrate pollution in stream water. This approach is based on the assumption that nitrate in stream water is contributed by non-point pollution from discharging watersheds, and nitrate concentration can be predicted based solely on land use type and stream water flow rate. Regional and seasonal variation did have some impact on nitrate concentration in stream water, but the relation was not clear enough due to the lack of data for watershed soil type, slope, and precipitation. More hydrological and geomorphic parameters may be incorporated into the model for future study.

ABSTRACT

This study focuses on Weeks Bay, a small sub-estuary of the Mobile Bay and one of only three designated Outstanding National Resource Waters in the state of Alabama. We assess the impact of LULC changes in its watershed through watershed modeling and regression equations. The watershed model is calibrated using USGS flow measurements on the main river. Water quality data collected between 1992 and 1996 is used in developing regression equations between TSS, NO_3, P and various LULC types. The 1992 NLCD has been used and assumed to represent the LULC conditions of the period from 1992 to 1996. Comparison of model simulations with observed data for the period [1990-2003] showed that urbanization caused increase in streamflows. The 2002 NLCD has been fed into Regression model and TSS, NO3, and TP concentrations are estimated. The similarities and differences in predictions with each method are investigated.

INTRODUCTION

Coastal areas all around the world are experiencing population increase. One of the consequences of population growth is urbanization and urban sprawl, which often have adverse impacts on the environment. Increased percentages of imperviousness may lead to rise in sediment and nutrients loading in the streams (Arnold and Gibbons 1996 and Nelson and Booth 2002). Urbanization has also shown to increase heavy metal (Callender and Rice 2000), and bacteria loadings (Gregory and Frick 2000). This study focuses on the rapidly urbanizing Weeks Bay watershed in Southwest Coastal Alabama. Weeks Bay is one of only three designated Outstanding National Resource Waters in the state of Alabama, which is the highest standard for water bodies with no point-discharges allowed. The 513 km^2 watershed is in Baldwin County, which has the 2nd fastest population growth rate in the state of Alabama. Land use and cover of the watershed has seen significant changes during the past decade. It is therefore anticipated that these human induced land use changes will impact the quality and quantity of the waters draining into the bay. This paper focuses on studying the relationship between LULC changes and water quality in the

Fish River Watershed (Fish River supplies about 75% of the fresh water of the bay) with the help of regression analysis and watershed modeling. Three separate groups have collected water quality data in the past at different times in the tributaries of the Fish River from 1994 to 2001 (Basnyat 1998, Lehrter 2003, and Geological Survey of Alabama, GSA 2003). Arial photos and on-site visits revealed that there has been a significant increase in urban areas in the watershed lately. Hence, we found a unique opportunity in this watershed for assessing LULC change impacts on water quality.

STUDY AREA

Weeks Bay Watershed (Figure 1) is located in Baldwin County, Alabama. It is a small sub-estuary of the Mobile Bay receiving freshwater from the Magnolia (~25%) and Fish Rivers (~75%). The total drainage is about 513 km^2. It consists of southern Pine Hills and coastal lowlands. Figure 1 shows the sampling sites used for data collection by Basnyat (1998) and GSA (2003); out of these we have chosen 10 sites for our project. Selection of sites was based on the amount of available data and LULC variability between 1992 and 2002 (Table 1). Major LULC types in the watershed are pasture, agriculture, evergreen forest and urban areas. Large fraction of the watershed was covered by pasture in early 1990's, which shrunk almost by half by early 2000's due to built out and conversion to sod farming (Table 1).

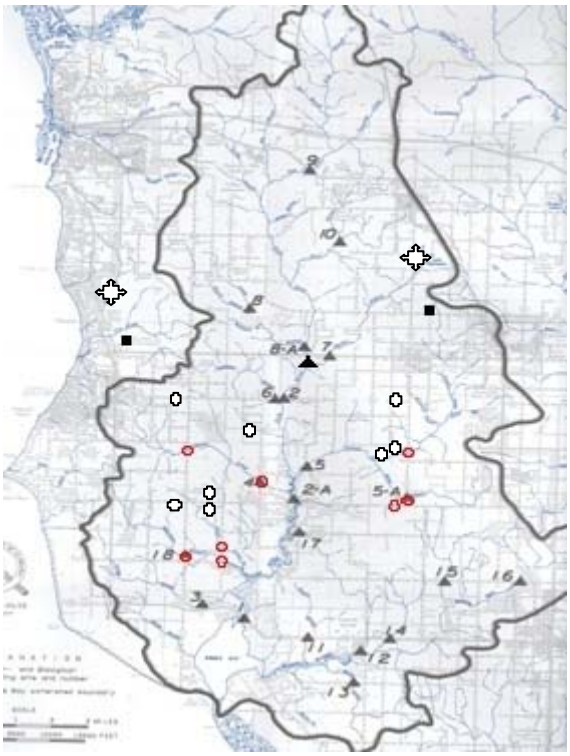

Figure 1. Weeks Bay watershed. (✣ : weather stations; ⬡,▲: Sampling sites)

WATERSHED MODEL

The watershed model selected in this study is the Soil Water Assessment Tool (SWAT). SWAT applications can be found all around the globe; e.g. Jha et al.2007 (Raccoon River, USA), Karim et al.2006 (Thur River basin located in the north east of Switzerland), Kang et al. 2005 (watershed containing rice paddy fields in the Republic of Korea). SWAT has been used in the past for evaluating the changes in water quality due to varying land use practices (Kalin and Hantush 2008).

The SWAT model requires specific information about elevation, soil, slope, weather, and land management practices within the watershed (Arnold & Allen, 1996). Spatial data used in the study for SWAT include a digital elevation model (DEM), LULC, soil data, climatic and stream flow records. National Elevation

dataset with a 1/3 arc second resolution (10 m pixels) was used for delineating the Fish River watershed and the drainage areas of the sampling sites. State Soil Geographic (STATSGO) and Soil Survey Geographic (SSURGO) data are the two types of spatially different digital soil data sets created by NRCS. Both were used in the model to check the differences in the model simulations with respect to each.

Table 1. Summary statistics of LULC types in the drainage areas of sampling sites.

LULC Type (%)	Minimum 1992 / 2001	Maximum 1992 / 2001	Average 1992 / 2001

Other *	8.2 / 3.9	32.7 / 36.8	15.3 / 19.4

* Wetland, Deciduous Forest, Mixed Forest, Water etc.

National Land Cover Data (NLCD) for 1992 was used as an input for LULC data. The choice of NLCD'92 was motivated by the fact that the period of previous data collections started in 1994, and 1992 NLCD is the closest LULC data available. The watershed in 1992 was dominantly pasture, forest, row crops, and urban.

Rainfall data for this project was available from two climate stations, one situated slightly outside one barely inside the watershed. 30 years of climate data was available. Temperature data was available only from one station. However this was not a concern as temperature does not show big spatial variations in Southern Alabama. Streamflow prediction, especially at early stages in model simulations, is highly dependent on the soil antecedent moisture condition. Thus, a warm up period of about a decade was used to minimize uncertainties due to antecedent moisture.

Flow calibration and validation for weeks bay watershed was completed by using the stream flow data from USGS gauge 02378500 (Fish River near Silver Hill, AL) (Same as Site 8A in Figure 1). The period of calibration was from 1990 to 1994 and validation period was from 1995 to 1998. We are currently calibrating SWAT for sediment and nutrients at subwatershed level by utilizing the past data reported in Basnyat (1998) and GSA (2003). These studies were conducted from 1994 to 1998 with major focus on TSS and NO_3 along with some other water quality parameters. P and PO_4 concentrations were also reported for some days, though at significantly low levels. The challenge is that they did not collect flow data; only concentrations of TSS and nutrient from grab samples were reported. At this stage we are unsure about model performance in simulating flow at subwatershed level. We recently installed

pressure transducers at those sites and are taking flow measurements to develop stage-discharge curves. Once we get flow data at those sites we will fine tune the model by further calibrating model parameters at subwatershed level. We also performed simulations for the period 2001-2003 to assess differences between streamflow for the periods with differing LULC. Performance of model was evaluated using mass balance error (MBE = Simulated / Observed - 1), coefficient of determination (R^2) and Nash-Sutcliffe efficiency (E_{NS}) (Kalin and Hantush, 2006).

REGRESSION MODEL

Multiple Linear Regression was performed to develop relationships between various LULC types and water quality parameters TSS, NO_3 and P. The data collected by Basnyat (1998) and GSA (2003) from 1994 to 1998 is utilized in development of these regression equations. Water quality parameters were treated as dependent variables and percentage area of different LULC as independent variables. Three different categories were considered for representing urban areas based on the 1992 NLCD. Below are LULC categories for which regression was carried out:

(i) Agriculture (AGR), Pasture (PAST), Evergreen Forest (FRSE), Urban(URB)
(ii) Agriculture (AGR), Pasture (PAST), Evergreen forest (FRSE), Urban High Density Residential (URHD), Urban Medium Density Residential (URMD), Urban Low Density Residential (URLD).
(iii) Agriculture (AGR), Pasture (PAST), Evergreen Forest (FRSE), IMPERVIOUS (Impervious), Urban Vegetation (Urban_Veget).

The percent imperviousness in category (iii) was estimated using the method described by ASCE/ESRI Impervious Surface Task Committee. The average imperviousness corresponding to low density, medium density and high density residential areas are given given as 25, 38 and 65%, respectively. We categorized urban areas not classified impervious as urban vegetation.

Regression equations were developed between percent LULC and concentration of sediment and nutrients using forward selection method of Statistical Analysis Software (SAS). Normality of data was tested using Shapiro-Wilk test. It was found from the test that the null hypothesis could not be rejected. In forward selection method SAS first calculates the fixation indices for each variable which is the measure of the contribution of that variable if it is included in the model. Probability (p- value) for these indices is compared to 0.5. If the value is less than 0.5 then the variable is included in the model. For choosing the next dependent variable SAS again calculates fixation indices for rest of the variables and it goes until there is no variable with p- value less than 0.5.

RESULTS AND DISCUSSIONS

SWAT Model Results

Figure 2 and 3 compare observed flow at the USGS station on the Fish River with SWAT simulated flow for the calibration and validation periods, respectively. It is clearly seen that SWAT was able reproduce observed flow. Table 2 shows SWAT model performance. Surprisingly the validation period shows slightly better performance, especially in MBE. We also run the model from 2001 to 2003 in prediction mode with the same model set up, which covers Lehrter's (2003) data collection period. Note that 1992 NLCD was used during model setup and 2001 NLCD show some substantial changes in LULC in some areas. Figure 4 compares models results with observed flow. Model performance is also reported in the last column of Table 2. SWAT overestimates streamflow on average by 16% in this period. From Figure 4 it is clearly seen that most of the increased flow is due to increase in high flows, a typical consequence of urbanization. As a matter of fact although SWAT underestimated flow by almost 8% during the calibration period, this underestimation diminished during the validation period and it turned into overestimation during the prediction period.

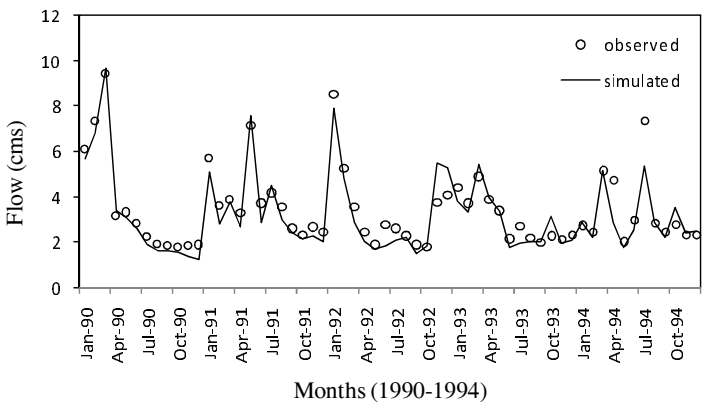

Figure 2. Comparisons of SWAT simulations with the observed data during calibration period (1990-1994).

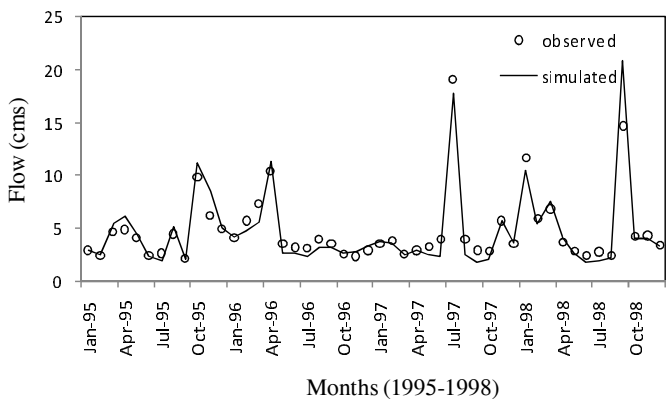

Figure 3. Comparisons of SWAT simulations with the observed data during validation period (1995-1998).

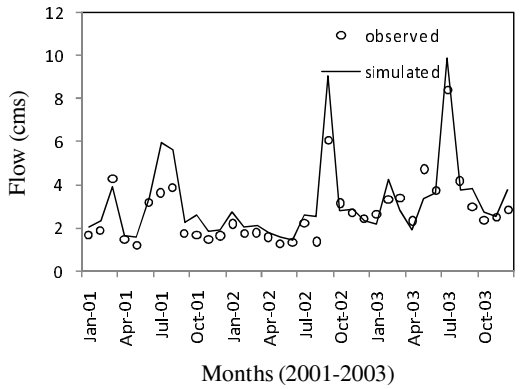

Figure 4. Comparisons of SWAT simulations with the observed data during prediction period (2001-2003).

Table 2. Model performance parameters for flow.

	Calibration (1990 – 1994)	Validation (1995 -1998)	Prediction (2001-2003)
R^2	0.89	0.91	0.82
E_{NS}	0.87	0.87	0.61
MBE	-7.7%	0.21%	15.91%

Regression of LULC vs. Water Quality

Regressing LULC percentages against average concentrations of TSS, NO_3 and P (all in mg/L) from various sites resulted in following equations.

$$TSS = -0.00081*AGR + 0.00038*PAST + 0.0129*URB + 0.028 \quad (R^2 = 0.56)$$
$$NO_3 = 0.169*AGR + 1.954*URB - 0.6649 \quad (R^2 = 0.45)$$
$$P = -0.00079*AGR + 0.04848 \quad (R^2 = 0.2)$$

Agriculture, pasture and urban percentages explain 56% of the variability in TSS concentrations; agriculture and urban areas explain 45% of the variability in Nitrate concentrations. The only significant factor in P was agriculture which barely explains 20% of the variation in Phosphorus concentrations. TSS showed the highest correlation against LULC percentages. P had almost no correlation. This was expected as measured P values were too small to get a meaningful relationship. A big surprise was having AGGR negatively correlated to TSS. There could be several reasons for this. It could be due to the nature of the agricultural activities. Sod and Orchard tree farming are widespread in the watershed, which are not known to produce heavy TSS loadings. Further, best management practices (BMP) around agricultural fields could be filtering out TSS extremely well. In fact, there are well established riparian buffers around most streams and creek in the watershed. Having high contribution from urban areas is not surprising at all due to two reasons. One is that the study watershed started urbanizing by early 1990's meaning there could be

many ongoing construction activities during that time span. Secondly, as urbanization results in flashier flows, one can expect higher streambed and stream bank erosion in urban areas. Nitrate results are not surprising at all with agricultural and urban areas being the major role players. Note that the reason for higher coefficients with urban areas is that urban percentage during this period was still relatively small.

Since LULC types don't cover a wide range in 1990's (see Table 1) we don't consider these regression equations reliable enough to be used in predictions. Still we fed 2001 LULC percentages into these equations and compared to data collected by Lehrter (2003) from 2000 to 2001. Figures (5-7) compares Lehrter's data with those predicted through regression equations. Box plots were first developed for 5 sampling sites to see the spread of data collected by Lehrter (2003). It is clear that there are no outliers for any of the parameters. The concentration values for three sites for NO_3 are higher than the other 2 sites (Figure 5). These higher concentrations can be attributed to the higher percentage of Agricultural areas in sub watersheds of these sites. For P (Figure 6) and TSS (Figure 7) spread was similar for all the sampling sites. Regression based NO_3 predictions significantly overestimate observed NO_3 values of Lehrter at all sites. On the contrary TSS and P values are within observed data ranges. This is quite interesting as NO_3 had the highest R^2 with P having the lowest. This once again shows the danger of using regression equations in predicting water quality parameters without having full LULC coverage.

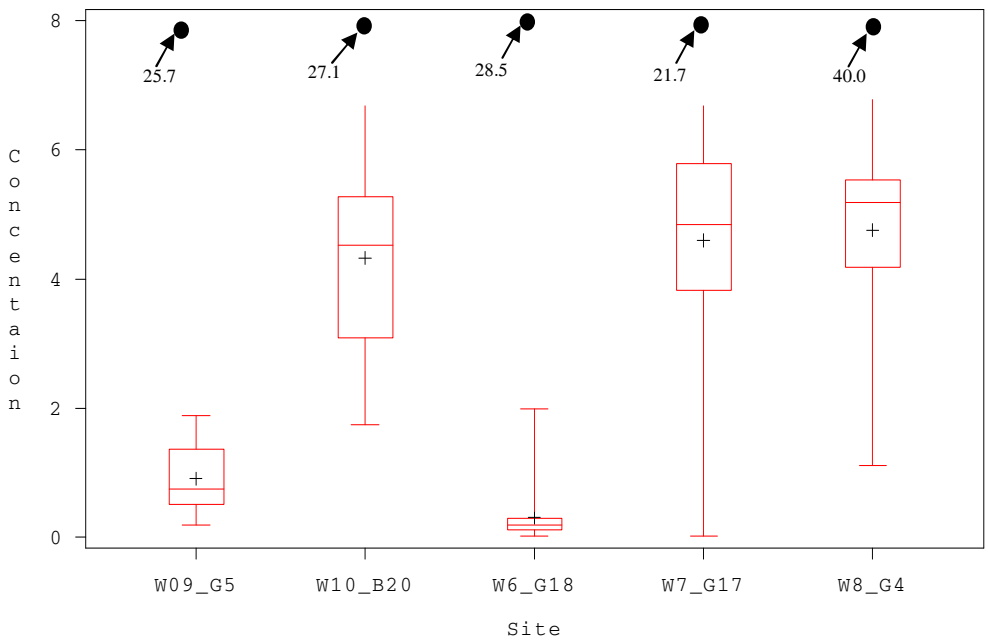

Figure 5. Box Plot for NO_3 concentrations for Lehrter (2003) data and its comparison with data developed from the Regression equations shown with (●).

It would be interesting to perform the same type of analysis using Lehrter's data and 2001 NLCD and then feed 1992 NLCD to those regression equations to see whether it can predict the 1994-1998 conditions. We expect that will have a higher predictive power as various LULC types in 2001 NLCD show more variability than

LULC of 1992 NLCD. Since we recently obtained Lehrter's data we did not have the chance to explore this facet yet.

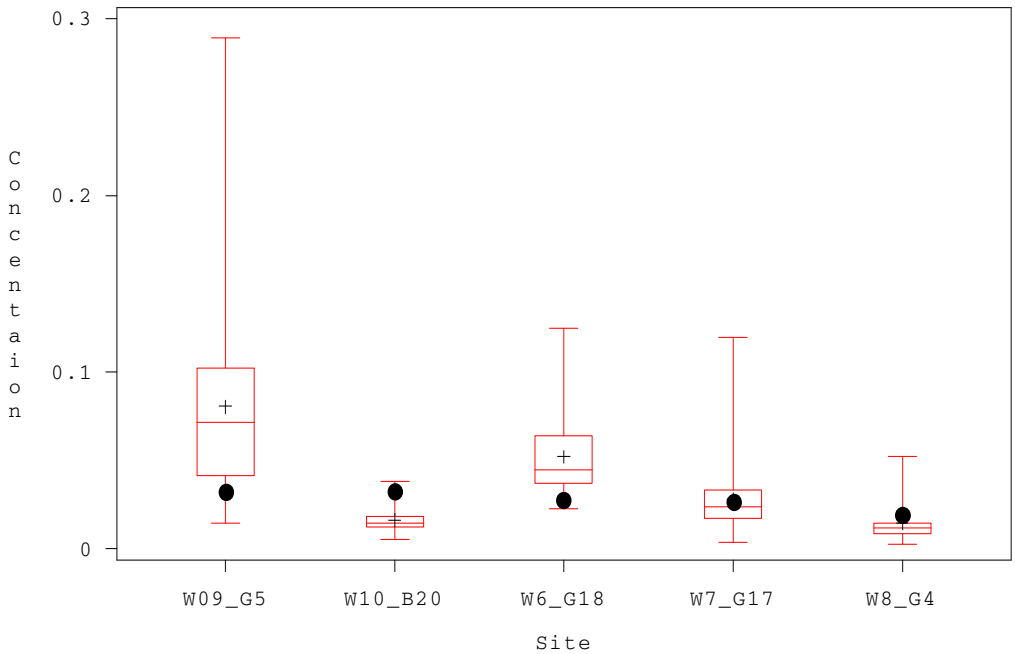

Figure 6. Box Plot for P concentrations for Lehrter (2003) data and its comparison with data developed from the Regression equations shown with (●).

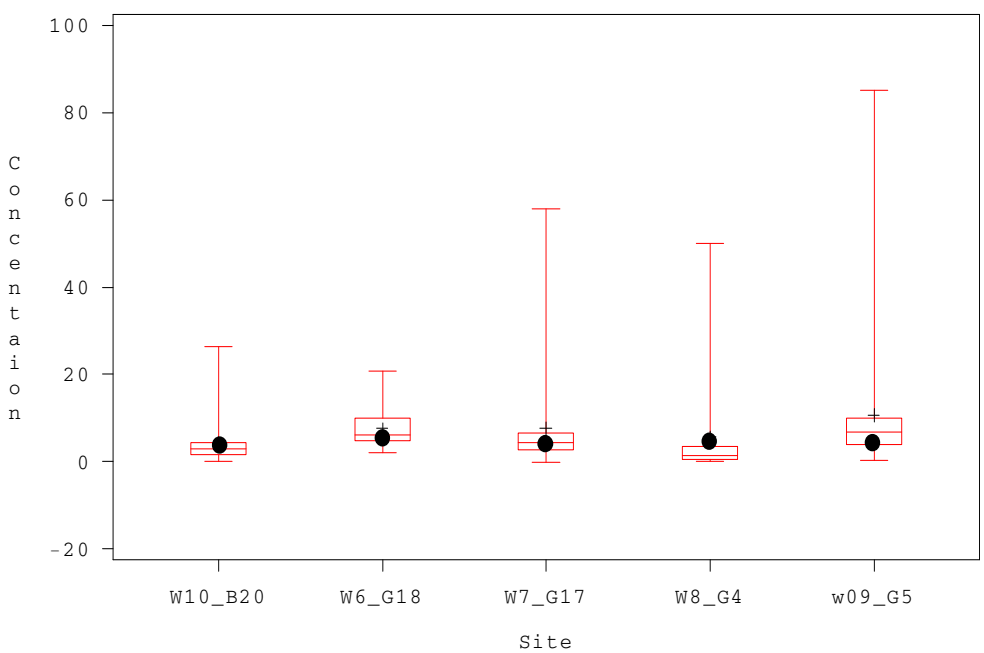

Figure 7. Box Plot for TSS concentrations for Lehrter (2003) data and its comparison with data developed from the Regression equations shown with (●)

SUMMARY AND CONCLUSIONS

In this paper we assessed the urbanization impacts in the Weeks Bay Watershed through regression and watershed modeling based approaches. Watershed model simulations revealed that urbanization has led to increased stream flow. Developed regression equations between land use/cover (LULC) and water quality data collected from 1994 to 1998 showed the limitations and the danger of using regression equations in such studies. It is suggested that in order to perform dependable regression based predictions, the data must come from several watersheds whose LULC should form a nice gradient, i.e. most LULCs should be represented and their percentages should cover a wide range, comparable to the range of the future expected LULC.

Empirical models usually work well within a particular range of dependent and independent values. Due to the fact that Weeks Bay Watershed is under constant stress of population growth and urbanization, regression based analysis is still a promising option as urban areas will keep growing. However, mechanistic hydrology and water quality models are still more efficient and effective means for assessing impacts of land use/cover (LULC) changes on water quality/quantity. Process based models like SWAT are effective in modeling natural process like hydrology of watershed. Their performance for the most part depends on the reliability of input data for the sensitive parameters.

ABSTRACT

The Cache River is located in the extreme southern part of Illinois, just north of the confluence of the Ohio and Mississippi Rivers. Major floods in both of the two rivers have significant impact on the hydrology and hydraulics of the Cache River. In 1915, a cutoff to the Ohio River was constructed east of Karnak that resulted in sub-dividing the Cache River watershed into the Upper and Lower Cache River watersheds. The Upper Cache River watershed consists of the eastern part of the watershed draining directly to the Ohio River through the Post Creek Cutoff. The Lower Cache River watershed consists of the western part of the watershed draining to the Mississippi River through a diversion channel at the outlet. However, part of the Lower Cache River can at times reverse flow, draining to the Upper Cache River and Post Creek Cutoff.

Hydrologic and hydraulic models have been developed to simulate the hydrology and hydraulics of the Cache River system to evaluate flow and water level conditions along the river under different alternative scenarios that can be implemented as part of a restoration effort for the Cache River. The hydrologic model that simulates the rainfall-runoff process for tributary watersheds is based on the HEC-HMS model. The model is used to compute runoff from tributary watersheds for selected storm events. Outputs from the HEC-HMS model are then used as inputs to the hydraulic model, UNET. The UNET model, a one-dimensional unsteady-flow dynamic wave routing model, is capable of modeling the complex hydraulics of the Cache River System that experiences flow reversals during flood events in the Lower Cache River.

ACKNOWLEDGMENTS

The work upon which this report is based was supported in part by funds provided by the Cache River Joint Venture Partnership (JVP), which includes the Illinois Department of Natural Resources (IDNR), The Nature Conservancy, the U.S. Fish and Wildlife Service, Ducks Unlimited, and the Natural Resources Conservation Service.

BACKGROUND

The Cache River is located in extreme southern Illinois, just north of the confluence of the Ohio and Mississippi Rivers (Figure 1). The total drainage area of the basin was 737 square miles (sq mi), or 1,909 sq km, until the construction of Post Creek Cutoff in 1915, which divided the Cache River basin into the Upper and Lower Cache River watersheds with 368 and 358 sq mi (953 and 927 sq km) of drainage, respectively. Karnak Levee (also known as Cache River Levee), along the western bank of Post Creek Cutoff near Karnak, separates the Upper and Lower Cache River watersheds. This levee was built in 1952 across the old Cache River channel and forces drainage from the Upper Cache River to flow directly to the

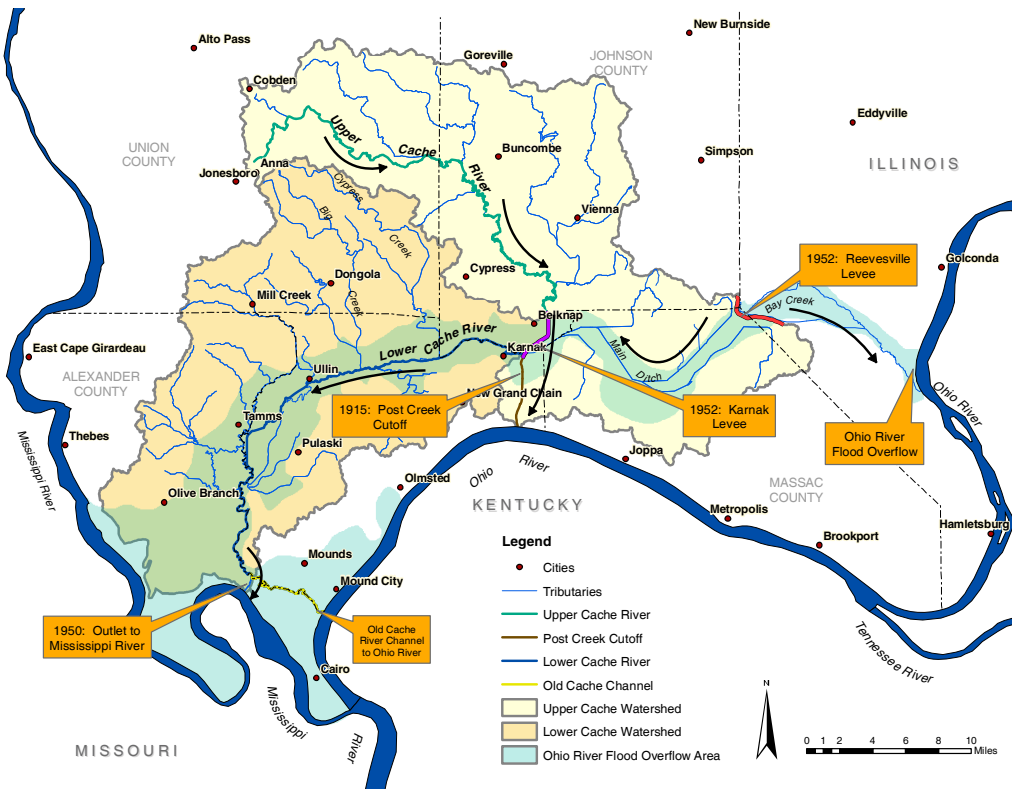

Figure 1. Historical major drainage alterations and current drainage pattern of Lower and Upper Cache River watersheds (Demissie et al., 1990a,b).

Ohio River through the Post Creek Cutoff. It also was designed to prevent any flood from the Upper Cache and Ohio Rivers from backing into the Lower Cache River. Karnak Levee was designed with two 48-inch (1.22 m) gated culverts to allow local drainage along the west side of the levee to flow to Post Creek Cutoff. Drainage from the Lower Cache River watershed was assumed to flow west into the Mississippi River. However, during flood events, some drainage from the Lower Cache River flowed east to Post Creek Cutoff through the culverts in Karnak Levee. Since 2002, however, Karnak Levee has been breached and the culverts washed away. It is now possible for major floods from the Upper Cache and Ohio Rivers to back into and flood the Lower Cache River floodplain and for flood waters from the Lower Cache River to flow to Post Creek Cutoff without any control.

Because of these alterations and the influence of the Ohio and Mississippi Rivers, the hydraulics of the Lower Cache River are very complex. Since the division of the Cache River basin into two watersheds, the Lower Cache River does not receive flow from the Upper Cache River to maintain a sustained flow in the downstream direction. Local tributaries are now the headwaters and the source of water for the upper portion of the Lower Cache River where the Cache River wetlands are located.

Big Creek, Cypress Creek, and Mill Creek are the three major tributaries that drain the upper portion (headwaters) of the Lower Cache River watershed. Big Creek has a drainage area of 51.7 sq mi (133.9 sq km) and flows into the Cache River at River Mile (RM) 24.1. Cypress Creek has a drainage area of 46.3 sq mi (120 sq km) and flows into the east side of the wetland at RM 29.4. Mill Creek has a drainage area of 53 sq mi (137 sq km) and flows into the Lower Cache River at RM 15.0. However, low to moderate flows from the upper third of the Mill Creek watershed are diverted to Indian Camp Creek (approximately 1 mile (1.6 km) northwest of the town of Ullin), which enters the Lower Cache River south of Ullin (RM 20.5). Several smaller tributaries also flow into the Lower Cache River. The most significant of these smaller tributaries, Limekiln Slough, has a drainage area of 22.1 sq mi (57 sq km) and flows into the west end of the Cache River Wetlands Area at RM 25.2.

Big Creek, Limekiln Slough, and Cypress Creek flow into the Lower Cache River where the channel bed elevation is the highest. East of the Cypress Creek confluence, the Lower Cache River has a downward slope to the east toward Karnak Levee. During low and moderate flows, the Cache River Wetlands Area is normally the divide between the two portions of the Lower Cache River that flow east towards Karnak Levee and west towards the Mississippi River (Allgire, 1991). During flood conditions, all or part of the wetland flows to the west. The location where the flow divides to the east or west is not constant and varies during flood events (IDNR, 1997).

Once water from tributaries enters the Lower Cache River, it can flow in an easterly direction toward culverts in Karnak Levee or flow in a westerly direction

toward the Lower Cache River outlet on the Mississippi River. If the flows are high enough to overtop streambanks, which is the case during most flood events, then water flows into the wetland areas, which have large water storage capacity. A combination of several factors determines which way water flows in upper parts of the Lower Cache River. Some of the factors are magnitude of the floods, channel capacity and slope, flood heights, floodplain storage, outlet capacity at bridge openings, and resistance to flow.

Demissie et al. (1990a, 2001, 2008) and IDNR (1997) provide more complete descriptions of the hydrology, land use, and climate of the Cache River, and the reader is referred to these publications for additional information.

The objective of the research that this paper is based on was to develop hydrologic and hydraulic models that can simulate the hydrology of the tributary watersheds and the hydraulics of the Lower Cache River. The models then were used to evaluate current conditions under different flooding possibilities and future conditions under different management scenarios, including a managed reconnection with the Upper Cache River.

HYDROLOGIC AND HYDRAULIC MODELING

The hydrology and hydraulics of the Lower Cache River were investigated intensively by updating models previously developed by the Illinois State Water Survey (ISWS) and the U.S. Army Corps of Engineers (USACE), St. Louis District. Two models, one for hydrology and the other for hydraulic simulation, were updated and used to evaluate different scenarios that represent reference conditions, current conditions, and future alternatives.

The hydrologic modeling system (HEC-HMS) developed by the Hydrologic Engineering Center of the USACE simulates rainfall-runoff processes for the tributary watershed to the Lower Cache River. The HEC-HMS model for the Lower Cache River watershed was prepared based on an earlier HEC-1 model developed by the ISWS. The present model was updated by calibrating and validating the model with recently collected ISWS hydrologic data. The model was used to compute runoff from tributary watersheds for 1- to 100-year storm events. Outputs from the HEC-HMS model for the different storm events then are used as inputs to the One-Dimensional Unsteady Flow through a Full Network of Open Channels (UNET) model. The UNET model for the Lower Cache River initially was developed by the St. Louis District and previously had been used by the ISWS for a research project on Big Creek. The UNET model is capable of modeling the complex hydraulics of the Lower Cache River where flow directions change over time. The UNET model was used to route flows through the Lower Cache River under different storm events and boundary conditions at the east and west outlets. Development of the current version of both models and their applications are discussed in this paper.

CALIBRATION AND VALIDATION OF HEC-HMS MODEL FOR BIG CREEK WATERSHED

The ISWS operates two raingages and two streamgages in the Big Creek watershed . Hourly precipitation and streamflow data since 2001 are available for calibration and validation of the Big Creek watershed HEC-HMS model using the SCS method for runoff simulation in this study. A storm event in September 2001 was selected for calibration purposes, and calibration results are shown in Figure 2 where the simulated runoff is compared to the observed streamflow at gaging station 502 on Big Creek. The simulation matches the observed data very well with less than 1 percent error on the peakflow and less than 5 percent error on the total runoff.

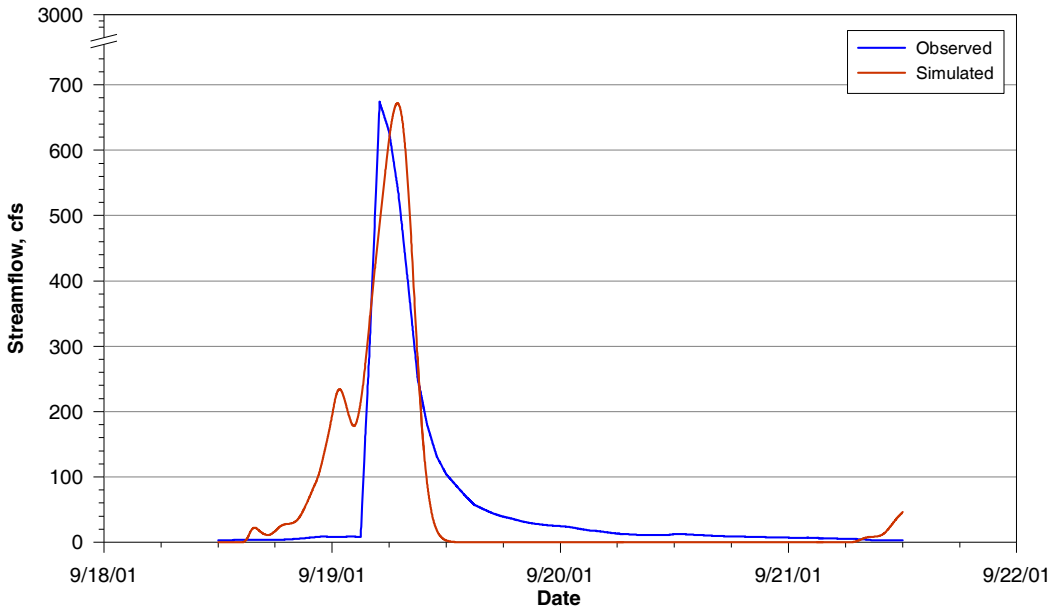

Figure 2. Comparison of simulated and observed flows at gaging station 502 of Big Creek for storm event in September 2001 for calibration of HEC-HMS model.

Calibrated model parameter values including the Curve Numbers then were validated by comparing simulated runoff and observed streamflow for a rainstorm event in January 2003 (Figure 3). As shown in Figure 3, the model reproduces the observed flows with less than 5 percent error on the peakflow and less than 10 percent error on the total runoff. The calibrated and validated HEC-HMS model then was used to generate runoff hydrographs for storm events of different frequencies and durations generated based on the third quartile of the Huff rainfall distribution (Huff and Angel, 1989). Runoff hydrographs for the tributary watersheds for storms with 1- to 100-year return periods were generated using the HEC-HMS model. These results then are used as input to the UNET model.

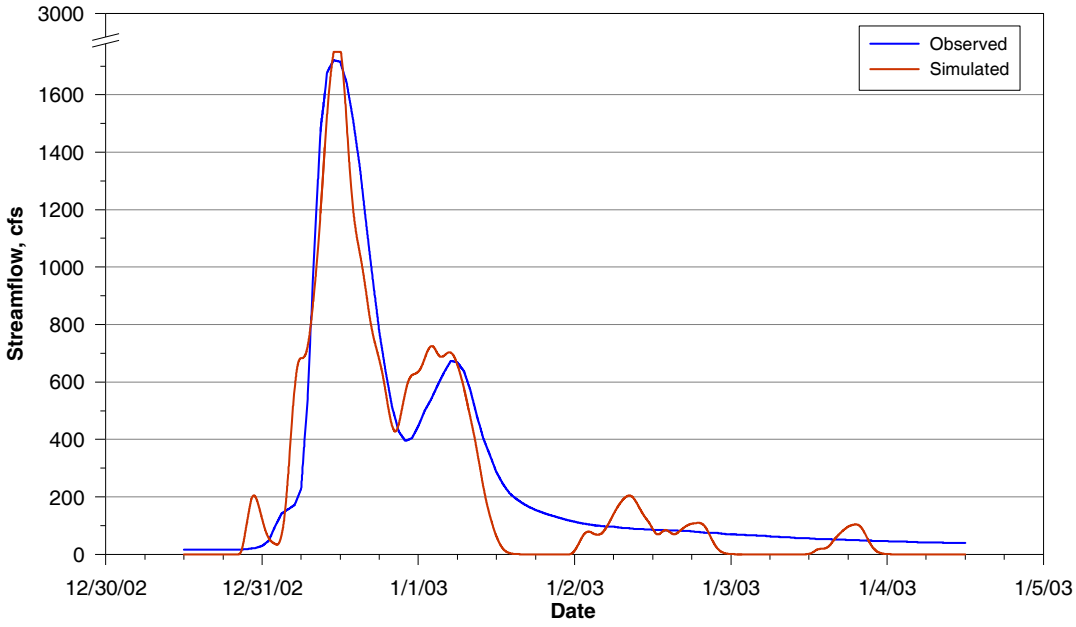

Figure 3. Comparison of simulated and observed flows at gaging station 502 of Big Creek for storm event in January 2003 for validation of HEC-HMS model.

HYDRAULIC MODEL DEVELOPMENT AND APPLICATION

In situations where the flow hydraulics are complex, resulting in reverse flows, and where the channel slopes are very low, analyses of hydraulics of flow use an unsteady flow, dynamic wave routing model. The UNET model (USACE, 1997), developed and maintained by the USACE, was chosen as the tool to analyze flow dynamics in the Lower Cache River. The USACE, St. Louis District developed several sets of data for use in UNET modeling of the Lower Cache River, including cross-sectional data of the channel and floodplain geometry (USACE, personal communication, 2000). For this study, the UNET data files from the St. Louis District were updated with new input hydrographs generated from the new HEC-HMS model. Even though no additional surveying was conducted outside the dredged segment of the river, some channel and floodplain cross sections have been extended based on DEM data to contain the 100-year flood elevations. New channel cross sections were used for the segment of the river dredged in 2005 based on survey data provided by Shawnee Survey and Consulting, Inc., which was contracted by the IDNR.

A schematic of the whole Lower Cache River as represented in the UNET model is shown in Figure 4 and includes the important features in the UNET model. Flood stages in the five reaches identified in Figure 4 are affected by different control structures and flow inputs.

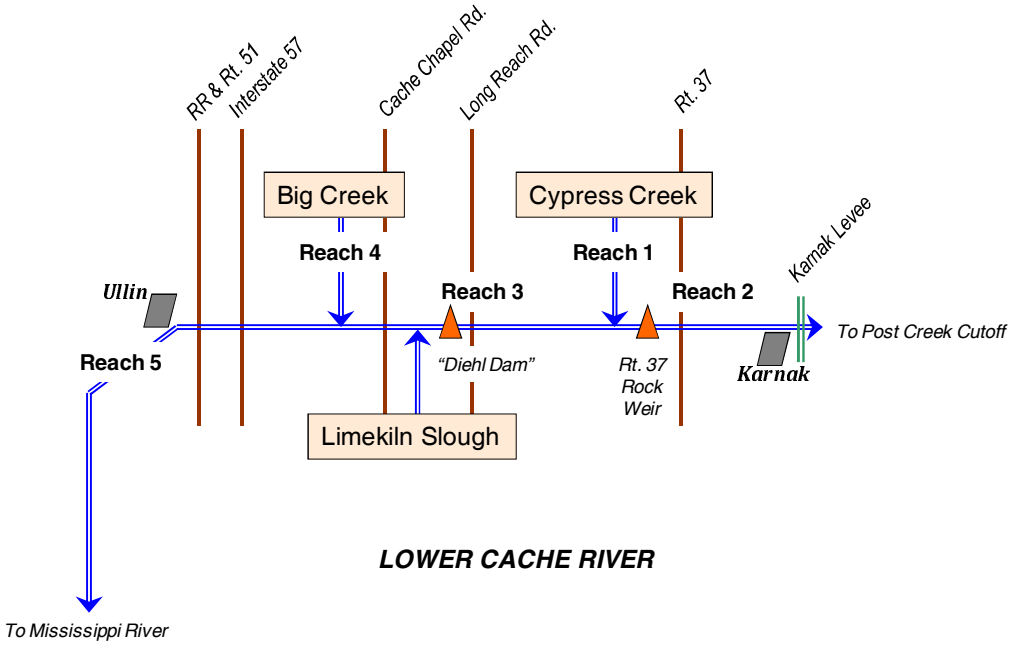

Figure 4. Schematic of UNET model for Lower Cache River.

Boundary Conditions for UNET Model

Boundary conditions for the Lower Cache River UNET model have to be defined for the confluence of Lower Cache River with the Mississippi River and the junction of the Lower Cache River with the Upper Cache River at Karnak Levee. Table 1 gives water surface elevations for 2-, 10-, and 100-year floods for the Mississippi River from the USACE Upper Mississippi River flood frequency study (USACE, 2004). In order to obtain the water surface elevations for different frequency floods at the junction of the Upper and Lower Cache River, flood frequency analysis was conducted for the Upper Cache River. The water surface elevations for the 2-, 10-, and 100-year floods at the junctions of the Lower Cache River with the Upper Cache River at Karnak Levee outlet/breach based on the frequency analysis are given in Table 1.

Table 1. Boundary Conditions for UNET Model.

Return period	*Mississippi River elevation at confluence with Lower Cache River*	*Upper Cache River elevation at Karnak Levee outlet/breach (ft-msl)*
2-year	318.20	319.00
10-year	325.20	334.05
100-year	331.40	341.51

SUMMARY OF RESULTS AND CONCLUSIONS

Hydrology and hydraulics of the Lower Cache River were investigated intensively by updating hydrologic and hydraulic models previously developed by the ISWS and the USACE, St. Louis District.

The two models then were used to evaluate selected scenarios in four categories: 1) reference/base condition (prior to levee breach); 2) current condition (with levee breach); 3) future alternatives; and 4) future alternatives with reconnection. The reference/base condition refers to the condition when the hydrology of the Lower Cache River was controlled on the east end by Karnak Levee with two 48-inch (1.22 m) gated culverts that prevented flow from Post Creek Cutoff into the Lower Cache River and by in-channel structures at Route 37 and "Diehl Dam" west of Long Reach Road. Because this condition was in existence for many years and had been agreed to by the drainage district and State of Illinois as acceptable drainage and water level management in the Lower Cache River, it was used as a reference for all other conditions and alternatives.

The current condition refers to conditions as they are now where a major change from the reference/base condition is the breach at Karnak Levee and the absence of the two 48-inch (1.22 m) culverts. The current condition will allow floodwaters from Post Creek Cutoff to flow back into the Lower Cache River. Both "Diehl Dam" and Route 37 Rock Weir are assumed to be in place.

Future alternatives refer to management alternatives under consideration by the JVP. The two main features include moving "Diehl Dam" 2,800 feet (853 m) west of its current location and installing an East Outlet Structure with stop logs in front of three 72-inch (1.83 m) gated culverts through Karnak Levee. This outlet structure will maintain low water elevations at desirable levels, allow increased outflow to Post Creek Cutoff during flood events, and prevent flow from Post Creek Cutoff into the Lower Cache River. Partial reconnection alternatives refer to future alternatives that re-establish the connection between the Upper and Lower Cache Rivers by diverting some flow from the Upper Cache River into the Lower Cache River. Under each of these four major categories, several different scenarios with different combinations of flood events and boundary conditions were evaluated.

For the reference/base condition, 100-year flood profiles were computed and mapped for eight different combinations of flood events and boundary conditions. For current conditions, seven different combinations of flood events and boundary conditions were evaluated and compared to the reference/base condition. Reconnection alternatives evaluated diverting water from the Upper Cache River under the reference, current, and future alternatives. Diversion of 200, 400, and 800 cubic feet per second or cfs (5.7, 11.3, 22.7 cu m/sec) was considered, and a combination of elevations for the East Outlet Structure and West Rock Weir were evaluated. All these alternatives are discussed in detail in the report by Demissie et al. (2008).

Based on analysis of all of these scenarios with different combinations of flooding, structural changes, and boundary conditions, the findings can be summarized as follows:

1) The current condition exposes the Lower Cache River corridor, especially the eastern portion, including the community of Karnak, to more flooding during major floods, such as 100-year or greater floods from the Upper Cache and Ohio Rivers. However, the current condition improves flood drainage for some parts of the area during more frequent 1-, 2-, and 5-year floods.

2) Installing the East Outlet Structure with stop logs and three or more 72-inch (1.83 m) culverts will lower flood elevations from the reference condition for the portion of the river east of Karnak Road Bridge, including the community of Karnak, because of increased outlet capacity of the larger culverts.

3) Moving "Diehl Dam" 2,800 feet (853 m) from its current location under current conditions will increase the area flooded by the 100-year flood by only 8 acres (3.2 ha). The additional acres flooded are distributed in small increments throughout the Lower Cache River floodplain. Water levels in the stream channel between current and proposed locations will be higher than the current condition during low- and moderate-flow conditions.

4) Partially reconnecting the Lower Cache River with the Upper Cache River by diverting some flow from the Upper Cache to the Lower Cache River will not increase flood elevations during major floods such as a 100-year flood but will raise flood elevations during more frequent 1- and 2-year floods. During low- and moderate-flow conditions, reconnection will not cause flooding, but will create slow-moving westerly flow in the Lower Cache River that does not exist under the current condition. More detailed cross-sectional surveys will be necessary to model low- and moderate-flow conditions more accurately, and the reconnection option should use an adaptive management approach that allows adjustments based on observations.

The Mississippi River: A National Resource

Nani G. Bhowmik, Ph. D. P.E., F. ASCE, D. WRE
Principal Scientist Emeritus, Illinois State Water Survey
Institute of Natural Resource Sustainability
University of Illinois, Urbana-Champaign, IL.

Abstract: The Mississippi River with its tributaries is the third largest river of the world. The river drains about 40% of the continental Unites States. The main stem of the river is about 3,500 km long travelling from Minnesota in the north to the Gulf of Mexico in the south. During this travel the river crosses also through 10 states. The present day river was formed during the last glacial melt, consequently the present day size and shape is too large for the flow and the sediment load. Thus the river valley has been filling up with sediments. For identification and management purposes the river has been divided into two segments, Upper Mississippi River and the Lower Mississippi river. The Upper Mississippi River extends from its headwater to its confluence with the Ohio River near Cairo, Illinois. Upper Mississippi River does not include Missouri River for management purposes even though the Missouri river do come and join the main stem of the river upstream of St. Louis. The river is also the main inland transportation artery of the United States. Over the year the river and its watershed has altered significantly. Currently, the Mississippi River States, the Federal Government and many no-governmental entities are working together to enhance the ecosystem of this great river.

The Basin

The drainage basin of the Mississippi River is shown in Figure 1. The total drainage area of the basin is about 3 million sq km. The Mississippi river was not always the major river in North America, Dobney (Undated). The river assumed its present form after the ice age. Before the ice age, the river probably followed a different path than one it occupies today. During the movement of ice sheet, the Missouri and Ohio rivers became ice marginal streams flowing along the leading edge of the glaciers. Subsequently these two ice marginal rivers came to a halt at the leading edge of the ice and thus were permanently absorbed by the Mississippi River. In Geologic times, the river has been filling the lower part of the country. As a matter of fact, the Mississippi River valley below its confluence with the Ohio River is called the Mississippi River delta. The deltaic region covers about 90,000 sq km areas extending over 219 counties of the Middle America.

For management purposes, the River is divided into two parts, The Upper Mississippi River from the headwaters to its confluence with the Ohio river and the Lower Mississippi river from Ohio river confluence to the Gulf of Mexico. Below its confluence with the Ohio river, it is sometimes called ‘poised’ stream, that is it has not shown much aggradation or degradation.. The river is flowing on the lowest valley slope, which it has attained over the last 2,000 years or more.

The Mississippi river is the third largest river of the world behind Congo and Amazon and its basin covers as area fourteen times that of Rhine. The river has more than 50 navigable tributaries with about 24,000 km of navigable streams and thousands of un-navigable stream km. The river either traverses or borders 31 states, making it truly a national resource. Figure 2 shows a photograph of the headwater of the Mississippi River at lake Itasca in Minnesota.

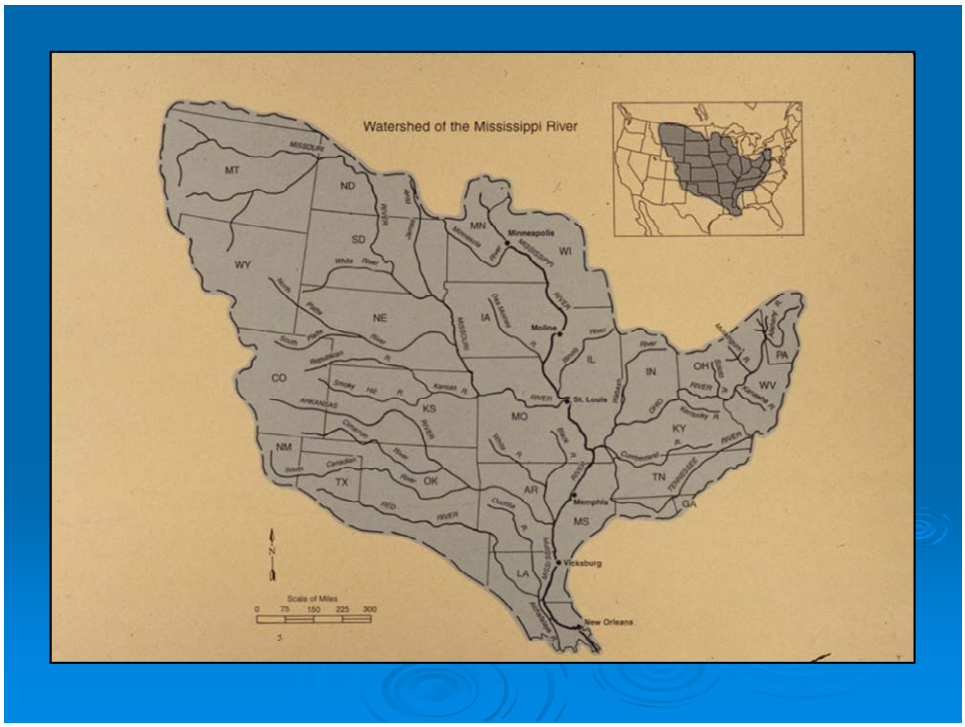

Figure1. Drainage Basin of the Mississippi River

Climate

These materials after Wendland (See Bhowmik et al, 1995). The Mississippi River flows from Minnesota to Louisiana, from a northern region with wet summers to a southern region that is wet all year without snow. In the northern region, winter daytime temperature occasionally rises above the freezing point, whereas in the south, winter nighttime temperatures only occasionally drop below freezing point. The frost free season in Minnesota is limited to about 150 days, varying form 120 to about 180 days, whereas at the mouth of the river at the Gulf of Mexico the frost free season is 290 days, varying from 230 to 345 days.

As might be expected, precipitation is substantially greater in the southern reaches than in the north. Average precipitation near the mouth is about 1,600 mm, whereas in the middle reaches it is about 1,000 mm and in the north is about 760 mm.

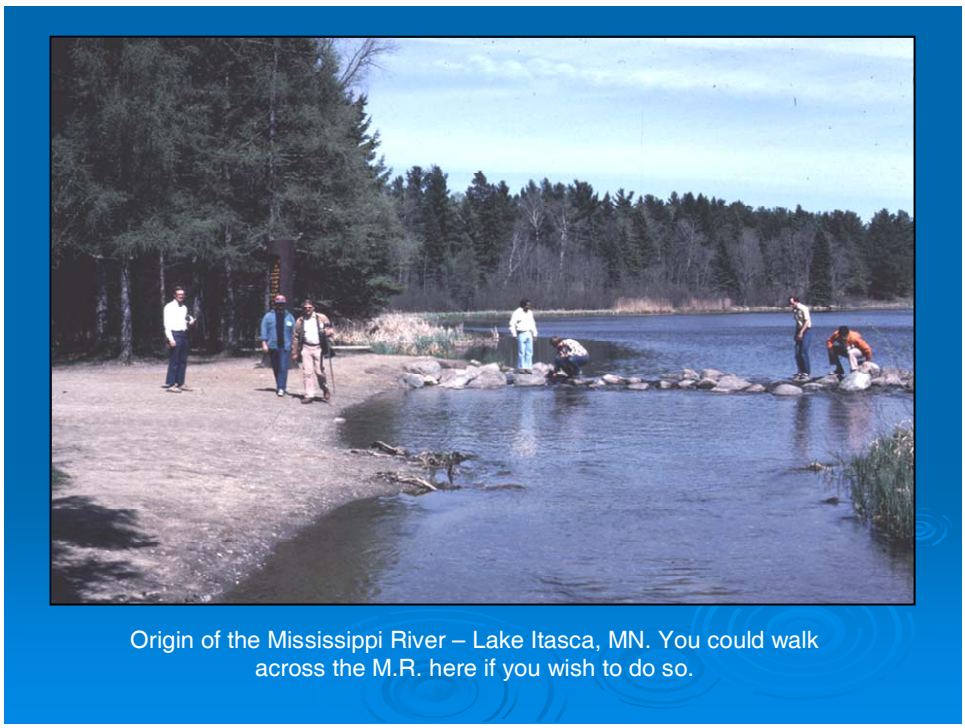

Figure 2. Origin of the Mississippi River in Lake Itasca, Minnesota

Agricultural Land

The Mississippi River with its major tributaries also contains most of the prime farmland in the country. Many wetlands on and along the basin has been drained to make them suitable for farming. Figure 3 shows the percent of farmland at locations throughout the United States. A close examination of this figure will show that this river valley and most of its tributaries essentially contain most of the prime farmland of the United states.

Similarly, as mentioned earlier most of the wetland along this river basin was drained for farming. This is quite predictable since the highly productive Mississippi River valley contains most of the 'hydric' soils, a major characteristic of wetlands that had to be drained for agricultural purposes. For example, in Iowa about 11% of the land that used to be wetland in 1780, has now about 1% wetland in 1980, Knapp (see Bhowmik et al, 1995).

Population

Within the main corridor of the Mississippi River, roughly 12 plus million people live and work producing more than $7 billion worth of agricultural and forest products and approximately $29 or more billion worth of manufactured goods. About 5% of the US population lives within this river corridor not including the drainage basin.

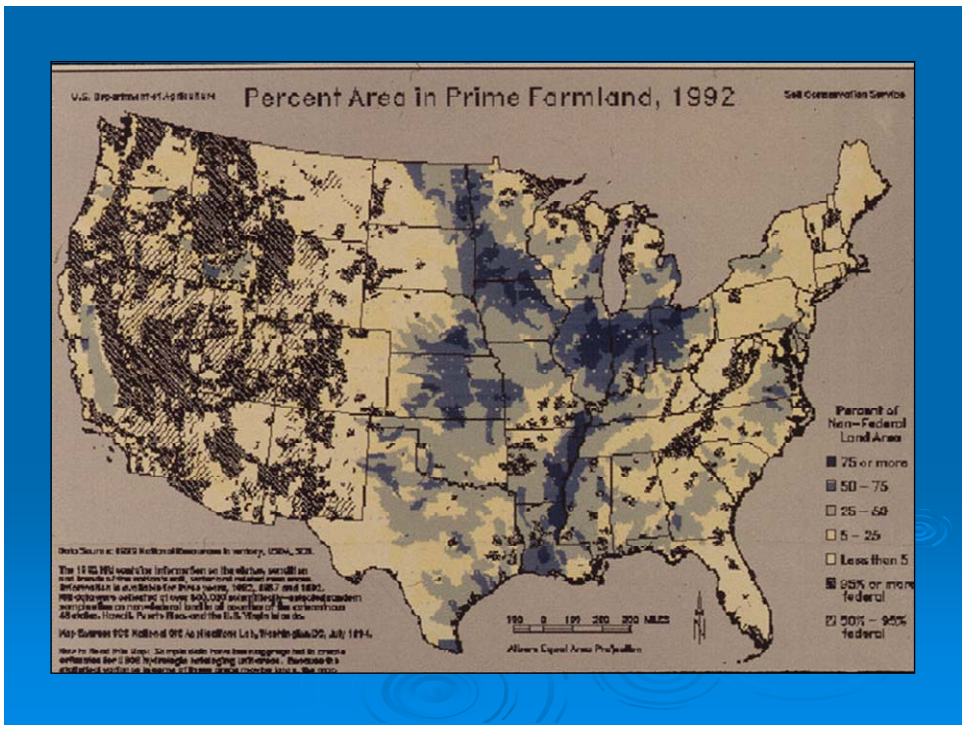

Figure 3. Percent of Prime Farmland in the USA

Navigation

The entire main length of the Mississippi River and its major tributaries such as, the Illinois, Missouri, Ohio, White, Yazoo, Ouchita, and Red Rivers is used extensively for commercial navigation. Significant amount of recreation navigation also takes place on all of these major rivers and many of its tributaries. The navigation system on the Upper Mississippi, Illinois, Ohio and few other tributaries is accomplished with a system of Locks and Dams. The Lock and dam system on the Upper Mississippi River is depicted in Figure 4.

Most of the Lock and dams on the Upper Mississippi River, Illinois River were constructed in late 1930s. The goals of these Locks were to maintain a low water depth of 2.75 m. The majority of the Locks and Dams are kept wide open during the flood periods thus the river behaves as an open waterway during those periods of time. Commercial traffic on the main stem of the Upper Mississippi River and Illinois River normally consist of a flotilla of Barges three wide and five long pushed by a tow boat. When fully loaded this flotilla could occupy an area 32 m wide, 335 m long with a draft of 2.75 m.

These Barge flotilla could move about 18 m/sec in the downstream direction and about 10 m/sec in the upstream direction. Movement of such a huge body within the Upper Mississippi and especially the narrower and shallower Illinois River is associated with significant amount of hydraulic and sediment related effects.

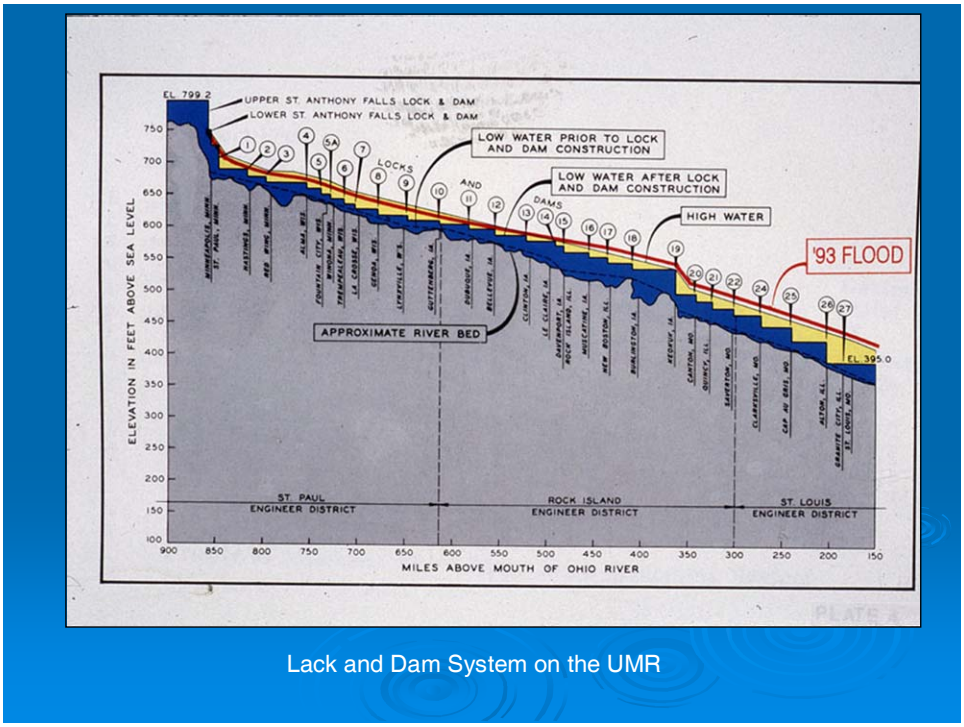

Figure 4. Lock and dam System on the Upper Mississippi River with the 1993 Flood Levels

The movement of barges generally will create waves, re-suspend sediments, create drawdown, make lateral change in the velocity distributions and sometimes generate lateral flows near the shorelines. Depending upon the size, speed, draft and direction of the barges, sometimes the return flows could be in the upstream direction when a heavily loaded barge flotilla moves at a high speed in the downstream direction. The Author with several associates have done tremendous amount of research in this topic and some of those results are being utilized now for the formulation of ecosystem restoration and navigation sustainability on the Upper Mississippi River and Illinois River.

Within the main stem of the Mississippi River below St. Louis, The Missouri River, and at few other river segments, the navigation is accomplished through the construction of river closing structures, wing dams and river training structures. All of these areas are designated as open river system.

In late 1990s, the river provided significant amount of U.S. grain export to other countries. With its multitude of tributaries, the river also provides facilities for thousands of miles of recreational boating, canoeing, fishing, camping and other outdoor activities. It is estimated that visitors spend more than $10 billion on the main corridor for various recreational activities.

Flows and Floods

A companion paper will go into details of flows and floods especially on the Upper Mississippi, Illinois and Missouri Rivers. Some mention is made here on the Great flood of 1993 on the Mississippi, Illinois and Missouri Rivers. The midsection of the Mississippi River especially that portion bordering the State of Illinois also was subjected to flooding during the spring of 2008. The 1993 flood was by far the largest measured flood on the Upper Mississippi River. During this flood extending more than 5 months near St Louis did impart a loss of $12 billion. However, flood control measures implemented over the years also save damages to the tune of $19 billion.

River Morphology

The Great floods such as the one that occurred in 1993 is also associated with some morphological changes within the main stem of the river. The Mississippi River attempted to shorten its length near the confluence with the Ohio River. This area is called the Dog Tooth Bend area. During the height of the flood a levee called, Len Small Levee was breached and in the ensuing days water started to flow through the breach. Finally the breach was as much as 1,600 m wide and some areas as much as 33 m deep. At the height of the flood about 20% of the Mississippi River flow was passing through this breach. This amounted to about 5,600 cms.

Figure 5. Areal View of the Levee Breach Near the Miller City at the Height of the 1993 Flood on the Mississippi River

Figure 5 shows an areal view of the levee breach at the height of the flood near the Dog Tooth Bend on the Mississippi River. This breach is located near the Miller City in Illinois close to the Ohio River. Fortunately the river was not successful to recreate a new channel at this location since the flow started to decrease. If the River was successful to recreate this new channel, it would have shortened the river from about 32 km to 10 km increasing the gradient accordingly. With this increased gradient, the velocity would have increased substantially making normal navigation much more difficult.

Erosion

As mentioned previously, the Mississippi River valley contains some of the important prime farmland in the USA. A plot of the sheet and rill erosion of the USA, will show that the so called "bread basket" of USA, i.e., the Central USA, is also subjected to highest erosion rates. In many instances the soil erosion rates exceeds the so called 'soil tolerance values'. However, since 1930's Best management Practices have been implemented on agricultural lands with a goal to reduce the erosion rates to soil tolerance values.

It is also a known fact that severe erosion will take place during extreme flooding events. The Great Flood of 1993 was no exception to this concept. For example, in Iowa, about 20% of the State lost more than 5.7 tons /hectares of top soil compared to a soil tolerance value of 1.9 tons/hectares. Most of the erosion occurred on the agricultural land as sheet and rill erosion and within rivers as bank erosion or cutting off of old meander loops or creation of new meanders.

Summary

The Mississippi River with all of its tributaries is the third largest river in the world. The river also drains about 40% of the continental USA with a small portion of Canada. The River is about 3,500 km long and traverses or borders 31 States. The present day Mississippi River resulted from the ice melt after the last glacier melted.. The river is divided into two Segments, Upper Mississippi River and Lower Mississippi River. This river basin also contains most of the prime farmland of the USA. The river is also a major navigation artery of the USA. Most of the grains that are transported for export do also pass through this river. The navigation traffic which is important for the economic well being of the country do also have some hydraulic and ecological impacts on the river.

The River, covering about 40% of the continental USA play an important role in the national scene. The river is also used extensively for recreational purposes. The river is also subjected to extreme natural variations from floods to droughts. The great Flood of 1993 on the Upper Mississippi, Missouri and Illinois River covered substantial portion of the mid-west. This flood was also associated with some morphological changes and surface and river erosion. Sediment deposition was also a major impact of the great flood.

With its numerous tributaries, the Mississippi River is a significant lifeline of the USA. The river also played an important role in the migration of population, music, art, transport of goods, cross cultural exchanges and an integrating force of the country. The river played and will play a significant role in the well being of the USA. The river is a true National Resource of the Country.

ABSTRACT

The Mississippi River is one of the world's truly great working rivers (Upper Mississippi River Conservation Committee, 2000), not only in terms of the essential services it provides to the nation (transportation, water resources, and hydroelectric power) but also in terms of its biological diversity and richness, and the ecosystem services (recreation, fisheries, carbon sequestration, water quality improvement, and sediment management) it provides to citizens throughout its watershed. Despite more than two centuries of intensive management and control, the Mississippi and its floodplains and tributaries still support diverse, globally-significant populations of aquatic and terrestrial species, many of which are threatened or endangered, and some of which are unique to the Mississippi River basin.

The Nature Conservancy is working with diverse partners from industry, government, and the natural resource community to develop an integrated "source to sea" conservation program based on ecologically sustainable management principles. This paper will discuss key aspects of Conservancy work with floodplain restoration and reconnection, hydrologic restoration, sediment and nutrient reduction, stream channel restoration, sustainable agriculture, and the USACE's Navigation and Ecosystem Sustainability Program at diverse sites including Boone River IA; Pecatonica River WI; Mackinaw River, Emiquon, and Spunky Bottoms IL; Big Woods and Cache River AR; and Mollicy Farms and Atchafalaya Basin LA

INTRODUCTION

At 2,320 miles, the Mississippi River ranks among the largest of the world's rivers, draining all or parts of 31 states and two Canadian provinces. It is a vital migration corridor for 60 percent of North America's bird species and provides critical habitat for a high diversity of fish and mussels as well as rare creatures like the Louisiana black bear and the elusive ivory-billed woodpecker. The river's delta—an area of land and water that links the river to the Gulf of Mexico—is one of the most ecologically rich places on Earth. The Mississippi has nurtured human life for more than 12,000 years. Native Americans and European settlers alike were drawn to

its shores by fish, game, fertile soils and dense forests. Today the river continues to play a vital role in the well-being of human communities who depend on it for water, food, jobs, transportation and recreation. It provides drinking water to 18 million people, links agricultural producers to markets around the world and provides hunters, anglers, boaters and other outdoor enthusiasts with exceptional recreational opportunities.

THREATS

Over time, the Mississippi has been altered in ways that are endangering its health and vitality. Once a vibrant body of water in harmony with its surroundings, the river has been extensively modified during the last century by locks, dams and levees. In most places, the river no longer inundates its floodplains during high water periods, contributing to a decline in the abundance and diversity of plant and animal life. With fewer flooded wetlands to filter the river's flows, increased run-off of excess nutrients and sediment has reduced water quality. Conversely, because of altered water flows into the Gulf of Mexico, coastal estuaries are being starved of needed sediment and a dead zone in the Gulf, where little plant and animal life survives, is increasing. The Mississippi River's delta loses 25 square miles every year, making it the fastest disappearing habitat in the world. Marshes, wetlands and islands protect coastal communities like New Orleans from flooding and storm events. If not conserved, scientists estimate that 20 percent of Louisiana's remaining wetlands will disappear completely in the next few decades. Coastal cities will be more at risk of catastrophic natural events, plants and animals will be lost and people's livelihoods will be impacted. The economic repercussions of lost fisheries alone are estimated at $500 million per year.

STRATEGIES

Working at local, state, regional and national levels with public agencies, private landowners, corporations and non-government agencies, the Lower Mississippi River Program is implementing diverse conservation strategies throughout the Mississippi Basin that include:

- *Water Quality Improvement* by promoting best management practices that reduce water-polluting runoff and sedimentation, through the use of expanded incentives and targeted education;
- *Ecologically Sustainable and Compatible Forestry* through reforestation of private lands and developing carbon sequestration projects throughout the region;
- *Restoration of Altered Hydrology* by working with the U.S. Army Corps of Engineers and other natural resource managers to stabilize river channels and reestablish the natural flow and function of key Mississippi River tributaries;
- *Reconnection and Restoration of Floodplains* through bottomland hardwood forest and wetland Restoration to reconnect blocks and corridors of forested land large enough to sustain native species and the natural ecological processes that keep them alive, by supporting federal incentive programs. for

forest and wetland protection, acquiring and restoring land and providing technical assistance to public and private land managers; and

- *Application of Natural Channel Design and Ecologically Compatible River Restoration and Stabilization* to soften the ecological impact of channel engineering and stabilization projects and to increase the diversity of in-channel and riparian habitats created during river stabilization and restoration activities.

CONSERVATION THAT WORKS FOR ALL

The Nature Conservancy has 50 years of conservation experience in the Mississippi River basin. Today, teams in 10 states are working in more than 30 priority project areas to address some of the river's most critical threats including habitat loss and incompatible land use. Application of conservation strategies such as reconnecting the river with its floodplain at places along the Mississippi and Illinois rivers, reforesting bottomland hardwood forests along rivers in Arkansas and Louisiana, and collaborating with partners on restoration of the Mississippi River delta and working with farmers to identify sustainable approaches to land use are paying economic and ecological dividends. Acquisition of land and conservation easements, working with private landowners on voluntary land management practices, partnering with state and federal governments and programs, and building support for the river—at both the highest levels of government and the community level—remain key components of the Conservancy's lasting conservation work. The Conservancy is also exploring market-driven approaches to habitat protection and restoration. Forests, wetlands and other habitats provide valuable services to humanity, including storing flood waters, keeping pollutants and sediment out of rivers and removing carbon dioxide from the atmosphere. Conservancy staff are analyzing the potential financial returns to landowners of adopting land uses aimed at the production of ecosystem services such as sustainable timber, recreation and nutrient retention rather than marginal agricultural activity. Issues impacting the Mississippi River—including habitat loss due to expanding crop production and urban development, impacts of hydropower, potential for carbon storage, restoration of water quality and conservation of biodiversity— link it to other great rivers around the world. Through the Great Rivers Partnership, an effort to advance conservation of large rivers, the Conservancy is collaborating with universities, government agencies, private businesses, landowners and other non-profit entities to share its science expertise and knowledge about the Mississippi River to accelerate progress on a local, regional and global scale.

TOWARD A SUSTAINABLE FUTURE

For centuries, the Mississippi River has pulsed through America's heartland, supporting an abundance of plants and animals and enriching human lives and livelihoods. Competing interests for use of the river and its lands have altered the river's seasonal flows, diminished water quality and caused species and habitat declines. But, with human interest, resources and ingenuity invested in conserving the

river, the wildlands that remain can still be conserved and hundreds of thousands of acres can be restored. The Conservancy's Mississippi River project is bringing people together to restore the health and vitality of this mighty waterway, a river that is so much a part of who we are as a nation and who we can become.

Abstract
The historical reconstruction of hydroclimate conditions over Sabah and Sarawak states of Malaysia was performed as a first step for the assessment study of climate change impact on water resources. The outputs of ECHAM5 GCM simulation from Max Planck Institute for Meteorology of Germany were downscaled to fine grid resolution data by means of a Regional Hydroclimate Model (RegHCM). The RegHCM, which is a coupled non-hydrostatic atmospheric and upscaled land surface process model, has been customized for Sabah and Sarawak region. A sequence of three model domains, respectively at 81km, 27km, and 9km grid resolutions, was used. The GCM output datasets in the 200-300 km spatial resolution during the historical period of 1970-2000 were downscaled into the 9 km grid resolution that is required for water resources analysis at the watershed scale. The detailed soil and land cover maps provided by Malaysian government have been processed for preparation of required model parameters: such as, roughness height, emissivity, albedo, leaf area index (LAI), soil hydraulic conductivity, and soil rooting depth. Sea surface temperature data in the GCMs was used in the downscaling exercise in order that the historical simulations are consistent with corresponding future simulations.

INTRODUCTION

A Regional Hydroclimate Model for Sabah and Sarawak (RegHCM-SS) has been developed and is being applied to the region of Sabah and Sarawak in order to downscale the available global historical atmospheric databases and global climate change databases (ECHAM5 GCM simulations data from the Max Planck Institute for Meteorology of Germany at a grid resolution of 1.85 degree by 1.85 degree) that are at very coarse resolution, to Sabah and Sarawak at fine spatial resolution of 9km by 9km.

The main objective of this study is to carry out a detailed study on the expected changes in the hydrologic regime and water resources at Sabah and Sarawak region of Malaysia that result from the global change of climate and also due to local landuse change. Development of a regional hydrologic/atmospheric hydroclimate model of Sabah and Sarawak (RegHCM-SS), and the preliminary hydrometeorological results from the downscaling of the historical control runs' results from the ECHAM5 Global Climate Model to the Sabah and Sarawak region by the RegHCM-SS are described in this paper.

The RegHCM-SS consists of two major model components: 1) a mesoscale atmospheric model component, and 2) a regional land surface hydrology model component (Chen et. al. 1996; Kavvas et. al. 1998). The atmospheric model component

of the RegHCM-SS is MM5 (the Fifth Generation Mesoscale Model) from NCAR (US National Center for Atmospheric Research). MM5 is a nonhydrostatic model which can be downscaled even to 0.5km spatial resolution, which makes it very desirable for downscaling climate study results to the scale of watersheds. As such, it is then possible to capture the effect of steep topography of Sabah and Sarawak at watershed scale (spatial resolutions <10km) on the local climatic conditions. In the RegHCM-SS, the land hydrology model is based on upscaled hydrologic conservation equations (Chen et. al. 1993; Chen et. al., 1994a,b). The land hydrologic processes in RegHCM-SS are linked to the atmospheric processes through a landsurface-atmospheric boundary layer module.

Regional Hydroclimate Model (RegHCM) of Sabah and Sarawak is run first with its initial and boundary conditions provided from the ECHAM5 GCM historical control runs' atmospheric data at an outer domain, covering the whole Sabah and Sarawak region and the surrounding areas, to be called "outer domain". Then, RegHCM is run over the inner domain with its initial conditions coming from ECHAM5 GCM control runs' atmospheric data, interpolated at 9 km, while its boundary conditions are provided from the simulation results of the outer domain RegHCM simulations during the historical period. The simulations of the inner domain RegHCM with these initial and boundary conditions provide comprehensive atmospheric data (precipitation, air temperature, radiation, wind, relative humidity, evapotranspiration) at 9 km spatial grid resolution at 1 hr time intervals.

The model parameters for the regional land surface hydrology model component of the RegHCM-SS are being updated by the newly-obtained datasets from the National Hydraulic Research Institute of Malaysia (NAHRIM). The new datasets include most recent vegetation cover and land use information of Sabah and Sarawak, soil survey data of Sabah and Sarawak, and grid based DEM at 3-arc-second spatial grid resolution (approximately 90 meters) derived from the SRTM datasets.

Reconstructed historical hydrometeorological conditions, simulated by the RegHCM-SS are discussed in this paper.

MODEL CONFIGURATION

MM5, as the atmospheric component of RegHCM-SS, is used to downscale global scale atmospheric data to the region of Sabah and Sarawak through several nesting procedures. The model configuration of RegHCM-SS is discussed in this section.

Mercator map projection is used in the updated RegHCM-SS. Horizontally, a nest of three model domains, respectively at 81km, 27km, and 9km grid resolutions, were used. Inner domain has 136 x 91 grids with a grid size of 9 km x 9 km. The inner domain of the updated RegHCM-SS encompasses the entire Sabah and Sarawak region and a portion of the northern section of the Borneo Island. In the vertical direction, the MM5 model for Sabah and Sarawak region has 23 sigma layers for both outer domain and inner domain. The top pressure level was chosen to be 20 mb.

The time interval for the output from the MM5 model can be chosen according to the needs of the RegHCM's hydrologic model component. In this project, we chose one-hour as the precipitation input time interval for the RegHCM-SS. Therefore, the MM5 model outputs were also in one-hour intervals.

MODEL INITIAL AND BOUNDARY CONDITIONS

RegHCM-SS requires atmospheric boundary conditions and initial conditions in order to simulate atmospheric processes and hydrologic processes in a geographical region. In this study, the ECHAM5 GCM historical control runs' atmospheric data sets provide the outer domain RegHCM-SS (MM5) with its initial and boundary conditions during its simulation of the historical atmospheric conditions over the Sabah and Sarawak region during the January 1993- December 1999 period.

A program has been developed to compile ECHAM5 GCM control runs' atmospheric data files and to retrieve the gridded data that cover the Sabah and Sarawak region. MM5 receives its boundary conditions from the ECHAM5 data set that has a grid resolution of 1.85 degrees. The atmospheric 3-D data set and the 2-D data set that the MM5 model requires for its boundary and initial conditions were retrieved from the ECHAM5 data sets. The ECHAM5 data sets provide 3-D temperatures, 3-D wind vectors, 3-D relative humidity, 3-D geopotential heights, 2-D surface pressures, etc. at every 6 hours. The MM5 model's boundary data on its outermost row of points were obtained by direct interpolation from the ECHAM5 data sets at 6-hour intervals. The initial conditions of MM5 were also obtained by direct interpolation from the ECHAM5 data sets.

MODEL PARAMETERS

Like many other physically based atmospheric-hydrologic models, RegHCM relies heavily on GIS data, such as soils, vegetation, land use/land cover, and topography in order to estimate its parameters. The following local data sets have been used in this study:

i) Malaysia Department of Agriculture (DOA) data on the region's vegetation and land use covers in a vector coverage format;
ii) Malaysia Department of Agriculture (DOA) data on the region's soils in a vector coverage format.

The roughness length and albedo parameter maps for RegHCM's inner domain at 9km resolution were constructed using both Malaysia DOA land cover dataset and USGS land cover dataset. The soil hydraulic parameter maps of saturation soil water content (porosity), residual water content, bubbling pressure head, pore size distribution index, mean saturated hydraulic conductivity, variance of saturated hydraulic conductivity, and soil depth were developed based on the Malaysia DOA soil dataset and the FAO soil dataset, USDA soil texture classification, and Brooks and Corey's hydraulic parameter relationships. The LAI values and monthly green fractions for RegHCM's inner domain grid mesh were generated from MODIS and NCAR datasets.

MODELING RESULTS AND VALIDATION

In this project phase on the historical simulations with RegHCM-SS, we have reconstructed the historical hydroclimate conditions during the period of January 1993 – December 1999 at hourly intervals at 9-km grid resolution over the whole Sabah and Sarawak region with the newly updated model configuration and model parameters. RegHCM-SS transformed the coarse time-space resolution ECHAM5 GCM historical control runs' atmospheric data during the period of January 1993 – December 1999 to 1-

hour-increment hydroclimate information at 9-km spatial resolution over Sabah and Sarawak region. Due to the limitation of space availability, the output variables of the hydroclimate conditions from the RegHCM of Sabah and Sarawak (RegHCM-SS) include precipitation and air temperature are presented here.

Figure 1 (left) shows the representative simulated distributions of monthly precipitation during January 1999. The black lines that are overlaid on each plot delineate the boundaries of the Sabah and Sarawak region. Figure 1 (right) shows the representative simulated monthly average air temperature. It can be seen that the downscaled model outputs reflect the topographic effect both in precipitation and air temperature distributions.

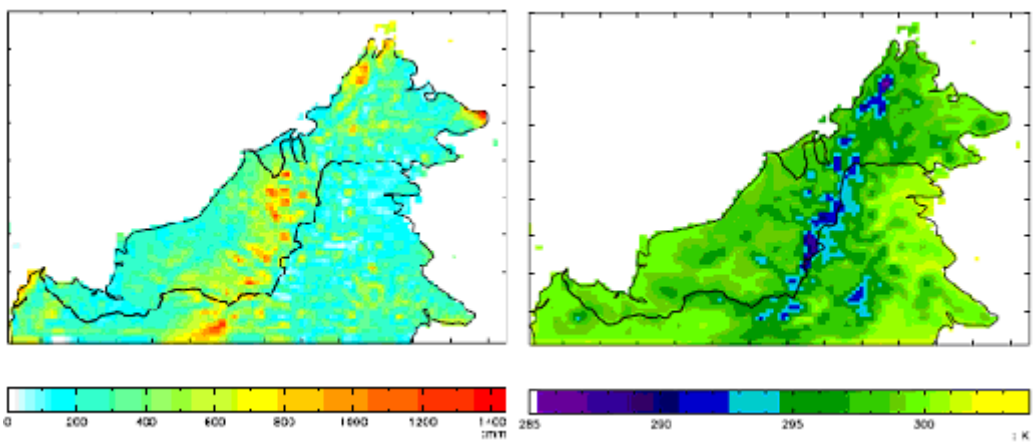

Figure 1 Representative computed total precipitation (left) and mean air tempeature (right) fields over Sabah and Sarawak region during January of 1999.

The computational results of RegHCM-SS during a historical period over the Sabah and Sarawak region were evaluated by comparing them against the observations in terms of rainfall. Although the GCM output of the historical control run was downscaled to the 9 km resolution, the simulated precipitation still is the average over a 9km X 9km grid area which is a much larger control volume than the corresponding observation at the point scale of a ground station. The precipitation field is known to be highly heterogeneous.

Therefore, the direct comparisons between the RegHCM-SS downscaled area-average precipitation over an 81 square kilometer grid area and the observed point location-scale rainfall may not be a good measure of the model performance. Additional two global precipitation databases, GPCP (Global Precipitation Climatology Project) (Huffman et al. 2001) and Willmott data (Terrestrial Precipitation:1900-2006 Gridded Monthly Time Series) (Willmott et al. 1985) were retrieved in order to obtain more appropriate comparisons.

The Global Precipitation Climatology Project (GPCP) quantifies the distribution of precipitation around the globe by merging the data from over 6,000 rain gauge stations, and satellite geostationary and low-orbit infrared, passive microwave, and sounding observations. The advantage of this dataset is the spatial coverage over the ocean because it relies not only on the ground observations but also on remotely sensed

precipitation data. However, the spatial resolution of 1 degree is still very large, and the time coverage of the data is very limited.

The other dataset that was retrieved is Terrestrial Precipitation:1900-2006 Gridded Monthly Time Series. This dataset is called "Willmott data" in this paper. The monthly total precipitation fields were developed by compiling several updated data sources and interpolating to a 0.5 degree by 0.5 degree of latitude/longitude grid. These data are available from 1900 to the present. Figure 2 shows the data points of Willmott data over the Sabah and Sarawak region. In this figure there is no data over the ocean since the dataset is based on the ground observation records.

The three datasets: ground observations, GPCP 1DD, and Willmott data, are compared, and it is found that the data, based upon observations at different spatial scales, result in quite different values. The authors believe that the data that represent averages over a finite-size grid area, such as the Willmott data, are more appropriate for comparisons to the model simulation results that themselves are area-averages, than the point-location-scale data of the ground stations. Consequently, in this study the Willmott data set was used for the evaluation of the performance of RegHCM-SS in reconstructing the historical rain fields over the Sabah and Sarawak region.

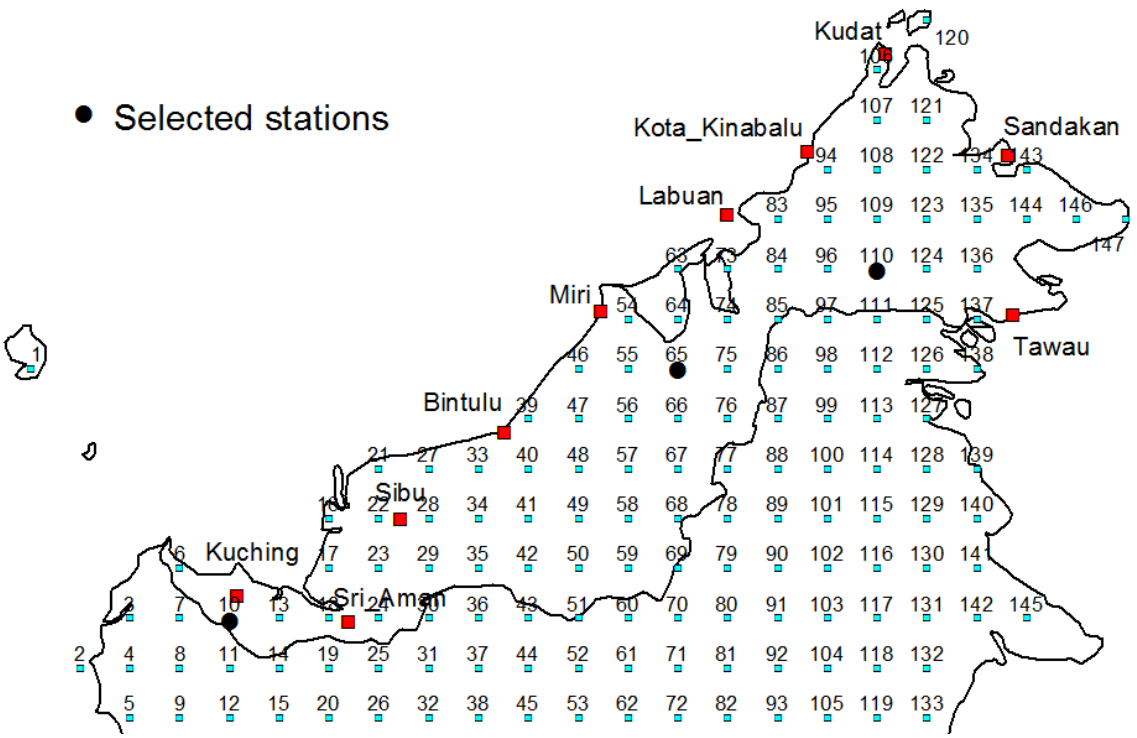

Figure 2 - Data points of the Willmott data network (shown by blue squares), and the ground observation network (shown by red squares). The 3 black data points were selected for demonstrative comparisons.

Figure 3 shows the comparisons of the monthly precipitation that were downscaled by RegHCM-SS from the coarse-resolution ECHAM5 historical control run data, against the Willmott data at 3 selected locations. At each of the graphs in this figure the Willmott precipitation data are compared against the area averages of the

RegHCM-SS downscaled precipitation for each grid area of the Willmott data. The location number of the data point that corresponds to the numbers in Figure 2 is indicated at the upper left corner of each graph. The selected stations are highlighted in Figure 2 with black dots. The RegHCM-SS simulated area average values are in the same value range as in the Willmott data at all 3 locations without any calibration or data assimilation.

SUMMARY AND DISCUSSION

In this study, the historical hydroclimate conditions were reconstructed by RegHCM-SS during the period of January 1993 – December 1999 at hourly intervals at 9-km grid resolution over the whole Sabah and Sarawak region with the newly updated model configuration and model parameters. RegHCM-SS transformed the coarse time-space resolution ECHAM5 GCM historical control runs' atmospheric data during the period of January 1993 – December 1999 to 1-hour-increment hydroclimate information at 9-km spatial resolution over Sabah and Sarawak region. ECHAM5 GCM historical control runs' data provided the initial and boundary conditions for the nested simulations of RegHCM-SS at 3 nestings centered over the Sabah and Sarawak region. At this stage of the model simulations, the output variables of the hydroclimate conditions from the RegHCM of Sabah and Sarawak (RegHCM-SS) include precipitation and surface air temperature.

In order to evaluate the RegHCM-SS performance in the reconstruction of the historical precipitation, its simulation results were compared against the spatially-averaged Willmott data at 0.5 degree grid resolution, over Sabah and Sarawak region. Since the atmospheric data that are reconstructed by RegHCM-SS are also areally-averaged (at 9km grid resolution), the comparison of RegHCM-SS simulations against the Willmott data make more sense than comparison against point location station observations. The comparisons of monthly precipitation, simulated by RegHCM, against corresponding observations of the Willmott data resulted in quite satisfactory results.

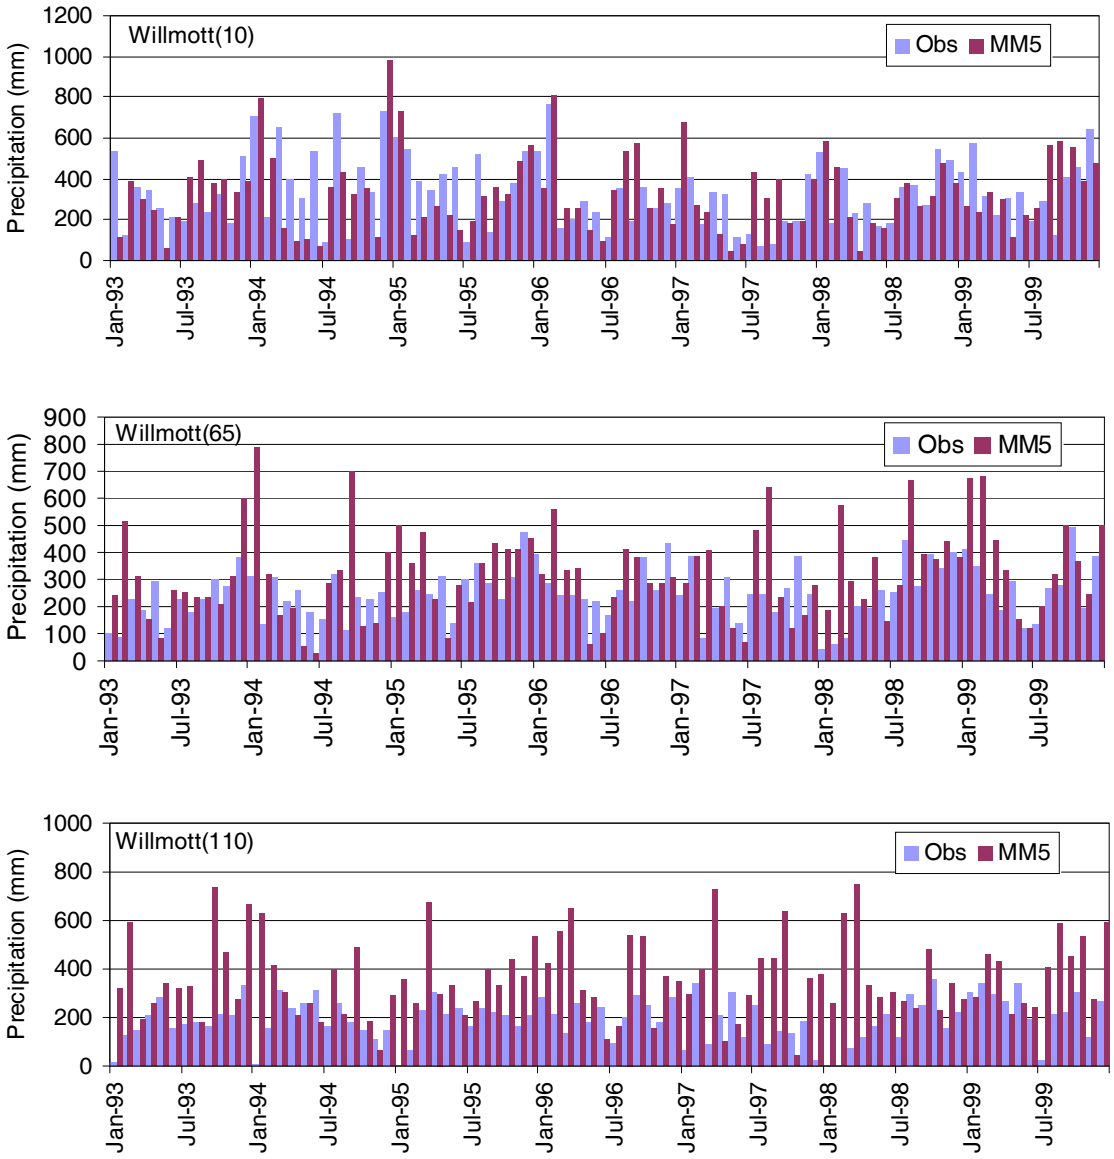

Figure 3 – Comparisons of the monthly precipitation that were downscaled by RegHCM-SS from the coarse-resolution ECHAM5 historical control run data, against the Willmott data at 3 selected locations

ABSTRACT

In order to obtain good regional hydroclimate simulation results, land surface properties such as leaf area index (LAI), albedo, emissivity, and roughness height are important for land surface hydrology modeling. A number of models have been proposed to describe the interaction between land surface and atmosphere during the last decade. The problem of these models is not taking account of spatial and temporal variability of the land surface properties within a computational grid. In an actual watershed, spatial distribution of vegetation is inhomogeneous, and its canopy varies seasonally. As such, it is necessary to consider the seasonal change of land surface properties in the land surface parameterization that is required for a regional hydroclimate model. The objective of this study is to understand the statistical characteristics of land surface properties. The satellite driven data from MODIS combined with local vegetation survey have been analyzed at a few selected watersheds in California in this study. The monthly spatial distributions of the land surface parameters have been computed. It was found that spatial distributions of the land surface parameters vary significantly in space and with seasons. This result indicates that non-stationarity as well as spatial variability of land surface parameters needs to be considered in land surface parameterization.

INTRODUCTION

The interface between the atmosphere and the land surface plays an important roll for the both of the atmospheric dynamics and land surface condition. The land surface processes such as infiltration, evapotranspiration and sensible heat exchange significantly affect on the simulation results of climate models of large scale models as well as in regional atmospheric models. The importance of the land surface parameterization is recognized to improve the climate model simulation results. During the last decade, a number of refined models have been proposed to describe the interaction between land surface and atmosphere. The problem of these models is not taking account of spatial and temporal variability of the land surface properties within a computational grid.

Kavvas *et al.* (1998) developed a regional-scale land surface parameterization based on areally-averaged hydrological conservation equations. Ensenble mean value of the land surface fluxes over a regional model grid cell were obtained by numerical algorithm for the arealy averaged equations with a mosaic scheme in this model in order to account for subgrid-scale spatial variability of land surface characteristics. Another stochastic upscaling technique to predict the dynamic probability density function for nonlinear hydrologic processes was developed by Kavvas (2003), and have been applied to the many hydrologic processes (For example, Ohara *et al*., 2008). This approach enables us to obtain not only the mean behavior but also the probability distribution of the state random variables of hydrologic process. This kind of stochastic upscaling approach may be applicable for the land surface processes. However in order to upscale the land surface processes using this approach, statistical characteristics of the processes need to be known because of the Gaussian assumption for the processes and the evaluation of time-space-dependent covariance terms in the Fokker Planck Equation of the upscaled processes.

The objective of this study is to understand the statistical characteristics of land surface properties. In order to improve the land surface parameterization and obtain the upscaled equations of land surface processes to account for the spatial variability in the computational grids, the characteristics of spatial distribution and seasonal change of the land surface properties, such as Leaf Area Index (LAI), albedo and emissivity are investigated and discussed in this paper. These parameters have been only crudely represented in the models due to limited observations. In this study, the derived parameters by MODIS (MODerate resolution Imaging Spectroradiometer) data is used in 1km spatial resolution.

DESCRIPTION OF THE LAND SURFACE PARAMETERIZATION

Two-way coupling scheme and areally averaged conservation equations (Kavvas *et al*., 1989) are employed in the land surface model, named Integrated Regional Scale Hydrologic/Atmospheric Model (IRSHAM). This made long-term realistic simulation possible at regional scale.

In order to calculate the latent heat flux from land surface it is necessary to calculate evapotranspiration (ET). The evapotranspiration rate can be estimated according to the moisture availability and the atmospheric conditions and the evapotranspiration rate from bare-ground and vegetated ground are estimated separately. When the water availability parameter h over bare soil, the water availability parameters for evaporation from the plant leaves, h_{vd}, and for transpiration, h_{vt}, (Noilhan & Planton, 1989) and the bulk transfer coefficient, C_H (Stull, 1988), are available by the Monin-Obukhov surface similarity theory, the aerodynamic formulas can be used to estimate the bare-ground evaporation (E_g) , the direct evaporation from canopy (E_{vd}), and the vegetation transpiration from canopy (E_{tr}).

Importantly, land surface temperature is determined from the heat budget of the land surface and therefore is also dependent upon evaporation. It means the

land/atmosphere is a nonlinear system with strong feedback and these are solved in a coupled way in this parameterization.

Areal averaging was applied to the land surface equations and areally-averaged hydrological conservation equations have been obtained (Kavvas, *et al.*, 1998). The areally averaged Green-Ampt models (Chen *et al.*, 1994a,b) for the infiltration and exfiltration process from/into the ground was incorporated in the land surface model and this physically based model provided the basis for the land surface hydrologic model in the IRSHAM. This areally averaged Green-Ampt models accounts for the heterogeneity of soils with in a computational grid by assuming a lognormal distribution of saturated hydraulic conductivity.

The characteristics of spatial and temporal variability of land surface parameters such as surface albedo, Leaf Area Index (LAI) and emissivity will be investigated in this paper. These land surface parameters significantly affect on the simulation results of the land surface model. Possibility for more reliable stochastic upscaling for the evapotranspiration and sensible heat exchange will be examined by computing the spatial autocorrelation function.

Following section, in order to obtain the statistical characteristics of land surface properties, the satellite driven data from MODIS will be analyzed at the foothills region in the northern California.

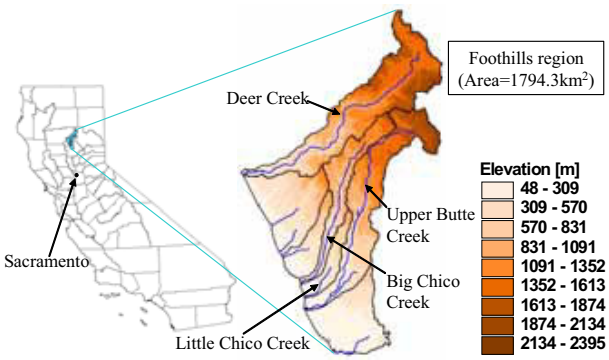

Figure 1. Map of the foothills region , California

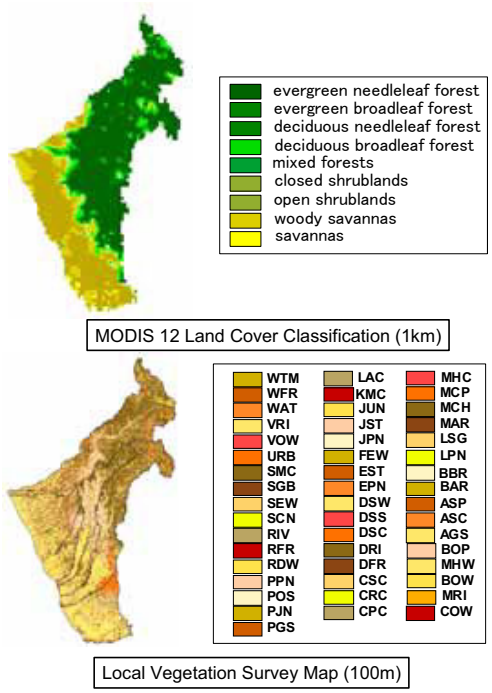

Figure 2. Vegetation map over the foothills region

STUDY AREA

The foothills region, encompassing Big Chico Creek, Little Chico Creek, Upper Butte Creek and Deer Creek watersheds, in the northern California was selected in this paper as shown in Figure 1. Infiltration of these watersheds into the groundwater aquifer

systems of Northern Sacramento Valley is very important for the water resources in this area.

Figure 2 shows MODIS12 land cover type map (upper) and Multi-source Land Cover Data (v02_1) published by CDFF (lower) in the foothills region. The local vegetation survey has the finest spatial resolution available (100m) and it provides the land surface cover types and vegetation type information. However, the satellite driven LAI, albedo and emissivity data is combined with MODIS 12 land cover classification data to obtain the seasonal change of the parameters for each land cover types in this paper.

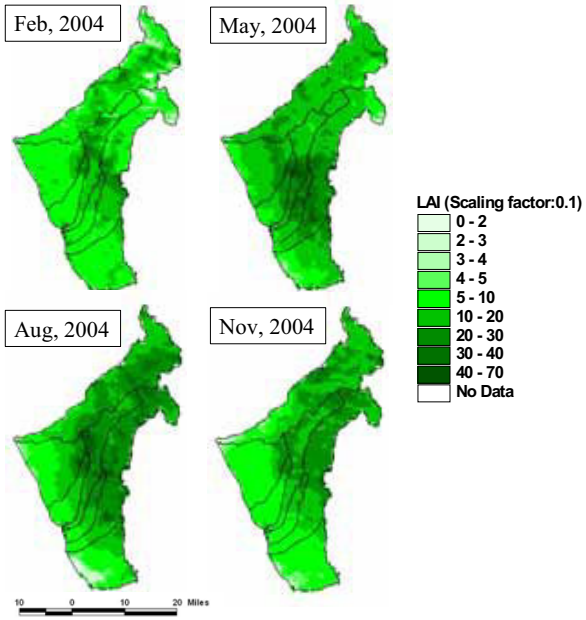

Figure 3. LAI distribution derived from MODIS observations over the foothills region

MODIS Leaf Area Index (LAI)

Leaf Area Index (LAI), defined as the area of leaves that covers a given unit of ground area. This property is essential to evaluate transpiration from the canopy in the land surface model.

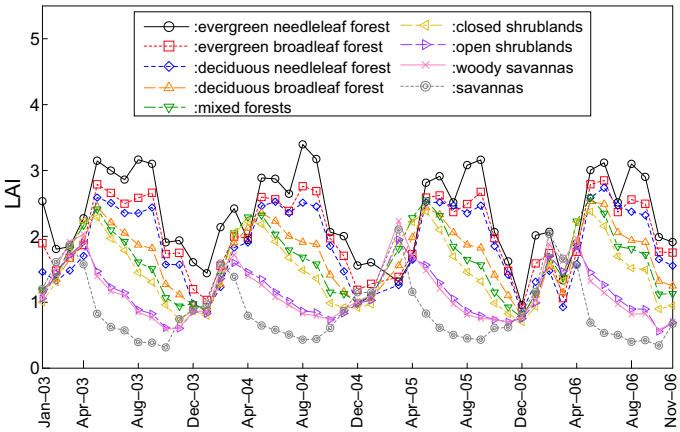

Figure 4. Monthly change of LAI based on MODIS observation (MYD15+MOD12)

Figure 3 shows the seasonal example plots of LAI derived from MODIS observations (MYD15). The LAI in MODIS is derived by comparing the observed and modeled surface reflectances for a suite of canopy structures and soil patterns. Spatial resolution of MODIS LAI is 1km. In order to establish relationships between the vegetation class and the estimated LAI, the land cover data derived from MODIS data (MOD12) are adopted in this study. Figure 4 shows the seasonal variation of LAI for each vegetation type. Seasonal change of LAI is clearly seen in Figure 4. From Figure 3 and 4, it is found that LAI values significantly change in spatially and temporally. It is because the vegetation canopies change seasonally. Figure 5 shows seasonal change of histogram (Relative frequency) of LAI. It seems that relative

frequency of LAI may be treated as the log normal distribution function. However, the histograms in some months do not seem to be the log normal distribution. Figure 6 shows the spatial autocorrelation coefficients of LAI and Albedo (discussed in later section). The spatial autocorrelation coefficients are calculated using the following equation.

$$g[LAI(\mathbf{x}), LAI(\mathbf{x}-r)](r) = \frac{\sum_{i=1}^{n}\left(LAI(\mathbf{x})-\overline{LAI}\right)\left(LAI(\mathbf{x}-r)-\overline{LAI}\right)}{\sqrt{\sum_{i=1}^{n}\left(LAI(\mathbf{x})-\overline{LAI}\right)^2\sum_{i=1}^{n}\left(LAI(\mathbf{x}-r)-\overline{LAI}\right)^2}} \quad (1)$$

Fig. 6 shows that the strong spatial correlation of LAI more than 0.5 values can be found , but it doesn't have a "long memory" in space. This exponential behaviour which autocorrelation coefficient approaches to zero sufficiently rapidly implies the process can be treated as the Gaussian process. Which means stochastic upscaling proposed by Kavvas (2003) can be applicable for this process. Ohara *et al.* (2008) focused on the spatial correlation function of the daily shortwave radiation in the upper Upper Cosumnes River watershed. They found the spatial correlation function of the daily shortwave has a "long memory" in space. However, after subtracting the local mean from the original radiation data, the obtained spatial correlation function appears to be a white noise and the delta correlation assumption was applied for the spatial distribution of daily shortwave radiation. This type of operation may be useful to approximate spatial correlation of LAI with the delta correlation assumption to evaluate the time-space-dependent covariance

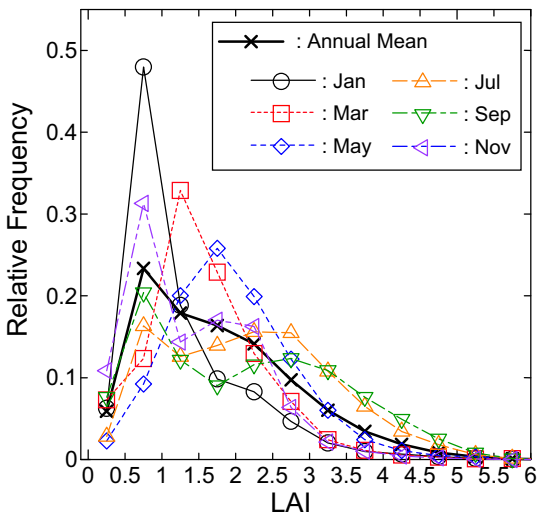

Figure 5. Monthly histogram (relative frequency) of LAI

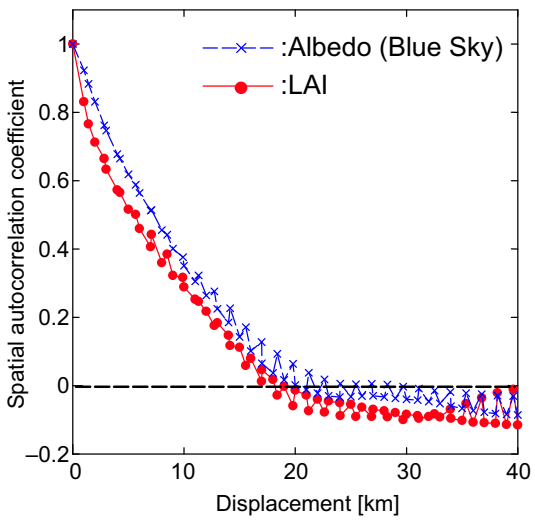

Figure 6. Spatial Correlation of LAI and Albedo over the foothills region

in the stochastic modeling approach.

MODIS Albedo

Seasonal change and spatial variability of surface Albedo are examined in this section. Albedo is defined as the ratio of upward to downward radiative flux on the land surface. This property is essential to evaluate the net shortwave radiation on the land surface in the energy budged equation of the land surface model. The MOD43 Albedo product provides both the white-sky albedos and the black-sky albedos (at local solar noon) for MODIS bands 1-7 as well as for three broad bands. Actual albedo (blue sky) of short wave band was estimated using the following equation.

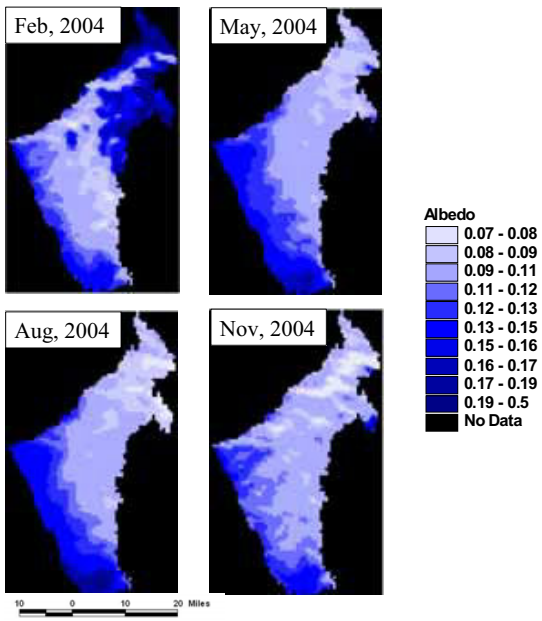

Figure 7. Albedo distribution derived from MODIS observations over the foothills region

$$ActualAlbedo = (1 - S(\theta, \tau(\lambda)))BSA + S(\theta, \tau(\lambda))WSA \quad (2)$$

where $S(\theta,\tau(\lambda))$ denotes a fraction of diffuse skylight, θ is the solar zenith angle, λ is the wavelength and $\tau(\lambda)$ is the atmospheric optical depth. It means the actual albedo values were determined based upon the solar zenith angle, wavelength and the atmospheric optical depth. The value of 0.5 as the fraction of diffuse skylight was used in this paper.

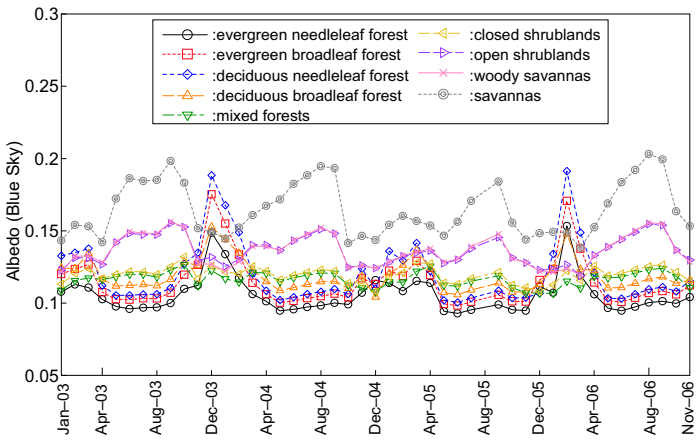

Figure 8. Monthly change of albedo based on MODIS observation (MOD43+MOD12)

Figure 7 shows the seasonal representative plots of Actual Albedo and Figure 8 shows the seasonal variation of Albedo for each vegetation type. Surface albedo

values for each vegetation type are increased during the dry periods and then decreased in the wet periods. The increase of albedo value in deciduous needleleaf forest and evergreen broadleaf forest during the wet periods is influenced by snow cover. From Figure 7 and 8, albedo significantly change in spatially and seasonally and these behaviors are similar to the LAI because the both of LAI and albedo values in this foothills region are based on the vegetation types. Figure 9 shows seasonal change of histogram (Relative frequency) of albedo. The annual and monthly mean distribution of albedo may be treated as the log normal distribution function. The spatial autocorrelation coefficient of albedo is shown in Figure 6 with LAI plots. The spatial autocorrelation coefficients are calculated using the same equation of LAI case written in Eq.(1). The spatial autocorrelation functions of albedo almost same as the spatial correlation coefficients of LAI. This is because of these 2 parameters depends on the vegetation types.

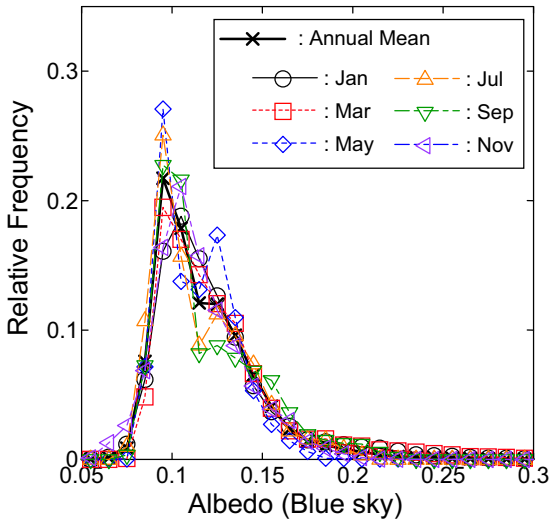

Figure 9. Monthly histogram (relative frequency) of albedo

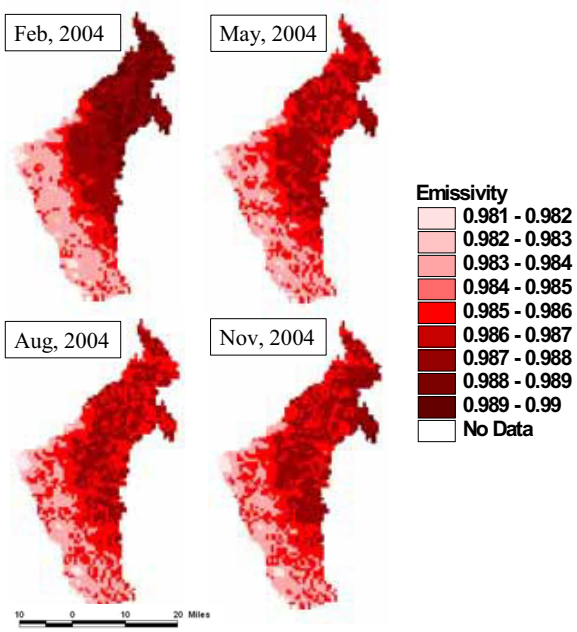

Figure 10. Emissivity distribution derived from MODIS observations over the foothills region

MODIS Emissivity

Finally, seasonal change and spatial variability of emissivity are focused in this section. Emissivity is defined as the ratio of thermal radiation emitted by a surface to that of a blackbody. This property is necessary to evaluate the net longwave radiation at the land surface. The MOD11 (1km resolution) emissivity values are estimated from land surface temperature and land cover types.

Figure 10 shows the seasonal example plots of emissivity and Figure 11 shows the seasonal variation of emissibity for each vegetation type. From Figure 10 and 11, emissivity values are spatially and seasonally changed, but the variability of the emissivity is apparently smaller than that of Albedo and LAI. It may be concluded that emissivity values of land surface can be treated as the constant value in seasonally.

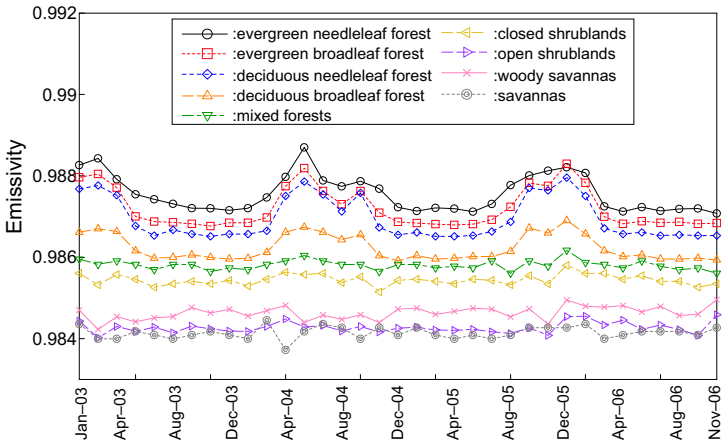

Figure 11. Monthly change of emissivity based on MODIS observation (MOD11+MOD12)

DISCUSSION

Spatial distribution of vegetation is inhomogeneous, and its canopy varies seasonally in an actual watershed. It is necessary to consider the seasonal change of land surface properties in the land surface parameterization that is required for a regional hydroclimate model. The seasonal change and spatial variability of Leaf Area Index, albedo and emissivity at foothills region in northern California are estimated from MODIS data in this paper. Also, monthly averaged histogram and spatial autocorrelation coefficient of Albedo and LAI were obtained. These results indicate that albedo and LAI values were significantly changed in seasonally and spatially. As such, it is necessary to consider the non-stationarity as well as spatial variability of land surface parameters in land surface parameterization.

Furthermore, strong spatial correlation coefficients of LAI and Albedo of more than 0.5 values were found but they don't have a "long memory" in space. This exponential behaviour which autocorrelation coefficient approaches to zero sufficiently rapidly implies the process can be treated as the Gaussian process. Which means stochastic upscaling proposed by Kavvas (2003) can be applicable for the land surface processes. And it was also found that provability distribution function of annual and monthly mean albedo and annual mean LAI can be treated as the lognormal distribution.

This exercise on the spatial and temporal variability of land surface parameters presented in this paper is important to examine the applicability of the stochastic upscaling approach for the land surface parameterization.

Modeling the kinematic wave parameters with regression methods

I. Haltas[1] (Assoc. Member ASCE)

[1] Northwest Hydraulic Consultants, 3950 Industrial Blvd Suite 100C, West Sacramento, 95691. email: ihaltas@gmail.com

Abstract

The momentum equation in the kinematic wave model is a power law equation and involves two kinematic wave parameters. It is a common practice to use Manning's equation to calculate the kinematic wave parameters. One can obtain a kinematic wave equation by inserting the momentum equation into the continuity equation. The kinematic wave equation becomes a partial differential equation with kinematic wave parameters that depend on the flow depth. However, working with a partial differential equation comprised of kinematic wave parameters that are independent of the flow depth is a lot more convenient. Here, regression methods were used to calculate the kinematic wave parameters that are independent of the flow depth for a trapezoidal channel cross-section, which is a common cross-section shape. The developed expressions for the kinematic wave parameters provided very good approximation for the momentum equation of the kinematic wave model.

Keywords: kinematic wave parameters; trapezoidal channel; least squares fitting; power law.

Introduction

The kinematic wave model is a simplified form of the St. Venant equations under the assumption that the bed slope is approximately equal to the friction slope (Lighthill and Whitham, 1955). Kinematic wave routing is frequently used for modeling both the overland and open channel flows due to its simplicity and accuracy. The kinematic wave model is defined by the following two equations:

Equation of continuity: $$\frac{\partial A}{\partial t}+\frac{\partial Q}{\partial x}-q=0 \qquad [1]$$

Equation of momentum: $$Q=\alpha \cdot A^{\beta} \qquad [2]$$

The parameters α and β in Eq. [2] are called as kinematic wave parameters and are commonly derived using Manning's equation,

$$Q = \frac{S^{1/2}}{n}\left(\frac{A^{5/3}}{P^{2/3}}\right) \quad [3]$$

In Equations [1]-[3]; A is flow area (m^2), Q is flow discharge (m^3/s), q is lateral inflow (m^2/s), S is bedslope of the channel (m/m), n is Manning's roughness coefficient ($s/m^{1/3}$), and P is wetted perimeter (m).
Let Eq. [3] be expressed in the power law form given in Eq. [2].

$$\frac{S^{1/2}}{n}\left(\frac{A^{5/3}}{P^{2/3}}\right) = \alpha \cdot A^{\beta} \quad [4]$$

Since both the flow cross-sectional area A and the wetted perimeter P depend on the cross-section geometry and the flow depth, it is not possible to find α and β parameters as independent of the flow depth except for some special cross-section geometries.

When Eq. [2] is inserted into Eq. [1] one can obtain a combined kinematic wave equation as follows,

$$\frac{\partial A}{\partial t} + \frac{\partial(\alpha \cdot A^{\beta})}{\partial x} - q = 0 \quad [5]$$

In Eq. [5] the kinematic wave parameters α and β depend on the flow depth. However, working with a partial differential equation comprised of kinematic wave parameters that are independent of the flow depth, is a lot more convenient than working with a partial differential equation comprised of kinematic wave parameters that depend on the flow depth. In a recent work of Haltas and Kavvas (2008) the technique they used for developing an ensemble averaged kinematic wave equation required a combined kinematic wave equation with kinematic wave parameters that are independent of the flow depth.

Overland Flow

In the case of the overland flow, flow is assumed to have a wide rectangular cross-sectional area where flow width is much greater than flow depth. Then, the flow area and the wetted perimeter can be written as:

$$A = w \cdot y \quad [6]$$
$$P = w + 2 \cdot y \quad [7]$$
$$y / w \approx 0 \quad [8]$$

Where w is the overland flow width (m) and y is the overland flow depth (m).
When Equations [6] and [7] are plugged into Eq. [3] one obtains:

$$Q = \frac{S^{1/2}}{n}\left(\frac{(w \cdot y)^{5/3}}{(w + 2 \cdot y)^{2/3}}\right) \qquad [9]$$

Rearranging the terms in Eq. [9] yields:

$$Q = \frac{S^{1/2}}{n}\left(\frac{y}{1 + 2 \cdot y / w}\right)^{2/3}(w \cdot y) \qquad [10]$$

By applying the approximation given in Eq. [8], to Eq. [10] one obtains:

$$Q / w = \frac{S^{1/2}}{n} y^{5/3} \qquad \text{or} \qquad q = \frac{S^{1/2}}{n} y^{5/3} \qquad [11]$$

In Eq. [11]; $q = Q / w$ is the flow per unit width (m^2 / s), the corresponding kinematic wave parameters are obtained as $\alpha = S^{1/2} / n$, $\beta = 5/3$. As such, the kinematic wave parameters for overland flow are independent of the flow depth.

Open Channel Flow

In practical applications circle, triangle, rectangle, and trapezoid are the most commonly used shapes for describing the channel flow cross-sections. In a study by MacArthur and DeVries (1993), the expressions for kinematic wave parameters were provided for circular, triangular, rectangular and trapezoidal channel flow cross-sections. In that study the kinematic wave parameters were calculated as independent of the flow depth for the triangular cross-sections. For the case of circular and rectangular channel cross-sections some assumptions were necessary to obtain the kinematic wave parameters as independent of the flow depth. However for the trapezoidal cross sections the calculated kinematic wave parameters were dependent on the flow depth. Here an attempt is made to derive expressions for the kinematic wave parameters that are independent of the flow depth for trapezoidal channel cross-sections. The triangular and rectangular cross-sections are special cases of the trapezoidal cross-sections. Figure 1 depicts a typical trapezoidal channel flow cross-section.

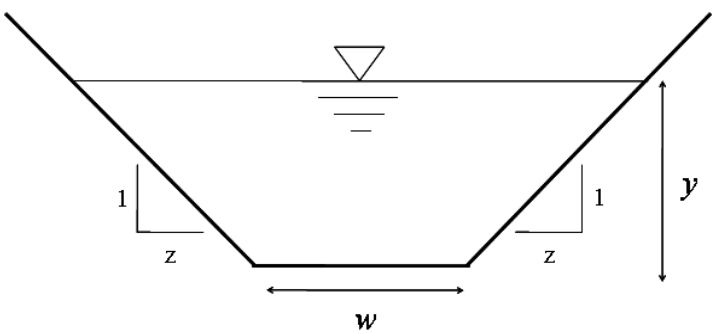

Figure 1: Trapezoidal Cross Section

From Figure 1, it follows that

$$A = y \cdot (w + z \cdot y) \quad [12]$$

$$P = w + 2 \cdot y \cdot \sqrt{(1 + z^2)} \quad [13]$$

$$Q = \frac{S^{1/2}}{n} \frac{(y \cdot (w + z \cdot y))^{5/3}}{(w + 2 \cdot y \cdot \sqrt{(1 + z^2)})^{2/3}} \quad [14]$$

In Eq. [14], the channel slope S, the roughness coefficient n, the channel side slope z, and the channel bottom width w are independent of the flow depth, yet the flow discharge Q is a function of the flow depth. As such, the equation form of Q, as given in Eq. [14], does not allow Q to be expressed in the power law form in terms of A and flow depth-independent kinematic wave parameters. However, regression methods can be used to derive the kinematic wave parameters as independent of the flow depth for some set of A and Q values.

Let's re-write Eq. [14] as follows:

$$Q = \frac{S^{1/2}}{n} \cdot \theta(z, w, y) \quad [15]$$

where

$$\theta(z, w, y) = \frac{A^{5/3}}{P^{2/3}} = \frac{(y \cdot (w + z \cdot y))^{5/3}}{(w + 2 \cdot y \cdot \sqrt{(1 + z^2)})^{2/3}} \quad . \quad [16]$$

Let

$$\theta(z, w, y) = c(z, w) \cdot A^{m(z,w)} \quad [17]$$

The functions $c(z, w)$ and $m(z, w)$ can be calculated by least squares fitting for some set of A and θ values as follows.

Power law-least squares fitting method

For the sequences $\{x_i\}_{i=1}^n$ and $\{y_i\}_{i=1}^n$ and for a function of the form $y = c \cdot x^m$ the least squares fitting gives the coefficients as (Weisstein, 2008):

$$b = \frac{n \cdot \sum_{i=1}^{n} (\ln x_i \cdot \ln y_i) - \sum_{i=1}^{n} (\ln x_i) \cdot \sum_{i=1}^{n} (\ln y_i)}{n \cdot \sum_{i=1}^{n} (\ln x_i)^2 - \left(\sum_{i=1}^{n} (\ln x_i) \right)^2} \quad [18]$$

$$a = \frac{\sum_{i=1}^{n} (\ln y_i) - b \cdot \sum_{i=1}^{n} (\ln x_i)}{n} \qquad [19]$$

where $m \equiv b$ and $c \equiv e^a$

Case study

Let a trapezoidal cross section as shown in Figure 1 has the bottom width $w_0 = 50$ meter and side slope $z_0 = 1$. Table 1 lists a range of flow depths y and the calculated A and θ values.

Table 1: A and θ calculated for a range of flow depths y

y_i	0.60	1.20	1.80	2.40	3.00	3.60	4.20	4.80	5.40	6.00
A_i	30.36	61.44	93.24	125.76	159.00	192.96	227.64	263.04	299.16	336.00
θ_i	21.29	67.47	132.42	213.66	309.72	419.57	542.48	677.91	825.43	984.71

For the sequences $\{A_i\}_{i=1}^{10}$ and $\{\theta_i\}_{i=1}^{10}$ listed in Table 1 the functions c and m are estimated as $c(z_0 = 1, w_0 = 50) = 0.095$ and $m(z_0 = 1, w_0 = 50) = 1.593$ by the least squares fitting method. Then the approximate momentum equation for this specific trapezoidal channel cross-section can be written as:

$$Q = 0.095 \cdot \frac{S^{1/2}}{n} \cdot A^{1.593} \qquad [20]$$

Note that, the momentum equation given in Eq. [20] is valid only for the trapezoidal channels with the specified dimensions. The calculated least squares fitting equation has a coefficient of determination $R^2 = 0.9998$. Although Eq. [20] is estimated for a specific range of flow depths as given in Table 1, it is still valid for flow depths outside of the specified range with poorer accuracy.

The above regression method can be repeated for sequences of channel side slope z_i, and the channel bottom width w_j to estimate the approximate numerical values of the functions $c(z, w)$ and $m(z, w)$. Table 2 and Table 3 list these estimated numerical values.

Table 2: Numerical values of $c(z_i, w_j)$ estimated with regression methods

100	1.630	1.626	1.617	1.606	1.594	1.583	1.572	1.562	1.552	1.543
150	1.639	1.636	1.629	1.619	1.610	1.600	1.591	1.582	1.574	1.566
200	1.644	1.641	1.635	1.628	1.619	1.611	1.603	1.596	1.588	1.581
300	1.650	1.648	1.643	1.637	1.631	1.624	1.618	1.612	1.606	1.600
400	1.653	1.652	1.648	1.643	1.638	1.632	1.627	1.622	1.616	1.611

Eq. [20] can be generalized so that it will be valid not only for a specified bottom width w_0 but for a variable bottom width w. Then Eq. [17] will take the form given as follows:

$$\theta(z_0, w, y) = c(z_0, w) \cdot A^{m(z_0, w)} \qquad [21]$$

Similar to θ, the functions $c(z_0, w)$ and $m(z_0, w)$ in Eq. [21] can also be formulated in a power law form by using the power law-least squares fitting method.
Let

$$c(z_0, w) = cc(z_0) \cdot w^{cm(z_0)} \qquad [22]$$

$$m(z_0, w) = mc(z_0) \cdot w^{mm(z_0)} \qquad [23]$$

Equations [22] and [23] are estimated for the sequence of channel bottom widths w_j and the corresponding $c(z_0, w_j)$ and $m(z_0, w_j)$ given in Table 2 and Table 3, as follows,

$$c(z_0, w) = 1.515 \cdot w^{-0.722} \qquad (R^2 = 0.997) \qquad [24]$$

$$m(z_0, w) = 1.340 \cdot w^{0.039} \qquad (R^2 = 0.929) \qquad [25]$$

Furthermore, the parameters $cc(z_0)$, $cm(z_0)$, $mc(z_0)$, and $mm(z_0)$ in Equations [22] and [23] can also be expressed as functions of the channel side slope z by using the regression methods, as follows,

$$cc(z) = -0.006 \cdot z^2 + 1.0431 \qquad (R^2 = 0.998) \qquad [26]$$

$$cm(z) = 0.0016 \cdot z^2 + 0.0131 \cdot z - 0.6505 \qquad (R^2 = 0.997) \qquad [27]$$

$$mc(z) = 0.0021 \cdot z^2 + 0.0489 \cdot z + 1.5438 \qquad (R^2 = 0.992) \qquad [28]$$

$$mm(z) = -0.0003 \cdot z^2 + 0.0046 \cdot z + 0.0117 \qquad (R^2 = 0.990) \qquad [29]$$

The actual values of $\theta(z, w, y)$, calculated using Eq. [16], are compared with those calculated using regression model Eq. [17] and the regression parameters given in Tables 2 and 3. The percent relative differences among the Eq. [16]-calculated and Eq. [17]-calculated $\theta(z, w, y)$ are shown in Figures 2-6 for different channel bottom widths w.

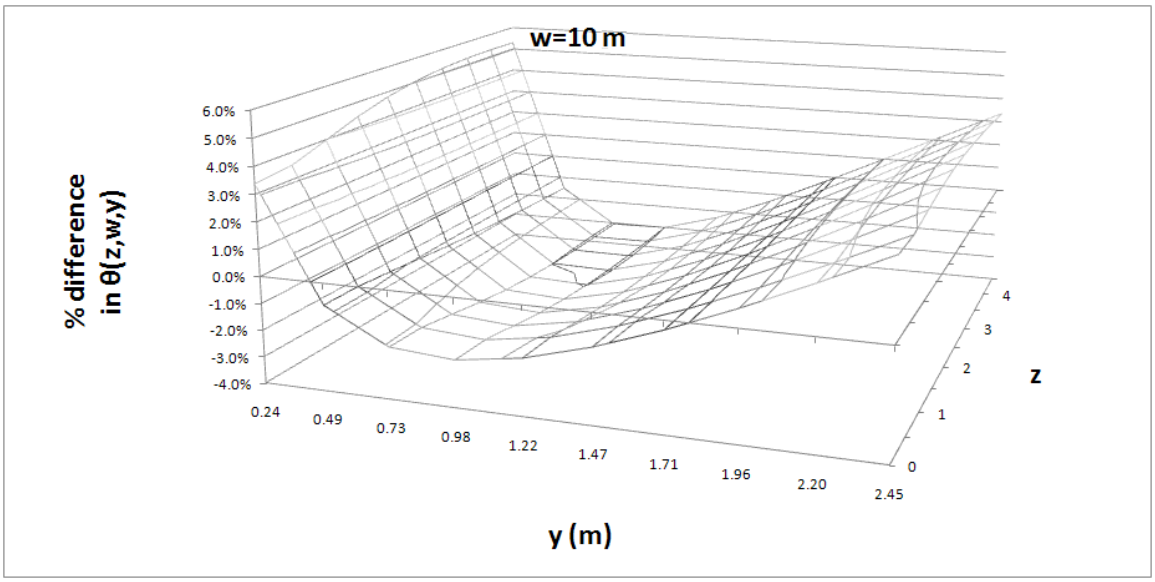

Figure 2: Percent relative differences among the Eq. [16]-calculated and Eq. [17]-calculated $\theta(z, w, y)$ for channel bottom width $w = 10$ m

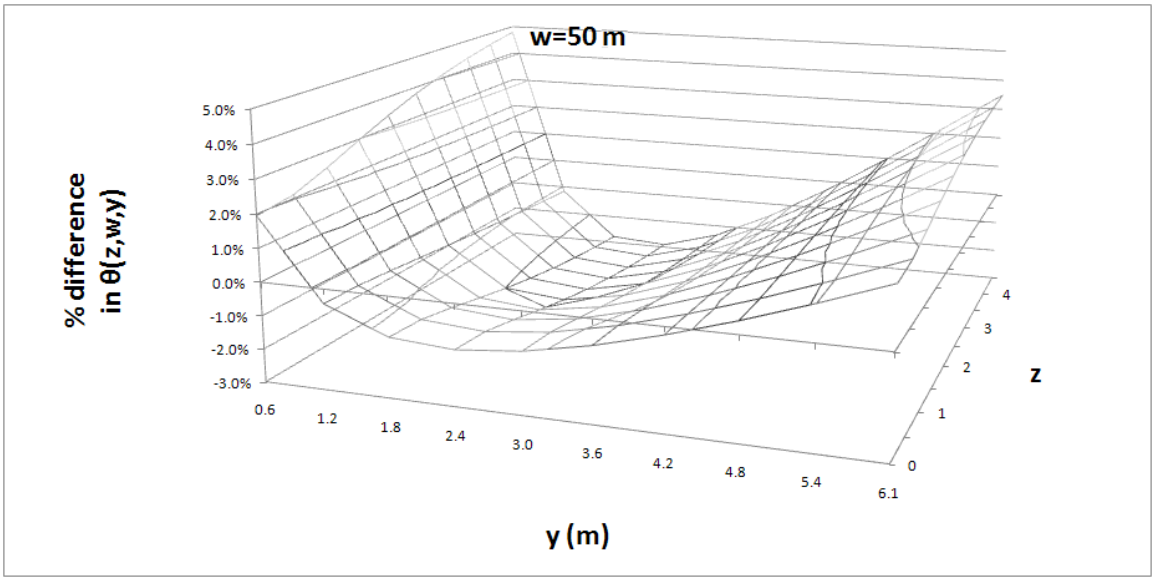

Figure 3: Percent relative differences among the Eq. [16]-calculated and Eq. [17]-calculated $\theta(z,w,y)$ for channel bottom width $w = 50$ m

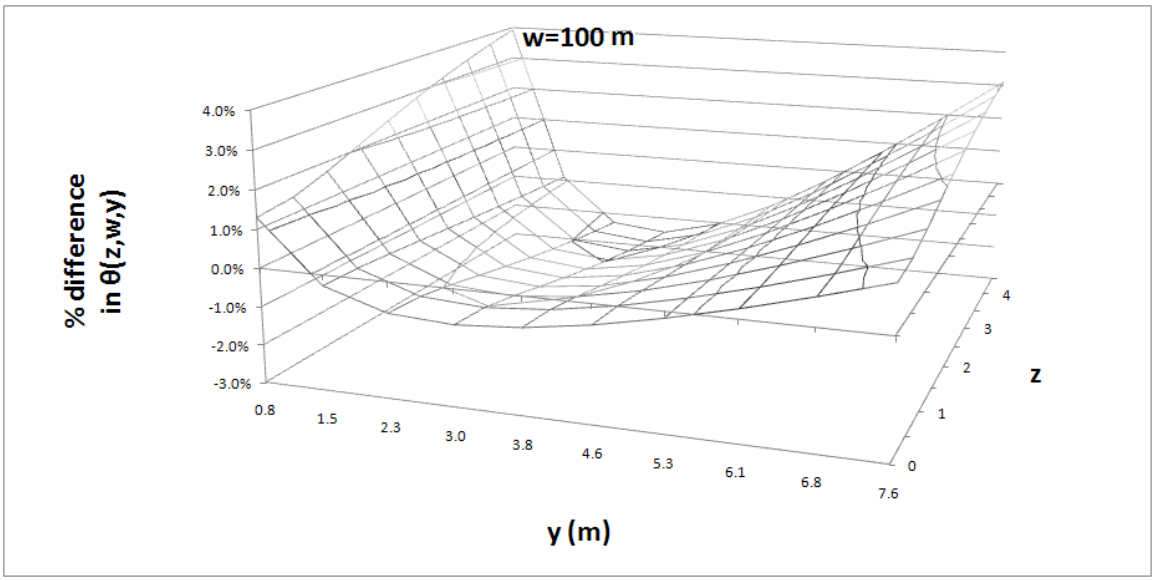

Figure 4: Percent relative differences among the Eq. [16]-calculated and Eq. [17]-calculated $\theta(z,w,y)$ for channel bottom width $w = 100$ m

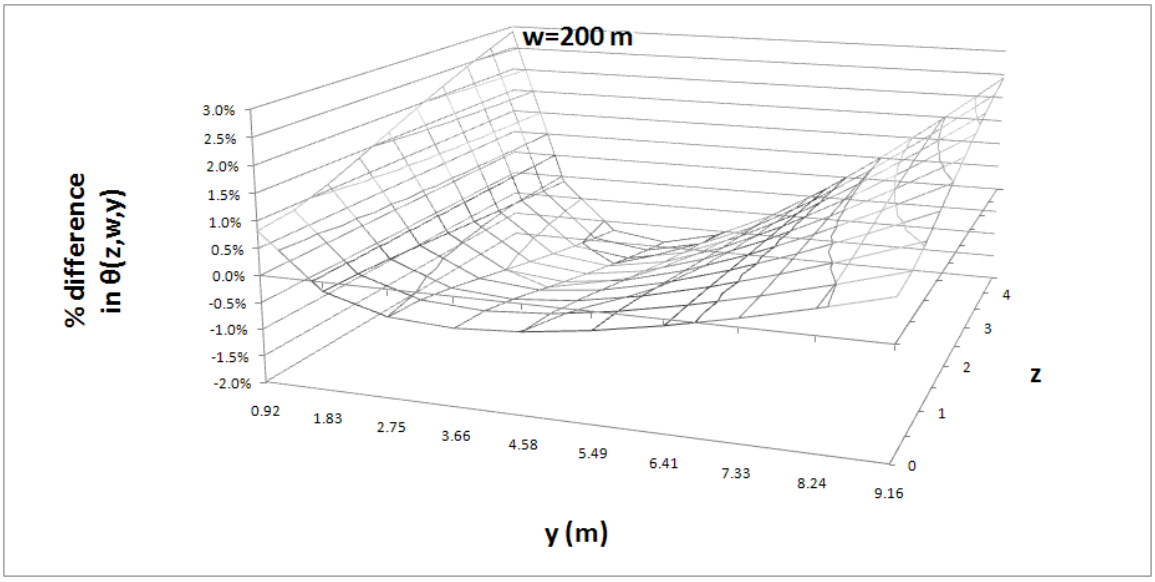

Figure 5: Percent relative differences among the Eq. [16]-calculated and Eq. [17]-calculated $\theta(z,w,y)$ for channel bottom width $w = 200$ m

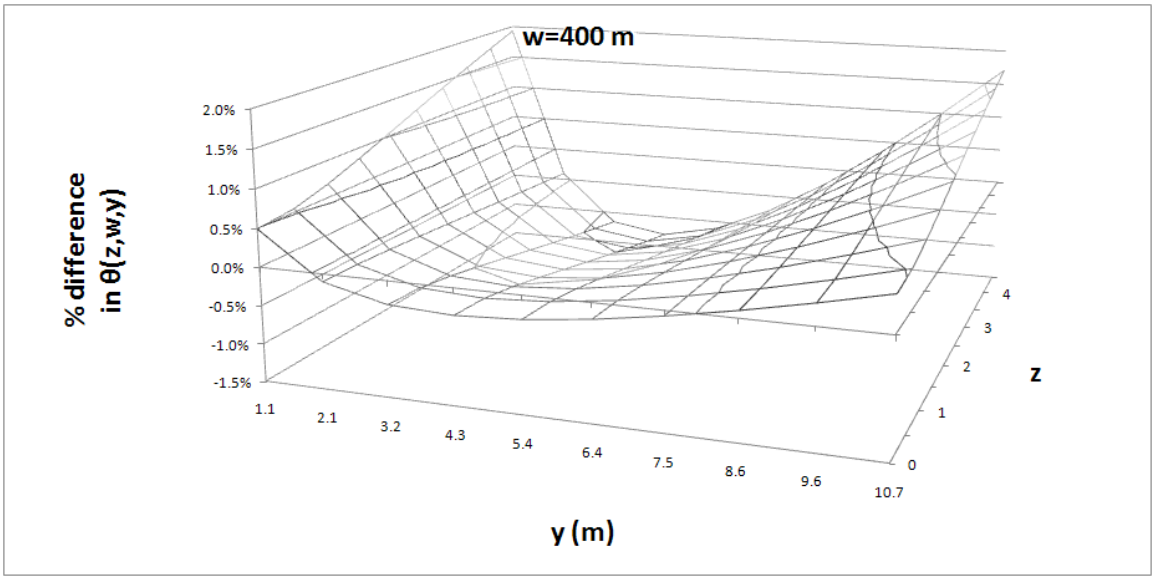

Figure 6: Percent relative differences among the Eq. [16]-calculated and Eq. [17]-calculated $\theta(z,w,y)$ for channel bottom width $w = 400$ m

As shown in Figures 2-6 the modeled $\theta(z,w,y)$ values are within %6 of the actual values of $\theta(z,w,y)$.

Finally, the two kinematic wave equations Eq. [1] and Eq. [2] are reduced into a partial differential equation with a state variable A and parameters, z, w, S, n, $c(z,w)$ and $c(z,w)$ that are independent of the flow depth, as follows,

$$\frac{\partial A}{\partial t} + \frac{\partial}{\partial x}\left(\frac{S^{1/2}}{n} \cdot c(z,w) \cdot A^{m(z,w)}\right) - q = 0 \qquad [30]$$

Discussion and Conclusion

When the Manning's equation is used for the momentum equation in the kinematic wave model, the kinematic wave parameters emerge as variables dependent on the flow depth except for some special cross-sections. In this study the kinematic wave parameters were modeled by using the power law-least squares fitting method in order to obtain these parameters independent of the flow depth. The estimated numerical values of the kinematic wave parameters for varying channel bottom width and channel side slope were also tabulated as a reference for future studies. Here the kinematic wave parameters were modeled only for trapezoidal channel cross-sections, yet they also cover the rectangular and triangular cross-sections. The power law-least squares fitting method was introduced as a tool and evaluated for its potential for modeling kinematic wave parameters. The modeled kinematic wave parameters provided very good approximation for the momentum equation of the kinematic wave model. Since the kinematic wave parameters were modeled as variables independent of the flow depth, the resulting kinematic wave equation is much easier to work with than the conventional kinematic wave equations.

Abstract

Sea surface temperature (SST) is an important link between global climate and regional hydrology, and consequently its use is ubiquitous in statistical and physical models for hydrologic prediction. Historical observations of SST are based on in situ measurements from ships and buoys. These measurements have large associated uncertainties that have been archived with the data, but are vastly ignored in the literature either because of lack of appropriate tools or because the benefits of engaging uncertainties are not well understood. In this study, a Bayesian framework is developed to incorporate data uncertainty when performing supervised (regression analysis) and unsupervised (principal component analysis) learning. The developed methods are applied to predict all Indian summer monsoon rainfall (AISMR) using SST as inputs. The benefits of engaging data uncertainties, which include better assessment of predictions skills, are discussed.

Keywords: Hydrologic prediction, data uncertainty, sea surface temperature, Bayesian learning, Indian monsoon

Introduction

A recent trend in hydrologic prediction models is to derive predictability from variables governing atmospheric and oceanic circulations that are measured using *in situ* and\or remote-sensing observations and have various sources of uncertainties. The magnitude of measurement uncertainties, which are now often quantified, differ from variable to variable and for a given variable vary substantially in space and time. This information, though available, is mostly ignored in traditional models because methods for engaging uncertainty are subjective, difficult, and the associated benefits are not well established.

In statistical hydrologic models, measurement uncertainties in data can influence various stages of model development including selection of predictors, estimation of model parameters, and quantification of prediction uncertainties. This

study develops a methodology to engage data uncertainty in principal component analysis and regression using Bayesian framework.

Principal component analysis (PCA) is arguably the most popular method to extract predictors in hydrologic prediction models. However, standard PCA (SPCA) ignores data uncertainty information in deriving principal components (PCs). Tripathi and Govindaraju (2008) developed Bayesian noisy PCA (BaNPCA) to overcome this problem and demonstrated that BaNPCA improves the performance of PCA by extracting PCs that have low data reconstruction error. However, BaNPCA algorithm is based on type-II maximum likelihood using local Gaussian approximation for the posterior distribution of the model parameters, an assumption that is likely to be violated if the sample size is small. This study develops an alternative algorithm for BaNPCA using *variational inference* or *variational Bayes* method (Jordan et al., 1999) that avoids local approximations thus making it more suitable for typical hydrologic data sets. The algorithm is termed as variational Bayes noisy PCA (VBaNPCA).

The predictors identified after PCA are mapped to the predictand by a functional relationship that takes form of a *regression* model if the predictand is a continuous variable, or *classification* model if the predictand is a categorical variable. This study considers the former case and employs relevance vector machine (RVM ; Tipping, 2001) as a regression model. Standard RVM does not account for measurement uncertainites in independent variabels. Quiñonero Candela et al. (2003) modified the RVM algorithm to engage that information during prediction phase and demonstrated its advantages for multi-step forecast. However, their method ignores uncertainty during RVM training phase, a limitation that, to our knowledge, has not been addressed in the literature. In this study, a methodology is proposed to utilize information of measurement errors in predictors during both training and prediction phases of RVM algorithm. The algorithm is based on variational principles and is termed as variational noisy RVM (VNRVM).

The following objectives have been set for this study: (i) to develop a fully Bayesian method (VBaNPCA) for deriving PCs by engaging data uncertainty information, (ii) to propose variational noisy RVM (VNRVM) that learns regression relationship when dependent variables have uncertainties, and (iii) to explore the benefits of proposed algorithms in predicting all India summer monsoon rainfall.

The remainder of this paper is structured as follows. Mathematical details of VBaNPCA and VNRVM are given in the next section. Following this, data used in the study are described and the methodology is presented. Results obtained are presented and discussed in the last section.

Mathematical formulation

The following notation are used: N samples of independent variables in p dimensional real space are denoted by $\boldsymbol{X} = [\boldsymbol{x}_n]^{\mathrm{T}}$ ($n = 1, \ldots, N$; $\boldsymbol{x}_n \in \Re^p$), and the corresponding dependent variable is given $\boldsymbol{y} = [y_n]^{\mathrm{T}}$ ($y_n \in \Re$). The independent variables are observed with known measurement errors given by

$$\tilde{\boldsymbol{x}}_n = \boldsymbol{x}_n + \boldsymbol{\zeta}_n \tag{1}$$

where $\tilde{\boldsymbol{x}}_n$ are the observed values of the n^{th} sample, and $\boldsymbol{\zeta}_n$ is associated measurement error following Gaussian distribution with mean zero and variance $\boldsymbol{B}_n^{-1}$.

Matrices are represented by upper case bold italic letters. All vectors are column vectors and are represented by lower case bold italic letters. Normal font italic letters represent scalars, $m \times m$ identity matrix is shown as $\boldsymbol{I}_m$, symbol $\langle x \rangle$ denotes expected value of a random variable x, and diag($\boldsymbol{x}$) represents a diagonal matrix with diagonal elements $\boldsymbol{x}$.

Variational Bayes noisy principal component analysis

The goal of PCA is to linearly map $\boldsymbol{x}_n$ from p dimensional real to q dimensional real space so that the transformed data $\boldsymbol{z}_n$ ($\boldsymbol{z}_n \in \Re^q$; $q < p$), for a given q, preserves maximum variance in $\boldsymbol{x}_n$. In probabilistic formulation of PCA, $\boldsymbol{x}_n$ is defined as linear transformation of $\boldsymbol{z}_n$ using following linear Gaussian latent variable model

$$\boldsymbol{x}_n = \boldsymbol{W}\boldsymbol{z}_n + \boldsymbol{\mu} + \boldsymbol{\varepsilon}_n \tag{2}$$

where $\boldsymbol{z}_n$ are the latent variables, $\boldsymbol{\varepsilon}_n$ is isotropic Gaussian noise $\boldsymbol{\varepsilon}_n \sim \mathcal{N}(\boldsymbol{\varepsilon}_n|0, \sigma^2\boldsymbol{I}_p)$, $\boldsymbol{\mu}$ is a p dimensional vector, and $\boldsymbol{W}$ is a $p \times q$ matrix. For notational simplicity, variance of the error term (σ^2) will be represented by τ, where $\tau = \sigma^{-2}$. Tipping and Bishop (1999) proved that if the prior distribution over $\boldsymbol{z}_n$ is zero mean Gaussian distribution, $p(\boldsymbol{z}_n) \sim \mathcal{N}(\boldsymbol{z}_n|0, \boldsymbol{I}_q)$, then the maximum likelihood solution of $\boldsymbol{W}$ contains principal directions of data matrix $\boldsymbol{X}$ in its column.

Tripathi and Govindaraju (2008) extended probabilistic PCA to engage measurement uncertainties of observed data in the analysis and developed a Bayesian framework for estimating model parameter $\boldsymbol{W}$. However, the algorithm was not fully Bayesian because apart from $\boldsymbol{W}$ other model parameters and hyper-parameters were estimated either by using Expectation-Maximization (EM) algorithm or maximum a posteriori (MAP) method that approximates a posterior distribution by a delta function at its mode. This approximation is justified when $N >> p$, a case seldom satisfied by hydro-climatic datasets including SST data. In this study, a complete Bayesian treatment of BaNPCA algorithm is proposed; the new algorithm is referred to as variational BaNPCA (VBaNPCA). Mathematically, the algorithm is given by Eqs.1 and 2. An important difference between BaNPCA and VBaNPCA is the introduction of true data $\boldsymbol{x}_n$ as a latent variable in VBaNPCA, which substantially reduces the mathematical complexity in estimating noise variance σ^2, a computational bottleneck in the earlier BaNPCA algorithm.

In VBaNPCA, the following hierarchical priors are assigned to model parameters and hyper-parameters

$$p(\boldsymbol{W}|\boldsymbol{\alpha}) = \prod_{j=1}^{p} \mathcal{N}(\boldsymbol{w}_j|0, \alpha_j); \quad \text{where} \quad \boldsymbol{\alpha} = [\alpha_1, \ldots, \alpha_q]^{\mathrm{T}} \tag{3}$$

$$p(\alpha_j) = \text{Gamma}(\alpha_j|a_0, b_0); \quad j = 1, \ldots, p \tag{4}$$

$$p(\boldsymbol{\mu}) = \mathcal{N}(\boldsymbol{\mu}|0, \beta_0^{-1}\boldsymbol{I}_p) \tag{5}$$

$$p(\tau) = \text{Gamma}(\tau|c_0, d_0) \tag{6}$$

where the column vector $\boldsymbol{w}_j$ denotes j^{th} column of $\boldsymbol{W}$. The priors are made broad or non-informative by setting $a_0 = b_0 = c_0 = d_0 = \beta_0 = 10^{-3}$. The posterior distribution for the model parameters and latent variables, $p(\Theta|\tilde{\boldsymbol{X}})$, where $\Theta = [\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{W}, \boldsymbol{\mu}, \boldsymbol{\alpha}, \tau]$, does not have a closed form and is therefore approximated. Herein, variational principles are employed to deterministically approximate $p(\Theta|\tilde{\boldsymbol{X}})$ by $Q(\Theta|\tilde{\boldsymbol{X}})$ such that $Q(\Theta|\tilde{\boldsymbol{X}})$ is similar to $p(\Theta|\tilde{\boldsymbol{X}})$ and at the same time has a closed form. The variational method used in this study has its origin in *mean field theory* (Parisi, 1988) where it was developed to approximate lowest-energy state in quantum mechanical calculations. It assumes that the approximating distribution $Q(\Theta|\mathcal{D})$ factorize as

$$Q(\Theta) = Q(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{W}, \boldsymbol{\mu}, \boldsymbol{\alpha}, \tau) = q(\boldsymbol{X})q(\boldsymbol{Z})q(\boldsymbol{W})q(\boldsymbol{\alpha})q(\boldsymbol{\mu})q(\tau). \tag{7}$$

where to make the notation uncluttered, explicit dependence of approximating distribution on data $\tilde{\boldsymbol{X}}$ is dropped. The optimal solution for the individual components in the factorized distribution are obtained by minimizing the Kullback-Leibler (KL) divergence (Kullback and Leibler, 1951) between $Q(\Theta)$ and $p(\Theta|\tilde{\boldsymbol{X}})$ with respect to those components. The optimal solution for the components of factorized distribution takes the following closed form

$$\begin{aligned}
q^\star(\boldsymbol{X}) &= \prod_{n=1}^{N} \mathcal{N}(\boldsymbol{x}_n|\boldsymbol{m}_{x_n}, \boldsymbol{P}_{x_n}^{-1}) \\
q^\star(\boldsymbol{Z}) &= \prod_{n=1}^{N} \mathcal{N}(\boldsymbol{z}_n|\boldsymbol{m}_{z_n}, \boldsymbol{P}_{z_n}^{-1}) \\
q^\star(\boldsymbol{W}) &= \prod_{i=1}^{p} \mathcal{N}(\acute{\boldsymbol{w}}_i|\boldsymbol{m}_{\acute{w}_i}, \boldsymbol{P}_{w}^{-1}) \\
q^\star(\boldsymbol{\alpha}) &= \prod_{j=1}^{q} \text{Gamma}(\alpha_j|a_\alpha, b_{\alpha_j}) \\
q^\star(\boldsymbol{\mu}) &= \mathcal{N}(\boldsymbol{\mu}|\boldsymbol{m}_\mu, \beta^{-1}\boldsymbol{I}_p) \\
q^\star(\tau) &= \text{Gamma}(\tau|c, d)
\end{aligned}$$

where column vector $\acute{\boldsymbol{w}}_i$ denotes i^{th} row of $\boldsymbol{W}$, and

$$\begin{aligned}
\boldsymbol{P}_{x_n} &= \boldsymbol{B}_n + \langle\tau\rangle\boldsymbol{I}_p \\
\boldsymbol{m}_{x_n} &= \boldsymbol{P}_{x_n}^{-1}[\langle\tau\rangle(\langle\boldsymbol{W}\rangle\langle\boldsymbol{z}_n\rangle + \langle\boldsymbol{\mu}\rangle) + \boldsymbol{B}_n\tilde{\boldsymbol{x}}_n] \\
\boldsymbol{P}_{z_n} &= \langle\tau\rangle\left\langle\boldsymbol{W}^{\text{T}}\boldsymbol{W}\right\rangle + \boldsymbol{I}_q \\
\boldsymbol{m}_{z_n} &= \langle\tau\rangle\,\boldsymbol{P}_{z_n}^{-1}[\langle\boldsymbol{W}\rangle^{\text{T}}(\langle\boldsymbol{x}_n\rangle - \langle\boldsymbol{\mu}\rangle)] \\
\boldsymbol{P}_{w} &= diag(\langle\boldsymbol{\alpha}\rangle) + \langle\tau\rangle\textstyle\sum_{n=1}^{N}\left\langle\boldsymbol{z}_n\boldsymbol{z}_n^{\text{T}}\right\rangle \\
\boldsymbol{m}_{\acute{w}_i} &= \langle\tau\rangle\,\boldsymbol{P}_{w}^{-1}\left[\textstyle\sum_{n=1}^{N}\langle\boldsymbol{z}_n\rangle(\langle x_{ni}\rangle - \langle\mu_i\rangle)\right] \\
a_\alpha &= a_0 + p/2 \\
b_{\alpha_j} &= b_0 + \left\langle\boldsymbol{w}_j^{\text{T}}\boldsymbol{w}_j\right\rangle/2
\end{aligned}$$

$$
\begin{aligned}
\beta &= \beta_0 + N\langle\tau\rangle \\
\boldsymbol{m}_\mu &= \langle\tau\rangle \beta^{-1} \boldsymbol{I}_p \textstyle\sum_{n=1}^{N} (\langle\boldsymbol{x}_n\rangle - \langle\boldsymbol{W}\rangle\langle\boldsymbol{z}_n\rangle) \\
c &= c_0 + N/2 \\
d &= d_0 + \frac{1}{2}\textstyle\sum_{n=1}^{N} [\langle\boldsymbol{x}_n^{\mathrm{T}}\boldsymbol{x}_n\rangle + \mathrm{trace}\left(\langle\boldsymbol{W}^{\mathrm{T}}\boldsymbol{W}\rangle\langle\boldsymbol{z}_n\boldsymbol{z}_n^{\mathrm{T}}\rangle\right) + \langle\boldsymbol{\mu}^{\mathrm{T}}\boldsymbol{\mu}\rangle \\
&\quad +2\langle\boldsymbol{\mu}\rangle^{\mathrm{T}}\langle\boldsymbol{W}\rangle\langle\boldsymbol{z}_n\rangle - 2\langle\boldsymbol{x}_n\rangle^{\mathrm{T}}(\langle\boldsymbol{W}\rangle\langle\boldsymbol{z}_n\rangle + \langle\boldsymbol{\mu}\rangle)].
\end{aligned}
$$

The expected values required in the equations were evaluated using following properties. For a Gaussian distribution, $p(\boldsymbol{x}) \sim \mathcal{N}(\boldsymbol{x}|\boldsymbol{\mu}, \boldsymbol{P}^{-1})$,

$$\langle\boldsymbol{x}\rangle = \boldsymbol{\mu}, \quad \langle\boldsymbol{x}\boldsymbol{x}^{\mathrm{T}}\rangle = \boldsymbol{\mu}\boldsymbol{\mu}^{\mathrm{T}} + \boldsymbol{P}^{-1}, \text{ and } \quad \langle\boldsymbol{x}^{\mathrm{T}}\boldsymbol{x}\rangle = \boldsymbol{\mu}^{\mathrm{T}}\boldsymbol{\mu} + \mathrm{trace}(\boldsymbol{P}^{-1}); \tag{8}$$

and for a Gamma distribution, $p(x) \sim \mathrm{Gamma}(x|a, b)$,

$$\langle x\rangle = \frac{a}{b}, \text{ and } \quad \langle x^2\rangle - \langle x\rangle^2 = \frac{a}{b^2}. \tag{9}$$

Variational noisy relevance vector machine (VNRVM)

Let the regression relationship between between independent variable $\boldsymbol{x}_n$ and dependent variable y_n be given by

$$y_n = f(\boldsymbol{x}_n, \boldsymbol{X}; w_0, \boldsymbol{w}) + \varepsilon = w_0 + \boldsymbol{w}^{\mathrm{T}}\boldsymbol{\phi}_n + \varepsilon \tag{10}$$

where parameter w_0 that allows for a fixed offset in the data is termed as 'bias'; $\boldsymbol{w} = [w_1, \ldots, w_M]^{\mathrm{T}}$ is weight vector; ε is noise term assumed to have zero mean Gaussian distribution with variance σ_ε^2 (precision $\tau_\varepsilon = \sigma_\varepsilon^{-2}$), i.e. $\varepsilon \sim \mathcal{N}(\varepsilon|0, \sigma_\varepsilon^2)$; and $\boldsymbol{\phi}_n = [\phi(\boldsymbol{x}_1, \boldsymbol{x}_n), \ldots, \phi(\boldsymbol{x}_M, \boldsymbol{x}_n)]^{\mathrm{T}}$ is a vector of basis functions. In RVM, basis functions are functions with one kernel associated with each data point in the training data, i.e. $M = N$. In standard RVM the complexity of the regression model is governed by assigning following hierarchical priors over bias and weight vectors

$$p(w_j|\alpha_j) = \mathcal{N}(w_j|0, \alpha_j^{-1}); \qquad j = 0, \ldots, M. \tag{11}$$

where α_j is a hyper-parameter with a non-informative uniform prior over log space as with σ_ε^2. Ideally, model parameters should be estimated by determining their posterior distribution using Bayes rule. Since this is analytically intractable, posterior distribution is estimated only for bias and weight vectors whereas point estimates are obtained for other parameters using type-II maximum likelihood approach that approximates posterior distributions by a delta function at their modes. This assumption is justified when number of data points (N) is very large because in that case posterior distribution is tightly concentrated around its mean. However, in typical hydrologic applications, N tends to be small and this approximation is rarely justified.

A complete Bayesian treatment of RVM through variational inference was proposed by Bishop and Tipping (2000). In this study, their method is extended to incorporate measurement uncertainties of input data into RVM learning.

As in VBaNPCA, the true input $\boldsymbol{x}_n$ is treated as a latent variable in VNRVM. The following prior distributions were assigned to model hyper-parameters and noise variance

$$p(\alpha_j) = \text{Gamma}(\alpha_j|a_0, b_0); \quad j = 0, \ldots, M \tag{12}$$
$$p(\tau_\varepsilon) = \text{Gamma}(\tau_\varepsilon|c_0, d_0). \tag{13}$$

The priors were made flat or non-informative by setting $a_0 = b_0 = c_0 = d_0 = 10^{-3}$. For this choice of prior distribution, the posterior distribution does not have analytical solution and is approximated using variational method described in the previous section. The approximation to the posterior distribution of model parameters and latent variables is given by

$$Q(\boldsymbol{X}, \boldsymbol{w}, w_0, \boldsymbol{\alpha}, \alpha_0, \tau_\varepsilon) = q(\boldsymbol{X})q(\boldsymbol{w})q(w_0)q(\boldsymbol{\alpha})q(\alpha_0)q(\tau_\varepsilon).$$

The optimal solution for $q(\boldsymbol{X})$ depends on the choice of kernel function and will be discussed shortly. Optimal solution for other components of Q were analytically estimated as

$$q^\star(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{w}|\boldsymbol{m}_w, \boldsymbol{P}_w) \tag{14}$$
$$q^\star(w_0) = \mathcal{N}(w_0|m_{w_0}, p_{w_0}) \tag{15}$$
$$q^\star(\boldsymbol{\alpha}) = \prod_{j=1}^{M} \text{Gamma}(\alpha_j|a_\alpha, b_{\alpha_j}) \tag{16}$$
$$q^\star(\alpha_0) = \text{Gamma}(\alpha_0|a_\alpha, b_{\alpha_0}) \tag{17}$$
$$q^\star(\tau_\varepsilon) = \text{Gamma}(\tau_\varepsilon|c, d) \tag{18}$$

where

$$\boldsymbol{P}_w = \text{diag}(\langle\boldsymbol{\alpha}\rangle) + \langle\tau_\varepsilon\rangle \sum_{n=1}^{N} \left\langle \boldsymbol{\phi}_n^{\mathrm{T}}\boldsymbol{\phi}_n \right\rangle$$
$$\boldsymbol{m}_w = \langle\tau_\varepsilon\rangle \boldsymbol{P}_w^{-1} \sum_{n=1}^{N} \langle\boldsymbol{\phi}_n\rangle (y_n - \langle w_0\rangle)$$
$$p_{w_0} = \langle\alpha_0\rangle + N \langle\tau_\varepsilon\rangle$$
$$m_{w_0} = \langle\tau_\varepsilon\rangle p_{w_0}^{-1} \sum_{n=1}^{N} (y_n - \langle\boldsymbol{w}\rangle^{\mathrm{T}} \langle\boldsymbol{\phi}_n\rangle)$$
$$a_\alpha = a_0 + 1/2$$
$$b_{\alpha_j} = b_0 + \left\langle w_j^2 \right\rangle; \quad j = 0, \ldots, M$$
$$c = c_0 + N/2$$
$$d = d_0 + \frac{1}{2} \sum_{n=1}^{N} [y_n^2 + \text{trace}(\left\langle \boldsymbol{w}\boldsymbol{w}^{\mathrm{T}} \right\rangle \left\langle \boldsymbol{\phi}_n\boldsymbol{\phi}_n^{\mathrm{T}} \right\rangle) + N \left\langle w_0^2 \right\rangle$$
$$+ 2 \langle w_0\rangle \langle\boldsymbol{w}\rangle^{\mathrm{T}} \langle\boldsymbol{\phi}_n\rangle - 2y_n(\langle\boldsymbol{w}\rangle^{\mathrm{T}} \langle\boldsymbol{\phi}_n\rangle + \langle w_0\rangle)]$$

and the required moments are estimated using Eqs. 8 and 9. For linear VNRVM, i.e. $\boldsymbol{\phi}_n = \boldsymbol{x}_n$, the optimal solution for $q(\boldsymbol{X})$ has a closed form given by

$$q^{\star}(\boldsymbol{X}) = \prod_{n=1}^{N} \mathcal{N}(\boldsymbol{x}_n | \boldsymbol{m}_{x_n}, \boldsymbol{P}_{x_n}^{-1}) \tag{19}$$

where

$$\begin{aligned} \boldsymbol{P}_{x_n} &= \boldsymbol{B}_n + \langle \tau_\varepsilon \rangle \langle \boldsymbol{w}\boldsymbol{w}^{\mathrm{T}} \rangle \\ \boldsymbol{m}_{x_n} &= \boldsymbol{P}_{x_n}^{-1} [\langle \tau_\varepsilon \rangle \langle \boldsymbol{w} \rangle (y_n - \langle w_0 \rangle) + \boldsymbol{B}_n \tilde{\boldsymbol{x}}_n]. \end{aligned}$$

For nonlinear regression, the distribution $q^{\star}(\boldsymbol{X})$ does not have closed from and was approximated using Metropolis-Hasting algorithm (Bishop, 2006).

Data used in the study

Sea surface temperature

Gridded sea surface temperature data available at monthly time step from HadSST2 (Rayner et al., 2006) prepared at the Hadley Centre for Climate Prediction and Research, UK, website `http://hadobs.metoffice.com/hadsst2/` were used in the study. HadSST2 is an un-interpolated sea surface temperature data set based on *in-situ* measurements of SST obtained mainly from ships and buoys. The climatological values were subtracted from the SST measurements to estimate anomalies. The resulting anomalies were gridded onto a 5^0 latitude by 5^0 longitude monthly grid by taking *winsorized mean*. Bias correction was applied on the gridded anomalies to remove spurious trends caused by changes in SST measuring practices, following the procedure of Folland and Parker (1995).

HadSST2 accounts for uncertainty arising from - (i) measurement and sampling errors (M&SE). Measurement errors are related to precision of the instruments used for measuring SST, while sampling errors are caused by estimating an area-averaged quantity from a finite number of noisy observations; (ii) bias due to different measurement practices over the observation period. The combined uncertainty was obtained by adding M&SE and errors due to bias correction, in quadrature, i.e. by taking square root of the sum of the squares of errors.

All India summer monsoon rainfall

The area weighted rainfall data for India (Parthasarathy et al., 1994) was extracted from Indian Institute of Tropical Meteorology, Pune, web site `http://www.tropmet.res.in`. The data extends from January 1871 to December 2006. Primary source of the data is India Meteorological Department. The time series of summer monsoon rainfall was derived by adding monthly rainfall values for monsoon months (JJAS).

Methodology, Results, and Discussion

HadSST2 dataset is available from 1850 onwards, but data from January 1901 to December 2006 were used in this study. The grid points with more than 50% of missing records were not considered in the analysis. The data were partitioned

into five non-overlapping sectors - (i) Tropical Pacific sector (30^0S – 30^0N), (ii) North Pacific sector (north of 30^0N), (iii) Tropical Atlantic sector (30^0S – 30^0N), (iv) North Atlantic sector (north of 30^0N), (v) and Indian Ocean sector (north of 30^0S) to reduce the influence of strong ENSO signals on variability of SST data outside of the tropical Pacific Ocean. The monthly SST anomalies were averaged to get seasonal anomalies for four seasons (DJF, MAM, JJA, and SON). Since the measurement errors in monthly anomalies were independent, the error variance in the seasonal anomaly was estimated by taking the average of error variance in monthly anomalies. Seasonal SST tendencies, defined as a change in SST anomalies from the previous season, were estimated and the associated error variances were calculated by adding variances in the anomalies of current and previous season. In the following, the term 'SST data' will refer to both SST anomalies and SST tendencies. The predictors for mean monsoon rainfall were identified from the SST data, one season lag to three years lag from the monsoon season. The data were partitioned into a training set (1901 to 1985) and a test set (1986 to 2006), only the former set was used for identifying predictors.

The models were developed following two approaches. In the first approach, SST data for each season in an oceanic sector were processed using PCA, the PCs obtained were correlated with AISMR to select predictors, which were then used by a regression model to learn a functional relationship between them and AISMR. The approach is referred to as *PCR*, which reflects the order in which the algorithms were applied, i.e. PCA, followed by correlation, and regression. In the second approach, termed *CPR*, AISMR data were first correlated with SST data at each grid points to select useful features. The selected features were subsequently processed by PCA to yield PCs, which in turn form input to the regression model. The advantages of the two approaches are complementary. On the one hand, in PCR, dimensionality of potential predictors is reduced by PCA that removes noise in the data but in the process may also remove important information resulting in poor performance. On the other hand, in CPR, all the information is retained and the predictors are searched in a much larger space of potential predictors leading to good results but possibly poor generalization performance.

Table 1 shows correlation and relative root mean square error (RRMSE) between observed and predicted values during training and testing periods using PCR approach by a set different algorithms. The following steps were taken to facilitate comparison among different algorithms

1. PCA: Only first three PCs of SST data from SPCA and VBaNPCA were used in the analysis;

2. Correlation: A feature was selected as a potential predictor if its Pearson product moment correlation with AISMR was greater or smaller than zero at 10% significance level.

3. Regression: The regression relation was learned using linear versions of RVM and VNRM algorithms.

PCA	Regression	Training		Testing	
		r	RRMSE	r	RRMSE
SPCA	RVM	0.80	5.52	0.33	6.97
VBaNPCA	RVM	0.88	3.09	0.52	1.57
	VNRVM	0.89	2.99	0.51	1.70

Table 1: Prediction of all India summer monsoon rainfall using PCR approach. The symbols r and RRMSE correspond to the correlation and relative root mean square error between observed and predicted rainfall values after normalization

The results indicate that the models engaging data uncertainty information perform better than the models that do not use it. VBaNPCA algorithm appears to significantly affect the prediction performance while other two methods, BaNCorr and VNRVM, only marginally alter the prediction performance.

Table 2 summarizes the results obtained form algorithms following CPR approach. For the results reported, the first step in CPR approach was performed using Pearson product moment correlation. The step involves selecting grid points in SST data for which the null hypothesis of no correlation with AISMR was rejected at 1% significance level. The selected feature were processed using SPCA and VBaNPCA to obtain predictors for the regression model. In VBaNPA, the number of predictors was automatically selected to be 11; for consistency, the same number of predictors were used in SPCA. The results in Table 2 corroborate the previous conclusion that the models engaging input uncertainty information improves prediction performance. Comparison of PCR and CPR approaches show that for training period the performance of CPR is not statistically different form PCR model, however, during testing it performs poorly, suggesting that including too many potential predictors may actually degrade the generalization performance of the model.

Correlation	PCA	Regression	Training		Testing	
			r	RRMSE	r	RRMSE
Pearson	SPCA	RVM	0.85	2.68	0.27	43.31
	VBaNPCA	RVM	0.84	4.42	0.35	7.42
		VNRVM	0.85	4.45	0.36	8.44

Table 2: Prediction of all India summer monsoon rainfall using CPR approach. The symbols r and RRMSE correspond to the correlation and relative root mean square error between observed and predicted rainfall values after normalization

The results obtained in this study suggest that incorporating measurement errors in hydrologic models improves their prediction performance and provides better assessment of their predictive capabilities.

Abstract

Due to the limitations of rain gauges in representing spatial rainfall variability, radar estimates are of particular importance, especially in areas subject to variable rainfall from convective storms. This study explores the use of a real-time adjustment of the reflectivity-rainfall (Z-R) relationship in determining radar rainfall estimates throughout the South Florida Water Management District (SFWMD). Level II reflectivity data from the Melbourne (KMLB) NEXRAD radar site, operated by the National Weather Service (NWS), was used in conjunction with 15-minute precipitation data from real-time gauges operated by the SFWMD. The coefficients A and b of the Z-R relationship were adjusted at each time step of the study period, based on gauge and reflectivity pairs obtained from the preceding 24 hours, allowing for variability within the Z-R relationship as the rainfall event progressed. Verification of the radar estimates was conducted with a separate set of rain gauges, not included in the estimation of A and b, using various graphical and statistical methods. To further explore the applicability of this study to the SFWMD, radar estimates currently being supplied to the District by means of a different algorithm were also verified with the same methods for comparison to the real-time adjusted estimates.

Introduction

Accurate prediction of rainfall events through the use of radar is becoming increasingly important for water management and planning activities, particularly in areas where the representativeness of rain gauge readings is limited by highly variable rainfall from convective storms. Inherent errors within the radar estimation process itself, such as the calibration of the relationship between reflectivity (Z) and surface rainfall rates (R), however, lead to uncertainties in the radar rainfall estimates. The complexities of the estimation process are increased due to the variation of the Z-R relationship with rainfall type and location, which has been represented by many different power-law equations (Battan, 1973). This variation is attributed in part to changes in the rainfall drop size distribution (DSD) which can exhibit inter-storm and intra-storm variability. Through the use of DSD measurements, Steiner and Smith (2000) showed that the multiplicative coefficient, A, is particularly sensitive to variation on a storm-by-storm basis. Variation within a single storm was also proven to be a significant source of uncertainty in radar estimates by Uijlenhoet et al. (2003)

in the evaluation of a squall line rainstorm. Lee and Zawadzki (2005) in an analysis of the scale dependence of DSD variability showed that most of the DSD variability occurred within storms or between storms within a day. Habib et al., (2008) showed that variability in Z-R relationships can have a significant effect on the simulation of streamflow. This variable nature of the Z-R relationship therefore justifies the exploration of real-time calibration of the Z-R relationship to account for changing rainfall characteristics. Legates (2000) showed that calibrating the Z-R relationship in real-time using a sample of gauge and reflectivity pairs from the preceding month, while including a correction to account for overshooting of the radar beam, demonstrated marked improvement over fixed Z-R relationships for an area of the Southern Great Plains. In a further study on real-time Z-R adjustment, Alfieri et al. (2008) analyzed the optimal length of time to be considered in calibration, which was determined to be between 8-24 hours, based upon calculated bias and random error of trial calibration windows ranging from 1 hour to 1 day.

In this study, we evaluated the performance of real-time estimation of the Z-R relationship for use in the South Florida Water Management District as an alternative to the radar estimates currently supplied to the District. Estimation is conducted for October 2007 using 32 real-time rain gauges in the proximity of the Melbourne NEXRAD radar site and the results are verified using 21 additional gauges. Statistical comparisons are made between the two sets of radar estimates for a quantitative analysis of the results.

Study Site and Data Sets

The South Florida Water Management District (SFWMD) is located in the southern part of the Florida peninsula, covering approximately 17,930 square miles and 16 counties from Orlando to the Keys. Highly variable rainfall events produced by convective storms are common in this area during the wet season from June to October. The task of the SFWMD to monitor the quality and supply of water in this area of Florida includes the maintenance and operation of 287 rain gauge stations throughout the district, of which, approximately 151 are operated on a real time basis. Also included in the domain of the SFWMD are four NEXRAD WSR-88D radar stations operated by the National Weather Service (NWS), which include KBYX in Key West, KAMX in Miami, KMLB in Melbourne, and KBTW in Tampa.

The focus of this study was the area of the SFWMD located within the coverage of the KMLB site over a period of one month (October 2007). Data from this radar was obtained as a Level II reflectivity product which is released in approximately 5-minute intervals on a radial grid of 1° x 1 km. This data was then converted to a 2 km x 2 km grid and averaged over a 15 minute interval to match the time scale of the gauges.

Of the real-time gauges operated by the SFWMD, 32 were chosen for use in the calibration of the Z-R relationship based on their proximity (120 km or less) to the KMLB radar (Figure 1). These tipping-bucket gauges use a supervisory control and data acquisition (SCADA) system to transmit data by way of microwave, telemetry, or telephone lines, which allows them to be used for real-time evaluation of rainfall events. An additional 18 gauges (referred to here as CR-10), which do not

operate in real-time, were chosen as an independent reference for the validation of the radar estimates.

Methodology

The benefit of a real-time adjustment of the Z-R relationship for use in constructing radar rainfall estimates was evaluated using pairs of corresponding real-time rain gauge and reflectivity data. The calibration of the Z-R relationship was based upon the standard power-law form of

$$Z = AR^b .$$

The coefficients A and b in the above equation were determined at each 15-minute time step of the study period. For each time step, the sample consisted of Z and R pairs corresponding to all of the selected real-time gauges for the 24 hours preceding the interval, which allowed for a continuous assimilation of new rainfall information into the estimation of the coefficients. After preliminary work was conducted using calibration windows of 1-24 hours, the length of 24 hours was chosen in an effort to eliminate complications due to insufficient sample size associated with shorter windows of time. Only the estimation of A and b for time intervals occurring within the first day of the study period was determined based upon time windows of less than 24 hours, depending on the available length of time preceding each.

The sample used in the calibration at each time step was restricted to data pairs during rainy intervals in which the R values were greater than the gauge minimum hourly detectable rain rate of 1.016 mm and in which the Z values were between 20 and 50 dBZ to account for ground clutter and bright banding. For time intervals where the specified restrictions led to a sample size of less than 30 (i.e. at the onset of a rain event), default values of 300 and 1.4 were used for the coefficients A and b, respectively, due to an insufficient number of data pairs with which to generate reliable A and b values. In all other instances, the values of A and b were determined from the Z-R sample using three regression analysis techniques. The first method is a commonly used procedure based on a least-square-fit regression technique, which showed less positive results than the other two methods and has not been included in this paper. The second estimation method (BIAS-RMSE) is based on bias removal and minimizing root-mean-square errors. The parameter A is determined in such a way that the total rainfall accumulations estimated by the Z–R relationship (i.e., summation of $(Z_i /A)^{1/b}$; i=time step) is set equal to the accumulation of reference rainfall ($R_{ref,i}$) as observed by the gauge, whereas b is sought by minimizing the summation of squared residuals between measured reference rainfall rates, $R_{ref,i}$ and the corresponding estimates of the Z–R relationship, $(Z_i /A)^{1/b}$. Values of A that fell outside of the range of 10-700, as well as b values that were < 1 or > 3, were considered to be unreasonable based upon currently accepted Z-R relationships. For time steps where the regression yielded an unreasonable value for either coefficient, the parameters were recalculated by fixing the exponent b at 1.4 and determining *A* in a similar manner to the BIAS-RMSE method.

In order to assess the performance of the real-time Z-R estimation method, the set of 18 CR-10 gauges, which were independent of the estimation of A and b, were

used for verification. Using the A and b coefficients that had been established for each time step with the real-time gauges, the Z-R relationship was applied with reflectivity data corresponding to the location of the CR-10 gauges for the time period of October 1 – 19, 2007. The rainfall estimates produced by this application of the Z-R relationship were then compared to the corresponding CR-10 gauges based on several graphical and statistical methods. To further demonstrate the specific applicability of the real-time adjustment of the Z-R relationship to the SFWMD, the radar estimates produced by the algorithm currently provided to the District (SFWMD-NRT) were also compared to the CR-10 gauges using the same methods of comparison. These methods include time series plots of rainfall events throughout the 19-day period, the correlation coefficient, standard deviation of errors, histograms of estimation errors, and the distribution of the probability of exceedance of the estimation errors.

Results

The values of the A and b coefficients that were obtained during the study from the BIAS-RMSE method are shown in the Figure 2. These histograms illustrate the variation of the A and b values from the standard values of 300 and 1.4, which are currently used by the SFWMD for estimating radar rainfall data. Figure 2 also shows the correlation coefficient between log (Z) and log (R) of the calibration sample at each time step, which gives an indication of the linearity that would be obtained using the least-square-fit regression technique.

Time series plots of rainfall were produced for various rainy increments throughout the study period (Figure 3). As can be seen from the plots, the real-time (RT) radar estimates follow the pattern of the rainfall fairly well, in both intensity and temporal location, with some underestimation observed in cases of high intensity rainfall. The SFWMD-NRT estimates show similar results in general, however, it is observed on several occasions that instances of extreme overestimation in the SFWMD-NRT is significantly reduced in the RT estimates. Similarly, the timing of the peak rainfall intensity is seen to be more closely captured by the RT estimates at several points throughout the study period. The correlation of both the RT and SFWMD-NRT estimates to each of the CR-10 gauges was measured using the Pearson's correlation coefficient, a measure of linear association. These results, which are shown in Figure 4, show that the correlation of the RT estimates falls mainly in the range of 0.5 to 0.7, while the SFWMD-NRT shows a wider range of values, with some as low as 0.1 and the majority in the 0.4 to 0.6 range. From this figure, it is observed that the RT estimates demonstrate an improved correlation to the recorded gauge rainfall intensity, as compared to the SFWMD-NRT estimates, in almost all of the gauges that were used, with some gauge sites (i.e. 1, 12, and 16) showing very large improvement.

Similarly, the standard deviation of the RT and SFWMD-NRT estimation error was also calculated at each gauge site (Figure 5), where the standard deviations of the error were defined as:

$$\sigma(R_{RT} - R_G) \text{ and } \sigma(R_{SFWMD-NRT} - R_G),$$

respectively. The standard deviation of the RT estimates ranged from approximately 2 to 7, which again showed positive improvement over the SFWMD-NRT at most gauge locations, particularly in the case of more extreme values (> 10) that were observed in some instances with the SFWMD-NRT estimates. The characteristics of the error of both sets of radar estimates were further analyzed by plotting frequency histograms of the error magnitudes (Figure 6). The error distribution for the RT estimates is approximately symmetrical about the zero mark with most occurrences of error falling within ± 2 mm/h. The frequency of zeros for RT is nearly double that of the SFWMD-NRT, while the wider tails of the SFWMD-NRT histogram reflect a higher frequency of error beyond the ± 2 mm/h range. In addition, the distribution of the SFWMD-NRT error is slightly skewed to the right, illustrating the higher frequency of positive errors which was observed previously in the time series plots.

Finally, the error distribution was characterized by its probability of exceedance, which was calculated as the probability that the error exceeded a certain rainfall threshold value. For all values of the rainfall threshold, the probability of exceedance was smaller for the RT estimates when compared to the SFWMD-NRT estimates (Figure 7). These distributions were further decomposed into separate plots of the positive and negative components of the error (Figure 8 and Figure 9). When comparing the positive errors of the two sets of radar estimates, the probability of exceedance for the RT is consistently less than the SFWMD-NRT, with the difference between the two becoming increasingly larger after the 20 mm/h threshold. After this point, the probability drops off steadily for the RT, while the decrease in the probability for the SFWMD-NRT is slower due to the presence of the several very large rainfall intensity values noted earlier. The probability of exceedance for the negative component of the error, however, shows more similarity between the two radar estimates. For error thresholds below 30 mm/h, the RT and SFWMD-NRT show comparable results, while at threshold values above 30 mm/h, the RT again shows smaller exceedance probabilities.

Summary and Conclusions

This study evaluated the performance of a real-time adjustment of the Z-R relationship for use in estimating rainfall from reflectivity at the SFWMD in southern Florida. The objective was to provide an alternative to the radar estimates currently provided to the District that would offer improved results through the incorporation of real-time variability of the Z-R relationship in the estimation procedure. The coefficients, A and b, were estimated at each 15-minute time step for a 19 day period in October, 2007, using real-time gauge and reflectivity data from the 24 hours preceding each time step. Comparison of the radar estimates based on these applied real-time Z-R relationships was conducted using an independent set of gauges excluded from the estimation process. An identical verification was conducted with the radar estimates (SFWMD-NRT) currently used by the District for comparison between the performances of the two radar data sets. Based on the results of the study, the following conclusions can be made:

- The overall performance of the RT estimates showed visual improvements over the SFWMD-NRT estimates in terms of matching the recorded rainfall on a quantitative and temporal scale.

- Further signs of positive improvement of the RT were observed with the correlation coefficient of the RT estimates being significantly higher than the SFWMD-NRT estimates for nearly all of the reference gauges and the standard deviation of the error being lower.
- The distribution of error for the RT estimates was shown to be narrower with a higher frequency of zero error, indicating that the tendency towards overestimation in the SFWMD-NRT estimation was not present to as great an extent in the RT estimates.
- Based on this study, it was recommended that the District consider developing Z-R relationship specifically for the District use to improve the radar rainfall estimation.

Abstract

The climate in California's central valley is distinctly divided into two seasons: wet and dry. Sacramento's six-month wet season runs roughly from mid-October through mid-April, while the dry season runs through the remaining six months from mid-April to mid-October.

While rainfall during Sacramento's "dry" season is not unheard of, it is relatively rare, especially in August. At one long-term climatological observing station in Sacramento from 1877 to 2006, there were 4024 non-missing daily August rainfall observations. Of those 4024 rainfall observation days, only 41 days (1.02%) recorded more than a "trace" and daily observations of more than 0.30 inches were reported just two times. The maximum August daily rainfall in Sacramento from 1877-2006 was 0.66 inches.

That is why the events of August 21-22, 2003 were remarkable. A series of unusually strong thunderstorms rolled through region during the late afternoon on August 21st and continued sporadically through the early morning hours of August 22nd. Rainfall totals in excess of 1.4 inches were recorded in 24 hours, more than double the maximum daily August rainfall observed in the 130 year record.

High resolution radar rainfall estimates were calibrated using gage observations from the local flood ALERT system. The gage-adjusted radar rainfall estimates were used to track the intense storm cells through the city of Sacramento and to the localized flooding that occurred.

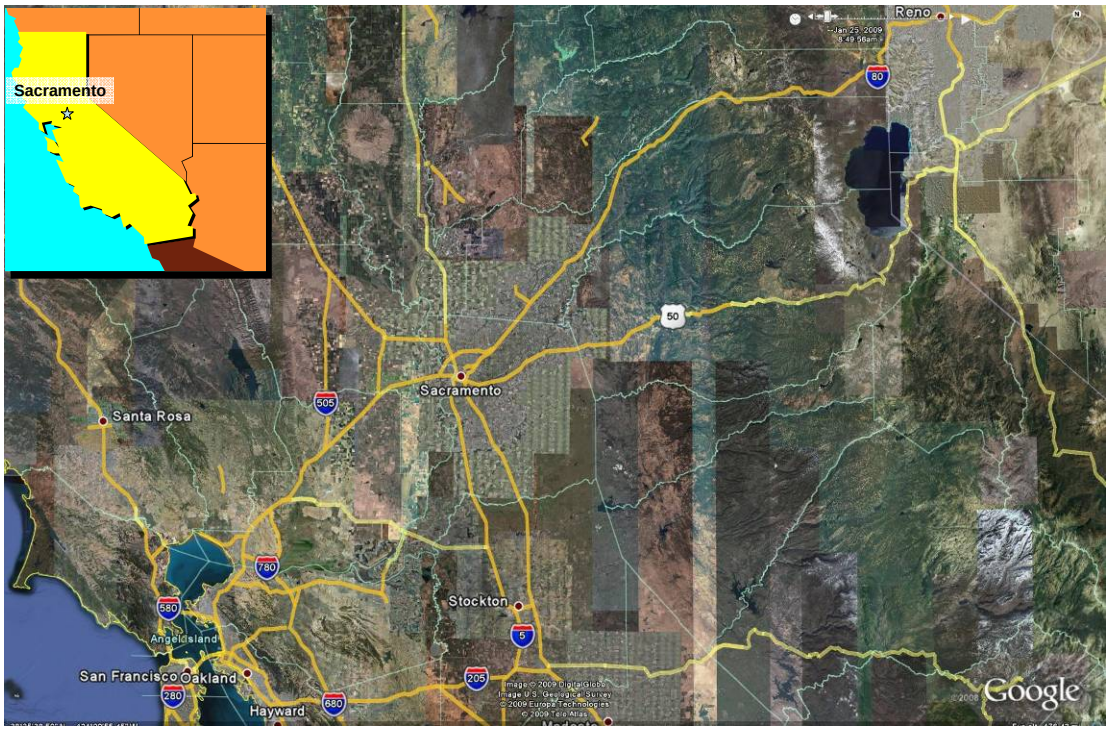

Figure 1: Map of Sacramento Region

Background

Located in northern California, roughly midway between San Francisco and Lake Tahoe, Sacramento enjoys a Mediterranean climate with typically hot dry summers and mild winters. The period October-April receives nearly 90% of Sacramento's 19.87 inches of annual rainfall, based on the latest climate figures for1971-2000. As noted in Figure 2, January is typically the wettest month with 4.18 inches of rainfall, on average, while July and August are the driest at 0.05 inches.

August in Sacramento is typically so dry that the maximum daily rainfall observed on seven August days from 1877-2006 was 0.00 inches and 0.01 inches on four others. The official maximum daily rainfall observed in August is 0.66 inches, which occurred on August 29, 1953 (Cline and Garcia, 2007).

From 1877 to 2006 there were 4024 non-missing daily August rainfall observations. Of those 4024 rainfall observation days, only 41 days (1.02%) recorded more than a trace and daily observations of more than 0.30 inches were reported just two times. Over the 130 year record, measureable August rainfall occurred about once every three years, on average, although the more recent experience (i.e. 1971-2000) is closer to once every year.

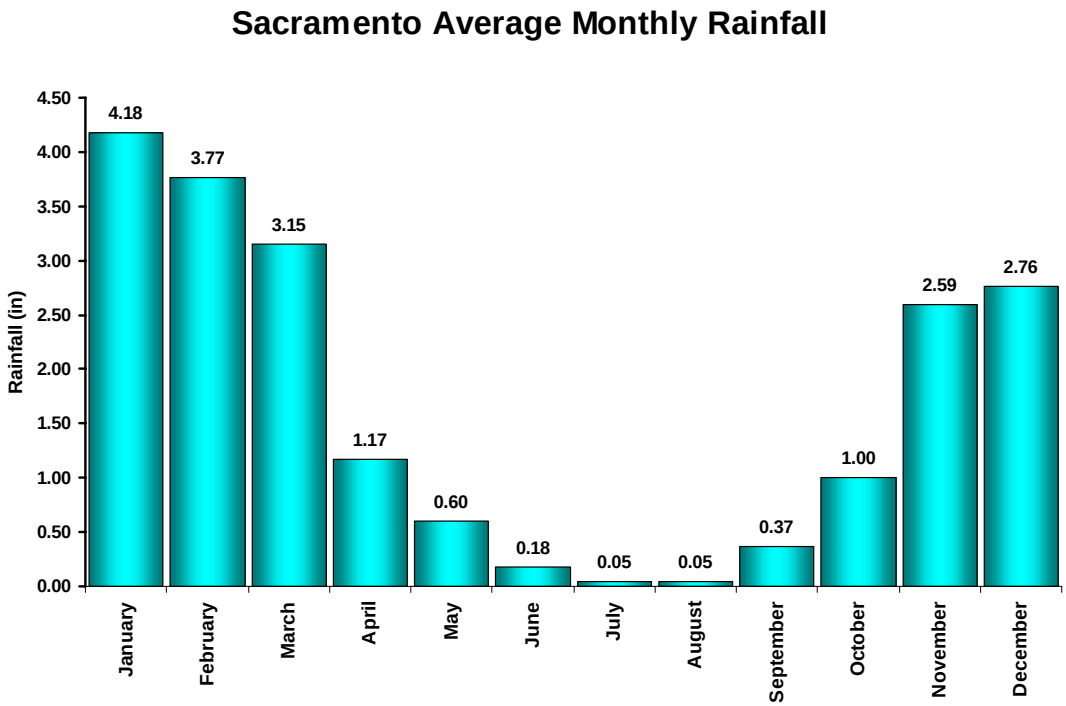

Figure 2: Sacramento Average Monthly Rainfall

August 2003

Despite the climatologically dry August conditions in Sacramento, occasionally enough moisture moves into the area, creating conditions for isolated thunderstorms and locally heavy downpours. Such was the case on August 21-22, 2003.

On August 20th, the Sacramento office of the National Weather Service (NWS) observed a significant surge of subtropical moisture headed to northern California on a collision course with an area of low pressure forecast to move onshore from the eastern Pacific on August 21-22. This mix of air masses was ripe for thunderstorm development and locally heavy rainfall as indicated by the 9:30 PM August 20, 2003 NWS Special Weather Statement shown in Table 1.

By mid-afternoon on August 21st, the first of a series of thunderstorm complexes with locally heavy downpours moved into Sacramento and lasted until about 10 AM on August 22nd. Table 2 presents the NWS Hazardous Weather Outlook issued at 3 PM on August 21st. In the end, the storms knocked out power to 22,000 homes and businesses, flooded city streets, and inundated approximately 100 vehicles to a depth of 6-7 feet in a temporary parking area at the California State Fair.

The magnitude of flooding at the California State Fair seemed surprising to observers at the site. While downpours on the afternoon of August 21st were briefly intense, the rainfall volumes didn't seem large enough to cause the deep flooding observed. An analysis of local rain gage observations and radar rainfall estimates was conducted to determine what caused the flooding.

...SHOWERS AND THUNDERSTORMS EXPECTED TO AFFECT NORTHERN CALIFORNIA THURSDAY AND FRIDAY...WITH LOCALLY HEAVY RAIN...

THE WEATHER PATTERN HAS TRANSITIONED INTO ALLOWING A SIGNIFICANT SURGE OF SUBTROPICAL MOISTURE INTO NORTHERN CALIFORNIA. SHOWERS AND THUNDERSTORMS ARE EXPECTED TO AFFECT THE SIERRA NEVADA OVERNIGHT. ADDITIONAL SHOWERS AND THUNDERSTORMS WILL DEVELOP AND MOVE ACROSS THE LOWER ELEVATIONS OF THE SIERRA NEVADA LATE TONIGHT. SOME OF THIS MAY AFFECT PARTS OF THE CENTRAL VALLEY LATE TONIGHT AND EARLY THURSDAY MORNING.

SHOWERS AND THUNDERSTORMS ARE EXPECTED TO BECOME MORE WIDESPREAD ON THURSDAY ...INCLUDING AREAS FROM THE COASTAL RANGE TO THE CENTRAL VALLEY AND EASTWARD TO THE SIERRA NEVADA. THE ACTIVITY WILL MOVE FROM SOUTH TO NORTH ACROSS THE STATE. THE PRECIPITATION WILL AFFECT THE CENTRAL VALLEY AND THE HIGHER TERRAIN. THEN ADDITIONAL WIDESPREAD SHOWERS AND THUNDERSTORMS WILL DEVELOP AND CONTINUE THURSDAY NIGHT INTO FRIDAY. DURING THIS PERIOD THE RAIN WILL BE LOCALLY HEAVY IN THE STRONGER SHOWERS AND THUNDERSTORMS. THIS WILL BE THE RESULT OF AN UPPER LEVEL LOW PRESSURE AREA IN THE EASTERN PACIFIC THAT MOVES INLAND THURSDAY NIGHT AND INTERACTS WITH THE DEEP UNSTABLE SUBTROPICAL MOISTURE THAT WAS CARRIED INTO THE REGION. PRECIPITATION WILL TAPER OFF FROM SOUTHWEST TO NORTHEAST ON FRIDAY.

THE HEAVIEST RAIN FRIDAY AFTERNOON WILL OCCUR OVER THE WEST SLOPE OF THE SIERRA NEVADA AND THE SHASTA COUNTY MOUNTAINS. NORTHERN CALIFORNIA EXPERIENCED A SIMILAR OUTBREAK OF SHOWERS AND THUNDERSTORMS EARLIER THIS MONTH. RAINFALL TOTALS ARE EXPECTED TO BE SIGNIFICANT FROM THURSDAY INTO FRIDAY.

IF YOU ARE PLANNING ANY OUTDOOR ACTIVITIES BE AWARE OF RAPIDLY CHANGING WEATHER CONDITIONS. THUNDERSTORMS CAN PRODUCE DEADLY CLOUD TO GROUND LIGHTNING...EVEN A FEW MILES AWAY FROM THE MAIN STORM CENTER. LOCALIZED AREAS OF HEAVY RAIN WILL CAUSE SMALL STREAMS TO RISE RAPIDLY.

NOW... AT 300 PM...DOPPLER RADAR INDICATED A THUNDERSTORM WITH HEAVY RAIN IN CENTRAL SACRAMENTO. THE THUNDERSTORM IS MOVING NORTHEAST AT 20 MPH AND IS PRODUCING LIGHTNING AND GUSTY WINDS. CALIFORNIA RESIDENTS AT THE STATE FAIR SHOULD TAKE COVER FOR AT LEAST THE NEXT HOUR THROUGH 4PM. MINOR URBAN FLOODING IS POSSIBLE IN MANY LOCATIONS THIS AFTERNOON. IF YOU ARE OUTDOORS...MOVE TO A PLACE OF SHELTER IMMEDIATELY IF A STORM APPROACHES. MOTORISTS SHOULD REMAIN ALERT FOR REDUCED VISIBILITIES DURING DOWNPOURS OF RAIN. POWELL

Rainfall Analysis

Sacramento County and nearby agencies, Placer County and the cities of Roseville and Folsom, collectively operate an automated rainfall and stream level information system known as ALERT (Automated Local Evaluation in Real-Time, http://www.sacflood.org/). The network of rain, stream, weather, and status sensors includes nearly 60 automatically reporting tipping bucket rain gages. Rain gage locations are shown on Figure 3. Recorded rain gage data including the date and time of each bucket tip were obtained from Sacramento County's Department of Water Resources.

These rainfall data were used by OneRain, Inc. (www.onerain.com) to calibrate 5-minute, 1 km resolution radar rainfall estimates for the storm event. The resulting gage-adjusted radar rainfall estimates of storm totals are shown on Figure 3. Also shown are the location of the California State Fair Grounds (CalExpo) and the contributing watershed to the flooded parking area, Chicken Ranch Slough.

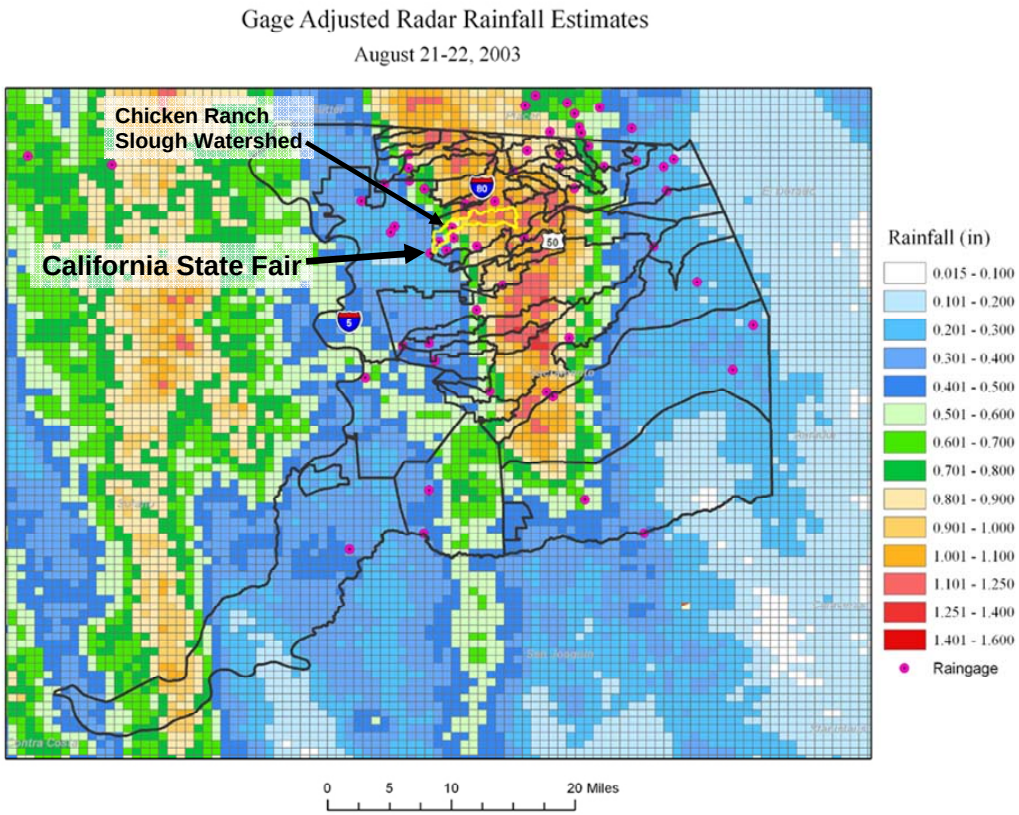

Figure 3: Sacramento County Watershed Map with Rain Gage Locations. Each rectangular grid cell or pixel represents 1 km^2 or 100 hectares (247 acres).

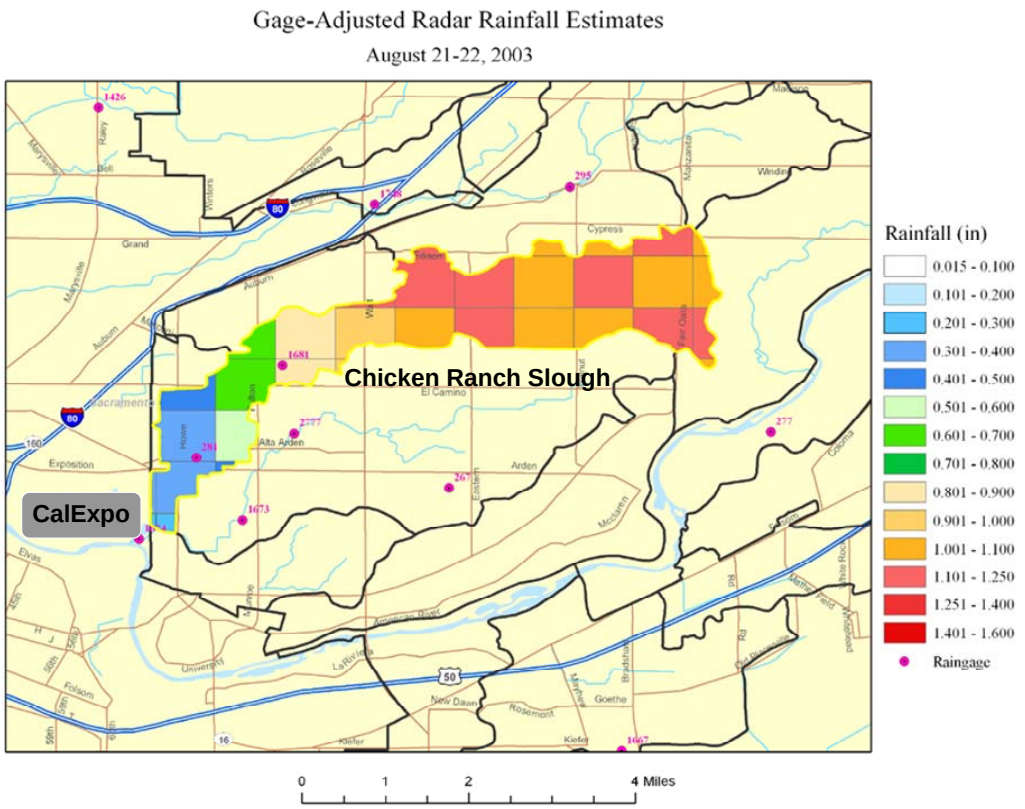
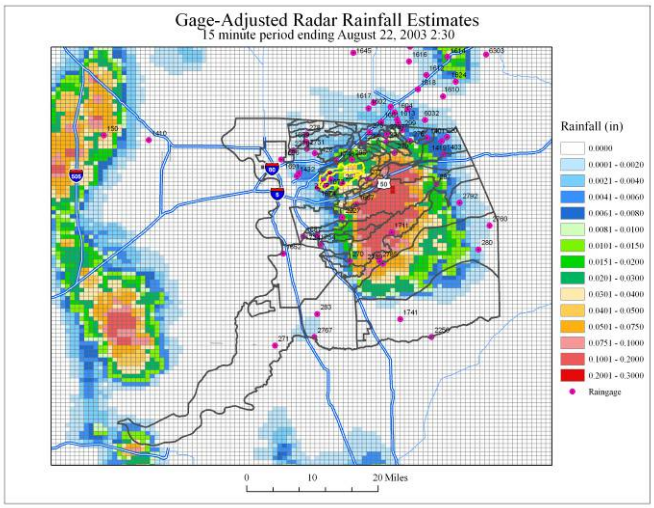
Chicken Ranch Slough includes approximately 20 km^2 (7.7 mi^2) of generally flat residential/commercial area gently sloping east to west/southwest. Total radar-estimated rainfall for the event exceeded 36 mm (1.4 in) at several locations along a north-south band of heavy rain in eastern Sacramento County.





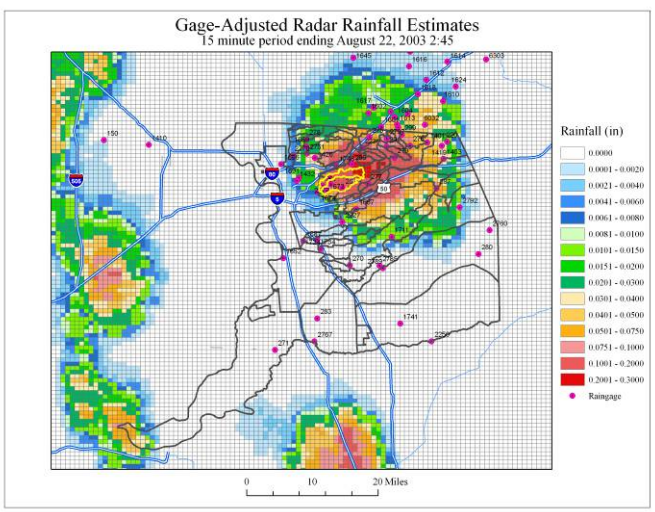


Figure 4: Isolated Close-up View of the Chicken Ranch Slough Watershed and Surrounding Area.

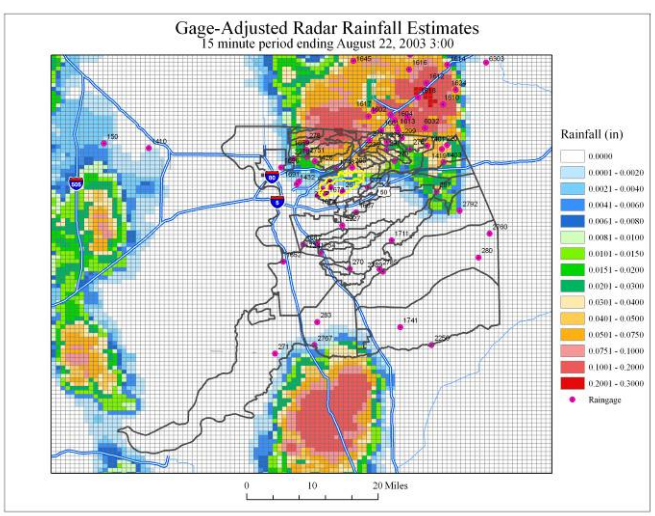
An isolated view of the Chicken Ranch Slough Watershed is shown in Figure 4. Rain gages in the vicinity of Chicken Ranch Slough are also shown. Radar rainfall estimates show a strong rainfall gradient from east to west with storm totals ranging from approximately 36 mm (1.41 in) to 6 mm (0.24 in) within Chicken Ranch Slough. The strong east-west gradient was caused by the northerly storm movement with heavier cells repeatedly tracking over the eastern half of the watershed. An example of the south to north movement of storm cells is shown in Figure 5A-C covering the period from 0215 to 0300 August 22, 2003.



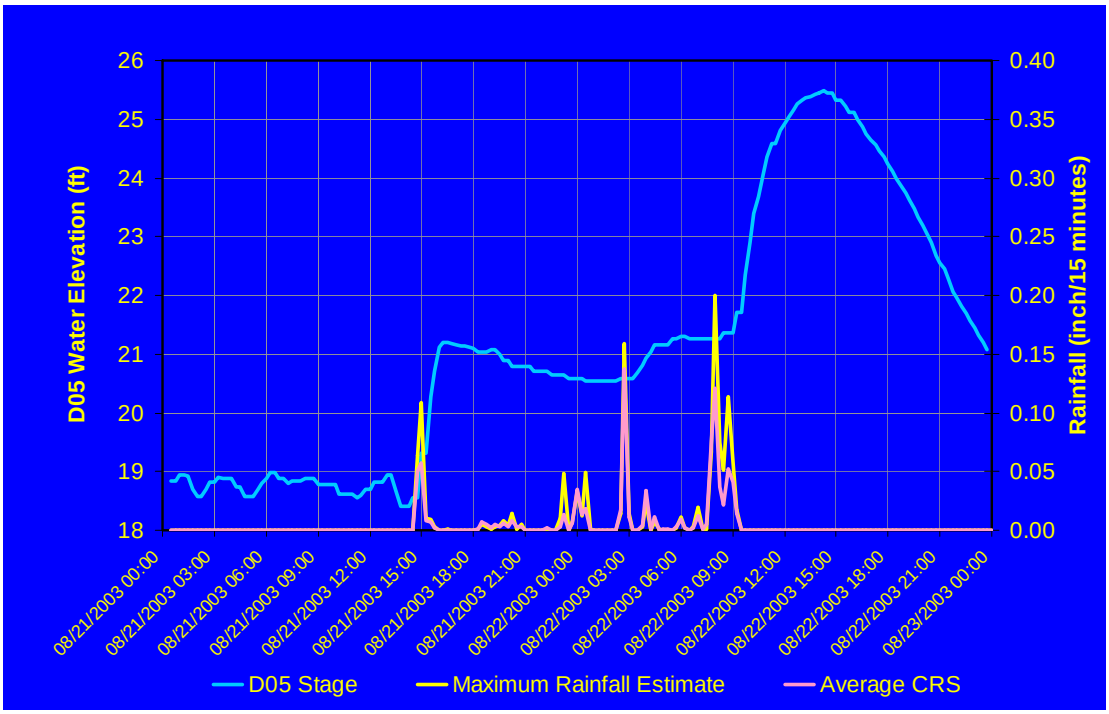
Although there were a number of rain gages in the immediate vicinity of Chicken Ranch Slough, only two gages were located within the watershed. Both of those gages were located in the western half of the watershed, which received much less rain than the eastern section. More than five times as much rain fell in upper portions of Chicken Ranch Slough than at the flooded parking area at CalExpo. The distance between the maximum and minimum storm totals in Chicken Ranch Slough was about 5 km (3.1 mi).

(A)

(B)

(C)

Figure 5: Storm Sequence - 0215 to 0300 on August 22



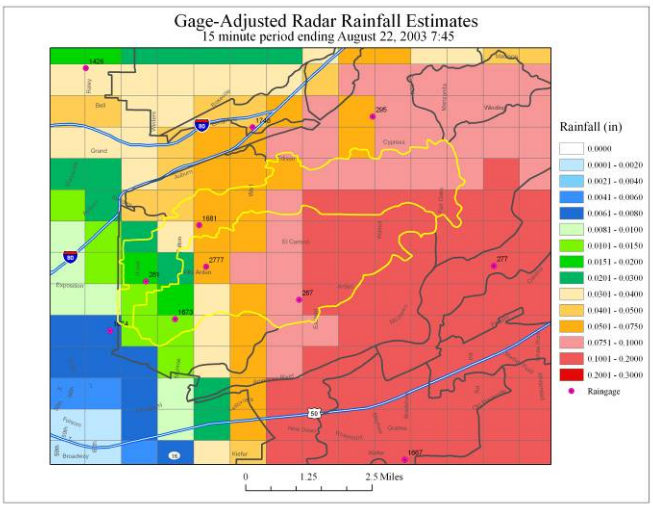


Figure 6: Chicken Ranch Slough Rainfall Response

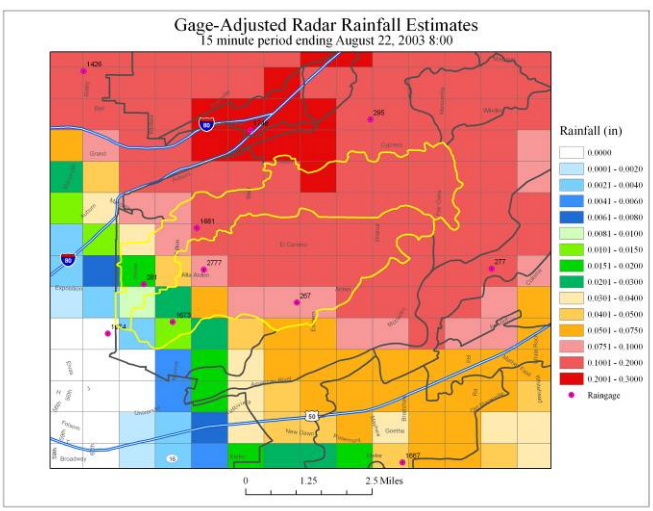
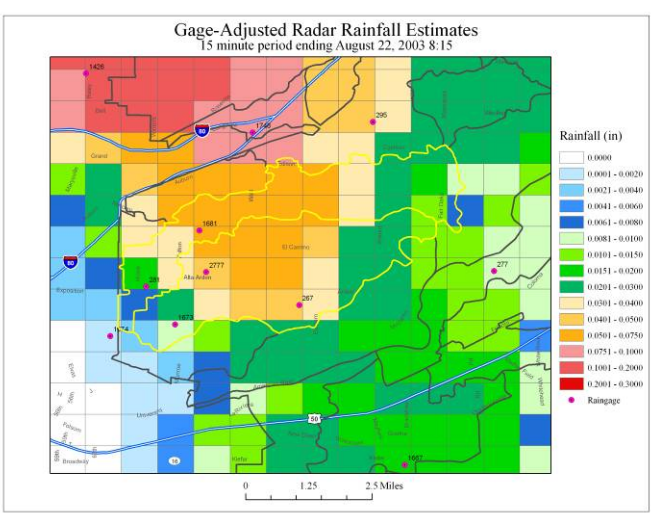
Chicken Ranch Slough's response to the series of storm cells on August 21-22 is shown in Figure 6 and compared to the watershed average radar estimated rainfall and the maximum radar estimated rainfall in the watershed. The water elevation indicated is the DO5 detention facility at the outlet of Chicken Ranch Slough.



Three main pulses of heavy rainfall are apparent. The first intense pulse occurred between 1400 and 1530 on August 21st, triggering an almost immediate response at the watershed outlet. The quick response suggests that the heavier rain was relatively close to the basin outlet. A second pulse occurred between 0200 and 0300 on August 22nd, which reversed the recession from the first pulse then contributed to a small increase in stage.

The largest pulse fell between 0715 and 0915 on the 22nd, producing an additional four-foot rise in water surface elevation. However, response to the third pulse took significantly longer, suggesting that the rain fell in the upper watershed. A time-step by time-step analysis of the radar rainfall estimates verified that heavier rain fell in the upper reaches of the watershed throughout this period. Figures 7A-C clearly show the heavier rainfall over the upper portions of Chicken Ranch Slough and the adjacent Strong Ranch Slough.



It is also interesting to note that the heavier rain occurred in the portion of Chicken Ranch Slough with no rain gages. Radar provided the information needed to determine the rainfall distribution throughout the watershed. Even the relatively dense network of Sacramento County rain gages could not adequately resolve the spatial distribution of rain falling on this small urban watershed.

Figure 7: Gage Adjusted Radar Rainfall Estimates Showing Heavier Rain in Upper Watershed

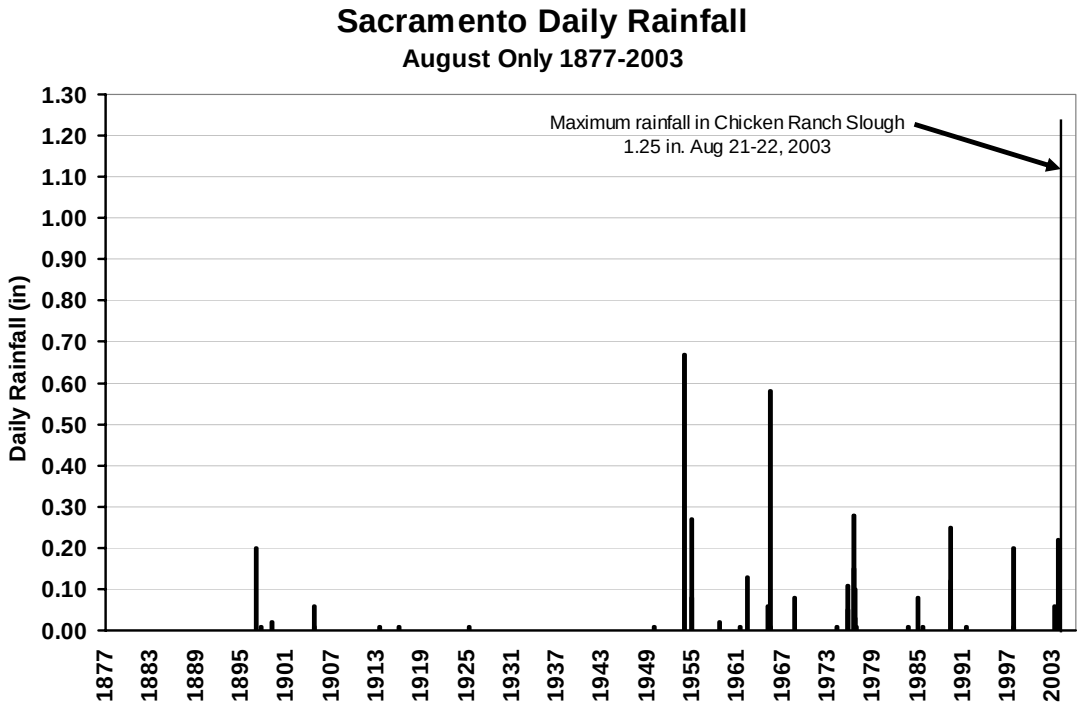

Figure 8: August Daily Rainfall from 1877 to 2003

Historical Context

To put the 24-hr rainfall of Aug 21-22 in historical context, Figure 8 shows the daily rainfall in each August from 1877 to 2003. While August rainfall in Sacramento does occur, significant amounts are rare. No more than a trace of rainfall occurred on 99% of the days since 1877. Only two days recorded more than 7.6 mm (0.3 in). The maximum August daily rainfall in the Sacramento record was 16.8 mm (0.66 in), which was also the greatest 2-day August total on record.

The maximum 24-hr radar estimated rainfall in Chicken Ranch Slough for the August 21-22, 2003 storm was 31.75 mm (1.25 in) or almost double the highest August daily rain gage reading since 1877. Perhaps more impressively, the *watershed average* radar rainfall estimate was 22.4 mm (0.88 in) for Chicken Ranch Slough or 33% higher than the daily August maximum rain gage measurement in Sacramento since 1877.

Another interesting observation that surfaced during this investigation is the apparent stark difference in the frequency of August rainfall in Sacramento between the pre-1950 record and the post-1950 record. From 1887-1950, just one day of rainfall greater than 0.10 inches was observed. Since 1950, at least ten such days were observed. While the cause of this apparent shift is not clear, it is consistent with a general change in weather volatility between the pre/post 1950 years. Since 1950, weather conditions in the Sacramento region have been generally been more volatile compared to pre-1950 conditions.

Summary
On August 21-22, 2003, an extreme rainfall event occurred in Sacramento, CA, during what is normally the driest part of the year. Average monthly rainfall for August in Sacramento is just 0.05 inches or about 0.25% of its annual total. However, on this date, a large plume of subtropical moisture moved into northern California colliding with an area of low pressure from the eastern Pacific. The result created conditions for rare August thunderstorms in Sacramento.

Local rainfall data from a network of automatically reporting tipping bucket rain gages were used to calibrate 5-minute, 1 km x 1 km resolution radar rainfall estimates. The resulting gage-adjusted radar rainfall data were used to assess the storm event and, specifically, the response of 20 km^2 Chicken Ranch Slough, whose discharge flooded nearly 100 vehicles parked near the California State Fair.

The radar data clearly indicated nearly 5 times more rainfall occurred in the upper reaches of Chicken Ranch Slough than occurred at the site of the flooded vehicles. Radar provided the ability to "see" between the rain gages in a relatively dense rain/stream monitoring network and accurately represent the highly variable rainfall topology associated with this event. Maximum 24-hr radar rainfall estimates during the event were double the highest observed August daily rainfall in Sacramento's 130 year historical record.

Abstract

Radar rainfall estimates derived from conversion of reflectivity are known to contain systematic and random errors (bias) that limit the quantitative use of radar rainfall in various applications. Enhancement of radar rainfall estimates is normally accomplished through gauge-adjustment procedures; however, those procedures require long integration periods to moderate sampling differences between the two sensors. To improve the efficiency of radar-gauge based adjustment techniques, classification based on storm microphysical information is needed. In this study, use of two auxiliary data derived from cloud-to-ground (CG) lightning measurements and a storm tracking algorithm was performed. This information was used to classify storms into thunderstorms (storms associated with CGs) vs. showers (storms without lightning) and according to the storm's maturity stage (i.e., growing, mature or decay stage). The radar rainfall data from South Florida Water Management District and for a period of twenty months were used. The radar rainfall estimates at 2-km resolution and 15-min time intervals, and corresponding rain gauge measurements from 120 gauges, and CG occurrences from the National Lightning Detection Network were used. Tracking was applied to the radar rainfall data to identify the storm families used in this analysis. The radar error analysis for different storm types and storm stages indicates that precipitation microphysical information is critical for improving radar rainfall estimation. It has shown that radar rain estimates tend to give stronger biases in storms of strong convective nature (both in terms of lightning occurrences and in terms of the growing stage of the storm), while showers and storms at mature stage tend to be better represented by the fixed climatological Z-R relation. Results from this study demonstrated that CG lightning and storm's maturity stage information could help reduce the variability in the Z-R conversion. Such classification may have a consequential effect on improving the efficiency of a mean-field bias-adjustment algorithm applied at higher temporal scales of aggregation (hourly, daily, etc.) for the radar rainfall estimate.

Introduction

The South Florida Water Management District (District) is responsible for managing and protecting water resources in a 46,439-square kilometer (17,930 square-mile) region. The area extends from Orlando to Key West and from the Gulf Coast to the Atlantic Ocean and contains the Lake Okeechobee. The area is also the site of an environmental restoration program based on the Comprehensive Everglades Restoration Plan. The District operates 2,898 kilometers (1,800 miles) of canals and more than 420 water

control structures. The District encompasses 16 counties and serves a population of over six million people. The District operates an extensive network of 279 active rain gauges in order to obtain rainfall data necessary for use in operations, planning, and regulatory aspects of water management. The rainfall data from 233 stations are available on a breakpoint basis. The breakpoint data can be obtained in a format of 15-minute, hourly, and daily intervals from the District's hydro-meteorological database, DBHYDRO. The rainfall data from the remaining 46 stations are available as daily rainfall (from non-recording rain gauges) in DBHYDRO database. Additionally, historical rainfall time series data from the District and other external government agencies are also available in DBHYDRO to both internal and external users (Pathak, 2008).

Next Generation Radar (NEXRAD) or Weather Surveillance Radar 88 Doppler (WSR-88D) data provide complete spatial coverage of rainfall amounts unobtrusively using a predetermined grid resolution (2 x 2 km). The NEXRAD rainfall dataset is limited due to its reliance on the measurement of raindrop reflectivity, which can be affected by factors such as raindrop size and signal reflection by other objects. Because the reflected signal measured by the radar is proportional to the sum of the sixth power of the diameter of the raindrops in a given volume of atmosphere, small changes in the size of raindrops can have a dramatic effect on the radar's estimate of the rainfall. For this reason, the radar is generally scaled to match the volume measured at the rain gauges in the region. The best of both measurement techniques is realized by using rain gauge data to adjust NEXRAD rainfall values (Pathak, 2006).

Four NEXRAD sites operated by the National Weather Service (NWS) cover the District: KBYX in Key West, KAMX in Miami, KMLB in Melbourne, and KBTW in Tampa. The District uses weather data acquired from NEXRAD in making operational decisions. The District has been acquiring NEXRAD data coverage from OneRain, Inc. since July 2002 (Huebner et al., 2003). In that time, the District has worked in conjunction with three of the other four Florida water management districts to develop a corporate database and methods for data access based on NEXRAD data coverage. The use of rain gauge-adjusted NEXRAD 15-minute data (i.e., taken at 15-minute intervals) by the District's Operations Control Center (OCC) is a major objective of the acquisition. The District is receiving the NEXRAD rainfall data as two types of datasets -- near-real time (NRT) and end-of-month (EOM). The District developed ArcIMS-based application for NEXRAD data retrieval. The application provides varied spatially and temporally aggregated datasets in tabular and image formats (Pathak, 2008). Since October 1, 2007, the District and other water management districts have been acquiring NEXRAD rainfall data from Vieux and Associates, Inc. (VAI) (Pathak, 2008). The use of 15-minute data (i.e., taken at 15-minute interval), rain gauge-adjusted NEXRAD data by the District's Operations Control Center (OCC) was a major objective of the acquisition for the District. VAI provides near real-time (NRT), 15-minute rainfall amounts by using the following process:

- Acquires 15-minute radar reflectivity volume scans from the NWS and uses an appropriate Z-R relationship to convert reflectivity values to rainfall intensities.

- Concurrently, 15-minute rainfall accumulation data from approximately 180 District telemetry rain gauge sites are sent to VAI via File Transfer Protocol (FTP)
- Gauges are compared to radar rainfall estimates to adjust radar rainfall amounts
- Adjusted radar rainfall depths are placed in a flat file and sent via FTP to the District
- The District checks the flat file for completeness and loads the data into the Oracle® database.

Prior to gauge adjustment of radar data, the radar data is normalized to minimize discontinuity in the data from various radar sites that may run hot or cold. Currently, the near-real-time data uses a uniform adjustment technique, such that a single (averaged) gage-radar (G-R) ratio is applied for the entire domain. Further, there is currently no quality control on the incoming rain gage data for the near-real-time processing. Although the effect of a single bad gage is tempered somewhat in the G-R ratio averaging process, a quality control algorithm is desirable. The advantages of uniform adjustment technique are that the adjusted radar volume is guaranteed to match the gage volume (averaged across the domain) and the process is relatively insensitive to erroneous gage data. The main drawback to this technique is that it assumes a constant G-R ratio, an assumption that becomes less appropriate as the size of the domain increases. Accuracy can decrease for large domains because the process allows storm structure and rainfall characteristics from isolated areas to impact the solution for the entire domain.

Near real-time data are verified each month and an end-of-month (EOM) verified set of 15-minute files is produced. The EOM files use 60 additional rain gauge measurements that were not available in real-time and a proprietary algorithm based on the modified Barnes Objective Analysis method to adjust radar rainfall values. An expert from VAI reviews the results to identify and correct any anomalies or apparent errors. When the EOM files are received by the District, the near real-time data are archived, primarily to preserve the information upon which operational decisions may have been made, and are replaced with the EOM verified data set.

The spatial gauge adjustment method uses a G-R ratio field that is not constant. Instead, each radar pixel has its own G-R value. This is achieved by calculating a G-R ratio at each pixel utilizing a Kriging-based distance weighting scheme that considers data from several nearby gauges. The Kriging method allows the geometry of the gage data to be considered in the interpolation and maximizes the use of the available data. G-R ratios at pixels that are coincident with gauge locations are used, but this calculated value is not forced on the pixel that is covered by a three dimensional rainfall field surface which covers a larger area. This provides consideration for intra-pixel variation and does not create artifacts in the resulting rainfall field surface.

The goal of this study was to develop and investigate an algorithm and methodology aiming at improving the accuracy of NEXRAD rainfall estimates on the basis of auxiliary datasets and advanced tracking techniques. Specifically, the study investigated NEXRAD radar rainfall versus rain gauge rainfall differences for a variety of storm life durations, types, locations/time of formation and maturity stages so that improvements to the accuracy of NEXRAD rainfall data could be achieved. The information and data for this

study were obtained from the District's NRDP database, GIS coverage maps and variety of other sources. The study developed a methodology that would be used to improve the NEXRAD rainfall data. The proposed method could be applied to the existing available data and its performance would be evaluated and assessed. Upon successful development and verification of the model, the model will be used in near-real time and QA/QC datasets.

The physical background of the study relies on the fact that Z-R variability depends on the microphysical properties of rainfall and specifically on the distribution of raindrop sizes per unit volume. A characteristic example of this Z-R variability is shown in one of the figures of Atlas et al. (1999) publication in the Journal of Geophysical Research-Atmospheres (copy of the Figure is shown below; see Figure 1) where they demonstrate separate regions of A and B coefficients for convective, stratiform and transition (from convective to stratiform) regimes. A point to note from Figure 1 is the distinct differences of the A & B coefficients in the convective vs. stratiform regimes (for the same B coefficient we note up to two times lower A value in convective regime relative to stratiform). Also note the difference between convective and transition convective regimes. The above indicate that a mean Z-R relationship could introduce up to 100% error in radar rainfall estimates of the individual storm types, which is an issue that needs to be moderated prior to any radar-gauge adjustment in real-time radar rainfall estimation. The study investigated ways to identify those distinct precipitation types based on auxiliary data such as lightning and storm maturity stage derived from tracking analysis and determines the impact of those regimes in radar rainfall estimation error.

Data Preparation and Study Area

The study area for tracking of convective systems for this work is South Florida and surrounding waters. The data used are ½-hourly IR images from the global-IR composite (Janowiak et al. 2001), 15-min NEXRAD radar rainfall fields and gauges provided by the district and Cloud-to-Ground lightning flashes (CG lightning flashes) from the National Lightning Detection Network (Cummins et al. 1998; Orville and Huffines 2001). The period of the data analysis is October 2007 to August 2008 for the VAI product. The gauges, CG flashes and IR data were acquired for the same period.

For storm tracking we applied an algorithm presented by Machado et al. (1998) to the IR and radar images to track the life cycle of convective systems in the above period. The first step in tracking storms is to identify and delineate convective systems (CS) in an IR array using a brightness temperature threshold value. The threshold brightness temperature selection is based on the following criteria: it represents levels in the atmosphere that must be crossed by the top of a cloud for lightning to take place, i.e. above the -15 to -20^{o}C level (Houze 1993), while being warm enough to pick up warm convective systems. The chosen threshold temperature values in this study are 258K for clouds and rain greater than zero for the radar estimates. A match for each of the CS delineated in the IR & radar images based on the selected thresholds is searched for in subsequent images until no match is found, or the end of the period for which the CS tracking is reached. The properties to be looked at to match CSs are presented in

Machado et al. (1998). The maximum speed at which a CS would travel is approximated to 60m/s (Machado et al. 1998), based on which we can deduce that a CS system can travel a maximum distance of 54 km between 15-min radar images (for this purpose the ½ hourly IR images are interpolated on the radar 15- minute intervals). This distance (0.5 deg radius around the center of mass of a CS area) is used here to restrict the search domain for a matching CS in consecutive IR/radar images. There can be some convective systems traveling with higher speed than this, however, such systems are expected to be very few and will be neglected to maximize computation efficiency. In summary, the first step in the tracking is to determine the locations of the pixels in a window of 0.5-by-0.5 deg domain about the center of mass of each convective system at time t0. The image at time t0+15min is then searched for all possible candidates within the domain. All convective systems have equal probability of being the continuation of the convective system at time t0, however, the system that has the highest number of matching parameters (listed in Machado et al. 1998) is selected. If a match is found properties of the convective systems such as the area, area expansion (the change in area), time rate of area expansion, direction of movement, shape (eccentricity), minimum temperature, modal temperature, and other relevant information is documented. If no match is found then the search will be conducted for the next cluster of convective systems (adjacent pixels of convective system). If the search is completed for all clusters of convective systems in the image under consideration, the search will then take place for new systems in the next IR image and the process repeats for all images for the period.

Systems tracked based on IR gave very few families as they were mostly generating or decaying outside the radar domain. Our alternative solution was to use the tracks from the radar rainfall fields using as threshold the 0.2 mm/h value and identify convective cells. An example of a tracking analysis based on radar data is reported in Figure 1 where we show the locations and life cycle of the storms in terms of rainfall volume, area, mean rainfall, and radar/gauge differences. A point to note is the distinct differences between radar-gauge errors in the growing stage vs. mature and decay stages. From the VAI tracking analysis of convective systems in the period Oct 07-Aug 08 we identified 4500 convective systems in Florida.

The convective systems have different life durations and analyzing their properties on a statistical basis requires grouping them on the same time scale. Hence, the life time of each tracked storm was normalized by its life duration, according to Eq 1, so that all systems can have developmental stages between 0 and 1. The normalization equation is:

$$t_n = \frac{(t - t_i)}{(t_d - t_i)} \tag{1}$$

where tn is normalized time, ti and td, are the times of initiation and dissipation, respectively, while t is the running time of the convective system's life evolution. Normalized times were divided into 10 equal intervals (i.e., 0.1 normalized time step) for which, the mean area expansion of the CSs, divergence, and other parameters from the different convective systems were grouped to compute statistics.

Summary of the convective system characteristics used in the herein analysis is shown in Figures 2 for the VAI product. Mean size of the tracked convective clusters is around

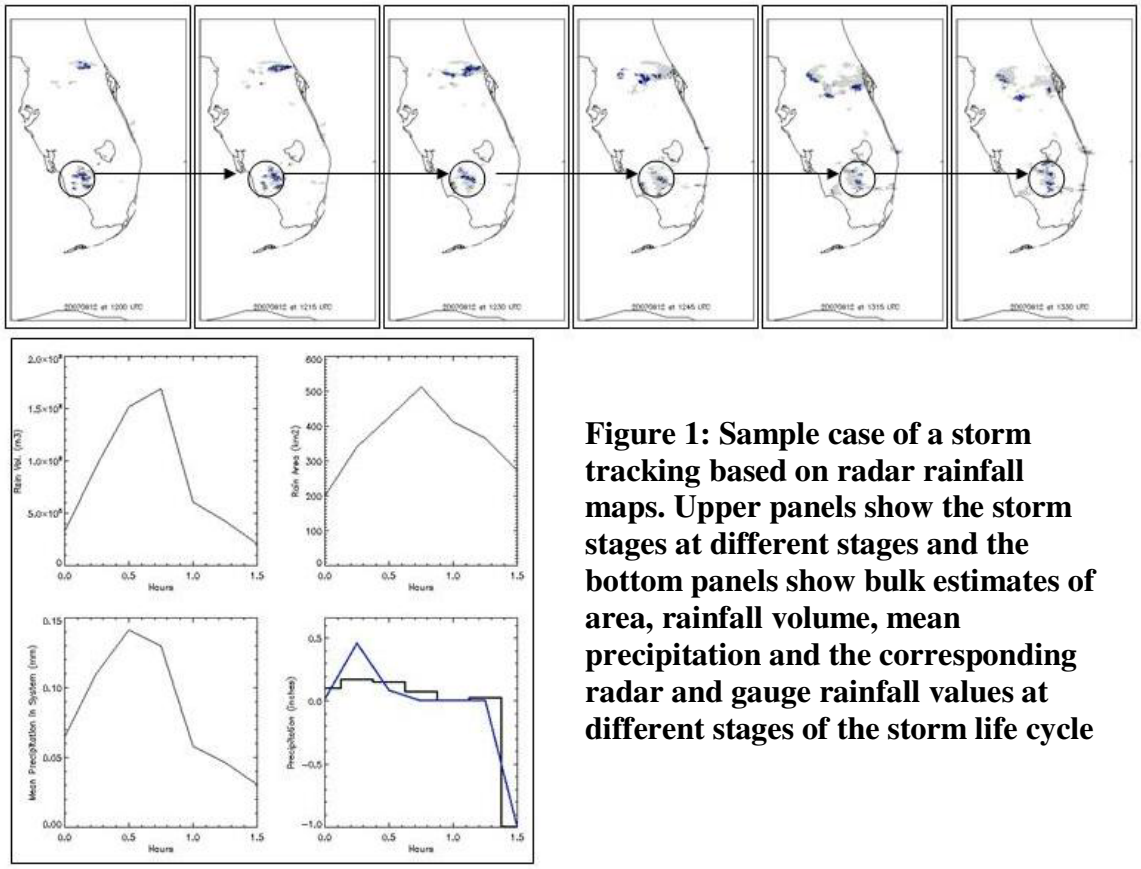

Figure 1: Sample case of a storm tracking based on radar rainfall maps. Upper panels show the storm stages at different stages and the bottom panels show bulk estimates of area, rainfall volume, mean precipitation and the corresponding radar and gauge rainfall values at different stages of the storm life cycle

10km in diameter of an equivalent circle, while in life duration most system lived between 1 and 3 hrs. A point to note is that the herein analysis does not include cases where families of convective systems merge or separate, so that we can establish a direct physical connection of the radar rainfall error (bias) on the maturity stage of a convective system.

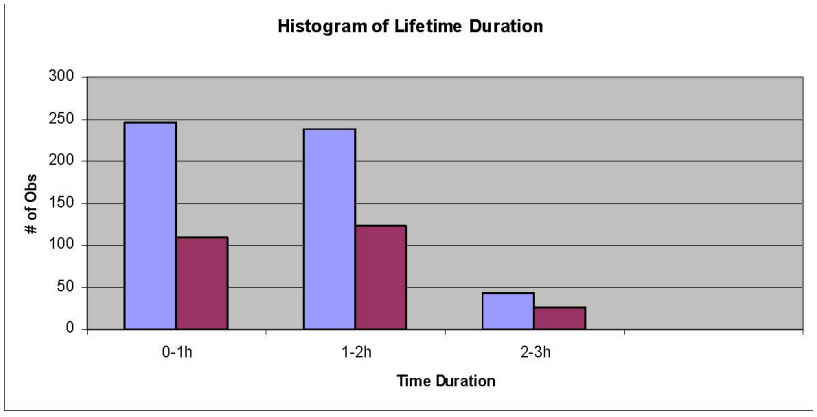

Figure 2: Life duration (in hrs) of the tracked convective systems (shaded bars correspond to clusters with available gauge data)

Data analysis and Results

The error statistics between radar rainfall and gauges are determined in two ways:

- using a Eulerian framework applied on each gauge location and using the lightning information from NLDN as a proxy of the convective nature of the estimated storm
- using a Lagrangian framework based on the storm tracking analysis and using the storm stage maturity as proxy of the convective nature of the storm

The two error analysis frameworks are presented in the figure shown below (Figure 3)

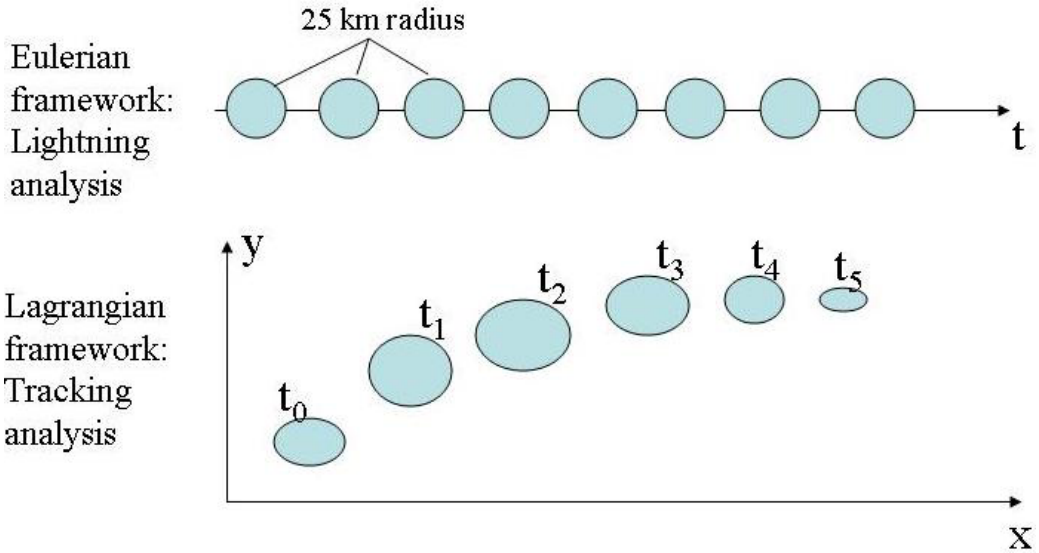

Figure 3: Two error analysis frameworks devised for the radar-gauge error statistics.

The top panel of Figure 3 shows the error analysis performed at each individual gauge location using radar-gauge pairs separated by storm type (i.e. T-storms vs. showers) classified using lightning information within a 25-km radius of the gauge location. The bottom panel shows the error analysis performed for each family of convective cells tracked based on the radar rainfall fields. The objective of this combined analysis is to demonstrate that microphysical related information for a storm can be used to minimize the systematic error in the radar reflectivity to rainfall conversion. Both the storm maturity stage and lightning occurrence are indicators that can be used to classify convective systems into thunderstorms vs. rain showers and into further growing mature and decay stages. In this analysis we consider T-storm origin rain associated with at least one CG lightning occurrence within 5 km radius and within the 15-min time interval of the radar estimate at a particular location.

The growth, mature and decay stages of the storms' life have been identified based on the convective systems area expansion defined through cloud top divergence. Specifically, the divergence values increase rapidly at normalized times below 0.3, while moderate values are noted between 0.3-0.7 and close to zero beyond 0.7. Repeated experiments of this nature for storms of different duration confirms that there are distinct stages in the

life of convective systems, which we herein classify in an ad hoc way by normalized times 0.3 and 0.7. Namely, normalized times below 0.3, 0.3-0.7 and greater than 0.7 are considered to group the majority of growing, mature and decay stages of the convective systems that were tracked in this study. In the following we present the radar vs. gauge error analysis based on the two error analysis frameworks.

Storm type dependence of radar rainfall error

In the following figures we present the frequency distribution of the gauge-to-radar ratios (i.e. error=gauge/radar) for the VAI product available at 15-minute intervals and classified by season (warm—wet season, cold—dry season, and transition period—north/south migration) and by storm type (T-storm—lightning occurrence vs. rain shower—no lightning occurrence). The warm/cold/transition periods are defined as following: warm—June to September; cold—November to April; transition periods—May and October. The histograms are presented below.

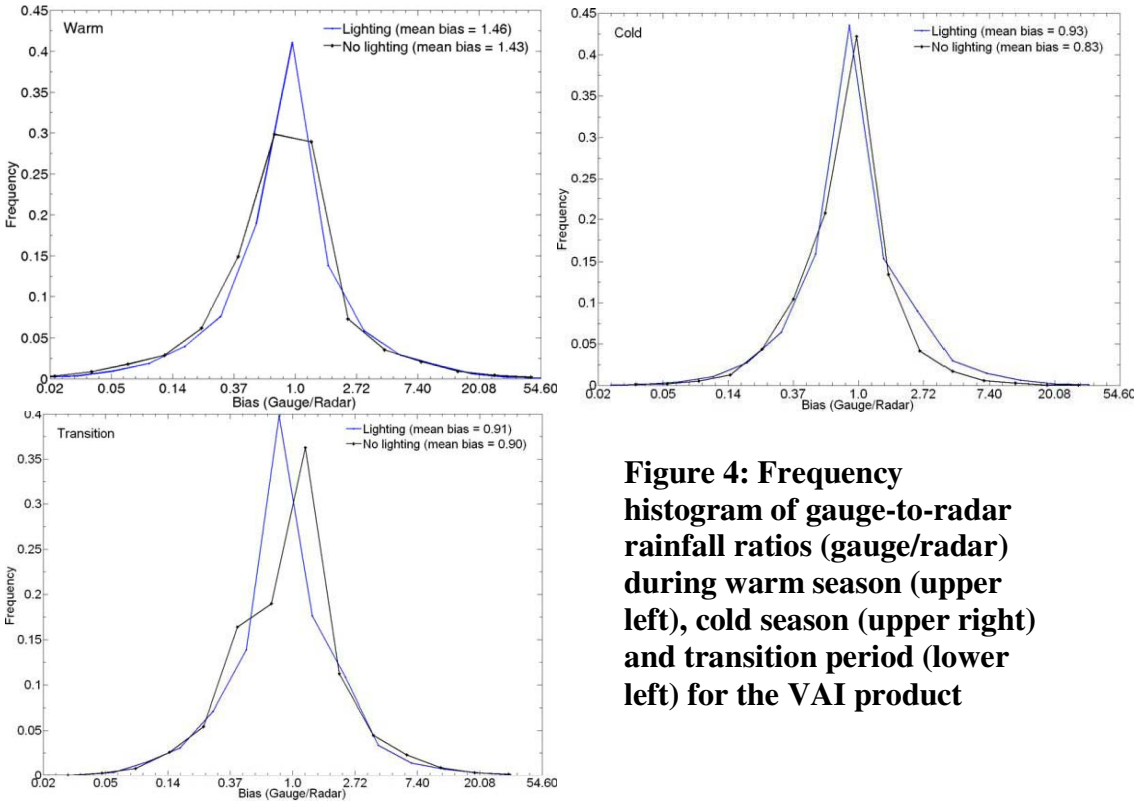

Figure 4: Frequency histogram of gauge-to-radar rainfall ratios (gauge/radar) during warm season (upper left), cold season (upper right) and transition period (lower left) for the VAI product

Several points are noted from the above radar/gauge bias histograms, but, most importantly that there is a distinct shift of radar-gauge ratios (named here Bias) towards radar overestimation in T-storms versus showers and less convective storm types during the transition period. A physical explanation is that in the transition period we expect mixture of storm case exhibiting differences between rain microphysics of the two storm types that reflect in the Z-R relationship parameters, which are commonly used over the whole radar domain. Since the existing radar algorithm does not differentiate the Z-R parameters between the two storm types the mean Z-R will exhibit different biases for

each storm type, as it is apparent in the above histograms of radar-gauge ratios. This issue has been discussed and demonstrated in the past by Anagnostou and Krajewski (1999a,b) who have shown that applying a precipitation classification prior to rain estimation moderates the variability in the Z-R transformation error. Another point to note is that the the data exhibits significant shift in the radar bias in the cold and warm months: 0.95 and 0.99 mean bias (radar/gauge ratio) for the T-storms vs. 0.89 and 0.95 for the non T-storms in the warm and cold seasons, respectively. Overall, we note a tendency for radar overestimation during rain showers, which is moderated or turns to weak underestimation during T-storms (SFWMD, 2008). The presented stats indicate that there is moderate difference in correlation between the different categories of storms, but, in relative RMS the errors tend to increase in most cases from non-lightning storm types (rain shower or less convective storm type) to T-storms associated with higher intensity CG flashes. A cause to this can be an increase in the systematic component of the error in the Z-R conversion. Collective evidence from the above statistics (histograms and Table) indicates that calibrating separately the Z-R relationship for T-storms vs. rain showers and using lightning data from NLDN in real-time in the algorithm of VAI could improve the consistency of the radar-rainfall conversion, which would consequently improve the efficiency of the overall bias adjustment of the rainfall products at the mean-field level. The new Z-R conversions would need to be implemented at the initial stage of the VAI conversion algorithm by ingesting in real-time lightning occurrence data from NLDN. Such lightning data can be available in real-time by the National Weather Service (SFWMD, 2008).

Storm maturity stage dependence of radar rainfall error

As explained in a previous section of this report the storms were tracked and classified according to their life stage (growing, mature and decay). The life stage dependence is depicted in the histograms of gauge to radar ratios presented for the three maturity stages of the storms (i.e., growing, mature and decay) as defined earlier in this paper. Figure 5 shows the histograms for the VAI product. The histograms of the two products show a common pattern of gauge to radar ratio values. For the VAI product the mode of the growing stage distribution (~1.6) is significantly larger than the mode of the decay stage distribution (~0.65), while the mature stage mode is between the two (~1.1). If we combine the information provided by the shape of the histograms with the mean values of the bias ratios shown on the figure one can note that the tendency is for the radar algorithm to underestimate during the growing stage, while overestimate in the mature and more significantly during the decay stage of the storms.

Specifically, the mean of the gauge-to-radar ratios for the different maturity stages of the VAI product are: growth (1.07), mature (0.90) and decay (1.00). growth (0.69), mature (0.67) and decay (0.73). The presented statistics indicate dependence of radar bias on storm maturity stage in the radar rain product. Specifically, we note an increased rain estimation bias in the growth stage relative to the mature and decay, which is consistent to the results of the comparison between T-storms and showers. Combination of storm tracking with the radar rainfall conversion algorithm could potentially provide a radar

algorithm superior to what currently is achieved based on a single Z-R conversion (SFWMD, 2008).

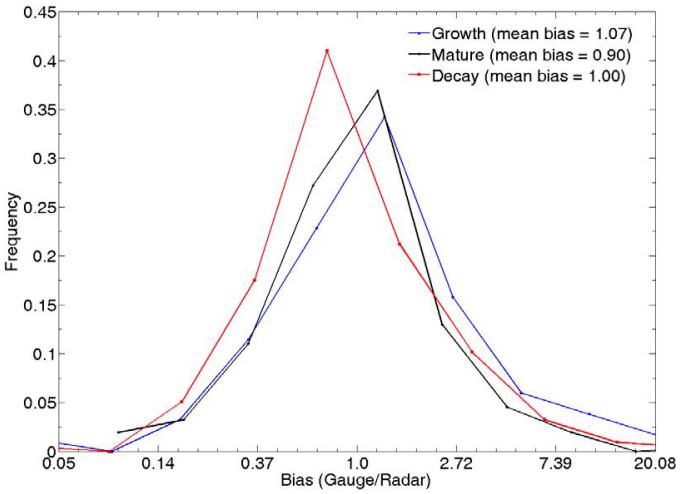

Figure 5: Frequency histograms of gauge-to-radar ratios (bias) for radar-gauge pairs of VAI product (period B) associated with the three storm maturity stages (growth, mature, decay)

Conclusions & Recommendations

The primary conclusion of the herein radar error analysis for different storm types and storm stages is that precipitation microphysical information is critical for improving radar rainfall estimation. Specifically, we showed that

- VAI rainfall product tends to give stronger biases in storms of stronger convective nature (i.e. growth stage and lightning occurrence)
- Rain showers and storms at mature & decay stage tend to be better represented by the existing Z-R conversion (VAI product)

Results from this study indicate that CG lightning information as well as information on the storm's maturity stage could help reduce the variability in the Z-R conversion (at least in the mean sense). Such classification would have a consequential effect on improving the efficiency of a mean-field bias-adjustment algorithm applied at higher temporal scales of aggregation (hourly, daily, etc.).

The results were based on limited radar rainfall data values from VAI products (one year). Future work should concentrate on acquiring larger datasets of the new radar rainfall products (i.e. VAI) to investigate improvements in the Z-R conversion. Based on the results of this report on radar rainfall error statistics we would recommend that the storm tracking and lightning frequency estimation procedures be further investigated for potential use in the operational radar rainfall algorithm to determine characteristic Z-R relationships for different storm types (T-storms vs. rain showers) and storm maturity stages. Such act would potentially lead to a reduction of the estimation uncertainty of the radar rainfall algorithm particularly in the real-time product, which can only include limited gauge information for the on-line radar bias adjustment (SFWMD, 2008). Future directions of this work should include:

- Quantitative estimation of climatological Z-R relationships for the different storm types based on a minimum of 2 years of radar, rain gauge, storm tracking and lightning data analysis
- Integration of the storm tracking and lightning procedures along with the newly determined Z-R relationships in the VAI system and verification of the system performance versus the current approach on the basis of a longer term (2+ years) radar-gauge validation record.

Abstract

Climatologically homogeneous rainfall regions were developed for the South Florida Water Management District (District) using statistical techniques in conjunction with physical meteorological processes. Rain gauge adjusted NEXRAD (radar) derived rainfall datasets were prepared and stored in the Florida State University (FSU) MPE database. The variability in these data then were analyzed both spatially and temporally to determine rainfall processes and local rainfall patterns. Spatial averages and correlation maps were developed to identify regions that vary similarly in the amount and timing of rainfall. The spatial variability of the multi-sensor rainfall data was identified using daily data. The climatologically homogenous rain areas were derived for four seasons, namely, wet, dry and two transitional seasons. Homogenous rainfall regions were also developed for the annual scale.

This paper will describe methodologies in detail and will present examples of the homogeneous areas, showing their locations and presenting their rainfall characteristics. It is believed that similar techniques could be used in other parts of Florida to identify areas having similar rainfall behavior. These approaches can be very useful in various hydrologic designs.

Introduction

The South Florida Water Management District (District) is responsible for managing and protecting water resources in a 46,439-square kilometer (17,930 square-mile) region. The area extends from Orlando to Key West and from the Gulf Coast to the Atlantic Ocean and contains the Lake Okeechobee. The area is also the site of an environmental restoration program based on the Comprehensive Everglades Restoration Plan. The District operates 2,898 kilometers (1,800 miles) of canals and more than 420 water control structures. The District encompasses 16 counties and serves a population of over six million people.

The District operates an extensive network of 279 active rain gauges in order to obtain rainfall data necessary for use in operations, planning, and regulatory aspects of water management. The rainfall data from 241 stations are available on a breakpoint basis. The breakpoint data can be obtained in a format of 15-minute, hourly, and daily intervals from the District's hydro-meteorological database, DBHYDRO. The rainfall data from the remaining 46 stations are available as daily rainfall (from non-recording rain gauges) in DBHYDRO database.

Additionally, historical rainfall time series data from the District and other external government agencies are also available in DBHYDRO to both internal and external users (Pathak, 2008).

The District operates a network of rain gauging stations to provide precipitation data for use in water management operations, modeling, and planning (Huebner et al., 2003). Several limitations have been shown to exist with sole reliance on point rain gauge measurements, including the introduction of error through the spatial extrapolation of such data. Accounting for spatial rainfall distributions is of particular concern in South Florida, where intense, highly variable convective rain events predominate in the wet season that starts in June and ends in October. Because of the tropical nature of summer rainfall in South Florida, the gauges give only representative rainfall measurements for long averaging periods, and can often miss or erroneously assess the magnitude of significant rainfall events (Pathak, 2008).

Next Generation Radar (NEXRAD) or Weather Surveillance Radar 88 Doppler (WSR-88D) data provide complete spatial coverage of rainfall amounts unobtrusively using a predetermined grid resolution (usually 2 x 2 km or 4 x 4 km). The NEXRAD rainfall dataset is limited due to its reliance on the measurement of raindrop reflectivity, which can be affected by factors such as raindrop size and signal reflection by other objects. Because the reflected signal measured by the radar is proportional to the sum of the sixth power of the diameter of the raindrops in a given volume of atmosphere, small changes in the size of raindrops can have a dramatic effect on the radar's estimate of the rainfall. For this reason, the radar is generally scaled to match the volume measured at the rain gauges in the region. The best of both measurement techniques is realized by using rain gauge data to adjust NEXRAD rainfall values (Pathak, 2008). Four NEXRAD sites operated by the National Weather Service (NWS) cover the District: KBYX in Key West, KAMX in Miami, KMLB in Melbourne, and KBTW in Tampa. The District uses weather data acquired from NEXRAD in making operational decisions. The District has been acquiring NEXRAD data coverage since January 2002 (Huebner et al., 2003).

Temporal and Spatial Variation of Rainfall in Central and South Florida

South Florida is a high-rainfall area, with frontal, convective, and tropical system-driven rainfall events. The heaviest rains in South Florida are produced by mesoscale convective systems – extra-tropical in the dry season and tropical in the rainy season. In Central and South Florida, 57 percent of total summer rainfall occurs on undisturbed sea breeze days, 39 percent on disturbed days, and 4 percent on highly disturbed days. Average Annual Rainfall varies across the District, with 1,118 mm (44 inches) in the Lower Kissimmee to over 1,600 mm (63 inches) in the Palm Beach rain areas. The annual average rainfall on the entire area managed by the District is 1,341 mm (52.8 inches). Ali and Abtew (1999) showed that the spatial structure and distribution of monthly rainfall differ in wet and dry seasons. In the study (Ali and Abtew, 1999), exponential semivariograms were fitted to each month of the year. The sill/nugget and range characteristics in the wet season exhibited weak stationarity with large correlation lengths, while the dry season exhibited strong stationarity with shorter correlation length. Average rainfall over 145 stations was used to evaluate the estimation error variance for the dataset (SFWMD, 2006). Based on the long period of record, the climatological setting of the District is summarized below.

- Dry season (November-April) monthly rainfall values are generally below 102 mm (4.0 inches).

- October rainfall values are below 102 mm (4 inches) in the western part and above 102 mm (4 inches) in the eastern part of the District.
- Average rainfall is higher along the east coast in the dry season and higher along the west coast in the wet season. The spatial range of average rainfall is 25 mm (1.0 inch) or less in the dry season and 51 mm (2.0 inches) or less in the wet season.
- October shows a significant break in rainfall, with higher east coast rainfall than west coast rainfall. In this month, a steep inland gradient 1.9 mm drop/km (3-inch drop/25 miles) is present.
- Wet season variograms exhibit higher nugget effects than those for the dry season indicating that the existing rain gauge network is less capable of resolving rainfall variation in the wet season than in the dry season.
- Rainfall maps show a change in pattern between seasons, with average rainfall that is higher along the east coast in the dry season and higher along the west coast during the wet season.

Many of the factors that determine rainfall over the Florida peninsula are mesoscale features including sea-breeze circulations and daytime heating. To adequately identify locations where these phenomena are most likely, a higher resolution analysis was desired. While larger-scale features such as fronts and tropical systems occasionally do provide large amounts of rainfall within the District, the rainfall statistics are dominated by mesoscale features. Seasonal analysis of rainfall supports this idea, with the exception of the drier winter months when frontally induced precipitation becomes a significant factor, particularly in the northern portion of the district. The goal of the study was to use multi-sensor-derived rainfall data on a 4 × 4 km grid to define homogeneous rainfall regions in the District in which rainfall varies similarly in space and time.

Methodology

In this study, the multi-sensor rainfall data within the District were statistically analyzed. The Florida State University (FSU) multi-sensor data set includes rainfall estimates for the period January 1996 through December 2005 that were prepared. The multi-sensor procedure optimally combines hourly rain gauge data with hourly radar-derived estimates from National Weather Service (NWS) radars. The FSU procedure is a variation of the Multi-Sensor Precipitation Estimator (MPE) that was developed by the NWS Office of Hydrology and is used by the NWS at its River Forecast Centers and Weather Forecast Offices. Details about the original NWS MPE procedure can be found in Fulton et al. (1998) and Dyer and Garza (2004), while FSU's modifications and use of the procedure are described in Marzen and Fuelberg (2005) and VanCleve and Fuelberg (2006). MPE combines the "ground truth" of the gauge-derived amounts with the spatial details provided by the radars. The output is available on a 4 × 4 grid at hourly intervals. For this study, the hourly data were added to produce daily rainfall amounts, and then they were analyzed in both space and time.

The first task of the study was to generate rainfall maps of the District on various time scales. The daily rainfall totals on the 4 × 4 km multi-sensor grid were summed on monthly, seasonal, annual, and multi-annual time scales. A 20 mile buffer surrounding the District boundaries was created and used to define our area of interest. All subsequent data processing was performed interior of this buffer. **Figure 1** shows summed rainfall over the District for the full 10 year period during which MPE data are available. Sea breeze regions along the east and west coasts

are easily identified, with maximum rainfall occurring in regions of irregular coastlines. Conversely, a region of anomalously lighter rainfall is located over and around Lake Okeechobee. A region of somewhat lighter precipitation extends north and south of the Lake to the borders of the computational area. Relatively light precipitation also is located at the southern tip of Florida where swampy conditions limit the development of strong land-sea temperature gradients that lead to sea breezes. **Figure 1** clearly reveals that rainfall is not uniform over the District.

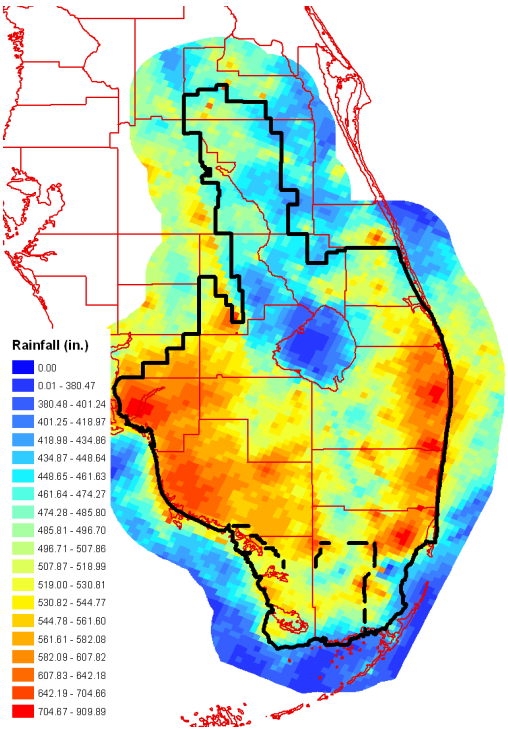

Figure 1: Total accumulated rainfall (in.) for the District based on MPE data between January 1996 and May 2006.

The second task was to complete a temporal analysis of rainfall. A time series of daily mean areal precipitation for the entire District was plotted in **Figure 2**. This time series was generated to gain insight into the regularity of seasonal transitions. It was hypothesized that the transitions were fairly irregular in time, and this indeed was confirmed by the time series. A moving filter to reduce noise was applied to the daily rainfall data to examine the periodicity of the rainfall signal. Specifically, for each day during the 10 year period, the filter calculated an average of the seven surrounding days and returned that average value. Thus, a running average was generated using the technique, with 365 seven day averages plotted each year. If strong seasonality were occurring, one should see a sine shaped curve each year, with one maximum and minimum at approximately the same times each year. **Figure 2** shows the absence of a clear seasonal transition since many minima and maxima occur independent of a one year signal. Because of this lack of a clear seasonal signal in the rainfall, the seasons were defined as follows.

i) Wet Season: June – October

ii) Dry Season: December – April

iii) Transition Spring Season: May

iv) Transition Fall Season: November

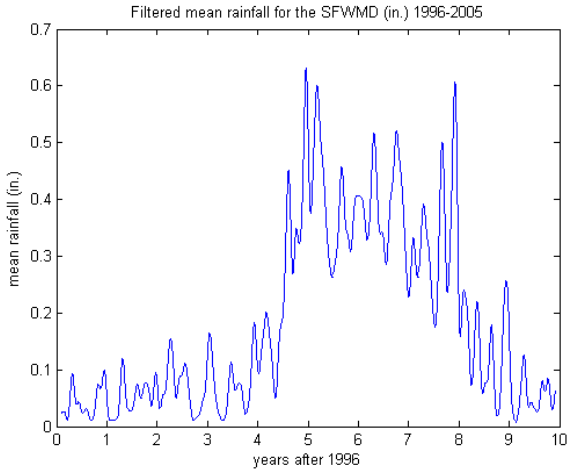

Figure 2: Time series of filtered mean areal precipitation (in.) for the entire District during the period January 1996 to May 2006.

The next task was to use correlation mapping to identify and define regions having homogeneous rainfall in space and time. An average rainfall accumulation were calculated for nine adjacent grid cells (denoted a "seed area") within the District for each day between 1 January 1996 to 31 December 2005. Seasonal versions (wet, dry, etc.) also were generated. The seeds created a quantity with which to correlate values over the remainder of the District. In this case, the "seed areas" were selected from the rainfall maps shown in **Figure 1**.

Specifically, regions that had similar rainfall accumulation and that corresponded spatially to known meteorological phenomenon like the sea breeze were used to define the "seed areas". The 9 point seed values then were correlated in time to every other 4 × 4 grid cell within the District. At the end of the process, the correlation was calculated for each grid cell and plotted in ArcGIS. A minimum correlation criterion was defined for each season, and all correlations greater than or equal to the criterion were plotted. The criterion was selected so that the sizes of individual correlation regions would be similar to the regions of relatively uniform rainfall accumulation.

The final task was to perform a sensitivity analysis of the aforementioned correlation procedure. It was hypothesized that the correlation regions would be highly sensitive to the selected seed areas. To identify such sensitivity, correlations outside of the correlation region were compared with those inside the region to show that the individual regions were, in fact, homogenous. Finally, statistics (mean, standard deviation, variance, and coefficient of variance) for each homogenous region were calculated to show the variability between different regions. By determining whether each region had unique statistics, the degree of homogeneity was determined. Although some differences occasionally were small between several rainfall regions, the correlation mapping technique allowed us to identify regional discontinuities in the time variability of rainfall in the District.

Results

As described above, the identification of correlation regions in combination with the mean rainfall for the different seasons allowed homogeneous regions in the District to be determined. This procedure was followed to define homogeneous regions during the spring, fall, and dry seasons, as well as for the annual time scale. Interestingly, during the fall season only two regions of correlation are required to define homogenous regions. Conversely, the maximum number of homogeneous regions was twelve during the wet season. The corresponding maps for

all seasons were developed and shown in the study report (FSU, 2008). As an example, **Figure 4** shows these homogeneous regions during the wet season.

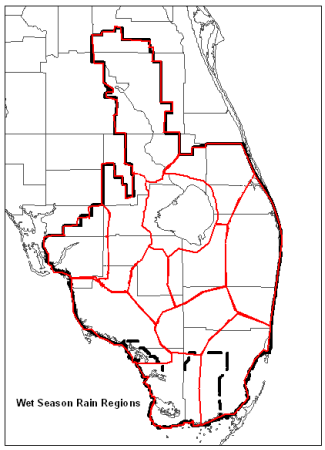

Figure 4: Twelve homogeneous rainfall regions during the wet season in the District.

Figures 5a shows the 10-year mean rainfall during the wet season (June – October) along with one example of a correlation region. In this example, strong correlations occur along the east coast of South Florida, in agreement with the sea breeze circulation that occurs in this area of convex coastline. Both rainfall accumulation and variability are fairly consistent within the region of correlation ≥ 0.6 (the value at which the colors begin).

Although some non-contiguous correlation regions also exist (e.g., northwest of Lake Okeechobee), they are not considered homogeneous since they are due to meteorological factors other than the sea breeze. **Figure 5b** demonstrates how the correlated area mimics the shape of the predominant meteorological forcing; in this case the sea breeze.

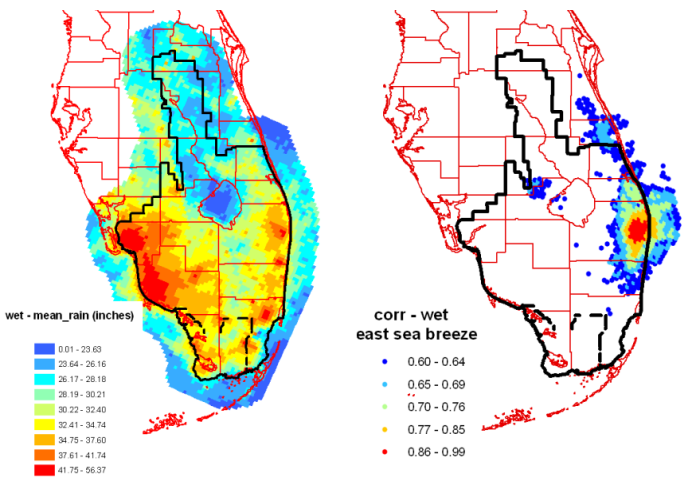

Figure 5a (left): Mean rainfall (in.) during the wet season (June – October) for the District. Figure 5b (right): Homogeneous correlation region containing the East Coast sea breeze. The minimum correlation criterion is 0.6.

Another example that demonstrates homogeneity is the correlation region over Lake Okeechobee which approximately follows the shape of the Lake. While the region of correlation ≥ 0.6 extends beyond the Lake itself, the greatest correlations (correlation > 0.75) are located almost exclusively over the Lake. Clearly the divergence generated by cool outflow in all directions away from the Lake's center creates subsidence over this region, thus limiting convective potential during the spring and summer months. **Figure 6a** and **b** compare mean rainfall with correlation over Lake Okeechobee during the wet season. The rainfall totals are significantly less over and around the Lake, and the correlation region ≥ 0.6 agrees closely with the area of diminished rainfall. This spatial consistency lends credence to the idea that rainfall is homogeneous within this region, being consistent in both space and time.

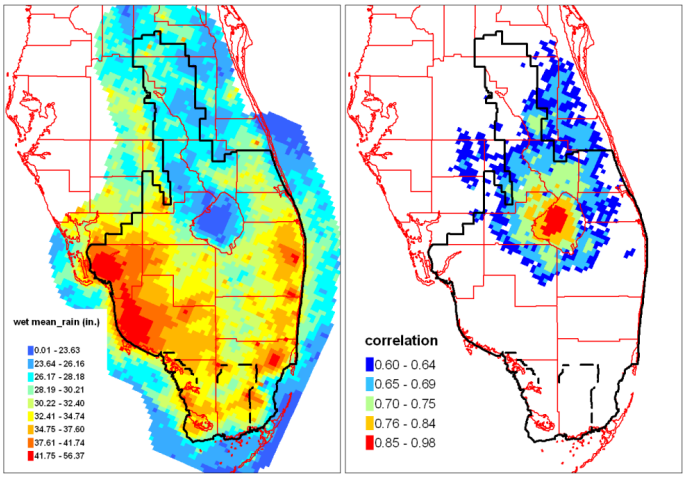

Figure 6a (left): Mean rainfall (in.) during the wet season (June – October) for the District. Figure 6b (right): Correlation region for the Lake Okeechobee region. The minimum correlation criterion is 0.6.

In the previous two examples, the rainfall anomalies associated with the sea breeze and Lake Okeechobee were easily identifiable sites for seed areas from which to calculate correlation with the remainder of the District. That is, by considering the meteorology of the region and by viewing the mean rainfall maps (**Figures. 5a** and **6a**), these seed areas were chosen. On the other hand, a few seed regions were identified because they were located between areas of obvious meteorological forcing. These areas most often were located in the center of the southern Florida peninsula where neither the East nor West Coast sea breezes or Lake Okeechobee contributes directly to their rainfall. Instead, the scenario that occurs most often during the wet season is that their convection results either from simple daytime heating or from the collision of thunderstorm outflow boundaries propagating away from storms associated with the various sea and lake (Okeechobee) breezes. Although these regions are not as easily defined by the mean rainfall maps in Figs. 5a and 6a, they become more apparent through correlation mapping.

Figure 7a and **b** show an example of such a case in the middle to western regions of the Florida peninsula between Lake Okeechobee and the Gulf Coast. The area is well defined by correlation, but not as clearly defined by a qualitative visual analysis of rainfall patterns. This technique also defined regions south of Lake Okeechobee toward the south coast (see **Figure 4**) where daytime instability and colliding outflow boundaries drive most of the wet season convection.

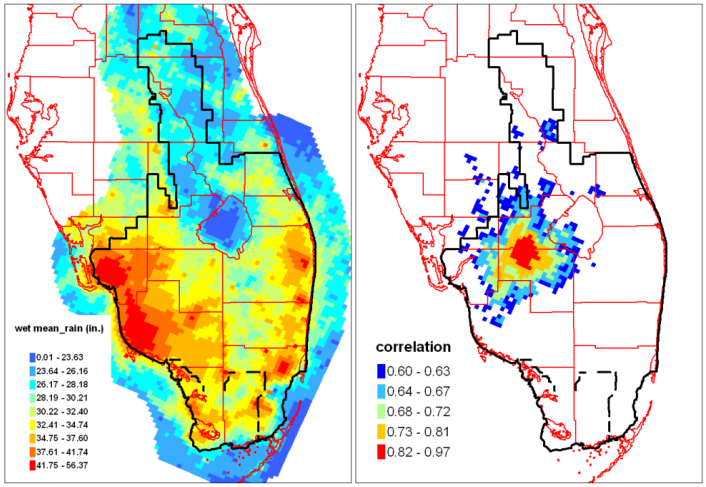

Figure 7a (left): Mean rainfall (in.) for the wet season (June – October) for the District. Figure 7b (right): Correlation region for the Northwest-Mid region. The minimum correlation criterion is 0.6.

After selecting a sufficient number of correlation seed points, the homogeneous regions were defined based on both the summed rainfall accumulation and the correlation regions. That is, those 4 × 4 km grid cells that were within the minimum correlation criterion, lay within similar characteristic accumulation areas, as shown in **Figure 1**, and generally were contiguous were considered to be homogeneous. Once the various homogeneous regions were defined, statistics for each region were calculated to ensure that each area truly was homogeneous and distinct from adjacent areas. The mean, standard deviation, variance, and coefficient of variance were calculated for all regions, for each season. **Figure 9** shows an example of the standard deviation of daily rainfall in the District and a histogram representation of each homogeneous region during the wet season. Statistical maps for all seasons were developed and shown in the report (FSU, 2008). **Table 1** below shows the statistics for each homogeneous region during each season.

In this example rainfall varies the most in the coastal areas where sea breezes are the prominent forcing mechanisms. These sea breezes vary somewhat from day to day due to the background synoptic patterns that determine their strength and inland penetration. Conversely, rainfall is more consistent in inland areas where daily rainfall depends more on daytime heating.

Table 1: Statistics - mean, standard deviation (std), variance (var), and coefficient of variance (coef_var) for each homogeneous region in the District for each season.

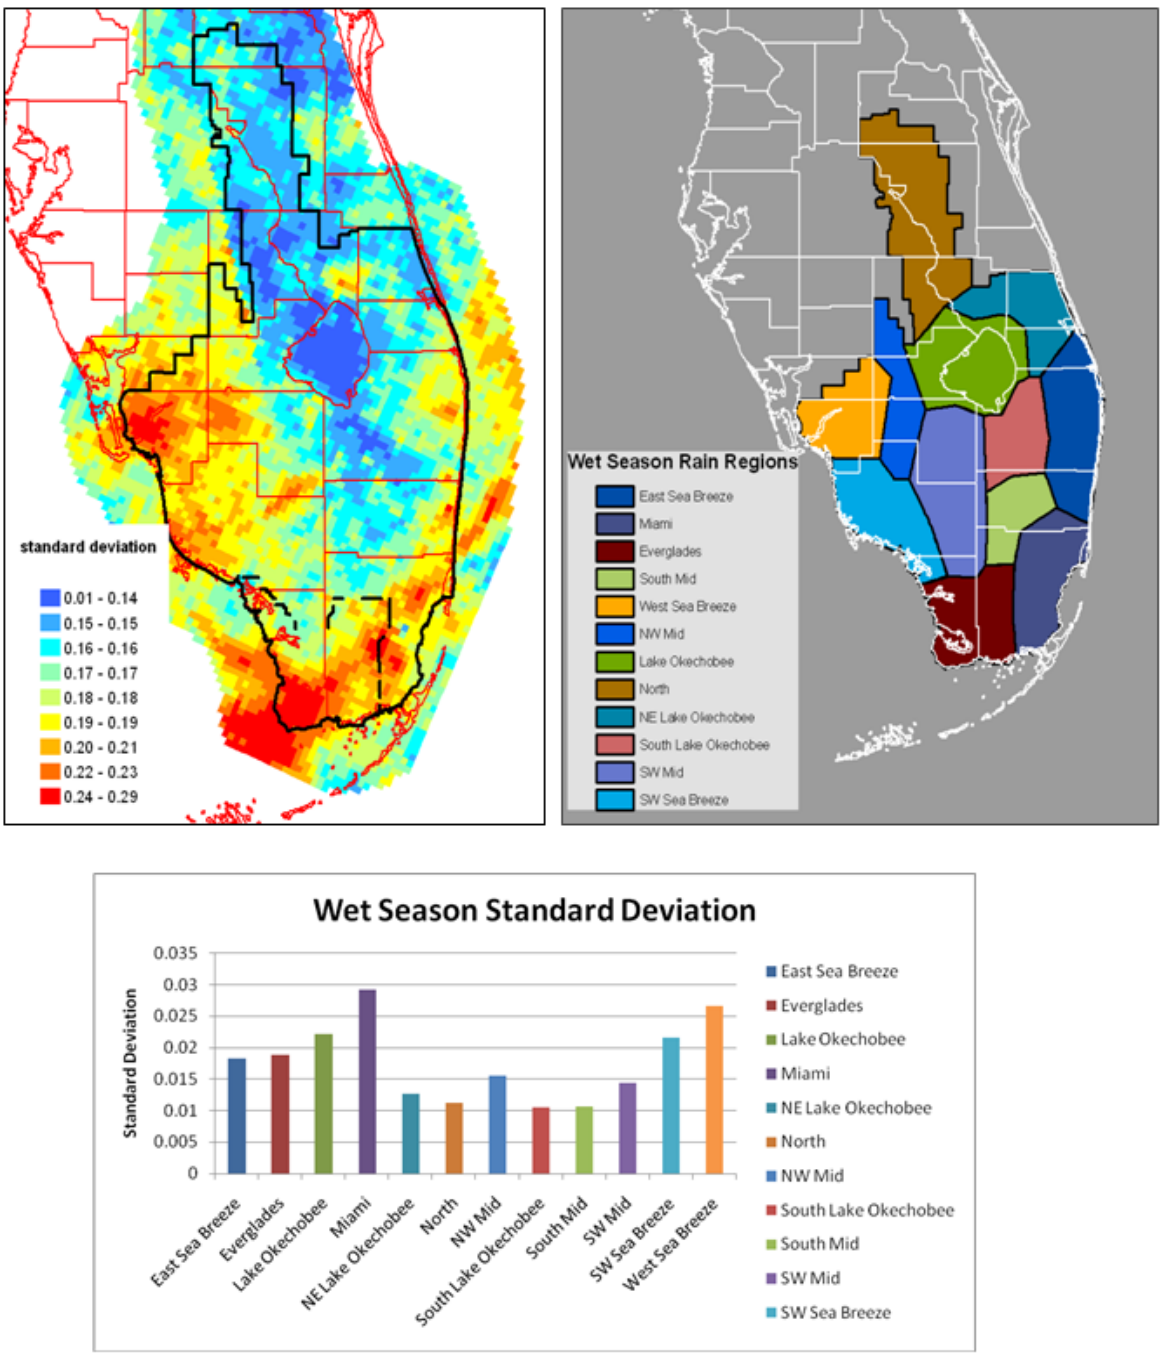

Figure 9: Wet season standard deviation (in.), map showing the wet season homogeneous regions, and the standard deviation (in.) within each region.

The final analysis was to verify that the regions developed in this study were homogeneous when compared to previously developed rain areas within the District. As an example, **Figure 10** shows the correlation of the Lake Okeechobee region with the remainder of the District during the wet season. **Figure 10** shows correlation between the Lake Okeechobee region and the rest of the District, with the new correlation criterion being correlation < 0.6. It is clear that the correlation decreases quickly away from the Lake, particularly in directions toward the sea breeze regions on the east and west coasts of the southern Florida peninsula. It is also important to note that there are no significant discontinuous regions of large correlation away from the original region defined by the Lake. These statistical differences between homogeneous regions also were noted in the histogram shown in **Figure 8**. The standard deviation in the Miami region is nearly 3 times greater than the deviation in the South Lake Okeechobee and South-Mid regions. Another way to test the homogeneity was to move correlation seed areas slightly and note any observed changes in the correlation region. The results showed that the scheme is sensitive to the choice of seed areas which emphasizes the importance of choosing regions of meteorological significance (regions defined by a specific meteorological phenomenon like a sea breeze). When perturbing the initial seed area location slightly within a sea breeze area, for example, little change is observed in the correlation region. The combination of these statistically observed (**Figure 9**) and spatially observed (**Figure 10**) differences lend merit to the homogeneity of the regions.

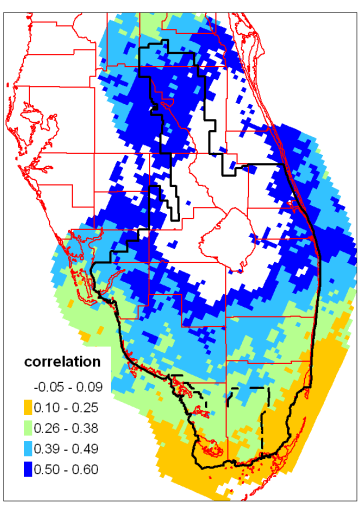

Figure 10: Correlations of the Lake Okeechobee region with the remainder of the District during the wet season.

Discussion and Conclusion

Homogeneous rainfall regions have been identified within the District by combining statistical information derived from multi-sensor precipitation data with known meteorological trends. The two predominant tools used in this procedure were mean rainfall and the spatial correlation of rainfall. By combining these two products, we could qualitatively determine the boundaries of the homogeneous regions. A spatial variability product also identified regions where less trust should be placed on the multi-sensor product when analyzing mean rainfall. The resolution of our rainfall data (4×4-km) is considerably better than in previous studies. Therefore, more detailed features could be identified in the mean rainfall maps. This higher spatial data

resolution provided added confidence in the significance of the results and the homogeneity of the defined regions. Although previous studies had defined as many as fourteen homogenous regions within the District, we believe that the meteorological and statistical information supports only as many as twelve truly homogeneous regions (during the wet season). During the other seasons, only 2-9 homogeneous regions could be identified (2 in the fall, 4 in the dry season, and 9 in the spring). These climatologically homogeneous rainfall regions will help water managers in making improved water management decisions.

Abstract

Accurate estimation of rainfall magnitudes and their spatial distribution plays an important role in hydrological applications such as flood risk analysis and river flow forecasts. In addition knowing the forcing data error structure is crucial part of hydrologic data assimilation system. Recent advances in radar and satellite based measurements have provided alternative methods for precipitation estimation. In this study, gauge, radar and satellite precipitation estimates are used to explore the impacts of different precipitation data sources on the accuracy of hydrological simulation over the Leaf River basin in Mississippi. The NEXRAD stage IV, 3B42 gridded TRMM, PERSIANN-CCS and rain-gauge data over the watershed are aggregated to similar resolution in time and forced to a conceptual hydrological model, SAC-SMA. The model performance with each of the rainfall estimates input has been assessed by statistical comparison of the simulated and measured streamflow at the watershed outlet. In this study, the standard error of satellite-based PERSIANN-CCS rainfall estimates conditioning on the assumed true field (i.e. radar rainfall) is obtained according to a multivariate function considering the spatial and temporal scales. Accepting the multiplicative nature of precipitation error, the Monte Carlo simulation based on log-normal distribution of error is conducted to generate the ensemble of precipitation and propagate them into a conceptual hydrologic model to investigate the impact of input error on streamflow simulation.

Introduction

Precipitation is the key hydrologic variable linking the atmosphere with land surface processes, and playing a dominant role in the climate system. Accurate measurements of precipitation on a variety of space and time scales are important not only to weather forecasters and climate scientists, but also to a wide range of decision makers, including hydrologists, agriculturalists, and industrialists (Ebert et al., 2007). In the past the assessment of water resources of a watershed used to be a complicated task due to limited data availability. However, nowadays an increasing number of radar and satellite-based rainfall products are available in near–real time over the Internet. Thus due to ease of accessibility and high-speed communications it is possible to download rainfall maps and digital data provided by national meteorological centers, government institutions, and university research groups in a matter of seconds. Thus owing to such wide spread availability and easy accessibility of satellite–based precipitation estimate has enhanced the hydrological modeling and forecasting at the watershed scale. However it is very crucial to assess the impact of the rainfall estimate from various sources on hydrologic simulations. In addition, quantification of associated errors of these products and evaluating their impacts on hydrologic response is essential in the usage of satellite products in high resolution hydrologic applications. In this study, the rainfall estimates from 3B42V6 gridded TRMM (Tropical Rainfall Measuring Mission) data, PERSSIANN-CCS (Precipitation Estimation from Remotely Sensed Information using Artificial Neural Networks-Cloud Classification System) and NEXRAD Stage IV data have been forced to conceptual hydrologic model and the resulting hydrologic response has been analyzed. Besides, the impact of input error on streamflow simulation has been investigated by generating the ensemble of precipitation to characterize the standard error of satellite-based PERSIANN-CCS

rainfall estimate and propagating them into a conceptual hydrologic model. This study builds upon the detailed analysis conducted by Moradkhani et al. [2006] and more recent study by Moradkhani and Meskele [2009].

Study basin and datasets

The study area selected is the Leaf River Basin (1944 Km^2) located north of Collins, Mississippi, United states which has been widely used in various studies (see [Moradkhani and Sorooshian, 2008] for list of references).

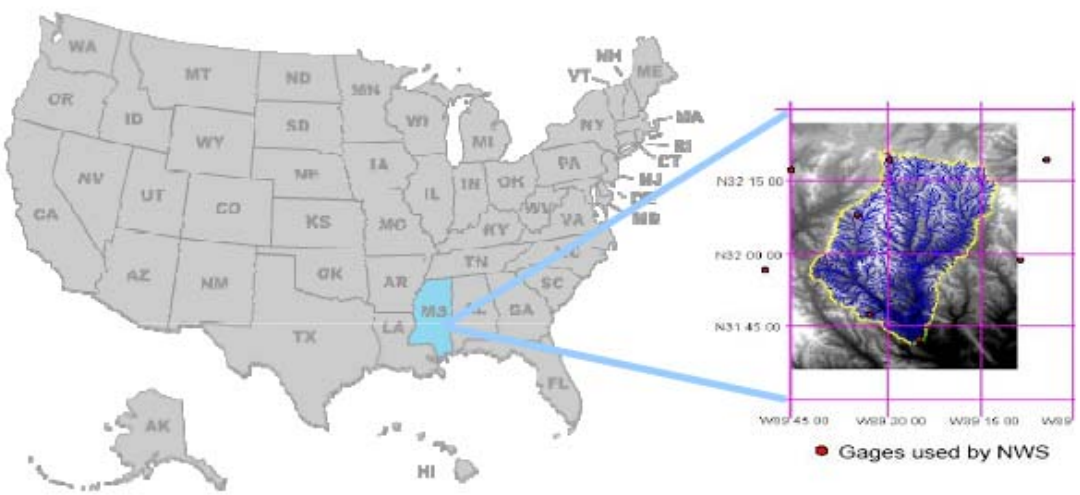

Figure 1. The location of Leaf River basin

The satellite-based precipitation data used was based on the 3B42V6 TRMM (Tropical Rainfall Measuring Mission) data and PERSIANN-CCS (Precipitation Estimation from Remotely Sensed Information Using Artificial Neural Networks- Cloud Classification System) product [Hong et al., 2004]. The TRMM Multisatellite Precipitation Analysis (TMPA) provides a calibration-based sequential scheme for combining precipitation estimates from multiple satellites, as well as gauge

analyses where feasible, at fine scales (0.25° x 0.25° and 3 hourly). The dataset covers the latitude band 50°N–S for the period from 1998 to the delayed present (Huffman et.al, 2006). The PERSIANN-CCS is a satellite infrared-based algorithm that produces global estimates of rainfall based on infrared brightness temperature image provided by geostationary satellites. These data covers 50°S to 50°N globally and an improved version of PERSIANN-CCS algorithm estimates rainfall at spatial 0.04° x 0.04° and temporal resolution of 30 minutes respectively. The other rainfall product used to estimate the error associated with the satellite product, is the National Weather Service WSR-88D Stage IV radar rainfall data. The Next generation weather radar (NEXRAD, formally known as the Weather Surveillance Radar-1988 Doppler -WSR- 88D) of the United States provides precipitation data are obtained from 158 Weather radar deployed by the Weather Service Agency across the country. The data was acquired from NCEP (National Center for Environmental prediction) for the same period and the spatial domain as that of PERSIANN-CCS which was used here as reference (true) rainfall field. The other hydrologic data sets used for the study were the rainfall from rain gages and temperature data extracted from National Climate Data Center (NCDC) and streamflow data from USGS for the period of 1948-2005. These data were utilized for calibrating and validating the hydrologic model.

Methodology

In the study the satellite based precipitation estimates were aggregated over the Leaf watershed and altered to same scale of daily accumulations before forcing them to the conceptual hydrologic model. The Sacramento Soil Moisture Accounting Model (SAC-SMA) is an operational conceptual model originally developed at the California-Nevada River Forecast Center located in

Sacramento, California as a "Generalized Stream flow Simulation System", [Burnash et al., 1973; Burnash, 1995] to ameliorate the region's operational capability of stream flow prediction. The model passed through extensive development and testing on the other catchments in United States before its streamflow determination capability got adopted as major component of the National Weather Service River Forecast System (NWSRFS).

The model consists of six sate variables that represent the soil water content of the upper and lower soil mantels in the form of free and tension water [Burnash, 1995]. The soil moisture storages in both zones vary due to the non linear dynamics of precipitation, percolation, evaporation and lateral drainage. The working principle of the model designates that the precipitation which falls on the impervious area of the catchment produces immediately a direct runoff while the part that falls over pervious area of the catchment infiltrates to the upper zone of the soil mantel. If there is water deficiency in the upper zone of the soil, it gets absorbed till the tension water requirement is met and then starts to flow as free water that percolates to meet the demand of the lower zone. The model has seventeen parameters of which four are considered fixed and the rest are to be calibrated using the Shuffled complex Evolution (SCE-UA) optimization algorithm developed at University of Arizona [Duan et al., 1992].

The model was run using rainfall estimates from TRMM, PERSIANN-CCS and NEXRAD IV for year 2004-2005 and the resulting output of stream flows were compared.

Regarding the satellite rainfall estimates uncertainty, in this study we consider the standard error of satellite-based PERSIANN-CCS rainfall estimates conditioning on the assumed true field (i.e. radar rainfall) which is obtained according to a multivariate function explained briefly by Hong, 2006. The error model illustrated on the paper as:

$$\sigma_e = f(\frac{1}{L}, \frac{\Delta t}{T}, P) = a.\left(\frac{1}{L}\right)^b.\left(\frac{\Delta t}{T}\right)^c (\hat{P})^d \quad (1)$$

Where, $\Delta t = T/N$ is the satellite sampling frequency assuming that the satellite makes N visits over area A during the period of T. This error model was calibrated for various spatial and temporal scales and also precipitation magnitudes which yield the parameters *a, b, c,* and *d* [Hong et al., 2006]. Based on the assumption of multiplicative nature of this error, the Monte Carlo simulation is used to generate the ensemble of precipitation and propagate them into a SAC-SMA model to investigate the impact of input error on streamflow simulation.

Results and discussion

The satellite-based rainfall estimate from the PERSIANN-CCS and TRMM are translated to stream flow hydrograph at the outlet of the Leaf River Basin and compared to the synthetic hydrograph from the NEXRAD Stage IV which is considered as a reference. The plot on Figure 2 shows that even though the hydrograph simulated by the TRMM captures the pattern of the synthetic hydrograph, it is distinctly underestimates the streamflow at the outlet of the catchment while the streamflow simulation from PERSIANN-CSS product comparatively yields better performance. The bias plot on Figure 3 also further strengthen the facts discussed above showing almost a bias of zero throughout for PERSIANN-CCS.

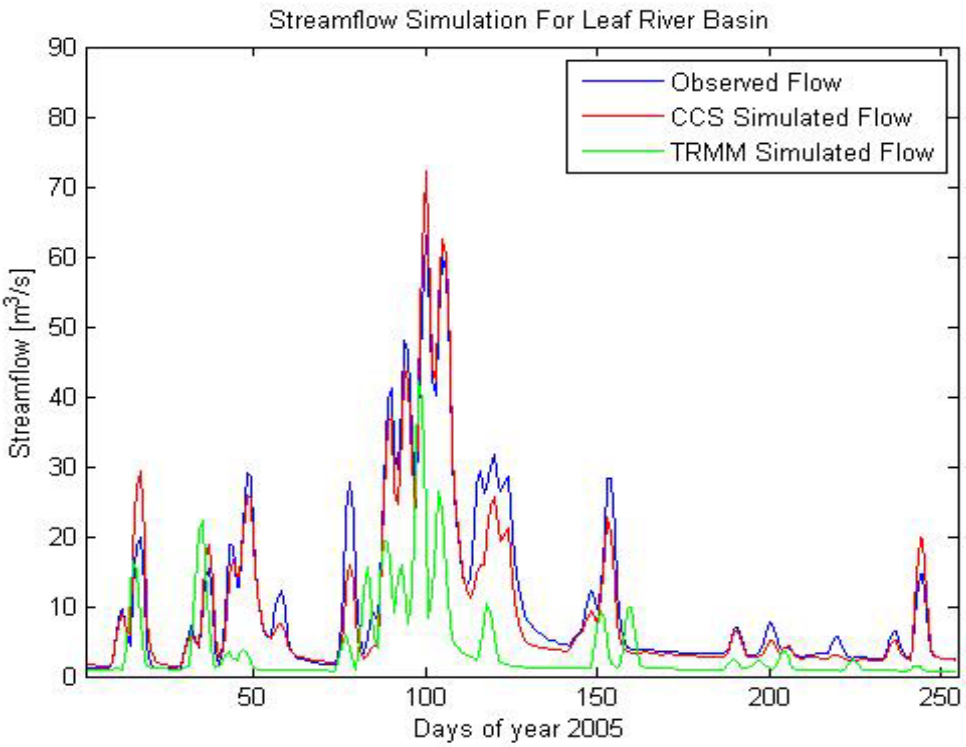

Figure 2 Streamflow simulations for Leaf River basin

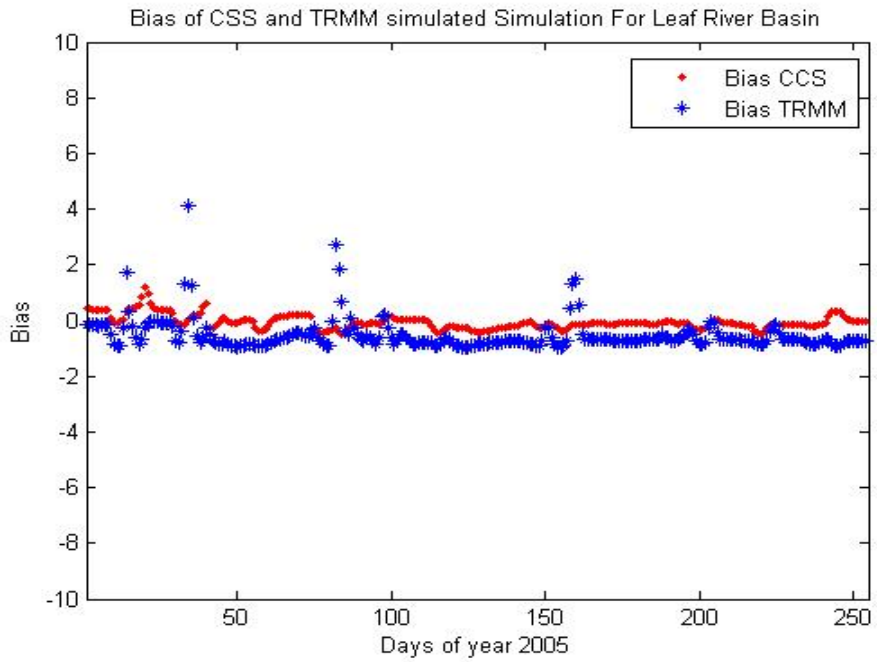

Figure 3 Bias plots for TRMM and PERSIANN-CCS simulated streamflow

The ensemble of satellite-based precipitation for PERSIANN-CCS data is also generated over the catchment and the hydrologic model is derived with this ensemble for the period of 2001 to 2005. For clarity the ensemble streamflow generation for the portion of year 2005 of analysis is displayed in figure 4. Then the model performance in hydrologic predictions is evaluated probabilistically through Normalized Root Mean Square Error Ratio (NRR) since it is a simpler procedure to investigate the quality of ensemble. Moradkhani et al., [2006] and Moradkhani et al., [2005a] used NRR according to [Anderson, 2001] to measure the ensemble dispersion for indicating how confidently the ensemble mean could be extracted from the ensemble spread. According to this method, the ratio of the time-averaged RMSE of the ensemble mean, R_1 to the mean RMSE of the ensemble members, R_2 is calculated and then the ratio is normalized by $E[R_a] = \sqrt{\frac{(n+1)}{2n}}$. This factor shows if the observation is statistically indistinguishable from n ensemble members [Anderson, 2001].

$$R_1 = \sqrt{\frac{1}{T}\sum_{t=1}^{T}[(\frac{1}{n}\sum_{i=1}^{n} y_t^i) - O_t]^2} \quad (2)$$

$$R_2 = \frac{1}{n}\sum_{i=1}^{n}\sqrt{\frac{1}{T}\sum_{t=1}^{T}[y_t^i - O_t]^2} \quad (3)$$

$$Ra = \frac{R_1}{R_2} \quad (4)$$

$$NRR = \frac{Ra}{E[Ra]} \quad (5)$$

Where, n and T are the ensemble size and length of analysis respectively.

It is desired that the ensemble yields *NRR=1*. However, *NRR>1* indicates that the ensemble has too little spread, and *NRR<1* is an indication of an ensemble with too much spread. *NRR* of the streamflow ensemble was obtained annually for the 5 years of simulation from 2001 to 2005. As seen in figure 5 the *NRRs* for all years are above 1 meaning that the streamflow ensemble is under dispersed. This could be explained in part as a result of a large number of ensemble members having zero precipitation creating very narrow ensemble of precipitation resulting in narrow streamflow ensemble. A detail analysis for a wide range of the probabilistic model performance measure is discussed in Moradkhani and Meskele, [2009].

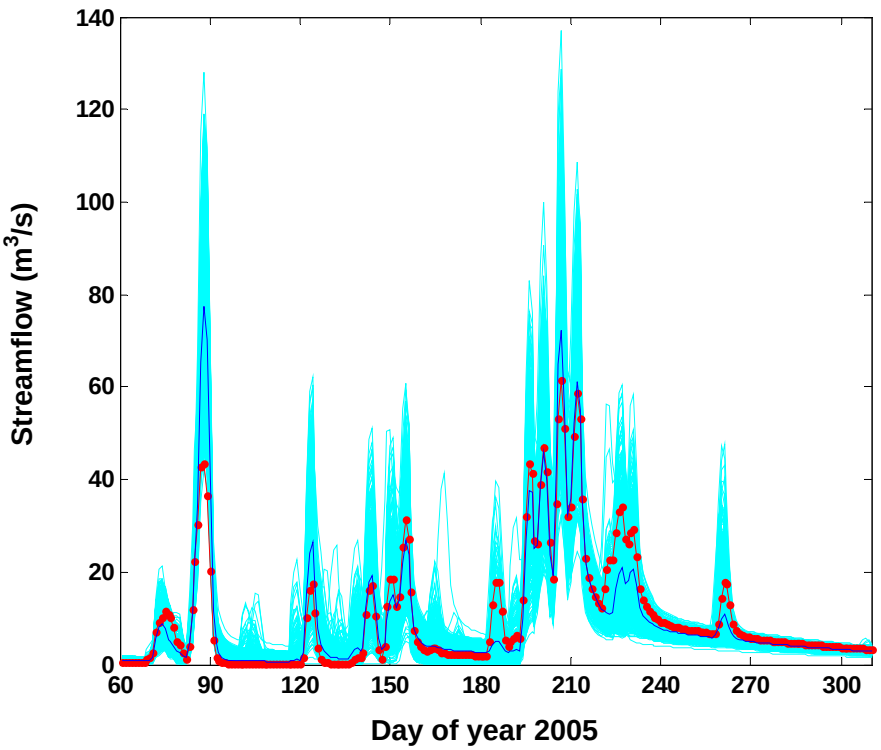

Figure 4. Streamflow ensemble generated by propagating the ensemble of erroneous CCS-PERSIANN rainfall product. The solid dotted line displays the synthetic truth by deriving the SAC-SMA model with radar rainfall data. The shaded area and solid line show the streamflow ensemble and the ensemble mean respectively.

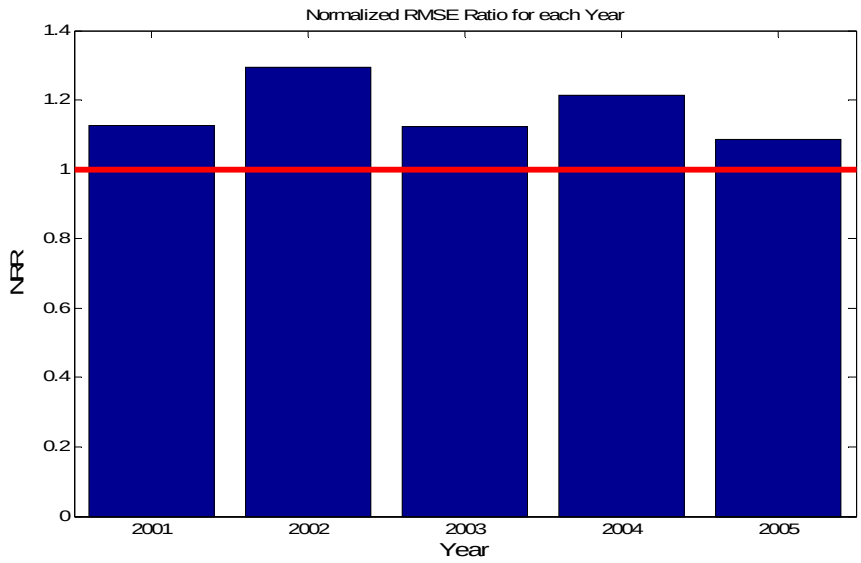

Figure 5. Annual Normalized Root Mean Square Error Ratio (NRR) for the streamflow ensemble generated by CCS-PERSSIAN Satellite precipitation ensemble. The solid line shows the ideal NRR=1.

Summary and Conclusion

In this study, we briefly attempted to evaluate the impact of different satellite based rainfall estimate on a streamflow generation using a conceptual hydrologic model and we performed a Monte Carlos simulation for ensemble generation and propagation of precipitation. It is obvious that an adjustment should be made to TRMM Rainfall estimate before driving the streamflow at an out let of a catchment to remove the systematic underestimation obtained.

An ensemble of streamflow simulation generated by PERSIANN-CCS was also probabilistically evaluated to assess the translation of precipitation uncertainty to a hydrologic simulation.

Abstract
National Weather Service (NWS) rain gauge data has been applied in rainfall-runoff models to estimate inflows to Texas' bays and estuaries for decades by the Texas Water Development Board (TWDB). In an effort to improve the spatial and temporal resolution of rainfall data, TWDB recently launched a pilot project to study the applicability of NEXRAD data for this purpose. Rainfall along the Texas coast is highly variable both spatially and temporally, especially during summer time, making NEXRAD data advantageous over the rather sparsely distributed rain gauge network. Comparisons of rainfall and of modeled runoff using NEXRAD and NWS raingage data are presented at the basin and watershed scale. Advantages and issues with the conversion to use of NEXRAD are presented. Future study will focus on use of distributed rainfall/runoff models to take advantage of the readily available digital data.

Introduction
Estimation of the timing and volume of fresh water that flows into Texas' bays and estuaries is an essential component of virtually all ecological analyses conducted on these systems. The Texas Water Development Board (TWDB) is responsible for estimating these inflows and has compiled this important information for over two decades. Although the majority of the flow reaching the coast is monitored by United States Geological Survey (USGS) stream gages, significant fractions of some contributing drainage basins lie below the gages (Figure 1). In total, 87 % of the entire drainage area is monitored by USGS gages, while the remaining 13 % is ungaged. Rainfall/runoff models have been used for this purpose for several decades (Longley, 1994).

National Weather Service (NWS) raingage data has historically been the primary source of rainfall data used to drive the rainfall/runoff models that were applied in the lower coastal watersheds shown in Figure 1. Both First-Order (FO) weather stations and Cooperative rain gages (Coop) have been used. FO data is generally considered to be of higher quality because these stations generally have better equipment and are maintained by trained professionals (Narasimhan et al. 2006). Nonetheless, Coop data is considered acceptable, and has been an important source of data for less populated areas where FO stations are sparse. FO and Coop raingages for the Galveston Bay and Matagorda Bay lower coastal watersheds are presented in Figure

2. While many of the watersheds contain one or more raingages within their boundaries, many also have none and suffer the possibility of being poorly represented by distant gages.

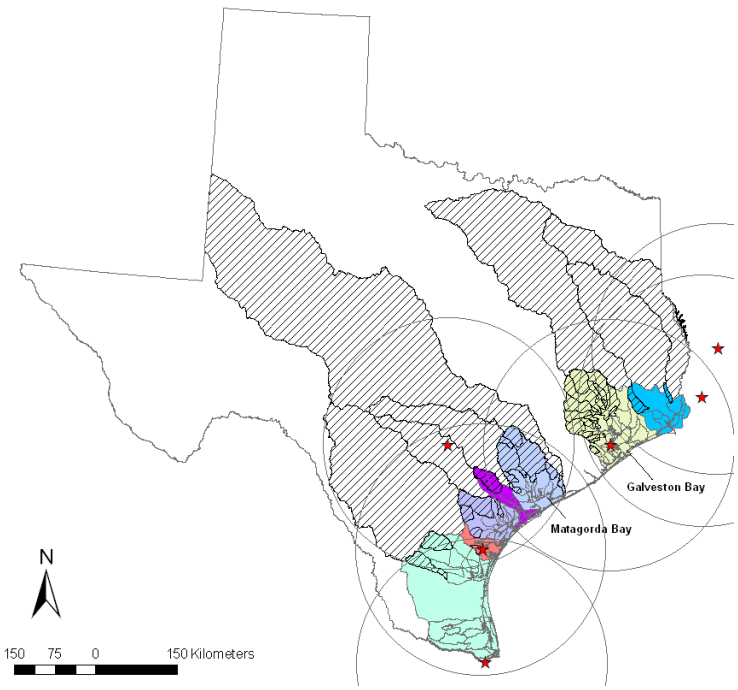

Figure 1. Major river basins in Texas with coastal WSRD-88 NEXRAD radar sites, indicated by star symbols, on the Texas gulf coast. Cross-hatched and shaded areas drain into Texas seven major bays and estuaries. Cross-hatched areas indicate areas monitored by USGS streamflow gages. Shaded areas represent the lower coastal watersheds for Texas' major estuaries where rainfall/runoff models were applied. Matagorda Bay and Galveston Bay watersheds are the focus of this paper. (NEXRAD sites from http://www.roc.noaa.gov/interactive/defaultIE.asp)

Perhaps the greatest limitation to improving the accuracy of runoff estimates to the coast has been the sparse distribution of the raingages in some areas of the coast. The wide spacing of gages in the network leads to the potential for spatial errors, the most extreme example coming from storms being completely missed by the raingages. Studies in Texas now focusing on the minor estuaries and smaller bays on the Texas coast require improved rainfall resolution to allow more accurate estimates of inflow to these systems.

With the improved availability and accuracy of Weather Surveillance Doppler Radar-88D (NEXRAD) data during the last decade, TWDB has embarked on a mission to improve it's estimates of coastal runoff through use of this higher resolution information. This paper describes TWDB's efforts to convert to NEXRAD and some of the issues relevant to that conversion. We provide comparisons between NEXRAD and raingage based estimates of areal rainfall, and results from a rainfall/runoff model that favorably support the improved quality of NEXRAD data in recent years.

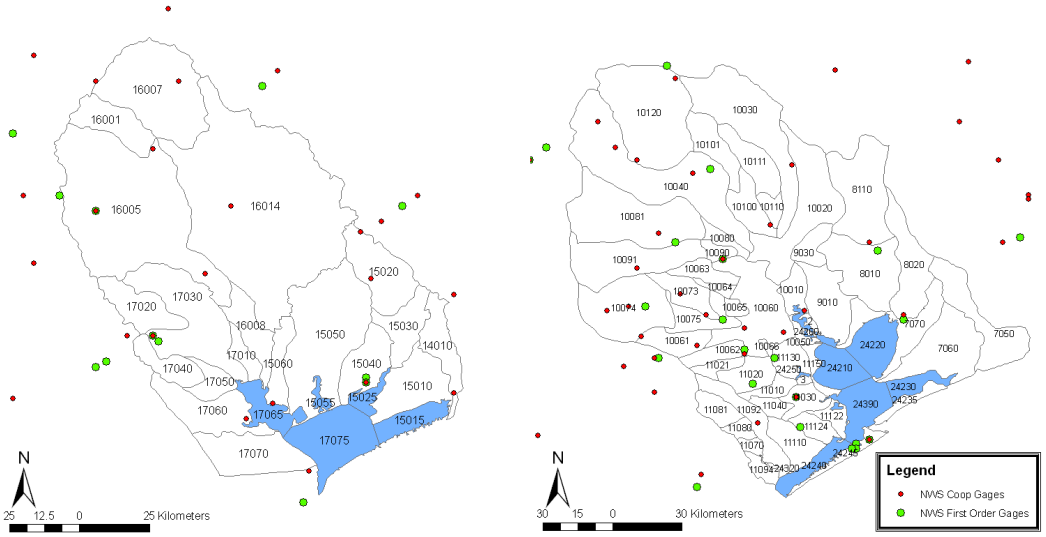

Figure 2. First Order and COOP raingages in the Matagorda Bay and Galveston Bay lower coastal watersheds Texas that are the focus of this study.

Spatial Characteristics of Rainfall on the Texas Coast

Rainfall varies significantly across Texas, averaging less that 11 inches (279 mm) annually in far west Texas and over 59 inches (1499 mm) per year near the Texas-Louisiana border (Narasimhan et al., 2007, Figure 3). From north to south along the gulf coast, annual average rainfall decreases from nearly 59 inches (1499 mm) to less than 27 inches (686 mm). Rainfall generated during spring and fall frontal passages is typically widespread and more spatially uniform, while summer rainfall is less organized spatially, with heavy convection-driven rainfall falling over smaller spatial scales. Spatial variability is more pronounced in coastal watersheds than in inland watersheds, as shown by Narasimhan and Srinivasan (2006) using spatial autocorrelation analyses of NEXRAD data for six study areas in Texas, including three along the coast.

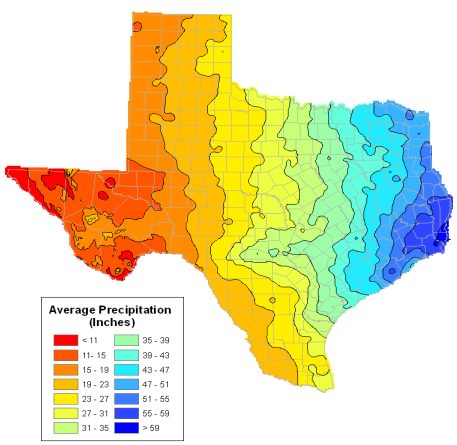

Figure 3. Mean annual rainfall in Texas, showing the spatial variation of rainfall across the state and along the Texas gulf coast (from Narasimhan, et al. 2007).

NEXRAD Rainfall Bias

NEXRAD data prior to 2000 has been shown to be biased relative to raingage data (Jayakrishnan, et al. 2004). Sources of bias, including spatial representation of the measurements, radar overshooting, topographical interference, issues with the Z-R relationship, distance from the radar, and so on are well documented (Breidenbach and Bradberry, 2001; National Weather Service 2002). Over time and with the goal of removing bias, algorithms have been proposed and developed to adjust the raw radar signal to FO raingage data, leading to NEXRAD Stage III (Seo and Breidenbach, 2002). Since about 2002, there have been no significant calibrations or adjustments to the correction algorithms (R. Srinivasan, personal communication). Comparison of NEXRAD Stage III rainfall data with raingage data using data from 1995-1999 (Jayakrishnan, 2004), from 2000-2004 (Narasimhan et al., 2006), and from 2000-2007 in the current study show that bias correction has improved.

Data and Methods

NEXRAD data for this study was obtained from the West-Gulf River Forecast Center (WGRFC), which covers the entire Texas gulf coast region. Raingage data was obtained from the National Climatic Data Center (NCDC). Daily accumulated data from both sources from 2000-2007 was used in this study to generate monthly and annual rainfall totals.

Some studies have compared NEXRAD rainfall to raingage data at the scale of the raingage (Young and Brunsell, 2008), while other that have compared spatially aggregated rainfall at larger scales using different means to distribute raingage data (National Weather Service, 2009). This paper takes the second approach and compares the spatially aggregated rainfall on the subwatershed and basin-wide scale. Area-weighted rainfall for each subwatershed in the lower drainage basins was prepared using Thiessen polygons for the raingage data, and by intersection of the HRAP grids with the watersheds for the NEXRAD data. Daily rainfall volumes were then accumulated to monthly and annual rainfall for comparison on a watershed-scale basis. Rainfall for the individual watersheds was also accumulated to allow basin-wide monthly and annual comparisons of NEXRAD- and raingage-based rainfall.

NEXRAD/Raingage Rainfall Comparison

Comparisons in this study were conducted for the two basins on the Texas coast that drain into Galveston Bay and Matagorda Bay (Figure 4). The Galveston Bay drainage basin includes drainage from the Trinity and San Jacinto River basins and intervening coastal basins. Approximately 86 % of the entire drainage is monitored by USGS streamgages, the majority of that coming from the Trinity River. Runoff from the remaining 14 % must be modeled. The Matagorda Bay basin includes drainage from the Colorado and Lavaca River basins. The majority of flow into Matagorda Bay is also gaged (96%), with the greatest portion of that coming from the Colorado River.

The lower basins draining into each bay are subdivided into sub-watershed units for which rainfall estimates were made using both NEXRAD and raingage data. Rainfall

estimates were made for both gaged and ungaged watersheds – in practice, a rainfall/runoff model was calibrated to USGS gaged flows in the gaged watersheds, and parameters from the gaged watersheds were then extrapolated to the ungaged watersheds to estimate runoff from the ungaged watersheds.

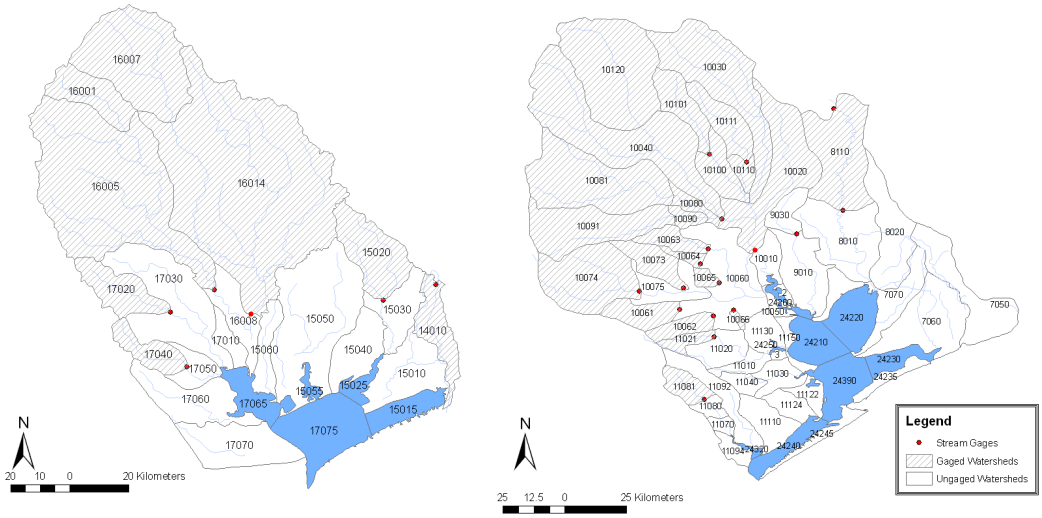

Figure 4. Lower coastal drainage basins for Matagorda Bay (left) and Galveston Bay (right) used in this study. Areas monitored by USGS streamgages indicated by shading.

Temporal Change in Bias

Comparisons between monthly basin-wide NEXRAD and raingage rainfall are presented in Figure 5. Variation of annual basin-wide NEXRAD bias from 2000-2007 is presented in Table 1. Here, bias is calculated as:

$$Bias_i = (PNEXRAD_i - PRaingage_i)/PRaingage_i * 100,$$

where $PNEXRAD_i$ is the mean annual NEXRAD rainfall for watershed i, and $PRaingage_i$ is the mean annual raingage rainfall for watershed i. The maximum annual bias for Galveston Bay watersheds was -15.1% in 2001, and for Matagorda Bay watersheds was +27.6% in 2002.

Bias during the first year (2000) of both records was small (Figure 5), where the cumulative rainfall for NEXRAD and raingage records track closely. However, the NEXRAD data for both basins experienced significant drift relative to the raingage data between 2001 and 2002, indicating large biases during those periods. Following 2003, the cumulative records increase in parallel, indicating that NEXRAD and raingage data are tracking relatively well again, suggesting a reduced bias. The short increase in bias shown in both records between 2001 and 2002 could be due to extreme events, storms not captured by the raingages, or other causes, but this was also a time during which changes to the bias algorithms were being modified (Srinivasan, pers. comm. 2009). Inspection of just the period between 2003 and 2007 suggests that while there are still differences between the NEXRAD and raingage

data on a monthly and annual basis (Table 1, Figure 5), the cumulative differences tend average out (Figure 6). For Matagorda Bay watersheds from 2003 to 2007, cumulative raingage rainfall was 5825 mm, while NEXRAD rainfall was 5905 mm, yielding a +1.4% bias. For Galveston Bay watersheds, the cumulatives were 6715 mm for raingage rainfall and 6538 mm for NEXRAD, or a -2.6% bias. There are clear differences in some months and years, some in which rainfall events might have been missed by the raingages as appears to be the case late in 2006 for Galveston Bay. In other cases events were clearly picked up by both NEXRAD and raingages, but the totals are different as appears to be the case late in 2007 for Matagorda Bay (Figure 5). However, the cumulative differences are small enough to suggest that after 2002 basin-wide rainfall estimates using NEXRAD match raingage estimates to the accuracy needed for our inflow estimates.

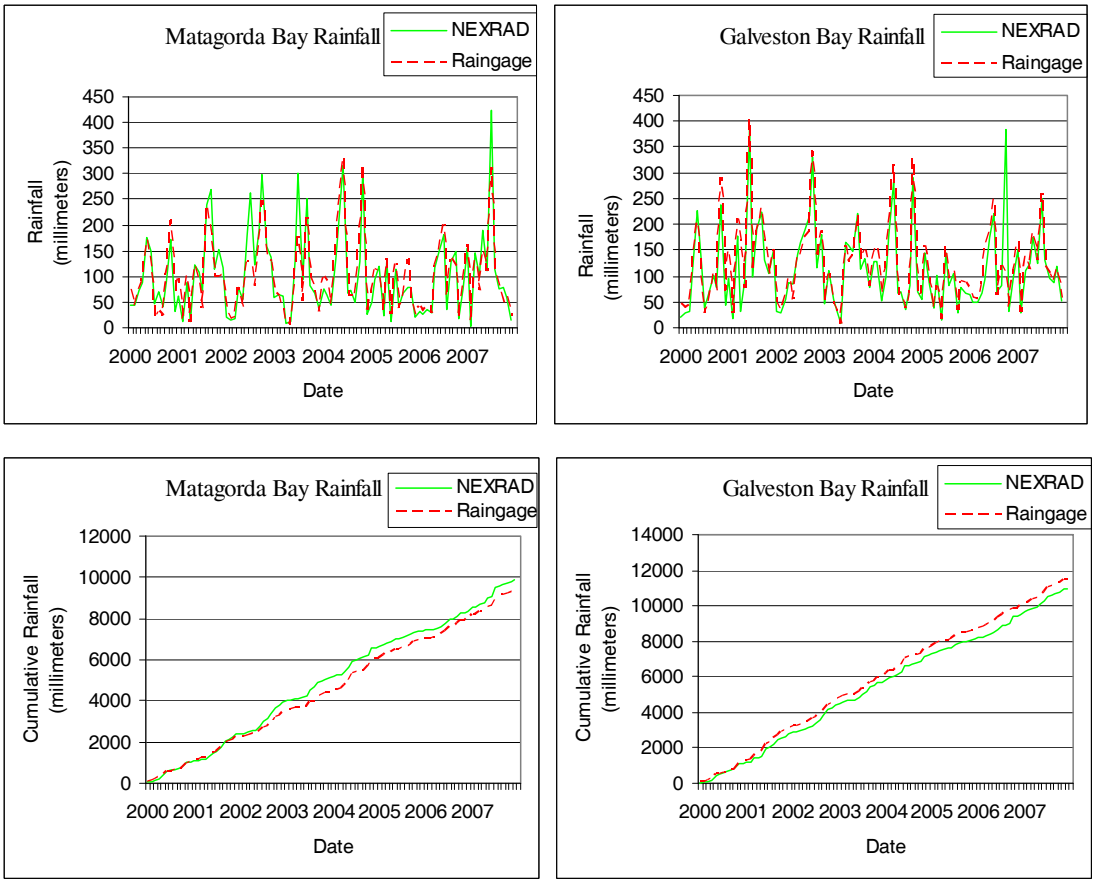

Figure 5. Monthly (top) and cumulative (bottom) basin-wide rainfall for Matagorda Bay and Galveston Bay watersheds, 2000-2007.

Areal Rainfall Comparison by Watershed

Based on the above findings, only 2003-2007 data is used in subsequent comparisons. Mean annual rainfall from 2003-2007 for 24 watersheds in the Matagorda Bay basin and 57 Galveston Bay watersheds are presented Table 2 and Table 3, respectively.

Table 1. Annual basin-wide rainfall for Matagorda Bay and Galveston Bay watersheds, 2000-2007.

Matagorda Bay				Galveston Bay			
Year	Raingage Rainfall (millimeters)	NEXRAD Rainfall (millimeters)	Bias (%)	Year	Raingage Rainfall (millimeters)	NEXRAD Rainfall (millimeters)	Bias (%)
2000	1037.34	1020.57	-1.62	2000	1154.94	1104.39	-4.38

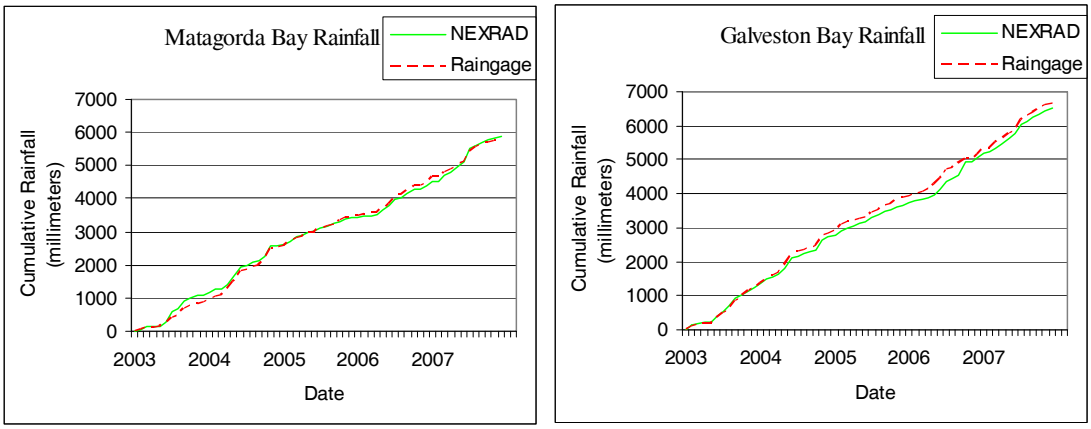

Figure 6. Cumulative basin-wide rainfall for Matagorda Bay (left) and Galveston Bay (right) watersheds, 2003-2007.

Mean annual raingage-based rainfall for Matagorda Bay watersheds, where the rainfall was spatially distributed using Thiessen polygons, varied from 976 mm to 1320 mm. Mean rainfall varied from 949 mm to 1395 mm for NEXRAD data. NEXRAD bias was positive for 16 of the 24 Matagorda Bay watershed for this period and ranged from -6.2% to +8.7%. The area-weighted mean annual rainfall for all of the Matagorda Bay watersheds was 1165 mm using raingage data, and 1181 mm using NEXRAD data, or a +1.4% bias.

Mean annual rainfall for the Galveston Bay watersheds varied from 1172 mm to 1627 mm for raingage data, and from 1165 mm to 1506 mm for NEXRAD data (Table 2). In contrast with the Matagorda Bay watersheds, NEXRAD bias was negative for 44 of the 57 Galveston Bay watersheds. The NEXRAD bias for the Galveston Bay watersheds varied from -16.5% to +5.6%. The area-weighted mean annual rainfall for all of the Galveston Bay watersheds was 1343 mm for raingaged data, and 1307 mm for NEXRAD data, or a -2.6% bias.

Table 2. Comparison of mean annual NEXRAD and raingage rainfall for Matagorda Bay watersheds, 2003-2007.

NEXRAD bias in both the Matagorda Bay and Galveston Bay watersheds are presented in Figure 7. The largest negative biases, shown in the darkest shade, appear towards the center and near the coast of both basins. A band of negative bias appears to run longitudinally through the Matagorda Bay basin. Positive biases, shown in light shades, are weak in the Galveston Bay basin, and lie on the eastern and western edges of the Matagorda Bay basin. While there may be some structure to the bias distribution, it is weak and balanced enough to not be of great significance in the big picture. Nonetheless, at this spatial scale of the watersheds shown, there remain clear biases between NEXRAD and raingage rainfall.

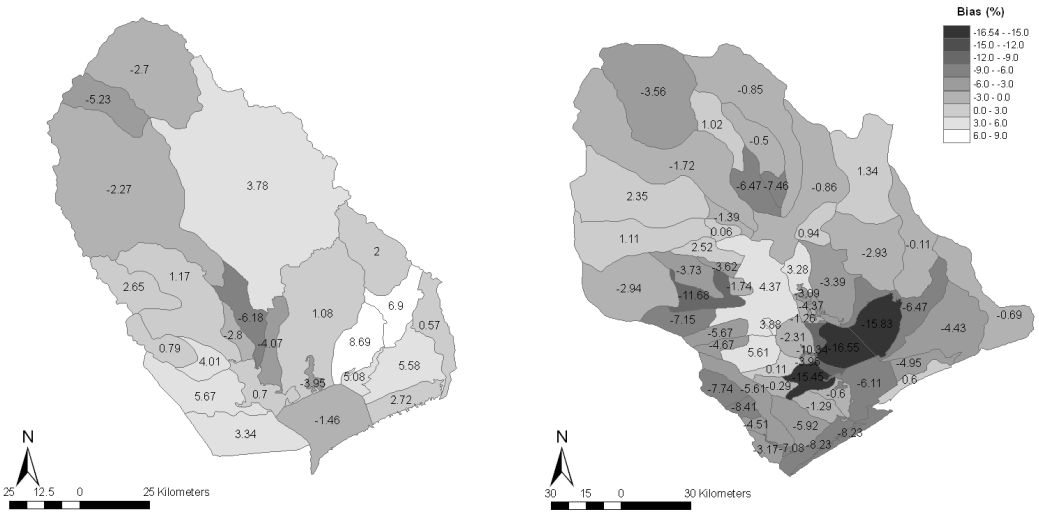

Figure 7. Spatial variation in NEXRAD bias relative to raingage rainfall for Matagorda Bay (left) and Galveston Bay (right) watersheds. Light shades indicate positive bias, and dark shades indicate negative bias.

Application of Rainfall/Runoff Models

Estimates for ungaged watersheds of freshwater inflows to Texas' estuaries made in the late 1970's were based on application of the Soil Conservation Service (SCS) TR55 Model (TWDB, 1983). This lumped-parameter model applies a watershed's Curve Number (CN) and a soil moisture parameter to estimate a monthly runoff from rainfall. Studies over the next two decades led to the development and application of the Texas Rainfall-Runoff Model (TXRR) at TWDB. TXRR is also a lumped parameter model and uses an approach similar to the SCS model to estimate total runoff from a rainfall event. It tracks subsurface soil moisture continuously, and provides a daily runoff output, an improvement to the TR55 model. In both cases, raingage-based rainfall data was used to drive the models. Thiessen polygons created based on the raingage network and overlain on the coastal watersheds were used to estimate the rainfall on each watershed.

Transition from raingage-based inputs to NEXRAD for our modeling purposes has

become feasible as NEXRAD data has become readily available and has improved in quality. However, prior to a full transition to NEXRAD, a clear understanding of the temporal and spatial differences between raingage and NEXRAD is needed. Based on the analyses presented above, at the scale of individual watersheds, there remain clear differences between raingage- and NEXRAD-based rainfall estimates at even monthly and annual time scales. In aggregate over the entire lower coastal basin watersheds, however, the differences between raingage and NEXRAD rainfall totals are lowered to the a few percent, which is acceptable for our purpose.

A further test of the applicability of NEXRAD data is to compare runoff estimates computed using raingage and NEXRAD data with the TXRR Rainfall/Runoff model. These comparisons are presented in Table 4 and Table 5 for the Matagorda Bay and Galveston Bay watersheds, respectively. TXRR model parameters for each watershed were identical between raingage and NEXRAD model runs.

The combined mean annual runoff for Matagorda Bay watersheds was 3484 million m^3 using raingage data, and 3913 million m^3 using NEXRAD data, a bias of +12.3% (Table 6). The bias in runoff varied from -20.8% to +31.9% for individual watersheds. Mean annual runoff for the Galveston Bay watersheds was 8658 million m^3 using raingage data, and 8366 million m^3 using NEXRAD data, a bias of -3.4%. Biases ranged from -31.2% to +16.6% for individual watersheds. For both the Matagorda Bay and Galveston Bay basins, runoff biases are amplified relative the biases observed in rainfall estimates.

Table 4. Comparison of TXRR runoff based on mean annual raingage and NEXRAD rainfall for Matagorda Bay watersheds, 2003-2007.

2006	2,122	1,932	-8.92	2006	7,006	8,907	27.14
2007	4,627	6,271	35.53	2007	10,976	10,672	-2.78
AVERAGE	3,485	3,913	12.31	AVERAGE	8,658	8,366	-3.37

The level of amplification of bias by the rainfall/runoff model when using NEXRAD data, particularly for Matagorda Bay, suggests that raingage-driven models previously calibrated against USGS streamflow will need to be recalibrated when driven with NEXRAD data.

Future Use of NEXRAD Rainfall Data

TWDB has developed hydrological inflow records for Texas bays and estuaries for the period 1941 to the present (TWDB 2008). Rainfall data used for this purpose was based on the NWS raingage network in Texas. The temporal continuity of the raingage network minimized concern for the introduction of artificial trends in calculated runoff using this data. This is significant given an interest for water planning and environmental purposes to identify the real changes in inflow patterns attributed to changing water demands due to population growth, urbanization, changes in agricultural patterns, and other factors. With the continued adjustments in the past of NEXRAD bias correction algorithms, older NEXRAD data may (prior to 2003) not be suited for use for our applications without additional post-processing to correct for evident biases. Although bias correction algorithms appear to have stabilized, TWDB will continue in the immediate future to rely on raingage data in parallel with NEXRAD data. This will allow continuity of the raingage-based hydrological record and the advantages offered by longer data sets. In the meantime, NEXRAD data will also continue to be applied to allow continued comparison to the raingage data. Based on comparisons of model outputs, use of NEXRAD will require recalibration of the rainfall/runoff models. Eventually, we hope to make a full transition to the use of NEXRAD data to reap the benefits of the high degree spatial resolution it offers. Additional plans by TWDB include the transition from the lumped-parameter TXRR rainfall/runoff model to models, such as the Soil and Water Assessment Tool (SWAT) that can more fully take advantage of the spatial resolution offered by NEXRAD and newly developed digital land classification data and curve numbers (Stukey et al. 2008).

Conclusions

Based on analysis of NEXRAD data, bias adjustments to NEXRAD data after 2002 appear to have reduced bias relative to raingage data at the basin-wide scale sufficient to make it suitable for use in determining total volumes of freshwater inflows from ungaged areas adjacent to Texas coastal estuaries. However, comparisons of model outputs indicate that rainfall/runoff models using NEXRAD data will need to be calibrated for use with that data. At the scale of smaller watersheds, significant differences remain between raingage and NEXRAD data. Given the superior spatial resolution of NEXRAD, it is likely that the NEXRAD data better reflects runoff for individual watersheds, and will improve our ability to estimate inflows to the small minor bays on the Texas coast. While our experience with NEXRAD grows, TWDB will continue using raingage data in the near future for continuity with historic records with the expectation of a more complete transition to NEXRAD in the future.

ABSTRACT

The NOAA National Weather Service (NWS) is actively conducting research toward operational distributed hydrologic models to improve its products and services to the Nation. Such models attempt to account for the spatial variability of basin features and meteorological forcings at high resolutions. Distributed models are viewed by the NWS as a pathway to provide high space and time resolution information for forecasting hydrologic conditions from flash floods to drought, including water resources forecasting. NWS field offices have been prototyping an operational distributed model since the beginning of 2007.

The purpose of this paper is to provide the engineering community an overview of some of the major issues and approaches developed as the NWS moves forward with distributed models using NEXRAD data for operational forecasting.

INTRODUCTION

Largely as the result of radar-derived precipitation estimates, ever-increasing computer power, spatial data analysis techniques, and the plethora of digital data sets of terrain, soils, vegetation, land use and other data, distributed hydrological models are routinely used for scientific studies, operational river forecasting, and engineering applications. The application of distributed models for operational river and flash flood forecasting requires careful analysis of models and data in order to achieve meaningful results. One basic question is: which model features should be chosen for a specific application? Another key question is: are high-quality precipitation and temperature data available to support distributed models? For over a decade, NWS NEXRAD and other radar-based precipitation estimates have been available for use in the operational, research and engineering communities. However, one must take proper account of the processing and quality of these estimates. For example, errors in such data may be magnified rather than smoothed by the many computational elements in a distributed model. Currently, these are areas of very active research in many institutions.

NWS DISTRIBUTED HYDROLOGIC MODELING

Distributed models are viewed by the NWS as a pathway to provide high space and time resolution information to meet an ever-expanding set of needs from flash floods

to drought, including water resources forecasting. One question faced by the NWS is common to any application or study: given a large number of models to choose from, which one is the most applicable? In addition, how will distributed models compare to the existing lumped model used by the NWS for current operational river forecasting? To address these questions, the NWS conducted the first phase of the Distributed Model Intercomparison Project (DMIP 1), focusing on basins in Oklahoma as test areas. Over a dozen government, private, and academic institutions participated in DMIP 1. Details of the rationale and design of DMIP 1 can be found in Smith et al. (2004), while Reed et al. (2004) present the overall results. One of the interesting results found by Reed et al. (2004) is that calibrated lumped models tended to outperform calibrated distributed models for basin outlet forecasts. However, some calibrated distributed models performed at a level comparable to, or better than, a calibrated lumped model (the current NWS operational standard).

The NWS is currently conducting the second phase of DMIP (hereafter called DMIP 2; Smith et al., 2009a) in order to investigate the use of distributed models in areas with mountainous terrain, orographic precipitation enhancement, snow accumulation and melt, and sparse data collection networks. The questions that arise here include: can existing data collection networks in mountainous areas support the use of distributed models? Or, are higher density data collection networks required? DMIP 2 experiments will leverage the enhanced data collection activities of the Hydromet Test Bed (HMT; www.hmt.noaa.gov). The purpose of the HMT is to expedite the delivery of research into operational weather and streamflow forecasting. As part of HMT, a suite of data collection platforms including 'gap-filling' radars, additional in-situ precipitation gauges, vertically-pointing radars, and other instruments are being used to provide enhanced observations of winter precipitation events in the North Fork of the American River. Another key question is: can distributed modeling more effectively capture the rain/snow elevation? NWS forecasters have stated that perhaps the greatest benefit can result from a better definition of the rain/snow elevation (Arthur Henkle, NWS, personal communication). The DMIP 2 experiments in the western basins will also provide an opportunity to test the performance of snow accumulation and melt models of various levels of complexity. Another key question relates to the ability to calibrate distributed models for use in mountainous areas.

DMIP 2 also includes additional modeling tests in the Oklahoma basins studied in DMIP 1, such as the ability of distributed models to compute soil moisture estimates. The goal here is to test the ability of distributed models to generate basin interior predictions when they are calibrated using only basin outlet streamflow observations.

Initial results from the DMIP 2 experiments in Oklahoma corroborate the DMIP 1 findings. Figure 1 shows the performance of all the eighteen participating DMIP 2 models for each of the test basins (Smith et al., 2009b). The statistic in this case is a modified correlation coefficient R_{mod} (McCuen and Snyder, 1975). Values of R_{mod} close to one are desirable. The results in Figure 1 are from calibrated models run over the calibration and verification periods. The results from two lumped models are shown as solid magenta squares and open black circles, respectively. All other plotting symbols represent the results of various distributed models. As seen in Figure 1, one distributed model (black open square) is one of the top two models for 10 out of 16 cases and is above the median of calibrated models in all but one case. Interestingly, the two lumped

models consistently perform better than the majority of distributed models for basin outlet simulations. As in DMIP 1, all models benefited from some type of parameter calibration, albeit to different degrees. Good initial values of model parameters seemed to enhance the calibration process.

Errors in the radar-derived precipitation data may contribute to this counter-intuitive finding regarding the good performance of the lumped models (see discussion below). Another factor may be that the spatial variability of precipitation may not be great enough to overcome the smoothing and damping of the rainfall signal as the precipitation moves over and through the soil to the outlet. While distributed models need to be applied wherever basin interior information is needed, such basins may not always benefit from distributed modeling compared to lumped models for basin outlet simulations. Interested readers are referred to Smith et al., (2004) and references therein for more discussion of this concept. Given these results, the NWS recommends the use of lumped and distributed models in operational river forecasting (Jones et al., 2009). Figure 2 shows an actual NWS forecast for a basin in Mississippi. In this case, both a lumped and a distributed model are run at an hourly time step. Jones et al. (2009) document several other NWS operational river forecast cases that benefit from distributed modeling.

The DMIP 2 soil moisture experiments in the Oklahoma basins also produced meaningful results (Smith et al., 2009b). Two models participated in this specific experiment and produced soil moisture estimates covering the state of Oklahoma: a modified version of the conceptual NWS Sacramento Soil Moisture Accounting model (SAC-SMA) and the Noah land surface model used in several NWS numerical weather prediction models. Analysis of these results indicates that both models produced good estimates of basin-average soil moisture.

Preliminary analysis of the results of the DMIP 2 western basin experiments yielded interesting results (Smith et al., 2009c). Six organizations participated in these experiments. One finding is that the gauge density in the two basins appears to support the use of distributed models based on point rain gage observations alone. As in the Oklahoma basin experiments, calibrated lumped models produced simulations that were as good as those from distributed models in an overall sense. However, in certain events, calibrated distributed models produced superior streamflow simulations compared to the lumped model. Ongoing analyses are aimed at understanding the source of the simulation improvements in these events. Some distributed models were able to replicate the diurnal snowmelt patterns that result in diurnal streamflow variations. This phenomenon is important to NWS forecasters when the diurnal snow melt patterns cause the river to fluctuate above and below flood stage.

USE OF RADAR-DERIVED AND OTHER GRIDDED PRECIPITATION ESTIMATES FOR DISTRIBUTED MODELING

The NWS Next Generation Radar (NEXRAD) and other weather radar platforms have provided the hydrologic modeling community with high-resolution precipitation estimates for well over a decade. A large volume of research has been conducted on the derivation and use of these radar-based precipitation estimates (e.g., Young et al., 2000; Stellman et al., 2001). As with other data forcings for hydrologic models, the impacts of

errors in the data must be understood. One area of investigation is the interaction between data error and modeling resolution. Koren et al. (2001) performed a numerical experiment to highlight this interaction. Figure 3 shows the hypothetical watershed used by Koren et al. (2001). The size of this basin is 10 by 10 NEXRAD precipitation grid boxes. The precipitation data was taken from the NWS Arkansas-Red Basin River Forecast Center (ABRFC) archive. Rainfall was transformed into runoff in each computational element using the Sacramento Soil Moisture Accounting model (SAC-SMA). The original precipitation data from ABRFC was modified by adding three levels of error, generated from white noise. The basin was modeled at several levels of resolution using the same precipitation data. In Figure 3a, the basin was modeled as a lumped area, with all 100 NEXRAD grid boxes averaged each hour. In Figures 3b and 3c, the basin was subdivided into 4 and 16 cells respectively. Lastly, the hypothetical basin was disaggregated into 100 cells, with each cell matching the nominal 4km x 4km sized of a NEXRAD precipitation grid box. The 'truth' scale and simulation in this experiment were taken as the finest resolution and resultant simulation, respectively. Simulations at each level of disaggregation were run over a multi-month period at an hourly time step.

Figure 4 shows the results of the experiment by Koren et al. (2001). The Y axis denotes an error statistic, in this case the peak volume error from the simulation at any scale compared to the 'truth' simulation. The X axis denotes the level of basin disaggregation. The errors from each level of disaggregation are shown for each precipitation forcing.

Looking first at the zero noise case, the simulation at the lumped scale has the largest error compared to the 'truth' simulation. As the basin is disaggregated further, the error decreases until it finally disappears at the finest resolution. Interestingly, disaggregation of the basin into finer computational elements using 'noisy' data does not follow this expected pattern. For example, basin disaggregation in the 25% noise case (green line) does not reduce the error to zero. Furthermore, basin disaggregation in the 50% and 75% noise level cases actually result in worse simulation errors compared to the lumped, zero noise level case. In this case, there appears to be a 'break point' at a disaggregation scale of between 20 and 30. Koren et al. (2001) believed that the errors in the precipitation data are multiplied rather than smoothed by the non-linearities of the rainfall-runoff model.

Another type of error in the NEXRAD precipitation estimates is shown in Figure 5. This basin is one of the study basins in the DMIP 1 and 2 experiments (Smith et al., 2004). In this case, use of the radar precipitation estimates in modeling the Elk River basin above the USGS gauge at Tiff City, Missouri. resulted in a large over-prediction of the observed hourly streamflow. Analysis of the NEXRAD precipitation estimates revealed the presence of 'bright band' contamination, caused by the radar beam encountering frozen precipitation and generating anomalously high signal returns. Trying to calibrate a hydrologic model in DMIP using this event would be very difficult. The NWS recommends that such events are ignored in model calibration. In manual calibration, the user simply ignores such events. In automatic calibration, the NWS sets the observed streamflow values in the time series to 'missing' so that any statistical procedure ignores such events. Islam et al. (2009) and Looper et al. (2009) discuss

similar analyses of radar-based precipitation. In both cases, bias correction of the radar-based precipitation estimates was found to be justified.

Yet another aspect of using NEXRAD precipitation estimates for distributed modeling concerns the quality of the data over time. Changes in processing algorithms and different levels of forecaster experience can result in time-varying biases in the precipitation data (Young et al., 2000). Such inconsistent data can complicate the process of model calibration (e.g., Reed et al., 2004). This aspect also arose in the DMIP 2 experiments in the western mountainous basins. The algorithm used by the NWS to generate gridded 4km gauge-only precipitation grids for distributed modeling was found to incorrectly handle gauge networks with time-varying densities. (Mizukami and Koren, 2009). Several strategies exist for dealing with this problem. Given a long archive of data, the most recent period may be of sufficient quality for model calibration. Such a strategy was used in DMIP 2 for the Oklahoma basins (Smith et al., 2009a). Other strategies include a simple bias correction performed on a monthly basis (Zhang et al., 2009). A comprehensive and ongoing effort to generate a consistent radar-based multisensor precipitation data set via reanalysis is being conducted at the National Climatic Data Center (NCDC; Nelson et al., 2006). For DMIP 2, and effort is underway to develop a new algorithm to generate gridded precipitation estimates from in-situ gauge networks.

Care must be taken in those cases in which NEXRAD or other radar-based precipitation data sets are used for river or flash flood forecasting and rain gauge data are used for model calibration. Analyses must be performed to compare the two forcings to avoid simulation and forecast biases due to the model parameters being calibrated with data having different statistical properties than the data used for forecasting (e.g., Johnson et al., 1999; Stellman et al., 2001; Bradley and Kruger, 1998; Westcott et al., 2008).

CONCLUSIONS

Operational use of distributed models for river and flash flood forecasting is continuing in the NWS. Comprehensive studies and operational experience have shown that distributed and lumped models can provide valuable information in the forecasting process. Both approaches should continue to be used. However, care must be taken to understand the precipitation data used in the model for calibration and forecasting. Many studies have provided useful guidance and procedures for data analysis. Good initial values of model parameters enhance the calibration of distributed models.

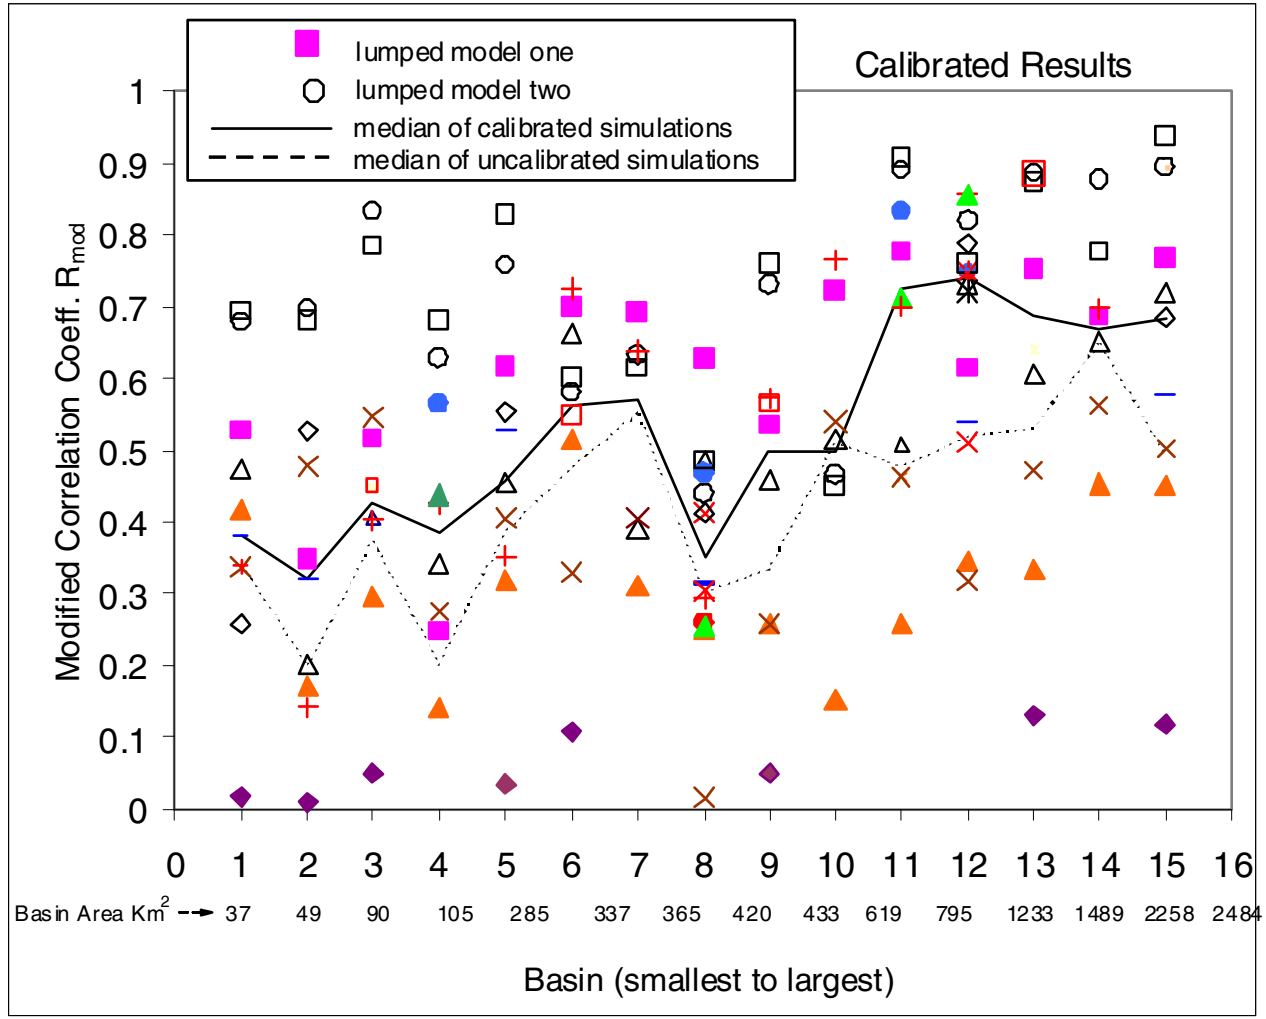

Figure 1. Results from the DMIP 2 experiments in the Oklahoma region. Each plotting symbol represents the overall calibrated Rmod statistic for the test basin. The two lumped models are denoted as a black open circle and a solid magenta square. All other symbols represent the results of distributed models.

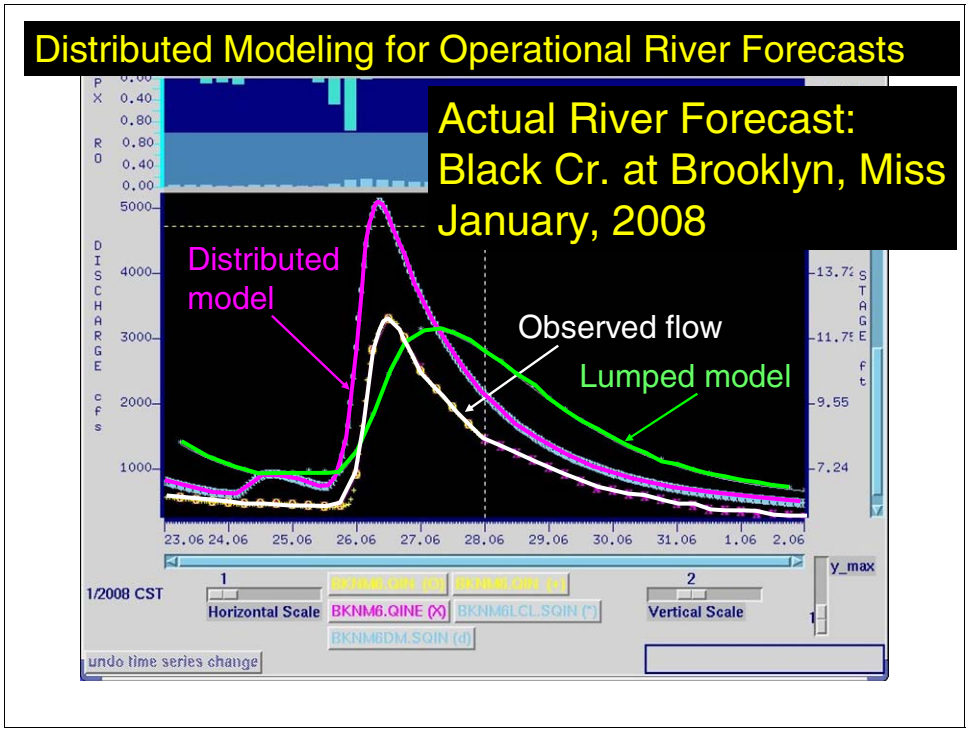

Figure 2. Lumped and distributed model river forecasts for Black Creek, Mississippi.

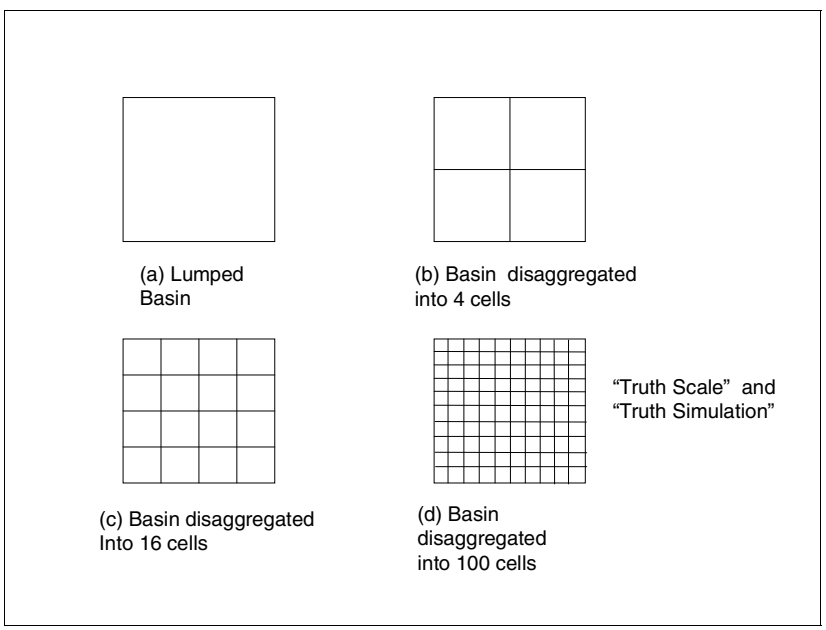

Figure 3. Hypothetical square basin used in the analysis of Koren et al. (2001). Note that the simulation from the finest level of basin disaggregation is considered the 'truth'. Simulations from other levels of disaggregation are compared to this 'truth' simulation.

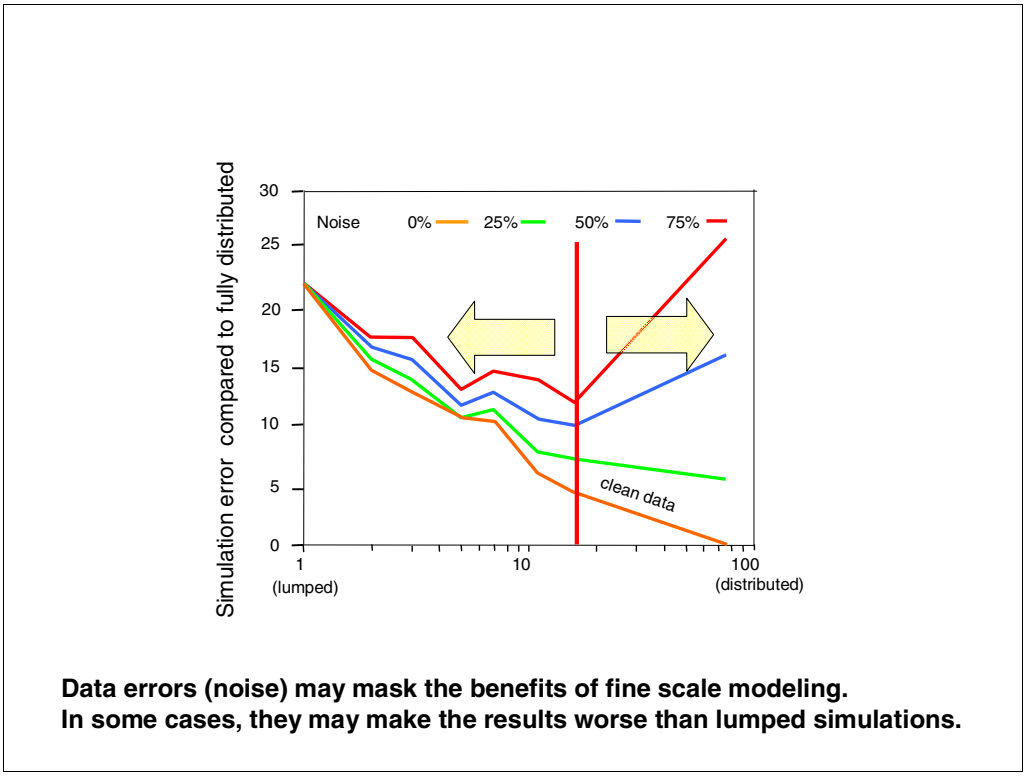

Figure 4. Results of simulations using the hypothetical basin shown in Figure 3. The broad yellow arrows indicate the 'break point' in basin disaggregation, beyond which further improvement in simulation accuracy can be achieved due to data errors.

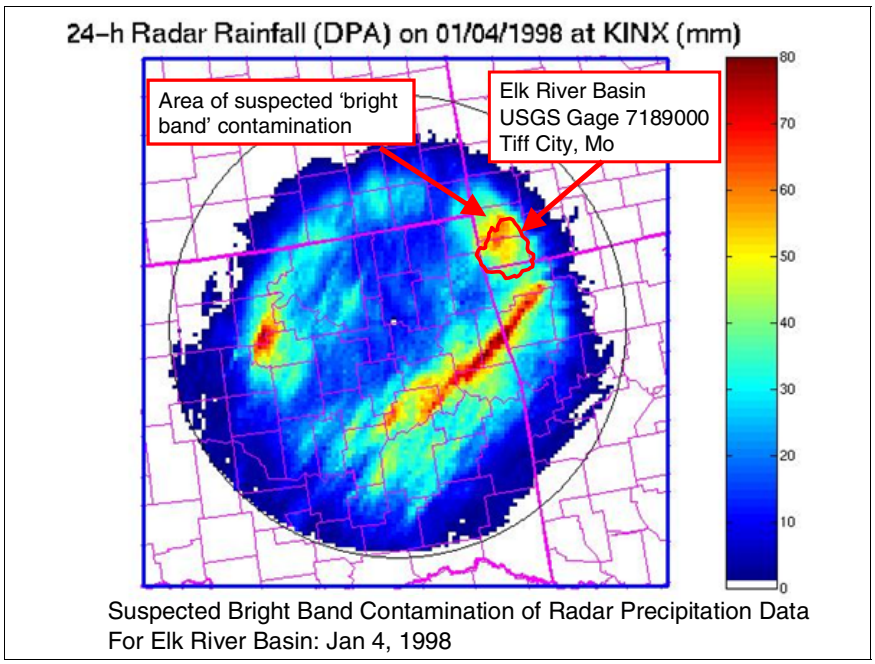

Figure 5. Example of 'bright band' contamination in the NEXRAD multi-sensor precipitation data for Jan. 4, 1998.

ABSTRACT

A flash flood forecasting system has been developed which combines distributed modeling and statistical analyses to produce gridded forecasts of return periods. A distributed hydrologic model (DHM) coupled to a threshold frequency (TF) post-processor, DHM-TF, is currently being tested over a Maryland-centered domain, and has verified well against National Weather Service (NWS) flash flood warning areas and verification points. The prototype system is currently running in real-time at the NWS Office of Hydrologic Development (OHD), and efforts are underway to test DHM-TF at several NWS field offices.

INTRODUCTION

Flash floods are a devastating natural disaster, causing millions of dollars of damage each year and putting many lives in danger. With the exception of excessive heat, flooding leads to more weather-related fatalities than any other cause. In 2007, the last year for which statistics were available, flash flooding caused 70 fatalities, 51 injuries, and 1.2 billion dollars in damage (NWS, 2009a). Half of flood-related deaths were caused when victims were caught in vehicles and swept away. Given these statistics, accurate predictions of flash floods are essential for the protection of life and property. Unfortunately, the nature of these events makes them quite difficult to monitor and predict. Flash floods feature a fast onset—less than 6 hours from the causative event (NWS, 2002)—are local in scope, and depend greatly on fine scale weather and land surface conditions.

Monitoring efforts are valuable but do not provide enough lead time for affected parties to take the action needed to prevent loss of life and property. Forecasts, which have the potential to increase warning lead time, can be produced by standard lumped hydrological modeling. However, these models are handicapped by the fact that they only provide information at basin outlets and cannot accurately represent the highly variable land surface and meteorological conditions that impact flash flooding. A promising alternative to lumped modeling is distributed modeling. Gridded distributed models more effectively represent the variable nature of meteorological forcing and land surface parameters and provide flood information at any grid point within the model domain. With this in mind, a method to use a distributed hydrologic model (DHM) in conjunction with a threshold frequency (TF) post processor (Reed et al., 2007) and NEXRAD precipitation data has been developed at NOAA's Office of Hydrologic Development (OHD). Forced by

Multisensor Precipitation Estimator (MPE) and High Resolution Precipitation Estimator (HPE) precipitation observations, and High Resolution Precipitation Nowcaster (HPN) precipitation forecasts, this modeling approach is focused on improving flash flood prediction capabilities by increasing forecast accuracy and usability (Kitzmiller et al., 2008). It also seeks to improve upon the current NWS flash flood warning lead time goal of 49 minutes through leveraging the two available hours of HPN precipitation forecasts (NWS, 2009b). Flash flood warning lead times have improved over the past several years (Figure 1), and DHM-TF forced by HPN output has the potential to lengthen lead times even more.

DHM-TF OVERVIEW

Operating on the Hydrologic Rainfall Analysis Project (HRAP) grid at a 4km resolution and hourly time step, DHM-TF produces gridded flow forecasts, from which gridded frequency forecasts are derived using historical simulations. These frequency forecasts are then compared against threshold frequency grids derived from local information for flash flood determination. DHM-TF relies on several hydrological modeling components to generate the required flow forecasts. These components, which include a gridded Sacramento hydrologic model, overland and channel routing algorithms, and a statistical post processor, are part of the research version of OHD's distributed model (Koren et al., 2004).

Hydrologic Modeling Components

The Sacramento hydrologic model (Burnash et al., 1973) represents spatially heterogeneous runoff processes over river basins ranging from tens to a few thousand square kilometers. It accounts for processes in which the freeze and thaw of soil moisture can have significant effects on water balance and soil moisture dynamics (Koren et al., 1999). Runoff from Sacramento is routed via a kinematic wave channel router (Koren et al., 2004). Routing is a key component of the DHM-TF flash flood forecast approach. Flash floods may occur near the causative rain event, or may occur downstream from the rainfall. The latter case is especially dangerous, as the lack of heavy rain in a particular area may provide residents or forecasters with a false sense of security. With routing enabled, DHM-TF is able to transport water from channels in areas of heavy rainfall to downstream points, providing an accurate simulation of the potential for flash floods along an entire river network.

Statistical Processing

Distributed hydrologic models have the potential to provide valuable gridded flow information, and yet, as with other models, may be subject to biases which limit their applicability without calibration or post processing. To solve this problem, DHM-TF utilizes a threshold frequency post processing approach. Rather than assuming that the exact magnitudes of the simulated flows are correct, DHM-TF relies on the concept that the relative ranking of the flows are accurate. That is, even if the flows are persistently biased, they will be internally consistent and thus can be correctly ranked against each other. It is this assumption which allows for the reliable conversion of flow values to return period values without need for accompanying observations. Reed et al. (2007) demonstrated the effectiveness of this inherent bias

correction for a simulation in the Dutch Mills basin of Arkansas. In particular, they showed that although raw model flow values may be biased, the probabilities of these model flows are accurate and able to support the calculation of return periods.

The statistical package which accomplishes this task depends on a high-quality long-term simulation of flow, which in turn requires high-quality hourly precipitation data as input. Flow values from this long term simulation are first passed through a routine which generates a grid of annual maximum peak flow values. A second routine fits the peaks to a log Pearson Type III distribution, and calculates a corresponding set of summary statistics which describe the distribution. Once the historical baseline simulation and associated computation of summary log Pearson Type III statistics are complete, real-time hourly simulations of discharge can then be ingested into a final DHM-TF routine. This routine utilizes the summary statistics to convert discharge into frequency and then return period for final display. Forecasters can compare these grids to locally derived threshold frequencies (and associated return periods) to aid in warning decisions. Local threshold frequencies may be derived from several sources of information such as known flood frequencies at selected river locations or frequencies associated with culvert designs. An in-depth discussion on this process can be found in Reed et al. (2007)

Taken together, the various components of the DHM-TF modeling approach produce flash flood forecasts which feature many advantages over traditional flash flood guidance. These include the ability to predict flash flooding at ungauged locations, a high resolution 4 km product (versus basin scale for standard flash flood guidance), a rapid update ability (every 15 minutes), and the production of verifiable small basin flow estimates.

NEXRAD PRECIPITATION DATA

Three NEXRAD-based precipitation products are used as input to DHM-TF: MPE, HPE, and HPN. The MPE uses a combination of radar and gauge input data and is produced hourly within the AWIPS environment by each RFC on a 4 km grid (Kitzmiller et al., 2007). Rainfall estimates from Doppler radar, gauges, and satellites are automatically ingested, and bias correction factors are developed from a comparison of radar and gauge data. After automatic derivation of a gauge-only field, and a bias-corrected radar field, a blended radar/gauge product is produced through an automatic merging of the two fields. Since manual adjustments of input fields may occur repeatedly over several hours as additional gauge reports are received, the final MPE field may not be available for several hours (Kitzmiller et al., 2008). Thus, although the high quality of the MPE product makes it ideal for the long term baseline DHM-TF runs, the long lag times and slow updating characteristics of the product makes real-time use in flash flood forecasting impractical.

Although not offering the rigorous manual quality control that defines MPE, HPE features a lower latency time (less than 1 hour), a more rapid update (every 15 minutes), and a higher resolution (1 km), and is thus better suited than MPE for real-time, flash flood operations. HPE leverages recent MPE gauge/radar bias information to automatically generate rainfall and rainrate products statistically corrected for bias. The process also ingests a user-defined radar mask which determines how

overlapping radars will be blended for each pixel within the domain of interest. HPE is slated for implementation within AWIPS during 2009 (Kitzmiller et al., 2008).

While MPE and HPE can be used by DHM-TF to bring model states up to the present, the most important aspect of the DHM-TF approach is its forecast capability which is powered by HPN data. Based on an updated extension of the Flash Flood Potential algorithm (Walton et al., 1985), the HPN process begins with the calculation of local motion vectors. These vectors are derived through a comparison of radar rain rates spaced 15 minutes apart, and are used to project current radar echoes forward in time out to two hours. Rain rates are then variably smoothed by a method based on the observed changes in echo structure over the past 15 minutes, as well as the current observed rain rate field (Walton et al., 1985; Kitzmiller et al., 2008).

CASE STUDY

Both the NWS Mid Atlantic River Forecast Center (MARFC) and the NWS Sterling Weather Forecast Office (WFO) have expressed interest in implementing DHM-TF. As such, DHM-TF developmental work and case study research is currently occurring over a 14,000 km^2 Maryland-centered domain which lies within both the MARFC and Sterling WFO areas of responsibility (Figure 2). Uncalibrated parameters for the gridded Sacramento model were taken from an *a priori* set of land surface parameters derived by Koren et al. (2000) using the National Resource Conservation Service State Soil Geographic Database. These parameters were complemented by a percent impervious area data set derived by Elvidge et al. (2004). Flow measurement data (cross sectional area and flow) at downstream gauges within the test domain were used to derive channel routing parameters. Values at upstream cells were derived using geomorphological relationships (Koren et al., 2004).

Even with automatic and manual error correction procedures in place, a time-changing bias was found in the MPE fields used to force DHM-TF over the Maryland domain prior to 2004. This bias stemmed from a truncation error within the NEXRAD precipitation processing scheme. Given the need for an accurate and internally consistent long-term flow simulation, a bias correction procedure was developed to account for this issue (Figure 3). In this procedure, monthly accumulations of Parameter-elevation Regressions on Independent Slopes Model (Daly et al., 1994) observation-based precipitation data are divided by monthly sums of MARFC MPE data. The resulting monthly ratios form monthly correction factors that are applied to all hourly MPE data within each particular month. Application of this procedure to the MPE fields greatly reduces the inconsistency in the bias of resulting distributed model flow fields (Zhang et al., 2009).

Simulations conducted over the Maryland test area with MPE, HPE, and HPN data fall into two categories: 1) retrospective, and 2) real-time.

Retrospective Simulations

A long-term retrospective flow simulation serves as the baseline for conducting both specific retrospective case studies as well as real-time operations. This simulation provides the annual maximum peak data which is used to construct the Log Pearson Type III distribution needed to convert flow values to return periods, and allows forecasted flows to be put into proper historical context. Currently 10

years in length, this simulation is forced by bias-corrected MPE data, and only needs to be updated once per year to generate new annual maximum peak data.

Leveraging the long-term Sacramento simulation, a case study was performed centering on Tropical Storm Hanna, which brought heavy rain to the Maryland region September 6th-7th, 2008 (Figure 4). The intensity and duration of the rain gave rise to eight flash flood warnings issued by the Sterling WFO for areas within Maryland and Virginia. Several local roads and large parkways were shut down due to flash flooding and several rescues and evacuations were necessary. Five of the warnings were outside the Maryland DHM-TF domain, and were not included in the case study. The remaining three were issued at 16:20Z, 17:58Z, and 19:12Z on September 6th, and collectively covered the period of time from 16:20Z on September 6th through 01:15Z on September 7th.

Flow return periods calculated by DHM-TF were plotted in Google Earth and are displayed in Figure 5 alongside the warning polygons defining the three flash flood warning areas mentioned above. In order to match the multi-hour time period covered by these flash flood warnings, the DHM-TF data displayed is the maximum return period generated by the model during the valid time of the three warnings. As can be seen, DHM-TF generates gridded return values above 2 years (approximately bankfull) in each of the three warning areas. In particular, where available, the DHM-TF output matches the coverage of the southernmost warning polygon over Washington DC very well. As DHM-TF is implemented in field offices, its use may allow forecasters to draw smaller warning polygons and reduce false alarms.

Further focusing on this warning area, Figure 6 depicts a large grouping of 4 km grid boxes where DHM-TF generates flash flood conditions. Two verification points where flash flooding was observed by ground spotters are also depicted, and align well with the DHM-TF output. One of the challenges of flash flood forecasting is verification. In many instances, no ground truth is available to corroborate a flash flood warning. Multiple factors can contribute to the lack of observations including population density, adverse weather conditions, and a lack of verification spotters. Recognizing the importance of ground truth, NOAA NWS is currently in the process of upgrading the warning and verification process. This effort, combined with focused, intense validation efforts such as the Severe Hazards Analysis and Verification Experiment (SHAVE, Ortega et al., 2009), will greatly improve the flash flood forecasting process, and will allow for improved validation of DHM-TF output.

Real-time Simulations

Although a valuable tool for research exploration, DHM-TF is ultimately aimed at expanding the operational flash flood forecasting abilities of NWS WFO and RFC offices. As such, much emphasis has been placed on the development of a robust real-time system of data archiving, model execution, and output visualization scripts. Figure 7 shows that two hydrologic model runs are required each time real-time execution is initiated: a state update phase, and a forecast phase.

In Phase 1, which begins 16 hours before present, Sacramento model states and river channel states are updated using MPE and HPE forcing data. The model makes use of a restart file which is saved by the previous state update run, and which contains soil as well as channel state information. MPE data is used for the first 12

hours, while HPE data is used for the remaining 4 hours. Once the model reaches the present time, HPN data is used to force the model 2 hours into the future. To allow water to flow through the channel system and further highlight downstream impacts, the model is run for an additional 4 hours, albeit without any precipitation data.

Once model execution is complete, the statistical processing routines convert flow output into gridded return periods. Automated scripts then produce plots of these return periods using the freely available GRASS GIS and Google Earth programs (no NWS product endorsement implied). Each program has its own strengths and weaknesses and the use of both ensures that the data will be accessible by a broad range of operational and research stakeholders. Google Earth excels at intuitive visualization, while GRASS is able to perform sophisticated geospatial analyses. Both still image and movie-type views of the data are produced each hour.

Currently, the real-time production cycle is executed once per hour. However, given the 15 minute updating of HPE data, the system could be configured to update as often as every 15 minutes by using more HPE data and less HPN data. In addition, as future upgrades to the HPN product extend forecast length past 2 hours, the DHM-TF system will be reconfigured to use all available forecast data.

FUTURE PLANS

The portability of DHM-TF will be increased through inclusion of the Snow17 snow model (Anderson, 1973) and through the derivation of a nationwide routing parameter dataset. The impact of increasing model resolution to 2km will be examined, and a study of the length of flow record needed to support DHM-TF operations will also be undertaken. Concurrent with the research outlined above, collaborative efforts with several National Weather Service WFOs and RFCs will seek to bring DHM-TF into operational forecasting environments. It is in these locations where DHM-TF will have the largest impact, providing increased flash flood warning time and forecast accuracy, potentially saving lives and property.

Abstract

This study presents two rain gauge-based re-adjustment schemes aimed at mitigating the biases in archival Multisensor Quantitative Precipitation Estimates (MQPEs) produced by the National Weather Service (NWS). The first and the second schemes re-adjust the MQPEs on monthly and daily scales to match two gridded gauge-only analyses at the respective time scale. These schemes were applied to archival MQPEs from the Mid-Atlantic River Forecasting Center (MARFC) for 1997-2006 and their effects were examined through streamflow simulations for twelve catchments in the state of Maryland. The results were compared with observed streamflow for two periods divided along November 2003, when a software error that contributed to earlier low bias was corrected. The results indicate that either scheme improved the temporal consistency of MQPE bias, though the monthly scheme was slightly more effective. Between the two periods, the adjustment schemes were generally more effective in the earlier one than the latter one.

Introduction

The National Oceanic and Atmospheric Administration's (NOAA) National Weather Service (NWS) routinely produces hourly Multisensor Quantitative Precipitation Estimates (MQPEs) based on radar and rain gauge observations. These MQPEs serve as forcing in its flash flood and river forecasting operations (Reed et al., 2007; Cosgrove et al., 2009), and their high spatio-temporal resolution (nominal 4 km) facilitates the calibration and the deployment of the NWS distributed hydrologic model (NWS-DHM, Koren et al. 2004). However, historical studies have found that archival MQPEs were subject to biases, and that the biases varied greatly over time (e.g., Hardegree et al. 2003). One of the factors that contributed to the historical biases is the truncation error (TE), a software error in the NEXRAD Precipitation Processing System (PPS) that led to erroneous rounding off of scan-to-scan precipitation accumulation less than 0.1 mm and therefore resulted in underestimation in earlier MQPEs prior to its fix around 2002-3 (Fulton et al. 2003).

The presence of the aforementioned biases, and more importantly their temporal inconsistency, greatly complicates model calibration. In order to mitigate these biases and reduce their historical inconsistencies, an attempt was made to post-process the MQPE's through rain gauge-based re-adjustment at monthly and daily scales. Chosen as references for the monthly and daily re-adjustment schemes are 2.5-minute, monthly Parameter-elevation Regressions on Independent Slopes Model (PRISM) outputs, and a 1/8th degree, daily gauge-only analysis produced by National Centers for Environmental

Prediction (NCEP) Climate Prediction Center (CPC), respectively. MQPEs from River Forecast Centers (RFCs) are adjusted such that the monthly or daily areal-average totals match those of the reference dataset at each grid cell. While MQPEs were created using mostly hourly gauge reports, the reference gauge-only analyses were based on a broader set of gauge records at hourly and coarser resolutions. The integration of the latter data is therefore expected to improve the quality of MQPEs.

In order to evaluate the effectiveness of the re-adjustment methods, a set of streamflow simulation experiments were performed for twelve catchments in the domain of the NWS Mid-Atlantic River Forecast Center (MARFC) for the period of 1997-2006. In these experiments, the MARFC MQPEs, and their re-adjusted versions based on the monthly and daily gauge are comparatively applied as forcings to the NWS-DHM (using the component models described below). The simulated streamflow time series over 1998-2006 are then evaluated against observed values obtained from the United States Geological Survey (USGS). To investigate the impacts of the TE and its correction on MQPE bias and the effectiveness of the re-adjustments, the observed and model simulated streamflow were stratified over two periods divided along November 2003 when the software update correcting TE took effect for the regional radar.

Radar and Multisensor Precipitation Estimation

The NWS precipitation estimation algorithms consist of radar-only and multisensor components. The major radar-only component is the Precipitation Processing System (PPS; Fulton et al. 1998), which produces real-time estimates of liquid ground precipitation. The PPS outputs are disseminated as Digital Precipitation Array (DPA, also referred to as Stage I products). In the legacy multisensor algorithms, the Stage I products underwent bias correction in the Stage II processing, and the results were quality-assured and mosaicked on a regional basis to produce Stage III data. The common map projection for all three stages is the polar stereographic Hydrologic Rainfall Analysis Project (HRAP) grids (nominal 4 km resolution in the central US; Greene and Hudlow (1982)). The legacy Stage II and III algorithms have since been replaced by the Multisensor Precipitation Estimator (MPE). MPE incorporates several algorithmic additions and enhancements, including mean-field and local correction (Seo et al. 1999, 2000; Seo and Breidenbach 2002), as well as methods for creating gauge-only and gauge-radar merged products (Seo 1998a and b). Stage III and the later MPE-based products are both referred to as the multi-sensor quantitative precipitation estimates (MQPEs).

Around 2000, analyses of PPS products revealed that scan-to-scan accumulation of amounts less than 0.1 mm was erroneously rounded off (Fulton et al. 2003). This "truncation error" (TE), as shown by Fulton et al. (2003), is most pronounced during prolonged light rain events, and could lead to considerable underestimation of the cumulative rainfall in the historical MQPEs. TE was corrected in three successive software releases during 2002-3 (Fulton et al. 2003).

At present, forecasters at NWS River Forecast Centers (RFCs) are responsible for running the MPE to create the MQPEs. Normally, a forecaster would quality assure hourly gauge records before ingesting them. Note that the current MPE framework only

allows the use of hourly gauge records. Nevertheless, forecasters at times disaggregate gauge reports at coarser resolutions (e.g., daily scale) to create artificial hourly records that would be ingested in creating the archival MQPEs.

Re-adjustment Methodologies

The monthly scheme uses the monthly Parameter-elevation Regressions on Independent Slopes Model (PRISM; Daly et al. 1994) as the reference. The monthly re-adjustment involves the following steps:

1) 2.4 arc-minute PRISM data are re-projected onto the HRAP grids;
2) Monthly cumulative precipitation from MQPEs is computed;
3) For each HRAP cell, the ratio of PRISM to MQPE monthly accumulation is computed.
4) Each hourly MQPE within that month is multiplied by the ratio grid computed in step 3 for every hour.

The daily scheme proceeds in an analogous manner, except using the CPC 1/8 degree gauge only analysis as reference. To ensure comparability between the PRISM and the CPC data sets, the latter was also adjusted so that the monthly total at each HRAP cell matches the former prior to serving as reference.

Study Sites and Experimental Design

Twelve catchments in the state of Maryland were selected to evaluate the hydrologic impacts of bias-adjustment. The size of catchments range from 84 to 1200 km^2 (Fig. 1; Table 1). The study catchments are under the umbrella of WSR-88D located in Sterling, VA (KLWX, at 38º58'31"N, 77º28'41"W), and each has been gauged continuously at its outlet by the USGS.

The NWS DHM (See description in Koren et al. (2004)) was implemented for each of the catchments. The model represents the landscape on the HRAP grid. The implementation for this study involves three model components. The first one is a snow module that relies on temperature to distinguish snow versus rain and computes snow accumulation and ablation (Anderson 1973). The second is the Sacramento Soil Moisture Accounting (SAC-SMA) module that computes runoff at each HRAP cell (Burnash et al. 1973; Koren et al. 2004). The third is a kinematic wave routing method (Koren et al. 2004). Model calibration was avoided to isolate the impacts of MQPE re-adjustments. Instead, a priori parameter values based on physiographic information (for SAC-SMA and routing) and values commonly used in RFC operations (as for snow model parameters) were used. The SAC-SMA a priori parameters were derived from soil texture and land cover. The cell-to-cell connectivity required for the kinematic routing model was determined from digital elevation model (Reed, 2003). Routing parameters were computed on the basis of site-specific flow measurement data provided by the USGS (Koren et al., 2004).

Hourly MQPEs for the period of 1997-2006 were acquired from the Mid-Atlantic River Forecast Center. The first five years of MQPEs (1997-2001) were produced using

the Stage III algorithm and the rest via the MPE. As indicated earlier, these MQPEs were re-adjusted via the monthly PRISM and the daily CPC schemes (note that the two schemes were applied independently from each other). Both the original and the adjusted MQPEs were then used to drive the model. Additional forcing data obtained include 6-hourly, 2.5 degree NCEP gridded temperature re-analysis (needed for the snow model), and monthly climatological potential evapotranspiration (PET) values. In assigning the initial conditions, it was assumed that upper and lower zone free water storages were each at half capacity, and the channels were dry. Under these assumptions, continuous simulations were performed at hourly time step for each catchment over the ten-year period. The hourly streamflow simulations were subsequently compared against hourly USGS discharge measurements for 1998-2007 (1997 was treated as the warm-up period for the model and the associated results were excluded in the comparison). The results were further stratified into the pre-TE correction (Jan. 1998 – Nov. 2003) and the post-TE correction (Dec. 2003 – Dec. 2006) periods to illuminate the impacts of TE on MQPE biases and on the effectiveness of the re-adjustments.

Simulation Results

The mean areal precipitation for each basin, along with the validation statistics of hourly simulation results, including percentage bias (PB) and correlation coefficients (CC) are shown for the pre and post-TE correction periods separately in Figure 2. The following features are evident for the earlier period:

1) Stream simulations based on unadjusted MQPEs show appreciable low bias;
2) Either monthly or daily re-adjustment scheme substantially increased the precipitation amounts and improved the low bias in streamflow;
3) For most basins, either scheme led to higher CC values;
4) The monthly scheme is more effective than the daily scheme in mitigating the low bias.

The period after TE correction is characterized by the following:

1) Streamflow simulations based on unadjusted MQPEs show low, but less conspicuous bias;
2) Either re-adjustment scheme reduced the precipitation amounts and induced a consistent low bias in the simulated streamflow;
3) For most basins each scheme also yielded improvements in CC, though the amounts of improvements are much less conspicuous relative to the earlier period.
4) Monthly and daily schemes performed comparably judged by PB and CC.

The results are further analyzed separately for the warm (April – October) and cool season (November to March). The validation statistics for streamflow are show in Figures 3 and 4. The following features are notable for the earlier period:

1) Streamflow based on re-adjusted MQPEs were still biased low for the warm season despite substantial improvements, whereas those for cool seasons are nearly bias-neutral.

2) The improvements in CC are more conspicuous for the cool rather than the warm season.

For the later period, notable observations include

1) Simulated streamflow based on unadjusted MQPEs shows considerable low bias for the warm season and high bias for the cool season;
2) For the warm season, each re-adjustment scheme reduced the precipitation amounts and thereby worsened the low bias ;
3) For the cool season, each scheme improved the high bias.

The bias for each set of simulations was computed for each year and the range in values was compared in Figure 5. It is evident that both re-adjustment schemes considerably improved the temporal consistency in the bias values.

Summary and Conclusions

This study presents monthly and daily-based re-adjustment schemes for mitigating the biases in historical MQPEs. Hydrologic simulations for twelve catchments in the domain of MARFC were carried out via a distributed hydrologic model to evaluate the efficacy of these schemes. Comparisons of original MQPE-based results with observations pointed to severe underestimation of streamflow in the period prior to TE correction (1998-Nov. 2003), and a lack of such a feature after TE correction. These observations suggest that a) MQPEs prior to TE correction were biased low, most likely as a consequence of TE, and b) the low MQPE biases were considerably improved with TE correction.

The simulation results further suggest that the re-adjustment schemes were highly effective in mitigating the low MQPE biases before the TE correction, and were less so thereafter. In addition, the two schemes yielded more conspicuous improvements in correlation coefficients in the earlier rather than the later period. Furthermore, the re-adjustment schemes were shown to be more effective during the cool season and less so during the warm season, as judged by PB and CC for streamflow simulations. Between the monthly and daily schemes, the former yielded more pronounced improvements in PB and CC on an overall basis. For the 9-year period studied here, each re-adjustment scheme was shown to improve the historical consistency in the bias of streamflow. These results suggest that applying these re-adjustment schemes may offer substantial benefits for hydrologic model calibration. These re-adjustment schemes are in the process of being evaluated in other RFC domains to determine their effectiveness under broader climate and hydrologic conditions.

Abstract

The Corps of Engineers is currently evaluating its portfolio of dams with regard to risk and related maintenance. A draft Engineer Technical Letter "Risk Analysis and Assessment for Dam Safety" is under review. This ETL describes processes that will be used for screening projects for planning of corrective actions. One of the contributing factors that must be uniformly evaluated across all projects is the development of inflow frequency curves (peak flow and volume frequency) that define the frequency curve in the mid-range events (1 in 500 to 1 in 3000) and then extend out to the probable maximum flood level. Currently, no extension method is uniformly accepted. Multiple methods exist to facilitate extension. The current effort being undertaken by the Hydrologic Engineering Center is to present the variety of methods and provide general guidance for curve extension that can be applied. A consistent method of curve extension allows for a uniform comparison of dams. This paper will provide an overview of the current status of the extension methodology.

Introduction

Currently there is no credible scientific approach to assign a single probability to a flood of the magnitude of the PMF. Additionally, no single method exists for extending gaged frequency curves out to the PMF level. Development of credible estimates of infrequent annual exceedance probabilities will rely on the use of data from multiple sources and a regional approach. The USBR has evaluated the limits of credible extrapolation that can be made from various data sources as shown below (USBR, 2004).

Type of data used for flood frequency analysis	Limit of credible extrapolation for annual exceedance probability	
	Typical	Optimal
At-site streamflow data	1 in 100	1 in 200
Regional streamflow data	1 in 500	1 in 1,000
At-site streamflow and at-site paleoflood data	1 in 4,000	1 in 10,000
Regional precipitation data	1 in 2,000	1 in 10,000
Regional streamflow and regional paleoflood data	1 in 15,000	1 in 40,000
Combinations of regional data sets and extrapolation	1 in 40,000	1 in 100,000

Clearly, none of these methods will produce a single estimate of the annual exceedance probability for rare events of the magnitude of the PMF.

Proposed Techniques

Several techniques have been used recently to assign an exceedance value to rare floods in the range of the PMF. Each of these methodologies are generally used in conjunction with gaged frequency analysis as a way of extending the gaged frequency curves out to events more rare than gaged data analysis would normally warrant. The following is a list of methods that have been selected for evaluation for inclusion in the Portfolio Risk Assessment for Corps dams:

1. Extension of Gaged Frequency Curves with Historic/Paleoflood information
2. Hydrologic Modeling using frequency based storm events
3. The GRADEX Method
4. Stochastic Event Flood Model (SEFM)
5. Regional Probability of the PMF

The following is a short description of each of the techniques:

Extension of Gaged Frequency Curves with Regional Historic/Paleoflood Information

This methodology is used to extend gaged frequency curves to a flood magnitude of the PMF. Historic floods and a range of possible probabilities can be estimated from both regional studies and paleoflood studies. The flood estimates and their probability ranges are plotted, and the gaged frequency curve could be extended out to the PMF by graphically fitting the curve to the mean estimates of the regional historic and paleoflood data.

Hydrologic Modeling Using Frequency Based Storm Events

Hydrologic rainfall runoff models (e.g. HEC-HMS) can be used to develop frequency curves or extend gaged frequency curves. Generally, at projects such as Corps dams, gaged inflow records of reasonable length are available for performing statistical frequency analysis using Log Pearson III techniques. The hydrologic model can be calibrated to historic storm events and the gaged frequency curve for the frequency range in which the gaged data are deemed most appropriate. The curve can then be extended by running storm events for frequencies outside the gaged data range (i.e. 100-, 200-, 500- and 1000-yr events).

Frequency based precipitation data can be obtained from the National Weather Service. Currently, for many states, the NWS has frequency based storm estimates out to the 1000- yr return period (NOAA Atlas 14). For those states that are not covered by NOAA Atlas 14, frequency precipitation estimates are only available up to the 100 yr event from NOAA. For more rare precipitation events, the user would need to look for local studies that have been performed on regional precipitation data within the region of interest, or a regional precipitation-frequency study would need to be performed.

In areas where gaged data are very limited (i.e. less than 20 years of record), then the use of a hydrologic model with regionally based precipitation estimates (NWS, Precipitation Frequency Data) is a viable method for developing frequency curves out to the 1000-yr event range. A general procedure is to develop the hydrologic model by estimating parameters based on physical information; calibrate the model to any significant events that are available in the short gaged record history; then apply frequency based rainfall events from the 2- to 1000-yr frequency to the model. The model parameters should be adjusted to get best estimates of peak flows and runoff volumes, but not to produce estimates that would be upper bounds.

The more typical case in the Corps of engineers is to utilize hydrologic models for extending gaged frequency curves out to the 1000-yr event. When a gaged frequency curve exists, and there is generally high confidence in that curve for the more frequent events, then a hydrologic model can still be developed as described in the previous paragraph. However, after the model is calibrated to all of the relevant historical events, and the frequency based rainfall events are applied, the model should be further calibrated to match the gaged frequency curve over the range of frequencies in which the gaged data are assumed to be the most appropriate.

GRADEX

The GRADEX technique is a method for extending volume frequency curves from the 200 to 500 yr range out to values in the range of the PMF. The methodology was first introduced by Guillot and Duband (1967, 1993), and later refined by Mauro Da Chunha Naghettini (1994) for his Ph.D. degree at the University of Colorado. In simple terms, the GRADEX methodology is based on computing a slope (Grade X) of the regional

precipitation frequency data, then applying that same slope to the runoff volume frequency curve for extending it out into the future. The basic concept is that the runoff volume frequency curve should be parallel to the rainfall volume frequency curve once you get up to the rare events in the 200 to 500 year range and larger. This assumes that during large events, the ground is saturated, and runoff properties are reaching an upper limit, such that any increased volume of precipitation will produce a corresponding increase in flood runoff volume. Figure 1 is a plot depicting the GRADEX technique. This plot was take from the USBR report "Hydrologic Hazard Curve Estimating Procedures (June, 2004).

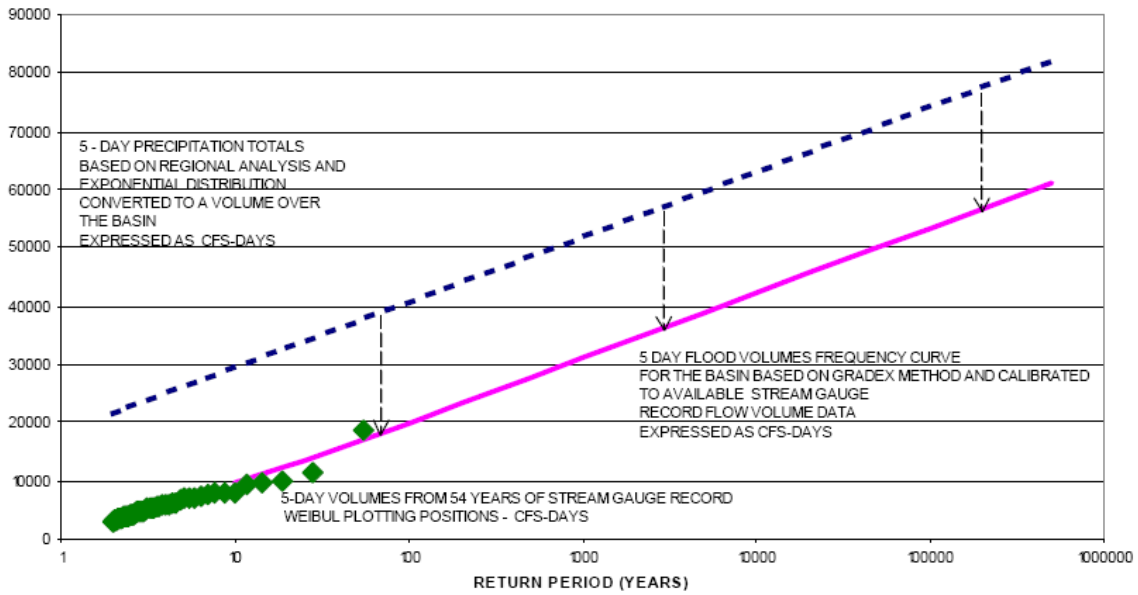

Figure 1. GRADEX Method of Volume Frequency Curve Calculation.

The user must gather daily precipitation records for all of the relevant gages in the region of interest. Records must be gathered for the full period of record of the gages, and the gaged record must be continuous. The user is required to first estimate a critical duration for the watershed above the dam (i.e. 1day, 2day, 3day, etc…). The critical duration is a function of the size of the watershed, the meteorology, runoff characteristics, and available flood storage volume of the reservoir. Each gaged record is analyzed individually and the top annual events for the critical duration are defined. The threshold precipitation value, statistics, and the top 10 percent of the events are then used as input data into the GRADEX computer program. Additional input required for the GRADEX program is mean annual precipitation for each gage, elevation of the gage, drainage area of the basin, critical runoff duration, mean basin elevation, mean annual precipitation for the watershed, and statistics about the flow duration frequency curve computed for the observed runoff data (Qmean, Qref, return period of the reference flow). The GRADEX computer program will then compute a slope for the regional precipitation and apply that to the volume frequency data provided. The output is a volume–duration frequency curve

that starts at the reference flow and reference return period entered (ex. 100 yr), and goes out to the 1,000,000 year return period.

Stochastic Modeling of Extreme Floods (SEFM Model)

SEFM is a stochastic event model that is generally used to extend a frequency curve out to the 200 to 500 year return interval range. However, one could also use it as a way to make an estimate all the way to a PMF level event.

The concept employed with this technique is the simulation of several thousands of years of annual flood maxima. This is accomplished using a deterministic, single event, flood runoff model. Hydro meteorological parameters are treated as variable. Monte Carlo sampling procedures are used to allow climatic and storm descriptive parameters to vary in accordance with season and historical observations. The simulation of any annual flood contains a set of climatic and storm parameters selected via the Monte Carlo technique that collectively preserve any dependencies between the parameters that are contained in the historical record.

The hydro meteorological inputs and their dependencies represent the detailed mechanics of flood generation. The table below, prepared for an SEFM application to Folsom Dam in California, indicates the complexity of the system parameters that are recognized by this method.

HYDROMETEOROLOGICAL INPUTS FOR STOCHASTIC MODEL			
MODEL INPUT		DEPENDENCIES	COMMENTS
1	Seasonality of Storm Occurrence	Independent	End-of-month storm occurrences
2	72-Hour Storm Magnitude	Independent	
3	Temporal and Spatial Distribution of Storms	Independent	24 Prototype Storms, 4-Day to 8-Day Patterns
4	Temperature Temporal Pattern	Varies by Prototype Storm	10-Day Pattern Indexed to Sea-Level Temperature and Freezing Level
5	Sea-Level Temperature	Storm Magnitude	For Day of Maximum Precipitation in storm
6	Freezing-Level	Sea-Level Temperature and Storm Magnitude	For Day of Maximum Precipitation in storm
7	Antecedent Precipitation	Independent	Precipitation Oct 1st to Date of Storm Occurrence Varies with Zones of Mean Annual Precipitation
8	Antecedent Snowpack	Antecedent Precipitation	Varies by Zones of Mean Annual Precipitation and Elevation
9	Antecedent Soil Moisture	Antecedent Precipitation Antecedent Snowpack	Varies by Zones of Mean Annual Precipitation, Elevation and Soil Type
10	Storage in Upstream Reservoirs	Antecedent Precipitation	Preserves Cross-Correlation of Storage in 5 Upstream Reservoirs
11	Initial Streamflow	Independent	Mean Monthly Inflow to Folsom Reservoir
12	Storage in Folsom Lake	Antecedent Precipitation	Utilizes Folsom Rule Curves and Storage in 5 Upstream Reservoirs

.

A summary of the steps that are performed by the simulation model are:

1. Select date (end-of-month) of occurrence of extreme storm.
2. Select all parameters associated with the occurrence of the extreme storm event.

3. Establish antecedent watershed and reservoir conditions at the onset of the extreme storm.
4. Conduct watershed modeling
5. Conduct reservoir routing of inflow flood.

On application of this procedure, various measures of project inflow can be assigned recurrence intervals. Figure 2 shows the SEFM computed relationship for Peak inflow discharge stochastically extended to an annual exceedance probability of 10^{-6}.

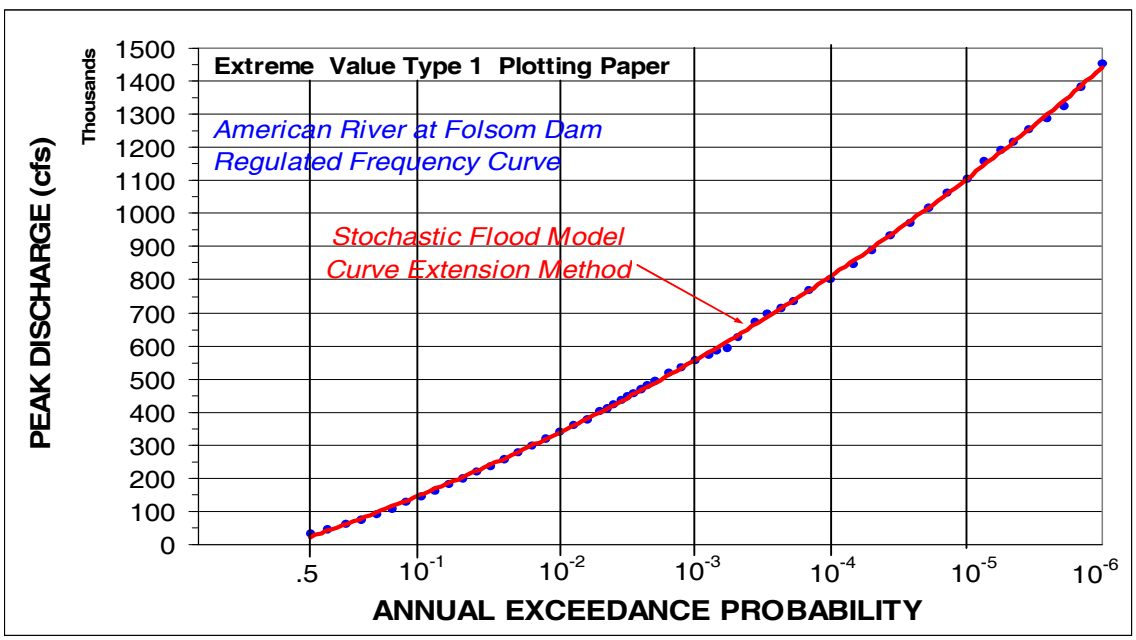

Figure 2. SEFM Model Results Extended to Probability of 10^{-6}

Regionalized Probability of PMF

The regional probability method is a way of estimating a probability of the PMF using regional precipitation data. The method outlined below is based on scaling the probability of the PMF by comparing regional historical precipitation data to that of the PMP, computing a historical to PMP precipitation ratio, then using that ratio to estimate a probability of the PMF within the established institutional range of probabilities. By utilizing regional precipitation data, this procedure would inherently include the effects of regional weather patterns, distance from moisture sources, orographic effects, etc. The method is easy to apply and would be a consistent procedure. In regions where historical precipitation has come close to the PMP, the method would yield a probability towards the more frequent end of the range. Likewise, in areas where historical precipitation is much lower than estimates of the PMP, the probability of the PMF would tend towards the less frequent end of the range.

The steps are:

1. An institutionally assigned range of probabilities for the PMF must be decided upon. A possible suggestion for the range is 10^{-3} to 10^{-7}.

2. Determine the storm duration that is most critical to the watershed of interest (24-hr, 48-hr, or 72-hr). Also determine the storm area size critical to the watershed. This should be the same storm area size that was used in the determination of the basin average PMP for developing the PMF for the watershed.

3. Determine the historically maximum observed precipitation volume that has occurred within the region of interest, for the storm area size and duration of interest. The region of interest would most likely extend into neighboring basins of similar hydrologic and meteorological characteristics. The idea is to find the largest storm that has occurred within the region, not limiting specifically to the basin of interest. One way to compute the maximum observed historical precipitation volume is to acquire maximum observed precipitation at all gages in the region of interest for the largest storms of record. Compute the area averaged (based on the selected storm area in step 2) maximum storm volume for the duration of interest (24, 48, or 72 hr). Other methods for obtaining maximum historical rainfall may be more appropriate depending on the area of the country you are in (such as using radar rainfall data, etc…).

4. Use standard NWS procedures for computing your basin average PMP (HMR reports).

5. Compute the maximum historical precipitation to PMP ratio within the region of interest for the Dam being studied.

6. Calculate the probability of the PMF using the following equation:

$$AEP = 10^{-[(1-Ratio)\times Range + Min.Value]}$$

Where:

Ratio =	Max historic storm precipitation divided by PMP for region of interest.
Range =	Corps institutional range for probability of the PMF (10^{-3} to 10^{-7})
Min Val =	Minimum value of Corps institutional range.

This equation will yield values close to 10^{-3} for areas that have experienced precipitation close to PMP values. Likewise, those areas that the historic precipitation is very low in comparison to the computed PMP values would have a PMF probability near the 10^{-7} value.

Method Blending

When multiple methods are applied it will be necessary to perform a graphical fit of all of the methods. This should be done by weighting the values of each of the methods for

each of the frequencies used to define the final curve. In other words, at higher frequencies, such as the 2 through 100 yr events, the gaged points and resulting LP III curve would be given a very high weight and the other methods would be given either low weights or zero. As you go out to less frequent probabilities, the weighting will change between the methods based on the perceived reliability of the estimates at that specific frequency. Obviously, this will require engineering judgment on the part of the team performing the study. An example plot of what this might look like is shown below in Figure 3. The newly developed Statistical Software Package, HEC-SSP, will have methods added to it to help facilitate the blending of the curves. It will take into account uncertainty data from each of the curves, or values, to generate the blended curve.

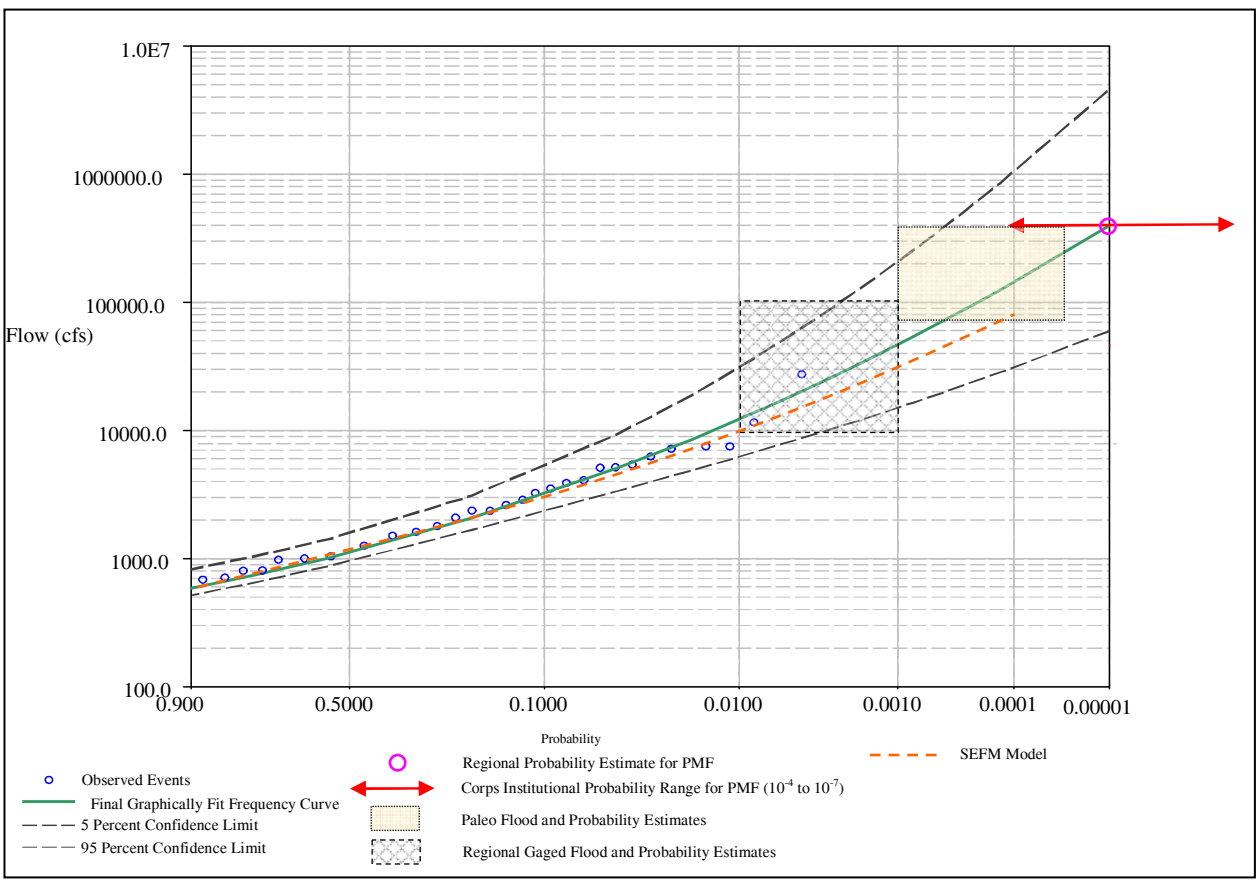

Figure 3. Example Flow Frequency Curve by Combined Methods

Conclusion

All the methods listed above have inherent shortcomings. There may be a very short gaged record, paleo flood is generally applicable in the western US, hydrologic models are usually based on the premise that the frequency of the runoff equals the frequency of the rainfall, GRADEX involves extrapolation, SEFM can be data and cost prohibitive and the regional PMF range requires an institutionally agreed upon range. All of these are challenges. Based on this, HEC's proposal is that no single method should be used for extending frequency curves out to the magnitude of the PMF. Rather, all of the methods described above, or appropriate combinations of the methods, should be used to extend

the gaged data frequency curve out to the PMF. This will require plotting results from all of the methods used, then extending the gaged frequency curve out to the PMF graphically.

If a dam is classified as a high hazard dam (i.e. large damage potential downstream and possible loss of life), then most likely all of the methods should be used together to make an estimate of the inflow frequency curve. However, if a dam is not classified as a high hazard dam, then maybe the appropriate combination of the methods could be used. At a minimum, the frequency curve could be developed by using the gaged data, hydrologic modeling with regional precipitation data, and the regional method for estimating the probability of the PMF. This level of analysis would probably be appropriate for the initial PRA studies. More detailed analysis could include the SEFM modeling method and/or the GRADEX method when deemed appropriate, and financially viable. Paleoflood estimates should only be used in areas where they are considered to be viable (such as in the western states).

ABSTRACT

Soil water content changes with time due to rainfall, infiltration, evaporation, and transpiration. This paper presents a physically-based coupled surface and variably saturated subsurface flow model to simulate the distribution of soil moisture in three dimensions. The flow in variably saturated soil is described by the 3D Richards equation in the mixed form, which is discretized using the finite volume method and solved implicitly using the modified Picard iteration. In the present model, the actual evaporation from bare soil is calculated using the physically-based relationship of VS2D method, which takes into account both constant and falling rate stages. The actual transpiration by plants is modeled using the root water uptake module with water stress compensation, which considers soil water pressure head and soil resistance to water flow. The model has been tested using published data.

INTRODUCTION

Temporal and spatial variations of soil moisture are receiving increased attention in climate studies because soil moisture is an essential element in processes that drive land surface water and energy fluxes, which affect ecosystem dynamics and biogeochemical cycles in the land-atmosphere system. To predict the hydrological processes at a watershed scale, especially in a long-term simulation, a hydrologic watershed model should be able to simulate rainfall-runoff, infiltration, evaporation, and transpiration.

Evaporation is the process whereby liquid water is converted to water vapor (vaporization) and removed from the evaporating surface (vapor removal). Theoretical consideration and laboratory and field observations have shown that evaporation following wetting is a variable process (Hillel, 1980; Jalota and Prihar,

1998) and it depends on both climatological parameters, such as solar radiation, air temperature, humidity, and wind speed (Ritchie, 1972; Parlange and Katul, 1992), and soil properties (Ritchie, 1972; Hillel, 1980; Wallace et al., 1999). Many equations exist in the literature to describe the evaporation rate (Lappala et al., 1987; Brisson et al., 1998; Wallace et al., 1999; Allen et al., 2005; Romano and Giudici, 2007). In numerical modeling, evaporation is often considered as an upper boundary condition in the flow equation.

Transpiration consists of the vaporization of liquid water contained in plant tissues and the vapor removal to the atmosphere. Transpiration depends on climatological parameters and soil properties, as well as the ability of the soil to conduct water to the roots. Numerical models simulating changes in soil water content with time rely on accurate estimation of transpiration due to root water uptake. Two approaches – microscopic and macroscopic – have been developed to simulate water uptake by plant roots.

The microscopic approach (Gardner, 1964) simulates the radial flow movement of soil water toward and into individual roots (e.g. Doussan et al., 1998; Personne et al., 2003). This approach is physically based, which requires the detailed geometry of the growing root system. Since those information are difficult and time-consuming to measure (Vrugt et al., 2001), this type of model is currently not practical in a watershed scale simulation.

The macroscopic approach treats the root system as an abstract object whose vertical distribution is described throughout the soil profile (Feddes et al., 1978; Molz, 1981; Li et al., 2001; etc.). The macroscopic water extraction is represented by a depth-dependent sink term that can be incorporated into the Richards soil water flow equation, which has been greatly used in many application-oriented hydrological models (e.g. Braud et al., 2005; Li et al., 2001 and 2006). Based on the concept of Feddes et al. (1978), macroscopic root-water-uptake modules are different in the way that the potential transpiration is distributed and/or potential transpiration is reduced by water stress. The distribution of potential transpiration has been based either on root distribution only (e.g., Feddes et al., 1978; Simunek et al., 1998; Li et al., 1999) or on both root distribution and soil water availability (Li et al., 2001). Various linear (e.g. Hoogland et al., 1981; Prasad, 1988) and nonlinear (e.g. Jarvis, 1989; Li et al., 2001) root distribution functions have been used in the root-water-uptake models.

Recent research shows that the macroscopic models can achieve a good compromise between physical realism, data requirement and facility of implementation for the solution of the Richards equation (Varado et al., 2006). Braud et al., (2005) and Varado et al. (2006) compared two root water uptake models with compensation mechanisms, proposed by Lai and Katul (2000) and Li et al. (2001), against the existing data set of various soil types. Li et al.'s module was recommended for inclusion as a physically-based infiltration-evapotranspiration module into a larger scale hydrological model due to its robustness (Braud et al., 2005; Varado et al., 2006).

He et al. (2008) developed an integrated surface-subsurface flow model. However, evapotranspiration was not taken into account since only single storm events were simulated. In the present study, for the purpose of long-term simulation, a module of simulating evapotranspiration has been implemented in the variably

saturated 3D subsurface flow model of He et al. The module has been verified by reproducing the results of problems involving a 1D infiltration and transpiration in layered soils and a 2D response to rainfall, evaporation and transpiration.

GOVERNING EQUATIONS

The water flow in variably saturated soil zone can be described by the Richards equation. Evaporation and plant transpiration are considered using sink functions. For 3D variably saturated soil, the mixed form of Richard equation can be written as

$$\Theta s_s \frac{\partial H}{\partial t} + \frac{\partial \theta}{\partial t} = \frac{\partial}{\partial x_i}\left[K_{x_i}(\psi)\frac{\partial H}{\partial x_i}\right] - Q_b^T - Q_b^E + Q_b^s \qquad (1)$$

where θ is the volumetric soil water content; Θ is the saturation of the soil; S_s is the specific storage; H is the total head for subsurface flow, which is equal to the sum of the soil water pressure head ψ and the elevation head z; K_x, K_y, and K_z are the hydraulic properties for unsaturated/saturated soil, usually defined as the product of the saturated hydraulic conductivity k_s and the relative permeability k_r, i.e., $K_i(\psi) = k_{si}k_{ri}(\psi)$ ($i = x, y, z$); Q_b^T and Q_b^E represent the actual transpiration and evaporation sinks, and Q_b^s represents other volumetric source and/or sink fluxes. The above parabolic equation is highly nonlinear, due to the nature of the hydraulic properties of soil layer $K_i(\psi)$ and soil water content $\theta(\psi)$, and can be applied for both saturated and unsaturated soil water flows. Here, the relationships suggested by van Genuchten (1980) or Brooks and Corey (1964) are used to describe the relative saturation and permeability functions.

In the present model, the net inflow of precipitation, infiltration, and evaporation is applied as a boundary condition at the ground surface, and Q_b^T is calculated as a point sink term distributed vertically over cells in the root zone. The treatment of rainfall and infiltration follows the way described in He et al. (2008), and only evaporation and transpiration are discussed herein.

Potential Evapotranspiration. Potential evapotranspiration (*PET*) is often used to determine the evaporation and transpiration rates. Generally, two different options can be used to calculate *PET*. The first option is the pan evaporation technique, which requires daily measured pan evaporation values and pan coefficients (Fares, 1996). The second method for calculating *PET* is based physically on the energy conservation method. There are a number of equations to calculate *PET*, such as Penman (1948), Monteith (1965), Priestley and Taylor (1972), and FAO Penman-Monteith equation (FAO, 1998). In most cases, *PET* is often calculated as an input reference at first, and then it is separated into potential evaporation (E_P) and potential transpiration (T_P). The partition can be performed using the Beer-Lambert law based on the leaf area index *LAI* (Huygen et al., 1971). In the present model, the FAO Penman-Monteith equation (FAO, 1998) is implemented to calculate *PET*.

Evaporation. Evaporation is a variable process, which depends on the atmospheric conditions and soil properties. A two-stage evaporation process is considered in this study. At first, evaporation is at a constant rate as long as the soil can conduct water to the soil surface at a rate equal to E_P. As the soil near the surface becomes drier, evaporation is reduced to below the potential value, which is mainly determined by the hydraulic properties of the soil and could be controlled both by atmosphere and/or by soil water content.

E_P can be calculated as a fraction of *PET* using the *LAI* of the soil surface as

$$E_P = \psi(LAI) \cdot PET \tag{2}$$

$$\psi(LAI) = \exp(-f_{sr} LAI) \tag{3}$$

where $\psi(LAI)$ is a function of the leaf area index *LAI*, and f_{sr} is the extinction coefficient for solar radiation (dimensionless). The value of f_{sr} varies from 0.4 to 0.5. Here, a physically based relationship used in the VS2D model (Lappala et al., 1987) is applied to predict the actual evaporation as

$$Q_b^E = Min\{k_{sz} k_{rz} SRES(h_{atm} - h_{top}), E_P\} \tag{4}$$

where h_{atm} is the pressure potential of the atmosphere; h_{top} is the pressure head at the first node on the land surface; and *SRES* is the surface resistance.

The atmospheric pressure potential can be determined as (Lappala et al., 1987)

$$h_{atm} = (RT / M_w g) \ln(h_r) \tag{5}$$

where R is the ideal gas constant; T is the absolute temperature; M_w is the mass of water per molecular weight; h_r is the relative humidity; and g is the gravitational acceleration.

Assuming that the pressure at the land surface is atmospheric and the pressure at the top cell is applied to the node of the first cell, *SRES* is calculated as

$$SRES = (2.0 / DZ_{top}) / (K_c / k_{sz,top}) \tag{6}$$

where DZ_{top} is the thickness of the top cell; K_c is the saturated hydraulic conductivity of the land surface material; and $k_{sz,top}$ is the saturated hydraulic conductivity of the first cell on the land surface.

Transpiration. The present study applies the macroscopic approach of the root water uptake concept to predict the actual transpiration rate, which considers the integrated properties of the entire root system. The actual amount of water taken up by a root system can be calculated using the following general relation:

$$Q_b^T = \beta_T T_P \tag{7}$$

where T_P is the potential transpiration rate, and β_T is the dimensionless empirical function depending, for example, upon the distribution of roots with depth, the type of plant, the availability of liquid water, and the minimum permissible pressure head. T_P is part of the *PET* and can be calculated as

$$T_P = PET - E_P = [1 - \psi(LAI)] \cdot PET \tag{8}$$

β_T can be expressed as

$$\beta_T = \alpha \cdot g(z) \tag{9}$$

where α is a water response function accounting for restriction to transpiration caused by soil moisture limitations, and $g(z)$ is a root density distribution function.

The present model implements four different water uptake models based on the different water response function and root density distribution function, which are the constant model (Feddes et al., 1978), linear model (Prasad, 1988), exponential model (Li et al., 1999), and exponential model with the water stress compensation (Li et al., 2001).

The constant model determines the root density distribution function as (Feddes et al., 1978)

$$g(z) = 1/z_r \tag{10}$$

where z_r is the bottom of the root zone depth. The water stress response function α ($0 \le \alpha \le 1$) is a prescribed dimensionless function of the soil water pressure head around the root zone, first introduced by Feddes et al. (1978). α can be calculated using the following expression of $\alpha_1(h)$:

$$\alpha_1(h) = \begin{cases} 0 & h \ge h_1 \text{ or } h \le h_4 \\ (h_1 - h)/(h_1 - h_2) & h_2 < h < h_1 \end{cases} \text{and} \begin{cases} 1 & h_3 \le h \le h_2 \\ (h - h_4)/(h_3 - h_4) & h_4 < h < h_3 \end{cases} \tag{11}$$

In Eq. (11), the water uptake function is set to zero if the soil water pressure is greater than h_1 (oxygen deficiency) or less than h_4 (the wilting point). If the soil water pressure is between h_2 and h_3, the water uptake function reaches its maximum value. The value of h_3 varies with the potential transpiration rate T_P (T_P=5 mm/day or 1 mm/day) (see Feddes et al., 1978).

The linear model expresses the root density distribution function as (Prasad, 1988)

$$g(z) = (2/z_r)(1 - z/z_r) \tag{12}$$

where z is the current depth and z_r is the bottom of the root zone depth. The water stress response function α is calculated using $\alpha_1(h)$.

The exponential model expresses the root density distribution function as (Li et al., 1999)

$$g(z) = g_0 \frac{\exp(-bz)\left[1.5 + 0.5\exp(-bz)\right]}{1 + \exp(-bz)} \tag{13}$$

$$b = 24.66 F_{10}^{1.59} / z_r \tag{14}$$

where F_{10} is the fraction of the root length density in the top 10% of the root zone and g_0 is the root density at the soil surface. The water stress response function α is calculated using $\alpha_1(h)$.

In the exponential model considering the water stress compensation, the root density distribution function is determined using Eqs. (13) and (14) of the exponential model (Li et al., 1999). The water stress response function α uses the following expression to consider the water stress compensation mechanism (Li et al., 2001):

$$\alpha = \alpha_1(h) \cdot \alpha_2(\theta, z) \tag{15}$$

$$\alpha_2(\theta, z) = \frac{\alpha_1(h) G(z)^{\lambda - 1}}{\sum_{z=0}^{z_r} \alpha_1(h) G(z)^{\lambda}} \tag{16}$$

where λ is the empirical parameter and $G(z)$ is the fraction of the total root length in a layer of thickness Δz at depth z.

The method used in VS2D (Lappala et al., 1987) is also implemented in the present model as an option to calculate the actual transpiration. This method is relatively easy to use and the expressions are not repeated here.

NUMERICAL SOLUTION

The 3D mixed form of the modified Richards equation is discretized using the finite volume method in space and an implicit scheme in time. To handle the nonlinearity of the system, the Picard procedure with under-relaxation is used to linearize the surface and subsurface flow equations. The subsurface flow model uses a rectangular hexahedral mesh (see He et al., 2008). The time derivative term for the volumetric soil water content in Eq. (1) is discretized using the Taylor series expansion presented by Celia et al. (1990). The diffusion terms are discretized by a central scheme, and the time derivative terms are discretized by the first-order backward implicit scheme. The discretized equations are solved by the Strongly Implicit Procedure (SIP) of Stone (1968). Accurate numerical solution and mass balance are reached when the convergence criteria of both the Picard iteration and SIP solution loops are satisfied at each time step. There are numerous methods suggested in the literature for computing the intercell average of the relative permeabilities between grid cells in the discretized equation (Desbarats, 1995; Dogan and Moltz, 2005; etc.). In general, the mean hydraulic conductivity between grid cells can be estimated using the distance-weighted arithmetic mean for unsaturated zone and the weighted harmonic mean for saturated zone, if the relatively fine space-time meshes used.

MODEL TESTING

1D Water Flow in a Field Soil Profile under Grass. This example uses the data set of 1D water flow in a field profile of the Hupselse Beek watershed in the Netherlands, obtained from the research report of SWMS3D (Simunek et al., 1995). The soil profile consisted of two layers, as shown in Figure 1. The soil layers A and B were 40 and 190 cm thick, respectively. The depth of the root zone was 30 cm. The hydraulic properties of the two soil layers were represented by the van Genuchten functions (1980). The saturated hydraulic conductivities k_s were 29.75 cm/day and 45.34 cm/day; the saturated moisture content values θ_s were 0.399 and 0.339; the residual moisture content values θ_r were 0.001 and 0.001; and the van Genuchten (1980) parameters (α, n) were (0.0174 cm, 1.3757) and (0.0139 cm, 1.6024) for layers A and B, respectively. The model simulates the period of April 1 to September 30 of the relatively dry year 1982. The soil surface boundary conditions involved actual precipitation and potential transpiration rates for a grass cover, as shown in Figure 2. The bottom condition consisted of a prescribed drainage flux (Simunek et al., 1995). The initial groundwater level was set at 55 cm below the soil surface and the initial moisture profile was taken to be in equilibrium with the ground water level. Figures 3 and 4 give the simulated cumulative actual transpiration and bottom discharge

amounts as obtained with the present model and SWMS3D, respectively. Figure 5 shows the simulated groundwater table with time. As can be seen from the figures, the results obtained with the present model agree well with those calculated with SWMS3D.

2D Problem Involving Rainfall, Infiltration, and Evapotranspiration. The present model is used to simulate a relatively complex 2D problem involving rainfall, infiltration, evaporation, and transpiration obtained from the technical report of VS2D model (Lappala et al., 1987). The computational domain consists of a clay layer with 1.5 m in depth and 3.0 m in width which overlies a 0.6 m thick gravel layer. A discontinuous sand layer with a thickness of 0.3 m and a length of 1.5 m is embedded in the clay at a depth of 0.4 m, as shown in Figure 6. Four recharge periods totaling 77 days were simulated. The first period was a 1 day rainfall event at a rate of 7.5 cm/day; the second period was a 30 days with a bare-soil potential evaporation of 0.2 cm/day; the third period was a 1 day rainfall event at a rate of 7.5 cm/day. The last period was a 45 days that consists of both evaporation and transpiration. The root depth was 35 cm. The user-defined variables that control evaporation and transpiration were assumed to remain constant throughout the simulation, with the exception of *PET*, root depth, and root pressure (Lappala et al., 1987). The other parameters used in the simulation can be found in Lappala et al. Initial conditions consist of an equilibrium head profile specified above a fixed water table at a depth of 2.0 m. The minimum pressure head is set at -1.00m. The hydraulic properties of the three different layers are represented by the Brook-Corey function. The saturated hydraulic conductivities were 5, 100, and 300 cm/day; the saturated moisture content values were 0.45, 0.40, and 0.42; the residual moisture content values were 0.15, 0.08, and 0.05; and the Brooks and Corey parameters (bubbling pressure head, pore-size distribution index) were (-50 cm, 0.6), (-15 cm, 1.0), and (-8 cm, 1.2) for the clay, sand, and gravel layers, respectively.

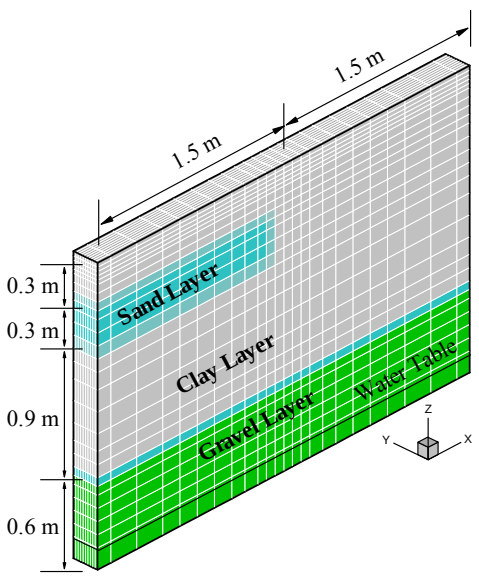

Figure 6. Computational domain of the 2D example

Figure 7 shows the pressure head versus time at four locations at the same depth of 0.33 m. The first two are in the sand lens and the last two are in the clay layer. The

results from the present model agree well with the pressure heads obtained from the VS2D model. There are some differences between the pressured heads in clay layer simulated by the two models, which may be due to the hydraulic properties of the clay soil. The present model solves the mixed form of the Richards equation, which is more mass conservative and more sensitive to the moisture content gradients, since a small moisture content change in the clay layer may require substantial pressure gradient.

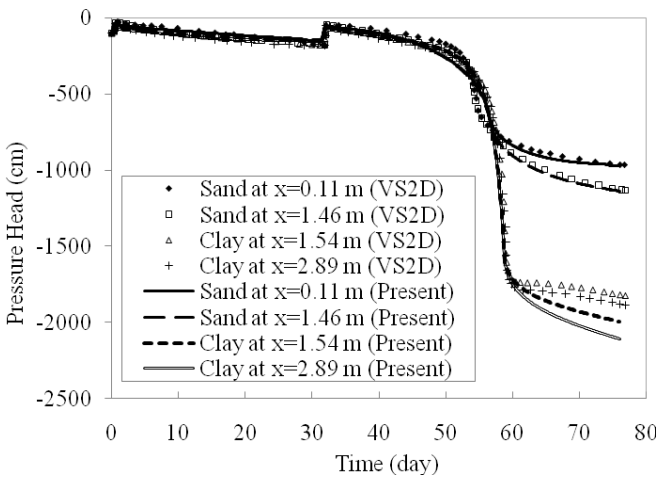

Figure 7. Simulated pressure head profiles at four locations for Ex. 2

CONCLUSION

This paper presents an evapotranspiration model that has been implemented into an integrated surface-subsurface flow model. The mixed form of the 3D Richards equation is discretized by the finite volume method and solved using the modified Picard iteration scheme based on Celia et al. (1990). Evaporation is applied as the upper boundary condition at the ground surface, while transpiration is calculated as a point sink term distributed vertically over cells in the root zone. The model has been tested against two sets of data in the literature and will be further verified and applied to field studies.

ABSTRACT

In the United States, the flow-frequency distribution established for use by federal agencies is the log-Pearson Type III (LP3). Fitting an LP3 requires the estimation of three log-space parameters: mean, standard deviation, and coefficient of skewness (skew). The resulting flow-frequency estimates for extreme floods are very sensitive to the value of the skew parameter. Many researchers and practitioners have made attempts to better estimate the skew, e.g., through regional skew maps and relating skew to physical watershed characteristics. These attempts have been mainly unsuccessful. In practice, using unfiltered LP3 fitted parameters to estimate project design flows and their associated confidence limits for floods greater than those recorded has lead to extreme flow estimates, which often exceed perceived physical basin limits.

In order to improve the LP3 extrapolations, a simple procedure was developed by which the skew parameter was adjusted such that the resulting flow-frequency estimates respected the physical basin limits. This procedure was applied to several major watersheds of the Sacramento and San Joaquin River system in California. In this application, the skew was adjusted such that the probable maximum flood had an annual exceedance probability (AEP) of 1-in-10,000 or less. Monte Carlo simulations were performed with an assumed underlying test flood-frequency distribution. The distribution was sampled with representative flood record lengths (50 and 100 years). Estimates and confidence limits of commonly used design frequencies (1-in-10 to 1-in-500 AEP) and the risk of flooding in the next 50 years were computed using both the standard (Bulletin 17B) procedure and the procedure with the described skew adjustment. The design flood estimates were compared for reasonableness and consistency with the expected, underlying test distribution values.

BACKGROUND

The principal challenging aspect of performing flood frequency estimation in the United States is the lack of available flow data to form the basis of the estimate. Since a primary interest in utilizing flow-frequency data is to estimate floods whose return intervals are beyond the coverage of the data, extrapolations must be made. As

federal procedures outline (IACWD, 1982), this extrapolation is based on a statistical procedure using the Log-Pearson Type III (LP3) distribution. For watersheds in California, Countryman and Tustison (2008) have recognized that due to the lack of sufficient data and the characteristics of the statistical estimation procedure, these extrapolated estimates often produce results which exceed, sometimes greatly, perceived physical basin limits, such as the probable maximum flood (PMF). This is not a desired product of the estimation procedure, and overestimates at these extreme frequencies may be indicative of overestimation at more frequent, design frequencies (1-in-10 through 1-in-500 AEP).

The authors of Bulletin 17B recognized that to extrapolate flow-frequency curves to exceedance probabilities less than those represented by the range of data for which the statistics were calculated was problematic and thus recommended physical hydrologic and/or meteorologic methodologies be considered when making such extrapolations (IACWD 1982). This paper proposes a simple technique which follows the standard federal Bulletin 17B procedure but adjusts the calculated skew value such that the resulting extrapolated estimates recognize physical hydrologic limits.

BASIC DATA

For this analysis, fifteen California Central Valley watersheds were chosen. The basins lie along the western slope of the Sierra Nevada mountain range. The geographic scope and elevation ranges for the watersheds varied considerably. Watershed data for the basins studied are shown in Table 1.

The 3-day annual maximum flow data was chosen as the basis for this analysis. This flow duration has the advantage of containing peak flood flows in California without having portions of the peak existing in two different time intervals. Additionally, the 3-day duration is the critical duration for the analysis of reservoir flood operations. That is, the reservoir volume set aside for flood control storage is based on a 3-day duration. Therefore, use of the 3-day flow volume is critical to the analysis of a flood system controlled by reservoirs in California. The statistical analysis presented in this paper would be equally applicable in a flood analysis based on peak flows or other durations.

Table 1. Watershed data (USACE, 2002).

Basin	Years of Record	Drainage Area (sq. mi.)	Maximum 3-Day Flow Rate (cfs)	Maximum Elevation (ft, msl)
American R.	100	1,888	166,000	10,400
Bear R.	93	292	32,000	6,000
Calaveras R.	53	363	18,000	6,000
Chowchilla R.	71	235	10,000	6,100
Cottonwood Cr.	58	927	38,000	8,000
Feather R.	96	3,624	244,000	9,100
Fresno R.	58	234	7,000	7,800
Merced R.	96	1,037	44,000	13,000
Mokelumne R.	93	677	39,000	10,000
San Joaquin R.	94	1,676	53,000	13,900
Shasta R.	67	6,421	168,000	14,100
Stanislaus R.	82	904	50,000	11,500
Stony Cr.	98	740	31,000	6,500
Tuolumne R.	100	1,533	92,000	13,000
Yuba R.	100	1,339	124,000	8,200

FREQUENCY CURVES

Graphically-derived frequency curves were developed for each watershed following the procedure outlined in Countryman and Tustison (2008). These curves were based on a combination of recorded data and expert opinion as to the exceedance probability of the PMF, and "standard project flood", SPF, (USACE 1965) for each of the basins. These frequency curves were assumed to be the underlying ("real") probability distribution of flood flows for each basin.

ESTIMATION (STANDARD)

Each of the "real" frequency curves was sampled in independent sets of 50 and 100 years of data for each watershed. This sampling was done 10,000 times in each case to form the basis for characterizing the resulting estimates. These sets of data were then used to estimate flow values at exceedance probabilities commonly used for design purposes (1-in-10 through 1-in-500 AEP) and compared with the underlying "real" frequency curve values. The mean, standard deviation, and skew were computed for each of the sample data sets. In addition, the 95% upper confidence bound (results not presented herein but available) was estimated for each of the data sets at the same frequencies as the estimates. The techniques outlined in Bulletin 17B were explicitly followed in this procedure. This estimation procedure is hereby referred to as the "standard" procedure.

ESTIMATION (BOUNDED)

As the authors have previously shown in Countryman and Tustison (2008), extrapolations made using the "standard" procedure often result in values which are significantly greater than the SPF and PMF values at the extreme frequencies. In order to improve the LP3 extrapolations, a simple procedure was developed by which the skew parameter was adjusted such that the resulting flow-frequency estimates respected the physical basin limits. The skew, as opposed to the other statistical parameters, was chosen for adjustment because the upper tail (extreme estimates) of the probability distribution is of primary interest, and, of the three LP3 fitting parameters, the extreme frequency estimates are generally most sensitive to the skew.

In this application, the skew was adjusted such that the resulting estimates reproduced the 1-in-10,000 AEP value from the underlying "real" frequency curve. This technique was intended to simulate knowledge of a physical bound, e.g. the PMF. Specifically, this estimation was done as follows: (1) estimate the statistical parameters (mean, standard deviation, skew) of the underlying distribution; (2) adjust the skew parameter until the frequency estimate at 1-in-10,000 AEP matches the 1-in-10,000 AEP value from the underlying "real" frequency curve; (3) form estimates and confidence bounds following Bulletin 17B procedures with the originally calculated mean and standard deviation and the new, adjusted skew value. This estimation procedure is hereby referred to as the "bounded" procedure. For comparison, the same quantities calculated using the "standard" procedure were computed with the "bounded" procedure.

RESULTS

Tables 2a and 2b show the skew values estimated from the historical record and mean and standard deviation of those using the standard and bounded procedures with the randomly generated data for record lengths of 50 and 100 years, respectively. In every basin for both 50 and 100 year record lengths, the mean skew value was reduced using the bounded procedure. This indicates the originally calculated (standard procedure) skew values were overestimates. An overestimated skew will result in the tail of the statistical distribution being too "fat", i.e., excess probability. This will lead to overestimation of the extreme values. As an example, Figure 1 shows histograms for the standard and bounded skew estimates resulting from the 10,000 sample data sets on the Stanislaus River. The mean calculated standard and bounded skew values and the skew calculated from the historical record are also shown for comparison. As this figure shows, the bounded skew values have less variation than those using the standard calculation. It is interesting to note that the mean skew value is considerably different using the two methods, with the bounded mean skew value being much less than the standard. Additionally, there is very little overlap of the two histograms.

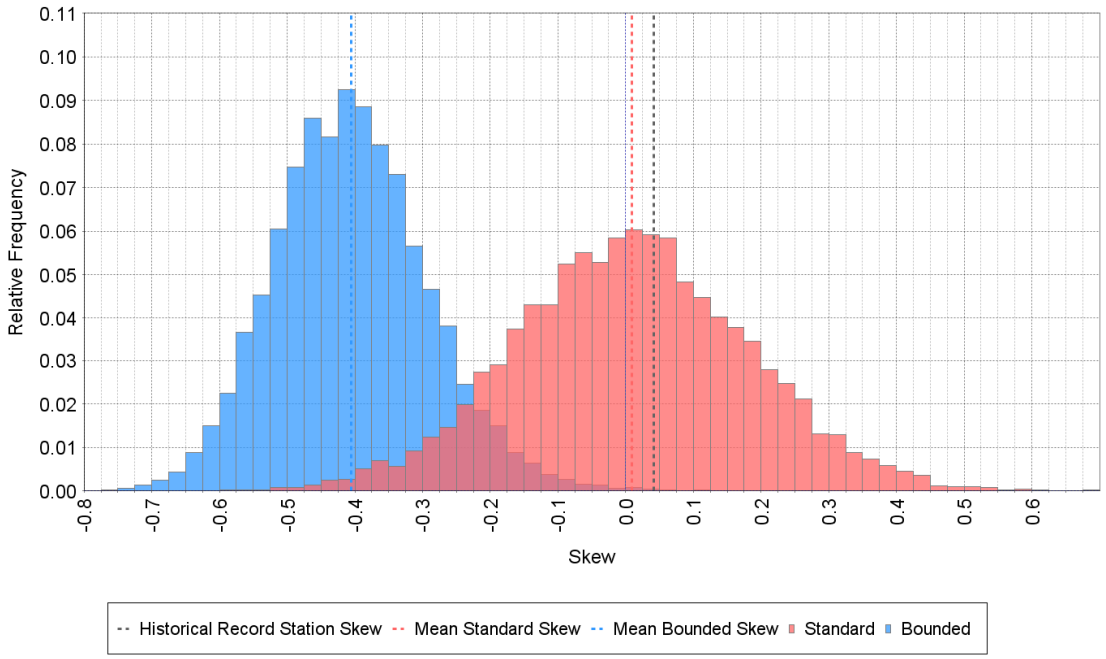

Figure 1. Stanislaus River: Comparison of standard and bounded skew values for 10,000 simulations of 100 year record length.

Figure 2 shows two histograms for the 1-in-100 AEP estimates: one using the standard method and another utilizing the bounded method. As this figure shows, there is much less variation in the bounded case versus the standard case. This was typical of the watersheds studied. Also, Figure 2 shows the bounded methodology underestimated while the standard methodology overestimated the "real" 1-in-100 AEP value.

Tables 3a and 3b show the normalized (by the underlying "real" value at each frequency) root mean square error (RMSE) of the flow estimates at the frequencies 1-in-10, 1-in-100, and 1-in-500 AEP, using the standard and bounded procedures with the randomly generated data for record lengths of 50 and 100 years, respectively. In every basin, for both 50 and 100 year record lengths, the RMSE value was reduced in the bounded case. However, the difference in RMSE between the standard and bounded cases was less for the more frequent estimates. The 1-in-10 AEP estimates showed little RMSE difference between the two estimation techniques, while the 1-in-500 AEP estimates fared much better for the bounded technique, as exhibited by RMSE values considerably less than their counterparts estimated with the standard procedure. The RMSE also decreased in the 100 year record length trials as compared with the 50 year record length trials for both the standard and bounded cases, as would be expected since the additional 50 years of data provided additional support to the estimation procedure.

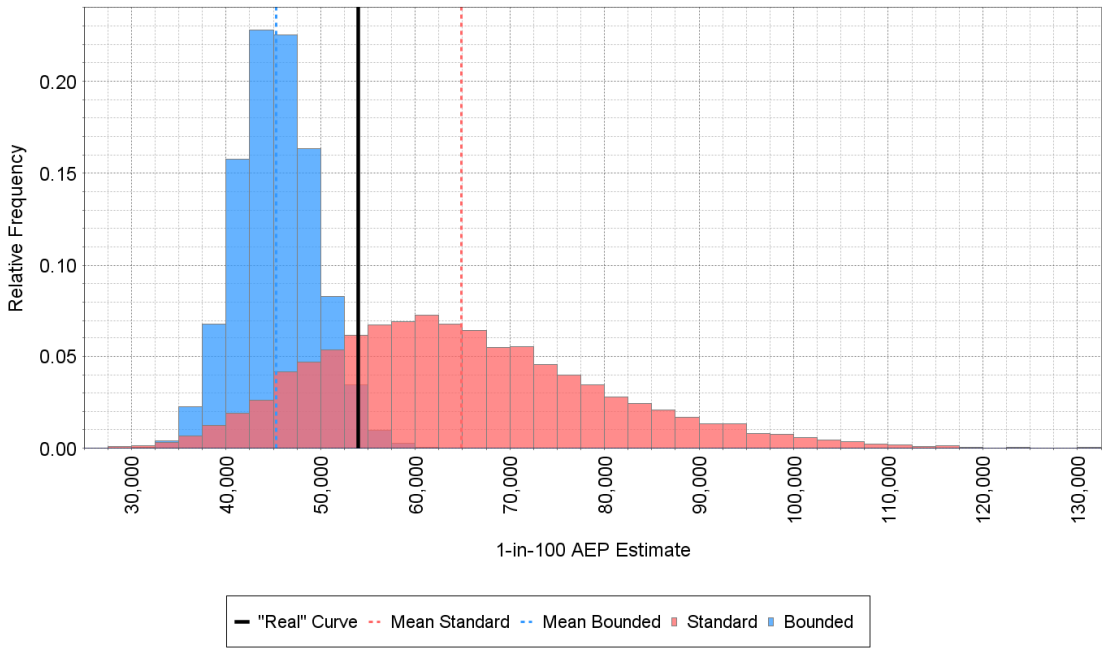

Figure 2. Stanislaus River: Comparison of standard and bounded 1-in-100 AEP estimates for 10,000 simulations of 100 year record length.

In addition to the RMSE, the mean bias of the standard and bounded estimates was calculated. The bias is defined as the difference between the estimate and the "real" value. Tables 4a and 4b show the calculated mean estimation bias values for record lengths of 50 and 100 years, respectively. As these tables show, the standard estimation method tends to lead to overestimation (positive bias values), while the bounded methodology tends to lead to slight underestimation (negative bias values). The bounded methodology did lead to considerably smaller biases, especially for the 1-in-500 AEP flow estimates. The degree of bias generally increased with the extremity of the flow being estimated. Record length had minimal effect on this bias magnitude, with a slight decrease in the overall bias magnitude with the increase in record length from 50 to 100 years. The tendency for the bounded methodology to slightly underestimate should be better understood before applying this method in practice, as the underestimation of a hydrologic design event could lead to severe repercussions, including underestimating threats to public safety.

Table 4a. Mean estimation bias (estimate minus "real") of common design frequencies using standard and bounded procedures for record length = 50 yr.

Tables 5a and 5b show the mean calculated risk of the estimated flow at the specified frequency being exceeded in the next 50 years for the design frequencies of 1-in-100, 1-in-200, and 1-in-500 AEP for record lengths of 50 and 100 years, respectively. The tabulated values should be compared with the theoretical risk of exceeding these respective frequency events of 0.39 (1-in-100 AEP), 0.22 (1-in-200 AEP), and 0.10 (1-in-500 AEP). When these comparisons are made, these tables show the standard procedure generally produced design event estimates with less risk of failure than would be expected at those frequencies. This means that designs using this procedure would tend to be overly conservative and perhaps more costly than necessary. The bounded procedure, on average, produced estimates which underestimated the risk of failure in the next 50 years. While this would potentially produce less costly designs for a given frequency, these designs would also underestimate the flood risk of the design, and potentially compromise public safety if left unchecked. Using both procedures, the mean calculated risk was decreased by adding the additional information in going from a 50 year to a 100 year record. The tendencies of these estimators to overestimate and underestimate the flooding risk of a design should be carefully considered when applying either of these techniques to a potential project.

CONCLUSION

Countryman and Tustison (2008) concluded by stating that the development of graphical frequency curves which incorporate design flood information such as PMF and SPF should be investigated as a replacement for the Bulletin 17B procedure. This paper presents a technique by which this objective is met. However, unlike a purely graphical technique, this procedure largely falls within the Bulletin 17B framework, only deviating where necessary to overcome the limitations of Bulletin 17B.

Although a purely graphical technique, by which the resulting frequency curve remains true to the observed data within its limited frequency range, is still preferred by the authors, the procedure recommended in this paper provides an alternative which: (1) remains within the guidelines of Bulletin 17B as closely as possible; (2) corrects the overestimation of flow estimates produced using the Bulletin 17B procedure at extreme frequencies; (3) provides more accurate estimates of the underlying flow-frequency relationship at the frequencies commonly used in water resources design (1-in-10 to 1-in-500 AEP).

FURTHER INVESTIGATION

Past attempts of the authors to relate the standard skew to physical basin parameters in the California (and others throughout the United States) have been largely unproductive. Perhaps, some of the difficulty can be related to the inherent variability in estimating the standard skew from the limited historical record. The authors would like to further explore the technique of skew adjustment. Of particular interest is to determine if the adjusted skew can be closely related to physical basin parameters. If so, this would potentially have significant implications to regional skew analysis.

Abstract

Noland Divide Watershed (NDW), locating in the Great Smoky Mountains National Park, is characterized as one of the watersheds to receive some of the highest acidic deposition in the US. It has been continuously monitored for deposition, soil water and stream water chemistry weekly and biweekly, since 1991. The long-term trend analysis over past 17 years (1991-2007) found that decreasing sulfate and proton in the precipitation, however stream sulfate concentration, pH and ANC did not show the same significant trends. In contrast, atmospheric deposition of nitrogen was found to be increasing over time, but stream nitrate concentration was observed to be declining, apparently due to increasing overstory vegetation uptake. This long-term study has found mean annual detention of sulfate, nitrate and ammonium of 60%, 3% and 95% respectively in the watershed. Sulfate is accumulated in soil matrix by soil adsorption. Ammonium was mainly converted to nitrate by soil mineralization and nitrification at surface soil layer, and combined with deposited nitrate to be uptaken by plant. Despite the decreasing nitrate concentration and stable sulfate concentration, stream recovery from acidification is not observed in the NDW, due to the depletion of base cations with decreasing stream base cation concentrations.

Introduction

The Noland Divide Watershed (35°34'N, 83°29'W), located in the Great Smoky Mountains National Park on the North Carolina and Tennessee border, is a small (17.4 ha), high-elevated (1700~1900 m) watershed (Figure 1). Two perennial first-order streams (NE and SW streams) drain the study area headwaters, and merge downstream as Noland Creek.

As part of the Integrated Forest study (IFS) program, stream acidification in the NDW was initially observed in the 1980's by Johnson and Lindberg (1992) and Cook et al. (1994). This watershed was characterized as one of the watersheds to receive the highest atmospheric deposition in US. After the IFS, GRSM resource managers initiated a long-term study utilizing the NDW site to further investigate impacts of acidic deposition on high-elevation forested watersheds and stream acidification. In 1991, the NDW was equipped with wet deposition, throughfall, soil lysimeters, and stream monitoring stations, designed to characterize and assess deposition, soil, and stream water chemistries, over time. In this article, analysis focused on estimating ion

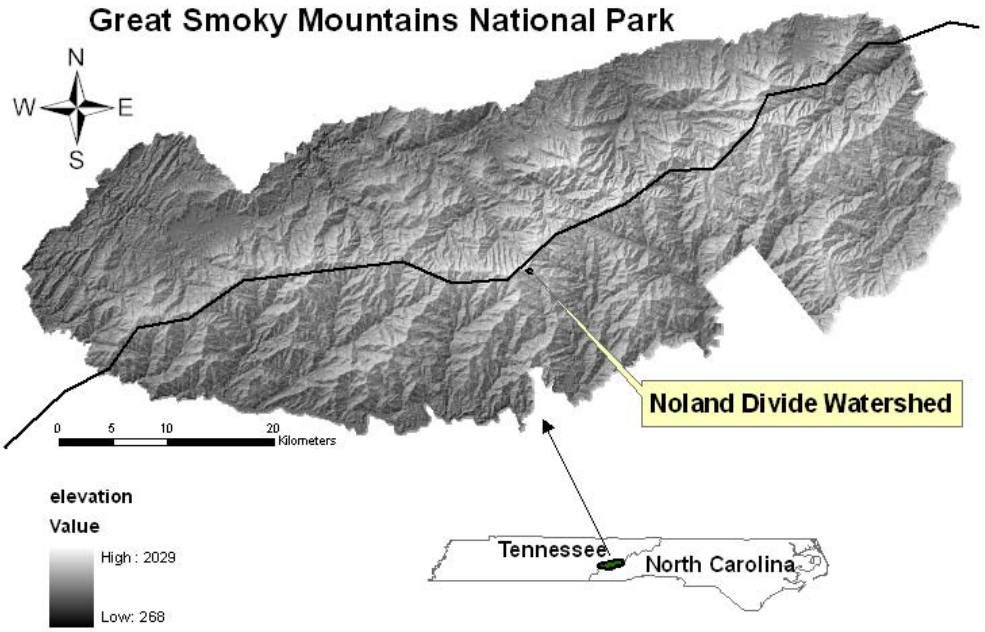

Figure 1. Location of Noland Divide Watershed (NDW) in the Great Smoky Mountain National Park (GRSM) at the border of Tennessee and North Carolina.

mass fluxes for long-term trend and annual input-output budgets using the NDW monitoring data from 1991 through 2007.

Methods

Study Area

The NDW is a fully forested basin, and its overstory vegetation was dominated by red spruce fir (*Pices rubens* Sarg, 77%) and interspersed patches of yellow birch (*Betula alleghaniensis,*19%) as well as Fraser fir (*Abies fraseri* (pursh.) Poir, 2.5%) (Baker et al. 2002). The invasion of balsam woolly adelgid (BWA, *Adelges piceae*, Ratzeburg) on spruce-fir forests (Nicholas et al. 1992) in 1970s resulted in a heavy mortality of the forest (Jenkins 2007). The BWA feeds in the bark fissures of *A. fraseri* trees over 4 cm dbh (Eagar 1984), resulting in the death of most mature fir. Recently, the forest has shown signs of recovery, indicated by increasing standing live biomass and growth (Van Meigroet et al. 2007).

The soils in the NDW are generally shallow with total depth below 1 meter throughout the NDW (Johnson and Lindberg, 1992). The soils are inceptisols with spodic characteristic classified as Dystrochrepts or Haplumbrepts (McCracken et al. 1962; Van Miegroet et al. 1993), with a silt loam to sandy loam texture. Soil layers were consisted of 4-cm thick Oi + Oe horizon of needles and leaves; 4-cm thick Oa horizon of mucky humus; 8-cm thick A horizon of dark, reddish-brown, mucky loam; 27-cm thick Bw horizon of dark brown, sandy loam; 35-cm thick Cb horizon of dark, yellowish-brown loam; and 20-cm thick C horizon of olive-brown, loamy sand

(Johnson and Lindberg 1992). Underneath the soil lies the Thunderhead Sandstone formation, thick-bedded, low porosity bedrock composed principally of quartz and potassic feldspar (King et al. 1968; Silsbee and Larson 1982).

Field data collection and laboratory analysis

Atmospheric deposition was collected by wet deposition and throughfall deposition. Wet deposition was collected at an open site (without forest cover) using a rainfall collector with a precipitation-triggered cover. Throughfall was collected during frost-free periods by covered collector buckets mounted with 90-mm diameter funnels minimizing evaporation, and during the frost season two open 5-gal collector buckets were used. Deposition water was collected and weighed biweekly to obtain a precipitation volume biweekly, computed by use of the water specific weight.

Soil water was collected monthly by ceramic suction lysimeters at three different soil depths. The shallowest lysimeter was placed in the A horizon, the intermediate lysimeter depth was placed in the Bw horizon, and the deepest lysimeter was placed in the Cb horizon. Lysimeters were installed in the same location as the throughfall collectors.

Grab samples were routinely collected from the SW and NE streams weekly from 1991-2000 and biweekly since 2001. Most samples were collected during baseflow conditions; however no effort was made to collect baseflow samples only. Each stream was also equipped with water quality sondes recording pH, conductivity and temperature. Float-type stage recorders were installed in stilling wells on 3.0-ft H flumes, in which discharge was calculated from flow depth according to standard H-flume tables in USDA-ARS (1979) and periodically verified. Water quality and stage data were recorded every 15 minutes on a Campbell CR10 data logger.

The collected water samples were transported to the University of Tennessee Water Quality Laboratory within 4 hours and, and analyzed for pH, conductivity, and ANC utilizing an autotitrator within 24 hours. Samples in holding were kept cooled at 4^{o}C. Samples were filtered by a 0.4-μm membrane and separated into two bottles for analysis of SO_4^{2-}, NO_3^-, Cl^-, and NH_4^+ by ion chromatography; and Ca^{2+}, Mg^{2+}, K^+, Na^+ by atomic absorption spectrometry (1991-1993, 1998-2003) and inductively-coupled plasma spectrometry (2003-2006). From 1993 to 1998, Na^+ and K^+ were measured by ion chromatography, but Ca^+ and Mg^+ were not measured. Measurement of ANC for wet deposition, throughfall, and soil water began in 2005. All samples met quality criteria set forth in a quality assurance/quality control (QA/QC) program, which included sample spikes, replicates, blanks and U.S. Geological Survey known samples; in addition to adherence to analytical equipment maintenance.

Water and chemical mass balance calculations

Annual throughfall and wet precipitations were computed by converting each volume collected biweekly to a depth (cm) based on the total surface area of the collection funnels/buckets, and summing each biweekly measurement to equate to an annual total. Water export from NDW was equal to the total flow from both SW and NE streams. Annual volume for total flow was computed by summing measured volumetric discharges (m^3 s^{-1}) per 15-minute increments for both SW and NE streams, combining these individual stream annual volumes (m^3), dividing total annual volume

by total watershed area (17.4 ha), and converting units to obtain estimates in cm yr^{-1}.

An annual chemical mass balance was estimated as the difference between total mass deposition (TD) and mass stream export, reported in flux units of eq ha^{-1} yr^{-1}. Per chemical, TD was calculated by the sum of wet deposition and dry deposition representing the entire atmospheric input to NDW. Wet deposition represents that portion captured from the open site. Dry deposition generally represents that portion computed by the difference between throughfall and wet deposition; however for Ca^{2+}, Mg^{2+}, K^+, H^+, and NH_4^+ dry deposition was calculated by using canopy uptake and leaching model (Ulrich 1983; Van der Maas et al. 1991; Cai et al. 2009). Total stream mass flux export was computed by summing eq yr^{-1} for both SW and NE streams, divided by the total NDW drainage area of 17.4 ha. Chemical mass balances for NDW in eq ha^{-1} yr^{-1} were computed as follow:

$$\text{Retention/depletion} = \text{TD} - \text{Total Stream Export} \quad (1)$$

where, retention is the chemical mass remaining in the watershed if positive, and depletion is the chemical mass removed beyond that amount entered through atmospheric deposition if negative.

Statistical analysis of chemistry among deposition, soil, and stream waters

Statistical analysis of water chemistry includes: 1) long-term trend analysis for chemical flux and concentration from 1991 to 2007; 2) multiple analysis of variance (MANOVA) among watershed hydrologic system compartments (i.e., atmospheric deposition, soil, and stream) to compare mean annual concentrations among compartments from 1991 to 2006. Mean annual concentrations were computed for the 16-year (1991-2006) monitoring period and hydrologic system compartments, specifically wet deposition, throughfall, soil water (A, Bw, and Cb horizons), and SW and NE streams. Compartments were compared using a MANOVA Tukey's HSD mean separation procedure (Hayter 1984). Significance groupings of mean concentration differences were indicated by superscript letters, e.g., A, B, C, etc. If the data did not share the same letter, it indicates there was a significant difference between those compartments. Statistical analysis was preformed with JMP® v.6.0.2 (JMP, 2005). Significant trend and differences were noted at $p < 0.05$. For analysis of temporal trend, only SW stream is selected since water chemistries between the NE and SW streams were found to be statistically similar (Cai et al. 2009).

Results and Discussions

Long-term trend of annual flux

From 1991 to 2007, wet precipitation and throughfall precipitation declined, from above 250 cm yr^{-1} in early 1990s to around or below 200 cm yr^{-1} in recent years, a decrease of approximately 20%. Precipitation was particularly low in 2007, because that year is the most severe drought year in US southeastern region since 1989 (Hampson 2008; Logan 2008). In response to the declining precipitation amount, the averaged annual stream outflow through SW stream was reducing from above 100 cm yr^{-1} to around 70 cm yr^{-1} during this study period. The hydrological temporal trend

can affect the chemistry fate through dilution effect and by changing the dominant biogeochemical processes due to varied flow pathway (Mulholland 1993).

Deposition flux and SW stream export of sulfate had similar decreasing trend, just like water precipitation and discharge. The significant downward trend of deposited sulfate flux was consistent to many other watersheds (Stoddard et al. 1999; Forsius et al. 2003). Greater decline of sulfate flux in throughfall than in wet deposition implied a proportionally greater reduction in dry deposition than wet deposition (Ukonmaanaho et al. 1998). This provided evidence that the reduction of emission of SO_2 was actually reducing the acidic deposition of sulfur, especially through dry deposition. Due to simultaneously decreasing trend of water volume and sulfate flux, sulfate concentration in SW stream did not show a trend over 17 years, indicating the NDW streams have not recovered from excessive sulfate deposition. This is consistent with the regression models by Robinson et al (2004; 2008) finding that there was little temporal variation of sulfate for streams at elevation above 1,067 m in the GRSM. Positive retention values in all 17 monitoring years indicated that the NDW was working as sink for sulfate. Although the retention amount varied from 1500 eq ha^{-1} yr^{-1} in some years to 500 eq ha^{-1} yr^{-1} in other years, the variation did not give significant temporal trend. The positive retention provided the evidence that this watershed was not saturated with sulfate yet and could accumulate more sulfate.

Wet and throughfall depositions for nitrate and ammonium, except ammonium flux in throughfall, did not have significant time trend. In contrast, retention of nitrate and ammonium in the NDW gave increasing trend from 1991 to 2007. Consequently, stream export of nitrogen, mainly in the form of nitrate, was decreasing over time. This is primarily because the spruce-fir forest in the NDW was recovering from the BWA by showing increased standing live biomass and uptake of nitrogen in 2000s than that in 1990s (Jenkins 2007; Van Miegroet et al. 2007). The nitrogen uptake by the overstory during 1993 to 1998 was observed to be 8 kg ha^{-1} yr^{-1} (Barker et al. 2002), which was increased to 11-15 kg ha^{-1} yr^{-1} in the following 5 years after 1998 (Moore et al. 2007). As a result, more nitrogen was assimilated by vegetation, leading to increasing retention and decreasing export of nitrogen from the NDW.

Throughfall deposition pH averaged 0.5 pH unit lower than that from wet deposition during the study period, and increased from 4 in 1991 to 4.2 in 2007. Wet and throughfall deposition pH increased at the rate of about 3.6×10^{-5} pH unit per day, leading to the declining trend of deposition H^+ flux, in which cloud be also partially attributed to declining precipitation. Sulfate and nitrate are the main acidifying anions in the NDW. Because of decreasing nitrate concentration and stable sulfate concentration, stream recovery from acidification (reflecting increasing pH and ANC) was expected. However, stream pH and ANC did not reflect the deposition pattern. SW stream pH remained around 5.8, while ANC fluctuated year to year without significant temporal trend. Some studies attributed the delay of stream recovery to the decrease in soil pools of base cations (Stoddard et al. 1999; Fölster et al. 2003). This could be evidenced by the declining total base cations concentration (slope = -0.0017 $\mu eq\ L^{-1}$, $p = 0.0211$, $n = 270$), despite of the relatively constant base cation deposition. The decreasing rate of total base cation was big enough to account for the declining nitrate concentration. As a result, the stream recovery of pH and ANC was delayed, leading to very small or no recovery at all. This indicates that watershed acidification

will continue for a long time until the soil cations are improved and the deposition of S and N is further reduced.

Ion input-output budget

Deposition water chemistry was dominated by SO_4^{2-} and NO_3^- inputs averaging annually 1,946 and 892 eq ha^{-1} yr^{-1}, respectively (Figure 2). Throughfall concentrations of 115.87 μeq L^{-1} SO_4^{2-} and 58.08 μeq L^{-1} NO_3^- were among the highest of the ion concentrations measured (Table 1). The influence of these two acid anions on proton equilibrium can be observed by the mean annual pH of 4.65 for wet deposition and 4.17 for throughfall. Also, mean annual ANC was –10.31 μeq L^{-1} for wet deposition and –56.79 μeq L^{-1} for throughfall. This indicated that acidification in this watershed was mainly caused by deposition of sulfate and nitrate. Less dominant, total annual deposition of Cl^- averaged 601.84 eq ha^{-1} yr^{-1} and NH_4^+ averaged 297.65 eq ha^{-1} yr^{-1}. Total deposition of base cations ranged from 144.31 to 451.66 eq ha^{-1} yr^{-1}. In general, annual wet deposition of ions were approximately 26 to 34% of total deposition, except for NH_4^+ at 82%. Wet deposition and throughfall NH_4^+ concentrations were similar at 14.08 and 18.01 μeq L^{-1}, respectively.

Stream export chemistry was dominated by Ca^{2+}, NO_3^-, and SO_4^{2-} averaging 49.30, 41.46, and 29.40 μeq L^{-1} in SW stream, respectively (Table 1). The data showed stream anions were dominated by NO_3^- although SO_4^{2-} dominated deposition anions. Annual SO_4^{2-} mass output and concentration were lower in the SW stream than the NE stream. These results provide some explanation to the higher pH and ANC found in the SW stream than in the NE stream. Annual pH averaged 5.83 and 5.59, and ANC averaged 11.75 μeq L^{-1} and 4.20 μeq L^{-1} for the SW and NE streams, respectively. Mean annual NH_4^+ concentrations of 0.72 μeq L^{-1} in the SW stream and 1.07 μeq L^{-1} in the NE stream, were small compared to other ions. Measurable stream ions also included: Na^+, Mg^{2+}, Cl^-, and K^+ with mass outputs averaging 497.35, 334.51, 331.47, and 200.62 eq ha^{-1} yr^{-1}, respectively.

Over this 16-year period in NDW, acid anions were retained. Retention of SO_4^{2-} was greatest among the anions estimated at 60.16%, whereas Cl^- was estimated at 44.92% and NO_3^- at 3.58% (Figure 2). Although NO_3^- retention appeared small, total inorganic nitrogen consisting of both NH_4^+ and NO_3^- was retained at 26.63%, presumably due to vegetative uptake. Johnson and Lindberg (1992) found that vegetation uptake to be approximately 15% of the NO_3^- inputs. Barker et al. (2002) found that the annual N sequestering in aboveground biomass was 8 kg ha^{-1} yr^{-1} in a NDW study. In addition, NH_4^+ retention was estimated at 95.69%, which represents conversion to NO_3^- in the soil rather than adsorption. This percentage is not uncommon in forested watersheds (Peterjohn et al. 1996; Willard et al. 1997). Consistent with the mass flux estimates for acid anions, concentrations of SO_4^{2-}, NO_3^-, and Cl^- were greater in the throughfall than the stream water.

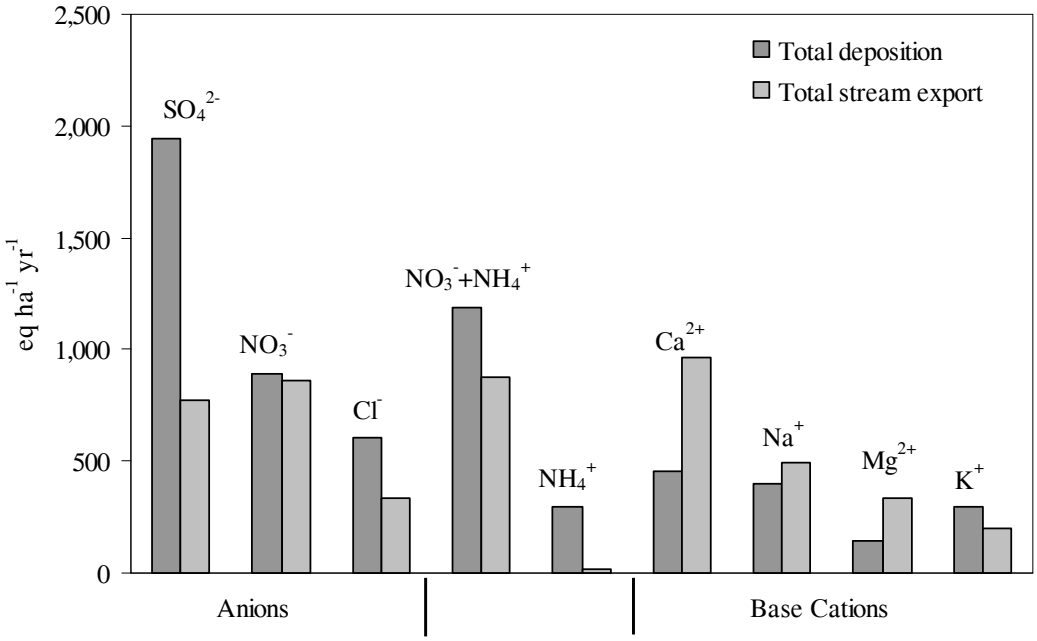

Figure 2. Mean annual fluxes in eq ha^{-1} yr^{-1} for total deposition and total stream export by SW and NE streams in NDW from 1991 to 2006 for major anions and cations.

In contrast to acid anions, base cations, except for K^+, were mostly exported with Ca^{2+} and Mg^{2+} mass export of 510.99 eq ha^{-1} yr^{-1} and 190.20 eq ha^{-1} yr^{-1}, respectively. (Figure 2). Loss of watershed base cations has been attributed to prolonged acidic deposition (Fernandez et al. 2003; Lawrence 2002; Tomlinson 2003). In NDW, the only cation retained was K^+, in which 31% was assumed assimilated annually into forest biomass. Castro and Morgan (2000) also found K^+ retention in a Maryland watershed, however K^+ export appears more typical among ion input-output budgets in northeastern US (Watmough et al. 2005). The export of cations from watersheds is of concern to the GRSM since mass export of base cations may impact the long-term health of forests (Tomlinson 2003; Holzmueller et al. 2007).

Concentration variation and biogeochemical processes among soil layers

Water chemistry changes were observed between throughfall and soil horizon A, which in most instances ion concentrations were significantly less in soil water than throughfall (Table 1). These ions included SO_4^{2-}, Cl^-, NH_4^+, Ca^{2+}, and K^+. Mean SO_4^{2-} decreased from 115.87 μeq L^{-1} in the throughfall to 91.39 μeq L^{-1} in soil horizon A, and Ca^{2+} decreased from 66.66 to 51.07 μeq L^{-1}. Mean annual NH_4^+ greatly decreased from 18.01 μeq L^{-1} in the throughfall to 2.87 μeq L^{-1} in the soil horizon A. Cations Mg^{2+} and Na^+ were found to be similar between throughfall and soil horizon A. The only ion to increase significantly in mean annual concentration from throughfall to soil horizon A was NO_3^-, increasing from 58.08 to 142.07 μeq L^{-1} indicating the occurrence of nitrification. Evidence suggests most of NH_4^+ deposition is converted to NO_3^- in the upper soil layer because the A horizon NH_4^+ concentration

Table 1. Mean chemical concentrations from late 1991 to 2006 for hydrologic system compartments. Stream ANC was measured for the 16-year period, but deposition and soil water ANC was only measured for two years (2005 and 2006). For one chemical, data sharing same letter are not significantly different among hydrologic system compartments.

Na^+	7.30^{C}	21.19^{B}	23.51^{AB}	22.84^{AB}	20.04^{B}	25.99^{A}	25.64^{A}

WD = wet deposition; TF = throughfall; A, Bw, and Cb = soil horizons; SW = southwest stream; and NE = northeast stream.

decreased, and NO_3^- and H^+ concentration increased (Table 1). For NO_3^-, nitrification and vegetation uptake are the dominant processes within NDW. Nitrification was observed by the abrupt increase of NO_3^- concentration and reduction of NH_4^+ concentration from throughfall to soil horizon A. Nitrification and mineralization of organic N both have a strong acidifying effect on the soil because of the net proton release during this oxidation process. Both these N processes may be involved in generating the NDW mean pH of 4.01 in the upper soil horizon water, which was significantly lower than pHs measured in throughfall and deeper soil horizons. Concurrently observed with the NO_3^- increase were decreases in mean ANC (–56.79 to –148.58 μeq L^{-1}) from throughfall to soil, observed as –56.79 to –148.58 μeq L^{-1}.

Within the soil column (A, Bw, and Cb horizons), mean annual concentration of several ions remained relatively uniform, including SO_4^{2-}, Cl^-, NH_4^+, Mg^{2+}, and Na^+ (Fig. 4). NO_3^- significantly decreased from 142.60 μeq L^{-1} in the A horizon to 78.24 and 85.60 μeq L^{-1} in the Bw and Cb horizons, presumably due to root uptake in soil (Table 1). Cation concentrations for Ca^{2+} and K^+ were also found to significantly decrease from the A horizon to the Bw and Cb horizons. Ca^{2+} concentrations in the A horizon decreased from 51.07 μeq L^{-1} to 31.04 and 35.93 μeq L^{-1} in the Bw and Cb horizons, respectively; and K^+ concentrations decreased from 23.19 μeq L^{-1} to 9.57 and 9.85 μeq L^{-1}. Mean annual pH of the soil water increased from 4.01 in horizon A to 4.41, and 4.47 in horizons Bw and Cb. Mean annual ANC also increased through

the soil horizons, as well from -148.58 μeq L^{-1} in the A horizon to –72.09 μeq L^{-1} in Bw horizon, and and further to –35.18 μeq L^{-1} in the Cb horizon. Other than ANC, pH and ion concentrations were similar between the Bw and Cb horizons.

Conclusions

Studies of long-term chemistry data from 1991 to 2007 showed that the control of sulfur emission was actually working in the NDW by reducing sulfate deposition. However, stream sulfate concentration remained constant during this study period, because of soil retention of more than 50% sulfate by adsorption. The relatively stable retention percentage of sulfate indicated the NDW was not saturated with sulfate and could accumulate more sulfate in future. In contrast to sulfate, stream nitrate was decreasing over time, even though deposition of inorganic nitrogen was increasing or relatively stable. This is primarily due to increasing plant uptake of nitrogen, which retain around 26.63% of total deposited inorganic nitrogen. Among them, more than 95% of deposited NH_4^+ was converted to NO_3^- in the shallow soil layer. The decreasing trend of nitrate concentration was compensated by decreasing trend of base cations, resulting in relatively stable stream pHs and ANC. Base cations, except K^+, was depleted from this watershed. Those results imply that the NDW streams are not recovered from acidification yet, and the depletion of base cations was prolonging watershed recovery from acidification. Findings from this NDW study provide essential information to understand the biogeochemical processes inside and predict future water chemistry in high-elevation GRSM watersheds.

Acknowledgements

Research for this project was funded by the U.S. Department of Interior, National Park Service Cooperative Agreement Grant No. 1443-CA-5460-98-006 (Amendment 10), and the US Environmental Protection Agency through the University of Tennessee Natural Research Policy Center, USEPA Grant No. EM-83298901-1. Because of the 17-year monitoring effort, the individuals who have helped in sample collection, laboratory analysis, and data management over the years are too numerous to list. In recent years, we are thankful for the support of Keil Neff, Tom Zimmerman, and Lee Mauney.

Estimation of TMDLs and Margin of Safety Under Conditions of Uncertainty

Mohamed M. Hantush[1]

[1] National Risk Management Research Laboratory, U.S. EPA, Cincinnati, OH, 45268; PH (513) 569-7089; FAX (513) 569-7105; email: hantush.mohamed@epa.gov

ABSTRACT

In TMDL development, an adequate margin of safety (MOS) is required in the calculation process to provide a cushion needed because of uncertainties in the data and analysis. Current practices, however, rarely factor analysis' uncertainty in TMDL development and the MOS is largely arbitrarily selected. This paper presents a formal methodology for the estimation of TMDL and MOS as a function of analysis uncertainty, degree of protection provided, and fuzziness in water-quality standards. The probabilistic methodology is demonstrated through a hypothetical lake-sediment phosphorus model and eutrophication problem. Impacts of parametric uncertainty on the TMDL distribution and MOS are discussed. The performance of the widely used first-order approximation (FOA), with Gaussian and log-normal assumptions, is tested against the Monte Carlo (MC) method. The dependence of the MOS on the degree of protection provided against violating water quality standard is computed.

INTRODUCTION

Section 303(d) of the Clean Water Act (CWA) requires all states to develop and implement Total Maximum Daily Loadings (TMDLs) for their impaired water bodies and water bodies threatened to become impaired. Estimating the maximum load of pollutants that will not exceed water quality standards is part of the TMDL process and implies a known cause-and-effect relationship; once impaired water bodies are identified through assessment of water quality data collected by a variety of monitoring techniques, computer modeling is typically then used to estimate required reduction in pollutant loadings such that water quality standards are met within MOS. The MOS is intended to account for uncertainty about the relationship between pollutant loads and receiving water quality, and to provide a given degree of assurance that water quality standards will be met. Explicit and implicit approaches have been used for the estimation or selection of MOS (Dilks and Freedman, 2004; and Shirmohammadi et al., 2006). However, these approaches are subjective and, with a few exceptions (Borsuk et. al. 2002; Zhang and Yu, 2004; and Shirmohammadi et al., 2006), rarely have reflected model uncertainty in the MOS. Further, the relationship between the MOS and the degree of protection provided is opaque, if not existing, in most of the currently practiced TMDLs (Dilks and Freedman, 2004). In a comprehensive report, NRC (2001) cautioned against the practice of arbitrary selection of the MOS and instead recommended uncertainty analysis as the base for MOS determination.

While in current TMDLs development, fixed water quality numeric targets are often imposed, it is likely that these criteria are themselves subject to uncertainty. That is, the adequacy of the criterion as a measure (surrogate) for the designated use is not clear cut. For example, in TMDL analyses discrete impaired and unimpaired cutoffs do not exist in natural systems (U.S. EPA, 1999) and a degree of uncertainty might be associated with the designated-use water quality target value; in which case it is no longer known with certainty. Further, methods for selecting target values for designated use indicators invariably vary among experts and states. A TMDL based on a single, predefined criterion, therefore, might lead to a false sense of reliability in maintaining the designated use of a water body even when model uncertainty is factored into the analysis.

This paper outlines a probabilistic methodology for the estimation of TMDLs under conditions uncertainty. A formal methodology for the estimation of MOS on the basis of analysis' uncertainty as well as uncertainty in water quality standards is presented. The methodology, which is suitable for measurable water quality standards, relates calculated TMDLs and associated MOS to a prescribed degree of protection provided.

TMDLs

TMDL is the maximum pollutant load a water body can receive without violating water quality standards within margin of safety (MOS). This total load includes point sources (waste load discharge), nonpoint sources (stormwater runoff and groundwater flow), as well as MOS, which provides a cushion needed because of uncertainty naturally associated with estimates. A TMDL therefore can be expressed as

$$\text{TMDL} = \Sigma \text{WLA} + \Sigma \text{LA} + \text{MOS} \quad (1)$$

where TMDL is the system loading capacity or maximum pollutant load; WLA is point sources (wasteload) allocation; LA is nonpoint source load allocation including natural background; and MOS is margin of safety intended to account for uncertainty embedded in the analysis.

The most common approach for the estimation of MOS is the explicit selection of MOS as a percentage of the TMDL, a concept that is equivalent to a safety factor. The implicit approach is another widely adopted approach in which the margin of safety is introduced implicitly through the use of conservative assumptions in calculating the allowable load. In the implicit approach, neither the degree of protection nor the magnitude of the resulting MOS is known (Dilks and Freedman, 2004). In the explicit approach, model uncertainty is neither calculated nor reflected in the selection of MOS, and the TMDL calculation becomes independent of the level of uncertainty in the analysis or modeling exercise.

A formal methodology is presented below for TMDL estimation under conditions of uncertainty and from which MOS can be computed as a function of reliability (or degree of protection provided) and fuzziness in the water quality standard.

PROBABILISTIC RISK-BASED APPROACH

By definition (Eq. 1), a TMDL is a conservative estimate of the total point source and nonpoint source load that a water body can assimilate without violating water quality standards. Rather than relying on arbitrarily selected MOS, a more transparent

approach is to fully utilize the uncertainty in model predicted water quality indicator to insure compliance with designated-use criterion, but with a desired level of confidence. Such an approach makes explicit use of both uncertain estimate of water quality indicator and fuzzy designated-use criterion in TMDL estimation. Mathematically, the problem can be posed probabilistically as limiting the risk of violating water quality standards:

$$P\{Y \geq Z\} \leq \beta \tag{2}$$

where Y is a water quality indicator (e.g., pollutant concentration [ML^{-3}]) describing the condition of the water body, measured or predicted by empirical or mathematical models; Z is water quality numeric target selected for designated-use attainment of the water body; and β is the acceptable risk or probability of failure whose choice is a matter of policy. Y is random due to combinations of model inadequacies, parametric uncertainty, and measurement errors. If Y is purely based on observations, its uncertainty stems from natural (spatiotemporal) variability and measurement errors. Z is a random variable if viewed as a fuzzy, measurable surrogate for designated-use attainment.

By treating Z as a fuzzy measure, but known with confidence to fall in some range [a, b], a mathematical expression for the probability of noncompliance $P\{Y > Z\}$ can be obtained by integrating the joint probability density function $f_{Y,Z}(y,z)$ over the domain of criterion violation and assuming statistically independent Y and Z

$$\begin{aligned} P\{Y > Z\} &= \int_a^b \int_z^\infty f_{Y,Z}(y,z)\, dy\, dz \\ &= 1 - \int_a^b F_Y(z)\, f_Z(z)\, dz \end{aligned} \tag{3}$$

Certain water quality problems require the exceedance of a minimum threshold (e.g., oxygen levels), in which case, none compliance risk is $P\{Y \leq Z\} = 1 - P\{Y > Z\}$.

Equation 3 is useful if the analysis permits any of the known family of parametric distributions for both water-quality variable and the regulatory criterion. For example, a parametric PDF may be fit to measurements of Y using the method of moments or maximum-likelihood estimates. A suitable distribution for Z is the triangular distribution, $f_Z(z) \sim T(a,z_m,b)$, especially when available information reveals a most likely value in addition to minimum and maximum values of the variable

The noncompliance probability, $P\{Y > Z\}$, can be computed with MC simulation or by evaluating the integral in Eq. 3, analytically or numerically, for specific CDFs and PDFs of Y and Z, respectively.

In the following section, we demonstrate application of the theory to a hypothetical eutrophication TMDL problem. The selected water quality indicator for designated-use criterion is chlorophyll *a* concentration.

LAKE-PHOSPHORUS TMDL APPLICATION

Figure 1 depicts the conceptual lake-sediment-phosphorus model. The lake is divided into two completely-mixed compartments, water body and bottom sediments. Flow and sediment transport within lake are assumed at steady-state. Sediments enter and leave the lake by advection, subject to deposition to the lake bottom, resuspension back to the water column, and burial. The bottom sediment layer receives

depositional flux, releases some of the sediments back to the water column, and is buried by sedimentation. Phosphorus is usually highly sorbed to sediment particles and the dissolved component is assumed to be at equilibrium with the adsorbed phase in both the lake water and the bottom sediment. Mass transfer of dissolved phosphorus is assumed to occur across the sediment-water column interface by diffusion, and sediment-bound phosphorus is subject to resuspension.

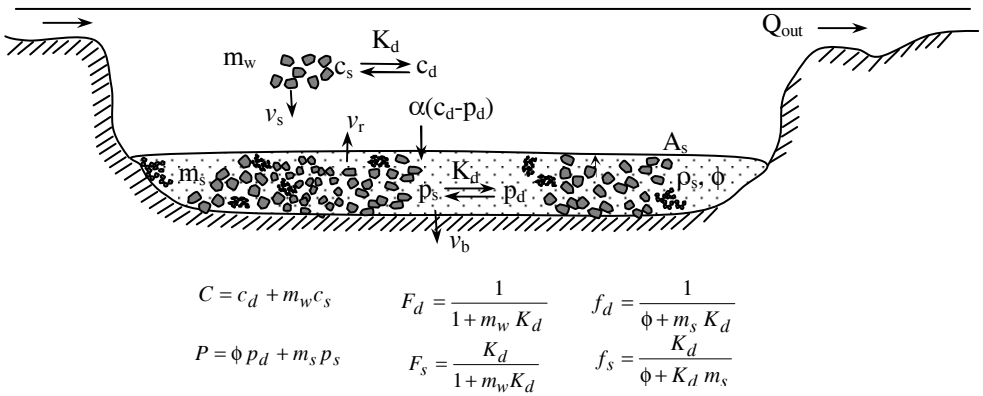

Figure 1. Schematics of lake-sediment phosphorus processes

Mass balance of sediment in lake can be described by the following ordinary differential equation (e.g., Chapra, 1997)

$$V\frac{dm_w}{dt} = Q_{in}\, m_{w,in} - v_s A_s\, m_w + v_r\, A_s\, m_s - Q_{out}\, m_w \tag{4}$$

Mass balance of lake-bottom sediment is

$$V_s\frac{dm_s}{dt} = v_s\, A_s\, m_w - v_r\, A_s\, m_s - v_b\, A_s\, m_s \tag{5}$$

Mass balance of total phosphorus in lake water

$$V\frac{dC}{dt} = Q_{in}\, C_{in} - v_s\, A_s F_s C + \alpha A_s (f_d P - F_d C) + v_r A_s\, f_s P - Q_{out}\, C \tag{6}$$

Mass balance of dissolved phosphorus in sediment

$$V_s\frac{dP}{dt} = v_s\, A_s F_s C - \alpha A_s (f_d P - F_d C) - v_r A_s f_s P - v_b A_s P \tag{7}$$

where m_w is sediment concentration in lake water [ML^{-3}]; $m_{w,in}$ is inflow sediment concentration [ML^{-3}]; m_s is lake-bottom sediment concentration [ML^{-3}]; C is total phosphorus concentration in lake water [ML^{-3}]; P is total phosphorus concentration in sediment layer [ML^{-3}]; V is lake water volume [L^3]; Q_{in} is lake inflow rate [L^3T^{-1}]; Q_{out} is lake outflow rate [L^3T^{-1}]; A_s is lake bottom surface area [L^2]; V_s is volume of sediment layer [L^{-3}]; v_s is settling velocity [LT^{-1}]; v_r is resuspension/recycling velocity [LT^{-1}]; v_b is burial velocity [LT^{-1}]; α is effective mass-transfer velocity coefficient at the sediment-water interface [T^{-1}]; f_d, f_s [L^3M^{-1}], F_d, and F_s [L^3M^{-1}] are partition coefficients relating dissolved and sorbed-phase phosphorus concentration to total phosphor concentration (equations shown in Fig. 1, where p_d is pore-water phosphorus concentration in bottom sediments [ML^{-3}]; p_s is sorbed phosphorus

concentration in bottom sediments [MM^{-1}]; K_d is phosphorus sorption coefficient [L^3M^{-1}]); ϕ is sediment layer porosity [L^3L^{-3}]; and ρ_s is sediment particle density [ML^{-3}]. For illustrative purposes, we assume $\alpha = D^*/\delta$, where D^* is free-water phosphorus diffusion coefficient [L^2T^{-1}]; and δ is thickness of sediment-water interface diffusion boundary layer [L].

The total phosphorus concentration and load input to the lake, respectively, are given by

$$C = c_d + m_w c_s \tag{8}$$

$$W = Q_{in} c_{d,in} + Q_{in} m_{w,in} c_{s,in} \tag{9}$$

where W is total phosphorus loading rate [MT^{-1}]; c_d is dissolved phosphorus concentration in lake water [ML^{-3}]; c_s is sediment-bound phosphorus concentration in lake water [MM^{-1}]; $c_{d,in}$ is inflow dissolved phosphorus concentration [ML^{-3}]; and $c_{s,in}$ is inflow sediment-bound phosphorus concentration [MM^{-1}].

Chlorophyll a, *Chl a*, which reflects the nuisance conditions caused by excessive algal blooms, is a more direct measure of eutrophication than total phosphorus concentration. For example, Schnoor (1996) report this Chl a-Total Phosphorus relationship

$$Y = 0.081\, C^{1.46}\ , \qquad R = 0.95 \tag{10}$$

where Y denotes *Chl a* concentration; both Y and C have the units of μg/L (mg/m^3).

Table 1 lists all model parameters, their units, and assumed probability distributions and related parameters selected from typical values and ranges reported in the literature. A hypothetical bottom lake surface area, A_s, of 5×10^6 m^2 is assumed. Dissolved phosphorus is assumed to be 5% of the sorbed phosphorus in (g/m^3): $c_{d,in} = 0.05\, m_{w,in}\, c_{s,in}$. Z is *Chl a* enforced water quality target concentration; it is assumed to be a random variable and follows a triangular distribution with minimum, most probable (mode), and maximum values of 2.7, 10, and 14 μg/L, respectively. $P\{Y>Z\} > 0.1$ implies a eutrophic condition at greater than 10% level of confidence, in which case, for the TMDL to be achieved with 90 % compliance, total phosphorus loading rate, W, should be reduced such that $P\{Y>Z\}\leq 0.1$.

Vollenwieder and Kerekes (1980) reported *Chl a* concentration between 2.7 and 78 μg/L as the range for eutrophication and 3 to 11 μg/L for mesotrophic status. The overlap is among the reasons for treating Z as a random variable whose probability distribution expresses the degree in one's belief that compliance based on particular Z values would restore or prevent the degradation of the water body.

Equations 4-7 are solved at steady state for C as a function of W and other related flow, hydrodynamic, and geochemical parameters. For simplicity, and without loss of generality, it is assumed that $Q_{out} = Q_{in} = Q$.

For each MC simulation 100,000 independent parameter sets were sampled by randomly generating parameter values from their respective PDFs in Table 1. An ensemble of model outputs was generated with 100,000 evaluations of the steady-state solution for C, and a similar size ensemble of Z was generated from its corresponding PDF in Table 1. The MC simulation and the sampled Z yielded $P\{Y \geq Z\} = 0.73$. A reduction in total phosphorus loading rate, W, was therefore needed to reduce $P\{Y \geq Z\}$ to 0.1 and achieve the TMDL at 90% compliance. From Eq. 9, it is

evident that either or both of the two variables $m_{w,in}$ and $c_{s,in}$ can be manipulated to achieve this target (recall, $c_{d,in}$ is assumed to be a fixed fraction of $c_{s,in}$).

Table 1. Lake-sediment phosphorus model parameters and assumed probability distributions

Parameter	Unit	Distribution	Parameter	Unit	Distribution
Q	m^3/yr	~N(2×10^8,2×10^6) [a]	D^*	m^2/yr	~U(1.5,2.32) [d]
$m_{w,in}$	g/m^3	~N(35,5)	δ	mm	~log-N(1.0,1.0)
$c_{s,in}$	g/g	~log-N(10^{-3},4×10^{-4})[b]	ϕ	m^3m^{-3}	~T(0.4,0.7,0.95)
v_s	m/yr	~log-N(37,20)	ρ_s	g/cm^3	~T(1,2.6,2.7)
K_d	m^3/g	~log-N(4.87×10^{-4}, 2.59×10^{-5})	Z	mg/m^3	~T(2.7,10,14)
v_b	m/yr	~T(8×10^{-4},0.005,0.01) [c]			

[a] N(λ, σ) denotes normally-distributed random variable with mean λ and standard deviation σ.
[b] log-N(λ, σ) denoted log-normally distributed random variable with mean λ and standard deviation σ.
[c] T(a,b,c) denotes triangular distribution of random variable with minimum value a, mode c, and maximum value c.
[d] U(a,b) denotes a uniformly distributed random variable in the interval [a,b].

Figure 2 depicts the results of two selected TMDL strategies; the first seeks the reduction of sediment loading concentration, $m_{w,in}$, and the second involves the reduction of sediment-bound phosphorus concentration, $c_{s,in}$. MC simulation and a nonlinear-based root's finding technique were implemented to identify the mean $m_{w,in}$, or mean $c_{s,in}$ such that $P\{Y \geq Z^*\} = 0.1$. The variance of both management-control variables was held constant during the search procedure. The search procedure was programmed and executed using MATLAB software.

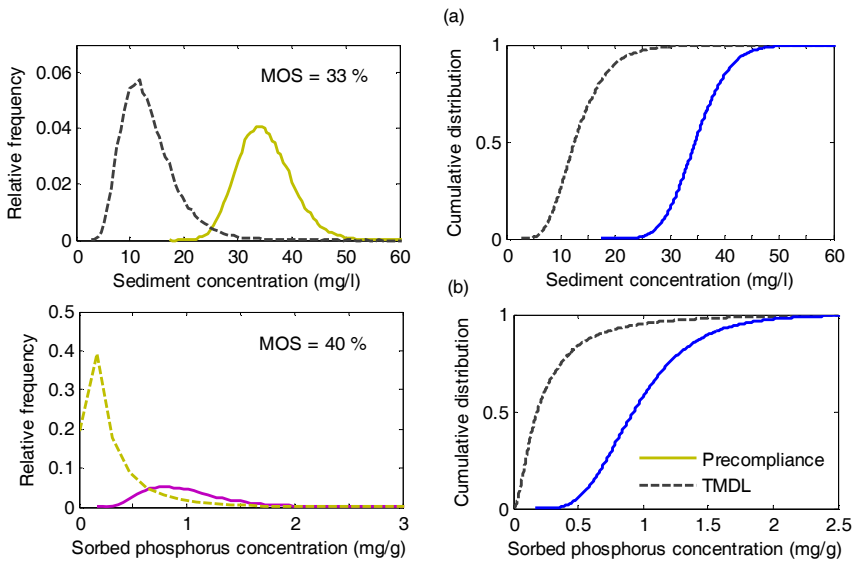

Figure 2. Monte Carlo simulated pre-compliance (solid-line) and 90% compliance (β =0.1) (dashed-line) relative frequencies and cumulative distributions: (a) Loading sediment concentration, $m_{w,in}$; and (b) loading sorbed phosphorus concentration, $c_{s,in}$. Results are based on MC simulation with 100,000 model runs.

The upper panel (a) in Fig. 2 shows relative frequency (100 bins) and cumulative distribution functions of pre-compliance sediment loading, $m_{w,in}$, and those required to achieve the phosphorus TMDL at 90% confidence (i.e., $\beta = 10\%$). The lower panel (b) shows similar output for the input sediment-bound phosphorus concentration, $c_{s,in}$. For the first strategy, an estimated 62% reduction in mean total phosphorus loading rate, W, was needed to meet the 10% requirement; whereas the second strategy yielded a higher 69% reduction in W.

The increased required load reduction in the second strategy compared to the first highlights the importance of parametric uncertainty on model estimated TMDL. Inspection of data in Table 1 shows higher uncertainty in $c_{s,in}$ than $m_{w,in}$: the coefficient of variation associated with the former is almost three times higher than the latter. Although not shown in a figure, the relative frequency of the computed total phosphorus TMDL was relatively more skewed to the left for the second strategy, in favor of higher probability densities for lower phosphorus loading rate values, than for the first strategy; again, this is attributed to higher uncertainty in $c_{s,in}$.

MARGIN OF SAFETY ((MOS)

Note that a TMDL has been computed taking into consideration uncertainty in the analysis and for a given risk of violating the water quality standard, but without an explicit reference to (or even the need for) the margin of safety (MOS). For completeness, however, MOS may be computed as a function of the desired degree of protection, but in a more rigorous and formal way than the aforementioned implicit and explicit approaches.

The MOS can be computed as the difference between required load reduction neglecting analysis uncertainty and the required load reduction taking into consideration the uncertainty. In a normalized form, MOS may be estimated as follows:

$$MOS = \frac{LR2 - LR1}{L_p} \times 100\,, \quad LR1 = L_p - L_c, \quad \text{LR2} = L_p^{*} - L_c^{*} \tag{11}$$

where L_p is pre-compliance load computed with expected parameter values (i.e., deterministic); L_c is compliance load computed with expected parameter values and expected Z; L_p^{*} is mean pre-compliance load based on random parameters and Z; and L_c^{*} is mean compliance load based on random parameters and Z. Noting that L_p is a first-order approximation of L_p^{*}, and for this particular example, $L_p \approx L_p^{*}$, we have

$$MOS \approx \frac{L_C - L_C^{*}}{L_p} \tag{12}$$

Note that the reduction in the required mean phosphorus load is expressed relative to the deterministic pre-compliance load. For the data in Table 1, MC simulation yielded MOS = 33% for the TMDL strategy involving $m_{w,in}$ as the management-control variable, whereas the strategy based on $c_{s,in}$ control produced MOS = 40%; these results are consistent with the estimated larger mean load reduction required for the second strategy, as discussed above.

Figure 3 plots MOS for the two management scenarios based on MC simulation of steady-state total phosphorus concentration, C, and normal and log-normal

approximation of *C*. For Gaussian and log-normal *C*, the mean and variance are estimated using First-Order Approximation (FOA) of steady-state *C* and evaluating the integral in Eq. 3 analytically for normal or log-normal *C*. MOS values computed on the basis of 100,000 MC model runs are deemed sufficiently accurate.

As the standard deviation of both $m_{w,in}$ or $c_{s,in}$ increases, the assumption of normality deviates and considerably overestimates the MOS values; this is evident when the coefficient of variation of both parameters exceeds one. The deviations are much less conspicuous for log-normal approximation of *C*; however, the computed MOS values underestimated the MC-based values.

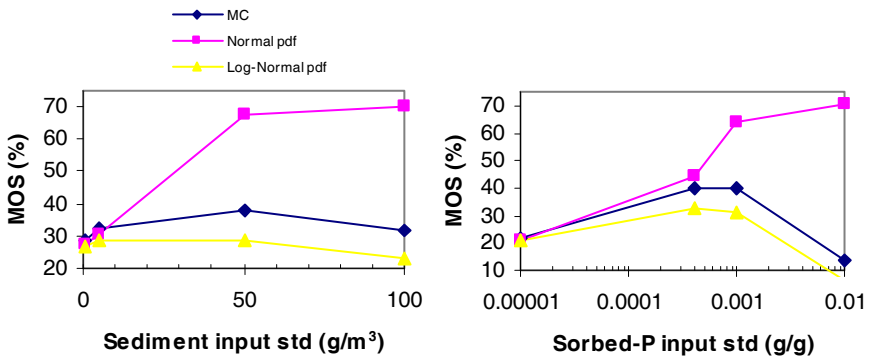

Figure 3. Comparison of MC method with FOA and normal and log-normal approximation of total phosphorus concentration, *C*.

The variation of MOS with β is shown in Fig. 4. The larger the value of β, the smaller the level of protection against violating the water quality standard, the smaller the MOS. Smaller β is associated with larger MOS, consequently, greater load reduction and costlier management actions.

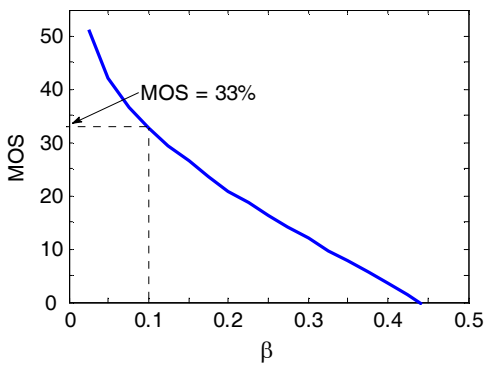

Figure 4. MOS versus β.

A NOTE ON BAYESIAN UPDATE

It's worth noting that as new monitoring data become available and more knowledge about the dynamics of total phosphorus are gained or better relationship between *Chl a* and *P* is identified, the computed TMDL distribution and associated MOS can be updated using Bayesian inferences and associated uncertainties might be reduced. With the knowledge gained and conditioning of prior TMDL and parameters'

distributions on new data, the initial TMDL forecast can be revised and improved. Consequently, reduction of the MOS can potentially lead to significant reduction in TMDL implementation cost. In this regard, Bayesian techniques that integrate model calibration with uncertainty estimation hold promise for adaptive TMDLs. Such techniques include the Generalized Likelihood Uncertainty Estimation method (GLUE) (Beven, 2006), classical Bayesian Analysis (e.g., Thiemann et al., 2001), and Ensemble Kalman Filtering (Kim et al., 2007). These methods are best positioned to address a TMDL within an adaptive implementation framework, because they combine the value of empirical evidence and modeling.

CONCLUSIONS

The margin of safety (MOS) in TMDL development is intended to account for the uncertainty embedded in the modeling exercise. Current practices, however, seldom consider model or analysis uncertainty as a basis for MOS estimation; instead, MOS is subjectively selected. Consequently, the relationship between calculated TMDL and MOS and the degree of protection provided is also left unknown in most of currently established TMDLs. This paper outlined a formal methodology for the estimation of TMDLs and required MOS under conditions of uncertainty.

A hypothetical lake-sediment phosphorus model illustrated the methodology; however, it can be extended to solve real TMDL problems through the use of system analysis and optimization. The PDF and CDF of the total phosphorus TMDL were derived using Monte Carlo (MC) simulation, and the associated MOS was computed on the basis of model uncertainty and as a function of the degree of protection provided (i.e., compliance probability).

The results showed that parametric uncertainty influences required mean total phosphorus load reduction, the probability distribution of required TMDL and associated MOS. Further, results illustrated that under relatively high parametric uncertainty the widely used first-order approximation and Gaussian or log-nomality assumption could lead to significant overestimation or underestimation of the MOS and exaggeration or underestimation of required load reductions to achieve the TMDL.

The value of monitoring and processes knowledge update on reducing uncertainty and revising TMDL estimation by means of Bayesian deductions has yet to be demonstrated and certainly constitutes an endeavor worthy of future research.

ABSTRACT

Probable maximum precipitation (PMP) is a common way to synthesize corresponding probable maximum floods (PMF) to design large hydraulic structures in short-data cases. The PMP for many stations in Iran and other places using the Hershfield formula is routinely estimated as the mean plus 15 standard deviations processed from one-day yearly maximum rainfall values. However, the value of 15 may not be suitable for all stations with different climatic specifications. In this paper, yearly maximum one day rainfall data of 23 synoptic and climatology stations in the four central provinces of Iran were analyzed in an attempt to estimate PMP for a one day duration based on an appropriate frequency factor. Based on the actual maximum daily rainfall data of these stations the highest value of frequency factors was found to be 7.63 for one day duration. The frequency factor obtained for each station was subsequently used to estimate one-day point PMP values. The mean ratio of one-day PMP values to the highest observed one-day rainfall was about 1.3 over the study area. The PMP maps are considered important tools to determine reliable and consistent estimates for any location in the area for large hydraulic structure designs. Using these PMP estimates a generalized pattern for the spatial distribution of one day PMP could be demonstrated.

Key words: PMP, precipitation, Iran, frequency.

INTRODUCTION

The need for the development of water resources has become of considerable importance with a view to ensuring sufficient potable and industrial water supplies, providing irrigation for food production, flood control and power generation. As a result, great amounts of money are invested each year for the construction of different water resources projects such as large dams, diversion dams, storage reservoirs, etc. Probable maximum precipitation (PMP) is a common way to synthesize corresponding probable maximum floods (PMF) in short-data cases.

The PMP is defined as the greatest depth of precipitation for a given duration that is meteorologically possible over a given station or a particular area and geographical location at a certain time of year (WMO, 1986). This definition has remained largely unchanged since first being introduced by United States meteorologists in the middle 1930's, and makes no allowance for the effects of climate change.

There are two main methods for calculating PMP including hydro-meteorological approaches and statistical analyses of extreme rainfalls. Due to the shortage of data for applying the first method, there is a great tendency to adopt the second one. In statistical approaches the estimates of PMP rainfall at a particular location or area are determined from the frequency distribution fitted to the annual maximum rainfall data. Therefore, the method requires a series of maximum annual daily rainfall at an observation point, yet the partial duration series may also be an alternative (Ghahraman, 2004).

Hershfield (1961, 1965) was a pioneer who developed a statistical method for estimating PMP values for small areas around the world. The use of the Hershfield method has shown that the PMP estimates obtained by this method are closely comparable to those obtained by the elaborate physical method. Having this in mind, several researches in Iran have employed Hershfield's statistical techniques extensively for estimating PMP for stations having a long period of rainfall records (Ghahraman, 1994; Khalaji, 2002). The purpose of this study is to carryout a study on the estimation of PMP for a 24-h duration using the Hershfield technique for 23 synoptic and climatology stations in four central provinces of Iran with sufficient daily rainfall data.

STUDY AREA AND DATA USED

Maximum annual daily rainfall data series of 23 synoptic and climatology stations in four central provinces of Iran (Tehran, Qum, Markazi and Semnan provinces) were used for PMP estimations. The provinces are located in arid and semi-arid parts of Iran.

The data were obtained from Iran meteorological organization archive. The stations with the data length less than 12 years were not considered in obtaining the estimates of the point PMP values. The names of the stations with record lengths larger than 12 years are given in table 1. The data lengths ranged from 12 to 52 years with a mean of 25 years.

METHODOLOGY

The Hershfield technique for estimating PMP is an adopted version of Chow (1951) technique of frequency analysis of rainfall. Hershfield (1961, 1965) considered that for PMP estimation, there is a value of frequency factor which will not be exceeded, say K_m. He then modified chow's equation as:

$$X_{PMP} = \overline{X}_n + K_m \sigma_n \tag{1}$$

Where X_{PMP} is PMP for a given set of data, $\overline{X}_n$ and σ_n are the mean and standard deviation of annual maximum, respectively. The K_m factor is simply calculated using the fallowing equation:

$$K_m = \left(X_1 - \overline{X}_{n-1}\right) / \sigma_{n-1} \tag{2}$$

Where X_1 is the highest observed annual maximum rainfall in the series, and $\overline{X}_{n-1}$ and σ_{n-1} are the mean and standard deviation of the annual maximum, respectively, when the highest value is excluded in calculating the parameters.

Rainfall data were thoroughly checked and any doubtful observations were discarded. For each station, the annual maximum series of a one day maximum amount of rainfall was selected and an array of annual maximum values of rainfall was formed.

HOMOGENITY OF THE DATA SERIES

The use of longer series in the estimation of PMP is only valid if they show no long-term changes in their behavior.

The homogeneity of all 23 series was checked bye a non-parametric Mann-Kendall rank test (WMO, 1966). The Mann-Kendall rank method has been suggested as a powerful test by Kendall and Stuart (1961). The statistic τ is computed by using the formula:

$$\tau = \frac{4\sum n_i}{N(N-1)} - 1 \tag{3}$$

Where: n_i is the number of values larger than the i^{th} value in the series subsequent to its position in the time series of N values. The expected value of τ in a random series is 0 and its standard deviation (σ_τ) is given by:

$$\sigma_\tau = \sqrt{\{(4N+10)/[9N(N-1)]\}} \quad (4)$$

The ratio of τ to σ_τ, is considered as an indication of a possible trend in the data. For no trend in the data series this value lies within the limits of ± 1.96 at the 5% level significance. Afterwards K_m value and the corresponding one day PMP value were determined using Eqs. (2) and (1), respectively, for all 23 stations.

An average factor of 1.13 (e.g. Tomlinson, 1980) was used to convert one day PMP estimates into 24-h PMP.

STATISTICAL ESTIMATES OF PMP

One day annual maximum rainfall values of 23 stations were analyzed to extract the station-based PMP estimates. The values of $\overline{X}_n$, $\overline{X}_{n-1}$, σ_n, σ_{n-1} and a coefficient of variability ($CV = \frac{\sigma_n}{\overline{X}_n}$) were also calculated. The frequency factor (K_m) was determined for each station using Eq. (2). The results are summarized in table 2. As indicated, the values are mostly less than 4. Only four values were found between 4 and 7.63, with the latter being the upper limit of the estimated K_m. As PMP deals with unusual rainfall values, the corresponding frequency factor must also be chosen from the extremely high values. One support for the K_m value 7.63 could be found in Desa et al (2001). These authors derived $K_m = 8.7$ as an upper limit for a humid region of Malaysia. Desa et al (2001) used 33 stations with 30-60 years of data each. Ghahraman (2008) in his studies on 30 stations in a watershed located at north-east of Iran derived a value of $K_m = 9.63$ and applied this value for PMP estimations. Yet it may be acknowledged that K_m is highly dependent on the climatic conditions of the study area. Hershfield (1965) showed that empirically derived coefficient K_m varies directly with rainfall duration and inversely with the mean of the series.

This result implies that $K_m = 15$, (Hershfield, 1961) gives an overestimated value for PMP in the study area.

Using K_m values, the mean and standard deviation for each station, one day point PMP values for all the stations were computed using Eq. (1). An average factor of 1.13 (e.g. Tomlinson, 1980) was used to convert one day PMP estimates into 24-h PMP. The values of the mean, the standard deviation and the corresponding PMP for all the 23 stations are given in table 2. The observed one day highest rainfalls, as well as the ratio of estimated PMP to these rainfall values, are shown to facilitate comparisons. For different stations this ratio varies between 1.18 and 1.53 with a mean of 1.3. Desa et al (2001) reported similar values ranging from 1.5 to 2.7 which are higher than those obtained in this study. Such variation may originate from: (a) stations with different microclimates, and (b) a different record length of stations. One possible reason may also be due to the dryness of the study area which may produce more severe rainfall and also more variability of rainfall among different years (it also

is supported by higher K_m values of Attrak watershed (Ghahraman, 2004) as compared with Malaysia.

CONCLUSION

The main purpose of this study was to introduce a simple standardized method of PMP computation. Statistical estimates of 24-h PMP for 23 stations in four central provinces in Iran were made using an appropriate frequency factor for each station.

Based on these PMP estimates, a generalized map could be prepared showing the spatial distribution of 24-h PMP. The PMP ranges from 44.1mm over Hosseinan station to 101.2 mm on the Shamsabad-Arak station. The ratio of 24-h PMP to the highest observation ranges from 1.18 to 1.53 with an average of 1.3. The mean ratio of 24-h PMP to the mean one day maximum rainfall was 2.62. The point PMP rainfall estimates can be converted into areal PMP estimates using a depth-area relationship. This method could be recommended for other regions; however, future records may be needed to verify the ensuing results of PMP and the corresponding resulted PMF values.

Table 2- Frequency factors and 24-h PMP estimates for stations in the study area

ABSTRACT

The Rational equation is often thought of as being less sophisticated and less accurate than regional flood frequency equations. As such, the application of the Rational equation is typically limited to small watersheds. This paper compares the Rational equation with regional flood frequency equations for 72 gaged rural watersheds in Kansas. The Rational equation is found to perform better than the regional flood frequency equations, as long as appropriate values of the Rational C are selected.

INTRODUCTION

Engineers have several options for estimating flood quantiles, or peak flood discharges for given return periods. These options include flood frequency analysis, regional flood frequency analysis, watershed modeling, and the Rational equation ($Q_T = C\ i_T\ A$). Although the Rational equation is widely used, it is often dismissed by engineers as a rule-of-thumb method. In most cases, the application of the Rational equation is limited to very small watersheds. The definition of 'small' varies, but typical upper limits for the equation range from 200 acres to one square mile. Due to these limitations, the Rational method is commonly used only for sizing storm sewer components and small culverts.

When designing large culverts and bridges, engineers generally use regional flood frequency equations or watershed modeling. Regional flood frequency equations are constructed via multiple linear regression analysis of flood quantiles and watershed characteristics. These equations are often thought to be more sophisticated and more accurate than the Rational equation.

The purpose of this paper is to compare the Rational equation with regional flood frequency equations. The comparison uses data for 72 gaged, rural watersheds in Kansas.

DATA

The watersheds selected for this study are smaller than 30 mi^2 and have USGS streamflow gaging records that are twenty years or longer. All watersheds used for this analysis are rural and are not significantly regulated by flood control structures. The 72 watersheds range in size from 0.17 to 29.6 mi^2, with an average size of 7.76 mi^2. The average watershed land cover is 62% (+/- 20%) grassland or pasture, 33% (+/- 20%) cropland, and generally less than 5% forest, urban, or other uses. Figure 1 shows the locations of the 72 gages across the State of Kansas, along with contours of mean annual precipitation.

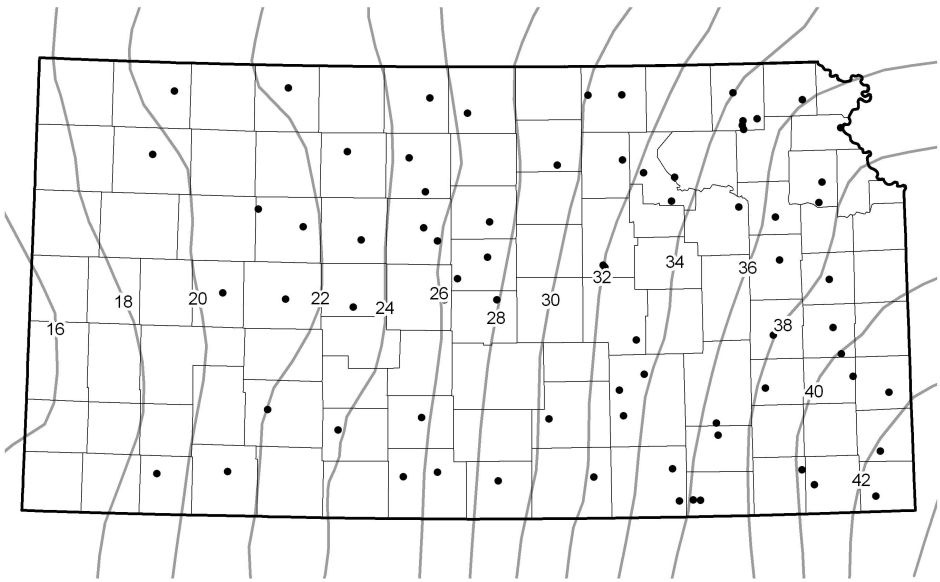

Figure 1. Locations of 72 Gaged Watersheds and MAP Contours

Six flood quantiles (the Q_2, Q_5, Q_{10}, Q_{25}, Q_{50}, and Q_{100}) were estimated for each watershed in accordance with Bulletin 17B methods using the software package PEAKFQ (Flynn et al. 1992). Watershed characteristics were assembled for all gaged locations; these characteristics are listed in Table 1. A brief description of how each variable was determined follows.

Drainage areas were delineated and measured in ArcGIS 9.2, using scanned and georectified USGS 7.5-minute topographic maps, also called Digital Raster Graphics (DRGs). The watershed shape factor was computed as:

$$Sh = \frac{L^2}{A} \tag{1}$$

where L is the main channel length (in miles) and A is the drainage area (in mi^2). The average main channel slope was determined as:

$$Sl = \frac{El_{85} - El_{10}}{0.75 \cdot L} \quad (2)$$

where El_{85} and El_{10} are the elevations (in feet) 85% and 10% of the way up the channel from the watershed outlet to the basin divide.

Table 1. Watershed Characteristics Used in Analysis

Symbol	Watershed Characteristic	Units
A	Drainage Area	mi^2
Sh	Basin Shape Factor	--
Sl	Average Slope of Main Channel	ft/mi
SP	Generalized Soil Permeability	in/hr
CN	NRCS Runoff Curve Number	--
i_T	Rainfall Intensity, $i(T,t_c)$	in/hr
MAP	Mean Annual Precipitation	in
MAE	Mean Annual Lake Evaporation	in
MAD	Mean Annual Precipitation Deficit	in

Generalized soil permeability (SP) was determined using the STATSGO soils database (USDA 1994) produced by the Natural Resources Conservation Service (NRCS). The NRCS runoff curve number (CN) was estimated using the hydrologic soil group of the watershed obtained from the STATSGO soils map of Kansas and the landcover as designated by the USGS National Landcover Dataset (NLCD) of 1992. The rainfall intensities for duration = t_c and recurrence interval T were obtained from the KDOT rainfall intensity-duration-frequency tables, which were in turn compiled from HYDRO-35 (Frederick et al. 1977) for durations less than or equal to one hour and from TP-40 (Hershfield 1961) for durations in excess of one hour. The mean annual precipitation was obtained from 1960-1990 climate normals (Rasmussen and Perry 2000). The mean annual lake evaporation was obtained from a National Weather Service (NWS) evaporation atlas (Farnsworth et al. 1982). The mean annual precipitaton deficit was computed as:

$$MAD = MAE - MAP \quad (3)$$

METHODOLOGY

Regional flood frequency relations are typically constructed using multiple linear regression of the $\log_{10}$ of peak discharge (Q_T) against the log-transforms of a variety of predictor variables. The basic form of such regional flood frequency equations is:

$$Q_T = 10^{\alpha} \cdot X_1^{\beta_1} \cdot X_2^{\beta_2} \cdots \quad (4)$$

where X_1, X_2, etc. are the predictor variables and α, β_1, β_2, etc. are coefficients determined using least-squares regression on the $\log_{10}$-transforms of the variables.

Regional flood frequency analysis was performed using the $\log_{10}$-transforms of the variables listed in Table 1. Forward stepwise linear regression was used to find equations for the flood discharges (Q_T). Regression relationships were compared on the basis of the coefficient of determination, R^2; the adjusted R^2; and the standard error of the estimate, S_e. Equations were evaluated for statistical significance using an F-test (H_0: regression not significant, H_A: regression is significant) with a confidence level equal to 95%. The statistical significance of each regression parameter was determined using a t-test (H_0: parameter coefficient equal to zero, H_A: parameter coefficient not equal to zero) also using a confidence level equal to 95%.

The data assembled for each location were also used to compute Rational C values for the six recurrence intervals (2-year through 100-year) by solving the Rational equation for C:

$$C = \frac{Q_T}{i \cdot A} \quad (5)$$

Multiple linear regression analysis was used to develop predictive equations for the Rational C as a function of the watershed characteristics listed in Table 1. The Rational equation was then compared against the regional flood frequency equations.

RESULTS AND ANALYSIS

Tables 2 and 3 give the best two- and three-parameter regression equations determined for the flood quantiles. The best two-parameter equations all include the drainage area and either the MAP or rainfall intensity as predictors. This is consistent with the standard USGS regression equations for Kansas for watershed areas less than 30 mi^2, which are of the form:

$$Q_T = a \cdot MAP^{\beta_1} \cdot A^{\beta_2} \quad (6)$$

The standard error (in $\log_{10}$ terms) for the two-parameter equations ranges from 0.199 to 0.260.

The best three-parameter equations all include the drainage area, MAP, and rainfall intensity as predictors – except for the equation for Q_2. The standard error (in $\log_{10}$ terms) for the three-parameter equations ranges from 0.178 to 0.245. For all but one flood quantile, the three-parameter equations shown in Table 3 were the best overall equations (in one case a four-parameter equation was slightly better).

It is interesting to note that the exponents on i and A in the three-parameter equations (Table 3) are all very near one. Young et al. (2009) demonstrate that the exponents for i and A are in fact statistically indistinguishable from one, and that the equations in Table 3 can be re-written in the form of the Rational equation, with C being a function of the mean annual precipitation.

Table 2. Two-Parameter Regional Flood Frequency Equations

Equation	Adj. R^2	S_e
$Q_2 = 0.00372\ A^{0.591}\ MAP^{3.155}$	0.804	0.210
$Q_5 = 0.0723\ A^{0.607}\ MAP^{2.529}$	0.795	0.199
$Q_{10} = 0.278\ A^{0.617}\ MAP^{2.253}$	0.766	0.211

Once the regression equations for Tables 2 and 3 were established, another analysis was performed to develop a predictive equation for the Rational C as a function of watershed characteristics. The Rational C was computed for each watershed for each recurrence interval using Eq. 5. Young et al. (2009) discuss the Rational C values established for the 72 watersheds in Kansas. This paper focuses on the development of a predictive equation for C. Forward stepwise linear regression showed that only one-predictor equations were statistically significant for the Rational C for all recurrence intervals. In each case, the best predictor of Rational C was the mean annual precipitation. Table 4 shows the correlations between the $\log_{10}(C_{25})$ and the $\log_{10}$s of the various watershed characteristics.

Table 4. Correlations Coefficients for $\log_{10}(C_{25})$ vs. $\log_{10}$(Predictor)

Predictor	Correlation Coeff.
A	0.07
Sh	-0.23
Sl	-0.02
SP	-0.42
CN	0.37
i_{25}	0.08
MAP	0.57
MAE	-0.47
MAD	-0.55

As shown in Table 4, the best predictor for the C_{25} was the mean annual precipitation. Interestingly, the MAP is a much better predictor of C than the NRCS runoff curve number (CN). This held true for all six recurrence intervals. Table 5 shows the regression equations for the Rational C for all six recurrence intervals, along with the standard errors for the Rational equation.

Table 6 lists the standard errors for the 2- and 3-parameter regional regression equations, along with the standard errors for the Rational equation. For all but the 2-year recurrence interval, the Rational equation yields lower standard errors than the regional regression equations.

Table 5. Regression Equations for Rational C with S_e for the Estimate of Q_T in Log Units

Equation		S_e (log units)
$Q_2 = C\ i_2\ A$,	$C = 0.0000366\ MAP^{2.53}$	0.192
$Q_5 = C\ i_5\ A$,	$C = 0.000440\ MAP^{1.97}$	0.176
$Q_{10} = C\ i_{10}\ A$,	$C = 0.00137\ MAP^{1.72}$	0.187
$Q_{25} = C\ i_{25}\ A$,	$C = 0.00397\ MAP^{1.48}$	0.209
$Q_{50} = C\ i_{50}\ A$,	$C = 0.000724\ MAP^{1.35}$	0.227
$Q_{100} = C\ i_{100}\ A$,	$C = 0.0121\ MAP^{1.24}$	0.224

Table 6. Comparison of Standard Errors (in log units) for the Regression and Rational Equations

Flood Quantile	S_e for 2-Param.	S_e for 3-Param.	S_e for Rational
Q_2	0.210	0.187	0.192
Q_5	0.199	0.178	0.176
Q_{10}	0.211	0.189	0.187
Q_{25}	0.232	0.210	0.209
Q_{50}	0.248	0.227	0.227
Q_{100}	0.260	0.245	0.224

DISCUSSION AND CONCLUSION

The findings of this study show that the Rational equation can outperform traditional regional regression equations, as long as appropriate values of the runoff coefficient are used. This contradicts conventional wisdom, which holds that the Rational equation is less sophisticated and less accurate than regression equations. The research for this study also indicates that the form of the rational equation is appropriate for watersheds larger than typically assumed. The correlation analysis presented in Table 4 shows that the Rational C is independent of drainage area.

One reason that the Rational equation may outperform regression equations is the Rational equation actually considers more predictive variables. At first glance, the Rational equation appears to include only three predictors: the C value, rainfall intensity, and drainage area. However, the rainfall intensity is a function of both watershed location (the local extreme rainfall climatology) and the watershed time of concentration. The time of concentration, in turn, is a function of the length and slope of the watershed main channel. As such, the Rational equation assimilates more information about the watershed than do most regional flood frequency equations.

The Rational method has been in widespread use for decades and has been used to design billions of dollars of drainage infrastructure. Many engineers assume that the Rational method is a rule-of-thumb technique, or that it is inferior to regional flood frequency equations. This paper demonstrates that the Rational method can actually work better than regional regression equations, as long as the Rational C values are properly determined for the area of interest.

The equations in this report were developed for watersheds in the State of Kansas and should not be used elsewhere.

ABSTRACT

Sediment particle transport can be viewed as a Markov chain. In a nonequilibrium condition, the interchange of sediment particles occurs not only between the bedload layer and the bed surface, but also across the interface between bedload and suspended load. The bedload transport rate is the product of the total particle volume in saltation and the average saltating velocity. We can quantify the number of saltating particles by modeling the occupancy probabilities vector of particles staying in three states (i.e., bed surface, bedload layer, and the interchange layer between the bedload and the suspended load.). The new stochastic bedload relation is validated against existing bedload model (Soong and Graf 1997). The influence of sudden changes in flow-sediment properties on the bedload transport rate is investigated in this preliminary study.

INTRODUCTION

Most of bedload transport formulas in literature were based on the empirical or semi-empirical flow-transport relations that are only valid for equilibrium conditions. Traditional stochastic bed load models aimed to solve for the equilibrium bedload transport rate by matching the rate of bed erosion with the rate of deposition (Einstein, 1950; Wu and Yang, 2004). Bedload transport can be in nonequilibrium even under the steady flow condition, as the quantity of moving particles in the bedload layer may vary. In the nonequilibrium condition, the interchange of sediment particles happens not only between bedload layer and the bed surface, but also across the interface between bedload and suspended load. Current stochastic approaches in the bedload transport mostly consider only the particle interchange between the bed surface and the bedload layer, and are restricted to equilibrium conditions. The proposed stochastic approach attempts to circumvent this deficiency by adding a bedload-suspended load interchange layer to model particle movement under nonequilibrium conditions.

Particle interchange across the bedload layer can be viewed as a Markov process. A Markov process is a stochastic process where the future development of the process only depends on the present value, not on the past ones. Markov process is simple to use and has broad applications to engineering systems. The number of instantaneous moving particle in the bedload layer can be quantified based on the master equations of the

Markov process. At each time step, a sediment particle may change its state from the current state to the adjacent state, or remain in the same state, in conformity with respective transition probabilities. These transition probabilities are functions of flow conditions and sediment characteristics, and their relations were frequently discussed in literature. The bedload transport rate may reach a constant value (i.e., equilibrium condition) given fixed transition probabilities in a long run. Once the values of transition probabilities vary due to sudden changes of flow and/or sediment conditions, the bedload rate would change correspondingly and deviate from its equilibrium value. The influence of suddenly changed flow-sediment properties on the bedload transport rate has not been fully explored in literature.

MODEL DEVELOPMENT

The bedload transport rate, q_b, is equal to the total volume of moving particles in the bedload layer multiplied by particle moving velocity ,

$$q_b = N_2 V_p u_s \tag{1}$$

where N_2 denotes the number of sediment particles in saltation (or rolling, sliding, as special cases of saltation.) per unit bed area. V_p is the average single particle volume. We define N_1 and N_3 as the number of bed particles and suspended particles, in an active exchange process with saltating particles, respectively.

$$N_1 = N \Pr_1, \quad N_2 = N \Pr_2, \quad N_3 = N \Pr_3 \tag{2}$$

where $N = N_1 + N_2 + N_3$ is the total number of sediment particles in the exchange process. $\Pr_i$ is the occupancy probability of particles in i state. $i = 1$ is the state of sediment particle resting on the bed surface; $i = 2$ represents the state of sediment particle in saltation in the bedload layer; $i = 3$ is the state of suspended sediment particle in an active exchange process with bedload particles. State 3 is postulated to be confined to a thin layer on the top of the bedload boundary, and it can be viewed as the exchange layer between suspended load and bedload. All bedload particles are entrained into suspension through this layer, and vice verse.

The total number N of exchanging particles is unknown. However, the number of active exchanging suspended particles N_3 can be taken as constant, which can be deduced from the equilibrium near bed suspended sediment concentration c_a. Here, the following relations derived by van Rijn (1984b) are followed:

$$c_a = 0.015\frac{d_{50}T^{1.5}}{aD_*^{0.3}},\quad T = \frac{(u_*')^2 - (u_{*c})^2}{(u_{*c})^2},\quad D_* = d_{50}\left[\frac{(s_s - 1)g}{v^2}\right]^{1/3} \tag{3}$$

where d_{50} = median diameter of sediment particle ($d_{50} = d$ here for uniform sediment particles); u_{*c} = critical bed-shear velocity obtained from the Shields diagram; $u_*' = g^{0.5}U / C'$ is effective bed shear velocity related to grains; U = mean flow velocity; $C' = 18\log(12R_b / 3d_{90})$ = Chézy-coefficient related to grains; R_b = hydraulic radius related to the bed obtained from Vanoni and Brooks (1957); d_{90} = 90% passing bed particle diameter; $s_s = \rho_s / \rho$ is the specific gravity; v = kinematic viscosity coefficient; a = reference level above bed. van Rijn (1984b) set a equal to half the bed-form height, or the equilibrium roughness height, with a minimum value of $0.01d$. In the present analysis, the reference level a is set equal to an average saltation height, h_s. The exchange layer between suspended load and bedload is hypothesized to have the thickness of one sediment diameter height. Then,

$$N_3 = \frac{c_a d}{V_p} \tag{4}$$

And total number N of exchanging particles can be found as

$$N = N_3 / \Pr_3 \tag{5}$$

The transition probabilities in the exchange process between these three states can be expressed as the following matrix:

$$P_{ij} = \begin{bmatrix} P_{11} & P_{12} & P_{13} \\ P_{21} & P_{22} & P_{23} \\ P_{31} & P_{32} & P_{33} \end{bmatrix} = \begin{bmatrix} 1 - P_{12} & P_{12} & 0 \\ P_{21} & 1 - P_{21} - P_{23} & P_{23} \\ 0 & P_{32} & 1 - P_{32} \end{bmatrix} \tag{6}$$

where P_{12} is the probability of bed erosion into bedload layer and defined as $P_{12} = P(F_L > W)$. Einstein (1950) assumed the lift force F_L acting on bed particle follows a Gaussian distribution. $W = (\rho_s - \rho)gV_P$ is the submerged weight. The formula of F_L is from Cheng and Chiew (1998):

$$F_L = C_L \frac{\pi d^2}{4}\frac{\rho u_b^2}{2} \tag{7}$$

in which u_b = instantaneous flow velocity approaching the bed particle; $C_L = 0.2$ is the

lift coefficient. Cheng and Chiew (1998) assumed that u_b follows the Gaussian distribution instead of F_L, and they derived the formula of P_{12}:

$$P_{12} = 1 - 0.5\frac{B-\overline{u_b}}{\left|B-\overline{u_b}\right|}\sqrt{1-\exp\left[-\frac{2\left(B-\overline{u_b}\right)^2}{\pi\sigma^2}\right]} - 0.5\sqrt{1-\exp\left[-\frac{2\left(B+\overline{u_b}\right)^2}{\pi\sigma^2}\right]} \tag{8}$$

$$B = \sqrt{\frac{4s_s gd}{3C_L}}$$

where $\overline{u_b}$ is the time averaged velocity acting on the bed particle, and $\overline{u_b} = 5.52u_*$ when we assume the bed particle level as $y_b = 0.6d$; $\sigma = \sqrt{\overline{\left(u_b - \overline{u_b}\right)^2}}$ is the longitudinal intensity of turbulence, and $\sigma = 2u_*$ (Cheng and Chiew, 1998).

It is assumed that the channel bed is formed by randomly packed spheres and the relative vertical position of bed particle is also random. A saltating particle may come to rest when it falls into a "hole" in the bed, which can be assumed to be of the Gaussian distribution. The value of P_{21} is related to bed irregularity and needs to be determined from experiment. In this paper, P_{21} is assumed to be proportional to P_{12}, and the ratio α_s has the magnitude of 0.1.

In turbulent flow, bedload is entrained into suspension when the vertical velocity fluctuation v' of the flow exceeds the settling velocity w of the sediment particle. The probability of suspension is $P_{23} = P(v' > w)$, which is also assumed to follow the Gaussian distribution. P_{23} is approximated as follows (Cheng and Chiew, 1999).

$$P_{23} = 0.5 - 0.5\sqrt{1-\exp\left(-\frac{2}{\pi}\frac{w^2}{u_*^2}\right)} \tag{9}$$

It is noted that the probability of the complementary event $P(v' < w) = 1 - P_{23}$ can be viewed as the probability of the termination of suspension (or deposition probability). But this happens throughout the suspended load layer. The deposition probability at the exchange layer between suspended load and bedload should be smaller than $(1 - P_{23})$. Let $P_{32} = \alpha_d(1 - P_{23})$ and α_d is a coefficient less than 1. We propose that α_d is equal to the ratio of N_3 to the total number of suspended sediment. This ratio can be determined from the suspended sediment concentration profile.

The occupancy probabilities of particles at i th step is denoted by

$$\mathrm{Pr}^{(i)} = \begin{bmatrix} \mathrm{Pr}_1^{(i)} \\ \mathrm{Pr}_2^{(i)} \\ \mathrm{Pr}_3^{(i)} \end{bmatrix} \tag{10}$$

After n exchanging steps

$$\mathrm{Pr}^{(n)} = \mathrm{Pr}^{(0)} P_{ij}^{\ n} \tag{11}$$

$\mathrm{Pr}^{(0)}$ is the initial occupancy probabilities. P_{ij} is the transitional probability The new $\mathrm{Pr}_2^{(n)}$ from Eq. (11) would lead to the bedload transport rate q_b after n exchanging steps using Eq. 1 and Eq. 3.

When n is large enough ($n > 500$), $\mathrm{Pr}^{(n)} = \mathrm{Pr}^{(n-1)}$ and q_b will approach a constant. This constant q_b is the bedload transport capacity as shown in Fig. 1. The time step is the exchange time t_e, which is the time necessary for sediment particle to make a single transition from one state to another. The ratio d/w is often used to represent the time scale of particle saltation in literature. Herein, assume $t_e = \alpha_t d/w$ and α_t is between 1-2. It is found that t_e has the magnitude at around 0.05 seconds.

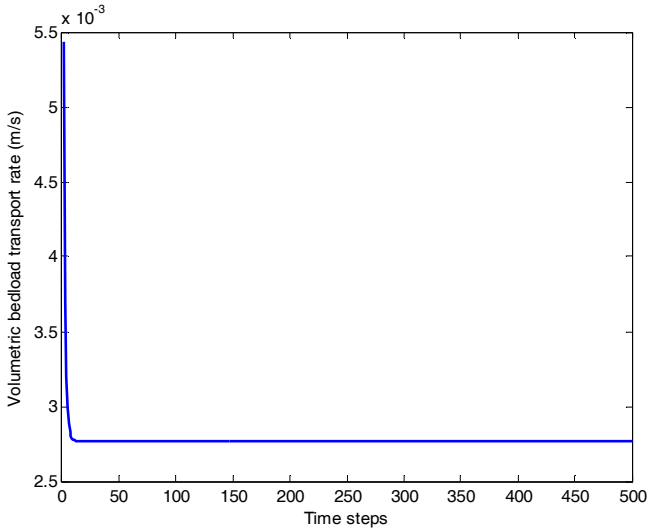

Figure 1. Volumetric bedload transport rate ($v_s = 0.5$ m/s; $h_s = 1.5d$; $d = 5.8$ mm; $U = 1.5$ m/s; averaged flow depth $h = 3$ m; channel width $b = 10$ m; bed slope $S = 0.001$; $s_s = 1.65$; $u_{*c} = 0.02$ m/s; drag coefficient $C_D = 0.5$; $\alpha_d = 0.8$; $\alpha_s = 0.05$).
Asymptotic transitional probabilities $P_{12} = 0.4378$, $P_{23} = 0.0083$, $P_{32} = 0.7934$, $P_{21} = 0.0219$. Note: all the following figures have the same parameter values.

MODEL VALIDATION

Graf's bedload formula

The bedload capacity results can be compared with the bedload transport formula derived under an equilibrium condition. The semi-empirical formula from Song and Graf (1997) is used here for this comparison:

$$\Phi = 10.4\mathrm{K}\Psi^{-1.5} \tag{12a}$$

$$\Phi = \frac{(q_b/q)UR}{\sqrt{(s_s-1)gd^3}} \qquad \Psi = \frac{(s_s-1)d}{RS_f} \tag{12b}$$

$$\mathrm{K} = \begin{cases} \Psi^{-1} & \Psi \le 14.6 \\ (1-0.045\Psi)^{2.5} & 14.6 < \Psi \le 22 \\ 0 & \Psi > 22 \end{cases} \tag{12c}$$

where Φ is the Einstein's dimensionless transport rate, and Ψ is the reciprocal of the dimensionless parameter of flow intensity; q the average flow rate per unit width ($q = UH$). R is the hydraulic radius, and herein $R = R_b$. S_f is the friction slope. Based on the given particle and flow conditions as depicted in Figure 1, it is found that the volumetric bedload transport rate by the proposed model agrees reasonably well with the bed load transport rate predicted by Soong and Graf (1997).

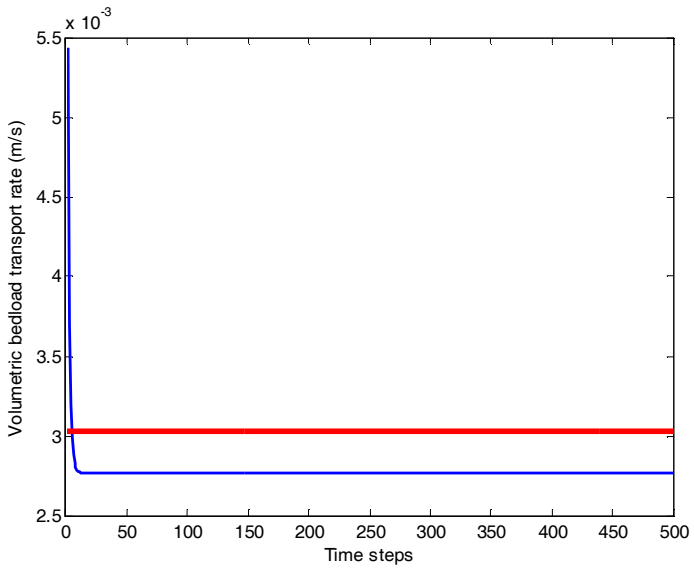

Figure 2. Comparison of the model results and calculated bedload transport rate from Graf's formula, under same input parameters as those used in Fig. 1. (The thick straight horizontal line is the result from Graf's formula).

DISCUSSIONS

Figure 3 shows that the small variations of transition probabilities make the bedload curve wavy. If N_3 is not constant, the q_b curve also becomes wavy as shown in Fig. 4. We can still see the trend of a constant q_b given that the mean value of N_3 is kept the same.

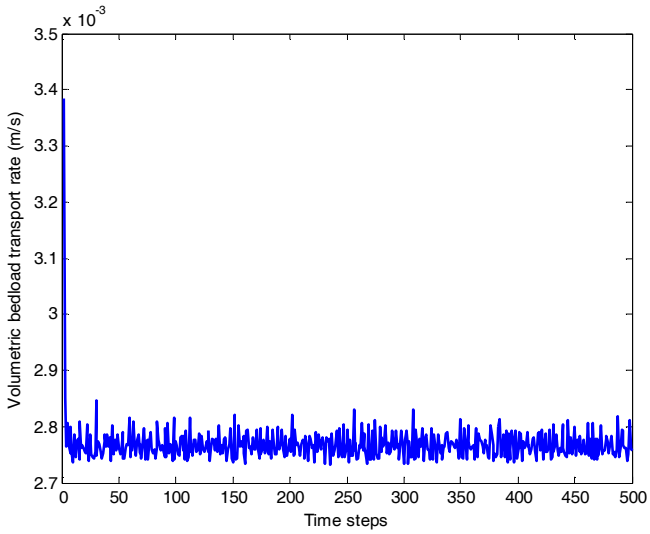

Figure 3. Bedload transport rate with one smaller order of uniform random noises in the erosion probability P_{12}.

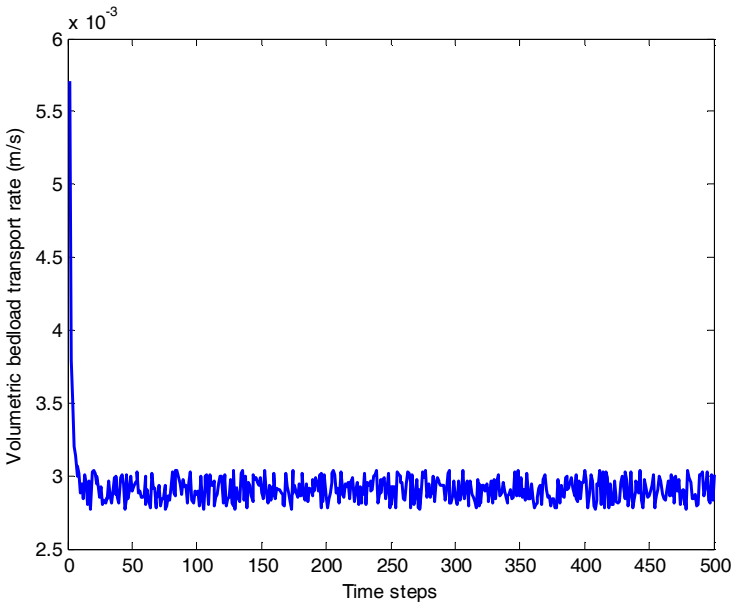

Figure 4. Bedload transport rate with one smaller order of uniform random noises in N_3 (N_3 = 472/m^2)

Below are the examples illustrating the impact of hypothetical abrupt changes to transitional probabilities and the bedload transport rates. The sudden change of flow and/or sediment condition leads to changes in the transition matrix. The instantaneous q_b will deviate from its transport capacity (Fig. 5-6). A sudden increase of entrainment probability (P_{23}) leads to the decrement of particle numbers in the bedload layer (N_2), and therefore q_b is decreased. q_b will increase with the number of sediment particles in the bedload layer when the deposition probability (P_{23}) increases. The theoretical examples herein manifest that the neglecting the exchange process between the bedload layer and the suspended layer may lead to non-negligible errors in bedload calculation when the flow and/or sediment conditions change.

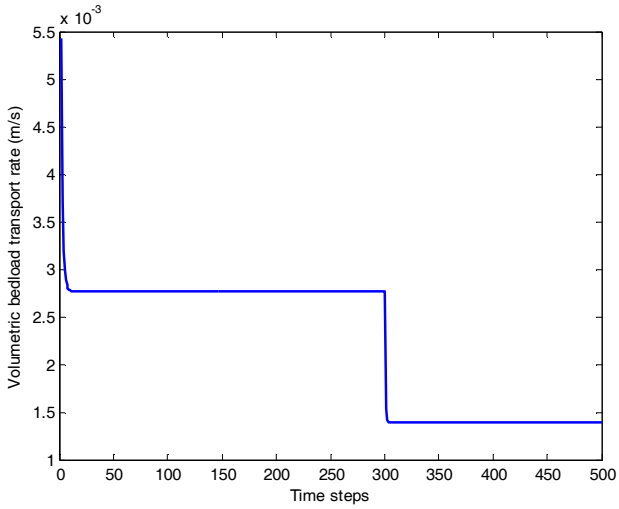

Figure 5. Sudden increase of entrainment probability from P_{23}=0.0083 to P_{23}=0.0166

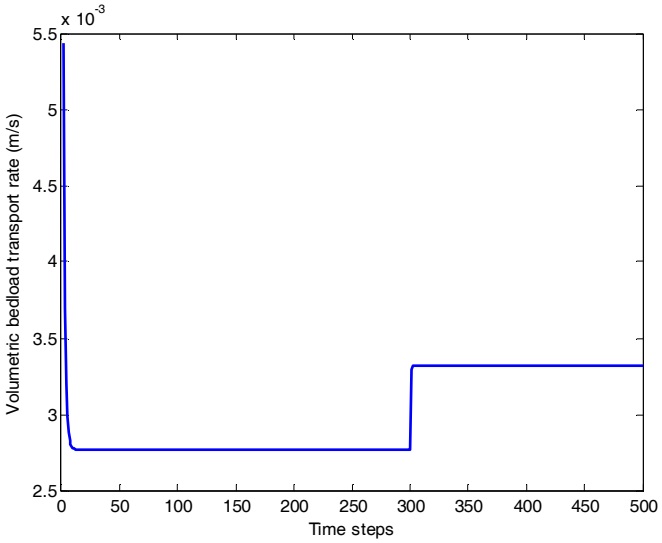

Figure 6. Sudden increase of deposition probability P_{32}=0.7934 to P_{23}=0.952

CONCLUSIONS

In a nonequilibrium condition, the interchange of sediment particles occurs not only between the bedload layer and the bed surface, but also across the interface between bedload and suspended load. A bedload-suspended load interchange layer is added to a stochastic bedload transport model. The proposed nonequilibrium stochastic bedload model can quantify the bedload transport capacity in an equilibrium condition, and also can demonstrated the influence of sudden changes flow-sediment properties on bedload transport rate.

Abstract

Hydrologic parameters and state variables estimation for the purpose of forecasting hydrologic system dynamics have been among the most challenging tasks in the filed of hydrologic modeling. Most of the efforts in this area can be categorized broadly into deterministic and stochastic approaches. The former approaches generally adopt the paradigm as an optimization problem and attempt to minimize an error cost function for estimating the optimum parameter set. The latter approach analyzes the problem in the discourse of estimation theory. Because of existing uncertainties associated with model structure, measurement and initial boundary condition, forecasts using the deterministic approaches lack the ability to explicitly address the mentioned uncertainties and so one can not relay only on the results of the first approach. Although several attempts have been made to develop a well scientifically accepted and robust framework to estimate hydrologic parameters in a probabilistic context, several open questions still exist. In this paper we introduce a new approach to employ Block Bootstrap resampling coupled with a global optimization algorithm to quantify probabilistic structure of hydrologic parameter space using nonparametric confidence interval analysis.

Introduction

At the early stage of hydrologic modeling, hydrologic parameters were determined by visual inspection and forecaster consensus of observed streamflow and model simulation of system behavior. In the past two decades several attempts have been made to enhance the accuracy and efficiency of hydrologic prediction via hydrologic model parameters estimation [Sorooshian and Dracup,1980; Duan et al., 1992; Beven et al., 1992; Gupta et al., 1998.; Moradkhani et al., 2005].

Generally, systematic attempts for parameter hydrologic estimation can be categorized into deterministic and probabilistic methods. Commonly, in the deterministic methods, in a batch mode process, the hydrologic parameter estimation is defined as an optimization problem to seek a global minimum and associated optimum parameters set as the mode of the forecast without explicitly addressing the associated uncertainty and error characteristics. In the probabilistic approach, parameters of a hydrologic model are considered as random variables and typically Monte Carlo analysis is employed to estimate the probability distribution or uncertainty around statistics of interest.

The approaches toward hydrologic parameter estimation via solving an optimization problem lead to development of some well known algorithms. Shuffled Complex Evolutionary (SCE-UA) Method [Duan et al., 1992], is one of those algorithms that has been widely used and extensively applied successfully to find global optima points of hydrologic optimization problems. The SCE-UA strategy combines the strengths of the simplex procedure of Nelder and Mead [1965] with the concept of controlled random search, competitive evolution and information shuffling.

In probabilistic approaches, researchers believe that because of hydrologic model structural inefficacy, observation and boundary condition uncertainties; hydrologic parameters shall be treated as variables with random nature and their efforts have been focused on estimating the probabilistic structure of the parameters space. In hydrologic prediction context, the generalized likelihood uncertainty estimation (GLUE) method [Beven et al., 1992] was among the first attempts which brought up this concept into the Hydro-science arena. The GLUE framework might be categorized as belonging to the general field of Monte Carlo rejection sampling techniques which benefits from a Bayesian scheme to update the likelihood associated with behavioral parameter sets. In GLUE method, the rainfall runoff model is run several times and each simulation is assigned a likelihood weight, based on the degree of closeness of the simulation to observation. Then a cut off threshold is employed to accept or reject each simulation and its associated parameter set.

In this study Block Bootstrap technique is employed to estimate the statistical characteristics of hydrologic parameters, using SCE-UA as one of the most robust optimization algorithms in the field of hydrology. In this method, based on a sample with finite length of observation (i.e. streamflow) the empirical bootstrap version of observation time series population is constructed to estimate the hydrologic parameters and their confidence intervals.

This paper is structured as follows. In the next section, a brief background on the non parametric bootstrap resampling for independent and dependent data is presented. A next section provides information about method and the proposed framework of hydrologic bootstrap parameter estimation. Implementation of the proposed method in a case study is also discussed, and at the end some results and subsequent

achievements are presented. Finally, conclusions and potentials for further research in this area are also discussed in section 6.

Review of Bootstrap Methods

Bootstrap method was originally proposed by *Efron 1979*, as a non parametric procedure for population inference from iid samples. Bootstrapping is a method for estimating the sample distribution of a random variable *R(***X**,*F),* which possibly depends on both **X** and an unknown distribution of *F* on the basis of the observed data [Efron, 1979]. Let **X**=(X_1,X_2,...,X_n) and x=(x_1,$x_{2,....}$,x_n) denote the random sample and its observed realization , respectively. For one independent sample problem the bootstrapping idea includes the following steps:

1. Construct of empirical probability distribution $\hat{F}$ (Bootstrap population), which is the nonparametric maximum likelihood estimator of the underlying population distribution function.
2. Draw random sample of size n with replacement from $\hat{F}$, say
   $X_i^* = (x_1^*, x_2^*, ..., x_n^*)$, $X_i^* \sim_{independent} \hat{F}$
   where $x_i^* \quad i = 1,2,...,n$ are bootstrap samples.
3. Estimate the sampling distribution of *R(***X**,*F)* by the resample (or bootstrap) distribution of, $R^* = R(\mathrm{X}^*, \hat{F})$.

More generally, the nonparametric empirical distribution $\hat{F}$ consists of multiple copies of the available random sample from real population. By assuming a large population size (i.e. N/n > 20), sampling without replacement from that large empirical population means sampling with replacement from a single copy of the random sample. Using resampling one could calculate the sampling distribution of interest (or estimator distribution). For dependent processes, the construction of approximate distribution (Bootstrap population) is more complicated and far less obvious than seminal proposal for independent setup by Efron, 1979. Block bootstrap (BB) is a technique to get *iid* samples from weakly dependent (strongly mixed) data structures [Künsch, 1989]. The commonly used block bootstrap method, known as Moving Block Bootstrap (MBB) was presented by *Künsch* [1989]. Let $\zeta_n \equiv \{X_1, ..., X_n\}$ denote an observation segment from a stationary time series $\{X_i\}_{i \in Z}$ and $R_n = r_n(\zeta_n; \theta)$ be a "root" or an approximation pivot, which has some functional dependence on the data. For example R_n might be of the form $R_n = \sqrt{n}(\overline{X}_n - \theta)$ or possibly a studentized version. $\overline{X}_n$ is sample parameter (i.e. mean) and θ denotes the population parameter (i.e. mean). The objective of the method is to estimate sampling distribution of R_n and its functionals. To describe the method in mathematical form, let l be the block size (integer value) and n be the sample size such that as $n \to \infty$ and $l \to \infty$ then $n^{-1}l \to 0$. Consider, $B_i = (X_i, ..., X_{i+l-1})$, $i = 1,...N$, $N = n - l + 1$ stand for all possible overlapping blocks of length l contained in ζ_n. In addition assume

$b = \lceil n/l \rceil$ denote the smallest integer not less than n/l, In this method b blocks are sampled at random with replacement from $\{B_1,....,B_N\}$ to generate pseudo time series by concatenating the elements of the resampled blocks (see figure 1). Let $\zeta_n^* = \{X_1^*,....,X_n^*\}$ be the first generated pseudo time series, then the MBB estimation of R_n is given by:

$$R_n^* = r_n(\zeta_n^*; \hat{t}_n)$$

Methodology and Framework

From statistical standpoint the available measurement of streamflow are samples from large populations which are not available. In fact the purpose of this study is to employ MBB as a nonparametric method in conjunction with optimization techniques to estimate population characteristics of hydrologic model parameters based on the available observation.

The principle of the proposed methodology for block bootstrap estimation of optimal hydrologic parameters is summarized in three main modules (see figure 2). As a consequence of module 1, any functionals of optimal hydrologic parameters marginal distribution (i.e. mean) can be estimated via implementation of the second module, using an independent bootstrapping of sampled hydrologic parameters. In the third module one can smooth the jagged sample distribution to estimate the density of optimal hydrologic parameters which can be used for ensemble prediction.

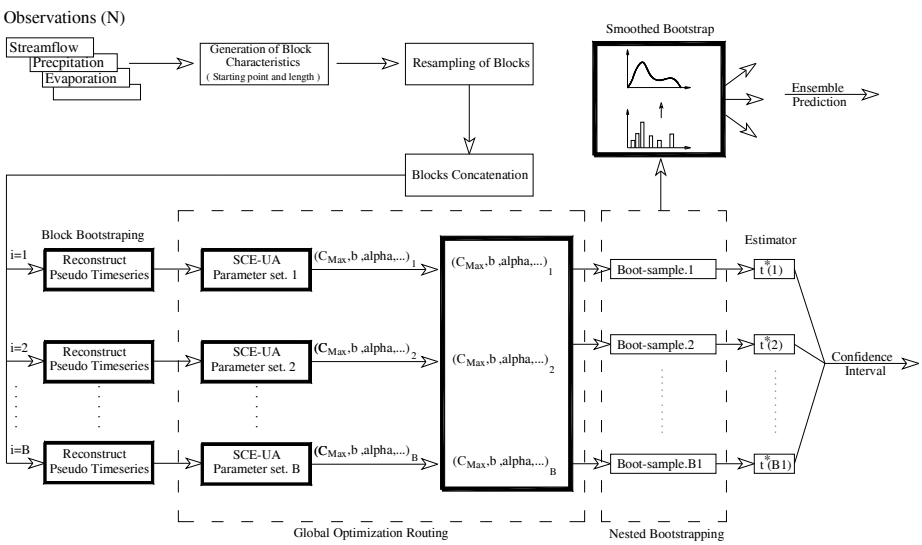

Figure 1: **Flow chart of Moving Block Bootstrap hydrologic parameter estimation using SCE-UA global optimization method.**

Implementation of the Method

The Leaf River as a subbasin of Pascagoula basin totally drains nearly 9200 square kilometers. The headwater of the river originates in west-central Mississippi. The basin has approximately total length of 170 kilometers and maximum width of 90 kilometers. The river falls 55 meters over its length. The basin topography is comprised a low rolling hills and ridges, characteristic of the coastal plain regions. Because of severe flood records, the basin has been a test basin in numerous studies [i.e. Yapo et.al, 1998, Moradkhani et.al, 2005]. We used forty years of reliable data set available in the Collins station (drainage area: 1944 km2) approximately 28 miles northwest of Hattiesburg, Mississippi.

HyMod (HYdrologic MODel [Moore, 1985 & Boyle, 2000]) as a parsimonious conceptual model has been used for the purpose of implementation of the proposed methodology in this study. The model is based on the probabilistic principle of spatial distribution of catchment runoff response to rainfall. HyMod consists of two series of connected linear reservoirs including three identical quick and a single slow tank to simulate catchment runoff response. The model requires the optimization of five parameters based on the observed streamflow data, including, the maximum storage capacity in the catchment (C_{max}), the degree of spatial variability of the soil moisture capacity (b_{exp}), the factor that distributes the flow between the two series of reservoirs (*Alpha*), and the residence time of the linear quick (R_q) and slow reservoirs (R_s). Feasible range of the model parameters are defined in table1.

Table 1: Feasible range of parameters

Parameters	Description	Minimum	Maximum
Cmax	Maximum storage capacity of watershed	1	1000
Bexp	Residence time for quick-flow tanks	0	2
Alpha	Distribution Factor	0	1
Ks	Slow flow tank residence time	0.0002	0.1
Kq	Quick flow tanks residence time	0.1	0.99

As mentioned, we employed SCE-UA to compute optimum hydrologic samples in MBB scheme. In calibration process, we chose root mean square error (RMSE) of the predicted flow and observation as optimization cost function.

$$\min(RMSE(e \mid N,o)) = \min\left\{\sqrt{Bias(e \mid N,o)^2 + Var(e \mid N,o)}\right\}$$

Where, N is sample size, *(e)* is the estimation (i.e mean of simulated flow) and *(o)* is the observation (i.e. mean of observed flow). Therefore it is obvious that by minimizing *RMSE*, the bias and variance of estimation are minimized.

In batch hydrologic calibration methods, it is clear that the estimated parameters have a functional dependence on the calibration length. To raise the major questions that we are going to answer in this study, we did several calibration experiments on Leaf River basin data set with different calibration periods. To resemble the law of large

number, we followed a cumulative calibration approach ranging from 1(1948) to 40 (1988) years (i.e. see figure 2). As the employed optimization algorithm is designed based on a competitive random search, it was also worthwhile to explore the sensitivity of the estimated optimal parameters on random initialization of the algorithm and local minima effects of error surface as well (see Duan et al., 1992). As an example, we repeated the calibration scheme for thirty times and the results for $C_{\max}$ parameter are displayed in figure 2.

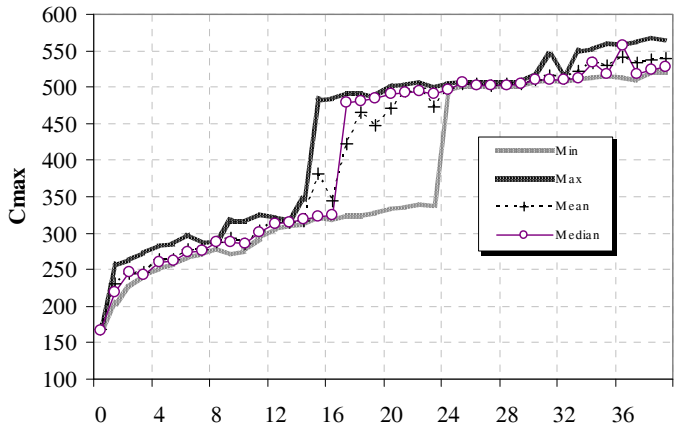

Figure 2 : Cmax ensemble variation and statistics

Accordingly, two questions may arise: (1) Is the available observation time series as large as it is required to ensure that the computed parameters are close to population expected value? (2) What is the degree of accuracy and confidence limits around the estimated hydrologic parameters based on the entire available calibration data set?

Assuming the functional dependence of optimal hydrologic parameters to the observed streamflow, we employed the original idea of moving block bootstrap algorithm for parameter estimation [Künsch, 1989]. To preserve physical and temporal properties of observed time series (i.e. streamflow) we used non-overlapping scheme for construction of pseudo time series. Using overlapped block scheme, means that we may have some pseudo time series for instance with two successive seasonal high flow regimes without any low flow between them. Therefore using overlapping scheme, we may have unrealistic pseudo time series.

Observations from October 1948 to October 1963 were used for block bootstrap calibration scheme. To implement MBB the fifteen years of the data were divided into annual non-overlapping blocks, the blocks were sampled with replacement based on a discrete uniform distribution and then concatenated to form pseudo time series. For each constructed time series an optimal set of hydrologic parameters are calculated using optimization algorithm with the same parameterization. So by implementation of the proposed methodology, we will end up with B (i.e. B=100)

bootstrap samples of optimal hydrologic parameters which can be used for density estimation and confidence interval analysis of hydrologic parameter estimator (i.e. mean, quantiles) as well.

One of the well known bootstrap CI estimation methods, is the so-called bootstrap-*t* is based on the assumption that the sampling distribution of the plug-in estimator in pivotal form can be characterized as a standard normal or student-*t* distribution in case of infinite and finite sample size. Pivotal properties of studentized bootstrap plug-in estimator lead to the assumption that studentized bootstrap sampling distribution $t(t^*) = \left[(t^* - \theta) / SE(t^*)\right]$ provides an unbiased approximation to the real world sampling distribution of $t(t) = \left[(t - \theta) / SE(t)\right]$ [Lunneborg, 2000], where $t, \theta, SE(.)$ are the estimator, population parameter and operator of standard error of estimation respectively. To perform bootstrap-*t* nonsymmetric confidence interval analysis, θ shall be a location parameter, *t* shall be a plug-in estimator of θ and we need to have robust computational method to estimate the standard error of the estimator from the bootstrap samples. It shall be noted that this method can be applied to location parameters include not only for example mean and median but also the quantiles of a distribution. To have the most robust CI analysis and avoid any prior parametric assumptions about population estimator distribution, we used a second level bootstrap estimate method to compute $SE(t^*)$ [Efron and Tibshirani, 1993]. In this method, simply, from each of the first level B bootstrap samples, we resampled *B1* random sequence and then computed the first level bootstrap estimator (t_b^*) standard error as follows:

$$SE(t_b^*) = \sqrt{\frac{\sum_{i=1}^{B1}[t_{bi}^* - \frac{\sum_{i=1}^{B1} t_{bi}^*}{B1}]}{B1 - 1}}$$

For having a satisfactory estimation of CI, as a rule of thumb *B* generally may be taken from 2000 to 5000 in size. On the other hand, the number of second level bootstrap resamples (*B1*) doesn't need to be as large as B, and might be selected perhaps between 50 to 150 [Lunneborg 2000]. It is worthwhile to mention that higher order bootstrap estimation of pivotal statistics provides a powerful and more accurate estimation method than single level bootstrap sampling techniques; however it drastically increases the computational burden of the problem.

The results of Bootstrap-*t* equal tail exclusion CIs analyses of the computed hydrologic parameter sets are presented in table 4. To make our estimation more robust against outliers, we chose 20% percent winsorization scheme to compute the mean and its confidence interval [Wilcox 2005]. As an example, studentized transformation of two bootstrap sampled hydrologic parameters is presented in figure 3. The results of the analyses indicated that in all cases bias and standard error of studentized transformation deviate form the ideal values (0,1) less than 5 percent. Although we don't have any specific information about the population distribution of

hydrologic parameters, based on the estimated bias and standard error of the pivotal distribution it can be concluded that studentized trimmed mean behaves acceptable as a strong pivotal statistics in the sense of possessing mathematical and shape stability. The results of confidence interval analysis of hydrologic parameter estimators are presented in table 2.

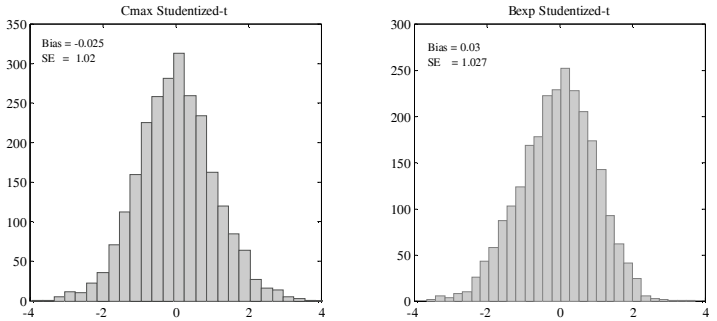

Figure 3: Bootstrap transformed sample distribution for mean of Cmax and Bexp

Parameters		2.5% Quantile	Winsorized Mean	97.5% Quantile
Cmax	*t* [1]	272.4628	406.44	576.3296

Summary and Conclusion

Hydrologic model calibration and analysis of the uncertainties associated with the forecasts is still a challenging process in hydrologic literature. Batch mode calibration scheme as the most commonly used method for hydrologic parameter estimation is not capable to explicitly address the uncertainty and confidence bound around the forecast. Moving block bootstrap resampling in combination with a robust optimization algorithm such as SCE-UA, can be a bridge to fill the gap between the existing parameter estimation concepts. In this new method, in parallel of using an efficient optimality scheme, the well accepted concept of the non-uniqueness of hydrologic parameters or behavioral parameters [Beven and Binley,1992] is also preserved.

In the MBB hydrologic parameter scheme, we followed the principal that the observation time series (may be corrupted with noise) as a segment of our process, contains the information to assess the system behavior. In general, in the presented method based on the available observations, several bootstrap versions of error surface are constructed as inputs of an optimization algorithm and consequently associated optimal hydrologic parameters can be computed. Then the drawn samples resulted from the MBB scheme, provide a platform for other bootstrap data analysis such as confidence interval and smoothed density estimation which finally can lead to a probabilistic hydrologic forecast.

In the performed real case study, we implemented MBB parameter estimation scheme for fifteen years of total available record (forty years). Computed parameters from that calibration length scale (see table 4), are well conformed to the computed parameters range for forty years of calibration (see figure 2). The computed expected value and associated confidence bounds completely cover the range of the calibrated parameters for the longer and even entire period of observation. It shall be noted that statistically speaking as an implicit results of law of large number, the calibrated parameters for the entire observation are more reliable descriptors of watershed runoff generation mechanism. As a result, it seems that the presented inferential statistical method can play a significant role for parameter estimation in watersheds with short record of observations.

Abstract

Stormwater system management with a set of objectives in urban watersheds is often achieved by effective design and use of detention ponds. These ponds help mitigate impacts of urban drainage from water quantity and quality perspectives. The design, site selection for these ponds, operation and management over time are important aspects of effective stormwater management. This involves costs to land developers and there is always a need for minimizing these costs at that same time fulfilling the objectives of the management with environmental and regulatory compliance. A nonlinear programming formulation and genetic algorithm (GA) based optimization approaches are proposed to design a single stormwater detention pond system in the current study. The optimization methodology is also extended to consider multiple detention systems. The main objective is to minimize the cost constrained on system performance related to pollution control. The optimization techniques employs analytical probabilistic models for urban stormwater management analysis which mathematically closed form are enabling them easily integrated into optimization frame work. The results provide optimal design parameters considering the runoff control and pollutant reduction considering environmental and regulatory issues. Application of the methodology for a case study system is demonstrated with results and the benefits of using GA based optimization approach are illustrated.

Introduction

To minimize the adverse impacts of urban development, storm water detention ponds have been are commonly used in watersheds. These ponds commonly known as stormwater management systems not only provide runoff quantity control such as peak flow attenuation, volume control and erosion but also runoff pollution control. In the era of eco-system based watershed developments, the role of stormwater management ponds have been very significant. They provide a sustainable development by minimizing the impacts of stormwater runoff. These ponds usually occupy valuable land and involve initial construction, as well as operation and maintenance, costs. The developer typically viewed as loss of developable lands which otherwise It is the objective of land developers and/or municipalities to minimize these costs of implementing stormwater management ponds while satisfying regional environmental regulations for runoff quantity and quality control

American Society of Civil Engineers /Environmental and Water Resources Institute
World Water & Environmental Congress 2009
May 17-21, 2009. Kansas City, Missouri, USA

At the planning-level analysis, typically statistical/analytical procedures are preferable for identifying least-cost system design variables that provide required level performance which are based on the regulatory requirements (Nix and Heaney, 1988; Segarra-Garcia and El Basha-rivera, 1996; Adams and Papa, 2000). The objective function for this study consists of minimizing the cost associated with the implementing stormwater management ponds that will comply the environmental regulations. Typical costs of ponds include the cost of land occupied by the ponds and pond construction costs. The cost of the land can be considered as purchase value of the land or opportunity cost of lands occupied by the ponds. The construction cost of the pond can be related the volume of the pond in terms of excavation and grading cost per unit volume. The phrases 'catchment' and 'watershed' are used interchangeably in this paper.

This paper presents a methodology for optimizing pond geometries through minimizing above mentioned costs for a single watershed as well as for a set of parallel watershed. Papa and Adams (1997) provided such formulation using dynamic programming technique however, this paper solves the problem using nonlinear optimization and genetic algorithm (GA) techniques. The regional watershed involves three parallel watersheds as presented in following Figure 1.

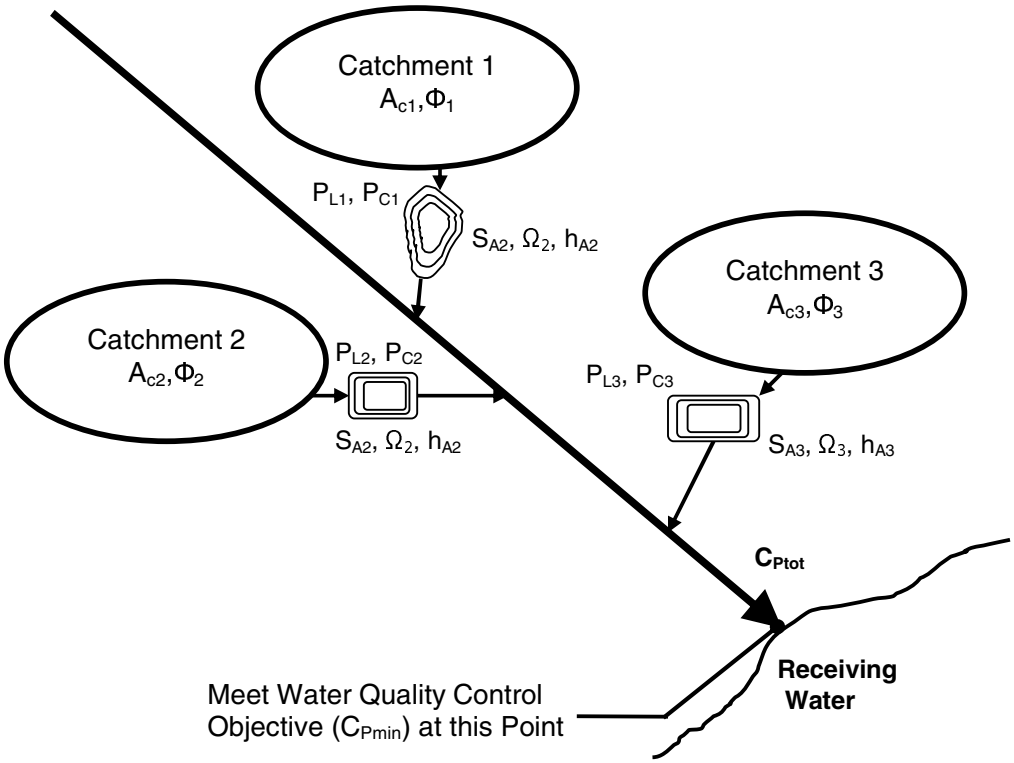

Figure 1: Schematic Representation of the Optimization Problem

American Society of Civil Engineers /Environmental and Water Resources Institute
World Water & Environmental Congress 2009
May 17-21, 2009. Kansas City, Missouri, USA

Optimization Formulation

In order to develop the develop the optimization methodology a system of sub-watersheds, each with a stormwater quality control pond upstream of its outlet, draining into a common collection system (e.g., trunk sewer) which subsequently conveys the stormwater to the local receiving water. This scenario is depicted in Figure 1 for system of three sub-watersheds. Each watershed is characterized by spatially by an area on its local topography, imperviousness and land cost as well as pond construction costs. The discharge from the trunk sewer is required to meet or exceed a defined quality control objective (C_{Pmin}). Based on this formulation, it is conceivable that different levels of water quality control can be provided at the outlet of each sub-watershed such that overall control of runoff quality meets or exceeds the regional environmental regulations for the group of sub-watersheds. Thus, the total cost of implementing stormwater quality ponds for all of the watersheds may be minimized by providing an optimal blend of individual watershed controls in the multiple watershed system, as opposed to providing uniform control in all watersheds.

The water quality control constraints can be expressed mathematically by:

$$C_{Ptot} = \frac{\sum_{i=1}^{n} C_{Pi} A_{Ci}}{\sum_{i=1}^{n} A_{Ci}} \geq C_{P\min} \qquad (1)$$

The objective function of the optimization scheme is to minimize the total cost of implementing the stormwater quality control ponds in each of the watersheds. The cost of implementing a single pond can be estimated by

$$P_{Pond} = P_L A_P + P_C V_P \qquad (2)$$

Where A_P and V_P are the pond surface area (m^2) and volume of the pond (m^3), respectively, P_{Pond} is the total cost of the pond (current \$), P_L is the present land value (\$/m^2) and P_C is the present value of construction and OMR costs (\$/m^3).

The decision variables in this design optimization procedure are the active storage volume of the pond (S_A expressed in mm uniformly distributed over the catchment), the controlled release rate from the pond (Ω expressed in mm uniformly distributed over the catchment per hour) and pond depth (h_A in m). It is therefore required to express the cost function (2) in terms of these decision variables as follows:

$$P_{Pond} = P_L \frac{A_C S_A 10}{h_A} + P_C A_C S_A 10 \qquad (3)$$

Using Equation (3) coupled with the pollution control model presented in the following section, a least-cost combination of above decision variables can be obtained for each of the watersheds

American Society of Civil Engineers /Environmental and Water Resources Institute
World Water & Environmental Congress 2009
May 17-21, 2009. Kansas City, Missouri, USA

based on the level of pollution control (C_P) required from the pond. The least The objective of the optimization scheme is to minimize the total cost of implementing the stormwater quality ponds in each of the sub-watersheds.

$$Minimize\left\{TC = \sum_{i=1}^{n}\left(P_{Pond}\right)_i = \sum_{i=1}^{n}\left(P_{Li}\frac{A_{Ci}S_{Ai}10}{h_{Ai}} + P_{Ci}A_{Ci}S_{Ai}10\right)\right\} \quad (4)$$

Analytical Model for Runoff Quality Control Performance

During planning-level analysis, the long-term runoff quantity and quality control performance of ponds can be easily obtained by employing analytical probabilistic models for urban stormwater management analysis. These models are based on derived distribution theory in which the probability density functions (PDFs) of rainfall characteristics (e.g., event volume, duration, average intensity and inter-event time) are transformed into PDFs of system performance depicting watershed hydrology, control system hydraulics and pollution removal processes. The input parameters include (i) parameters of PDFs of rainfall characteristics (λ, ζ and ψ are the parameters of the exponential PDFs of the meteorological characteristics of rainfall event duration, rainfall event volume and interevent time, respectively), which are obtained from the long-term rainfall records, constitute the input parameters, (ii) watershed parameters such as runoff coefficient (Φ), which can be obtained from the watershed imperviousness, (iii) control system parameters such as pond storage volume (S_A), pond outflow rate (Ω) and pond depth (h_A), (iv) particle size distribution and corresponding settling velocity.

This paper focuses on the use of stormwater quality control ponds, particularly extended detention dry ponds. Adams and Papa (2000) presents following expressions for predicting the total suspended solids (TSS) from the detention basin:

$$C_P = E_d\left[1-\left[\frac{\frac{\lambda}{\Omega}}{\frac{\lambda}{\Omega}+\frac{\zeta}{\phi}}\right]\left[\frac{\frac{\psi}{\Omega}+\frac{\zeta}{\phi}\exp\left\{-\left(\frac{\psi}{\Omega}+\frac{\zeta}{\phi}\right)S_A\right\}}{\frac{\psi}{\Omega}+\frac{\zeta}{\phi}}\right]\right] \quad (5)$$

where the annual fraction of runoff controlled is treated in the pond at an efficiency of E_d given by

$$E_d = \sum_i F_i\left\{1-\left[1+\frac{V_{Si}}{nh_A}\frac{S_A}{2\Omega}\right]^{-n}\right\} \quad (6)$$

American Society of Civil Engineers /Environmental and Water Resources Institute
World Water & Environmental Congress 2009
May 17-21, 2009. Kansas City, Missouri, USA

The overall removal efficiency, E_d is based on settling of suspended solids in turbulent conditions, where n is the turbulence factor expressing the settling characteristics of the pond, V_{Si} and Fi are the average settling velocity and the fraction of total mass of solids contained in the ith size fraction, respectively, of the settling velocity distribution of suspended solids in the stormwater runoff. The terms ζ, λ, and ψ are parameters for the exponential distribution of probability density of the rainfall characteristics of rainfall event volume, event duration and interevent time, respectively. The detail description of the model can be found elsewhere (Adams and Papa, 2000).

Papa et al. (1997) present a comparison of results from the above analytical model with continuous simulation model results for the pollution control performance of extended detention dry ponds and concluded that the results compare favorably.

In the present study, the rainfall characteristics values are taken from the statistical analysis of hourly rainfall data for the period 1960 to 1992 from the Toronto Pearson International Airport based on a 2 hour interevent time definition (Adams and Papa 1997). The corresponding parameter values are: ζ=0.20 mm^{-1} (inverse of mean rainfall event volume), λ=0.282 hr^{-1} (inverse of mean rainfall event duration), and ψ=0.23 hr-1 (inverse of mean rainfall interevent time), respectively. In addition, a commonly used settling velocity distribution of suspended solids in storm water is used for estimation of removal efficiency with a value of n = 3 for the pond settling performance factor.

Optimization of Pond Design for Single and Multiple Watersheds

Papa and Adams (1997) developed an optimization procedure to evaluate the values of decision variables (S_A, Ω, and h_A) of a stormwater quality control pond based on a cost function (3) and the required levels of pollution control performance. They investigated the behavior of pollution control as a function of the decision variable values and suggested a strategy to optimize the geometries of a stormwater quality management pond.

For the multiple watersheds, they employed a dynamic programming procedure for estimating the optimal combination of stormwater management pond decision variables for achieving a prescribed minimum level of pollution control at the common discharge outlet. The objective of the procedure is to minimize the overall cost of implementing ponds by providing varying level of control in each of the watersheds while meeting the required level of control at the common outlet. The Dynamic Programming transforms the multiple watershed (stage) problem into a series of single watershed problems, then combines the solutions of the individual problems to obtain the solution policy of overall (multiple watershed)

In the present study, a similar strategy is adopted for the design of a SWM pond; however, the decision variables are optimized to meet both performance levels of runoff quantity and quality simultaneously at the minimum cost. Papa and Adams (1997)

Limitations of DP Solution

Dynamic programming (DP) formulation was adopted in the previous study by Behera et. al., 1999). The catchments were used as stages in the DP formulation along with the level of control as a state variable at each stage. The state variable is discretized into several classes to enable the solution of the problem. Dynamic programming formulations are generally plagued by two limitations: 1) curse of dimensionality and 2) computational intractability. These two limitations are not a concern in the current context as the state variables number is limited to one and the number of finite stages will not introduce any computational intractability problems. However, the discretization level (i.e., the number of classes) of the state variable in case of a discrete DP will affect the optimal solution. Finer discretization schemes will result in more computational time while coarser schemes will result in sub-optimal solution. In order to improve the solution, a non-linear optimization formulation based on traditional optimization solvers or state-of-the-art optimization techniques such as genetic algorithms can be experimented. In the current study, two optimization formulations based on non-linear programming (NLP) and genetic algorithms are investigated.

Genetic Algorithm based Optimization

Genetic Algorithms (Holland, 1975) are well researched and applied optimization techniques in civil engineering and other disciplines. A GA deals with a population of individual solutions which undergo constant changes by means of genetic operations of reproduction, crossover and mutation (Goldberg, 1989). A solution of GA is represented as a string of decision variables (also referred to a chromosome) that evolve through generations to further improve its fitness. In the first step, the GA searches for the optimal decision variables associated with a specific objective function. The objective function used in the current study is same as defined in equation # 3. The method uses the basic structure of GA optimization involving selection, crossover, and mutation processes to obtain an optimal functional form by selecting functions of decision variables (model inputs) and mathematical operators that maximizes or minimizes the fitness of the function. Mutation and crossover parameters are used to select individuals from an initial population size.

Results and Analysis

The optimization formulation developed for the three catchment (i.e., watershed) problem is solved using a conventional dynamic programming model. The basic parameters used for the hypothetical problem are provided in Table 1. In case of DP, the watersheds are regarding as multiple stages and the state variable is discretized for solution of a discrete DP. A spreadsheet based DP is developed and solved for this purpose. Results related to the DP formulation are provided in Table 2. For all the formulations, the pond depth values are restricted to a range of 1 – 3 m. A value of 0.5 (50%) is used for $Cp_{min.}$

Table 1: Data for Example Problem:

Description	Watershed 1	Watershed 2	Watershed 3
Area (ha)	100	40	70
Runoff Coefficient, Φ	0.3	0.6	0.7
Cost of Land, P_L ($/m^2)	40	70	90
Cost of Construction , P_C ($/m^2)	20	40	60
Minimum Pond Depth, h_A, (m)	1.0	1.0	1.0
Maximum Pond Depth, h_A (m)	3.0	3.0	3.0

Table 2. Optimal Design Policy using Dynamic Programming (DP)

Design Variables	Watershed 1	Watershed 2	Watershed 3
Pollution Control, C_P^* (%)	63.0	52.5	30.0
Pond Depth, h_A^*, (m)	1.0	1.70	3.00
Storage Volume, S_A^* (mm)	4.74	6.18	2.68
Release Rate, Ω^* (mm/hr)	0.19	0.30	0.22

The hypothetical multi-catchment optimization problem is solved using two optimization methodologies, namely 1) non-linear optimization and 2) genetic algorithms. The non-linear optimization formulation is solved using Microsoft Excel solver which uses a generalized reduced gradient (GRG) nonlinear optimization algorithm for solution. However, there is no restriction on the type of approach or solver used for solution of the mathematical programming formulation. Results related to nonlinear optimization are provided in Table 3. The non-linear optimization resulted in a total cost of $619,728

Table 3. Optimal Design Policy using Non-Linear Programming Formulation

Design Variables	Watershed 1	Watershed 2	Watershed 3
Pollution Control, C_P^* (%)	62.9	52.49	29.99
Pond Depth, h_A^*, (m)	1.095	2.208	2.464
Storage Volume, S_A^* (mm)	0.200	0.255	0.254
Release Rate, Ω^* (mm/hr)	4.290	4.613	3.625

The application of GA is based on the selection of decision variables and the algorithmic parameters. The mutation and crossover parameters are selected as 0.1 and 0.4 respectively. An initial population of 200 is selected for the GA process to continue. Results related to GA optimization are provided in Table 4. The GA optimization resulted in a total cost of $625,625

American Society of Civil Engineers /Environmental and Water Resources Institute

Release Rate, Ω^* (mm/hr)	5.259	4.310	3.615

The non-linear programming formulation and genetic algorithms techniques provide optimal solutions for the hypothetical problem. However, the real values obtained for the pond depth are impractical for application in the field. A formulation that can use only discrete values (pre-fixed values) of pond depth is required. The formulation is identified as mixed integer nonlinear programming (MINLP). A total of 6 discrete pond depths, i.e., 0.25, 0.75, 1.25, 1.75, 2.25 and 3 meters are used for the formulation. All the constraints and the objective function apply for this formulation except additional constraints defined in equations 7 and 8 are included.

$$h_{Ai} = \sum_{m=1}^{6} y_{im} ds_{im} \qquad \forall i \tag{7}$$

$$\sum_{m=1}^{6} y_{im} = 1 \qquad \forall i \tag{8}$$

The variables, y_{im} and ds_{im} are binary variables and discrete pond depths associated with catchment, i. The index variable, m, represents the number of discrete pond heights used in the formulation. The entire formulation can solved using these additional constraints (equations 7 and 8). GA optimization with restrictions on the pond depth limited to 6 possible values is carried out. The decision variables for relate rate and storage volume are fixed based on the previously obtained best solution using nonlinear programming formulation. Results related to this scenario are shown in Table 5. The GA optimization with restrictions on the pond depth sizes resulted in a total cost of $582,643.

Table 5. Optimal Design Policy using GA with restrictions on the Pond Depth

Design Variables	Watershed 1	Watershed 2	Watershed 3

Conclusions

A hypothetical regional stormwater system containing multiple catchments (watersheds) with detention ponds is optimized using two optimization methodologies. These methodologies include traditional non-linear optimization and genetic algorithms. The basic nonlinear programming formulation is also modified to adapt discrete values for the pond depth. The formulation with discrete values is referred to as mixed integer non-linear programming (MINLP) with binary variables. The nonlinear programming and genetic algorithm formulations provided improved solutions compared to the traditional DP formulation. These formulations overcome the restrictions and limitations of DP formulation associated with state variable descretization. The formulation using MINLP resulted in lowest objective function value and also provided a mechanism to arrive at practical dimensions for pond depths. The formulations using GA resulted in different levels of pollution control in different watersheds compared to those achieved by traditional DP and nonlinear optimization.

Abstract

The primary goal of this research is to compare and analyze the results from three statistical procedures used for producing long-lead streamflow forecasts. The models and techniques covered in this work include principal component analysis, z-score regression, and independent component analysis. These procedures were tested on a three watersheds in the Pacific Northwest while merits and disadvantages of each procedure are explored and recommendations are made useful in providing more accurate, reliable and skillful seasonal forecasts.

Introduction

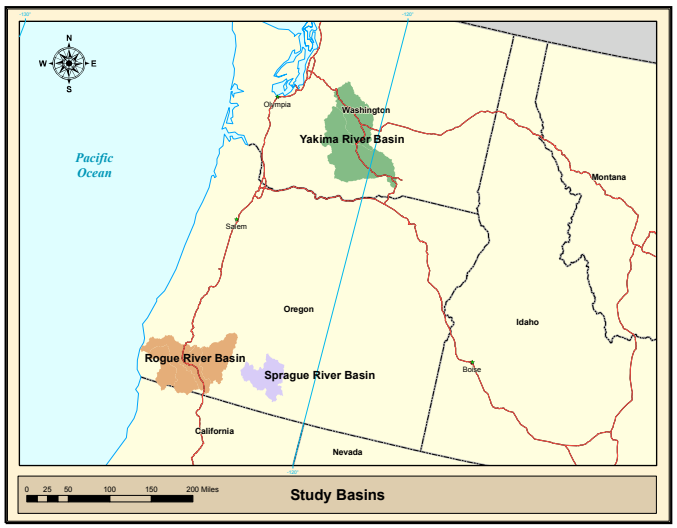
Water in the western US is an essential part of the physical environment and is needed to sustain the growing communities of the region. An integral tool for successful and efficient management of western water supplies is accurate and reliable forecasts of seasonal streamflow volumes. Seasonal streamflow forecasts represent an estimate of the range of total volumetric flow expected to occur over a particular period at a specific point in a basin. These forecasts are possible in the western US because much of the streamflow in this area is the result of the accumulation of seasonal snowpack over the winter months and the melting of this snowpack over the spring and summer. This pattern of snow accumulation and melt makes it possible for forecaster to provide water supply forecasts with lead-times of several months. This lead-time is essential for the planning of reservoir and flood control management, navigation, hydroelectric generation, fish and wildlife management, and maximizing the efficiency of existing water systems (Palmer 1988). The purpose of this paper is to 1) review the current status of models and techniques utilized for water supply forecasting in the Western US; 2) present a case study from three Pacific Northwest basins using three different statistical forecasting models; 3) compare and analyze the model results.

Operation Streamflow Forecasting in the Western US

The Natural Resource Conservation Service (NRCS), formally the Soil Conservation Service (SCS), was the first agency in the US tasked with collecting snow related data and providing forecasts of future water supplies (Fisher and Portland State University 2000). The NRCS have been generating long-lead seasonal volumetric streamflow forecasts throughout the western US since the 1930's. Traditionally, the primary recipients of the forecasts were agricultural users for irrigation water management. The Division of the NRCS responsible for these forecasts is the National Water and Climate Center (NWCC). Currently, in partnership with the National Weather Service (NWS) and local cooperating agencies, the NRCS-NWCC produces seasonal

volumetric water supply forecasts monthly, January through June (Pagano and Garen 2003). All of the NRCS generated forecasts are for streamflow volumes that would occur naturally without any upstream influences, unless specified otherwise. The forecasts are done on the first of each month and include the forecast location, the forecast period, the long-term historical average streamflow volume, and the forecasted streamflow volume. There are three forecasted streamflow volumes published for each location and forecast period. The three forecasts correspond to each of the 10%, 50%, and 90% exceedance probabilities. The three separate forecasts express the uncertainty in the model and the wider the spread among the forecasted values, the greater the uncertainty in the forecast (Pagano and Garen 2003). Generally, as the season progresses the forecasts become more accurate. The forecast error early in the season is primarily due to unknown future precipitation after the forecast issue date and during the runoff period, but also include uncertainties associated with the prediction methodologies and the spatial coverage of the data network.

Current Operation Streamflow Forecasting Models and Techniques



The NRCS-NWCC relies on a statistical regression-based model for developing seasonal volumetric streamflows in the Western US. Linear regression, in various forms, is the methodology currently used at the NWCC. The NWCC develops linear regression equations for specific locations in a basin, which relates monthly predictor variables, such as snow-water equivalent, precipitation, antecedent streamflow, and climate teleconnection indices, to compute the median value of the seasonal water volume forecast distribution. At locations in a basin where linear relationships do not exist between streamflow volumes and predictor variables, nonlinear equations are used in which transformed streamflow values are predicted by a linear equation (Pagano and Garen 2003). Statistical models have the advantage that they are relatively simple and straightforward to calibrate, maintain and use, and they are usually acceptably accurate (Garen 1992). The disadvantages to using a regression model are that they require long historical records, do not represent all known physical processes that affect streamflow, work only for seasonal volumes, and the equations are typically developed to be run only at the beginning of the month.

Study Area

Three basins in the western US have been used for analysis in this paper, the locations of which are shown in Figure 1. A more detailed analysis of three forecast points within these basins was conducted and a description of these forecast locations and subbasins is provided below.

Yakima River at Cle Elum, Washingtion

The Yakima River is located in central Washington in the Yakima River Basin and is approximately 215 miles in length. The Yakima Basin drains approximately 6,150 square miles of area and has a 30-year mean annual unregulated streamflow of 4.2 million acre-feet at Cle Elum, Washington. The basin is bordered on the west by the Cascade Mountains, on the north by the Wenatchee Mountains, on the east by the Columbia, and on the south by the Simcoe Mountains and the Horse Heaven Hills. The climate in most of the basin is dry, with a mean annual precipitation over the entire basin

of 27 inches. Most of the precipitation in the basin falls during the winter months as snow in the mountains. The basin is primarily comprised of forest, rangeland, and cropland.

Sprague River near Chiloquin, Oregon

The Sprague River is located in southwestern Oregon in the Upper Klamath River Basin and is approximately 75 miles in length. The Sprague River drains an arid volcanic plateau east of the Cascade Mountains that is approximately 1,600 square miles in area. The basin has a 30-year mean annual unregulated streamflow of 2.3 million acre-feet near Chiloquin, Oregon. The headwaters are located along Winter Ridge and Gearhart Mountain, and flow towards the broad valley of the Sprague River near Bly and Beatty. The climate in most of the basin is much drier than that of western Oregon, and has more extreme temperatures, especially in the winter months. Mean annual precipitation in the headwaters of the basin range from 30 to 40 inches, and 10 to 20 inches in the valley near Chiloquin. Snowfall accounts for 30 percent of the annual precipitation in the valleys and as much as 50 percent in the mountains. The basin is primarily comprised of forest, rangeland, and cropland.

Rogue River at Raygold, Oregon

The Rogue River is located in southwestern Oregon in the Rogue River Basin and is approximately 220 miles in length. The Rogue River drains an area between the Cascade Mountains and the Pacific Ocean that is approximately 5,160 square miles. The basin has a 30-year mean annual unregulated streamflow of 2.5 million acre-feet at Raygold, Oregon. The Rogue headwaters originate in the Cascade Mountains near Crater Lake and the river flows westerly towards the Southern Oregon coastline where it empties into the Pacific Ocean near the city of Gold Beach, Oregon. Much of the western basin is comprised of volcanic tuffs and ash flows, whereas the eastern basin is comprised of layers of basalt flows. The climate of southwestern Oregon is cool and wet in the winter and among the hottest and driest in the western Cascades in the summer. Mean annual precipitation in the headwaters of the basin range from 20 to 30 inches, and 80 to 100 inches near the Oregon coast. The basin is primarily comprised of forest, farmland, and rural communities.

Data Network

Snow-water equivalent, precipitation, teleconnection indices, and streamflow data were used to create both the dependent and independent variables of the models presented in this paper. The data period of record used for the models in the study ranged from 1981 to 2007. A list of the variables is provided in Tables 1-3.

Snow-Water Equivalent and Precipitation

The snow-water equivalent and the majority of the precipitation data were obtained from a network of measurement sites owned and maintained by the NRCS NWCC called SnowTelemetry (SNOTEL) sites. The snow and precipitation data used in this paper are monthly aggregations. In addition, a manual snowcourse site was used in the Yakima Basin and two additional precipitation sites were used in Rogue Basin, Crater Lake National Park and the Medford airport.

Climate Teleconnection Indices

Two large-scale climate teleconnection indices were also selected for predictor variables because of their potential to reduce forecasting uncertainty by providing insight into future climate and weather variability. This paper uses the Southern Oscillation Index (SOI) and a revised Trans-Niño Index (TNI*). SOI is a record of the monthly or seasonal fluctuations in the normalized surface air pressure difference between Tahiti and Darwin, Australia. Much research has been done to understand the relationship between SOI and streamflow in the US (e.g. (Koch and Fisher 2000), (Fisher and Portland State University 2000), (Gutiérrez and Dracup 2001), (Piechota et al. 1997)). TNI is a measure of the standardized sea surface temperature gradient between region Niño 1+2 and Niño 4 (Trenberth and Stepaniak 2001). A revised TNI method is discussed in (Kennedy 2006) and it was shown to have statistically significant correlation with streamflow in the Upper Klamath Basin.

Steamflow

Two of the forecast locations – Cle Elum and Raygold – required adjusted streamflow values be calculated because of reservoir regulation and diversions upstream of the forecast point. The corrected volumetric streamflow for these locations were obtained from NRCS-NWCC. The Sprague River is unregulated and therefore the streamflow data was available directly from the USGS website. All of the streamflow values used in this paper are monthly aggregations of flow volume, in thousand acre-feet.

Statistical Hydrologic Models

Statistical models are based upon information that use observed data to identify relationships in a system. Statistical procedures are useful in highly uncertain systems and when dealing with complex models of physical processes that make it difficult to constrain model parameters. The three statistical models covered in this paper are variations of multiple linear regression models.

Multiple Linear Regression

Much of statistical hydrologic and weather forecasting is based on linear, least-squares regression. Multiple linear regression (MLR) describes the linear relationship between several predictor variables and a dependent variable. The models developed in this study use ordinary least squares (OLS) regression, which chooses the surface that minimizes the sum of the squared errors. The errors are first squared, and then summed, in order to prevent cancellations between positive and negative values. Other error measures are possible, but the statistical procedures discussed here use the OLS

regression. Further OLS regression details should be referred to (Edwards), (Berry 1993), (Younger 1979). When using MLR to summarize the relationship between several predictor variables and volumetric streamflow, one must use caution to ensure that the predictor variables used do not contain redundant information. If the predictor variables have minimal correlation among themselves, then application of the OLS regression methodology works as intended. If, on the other hand, the predictor variables are mutually correlated, then the predictor variables contain redundant information, and this condition leads to parameter estimates that are biased. In the case of using climatic variables for predictor variables, often there are correlations among the predictor variables themselves, which is referred to as multicollinearity. Ideally, when utilizing multiple regression models, it is best to avoid correlations between the predictor variables. However, in observational studies such as streamflow forecasting, it is difficult to break the covariation of the predictor variables used to capture the physical processes of a hydrologic system, and therefore some level of multicollinearity will have to be accepted. Several remediation techniques are available for dealing with datasets that would otherwise give bias parameter estimations. The following section discusses three such strategies.

Principal Component Analysis

PCA is an ordination technique that is used to order multivariate data. PCA is a technique that creates new variables from the original predictor variables that can be scored and ordered. These new variables, called principal components, are composites of many of the original predictor variables and they represent a smaller number of variables that maintain the important patterns in the data (Gotelli and Ellison 2004). The principal components are calculated in such a way that the first principal component accounts for as much of the variability in the data set as possible, and each succeeding component accounts for as much of the remaining variability as possible. In addition, and most importantly, the principal components created from PCA are uncorrelated, which allows them to be used in multiple linear regression. PCA produces the same number of principal components as there are predictor variables and they are generated from linear combinations of the predictor variables. Principal components are calculated by multiplying each predictor variable times a corresponding loading and summing the results. The loadings used in the linear equations are the elements of the eigenvectors, which are calculated from the sample variance-covariance matrix of the standardized predictor variables. The steps used in a PCA for volumetric streamflow forecasting are fully explained in (Garen 1992). One of the strengths of PCA is that it is a non-parametric analysis. As long as the assumptions of the analysis are met, then the calculated principal components are unique and independent of the user. Further PCA details should be referred to (Gotelli and Ellison 2004), (Shlens 2005), (NRCS 2007), (Garen 1992), (HyvMarinen et al. 2001), (Westra S et al. 2007).

Z-Score Regression

The Z-score regression methodology combines individual predictor variables into a composite index that then becomes the independent variable used in a regression. The main objective of the Z-score procedure is to weight those variables that are more highly correlated with the dependent variable and give less emphasis to those variables whose

correlations are lower. The Z-score method is based on correlations between the predictor variable and the dependent variable, and differs from the principal component method in that the loadings used in PCA have no knowledge of the dependent variable. In addition, the Z-score method weightings have no knowledge of the correlations among the predictor variables themselves. The computational steps for Z-score regression are outlined in full detail in (NRCS 2007). One advantage to using the Z-score method for streamflow forecasting purposes is that the method is able to deal with sets of predictor variables that have missing values or have varying periods of record. Other regression methods will generally require that the data for each independent variable be complete for the duration being analyzed. Steps would have to be taken to account for the missing data, such as estimating the values or removing the variables from the regression all-together.

Independent Component Analysis

ICA is a method that separates mutually independent signals, or components, from explanatory variables using higher-ordered statistical characteristics. The standard form of ICA suggests that the observed signals are linear mixtures of unobserved multidimensional independent signals. Typically it is assumed that there is the same number of sources as there are observations. The noise-free linear form of ICA expresses observed variables as the resulting mixture model

$$x = As$$

Where x is the observed data, A is the mixing matrix, and s represents the independent components with zero mean and unit variance. The objective of ICA is to estimate the mixing matrix and the independent components given only the observations. ICA solves the estimation problem by maximizing independence among the independent components by some measure of non-normality (Hyvarinen and Oja 2000). In this paper, a fixed-point algorithm (FastICA) for ICA is applied to a set of predictor variables in order to extract significant components that are statistically independent. The extracted components are then used in a regression analysis, similar to PCA, in order to construct a model for forecasting purposes. A full description of the computational steps used for ICA can be found in (Hyvarinen and Oja 2000), (HyvMarinen and Oja 1997), (HyvMarinen et al. 2001). The major advantage to using ICA, in comparison to other component extraction techniques, is that ICA not only decorrelates the input data, but it also addresses the high-order dependencies. The ICA procedure used in this paper was implemented using Matlab software and the FastICA algorithm for estimation of the independent components.

Application of Statistical Techniques to Three Pacific Northwest Basins

The major objective of this study is to provide an evaluation and comparison of different statistical modeling techniques for producing seasonal streamflow volume forecasts. The three statistical models were developed to forecast the April to September volume. The snow-water equivalent predictor variable used from each site was the April 1st value, because this quantity, when considering the April to September forecast window, gives a good physical indication of the available water in the basin. Following

the same reasoning, this paper used an aggregation of monthly precipitation values from October through March for all of the precipitation predictors. In order to determine statistically significant climate indices a correlation analysis was performed, similar to the methodology in (Opitz-Stapleton et al. 2007), which used 3-month average climate values that were lagged for a period of 12 months and correlated with streamflow. The 3-month season that gave the highest Pearson's correlation coefficient with the Apr-Sept streamflow volume was selected as the predictor variable in the models. A summary of the selected variable time periods is presented in Tables 1-3.

Model Results

A summary of the results from the three models is presented in Tables 4-6. Each regression model was evaluated using the entire period of record and the root mean square error was calculated as a performance measure for each model. Model simulations were performed using different combinations of predictor variables in order to identify statistically significant predictors. In addition, each model was run using a cross-validation procedure to get a sense of the models stability and overall forecasting capabilities. The cross-validation standard error and the cross-validation coefficient of determination were calculated from the model simulations. After every combination of the predictors variables were analyzed, the models were then ranked by the cross-validation standard error in order to gain insight into which predictor variables provide the most predictive power. The top five equations in Tables 4-6 are the optimized solutions for PCA, while the bottom five equations are the optimized equations using ICA. The optimized Z-score equations were consistent with the PCA equations; however, it was found that the ICA model typically selected a slightly different combination of predictors for an optimal solution.

Conclusion

Forecast models used in operation settings are not selected based solely on the lowest standard error, but rather use an optimization algorithm to assist the forecaster in selecting a skillful model that is also physically meaningful. The results of this study show that the three statistical techniques provide a good tool for exploring a set of predictor variables and identifying the statistically significant ones. The three techniques typically identified the same dominant predictor variables, however the models did not converge at the same optimal solution. Additional model simulations, using different forecast windows and lead-times, and further analysis of extracted independent components based on predictor selection is necessary in order to fully understand the performance and forecasting capabilities of ICA. The authors of this paper are planning additional research in these areas.

Abstract

Lake Houston serves as the primary drinking water source for the City of Houston. Water quality is a problem in Lake Houston due to pollutant loads coming from the influent watersheds, therefore hydrologic models and water quality predictions are key to the operation of the City of Houston drinking water treatment plants. Cypress Creek is one of the watersheds that drains into the lake and has mixed use including urban and agriculture. Rapid urban development is a concern to the water quality of Lake Houston. Water quality issues of potential concern for the lake include nutrient enrichment and aquatic life use. Statistical trend analysis and loading curves have been analyzed using data collected by the USGS at 2 sites in Cypress Creek with corresponding City of Houston water quality data at the sites for the past 10 years to characterize the behavior of the pollutant source and watershed.

Introduction

Lake Houston is the primary source of drinking water for the City of Houston. Over 146 billion gallons are treated annually for 2 million customers (City of Houston, 2008). The lake is impaired for bacteria (TCEQ, 2008) and has concerns for nutrients and Chlorophyll-A (TCEQ, 2008). The watersheds flowing into the lake are also impaired for bacteria and have concerns for nutrients and depressed dissolved oxygen. With rising water treatment costs, the degraded influent has become a key concern for the City of Houston and thus protecting the watersheds is a chief priority. In order to efficiently manage the water quality an understanding of the watersheds and the relationship between pollutant loads and the influent flows is required.

Cypress Creek watershed is located northwest of Houston, Texas in Harris county and drains to Lake Houston (Figure 1). The watershed is primarily undeveloped and encompasses 109,757 Ha. The creek is gauged by the USGS at Grant Road (08068800) and near Westfield (08069000). Water quality samples are analyzed by the City of Houston at 11332 and 11328 stations that correspond to these stations. The land use of the area draining to each station is detailed in Table 1.

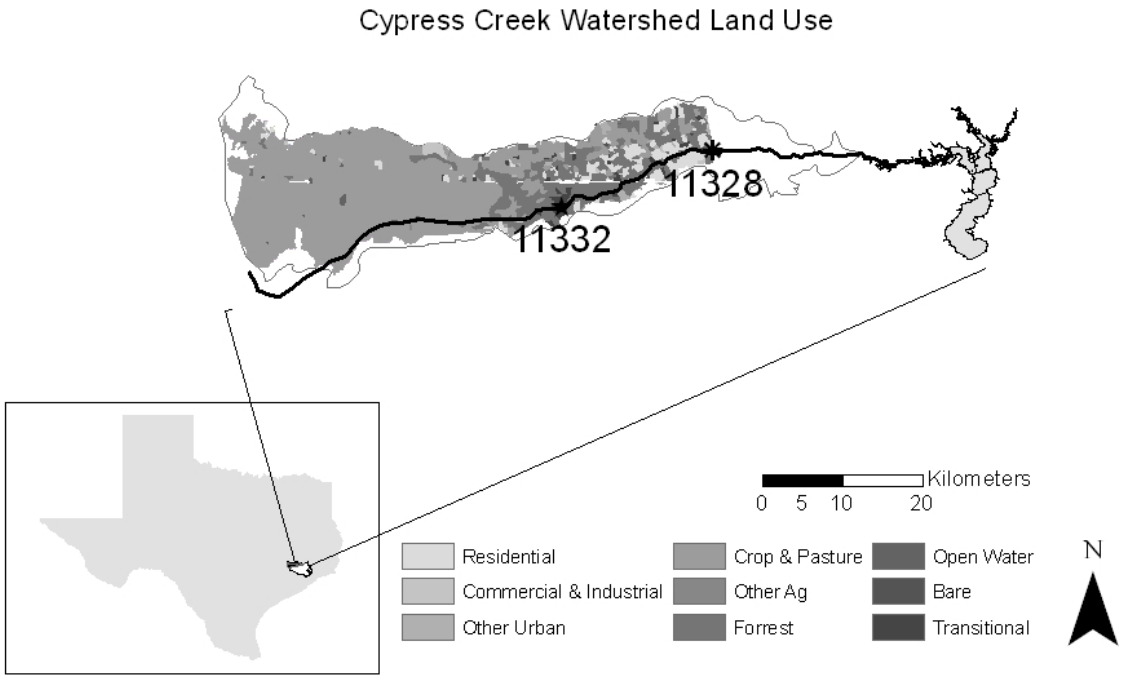

Figure 1: Cypress Creek Watershed

Table 1: Land Use Breakdown by Drainage Area of Water Quality Sampling Station

	Percentage of Drainage Area	
Land Use	**11332**	**11328**
Residential	1.47	6.73
Commercial & Industrial	0.86	0.95
Other Urban	0.14	0.80
Crop & Pasture	87.56	69.64
Other Ag	0.09	0.17
Forrest	8.51	18.68
Open Water	0.52	0.41
Bare	0.00	0.04
Transitional Area	0.83	1.91
Total Area (Hectare)	42,104	58,942

Statistical trend analysis and loading curves are analyzed using data collected by the USGS at 2 sites in Cypress Creek with corresponding City of Houston water quality data at the sites to characterize the behavior of the pollutant source and watershed.

Trend Analysis

Long-term water quality data is commonly used to detect trends in pollutants over time and also to identify, describe, and explain major factors that affect trends in water quality (Yu, 1993). The Mann-Kendall test, also known as Kendall's tau statistic is a nonparametric test for monotonic trends in a time series (Kaha, 2004),

derived from a rank correlation test for two groups of observations (Haan, 2002). This test is tolerant of outliers but requires that data are serially independent (Hamed, 1988). The Mann Kendall test is robust towards missing values, seasonal effect and non-normality (Larsen et al, 1999). Previous research has applied Mann-Kendall test to identify longer term effects of urbanization (Boeder, 2008) and to link stream flow with long term meteorological changes (Burn, 2002).

The Seasonal Kendall test is applied to address situations were data displays seasonality (Hirsch, 1982). By dividing the data into seasonal groups, performing the Mann-Kendall test on each seasonal group, and then summing the results, the effect of seasonality is removed (Hirsch, 1984). In effect the effects of dependence between the seasons is eliminated. This method has been used in various applications including assessment of the effect seasonality has on detecting the effect of acid rain on lake water quality (Taylor, 1989), assessment of spatial-temporal water quality variability (Krusche, 1997), and assessment of the effectiveness of water quality management strategies (Cude, 2001).

Load Duration Curves

A flow duration curve provides information about the percentage of time a particular stream flow was exceeded over some historical period thus providing a hydrologic "signature" of a catchment (Cigizogulo, 2000). This technique has been used in addressing water quality concerns in TMDL (Total Maximum Daily Load) programs (Cleland, 2003).

Load duration curves (LDC) are constructed by plotting the actual load over the allowable pollutant load as calculated by the product of stream flow and either the measured concentration or the water quality standard (Bonta, 2003). Actual loads that fall below the allowable load curve are considered to be in compliance with water quality standards whereas points above the line indicate water quality exceedances. The LDC is then examined to determine the flow conditions where a majority of exceedances occur. Flow conditions are divided into different categories of flow: 0 to 10% exceedance, High Flows; 10-40% exceedance, Moist Conditions; 40-60%, Mid-Range Flows; 60-90% exceedance, Dry Conditions; and 90-100% exceedance, Low Flows (Cleland, 2002).

Exceedances that occur during high flows are associated with rainfall events and pollutant sources characterized as non-point. In contrast, exceedances that occur during low flows are associated with dry weather and pollutant sources characterized as point sources (Bonta, 2002).

Method

Water quality data was collected by the City of Houston Health and Human Services and Water Quality Control departments at three locations within Cypress Creek ranging from 1996 to 2007. Stream flow discharge was measured by the USGS at the

same locations of water quality sampling. Data from 1996 to 2007 was used for both stream flow and water quality parameters.

The USGS trend testing utility (Helsel, 2006) was used to test for trend in stream flow and water quality parameters including dissolved oxygen, pH, total alkalinity, total organic carbon, chloride, sulfate, ammonia, nitrate, nitrates and nitrites, orthophosphate, and total phosphorus and *E. coli*, using Mann-Kendall test at 95% confidence level. Then the same utility was used to test for seasonal trends using a 4 season division of data using the Seasonal Kendall test at 95% confidence.

The *E. coli* dataset is the compilation of fecal coliform and *E. coli* sampling. This is necessary due to the limited time period of *E. coli* measurement, that does not fill the necessary sample size of 10 years required for Mann-Kendall and Seasonal Kendall trend detection. Garcia-Armisen et al. reviewed fecal coliform to *E. coli* ratios for different methods and found that a 1:1 ratio could be used for fecal coliform to *E. coli* ratios when a fecal coliform enumeration technique, MF using TTC Tergitol agar (SM9222D) and IDEXX colilert for *E. coli* were used (2007). These were the techniques used by both the City of Houston Health and Human Services and Water Quality Control (H-GAC, 2005) therefore the fecal coliform and *E. coli* datasets were combined to create the large enough dataset.

Load duration curves were developed for the constituents *E. coli*, orthophosphate, total phosphate, and nitrates at sites 11332 and 11328. Although ammonia measurements were made, the samples never exceeded the concern criteria, therefore load duration curves would not provide useful analysis. For *E. coli*, the water quality standard of 126 cfu/dL was used. The screening levels of 1.95 mg/L, and 0.69 mg/L were used for nitrates and total phosphorus respectively. Load duration curves were not constructed for site 11330 because the data collected by the USGS and the City of Houston did not overlap.

Results

The results of Mann-Kendall test for trend are summarized in Table 2 for station 11328 and Table 3 for station 11332. The tests were assessed at a 95% confidence level, therefore in order to reject the null hypothesis of no trend, Zs must be greater than 1.96 and Kendall's tau greater than 0.4. The p-values, Kendall's tau and magnitude of each test are reported. For station 11328, there were no statistically significant trends for any of the water quality parameters tested for both the Mann-Kendall and Seasonal Kendall tests. At station 11332, only total organic carbon showed statistically significant trends both overall and seasonally. In both cases the trend is decreasing over time.

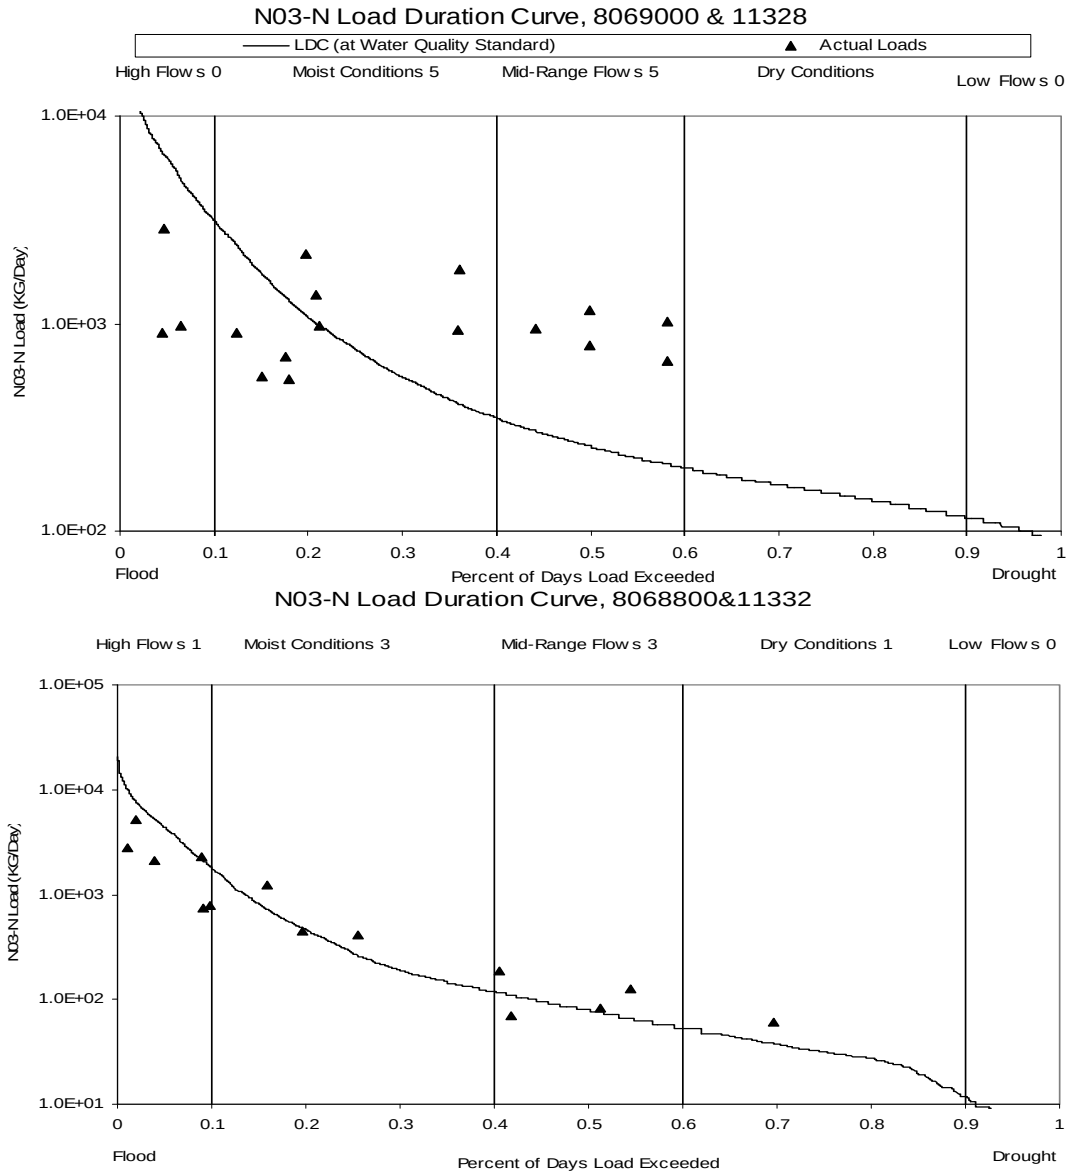

Figure 3: Nitrate Load Duration Curves for Station 11328 and 11332

Discussion

A majority of the water quality parameters showed a lack of trend at both stations within the watershed. Total organic carbon at station 11328 was the only constituent that had statistically significant trend (Table 3) both overall and seasonally. It is hypothesized that the decrease in organic carbon is due to improved land management and best management practices which prevent more organic materials and chemicals from entering the stream than previously practices allowed. The record of water quality data is quite short, encompassing only 11 years. The Mann-Kendall and Seasonal Kendall requires at least 10 years of data. With a longer time period of sampling, testing for trend will have greater statistical strength, with the potential for observing trends not detectable at this point. In addition, the *E.coli* constituent was

the combination of fecal coliform and *E. coli* testing, in order to meet the 10 year requirement. With two more years of *E. coli* testing, the fecal coliform data will not be needed to supplement the dataset, decreasing the uncertainty of the dataset. Unfortunately, trend detection did not provide new analysis for the characterization of the watershed or pollutant sources.

Future trend detection analysis could be improved by customizing the seasonal division of time for Cypress Creek. Multivariate analysis, including temporal cluster analysis should be performed to analyze the variance within the water quality dataset in order to cluster time periods into optimal seasons for Cypress Creek. This would provide a basis for improved seasonal trend detection, and could provide detection of trends obscured by the current seasonal division.

Analysis of the load duration curves for *E. coli* (Figure 2) show that exceedances occurred during all ranges of flows for both stations. This indicates that the sources of *E. coli* within the drainage areas most likely include a combination of point and non-point sources. It should be noted that for station 11332, all samples exceeded the water quality standard. Given this degradation of water quality combined with the eventual use of the water as drinking water, greater sampling frequency for further study would be appropriate. More frequent sampling would provide should be utilized to identify the behavior of stream pollutant loading for spatial and temporal characterization of the pollutant point and non-point sources.

Both stations exhibited exceedances of the nitrate screening level primarily within the moist conditions and mid range flows. As such there is little conclusive evidence for characterizing the source of nitrate. Although the presence of exceedances with the moist conditions suggests a non-point source associated with runoff, the lack of exceedances during high-flows contradicts this. However it should be noted that there are fewer sampling points in the dry conditions and low flows, allowing the potential for sampling bias. Both stations exhibited exceedances of the total phosphorus screening level primarily within the moist conditions and mid range flows in a similar manner to the nitrate loading curves. As such, there is little conclusive evidence for characterizing the source of phosphorus. The sampling bias present should be addressed with further water quality sampling a greater variety of flow conditions. Furthermore sampling throughout a storm event, to analysis of pollutographs would provide greater evidence for characterization of the watershed and pollutant sources.

Conclusions

Trend analysis using Mann-Kendall and Seasonal Kendall at 2 stations within Cypress Creek watershed only detected statistically significant trend for total organic carbon at 1 station. Analysis of load duration curves determined that a combination of point and non-point sources were contributing to pollutant loads that exceeded the water quality standards. The present analysis, with its limited dataset was limited in its utility for characterization of the watershed and its pollutant sources. Given the

severity of water quality violations and the city of Houston's dependence on the water for domestic consumption, it is important that more frequent sampling be performed through a wider range of flow conditions in order to study the nature of water quality violations and characterize the sources and behavior of pollutant sources. With further study of the stream, water quality trends and source characterization will provide valuable information for appropriate watershed management.

[1] Assistant professor, Department of Irrigation and Drainage Engineering, University of Tehran, Iran; Email:Banihabib@ut.ac.ir
[2] M.Sc. Irrigation and Drainage Engineering, University of Tehran, Iran; Email:Azar.Arabi@gmail.com

Abstract
The main purpose of this research is comparing the capability of HEC-HMS model and dynamic artificial neural networks (DANN), forecasting lead time of Golabdare-Darband basin in the north of capital city Tehran. Five scenarios are defined for different land uses, including conditions of 1955, 1988 and 2001, suitable and unsuitable land use of the basin. Floods with different return periods are simulated. The result of HEC-HMS model is used as training and test data of ANN network. The result of artificial neural network showed that the number of rainfall and runoff delays has optimal. Comparison of forecast lead time in two models shows that the lead time increases by decreasing in returned periods. Comparison of forecast lead time of five scenarios shows the scenario of unsuitable management of the watershed has the shortest lead time by using both models. The longest forecast lead time is for the scenario of 1988 land use by using DANN model and the scenario of 1955 land use for HEC-HMS model. The difference comes from instability of simulation by DANN.

Keyword: Artificial neural network, HEC-HMS model, Land use, forecast lead time

1-Introduction

Inundation damage has been estimated several billion pounds in UK in the past five years, while on an international scale, flooding threats lives particularly in tropical and subtropical regions [8]. Although global warming is now recognized as a real threat, there has been little success in establishing protocols for the reduction of greenhouse gases. Therefore, an increase in the occurrence of flooding is likely to continue into the future [8]. For these reasons, flood forecasting is becoming more High-priority for both flood control and watershed management purposes. There are several integrated flood forecasting systems available. These systems generally comprise several interacting components, which usually include a rainfall-runoff forecasting model, a database for the management of historical and real-time data, a dissemination module which issues warnings to hydrologists monitoring the catchment, and a component which continually evaluates and updates the forecasting outputs (Nemec, 1986). Using flood forecasting and flood warning systems accompanied by structural methods would increase flood control plans efficiency. In this case advanced models are needed to increase the accuracy of forecast lead time and to recoginize urbanization affects on lead time.

Some researchers analyzed runoff of basins by different hydrologic models. Kneale, P. et al (2000) compared the results of nine evaluation measures and two forecasting models. The models that they used in the study are artificial neural networks trained with back propagation (BPNNs) and a Time Delay Neural Network (TDNN). Networks were trained to forecast stage on the River Tyne, Northumbria, for lead times ranging from 2 to 6 hours with minimal data. The training data set consisted of continuous data for one winter period and validation was undertaken using data from winter periods for three other years. The results showed that the TDNNs performed better than the BPNNs although the evaluation measures indicate that the performance of these particular models is not yet sufficient for operational purposes [7]. Matreata.,M(2005) compared artificial neural networks and fuzzy logic in hydrological forecasting systems. Their results showed that Both artificial neural networks and fuzzy logic modeling systems offer the potential for a more flexible, less assumption approach to hydrological processes, and they have already been demonstrated as successful substitutes for the classical rainfall – runoff models, and also as tools for real time updating of hydrological forecasting models and especially for the multi model approach [9]. Dawson.,C.W. et al(2002) evaluated two neural networks including the popular multilayer perceptron (MLP), and the radial basis function network (RBF). Using six-hourly rainfall-runoff data for the River Yangtze at Yichang (upstream of the Three Gorges Dam) for the period 1991 to 1993, it was shown that both neural network types can simulate river flows beyond the range of the training set. In addition, they demonstrated that the popular Gaussian function, often used in RBF networks, is not necessarily the ‘best’ function to use in river flow forecasting [3]. Piotrowski., A. et al (2006) compared Multi-Layer Perceptron and Radial-Basis Function Neural Networks, along with the Nearest Neighbor approach and linear regression for flash-flood forecasting in the mountainous Nysa Klodzka river catchment. It turned out that the Radial-Basis Function Neural Network is the best model for 3 and 6 hours lead time prediction and the only reliable one for 9 hours lead time forecasting for the largest flood used as a test case [11]. Vieux, B.,E et al (2002) simulated flash floods and debris floods of a basin in Taiwan by VefloTM model. They could estimate two peaks of hydrograph with the least error [13].

Camorani,G et al (2005) investigated the possible effects of recent land use changes on the frequency regime of floods for reclaimed lands. They modeled the runoff concentration behavior of a reclaimed area located in the Po river plain near city of Bologna (North of Italy), using the combined application of a semi-distributed rainfall-runoff model, and a hydrodynamic stream flow routing model. The results showed significant sensitivity of flood frequency regime of the reclaimed land to land use changes; moreover sensitivity tends to increase as the recurrence interval of the rainfall event decrease [6]. Ad De Roo et al (2003) investigated the causes of the flooding and the influence of land use in the Oder basin in Italy by LISFLOOD model. This study has demonstrated that the proposed measure for flood control by the international Oder commission leads to a significant improvement and reduction in flood risk in the Oder catchment, especially for downstream reaches. Historical land use changes showed an increase in forecasted an urban area between 1780 and 1995, which hydrologically are balancing out each other in terms of discharge. It had been shown that the use of flood forecasting in reservoir management can also reduce downstream flood risk. Finally, it is expected by urbanization growing, flood risk in the next 30 years slightly increases [1, 4]. The examination of last scholarly showed different type of artificial neural networks and hydrologic models were used, predicting and simulating basins flood events, but the effect of land use changing by watershed management was not considered in different periods, accordingly it affected flood hydrograph and forecast lead time. Remarkably, the aim of this paper is evaluating the effects of land use changes on flood forecast lead time for different defined land uses, including land uses of the years 1955, 1988 and 2001, suitable and unsuitable watershed management of the basin in future.

2-Case study

2-1- Study area and data set description

The case study considered in this research is the Golabdare-Darband basin, located in the north of Iran (Tehran). The study areas including subbasins are shown in figure 1. The Golabdare-Darband basin is located in north of capital city Tehran, Iran. It has an area of approximately 739.2 ha. Several watershed management projects have been done in this basin such as mechanical measure (including check dams and detention dams), biological measure and other non-structural methods [2]. The land use of 1955, 1988 and 2001 are defined by using watershed management reports. The land use of 1988 and 2001 are considered the condition of before and after watershed management respectively. Suitable and unsuitable watershed management scenarios are defined on the base of land use of 2001 including following assumptions:

The unsuitable watershed management scenario has two assumptions as follows:

- In sub basins close to the city, the poor vegetation landuse is changed to urbanization land use.
- The pasture land use is changed to poor pasture in all sub basins.

The suitable watershed management scenario has four assumptions as follows:

- In sub basins close to the city, 50% of poor pastures were changed to wooded land use and the other 50% of area of the sub basins are changed to pasture.

- In other sub basins, 50% of the poor pastures landuse were changed to dense pasture.
- In sub basins close to the city, 50% of poor lands are changed to Garden and the remained 50% are changed to poor pasture.
- In other sub basins, 50% of uncovered lands are changed to pasture and the other 50% are changed to poor pasture.

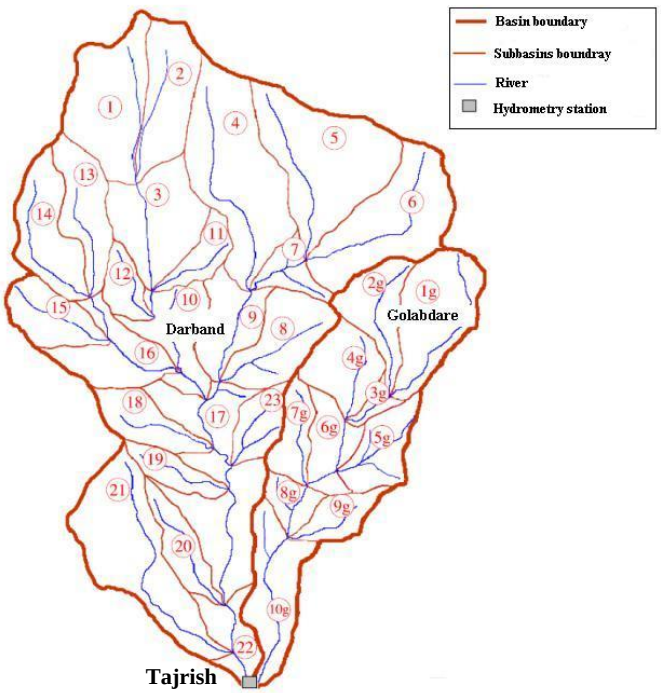

Figure. 1. Golabdare-Darband and sub basins

Stage and rainfall historical data are used for calibration of HEC-HMS model. Then, the floods of are different return periods simulated by calibrated model. Temporal pattern B of Niyavaran station has been recommended for Golabdare-Darband basin that is shown in Table 1. Rainfall intensities of different return periods are shown in Table 2 for duration of one hour [12].

Table. 1. Distribution of rain pattern in Niyavaran station

Time(percentage)	Rainfall(percentage)
25	19.41
25	29.01
25	40.74
25	11.01

Table. 2. One hour rainfall intensity in Niyavaran station

Return Periods(Year)	10000	1000	200	100	50	25
Rain (mm/h)	41.65	33.04	27.5	24.4	21.6	19.1

2-2-1- Rainfall-runoff model

HEC-HMS hydrologic modeling program is used in flood studies throughout the United States. The model was developed by the US Army Corps of Engineers, and it is designed to simulate the precipitation-runoff processes of dendritic watershed systems (USACE, 2005). The physical representation of the watershed is accomplished with a basin model. Various hydrologic elements are connected in a dendritic network to simulate runoff processes. A variety of methods are available for simulating infiltration losses, transforming excess precipitation into surface runoff, computing baseflow contributions to subbasin out flow, flow routing etc. Outflow from a sub-basin is computed from rainfall data by subtracting losses, transforming excess precipitation and adding base flow [2].

2-2-2- Dynamic artificial neural network

One of the ANN models that can deal with the time memory are the dynamic networks. Dynamic networks employ the dynamic feedback mechanism to handle the memory. The dynamic feedback mechanism means that the output of neurons in the hidden layers or the output layer can also be the input of the network itself. In dynamic networks, the memory of the system is embedded implicitly within the network, so the amount of input data is much less than that of the static networks. The Dynamic network also requires the data of the current rainfall, the past rainfall and the past runoff as its input. It can be explained using the following equation:

$$Q = F(pi(t), pi(t-1),...pi(t-k), Q(t-1), Q(t-2),...Q(t-h)) \qquad i = 1,2,...,g \qquad (1)$$

where F is the dynamic network, and pi(t) and Q(t) are defined earlier. The drawbacks of the ANN based rainfall–runoff models arise from the methods to construct memory in the networks and the style of input data. The first drawback results from the evaluation of the memory length. In this paper, output of neurons in the first hidden layers and the output layer are the delay input of the network.

3-2- Expected Lead Time Concept

The forecast lead time varies from storm to storm and location to location. Dotson and Peters (1990) noted that lead time is influenced by spatial and temporal variability of precipitation (the growing and decay of rainfall cells within the storm), rainfall-runoff response characteristics of the watershed, and antecedent soil moisture conditions. The forecasted lead time varies from storm to storm depending on multiple factors. Figure 2 is a hydrograph, showing the flow versus time. Conceptually, Figure 2 illustrates how the warning time is computed for each event. Initially, time is required for system operators to gather, evaluate, and forecast based on available data. This data collection and evaluation time is labeled Tr in the figure (recognition time). The forecast lead time, labeled Tlt in the figure, is the duration of time between threat recognition and threshold limit, that is, the time before the threshold limit when the system operators are first able to forecast an extent. To compute Tlt, we first use the entire rainfall hyetograph to compute a “true” runoff hydrograph, as shown by the solid line in the figure. This is the runoff that will occur when the rainfall event has finished. The time of actual extent, labeled TE, is the time when the flow from the true hydrograph exceeds the threshold. The dotted line represents the forecasted flow hydrograph based upon the precipitation up until the

time of forecasting, TF. As illustrated, as TF is stepped forward in time, additional precipitation will be used in the forecast [10].

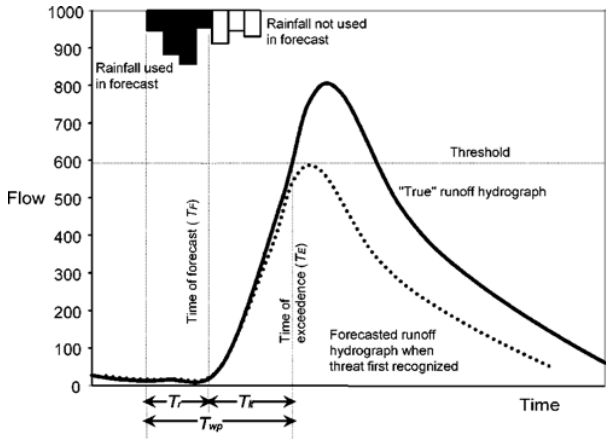

Figure. 2. Warning time components from hydrologic perspective (adapted from USACE 1996a)

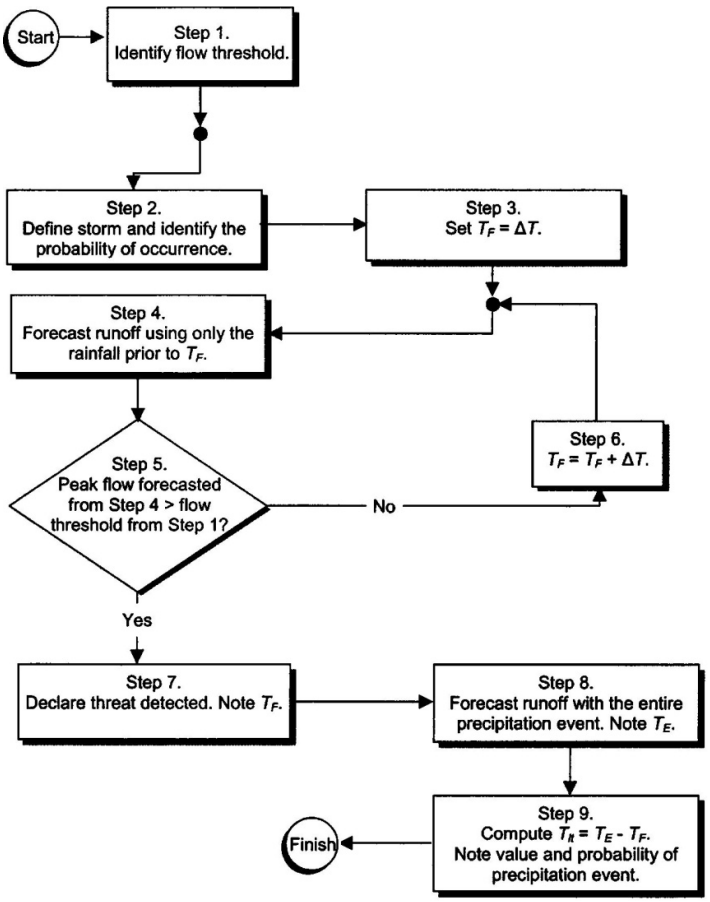
3-2-1- Computation Steps

Figure 3 conceptually shows the steps taken to compute TL. As noted, a calibrated rainfall-runoff model, HEC-HMS model, and hypothetical frequency-based events appropriate for the watershed are required to use this procedure. In Step 1 the TL is computed to identify the vulnerable site and the flow threshold for which the value will be computed. The flow threshold is the flow where property is first damaged or lives are put at risk. It can be identified using topographic information, elevation data for vulnerable structures and infrastructure, and simple channel models. The flow threshold is 25-year flood peak in Golabdare-Darband River. In Step 2, the first frequency-based storm is developed. To develop the storm, a time interval, DT, must be selected. Typically, this value is selected based on the time increment from the rainfall-runoff model. For the computations, this same time interval will represent the likely interval between successive forecasts or examination of data for identifying a threat. Therefore, DT is likely to be a relatively short increment, here we used 1 minute. Initially, we set TF equal to 0, the time when the first rain starts falling. In Step 3 we set TF equal to the end of the first DT. Therefore in Step 4, when the first forecast is made, only the precipitation that occurs during that first DT is used for the forecast. Once the forecast is complete, the peak forecasted flow is compared to the flow threshold (25 year peak flood in 1988), Step 5. If the forecasted flow is less than the peak flow, as illustrated in Figure 4(a), the precipitation that has fallen prior to TF is not sufficient to cause a great enough runoff to exceed the downstream threshold. Therefore, TF is advanced by another DT, Step 6, and the runoff is forecasted. This recursive forecasting, illustrated in Figure 4, is repeated until the peak forecasted flow is equal to or greater than the flow threshold. If the flow threshold is exceeded, as illustrated in Figure 4(b), we declare that a warning would be issued and note TF, Step 7. This computation scheme simulates the gradual formation of a storm, observation of the data over time, and attempts detection of the flood event. In Step 8, the entire precipitation event in the forecast model is used to compute the runoff hydrograph from which TE can be computed. This represents the “true” runoff hydrograph. In Step 9, the forecast lead time for that specific precipitation event is then computed as the difference between TE and TF. Note that if the precipitation

event is not large enough to exceed from the threshold, then the value will not exist for that event [10].



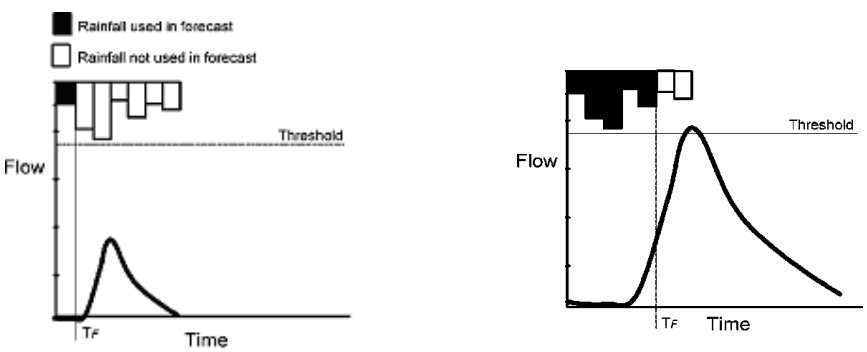


Figure 3. Steps to compute expected forecast lead time

(a) **(b)**

Figure 4. Schematic of forecasted flows with various times of forecast

The Best structure of dynamic artificial neural network is selected by Ka as follows:

$$ka = EQ_{pa} \times RMSE_a \tag{2}$$

(4)

$$RMSE_a = \left(\frac{RMSE_{10000} + RMSE_{1000} + RMSE_{200} + RMSE_{100} + RMSE_{50} + RMSE_{25}}{6}\right) \quad (3)$$

$$EQ_{pa} = \frac{EQ_{p10000} + EQ_{p1000} + EQ_{p200} + EQ_{p100} + EQ_{p50} + EQ_{p25}}{6}$$

$RMSE_a$=Root Mean Square Error
EQ_{pa}= Peak of discharge Error

3-Result

Table 5 shows the result of artificial neural network. Also the lead time of scenarios are shown in figure 5 for different return periods. The results show the forecast lead time of 1988 is longer than 1955, due to better land use in 1955 compare to 1988 scenario. Accordingly, the forecast lead time is decreased by increasing in return periods. The results show 1955, 1988, 2001 and suitable watershed management scenarios do not declare the threat detected for the 25-year flood. The forecast lead time is decreased from 20 min (1988 scenario) to 7 min (unsuitable watershed management) in 10000-year flood. The results clarified the land use of 1988 causes the longest forecast lead time and unsuitable watershed management has the shortest forecast lead time.

Table 5. Forecast lead time and its parameter in different return period(by DANN)

Parameters	Scenarios	25 year	50 year	100 year	200 year	1000 year	10000 year
T_f	1955		49	41	39	35	30
	1988		35	31	28	23	16
	2001		51.63	48.70	46.38	41.23	34.94
	Unsuitable management	53.30	49.10	45.46	41.81	36.74	29.98
	suitable management			54	49	45	37
T_E	1955		60.40	50.8	48.4	44.10	38.4
	1988		58.8	52.50	49	43.6	36.2
	2001		38.52	36	35	30	24
	Unsuitable management	42	39	36	33	28	22
	suitable management			39	36	33	26
T_L	1955		11.40	9.80	9.42	9.06	8.36
	1988		23.8	21.5	20.99	20.6	20.23
	2001		13.11	12.70	11.38	11.23	10.94
	Unsuitable management	11.23	10.10	9.46	8.81	8.74	7.98
	suitable management			15	13.46	12.12	11.2

No need for warning

Table 6 shows the result of HEC-HMS model. The forecast lead time of scenarios in return periods are shown in figure 6. The results show the forecast lead time has decreased from 14min to 3min in different scenarios. Therefore the 1988 scenario has the longest lead time and the unsuitable watershed management scenario has the shortest lead time, due to better land use in 1988 compare to other scenario. The results show the forecast lead time is decreased by increasing in return periods. The 1955, 1988, 2001 and suitable watershed management scenario do not declare the threat detected for the 25-year flood.

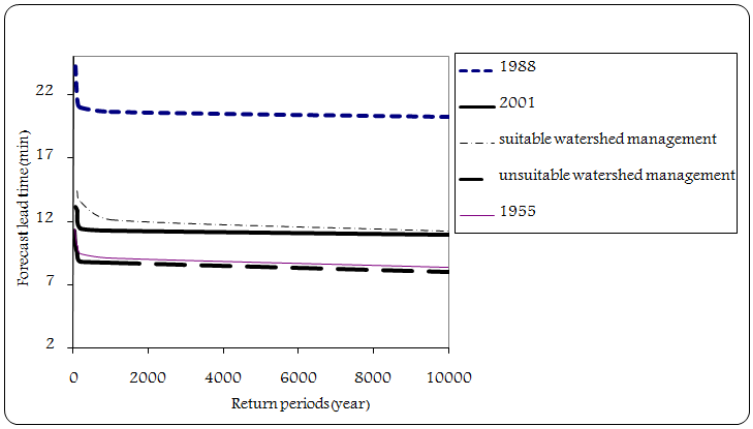

Figure 5 . Forecast lead time in return periods (DANN)

Table 5. Forecast lead time and its parameter in different return periods (by HEC-HMS)

Scenarios	Parameters	25 year	50 year	100 year	200 year	1000 year	10000 year
1955	T_F			43.625	39.919	35.205	30.365
	T_E			55.985	50.122	43.976	37.786
	T_L			12.36	10.204	8.771	7.421
1988	T_F		43.07	39.27	36.1	32.09	26.84
	T_E		56.97	51.18	46.7	41.37	35.71
	T_L		13.9	11.91	10.6	9.28	8.87

	T_L	8.9	4.8	4.3	3.9	3.2	3
suitable management	T_F		55.6	42.9	39.3	34.7	30
	T_E		63.1	54.1	48.4	42.6	36.6
	T_L		7.50	11.30	9.10	7.90	6.70

No need for warning

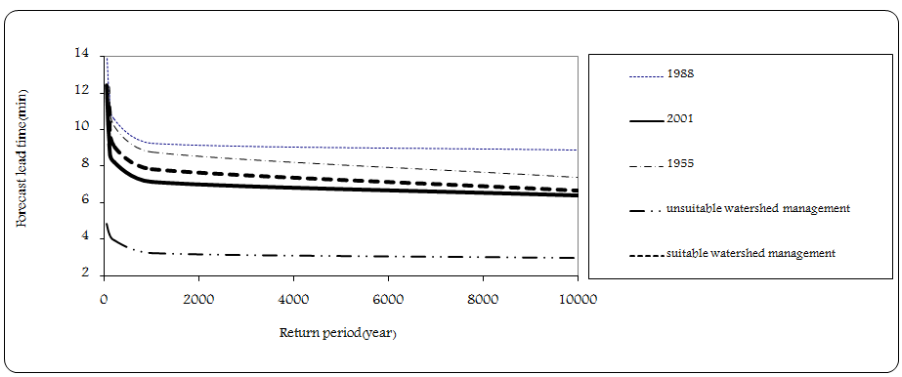

Figure 6 . Forecast lead time in return periods (HEC-HMS)

The results show that land use of 1988 caused the longest forecast lead time in both of models.While unsuitable watershed management has the shortest forecast lead time. However dynamic artificial neural network (DANN) estimated longer forecast lead time for different returns periods than HEC-HMS model but that it caused by the oscillation of simulation of hydrograph. Therefore dynamic artificial neural network estimate less accurancy than HEC-HMS models.

4-Conclusion

In this paper, the effect of land use on forecast lead time has been analyzed with dynamic artificial neural network. To sum up, the most important results can be pointed out as follows:

- The scenario of 1988 causes the longest forecast lead time and the land use of unsuitable watershed management causes the shortest forecast lead time in both models.
- Unsuitable watershed management land use causes shorter lead time.
- Artificial neural network has different results in scenarios for forecast lead time, due to oscillation in simulation hydrograph.
- The result showed that the simulation by HEC-HMS model is more stable than dynamic artificial neural network (DANN).

ABSTRACT

Hydrologic processes have been affected by human activities which include both direct and indirect interferences. The indirect human interferences such as land use and land cover change have been studied and modeled in many watersheds around the world. These kinds of human interferences, resulting in land surface changes, usually affect the rising limb and the peak of a hydrograph. The streamflow recession process, are not much affected by the land surface condition and the impacts of indirect human interferences are trivial; however the direct human interferences such as water withdrawals and return flows may affect the recession dynamics significantly. Direct human interferences are difficult to observe and model, and are usually assumed to be known and additive to streamflow. This paper provides a recession analysis involving groundwater pumping and effluent discharge as variables. The analysis is applied to an urban watershed in the Chicago area. Based on the historical streamflow observation during the last half century, the analysis provides results that explain the impact of direct human activities on the streamflow recession process. Moreover, the analytical method allows retrieving human water use data such as groundwater pumping and return flow, which change with socioeconomic development and policy reforms, as long as the streamflow observation is available and long enough. The analysis is verified with the data of the case study watershed and can be applied to other watersheds under intensive human interferences.

Introduction

With the increasing demand of domestic, agricultural, commercial, and industrial uses, humans are increasingly significant components of the global hydrologic cycle and human activities have transformed hydrologic processes crossing the various scales from local to global (NRC, 1992). Human being affects the hydrologic system indirectly by changing the driving forces such as climate and boundary conductions such as vegetation and land use, soils, and topography; human being also directly exerts on water flow or storage by river diversion, groundwater pumping and return flow, which strengthens the connections between the various hydrologic components. For instance, groundwater is a major source of water supply in many areas.

Within a holistic system composed of human and natural sub-systems, the change of human activities propagates within the system and causes changes of other components. It no longer makes sense to study only natural hydrological cycles in watersheds with intensive and extensive human activities (Oki and Kanae, 2006). Indirect human interferences, such as land use change and climate change, have been studied extensively in past decades (e.g., Cörösmarty et al, 2000). We may define land use change and climate change as indirect human interferences to hydrologic systems and define water withdrawal and return flow as direct human interferences. Indirect human interferences usually affect the rising limb and the peak of hydrograph while the direct interferences may have a dominant impact on the declining limb with the flow recession process. Low flows including base flows are usually critical to ecosystem habitats and are important targets of watershed restoration.

However fewer studies have touched the direct human interferences. Recently some studies emphasized the necessity of considering the direct human interferences in hydrologic modeling (Claessens et al. 2006). A number of indicators have been used to measure the degree of direct human interferences to hydrological systems regarding water demand (Vörösmarty et al., 2000), water scarcity (Oki and Kanae, 2006) and water use regime (Weiskel et al., 2007). Some studies used the differences of observed streamflow and the simulated natural flow as an indicator of human interferences (Cong, et al., 2008). However, water uses are still not yet a major focus of scientific studies, the level of integration of water use data with standard

hydrologic data is limited and fundamental understanding of the role of water use in the hydrologic cycle is not clear (NRC, 2002).

Furthermore, natural systems interact with human systems in a dynamic, nonlinear form (Liu et al., 2007) in the so called coupled human and nature systems. However, direct human interferences are difficult to observe and model, and are usually assumed to be known and additive to streamflow. Such simply abstraction or addition of water to the output of mass balance equation may not be a proper way to address the impact of human interferences. It is necessary to simulate human activities and natural processes in a coherent framework. The challenges include data availability and accuracy of human activities and the nonlinear interaction and dynamics of coupled human and natural systems. Data of human interferences, corresponding to the spatial and temporal resolution of physical processes are usually incomplete or even unavailable (Wang and Cai, 2007). Moreover, a consistent, conceptual model that integrates human activities and hydrologic processes and is meaningful with respect to the current data availability is still needed.

The focus of this paper is on the estimation of direct human interferences to hydrologic processes in heavily managed watersheds. We study a specific hydrologic process – the streamflow recession and we argue that direct human interferences at the watershed scale can be reflected by the declining limb of hydrographs, associated with low flows in streams. We extend the recession analysis of natural watersheds to incorporate specific forms of human interferences including groundwater pumping and return flow. An analytical solution is derived under the various natural characteristics and human water use forms. The closed-form equations involved both natural and human system parameters allow retrieving some unknown parameters given the observation of other parameters. The analysis is applied to the Salt Creek Watershed, an urban watershed located in the Chicago area. The changes of the recession pattern of observed hydrographs are simulated by the extended recession analysis model and explained by the water use regime in the study area. Moreover the pumping and effluent discharge rates during the past half century in the Salt Creek Watershed are retrieved using observed streamflows.

Recession analysis of natural watersheds

The storage-discharge relationships, recession curves and recession slope curve have been discussed in the literature since 1900s (e.g., Brutsaert and Nieber, 1977). The conceptual

power-law storage-discharge model has been used to analyze the base flow behavior at the catchment scale (e.g. Wittenberg, 1999):

$$S = aQ_s^{\,b} \tag{1}$$

where Q_s (m^3) is the amount of discharge from groundwater which directly interacts with the stream, and it equals the streamflow under the recession period when quick flow ceases; S (m^3) is the volume of water stored in aquifer; a (m^{3-3b} s^b) and b (m^0) are watershed parameters. Neglecting evapotranspiration, the equation of continuity or the storage equation during recession is

$$Q_s = -\frac{dS}{dt} \tag{2}$$

For a linear model ($b = 1$), the recession of baseflow is described by the exponential function $Q_s(t+\Delta t) = Q_s(t)e^{-\Delta t/a}$. For a nonlinear model, the recession curve can be modeled as (Wittenberg, 1999):

$$Q_s(t+\Delta t) = \left[\frac{(1-b)\Delta t}{ab} + Q_s(t)^{b-1}\right]^{1/(b-1)} \tag{3}$$

The parameters (a and b) of the storage-discharge relationship vary over different basins. For a given watershed, the change of groundwater system parameters in a short time period such as 50 years can be negligible. Although land use change and groundwater pumping may change the compaction of soil and the path way of groundwater flows, it is reasonable to assume the changes of the parameters are small. The values of a and b can be estimated by observed natural flows when human interferences do not exist or are not significant.

Recession analysis with pumping and effluent discharge

The storage-discharge relationship, is still valid under human interferences. If pumping and evapotranspiration are considered during the recession period, Equation 2 can be rewritten as:

$$\frac{dS}{dt} = -Q_s - Q_p - Q_{et} \tag{4}$$

where Q_p (mm d^{-1}) is the pumping rate from the aquifer which interacts with the streamflow; Q_{et} (mm d^{-1}) is the groundwater evapotranspiration rate (but it does not include the irrigation water consumption by crops). In an urban watershed, the total streamflow during the recession stage is the sum of base flow and effluent discharge

$$Q = Q_s + Q_e \tag{5}$$

where Q_e is the return flow.

For the case b=1/2, the base flow is obtained by assuming pumping and evapotranspiration rates are constant during the integration period

$$Q_s(t+\Delta t) = \left(Q_p + Q_{et}\right)\tan^2\left[\arctan\sqrt{\frac{Q_s(t)}{Q_p+Q_{et}}} - \frac{\sqrt{Q_p+Q_{et}}}{a}\Delta t\right] \tag{6}$$

where Δt is the time step such as one day. If $b \neq 1/2$, the integration of Equation (6.7) can be represented by hypergeometric function. Substituting Equation 5 into Equation 6 and eliminating $Q_s(t)$:

$$Q(t+\Delta t) = Q_e + \left(Q_p + Q_{et}\right)\tan^2\left[\arctan\sqrt{\frac{Q(t)-Q_e}{Q_p+Q_{et}}} - \frac{\sqrt{Q_p+Q_{et}}}{a}\Delta t\right] \tag{7}$$

Application to Salt Creek Watershed

The Salt Creek in DuPage and Cook Counties, Illinois, is a tributary to the Des Plaines River in urban Chicago. The Salt Creek watershed covers about 384.6 km^2 of the northeastern Illinois. Residential area occupies 49% of the land use in the watershed. Approximately 23% of the total watershed area is impervious surface. There are 31 point-sources in the watershed, among which there are 11 municipal permits in the watershed, 10 of which are major facilities that have design flows of 0.01 mm d^{-1} or greater (CH2M HILL, 2004). The streamflow is impaired by pollutants such as nutrients, metals, pathogens, etc. associated with effluent discharges.

Figure 1 shows the recession curves during January of 1951 and 2005, respectively. Not only the changing magnitude but also the shapes of the two recession curves are very different.

The recession in 1951 is much steeper than that in 2005. It is reasonable to assume that the human interferences in 1951 were negligible since substantial population increase occurred after 1950s (Spieker, 1970). Thus the watershed could be treated as a natural. In winter (December, January and February), the evapotranspiration loss from groundwater is low and a small value is assumed for Q_{et}. We then test the best parameter value for b in this particular watershed and estimate the value of a. Multiple values of b are chosen, and the best value of a is found under the given value of b by minimizing the RMSE between the observed recession curve and the simulated one. The best value of b is around 0.5.

The estimated pumping rates and return flows are plotted in Figure 2 with observed daily streamflow. The return flow increased significantly in the 1960's, and became stable after the 1980's around the value of 0.36 mm d^{-1}. The number is consistent with the assessment provided by a report sponsored by the Illinois Environmental Protection Agency, in which the effluent discharge is assumed to be constant with the estimated value of 0.35 mm d^{-1} during 1990~1999, and the report projected the change of effluent discharges up to 2020 according to the demographic and socioeconomic development projection in the watershed (CH2M-HILL, 2004).

From Figure 2, the estimated pumping rate increased significantly in the 1960's, which is consistent with the sharp increase of effluent discharge in the same period. In 1965, the estimated pumping rate from the shallow groundwater is estimated as 0.130 mm d^{-1}. According to a USGS report (Spieker, 1970), nearly all the public water supplies in the Salt Creek Watershed depended on groundwater in 1966. Of the total pumpage of 0.355 mm d^{-1}, 0.226 mm d^{-1} was pumped from the deep aquifers, and 0.129 mm d^{-1} was pumped from shallow, unconfined aquifers which directly interact with the streamflow (Spieker, 1970). This then validates the estimation of the water withdrawal from groundwater resulting from the recession analysis. The estimated pumping rates decrease in the 1970's and 1980's; after the 1990's, the pumping rate decreases to 0.01 mm d^{-1}. The reason of decreasing groundwater pumping is the use of water from Lake Michigan. The allocation delivered from Lake Michigan for water supply in the area began with a small amount before 1975. Around 1992-1993, many communities in the Salt Creek watershed obtained water allocation right.

Conclusions

Direct human activities such as groundwater pumping and effluent discharge affect flow recession processes, associated with the alteration of the rising limb and the peak of hydrograph by indirect human interferences such as land use change. The changes of human interferences over years cause the dynamics of low flow regime in heavily managed watersheds. To understand the impact of direct human activities on flow recession, this paper extends recession analysis to incorporate direct human interferences such as groundwater pumping and effluent discharge. The analysis is applied to the Salt Creek Watershed. During the past century groundwater pumping and effluent discharges associated with the socioeconomic development in the area have caused a significant increase of the low flow magnitude, but a decrease of the flow variability. The change of the low flow regime reveals the path and form of water supply in the area through growing groundwater pumping during 1955-1970 (including deep groundwater depletion) and the switch from groundwater pumping to water diversion from Lake Michigan during 1975-1993.

Conventionally direct human interferences such as water withdrawals and return flows are added or distracted from storage or streamflow assuming a linear relationship between the human and natural system. Our study, which integrates water uses as endogenous variables in the recession analysis model, illustrates nonlinear impacts of human interferences on low flows in the case study watershed, which is probably related to dynamics of both water uses and natural processes.

Water withdrawals and return flows are usually difficult to observe and model and they are usually treated as known, deterministic parameters in hydrologic modeling, which can cause biased errors in model parameter estimation and model prediction (Hejazi et al., 2007; Wang and Cai; 2007). Given flow and evapotranspiration observation or assessment, our analytical model can be used to retrieve human interferences, as demonstrated in the case study watershed. Such a procedure is very useful for coupled human - natural system analysis since the data of human systems are usually incomplete or unknown.

The method provided in this paper can be applied to other urban or agricultural watersheds. For some watersheds the physical parameter of b may not be 0.5, then Equation (6.12) will not be applicable and approximation solution will be developed using the same reasoning methods proposed in this paper. In agricultural watersheds, pumping for irrigation

varies seasonally and so does return flow. Moreover, the uncertainties of streamflow observation and the physical parameters of the recession equations need to be considered for sensitivity and uncertainty analysis.

Historical changes in the streamflow in Kansas streams: variation, causes and implications

Jonathan P. Aguilar[1], James K. Koelliker[2] and Nicole Marie Dick[3]

Abstract

Over the past decades, the streamflow characteristics in the Great Plains streams have changed substantially. These changes have affected the use and allocation of water in the watershed, as well as the lotic ecosystem in the stream network. Changes have affected and will continue to affect the management decisions within the watershed. Our study was undertaken to determine the extent of change in the median and low flows of streams across the state of Kansas and to identify the probable factors affecting these changes, as well as its implications. Several unregulated streams were analyzed by using streams with more than 60 years of daily discharge data. The analysis focused on the median and low flows of the streams. The state of Kansas was divided into four regions, representing roughly the west, central, northeast and southeast sections of the state. Several factors believed to affect the streamflow were identified and their influence was modeled over time. A multi-variate statistical model was run. The results show changes in streamflow pattern have been experienced by Kansas streams. Over the decades, western and central Kansas streams are losing flow, while the eastern streams are gaining flow. Results also show that a climate factor, in terms of water deficit, dictates the regional differences in streamflow. It was apparent that anthropogenic activities of land use, water use and water conservation practices play a significant role in streamflow changes. The role of the physical factors, such as soil type and potential recharge, cannot be downplayed. An interesting result in this study shows that the magnitude and the effects of the factors on the streamflow pattern differed across the regions of the state. There is convincing evidence that the riverine ecosystem has been affected by the changes in the streamflow patterns. Results of this study could be useful to decision makers, water users, watershed stakeholders, and environmental conservation advocates in addressing problems and concerns related to stream and river management.

KEY TERMS: streamflow; instream flow; streamflow changes; streamflow pattern; Kansas streams; unregulated flow; modeling; statistical model; streamflow factors;

Introduction

Evidence of streamflow changes

Most of Kansas' streams were categorized by some authors as intermittent flashy (Olden and Poff, 2003; Poff, 1996). This is partly due to the fact that most of the precipitation in Kansas is of short duration and high intensity and storms cover a relatively small area. Another controlling factor is the land cover which is generally perennial grass underlain with mostly slowly permeable soil (Sophocleous, 1998), except in the alluvial floodplains and the southeast and south-central regions. Unlike forest trees, grasses tend to hold the surface runoff only for minimal period of time and thus contribute to the flashy characteristic of stream flow. With precipitation ranging from 46 centimeters (18 inches) in the west and a little more than 102 cm (40 inches) in the east, Kansas is considered a semiarid region (Committee on Integrated Observations for Hydrologic and Related Sciences, National Resource Council, 2008).

Today, tributary streams in Kansas might already be categorized as harsh intermittent. In western Kansas, groundwater extraction from aquifers became the most evident human impact in that region. The streams in the area once considered perennial became intermittent as the water table fell below the stream bed and caused the stream to dry up during periods of no rain. The condition is greatly exacerbated in the area considering that the western region receives minimal rainfall, in addition to being theoretically water deficit (i.e. more potential evapotranspiration than precipitation). On the other hand, agriculture, as well as, communities built retention dams along the streams and applied land conservation practices such as terraces and residue management on agricultural fields to conserve water and reduce evaporation and soil erosion. This has a positive effect in terms of water use efficiency and conservation in agriculture, but rather a negative effect on the streams as this reduces runoff from the field. This also has similar effects on the numerous water-harvesting techniques, such as farm ponds and reservoirs that are in operation within the farm lands. It might be argued that these practices also encourage recharge of the aquifers. However, the rate of recharge in western Kansas is so low (~0.6 cm per year) thus, negligible compared to the current rate of groundwater abstraction (Hansen, 1991; Sophocleous, 2005). On the downstream side, the presence of large dams and reservoirs cut the continuity of habitat along the streams and generally control the stream flow discharge further downstream of the structure.

Physical evidence of changes have been documented by photographs at certain stretches of streams across Kansas. For example, a dramatic change in streamflow had happened only in a matter of more than a decade (Figure 1) at a section of Arikaree in extreme northwest Kansas. The base flow of the river is fed by groundwater flow, but because of the agricultural activity in the area, the groundwater level has dropped and is no longer able to sustain the flow in that stretch. In 2006 pioneer species (e.g. wild grasses) had taken over much of the river bed. This is a

typical observation of the streamflows in western Kansas where the once effluent streams, where groundwater supply the base flow, have now become influent streams (Jordan, 1982; Ratzlaff, 1994; Sophocleous, 2000; Szilagyi, 2006).

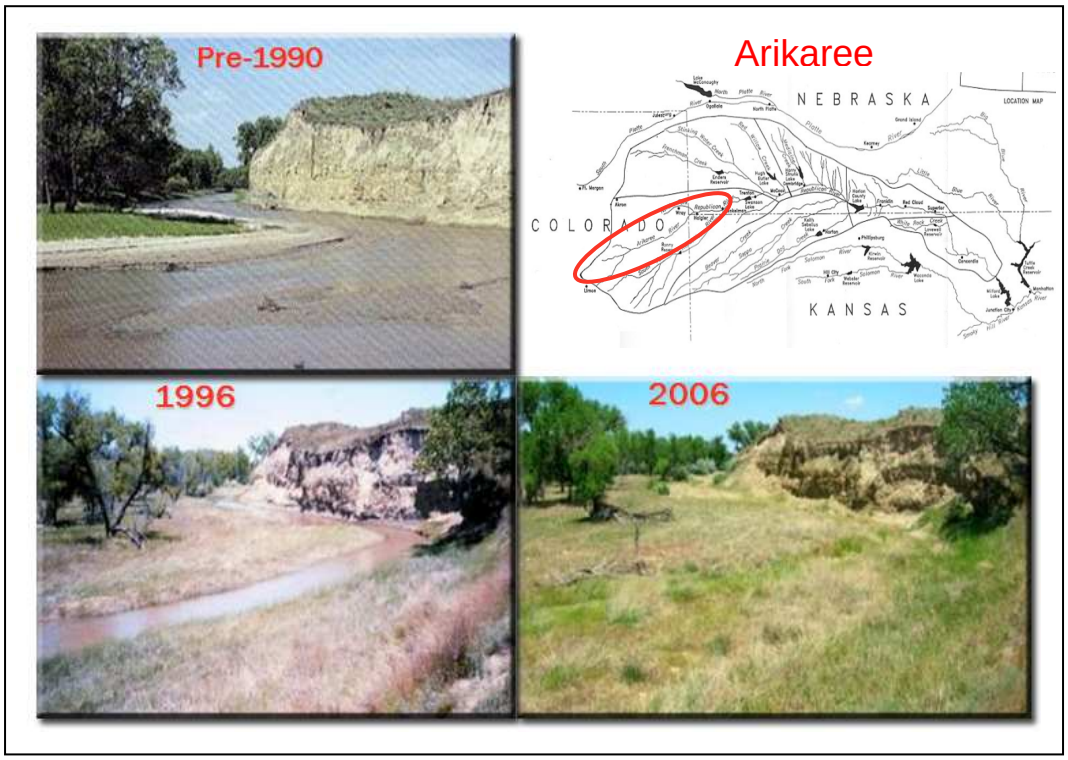

Figure 1. Physical evidence of the condition is depicted by these pictures taken from the Arikaree River in extreme northwest Kansas. Photo source: Kansas Department of Wildlife and Parks.

Changes in the runoff have also been documented in several watersheds of Kansas. Ratzlaff (1994) noted these changes in hydrology at least for the period of 50 years since 1940 in 27 watersheds across Kansas. According to the study, in western Kansas watersheds runoff has declined by as much as 93 percent. These changes were a cumulative effect of changes that was happening in the watershed starting around the 1950s (Ratzlaff, 1994).

Past research

There are now an increasing amount of evidence that the streamflow characteristics of the Great Plains rivers and stream have changed over the past century (Eberle et al., 2002; Perry et al., 2004; Szilagyi, 2006). Attempts to link the streamflow changes to the aquatic ecosystem are also available but limited. In the study that have been reported to the USGS, Perry (2004) made estimates of the median flows of the streams across Kansas using the 1999 surface water register. The study used a median flow of 1.7 cubic meter per minute (1 cfs) as the threshold delineating the sections of the streams with flow. Western Kansas showed not only many streams below the threshold flow, but more alarmingly a long, continuous stretch of the

condition (Figure 2). It should be noted that all the stream segments shown in Figure 2 were considered perennial by the USGS in the 1950s. Another attempt to understand the streamflow patterns was conducted in the Republican River which identified human-induced changes in the basin as the major cause of the declining flow (Szilagyi, 2006). However, there has not been a single research study that focused on Kansas with emphasis or at least in relating the changes to the aquatic ecosystem to other factors.

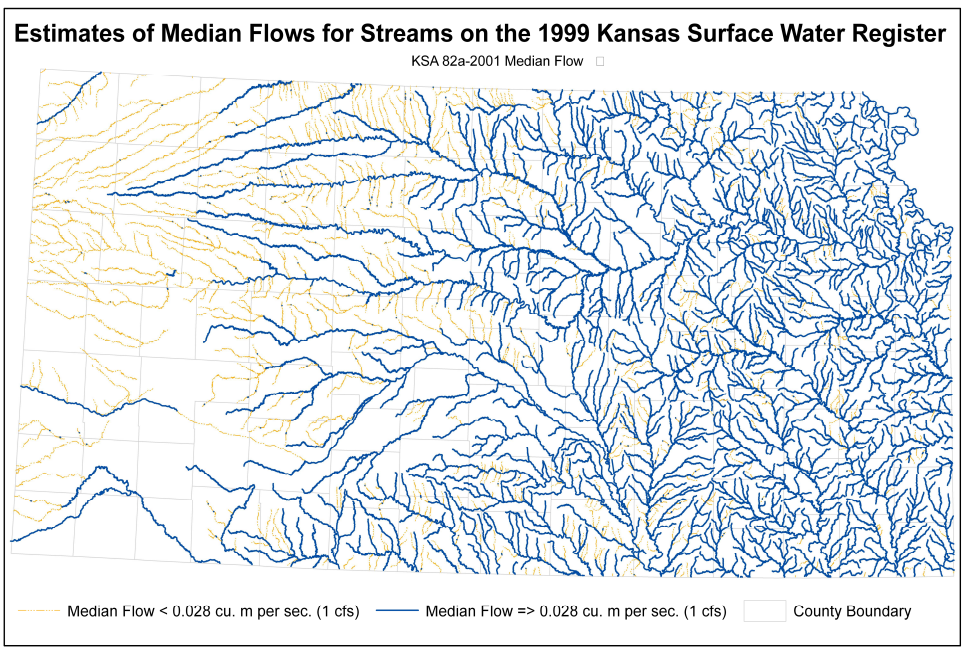

Figure 2. Estimates of median flows for streams on the 1999 Kansas surface water register showing stream reaches below and above a threshold flow of one cubic feet per second. Adapted from Perry et. al (2004).

Methods

Streamflow data

The major emphasis of this study is on streamflow data. USGS gauging station throughout Kansas were considered, but analysis was conducted only on those gauging stations considered unregulated as indicated in the remarks of the USGS Water-Data Reports (Putnam and Schneider, 2003). Another consideration in the selection of gauging stations was on the length of the daily data record. At least 60 years of continuous available data were included in the analysis in order to establish a good historical representation of the period. The records were divided into three 20-year periods. Only streamflow data labeled “approved” by the USGS were included. Kansas is also known to have a wide range of climatic variability across the state (Sophocleous, 1998). Thus, the gauging stations selected for this study where partitioned into four regions, namely west, central, northeast and southeast regions

(Figure 3). Three stations were selected to represent each region. Several flow parameters were computed but for this specific study, much of the focus was on the median to low flows only.

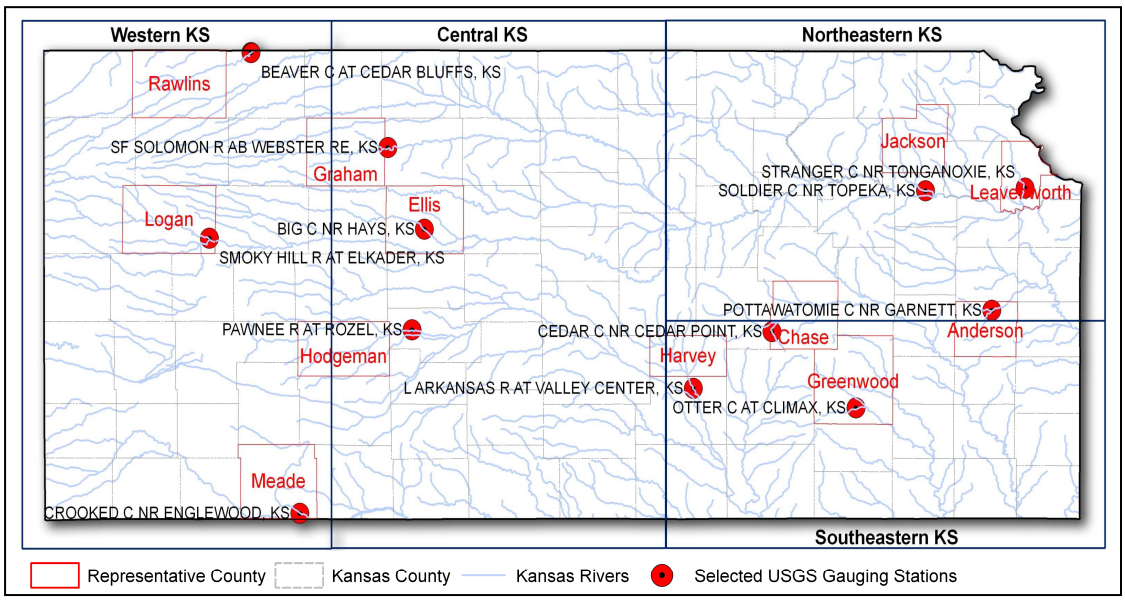

Figure 3. Location of the selected USGS gauging stations in reference to the regional assignment and the representative counties used in the study.

Statistical Model

One of the approaches in determining factors contributing to a certain phenomenon is by running a multi-variate, statistical model. The data was subjected to different statistical analyses. A state-wide analysis was first conducted followed by a regional approach. Several physical and anthropogenic factors were identified as related to the streamflow. The physical factors are recharge rate, soil type and climate, while the anthropogenic factors are water use, land use and soil and water conservation practices. Historical data was sparse and, in most cases, are on per county basis. Thus, representative counties covering most of the watershed area for each given gauging station were considered.

Recharge rate

Recharge is the infiltration of water into the saturated zone or groundwater. The rate at which the water infiltrates after saturating the initial profile is the recharge rate. There are many factors that affect the groundwater recharge rates such as the general soil texture within the soil profile, amount and intensity of precipitation, and land cover and vegetation among others. The groundwater recharge rates were taken from the maps generated by Hansen (1991) and Sophocleous (2005). The values of the recharge rates are actually the potential natural recharge rates for the county.

Soil type

Soil type influence several processes in the soil-water relationship, one of which is surface runoff. Surface runoff refers to the loss of water from an area by flow over the land surface. Surface runoff classes are based on slope, climate, and vegetative cover. The concept indicates relative runoff for very specific conditions. In the US Soil Survey Geographic (SSURGO) database (http://soils.usda.gov/survey /geography/ssurgo) where the data was taken, it is assumed that the surface of the soil is bare and that the retention of surface water resulting from irregularities in the ground surface is minimal. The classes are labeled as negligible, very low, low, medium, high, and very high. These were then assigned numerical values with a scale of 1-10, with 10 as having negligible surface runoff.

Water Use

The water use data was taken from the Kansas Geological Survey's (KGS) Water Information Management and Analysis System (WIMAS) database (http://hercules.kgs.ku.edu/geohydro/wizard/index.html). It contains the information of all the water rights issued in Kansas. The data dates backs in the 1950s when the first water rights were issued. Water rights are the maximum permitted amount of water that can be extracted from water sources such as river and groundwater. Average volume of water use for the county in cubic meter (acre-foot) was used in the analysis.

Land Use

The values used for land use were the average percent cropland of the representative counties. The Kansas State Board of Agriculture, which publishes Kansas Agriculture Annual Report, was the source of data for land use. Part of the publication was the area of land per county that is harvested to specific crops and the aggregated area was used in this study. It is important to note that especially in the western region of Kansas including some counties in the central region, fallowing is being practiced and was included in the cropped area. Fallowing is a farming practice that conserves the water in order to achieve a more dependable wheat production. Fallowing was originally practiced in a 2-year cycle with one crop grown per cycle, but recently the prevailing practice is to have a 3-year cycle with two crops grown per cycle. This generally shortens the fallow period while making the land more productive. It is said that for an inch (2.5 centimeter) of water stored during fallow, it is translated into a certain number of bushels (tons) of grain.

Conservation practices

Conservation practices refer to the adoption of soil and water conservation practices on the farm. The adaption varies over time and extent of area. There are no data available on this aspect for Kansas. Estimation of this factor was based on expert judgment. Dr. Koelliker is one of the leading hydrologist and watershed modeler in Kansas. He was also involved in several water conservation projects across the state and thus is knowledgeable enough to give some figures on the estimated adaption of the practices. A scale of 1-100 was used giving 100 to counties with full adoption of soil and water conservation practices.

Results and Discussion

Frequency analyses of flow were conducted and based on the median and low flows, there is a large difference between the flow pattern in the west and east (Figure 4). To show the trends across the large range of flows and to discount watershed size, trends over time are shown relative to the long-term average for each region. The western and central regions exhibit a general decreasing flow trend and the eastern regions show an increasing flow trend.

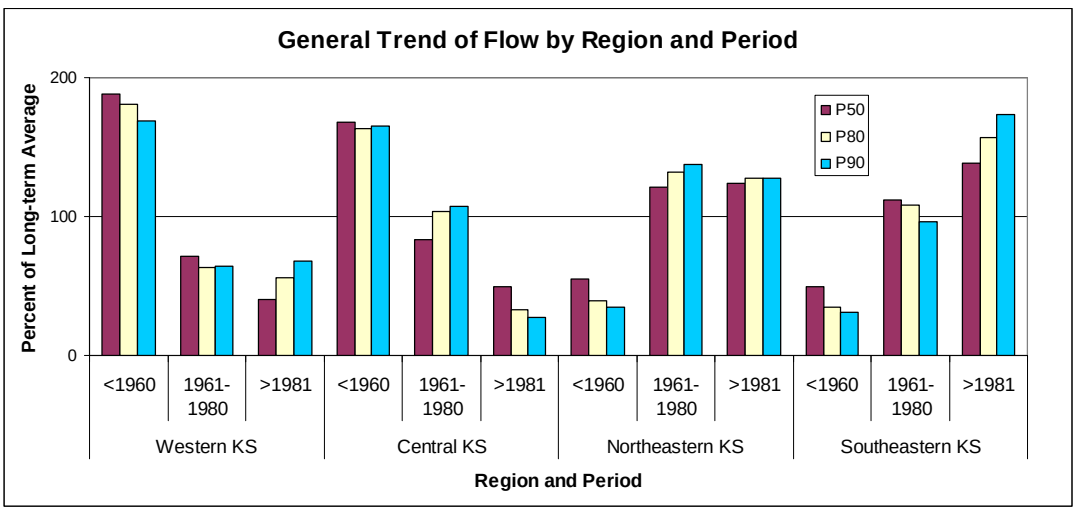

Figure 4. General trend of flow across Kansas by period and regions computed based on the long-term average for each region. P50 represents median flow, P80 is a low flow and P90 is a very low flow.

Correlation between paired parameters was determined using the Pearson correlation method. It showed that climate is highly correlated to the streamflow (Table 1). Thus, high correlation is good in a sense that variation in the streamflow across the state also reflects the variation of climatic factors in the area. However, the large climate effect conceals the probable effect of other variables on the streamflow. It was also observed that analyzing the data on the state-wide basis somehow produces some cancelling effects on the contributions of the individual variables. This reflects the high variation of parameters from east to west across Kansas.

Running the statistical analyses on the regional basis proved to be a better approach. Correlation among the paired parameters was conducted. Surprisingly, based on the tests, climate could be expressed as a function of recharge rate and soil type at each region. When climate was removed from the set of variables, the co-linearity between the variables disappeared except for the southeastern region. But as diagnostic tests are concerned, climate can mask the effect of other variables and thus could be removed in the succeeding analysis.

Using the backward elimination technique in regression, the only significant variable in the model for the whole state is recharge rate at the 90-percent confidence

level. The resulting model has an R-squared value of 0.39 which is high enough considering the varied hydrologic condition of Kansas. A similar exploratory analysis was also done for the data in each region. Climate also has a high correlation with the streamflow and can conceal the probable effect of other variables. The regional analysis generated a summary of statistical results as presented in Table 1.

Table 1. Summary of the model results which used backward elimination regression

Region	Significant Variables (α = 0.1)		R-squared	
	P50 Flow	P90 Flow	P50 Flow	P90 Flow
All	***Climate***	***Climate***	0.52	0.35
	Land Use (-)	Soil (-)		
		Land Use (-)		
Western	***Recharge Rate***	***Water Use***	0.96	0.96
		Recharge Rate		
Central	***Soil***	***Soil***	0.93	0.66
	Practice (-)			
Northeastern	***Land Use*** (-)	***Land Use*** (-)	0.93	0.94
	Practice	Practice		
		Water Use (-)		
Southeastern	***Recharge Rate*** (-)	***Recharge Rate*** (-)	0.74	0.75
	Soil	Practice		
	Practice	Water Use (-)		

Bold – most significant predictor
(-) – negative value in the model (i.e. reduces flow)

In general, there is a higher degree of confidence in doing the regional analyses than the state-wide analysis. The model's R-squared values are at a high of 0.97 to a low of 0.74, which are still relatively acceptable values. This shows that there is a good interaction between the significant variables and the streamflow values.

The result shows that from western region to southeastern region, which could be also interpreted as going from west to east of the state, the recharge rate changes from a positive correlation to negative. Conversely, soil and water conservation practices have a positive influence on the streamflow from the eastern section of the state, then a negative influence on the central section and eventually become insignificant on the western section. Soil type, on the other hand, has a varying response to different regions of the state. It tends to have negative influence on the streamflow in the western region, and a positive influence in central and southeastern regions. In the northeastern region, soil type is insignificant as far as changes in streamflow are concerned. Land use exhibits a negative correlation with streamflow in central and northeastern regions only. The other two regions show insignificant correlation to land use.

CONCLUSIONS

This study has showed changes in streamflow pattern have been experienced by unregulated Kansas streams. These changes differ depending on the location within the state. Western and central Kansas streams are losing flow over the decades, while eastern streams are gaining. Statistical models were used to identify the causes of these changes in streamflow. A good relationship between what is happening in the watershed and the streamflow resulted. The factors identified behave differently between the regions. It was clear though that climate is the overarching factor that dictates the differences among the regions of the state. Between regions, however, there are different factors that dominate. Interestingly, the recharge rate factor was found to have a different effect on the streamflow depending on the region. One thing is definite, anthropogenic factors (i.e. land use and water use) are substantial players on the fate of the stream flow pattern.

There is convincing evidence that the riverine ecosystem has been affected by the changes in the streamflow patterns. An analysis of fish communities in the Little Arkansas River Basin (LARB) by Strong et al. (1998) showed that during the last 100 years, fluctuation in the fish community composition was evident. Agriculture, industry and habitat restrictions are perceived to be playing a role in determining the fish community composition in the area (Strong et al., 1998). Although prairie fish living in upstream tributaries are able to survive the typical drought condition, the intensity and the increasingly harsh conditions (Walks et al., 2007) they are experiencing recently are probably making a toll on them. In a recent article on the status of imperiled North American and diadromous fishes, one of the major threats to at-risk fishes is habitat degradation and introduction of non-indigenous species (Howard L. Jelks et al., 2008). It is apparent that anthropogenic activities are affecting the balance in the aquatic ecosystem through modification in the streamflow patterns.

The results of this study are useful for decision makers and stakeholders in being aware that the factors causing streamflow changes may differ from one region to another. Thus, decisions made in response to the different activities within the watershed may result in different streamflow changes.

There is one caveat in this study; the assignment of the regions is more arbitrary rather than based on scientific delineation or grouping. Care should be practiced in making decisions based on the regional delineation made on this study. It is advisable to use established ecoregions if the application will deal with ecosystems or other environmental groupings and phenomena.

ABSTRACT

The AGNPS model was used to model agricultural BMPs for the Delaware Inland Bays . Corn, soybeans and wheat were the crops used in the simulation. Conventional tillage with a winter cover crop along with minimum tillage and no-tillage with and without a winter coverage crop were simulated as BMPs. The model was calibrated with water quality and flow data from Stockely Branch, a 1359 ha watershed. The model was successful in predicting total runoff, but there was some variation in predicted and measured nitrogen and phosphorus loads for the nine storms used to calibrate the model. Nitrogen loads were more accurately predicted then phosphorus loads. For BMP simulations, winter cover crops had a large effect in reducing nitrogen and phosphorus loads regardless of tillage.

INTRODUCTION

One of the major recreational areas in Delaware is the Inland Bays. The Inland Bays are next to the Atlantic Ocean in Southern Delaware. The Bays are estuaries and are inhabited by plants and animals which are typical of the Mid-Atlantic region. Delaware's Inland Bays consist of the three interconnected water bodies, Rehobeth and Indian River Bays. The Assawoman canal connects Little Assawoman and Indian River Bays. The three bays and their tributaries have a surface area of approximately 8300 ha and a drainage area of approximately 77800 ha. The Inland Bays are tidally flushed, with estimates typically converging on 90-100 days for Indian River Bay and 80 days for Rehobeth Bay (Price, 1997). No flushing estimates are available for Little Assawoman Bay. Groundwater is a highly significant component of freshwater flow into the bays. About 70 to 80 percent of total freshwater stream flow is composed of groundwater discharge. Groundwater also flows under the bay shores and discharges directly into the bays (Andres, 1992).

A Comprehensive Conservation and Management Plan (CCMP) was completed in 1995. In the CCMP, two major priorities identified were eutrophication and habitat loss (DNREC, 1995). Overall, the Inland Bays are highly eutrophic. Total nitrogen concentrations are generally in excess of 1.0 mg/L and total phosphorus concentrations generally range from 0.1 to 0.2 mg/L (Price, 1997).

The Total Daily Maximum Load (TMDL) set for the Inland Bays requires nonpoint source phosphorus loads to be reduced from 40 to 65% and nitrogen loads reduced from 40 to 85% in the different tributaries from baseline loads established from monitoring data collected from 1988 to 1990 (DNREC, 1998). The Agricultural Nonpoint Source Pollution model (AGNPS) was used on Stockely Branch one of the sub-watersheds of the Inland Bays to model different agricultural best management practices (BMPs). Water quality data was collected on Stockely Branch from 1976 to 1980 that was used to calibrate the model. Stockely Branch is also a USGS gaging station so long term flow data was available.

AGNEPS PROPERTIES AND PREVIOUS WORK

The Agricultural Research Service in conjunction with the Minnesota Pollution Control Agency and the Soil Conservation Service developed the AGNPS model to analyze and predict runoff water quality from agricultural watersheds. The model is an individual storm event model and not a continuous simulation model. Over the years since its development it has been used worldwide. One of the features of the model is it allows users to pinpoint potential areas of high nutrient loads through a uniform grid cell approach (Comis, 1995). The model routes a single rainfall event through the grid in a step by step manner allowing the user to evaluate any single grid in the watershed. For watersheds > 800 ha, a grid cell size of 16 ha is recommended (Young et al., 1989). For smaller watersheds accuracy can be increased by reducing the size of the cells.

Twenty-one parameters are used to describe each cell of the watershed. The model simulates hydrology, erosion and sediment and chemical transport. For the hydrology component, routines from the CREAMS model are used. Peak runoff and total runoff volume are estimated by the runoff curve number method. The model uses a modified version of the Universal Soil Loss Equation to estimate upland erosion. Using a soil breakdown of five particle sizes, a modified Bagnold stream-power equation determines the amount of soil detached and deposited. Nitrogen, phosphorus and COD are estimated with equations developed for the CREAMS model.

A study on Highland Silver Lake in Illinois found the model could simulate runoff accurately, but underestimated sediment loadings and over estimated nutrient loadings (Lee, 1987). A study on three watersheds near Coshocton, Ohio, agreed with the underestimate of AGNEPS sediment yield. The underestimation occurred especially for heavy rainfall events (Wu et al., 1993). The AGNPS model was used to predict sediment loads on two watersheds in Iowa and Nebraska. Predicted yields compared favorable with the measured values. Agreement between actual and predicted values was also found for runoff and sediment yields for three different types of watersheds in Mississippi (Young, et al., 1989).

MODEL INPUT DATA

AGNPS analyses a set number of equally sized user grid blocks overlaid on the entire watershed. The Stockely Branch watershed was divided into 35 cells based on a 40.5 ha grid cell. By digitizing the topography from the USGS, Georgetown Quadrangle in Sussex County, Delaware and the land uses, soils group and channel characteristics from the aerial photographs found in the 1974 Soil Survey of Sussex County, a composite map of the topography , land use, soils group and chancel characteristics was developed for the Stockely

Branch watershed (Ireland and Matthews, 1974). All physical data input for the cells were derived from this composite map. The land use for the watershed is summarized in Table 1. Most of the soils on the watershed are sandy loam or loamy sand. Slopes on the watershed are generally <0.75%. The average annual rainfall is 1110 mm. It is distributed fairly uniform over the 12 months. The watershed area is 1359 ha.

The current study relied on weather data gathered from weather station 073570 located in Georgetown, Delaware, 16 km northwest of the site. The historic precipitation data from weather station 073570 for the years 1976 through 1980 was available electronically through the state climatologist's web page. All data was entered into an Excel spreadsheet and converted to metric units for use with the watershed model.

Table 1. Land use for the Stockley Branch Watershed

Land Use	Area (ha)
Industrial/Commercial	12
Low Density Housing	21
High Density Housing	14
Cropland	738
Pasture/Grassland	12
Orchard	12
Chicken Houses	3
Forest	544
Wetlands	1
Water	2

Each cell requires 26 inputs. Although most input values remained constant for all storm events, values for the runoff curve number, Manning's overland flow coefficient, cropping factor C and surface conditions constant were changed for some storm events to reflect the conditions at the time of the storm event. To determine how each of these input values changed for the 35 cells, a combined land use and growing stage system was outlined for a specific crop rotation and management practice and values were modified based upon data in Wischmeier and Smith (1978). A common cropping regime was assumed for the entire watershed and each cell's inputs varied based upon land use.

The crops selected to model were chose based on prevalence within the Stockely Branch watershed and the Delmarva Peninsula. Corn, soybeans and winter wheat are the main crops grown in this geographic region and were selected for the BMP simulations. Based on the selected crops, crop specific dates were estimated based on common cropping practices. For calibration of the model for the period 1976 to 1980, a corn/soybean rotation without a cover crop and conventional tillage was used. The cropping and tillage dates and fertilizer application rates and dates for the corn/soybean rotation without a winter cover crop are presented in Table 2.

SENSITIVITY ANALYSIS

The following input variables were chosen for the sensitivity analysis:

- Curve number

- Land slope
- ULSE soil factors K and C
- Field slope length
- Manning's overland flow coefficient
- N and P fertilizer application rates
- N and P availability levels
- N and P nutrient decay

Table 2. Crop Specific Design Dates for a Corn/Soybean Rotation and No Winter Cover Crop

Crop Rotation	Date	Action
Corn/Soybean Rotation Without a Winter Cover Crop	April 15	Apply 75.5 kg/ha Nitrogen Fertilizer and 22.4 kg/ha Phosphorus
	April 30	Moldboard plow (Optional with Management Practice)
	May 21	Apply 140 kg/ha Nitrogen Fertilizer and 22.4 kg/ha Phosphorus
	May 25	Disc (seedbed period)
	May 30	Plant Corn
	June 15	Period 1 (10 percent canopy cover)
	July 1	Period 2 (50 percent canopy cover)
	July 30	Period 3 (75 percent canopy cover)
	October 15	Period 4 (Harvest Crop, Crop Residual)
		Fallow over Winter months
	April 15	Apply 75.5 kg/ha Nitrogen Fertilizer and 22.45 kg/ha Phosphorus
	May 15	Modlboard plow (Optional with Management Practice)
	May 21	Apply 140 kg/ha Nitrogen Fertilizer and 56 kg/ha Phosphorus
	June 25	Disc (seedbed period)
	June 30	Plant Soybeans
	July 15	Period 1 (10 percent canopy cover)
	August 15	Period 2 (50 percent canopy cover)
	September 15	Period 3 (75 percent canopy cover
	October 15	Period 4 (Harvest Crop, Crop Residual)

A single input variable was adjusted to either plus five (5), plus ten (10), plus twenty (20), minus five (5), minus ten (10), or minus twenty (20) percent of the original value. After the adjustment, a simulation was performed and the change in the output variables was noted. The collection data was then manipulated to find the absolute sensitivity for the relationship between a single input and single output variable. Absolute sensitivity was defined as the percent change in output divided by the percent change in input. Some of the sensitivity analysis is summarized in Table 3.

Of the input values evaluated in the sensitivity analysis for AGNPS, the curve number demonstrated the most significant effect of any input variable. The curve number seemed to have an effect on most output variables. Other variables analyzed did not show the same prevalence as the curve number. Other inputs seemed to influence only one or two output variables. For example, changing the Manning coefficient only had a small effect on peak runoff rate. Land slope did not change any of the parameters. The K and C factors affected sediment yield and nitrogen and phosphorus sediment loads.

Table 3. Summary of Sensitivity Analysis for Selected Variables (% change in output for given % change in input)

Input Variable	Change (%)	Total Runoff Volume	Peak Runoff Rate	Sediment Yield	Soluble Total N	Soluble Total P
CN	+20	5.1	6.3	2.0	40	45
	-20	-3.3	-3.7	-1.8	-6.1	-10
Manning's n	+20	0	0.04	0	0	0
	-20	0	0.04	0	0	0
N&P Application	+20	0	0	0	0.82	0
	-20	0	0	0	-0.86	0
N&P Decay	+20	0	0	0	-0.67	-3.0
	-20	0	0	0	0.79	6.0

MODEL CALIBRATION

Water quality data was collected for nitrogen and phosphorus at the watershed outlet from July, 1976 to June, 1980. A total of nine storms were selected for calibrating the model. The storms selected varied in size, duration and season of the year. The model was first calibrated for runoff where the storm simulated runoff volume was compared to the storm total runoff volume measured at the USGS gaging station. An average total flow was computed for x days, where x was the number of days runoff increased due to the storm event. The baseflow proceeding the storm was subtracted from the average daily storm flow to compute the total runoff. The curve number was adjusted for each storm based upon the initial moisture conditions. For calibration purposes it was assumed half of the cropland was in soybeans and half was in corn, no winter cover crop was planted and conventional tillage was used on all of the cropland. The calibration results are summarized in Table 4. For the nine storm events the model under predicted runoff volume for four of them and over predicted the volume for four storms.

Soluble nitrogen and phosphorus concentrations in the runoff were adjusted to fit the actual runoff concentrations by manipulating the levels of the fertilizer applied parameters. Nitrogen and phosphorus decay values were assumed to stay constant for each storm event. In order to obtain a satisfactory calibration between predicted and measured nitrogen and phosphorus concentrations a constant fertilizer application rate could not be used. For example the June 1979 storm required 280.2 kg/ha of nitrogen and 134.4 kg/ha of phosphorus and the March 1980 storm required 123.3 kg/ha of nitrogen and 134.5 kg/ha of phosphorus. The R^2 values for predicated versus measured concentrations for calibration of the nine storms were 0.725 for nitrogen and 0.527 for phosphorus. The model under predicted phosphorus concentrations for most of the storms. One reason for the large under prediction for some

storms could have been the model concentrations are soluble phosphorus and for the measured phosphorus concentration samples were not filtered, so total phosphorus was measured. Sediment concentrations in the Stockley Branch watershed were very low.

Table 4. Calibration Results for AGNPS

Storm	Rainfall (mm)	Moisture Condition	Runoff (mm)	N Conc Mg/L	P conc (mg/L)
Nov 1978			0.76	4.43	0.32
Actual Model	27	II	0.51	4.42	0.33
Dec 1978			1.02	5.70	0.27
Actual Model	29	II	1.02	5.59	0.23
Mar 1979			33.7	4.38	0.16
Actual Model	62	III	23.6	4.27	0.11
June 1979			19.6	6.00	0.18
Actual Model	84	II	19.1	3.59	0.05
Sept 1979			1.27	4.04	0.38
Actual Model	54	I	0.51	3.71	0.11
Dec 1979			2.29	4.77	0.35
Actual Model	24	III	2.79	4.56	0.27
Mar 1980			5.59	3.99	0.41
Actual Model	53	II	6.10	4.04	0.14
April 1980			10.4	2.78	0.16
Actual Model	41	III	12.4	2.85	0.17
April 1980			5.84	3.82	0.17
Actual Model	26	III	4.28	4.28	0.25

BMP SIMULATION

The following BMPs were simulated:

a. Conventional tillage with a winter cover crop (CTW)
b. Minimum tillage without a winter cover crop (MT)
c. Minimum tillage with a winter cover crop (MTW)
d. No-tillage without a winter cover crop (NT)
e. No-tillage with a winter cover crop (NTW)

The BMPs were compared to conventional tillage without a winter cover crop (CT). A corn and soybean rotation was used for all tillage systems without a winter cover crop. For the winter cover crop simulations, a corn-winter wheat-soybean rotation was used. It was assumed the winter wheat was harvested in July a rye winter cover crop was planted in the fall and full season soybeans planted the following spring.

The three tillage operations were associated with a different degree of surface roughness, lending way to establishing curve numbers and surface roughness coefficients. By not removing the surface residue, no-tillage was correlated with the lowest curve numbers and the highest surface roughness coefficients. Conventional tillage by moldboard plowing and disking was associated with the highest curve number and the lower surface roughness coefficient. The curve number and surface roughness coefficients for conservation tillage were established

in the middle of the other two simulated tillage practices. Secondly, the cropping factors were established for the simulations. Modifications resulted in changes to the cropping factor, the tillage practice factor, the maximum leaf area index, the curve number and the planting, fertilizing and harvesting dates. Changes in the curve number were based on the planting and harvest date as well as tillage operations. Lower curve numbers were associated with more ground cover resulting from lower impact cropping practices. Planting and harvest dates were varied only with the addition or subtractions of a winter crop in the BMP simulations. Input values for C, Manning's n, surface conditions constant and curve number were adjusted in each cell based upon land use. Values established at the time of harvest were maintained until the next tillage or planting operation.

The simulated annual runoff and nutrient loads for the different BMPs for 1979 are summarized in Table 5. The weather data and crop rotations were used to simulate BMPs for the period of 1976 to 1979. There was very little difference in the amount of surface runoff for the three tillage systems without a cover crop. There was a reduction in organic N and P nutrient loads with the NT compared to the CT. This would be expected since the sediment load was reduced from 3012 kg/ha for CT to 573 kg/ha for NT. There was very little difference in the amount of soluble nitrate and soluble phosphorus loads for the three tillage systems without cover crops.

Table 5. Annual Runoff, Sediment and Nitrogen and Phosphorus Predictions for Different BMPs

BMP	Runoff (mm)	Sediment (kg/ha)	Org N (kg/ha)	Soluble NO_3-N (kg/ha)	Org P (kg/ha)	Soluble P (kg/ha)
CT	223	3012	8.74	13.38	4.35	0.12
MT	207	1020	3.71	12.55	1.86	0.12
NT	223	573	2.44	13.38	1.20	0.12
CTW	102	1861	5.55	5.81	2.80	0.04
MTW	97	621	2.37	5.02	1.21	0.03
NTW	110	391	1.53	6.62	0.80	0.06

When a winter cover crop is introduced as a BMP, there was a large decrease in the annual nitrogen and phosphorus loads simulated by AGNPS. The CT organic N load was reduced from 8.74 kg/ha to 5.55 kg/ha and the organic P load was reduced from 4.35 kg/ha to 2.60 kg/ha. Both the soluble nitrate and soluble phosphorus loads were reduced for all three tillage systems with the winter cover crop. The CT soluble nitrate load was reduced from 13.38 kg/ha to 5.81 kg/ha and the soluble phosphorus load was reduced from 0.12 kg/ha to 0.04 kg/ha. In general the total phosphorus loads simulated by AGNPS were considerably higher than any measured phosphorus loads in the watershed. In 1979 the measured total phosphorus load was 1.49 kg/ha and the total nitrogen load was 27.8 kg/ha. Measured nitrogen loads were closer to simulated total nitrogen loads for conventional tillage.

Based upon the BMP simulations, it appears introducing a winter cover crop like wheat or rye would have a significant effect on reducing nitrogen and phosphorus loads in southern

Delaware. For no-tillage the annual total nitrogen load was reduced by 48% and the total phosphorus load was reduced by 35 % when a winter cover crop was used.

CONCLUSIONS

The AGNPS model can be used for simulating BMPs for southern Delaware watersheds. The model did a reasonable job of simulating runoff for individual storms when it was calibrated, but there was considerable variation between simulated and measured nitrogen and phosphorus loads for some individual storms Overall, the model was better in simulating nitrogen loads than phosphorus. Introducing winter cover crops has a large effect on reducing nitrogen and phosphorus loads regardless of the tillage operation.

ABSTRACT

The principal freshwater inflows to the Galveston Bay system originate from the Trinity and San Jacinto river basins. It is hypothesized that the magnitude of these inflows to Galveston Bay is an important control on the productivity of the system. There is a distinct seasonality in the historical flows into Galveston Bay, being bimodal with high flows in the spring and fall. Often these inflows appear as intense seasonal pulses of flow (i.e. "seasonal freshets"). Many biologists hypothesize that organisms present in the bay at key lifestages are adapted to these seasonal pulses of inflow. In order to evaluate this hypothesis quantitatively, it is necessary to first characterize these seasonal freshets. An objective technique for identifying these seasonal freshets is derived and applied to the varying watersheds contributing to Galveston Bay. These results have been utilized as a representation of inflows to Galveston Bay in subsequent analyses of organism abundance.

INTRODUCTION

Galveston Bay, the largest estuary on the Texas coast (600 square miles, or 384,000 acres), is a shallow estuary in a drowned river delta (TSHA 2008). Numerous economically and ecologically important organisms utilize habitat areas within this system as a nursery, with various habitat types providing sufficient conditions for survival and development (Minello 1999; Weinstein 1979). Freshwater inflow demonstrates its ecologically important functional roles in several ways: through the transportation of sediments and nutrients; the maintenance of varying salinity gradients; maintenance of wetlands, plant, and animal productivity; and the maintenance of economically important fish and shellfish populations.

The principal freshwater inflows to the Galveston Bay system originate from the Trinity and San Jacinto river basins. The varying hydroclimatology of these watersheds, in which precipitation is almost entirely rainfall derived from deep convection, often results in patterns of freshwater inflows operating as intense seasonal pulses of flow (i.e. "seasonal freshets") to the Galveston Bay ecosystem. Figure 1 displays the occurrence of seasonal monthly rainfall maxima in Texas, wherein it can be seen that the seasonal magnitude of these maximum rainfall amounts vary in space and time (Ward, 2000).

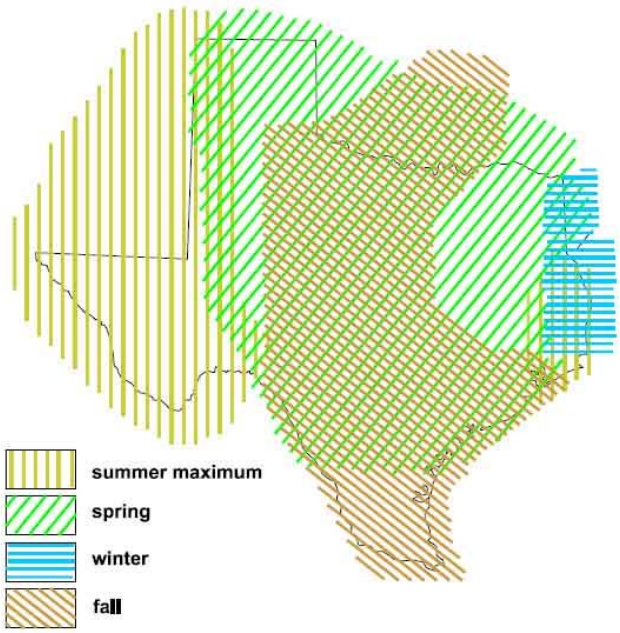

Figure 1. Regions of seasonal rainfall maxima

An objective technique for identifying these freshets has been derived and applied to watersheds contributing to Galveston Bay. The purpose is to improve upon the characterization of the hypothesized characteristics of these pulses of flow believed to determine, among other factors, relative organism abundance in the estuary. Past efforts to search for such a dependency in the Galveston estuary (e.g. Longley, 1994, TPWD, 1998) have utilized calendar monthly flows (or sums thereof) as independent indicators of these seasonal freshets. It is hypothesized that such a practice might not sufficiently depict these events, and by artificially partitioning the freshet into varying time bins, may in fact contribute to the unexplained variance to any dependency upon seasonal freshet events.

It is thus necessary that an objective, quantitative method be developed for identifying seasonal freshet events in a hydrological record for at least three reasons: (1) such freshet determinations would need to be made for a large number of hydrological data extending over many thousands of records (i.e., extended periods of daily-flow data); (2) such a technique would need to be applicable over multiple watersheds with varying hydroclimatologies; and (3) freshet identification must avoid any selection bias of the researchers.

HYPOTHESIS

Taking advantage of the aforementioned fact that Texas hydroclimatology is dominated by deep convection, the quantitative characterization of such seasonal freshet events was developed utilizing what is essentially the characteristics of the impulse-response function of the storm-runoff event. A useful model of this, essentially impulse-response function, is given by:

$$Q(t) = a\, t^n\, exp\{-k\, t^m\} \tag{1}$$

Where m≤1 and n≥1. It is desirable to express the parameters a and k in terms of readily measurable properties of the hydrograph, e.g. the rise time t_r and peak flow Q_p, whereupon:

$$k = (n/m)\, t_r^{-m} \qquad a = t_r^{-n}\, exp\{n/m\}\, Q_p \tag{2}$$

The simpler versions of this model are those with n and m close to 1. An example of (1) with $n = 2$ and $m = 1$ fitted to the data of a runoff event on the Trinity River watershed is shown in Figure 2. A convenient index to the runoff signal is the proportionate response d $logQ/dt$. Both the analytical equation from (1) and the numerical finite-difference approximations from field data are superposed on the plot of Figure 2. (Of course, real hydrographs have the property that d $logQ/dt \rightarrow 0$ quickly after the storm hydrograph, which equation (1) may not.)

The seasonal freshet is created by a sequence of these individual storm events, usually superposed, and the combined hydrographs further distorted by the possible effects of reservoir storage on the watershed. Nonetheless, seasonal freshets have been considered to retain three properties: (1) a long term rise and subsequent recession of flows (usually with multiple extrema); (2) a well-defined onset with a relatively sudden rise in inflow; and (3) a protracted recession.

CONTRIBUTING WATERSHEDS

Assessing the potential relationship between relative organism density and flow requires the development of hydrologic data for the Galveston Bay system drainage, and the formulation of the parameters of flow to serve as variables in subsequent analyses. Watersheds contributing to the Galveston Bay system have been considered and evaluated in these analyses, with a focus upon the Trinity River Watershed (TRNTY), the San Jacinto Watershed (SNJAC), the Coastal Watershed (COSTL), and the Total Galveston Bay Watershed (TGALB). Daily flow amounts have been compiled for the USGS gages contributing to the Galveston Bay system and combined with modeled estimates of daily flows from the ungaged coastal watersheds utilizing the Texas Water Development Board's Texas Rainfall-Runoff Model, TxRR, output (Matsumoto, 1992).

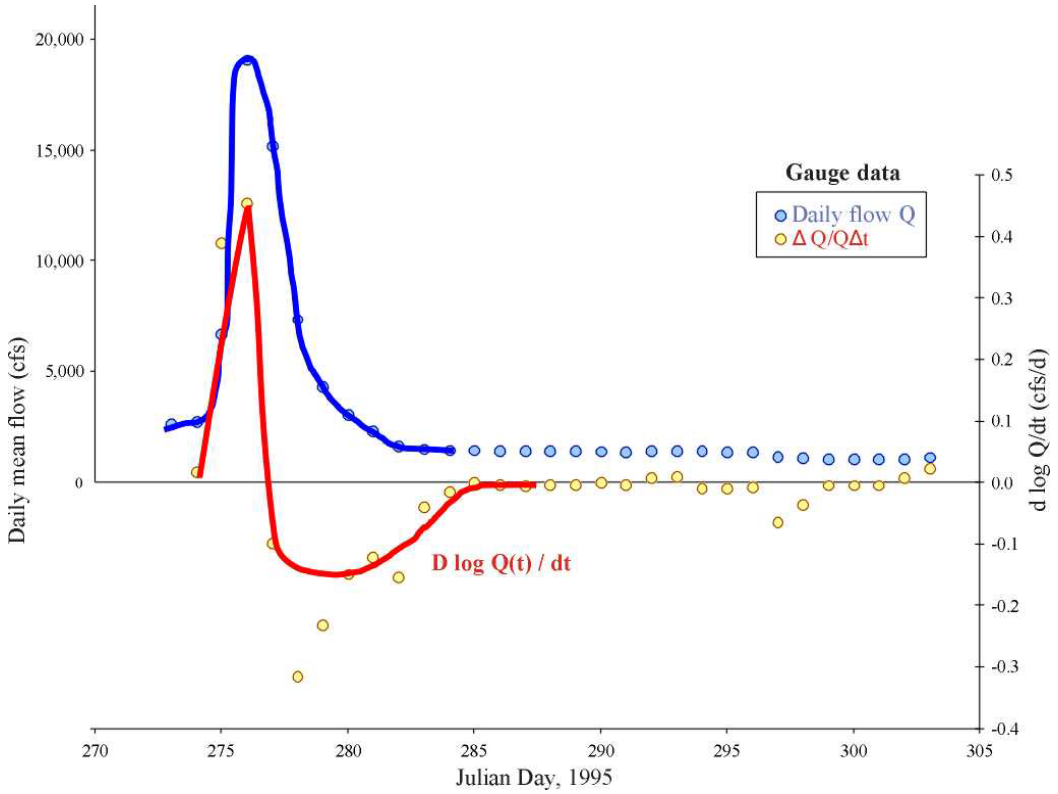

Figure 2. Storm hydrograph October 1995, Trinity River Watershed, with model of equation (1)

METHODOLOGY

In order to first identify the freshet, it is necessary to first apply smoothing to the daily flow data. To take advantage of the aforementioned derivative of the logarithm of flow, this smoothing has been applied to the daily flow data (represented as the light blue line in Figure 3 below) by using a sliding 45-day centered average (the dark blue line in Figure 3, necessary to evaluate both forward and backward in time). The 45-day average has been selected, as it has been deemed to be the appropriate level of sensitivity. A sensitivity analysis was performed utilizing 30-, 45-, and 60-day averages, whereupon results were found to be either too sensitive (for the 30-day average, wherein individual storms were identified) or not sensitive enough (for the 60-day average, where often multi-season freshets were identified). Thus the 45-day average was utilized for identifying a watershed's seasonal pulse from the individual storm events for a given year's hydrology.

The (sliding) slope of the 45-day centered average regression of the 45-day average flow data was calculated and normalized by the maximum of either the POR-median flow or the centered 180-day mean flow, termed m/Qmean. The normalization to the maximum of the period of record (POR) median flow or the centered 180-day mean flow allows for the identification of freshets during wet and dry periods. This identifies a rate of change in flow relative to the magnitude of flow occurring in the surrounding six months (in units of /time), allowing for freshets to be

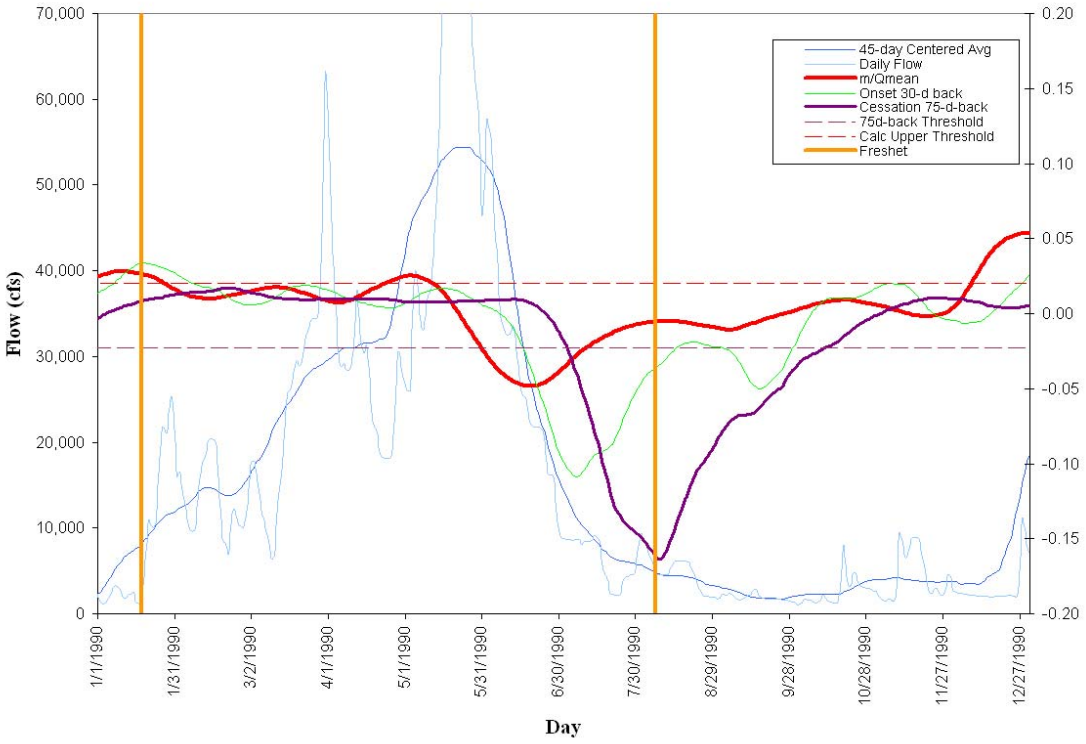

Figure 3. FRESHET Application to 1990 Trinity Watershed Flows

identified with respect to their relative magnitude in a given year (i.e., a small event in a wet year might not be identified as a freshet, but in a dry year would be considered a freshet event). Rather than subjectively culling these data out, the method applied has been developed to objectively capture this information via the method described and let subsequent analyses inform as to whether such events hold any statistical significance. Singular maximum threshold criteria are developed and applied (plotted as the upper horizontal dotted line on Figure 3). These criteria (also in units of /time) identify the *occurrence* of a freshet, and have been developed through the consideration of the distributions of the positive local maxima of the m/Qmeans. While there are many local maxima of m/Qmean (as displayed in Figure 4, depicting a time series plot of local maxima for the Trinity watershed), the focus is on those with the higher values. The question of course is: "where to draw the line (*vis. a vis.* the threshold)?"

As depicted in Figure 4 by the bold red line, the POR average of the positive local maxima of the m/Qmeans does yield an adequate depiction of the magnitude of variability of these local maxima over the entire POR, its mathematical benefit being that it takes into account both extreme values in its calculation, is a depiction of the average long-term characteristics of the system, and neglects those cases where a maximum occurs when the slope of smoothed flows are increasing coming out of a negative slope at the end of a freshet. Thus the POR average of the local maxima for the m/Qmeans is utilized for the *threshold* of identifying that a freshet has occurred. A maximum of the m/Qmean is then calculated (represented as the bold red line in

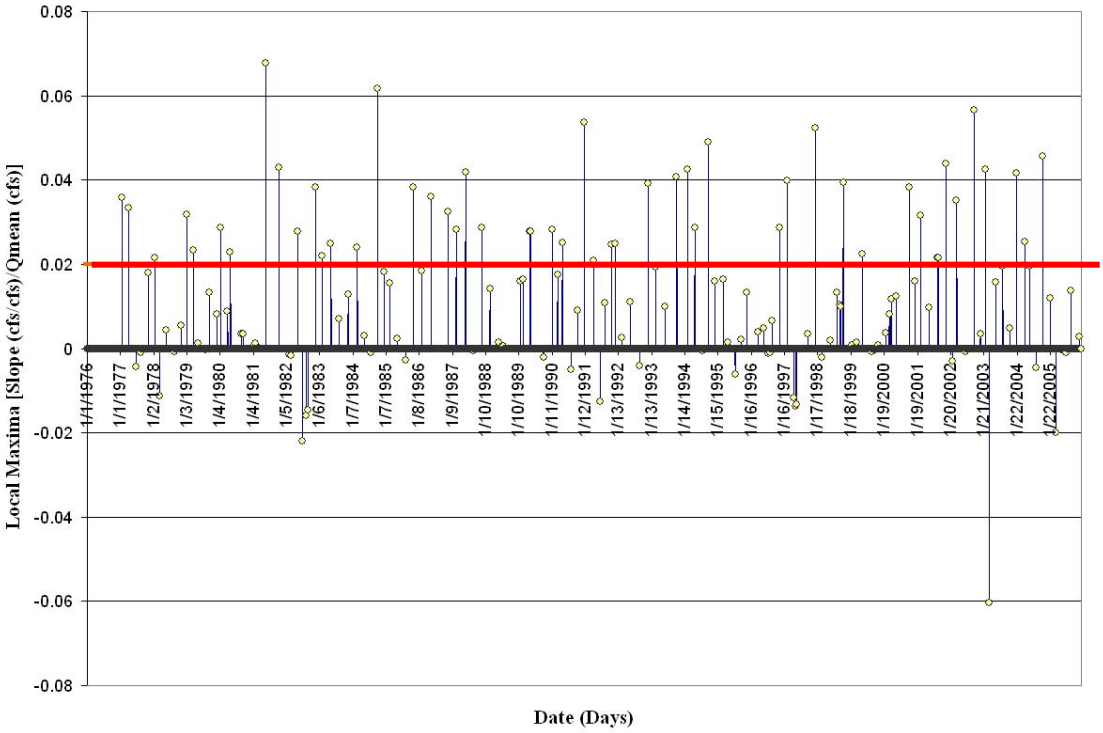

Figure 4. Local Maxima of m/Qmean Time Series for the Trinity Watershed (1977-2005)

Figure 3). When this value achieves a maximum above the threshold, a freshet is identified as *having* occurred.

Upon inspection of the methodology described thus far, due to the fact that a centered average has been utilized, one would note that freshets would typically be identified with onsets slightly earlier than their actual occurrence in the daily flow record. The centered average, by definition, looks 22 days into the future, pulling the average slightly upwards upon the approach of a storm event; hence, the premature identification of the onset when utilizing the centered average. Further calculations are necessary to specifically identify not only the occurrence of a freshet, but the specific timing of the onset and cessation of the freshet event.

To identify the actual timing of the onset of the freshet, a second calculation is performed, this time utilizing a 30-day backwards slope of the 45-day average flows divided by the 45-day average flow, termed the 30-day backwards amount (represented as the thin green line in Figure 3). The date of the first local maximum of the 30-day backwards amount occurring on or after the date a maximum m/Qmean occurs over the threshold identifies the *onset* of the freshet. The utilization of a backwards regression allows for the more precise identification of the onset of the freshet. The first maximum occurring after the identification of the occurrence of a freshet represents the identification of the onset. The onset is calculated as the day number in the year relative to the start of the year.

The identification of the timing of the cessation of a freshet is equally important. Initial evaluations considered a 30-day sliding backwards averages as a viable alternative for utilization in identifying the cessation of a freshet. It is

conceivable that the utilization of the 30-day backwards average as a threshold amount is too sensitive and short a time period, and longer backwards amounts utilizing a POR average of localized minima would be more suitable. The hypothesis herein is that if the bay is truly a slow responder, then the bay should be mathematically allowed more time to note that a freshet has ceased. Indeed, this is reflective of an impulse/response mechanism for salinities found in many bay systems.

While it is acknowledged that this amount might ultimately differ in its final time period, the current estimation is that it would still be greater than 30 days. Table 1 presents comparisons of identified freshets utilizing the POR average m/Qmean threshold for freshet identification and the usage of various 30-, 45-, 75-, and 90-day backwards sliding averages. For the Total Galveston Bay watershed (TGALB), there are approximately 41 freshets over the period from 1977-2005 (although this varies depending upon the backwards average utilized). As depicted by the shaded cells in Table 1, the difference between the usage of a 90-day backwards average and a 75-day backwards average is minor, yielding only 3 freshets whose magnitudes differ by more than 20%. Similarly, there is a minor difference between the usage of the 30-day backwards average and the 45-day backwards average, as again the comparison yields only 3 freshets whose magnitudes differ by more than 20%. The comparison of the 75-day backwards average and the 45-day backwards average shows that 9 out of the 41 freshets (roughly a fifth) have magnitudes that differ by more than 20%.

As there are only slight differences between the 30- and 45-day backwards averages, considering that the objective of this effort was to characterize the seasonal pulses rather than individual events, the 45-day backwards average has been utilized. On the other end of the spectrum, since the 90-day and 75-day backwards averages yield slight differences, the 75-day backwards average has been utilized since the 90-day backwards average occasionally yields extremely long (i.e. multi-year) freshets.

Thus, for subsequent statistical evaluations the 75- and 45-day backwards amounts for the identification of the timing of the cessation of freshets have been utilized as the minimum threshold values (e.g. once the value crosses the threshold, the first minimum beneath the threshold is identified as the cessation of the freshet). Figure 3 above depicts this for the 75-day backwards average. While the m/Qmean for the centered average is similarly utilized in both characterizations, the statistical evaluation of both characterizations of freshets offers a means to evaluate whether organisms are responding to the longer term pulses of flow or more frequent pulses of flow.

RESULTS

Once the onset and cessation of freshet events are identified, calculation of the magnitude and duration of the freshet is easily accomplished. This methodology yields parameters of onset, magnitude, and duration for each identified freshet. These identified seasonal freshets have been found to extend over a duration of just a few weeks to several months, as shown via the time series plot in Figure 5, with the average volume of Galveston Bay depicted in red. As can be seen from this plot, the freshets indeed exhibit an often bimodal pattern, with the intra-annual summer

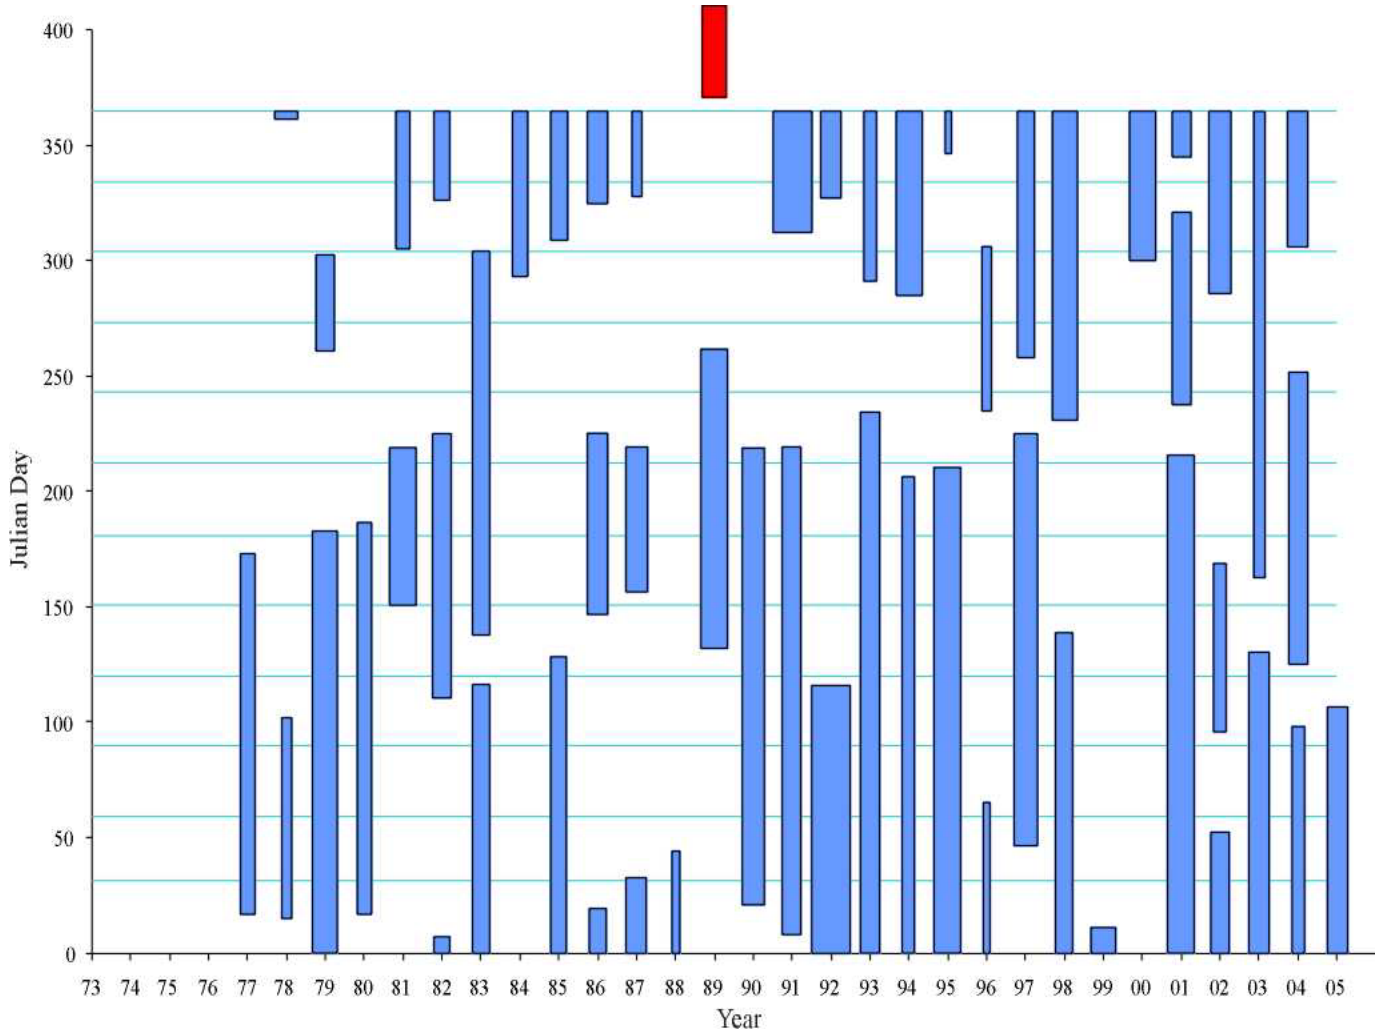

Figure 5. Total Galveston Bay Freshet Time Series utilizing 75-day Backwards Average

drought clearly visible. Also worth noting is that it appears that freshets initiate during the late part of the calendar year, and will span into the next year, suggesting *a priori* decisions to parse hydrologic data into calendar periods might introduce unexplained variance into subsequent analyses.

The results of these hydrologic characterizations have been utilized as representations of inflows for the various watersheds to Galveston Bay in subsequent analyses of relative organism abundance and compared with the more standard representation of annual flow for the same watersheds. As seen in Table 2, of the regressions wherein statistically significant relations were determined, approximately 73% of those regressions utilized hydrologic data wherein the watershed was represented with the parameters of onset, magnitude, and duration of the seasonal freshets. The utilization of this objective methodology for each watershed possibly allows for a level of objectivity to the process that has been previously lacking.

Table 2. Percentage of Regressions wherein Freshet Characterization Yields Greater Explained Variances

Total	Count	%
Freshet	74	73%
Annual	28	27%

ABSTRACT

Runoffs collected by the rivers provide water needed to sustain unique ecosystem in an arid basin. Diversion for agricultural application could cause damages to the vulnerable ecosystem. The authors assessed runoffs in the mountainous area, interaction of river water and groundwater, and consumptive uses of water in different geographic units such as desert, manmade oasis, marsh land and terminal lakes in the arid Qaidum Basin in North Qinghai-Tibet Plateau. The Xiangride River collects approximately 510 million m^3 runoffs annually, of which 140 million m^3 is diverted for agricultural irrigation. It then recharges underlying aquifer and provides water for vegetation along the river. The water eventually disappears from the riverbed and reappears as springs, forming the Qaidum River at approximately 20 km downstream. It collects about 90% of seepage water. It is concluded that irrigation diversion has caused groundwater level decline and shift of the spring belt downstream, resulting impacts on ecosystem.

Key words: runoff, interaction of surface water and ground water, oasis irrigation, ecosystem, arid region, Xiangride River, Qaidum River, Qinghai-Tibet Plateau, Qaidum Basin

INTRODUCTION

Human activities (mostly water extraction and diversion) upstream usually reduce water availability in the lower area of the basin, induce lower water table in the lower area, and reduce the vegetation cover, making the arid lands more receptive to wind erosion in arid close basins. In the same time, human activities are modifying the water budget of the terminal lakes, resulting in a local climate change which desiccates the lakes partially or completely into playas (Gill and Cahill, 1992). In those disturbed arid close basins, when terminal lakes undergo anthropogenic desiccation and form playas, the resulting geological process may constitute particulate air pollution, which in turn have major environmental,

economic and health impacts on the human system(Gill, 1996). Probably the most notorious example of the creation of a dust storm resulting from the draining of a saline lake is the Aral Sea in Central Asia. In Aral Sea basin, large scale irrigation along the tributaries Amu Darya and Syr Darya has reduced this inland water body, once the fourth largest in the world, by half it's area and three quarters of it's water volume. The desiccation of Aral Sea results in the collapse of fishing industry and many serious human health problems. And disappearing delta areas cause the extinction of habitats and endemic species (Glantz, 1998).

To understand the situation of disturbed inland river basins and to assess the environmental impacts induced by human activities, researchers have conducted studies on water balance of the inland river basins (Lei et al., 2001; Gao et al., 2004). In this paper, the authors present a case study of Xiangride and Qaidum Rivers located in the southeastern of Qaidum Basin in Northwest China. Water availability, water uses, and impacts of oasis irrigation upon ecosystems within the Xiangride-Qaidum river basin were analyzed using sporadic data.

STUDYING AREA: AN SPARSELY GAUGED ARID BASIN WITH SPECIAL ECOLOGICAL VALUES

The inland Xiangride and Qaidum Rivers are located within the arid Qaidum Basin in North Qinghai-Tibet Plateau, China (Fig.1). Qaidum Basin is an arid basin on the north Tibetan Plateau, located in between 35°00′-39°20′N latitude, 90°16′-99°16′E longitude. With 800 km in length from west to east and 300 km in width from south to north, Qaidum Basin extends from northwest to southeast. The basin is bounded on the south by the towering Kunlun Mountains which have many peaks in the western part exceeding 6,000 meters above sea level, and on the northwest and northeast by Altun and Qilian mountain systems. The elevation in the lowest central area of the basin is 2,675 meters. Qaidum Basin is the highest and the third largest close basin in China. Unlike many other arid zones in the world, the basin exhibits the geomorphologic features of high altitude and low air pressure. The total area of the interior drainage is 0.275 million sq km, of which 54.8 percent (150.8 thousand sq km) is covered by mountains and 45.2 percent (124.2 thousand sq km) by plain area. The plain area in the basin is characterized by low rainfall and high evaporation. The average annual precipitation is approximately 200 mm over the basin, but less than 50 mm in most of the area. The plain area contributes almost no runoff to the river system in the basin. Qaidum Basin is fully dependent on precipitation in mountain range. There are two tributaries for Xiangride River. The eastern tributary flows through a natural regulating lake named Tuosuo Lake, which has a water surface area of 253 km^2, and a catchment area of 3,175 km^2. The western tributary flows through a lake named Ala Lake, which has a water surface area of 73 km^2. The Xiangride and Qaidum Rivers flow through mountain range, piedmont diluvial-alluvial plain, alluvial-lacustrine plain, finally reaches two saline lakes named North Huoluxun

Lake and South Huoluxun Lake respectively.

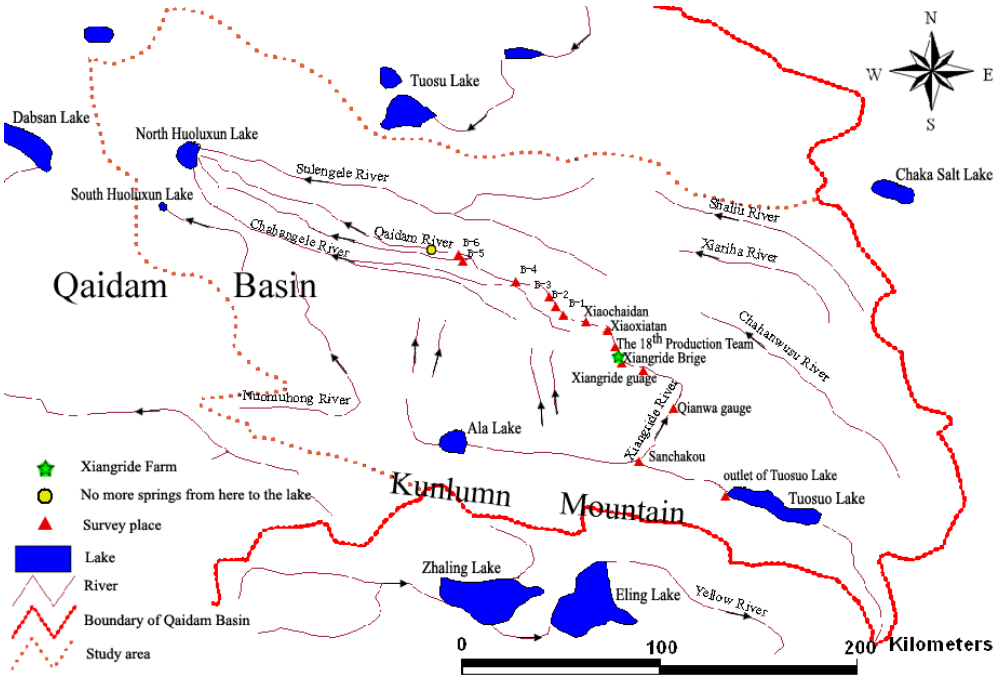

Figure 1 Water system of Xiangride-Qaidum river drainage basin.

The Xiangride River supplies water for agricultural irrigation in Xiangride oasis and ecosystem in the basin, while Qaidum River sustains water supplies for the unique high altitude wetland and desert ecosystem down to the terminal lakes. Between piedmont and spring belt, there is a desert zone. Within and below spring belt, there are marshes, meadow, rivers, lakes, salina and salt shell. These wetland and grass land are the pasturing land, and habitats of many field animals including endangering black neck crane. Xiangride farm is located in the alluvial-diluvial fan outside the mouth of the mountain valleys. Xiangride farm, well-known for its high spring wheat yield record of 15,159kg/ha, is one of the important agricultural irrigational oases in Qaidum Basin. Xiangride Oasis is the major water user in Xiangride-Qaidum Basin as it diverts 140 million cubic meters per year, 30 percent of the Xiangride River flow of 463 million cubic meters. Therefore it is very important to understand runoff formation and its impacts on agricultural irrigation and ecosystem.

METHODOLOGY

Data and Field Survey

All the existing hydrological data for the study area as well as peripheral areas surveyed and kept by different organizations were compiled. Based on assessment of historic data, major data gaps were identified. An integrated catchment investigations involving landform, soil, vegetation, surface water and ground water were carried from the mountain head area to the terminal lake in the bottom within 2003-2006. Additional precipitation, river flows, ground water table,

irrigation water division and drainage data were collected at selected sites. A total of 16 precipitation gauge station and 7 ground water table observation stations, river flow measurements at 10 spring river sections (see Fig.1), monthly flow data for 10 canal sections and 3 drainage sections over 2 years were added as part of this study.

Data Analysis

Time series statistical analysis methods were used to interpolate and extrapolate fragmentary hydrological data. Due to similarity some parameters such as runoff depth were used across the basin. Water balance method was used to assess the seepage of river bed and total water resources quantity from the mountain area.

There were three hydrological gauge stations along the Xiangride River. The two of them, Qianwa gauge and the Xiangride gauge, have over 40 years of recorded hydrological data, which are used to assess the average annual runoff at the two sections. The Tuosuo Lake gauge station only has 7 years of flow data. The recorded data are not enough to calculate the average annual runoff directly. To obtain this average annual runoff, it's assumed that annual runoff in the upper gauge is proportional to that of downstream gauges, and the following equation is used for estimation:

$$AAR1 = AAR2 \times STAAR1 / STAAR2 \quad (1)$$

Where AAR1 is the average annual runoff at section 1, AAR2 is the average annual runoff at section 2, STAAR1 is the short-term average annual runoff at section 1, and STAAR2 is the synchronous short-term average annual runoff at section 2.

RESULTS AND DISCUSSION

Formation of Source Water in Mountain Range

In Xiangride-Qaidum River basin, the water is originated in the mountain range as the river and its tributaries collect runoffs as well as spring discharges. The surface runoff flowing out of the mountain area is almost the sole water source for the middle and lower reaches.

Using the equation 1, the average annual runoff at Tuosuo station and Qianwa station as AAR1 and AAR2, the average annual runoff for the period from 1963 to 1969 at Tuosuo station and Qianwa station as STAAR1 and STAAR2, and obtained the average annual runoff at Tuosuo station. The average annual runoff and the runoff depth of the sub-drainage zone in the mountain area are shown in

the following Table 1.

Table 1 Average annual runoff of sub-drainage units in mountain area

Sub-drainage unit	Drainage area (km^2)	Average annual runoff (10^4 m^3)	Average annual runoff depth (mm)
Headstream-Tuosuo	3175	13130	41.4
Tuosuo-Qianwa	6703	29550	44.1
Qianwa-Xiangride	2461	2617 (8540*)	10.6 (34.7*)
Total	12339	45297 51220* 51030**	36.7 41.5* 41.4**

*Assessment after adjusting the river bed seepage between Qianwa and Xiangride.
** Assessment after further considering the water storage change in Tuosuo Lake.

The average annual runoff depth of Qianwa-Xiangride drainage unit is only 10.6 mm, obviously less than those of the other two drainage units. After comparing with other neighboring drainage basins with similar landform and vegetation, it was concluded that seepage losses account for such low run-ff depth for the reach between Qianwa and Xiangride stations.

After the analysis of the spatial relationships and comparison of the landform and vegetation coverage among the 4 drainage areas, it was estimated that the most possible value of average annual runoff is between 34.7 mm and 44.1 mm for the Qianwa-Xiangride drainage unit. In order to avoid overestimating the water resources amount, the runoff depth of the Qianwa-Xiangride drainage unit was revalued to 34.7 mm, the average annul runoff was adjusted to 85.4 million cubic meters, a total seepage of Qianwa-Xiangride reach of 59.23 million cubic meters was calculated based on water balance.

Another fact about the runoff from mountain area should be noted. After the construction of Xiangride Farm, for guaranteeing water for irrigation while draught, a adjusting gate was constructed in the outlet of Tuosuo Lake and the outlet bottom was cut down for discharging water easier. Now the water level of Tuosuo Lake is about 3 meters lower than that in 1960's. The lake area is 253 km^2. The water storage in the lake decreased about 759 million m^3 over 40 years or 19 million m^3 annually. This means the annual runoff for gauges at Qianwa and Xiangride should be reduced 19 million m^3.

Seepage along Xiangride River in Plain Area

The Xiangride River flows into a piedmont diluvial-alluvial plain after it runs out of the Xiangride hydrological gauge station. The plain area is extremely arid and there is almost no surface runoff discharge into the river. The river water will infiltrate through the river beds, recharging underlying aquifer, and eventually

disappear from the river due to seepage along the river bed made up of cobblestone and sand.

Based on the data collected, the average annual accumulated seepage rate along the Xiangride River was calculated, and shown in Table 2. The accumulated seepage rate varies along the river bed.

$$y = 0.0006x^3 + 0.0774x^2 + 0.0265x \quad (R^2 = 0.9949) \qquad (2)$$

Where y is the accumulated seepage rate, and x is the length of the reach from Xiangride Hydrological Gauge. The equation shows that the accumulated seepage rate increases nonlinearly with the increase in the length of the river reach. The historic records show that the river can't reach the Qaidum River even with a runoff up to 30 cubic meters per second. However it is still not clear how much water is needed to maintain continuous flow from the Xiangride River to the Qaidum River due to lack of data.

Table 2 Seepage along the Xiangride River

Site	Length of the reach form Xiangride Hydrological Gauge(km)	Average annual accumulated seepage rate (%)
Xiangride Hydrological Gauge	0	0
5km below Xiangride Hydrological Gauge	5	5.00
10km below Xiangride Hydrological Gauge	10	9.75
water diverting inlet	12	11.56
Xiangride Bridge	14	14.21
The 8th Production Team Village	20	41.15
Xiaoxiatan Village	32	100.00

Irrigation Division and Consumptive Uses in Xiangride Oasis

On average, Xiangride oasis diverted 140 million m^3 of water annually from the Xiangride River. About 60 million m^3 is consumed by crop evapotranspiration. About 5 million m^3 returned to the Xiangride River at Xiaoxiatan village. About 75 million m^3 recharged the underlying aquifer as deep percolation from the farm field.

Spring Flow Gathering and Consumptive Uses in the Qaidum River

Usually the Qaidum River appears around Xiaochaidan village where

groundwater discharges as springs. The river flow increases continuously as it collects water from springs. The relationship between runoff and the length of the river is shown in Figure 2. In the first 5 km of the river, the river flow increases very slowly because of a small drainage area. From the 5th km to the 25th km, the river flow increases linearly with the river length and reaches a maximum flow of 6 m^3/s. After the 25^{th} km of the river, there is no prominent tributary which drainages into Qaidum River. And below the 34^{th} km of the river, bifurcated channels emergence, and the river flow decreases. The groundwater still feeds the river here, so the river water does not decrease rapidly. Below the 86^{th} km of the river, there is no more groundwater discharge (judged by vegetations and no existence of springs), and the vegetation disappears. Because of the rapid evaporation, the flow decreases rapidly, and the area is covered by playas here.

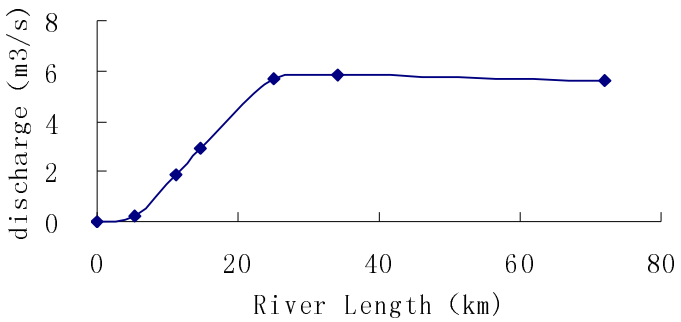

Figure 2 Changes in flow along the Qaidum River

Evaporation from the Terminal Lakes

Parallel to the Qaidum River, there are two other rivers which drainage into North Huoluxun Lake, which named Chahangele River and Sulengele River respectively. In the terminal area of these three rivers, their multiple channels interconnect each other. The average discharge from the Qaidum River is about 5.6 m^3/s, and the summation of discharges from the Chahangele River and Sulengele River is about 6 m^3/s. The average annual water supply of the terminal area is about 0.366 billion cubic meters. The current water surface of the terminal lake, North Huoluxun Lake, is 76.55 km^2. According to data of the evaporation gauge in Qarhan Lake (fresh water, 2,150 mm/year), the annual evaporation of North Huoluxun Lake is less than 2,150 mm, because fresh water is easier to evaporate than saline water. And the annual accumulated evaporation of North Huoluxun Lake is less than 164.58 million cubic meters.

Temporal Variation of Flow of Qaidum River

The historical data shows that the biggest flood in Xiangride-Qaidum River basin was in July 1959 (Fig. 3). The biggest discharge of Zongjia station is 147 m^3/s, while at Xiangride station it is 560 m^3/s. The Qaidum River is fed only by groundwater usually, but it's obvious that there was surface water drainage into

the river in July 1959. From 1956 to 1962, except July 1959 when flood occurred, the discharge of Qaidum River was very stable; the discharge didn't increase even during wet periods.

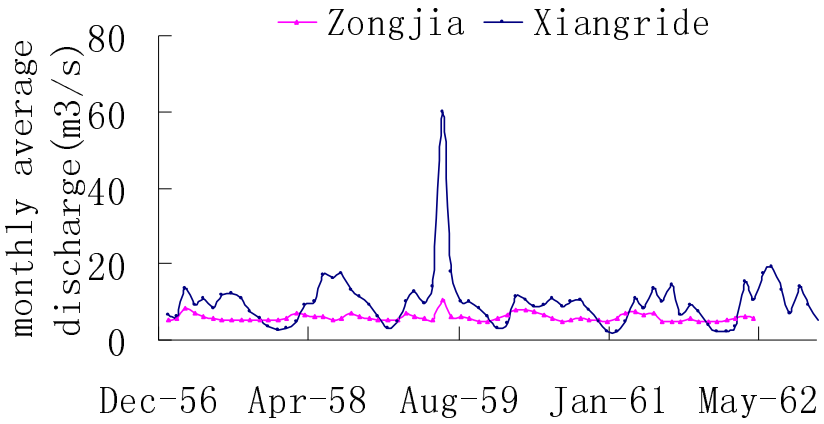

Fig 3 Flow chart of Zongjia and Xiangride gauge station

The comparison of the current discharge with the historical average annual discharge shows no obvious difference in the river discharges as shown in Table 3. There is no evidence to suggest that Qaidum River has changed since the Xiangride Oasis farm was established inn 1958. It seems that decades of water diversion from Xiangride River has not yet change the Qaidum River flow evidently. However the heading of the river (the spring belt) has moved downstream for about 1 km. The land surface gradient there is about 1/1000. If we assume the gradient of ground water table is similar to that of landform, it can be concluded that the ground water table has declined about 1m for last 40 years. As runoffs from the mountain range didn't decrease but increased a little, therefore the possible cause for groundwater level is the irrigation water division and consumptive uses of Xiangride oasis.

Table 3 Comparison of the Historical and Current Runoff in Zongjia Station Section (m^3/s)

Section	Location		Runoff	Note
Zongjia station	Between Section B-5 and Section B-6	1957.1-1962.5	5.905	Average annual runoff
		1965.9-1969.12	5.299	Average annual runoff
Section B-5	97°10′10.1″E 36°25′49.5″N	2005.8.27	5.426	Daily runoff
Section B-6	97°08′47.7″E 36°26′14.3″N	2005.8.27	5.840	Daily runoff

CONCLUSIONS AND DISCUSSIONS

In sum, the Xiangride-Qiadum river basin is a complex system in an arid region. In Xiangride-Qaidum River basin, the source water is originated from the runoffs in the mountain range. The average annual runoff of Tuosuo Lake drainage area is 131.3 million cubic meters. With consideration of the river seepage of 59.23 million cubic meters, the Tuosu-Qianwa drainage unit and Qianwa-Xiangride drainage unit provides 295.5 and 85.4 million cubic meters, respectively.

The average annual accumulated seepage rate along the Xiangride River increases nonlinearly with the length of the river reach. Additional study is recommended to gain a better understanding of surface water and groundwater interaction.

The average annual water discharge into the terminal area is about 0.366 billion cubic meters. And the annual accumulated evaporation of North Huoluxun Lake is less than 164.58 million cubic meters. The exact estimation of evaporation of the entire Xiangride-Qaidum River basin needs further study.

Though the discharge of the Qaidum River does not show significant impacts of irrigation on the river flow, its heading water (spring belt) has moved downstream for about 1 km due to irrigation diversion and consumptive uses of water in the irrigation oasis. Further studies are recommended to assess the impact of the water diversion on the Qaidum River basin including water quality, ground water level and vegetations.

DESIGN AND IMPLEMENTATION OF OPTIMIZED HYDROLOGIC UNIT WATERSHEDS FOR RAINFALL-RUNOFF MODELING

Ivan Rivas[1], MS, M. ASCE.
Larry A. Roesner[2], PhD, P.E., Fellow, ASCE.

ABSTRACT

The construction of rainfall-runoff models represents one of the most complex and challenging problems in water resources engineering. This is particularly true for urban watersheds in which, the entire watershed is discretized in smaller sub-basins and additional systems need to be modeled such as the drainage network.

This work was aimed at developing a methodology for the development of a rainfall-runoff model that characterizes a complete drainage area using SWMM5. ArcHydro was used to sub-divide the entire basin in sub-watersheds; then, a kinematic wave cascading plane approach was used to convert irregular sub-watersheds to regular shapes. The so-called Hydrologic Unit Watershed (HUW) represents a synthetic sub-watershed, in which their hydrologic parameters are chosen by constrained optimization.

Rather than using individual storms for calibration, the goal was to minimize the difference between the flow duration curves of the model output and observed discharges.

1. INTRODUCTION

The simulation of rainfall-runoff relationships has been a prime focus of hydrological research for several decades and has resulted in an abundance of models having been proposed (Kokkonen, 2001). Accurate and reliable modeling of stormwater runoff and associated phenomena has been in the past and continues today to be a challenge (Urbonas, 2007). Rainfall-runoff models have been under a continuous state of evolution (Hundecha, 2004).

Urbonas (2007) pointed out that for distributed rainfall-runoff models such as SWMM, research and studies are needed to develop guidance in how discretisize a study catchment properly, at least from the end user's perspective. Urbonas (2007) specifies that an issue not solved yet, is how to reduce an irregular shaped catchment with an array of street and development patterns into regular shapes called for in models such as SWMM to get consistent and accurate results.

2. MODEL DESCRIPTION

2.1 Digital Elevation Model (DEM)

DEM was obtained through The USGS National Map Seamless Server (2008a). The website provides The National Elevation Dataset (NED) with a 1/9 Arc Second resolution (approximately 3 meters). One Arc Second is the $1/3600^{th}$ of a degree (1 second) of latitude or longitude. The length of arc subtended is approximately 30 meters.

ArcHydro (2003) was used to discretisize the watershed. Sixty-five (65) sub-watersheds were obtained with an average size of 43 acres. Also, overland slope was computed through the DEM, using the command Slope from Spatial Analysis. For modeling purposes, overland slope was calculated for the whole watershed and then separated to each of its sub-catchments.

2.2 Hydraulic routing

Unlike undeveloped watersheds, urban watersheds present an additional component to be modeled, the drainage network. However, even if there is an existing GIS shapefile with all links and their corresponding geometric features, modeling the complete network may not feasible in large watersheds. Since this task would represent a big engineering effort to model every single storm drainage structure (i.e., gutter flow towards a drop inlet). Therefore, realistic simplifications should be made.

Some attempts have been made to obtain a comparable drainage network. Brink (2004) suggested creating a routing channel with the objective of accounting for in-system storage and attenuation that would occur within a given sub-watershed area (A). Brink (2004) developed empirical relationships for channel length (L_o) and channel width (W_o) of this routing channel as a function of the sub-catchment area. Brink (2004) found good results when: $L_o=\sqrt{A}$ and $W_o=0.50\sqrt{A}$.

Espey et al. (1977) developed a set of generalized equations for the construction of unit hydrographs using a study of 41 watersheds ranging in size from 0.014 to 15 mi^2, and impervious percentage from 2 to 100 percent, nine of the watersheds were located in North Carolina. For this study, using a 24-h SCS Type II storm with an average recurrence interval of 1-Yr, precipitation depth was estimated to be 2.87 in (NOAA, 2008), rainfall excess was estimated and peak discharges were computed using the methodology by Espey (1997) for eight experimental sub-watersheds ranging from 5 to 140 acres.

Then, these sub-watersheds were tested in SWMM5 and the length of the main channel was optimized to match the peak runoff. The best agreement of peak flows were found when the collector channel length was equal to $L_o=A^{0.59}$. The latter result is quite similar with the relationship provided by Brink (2004).

2.3 Characteristic Width Estimation

Huber et al. (1988) suggested combining many sub-catchments into a single lumped or equivalent and calibrate the sub-catchment width. Reducing the width increases the flow length and storage within a subarea, resulting in an effective way to attenuate the runoff hydrograph without modeling in-system storage and pipe networks (Brink et al., 1996), for this reason, the width parameter is often the primary parameter adjusted to obtain desired peak flow rates and hydrograph shapes. Since travel time is larger, this results in more time for infiltration to occur and therefore, infiltration volume might be overestimated. Overall, calibration of the watershed width may lead to unrealistic large runoff lengths.

Another approach is to estimate the runoff length (L), the actual distance that flow typically could be expected to travel before reaching an impervious surface or a natural channel in an urban environment (usually from 100 to 300 feet). Then, compute the Width (W) as W=A/L. Rivas et al. (2007) found the latter procedure successful in large urban watersheds, however, this task requires the estimation of runoff lengths from aerial images.

2.4 Conversion of irregular watersheds to regular watersheds

ArcHydro sub-watersheds present irregular shapes that need to be converted to regular shapes to use in SWMM5. The current state-of-practice recommends the width to be twice the length of the central channel in a symmetric watershed or equal to the length of the side channel along the watershed boundary (Huber et al., 1998).

Guo et al. (2008) developed a methodology to convert an irregular watershed to its equivalent rectangular watershed. A Kinematic Wave (KW) cascading plane is specified by the plane's area, width and slope (Guo et al., 2008); where the continuity and energy principles were interpreted to preserve the watershed area and vertical fall over the receiving waterway's length. After numerous tests Guo (2008) confirmed that the watershed and KW shape factors provide a consistent and stable basis for watershed geometric conversion. In this study, sub-watershed widths were estimated using the KW cascade plane approach.

3. STUDY AREA AND DATA SOURCE

3.1 Watershed Location

The case study is the Pigeon basin located in the metropolitan area of Raleigh, NC. The main properties of this basin are described in Table (1)

Table 1. Watersheds properties (Year 2000)

Watershed Name	Area (mi^2)	TIA[1] (%)	Population density (hab/mi^2)	Housing density ($homes/mi^2$)	UII [2]
Pigeon	4.45	30.62	3,275	239	100.00

[1] *TIA* – Total Impervious Area.
[2] *Urban Infrastructure Index* is a multi-metric parameter that represents the degree of development in the watershed. The UII includes census, socioeconomic, infrastructure, land use and land cover metrics that correlated with population density (McMahon and Cuffney, 2000). However, in this case, UII represents a specific index developed for a set of 30 watersheds in North Carolina, ranging from 0 to 100 (Giddings et al., 2007).

3.2 Channel Routing

Natural streams are an integral part of the drainage system. Preliminary site investigations were performed to identify main conveyance features of the main streams. Field work was done during November 2005 to obtain the cross sections in main channels using level and rod methods as described by Harrelson et al. (1994). Streams cross sections were taken at approximately 2,500-foot intervals along main channels (Pomeroy, 2007). Channel Manning's roughness was estimated during the field work by following the guidelines provided by Chow (1959), Arcement and Schneider (1989). Finally, the geographic coordinates of the cross sections were mapped in GIS with a GPS unit eTrex Legend (Garmin, 2008).

3.3 Hydroclimatology

Precipitation data constitutes the main input to the model, it comes in a spatial distribution of precipitation over time. USGS rain gage (Site No. 0208732885) located at Marsh Creek, New Hope NC, provided 15 min rainfall data (USGS, 2008b). Rain gage was located 10 miles Northeast from the watershed. Evaporation was modeled to account losses, monthly average records were found from 1948 to 1992 (Purvis, 2008). Pan evaporimeter was located at Chapel Hill NC, 25 miles Northwest from the watershed.

3.4 Discharge

USGS streamflow gage No. 0208732610 provided data for calibration. The period of record was from July 4th, 2002 to October 28, 2003 (1.32 years). Flows were registered with a 15 min interval (USGS, 2008c).

3.5 Imperviousness

For modeling purposes, two types of impervious areas have been identified. The first type, effective impervious area, comprises those impervious surfaces that are hydraulically connected to the channel drainage system. Streets with curb and gutter and paved parking lots that drain onto streets are examples of effective impervious surfaces. This area is known as *Directed Connected Impervious Area* (DCIA). The second type, non-effective impervious area, comprises those impervious surfaces that drain to pervious ground such as roof that drains onto a lawn. The sum of both is known as *Total Impervious Area* (TIA). Alley and Veenhuis (1983) developed the following empirical relationship between TIA and DCIA from a highly urbanized portion of Denver, using 14 basins:

$$DCIA = 0.15\ (TIA)^{1.41} \quad \ldots (1)$$

The coefficient of determination (r^2) for the regression equation (1) was 0.98 and the standard error of estimate 7.5%. Since the original parameters proposed correspond to a region in Denver, they were modified to 0.13 and 1.35.

3.6 Infiltration

Initial estimates of a watershed's soil infiltration were obtained through Soil Conservation Society (SCS) maps (USDA, 2008). These maps classify soils into Hydrologic Soil Groups A, B, C, and D. Horton Method was used to model infiltration.

3.7 Groundwater Simulation

Baseflow was removed from the USGS record in a monthly basis. Interflow is the residual groundwater flow that occurs after each storm event; this interflow is not as deep as the baseflow of a watershed and it feeds into stream channels at a slower rate than the flow of runoff produced by the same event. Interflow was modeled through the groundwater component in SWMM5, this allowed to match the USGS monitored records for the frequent, small events. Several soil texture classes were simulated as aquifer material and tested during calibration, the best aquifer material was determined to be Sandy Clay, whose hydraulic properties are shown in Table (2).

Table 2. Soil Textures Used in Aquifer Calibration

Soil Texture Class	Hydraulic Conductivity (in/h)	Porosity (fraction)	Field capacity (fraction)	Wilting Point (fraction)
Sandy Clay	0.02	0.43	0.321	0.221

3.8 Flow Routing

The dynamic wave flow routing method was used in SWMM5. This routing method was selected over the kinematic wave method because it solves the complete one-dimensional Saint Venant flow equations and therefore produces the most theoretically accurate results (SWMM 5.0.013, 2008).

4. MODEL CALIBRATION

Calibration to a single storm is not appropriate for continuous simulation modeling because adjustments of variables to match runoff from one event may over or under adjust variables and inhibit matching of other events (Pomeroy, 2007). Therefore, calibration was done to the 1.32–year record through the flow-duration curves. Table (3) shows the needed input data, where highlighted variables were treated as calibration parameters.

Table 3. Watershed model input data

WATERSHED MODEL INPUT DATA		
Sub-catchment Characteristics	**Channel Conveyance**	**Calibration Data**
Drainage area	Cross sections	Rainfall depth
Width	Bottom slope	Streamflow records
Overland ground slope	Length	
Overland flow slope	Roughness	
Soil Infiltration rates		
DCIA coefficients		
Depresion storage		
Overland flow roughness		
Groundwater parameters		

Parameters chosen by calibration

Model calibration followed the Ordered Physics-Based Parameter Adjustment (OPPA) method after Vieux and Moreda (2003). Finding the best parameters to represent the watershed was done by constrained optimization. That is, setting constraints on the search by establish a range of feasible parameters. The calibrated watershed parameters are listed in Table (4)

Table 4. Calibrated Parameters

IMPERVIOUSNESS		Infiltration				DCIA Parameters		Depression Storage		Manning's Roughness	
GIA	DCIA	fo (in/h)	fc (in/h)	Tw (days)	K (1/h)	K1	K2	Imp	Perv	Imp	Perv
30.62	14.25	4.23	0.70	7.00	3.80	0.13	1.35	0.07	0.25	0.012	0.30

5. RESULTS AND DISCUSION

Even when specific calibration for individual storms was not attempted, the built model showed a good behavior as shown in Figure (1) for different storm sizes.

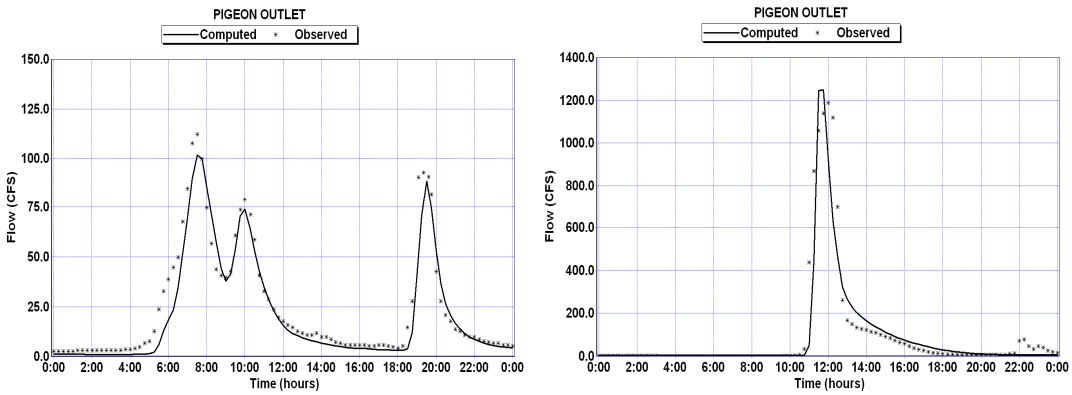

Figure 1. Model output (Storm 1: July 2, 2003 and Storm 2: Aug 08, 2003)

The resulting flow-duration curves are shown in the next Figure (2). The model was able to match the observed flows for the entire flow record.

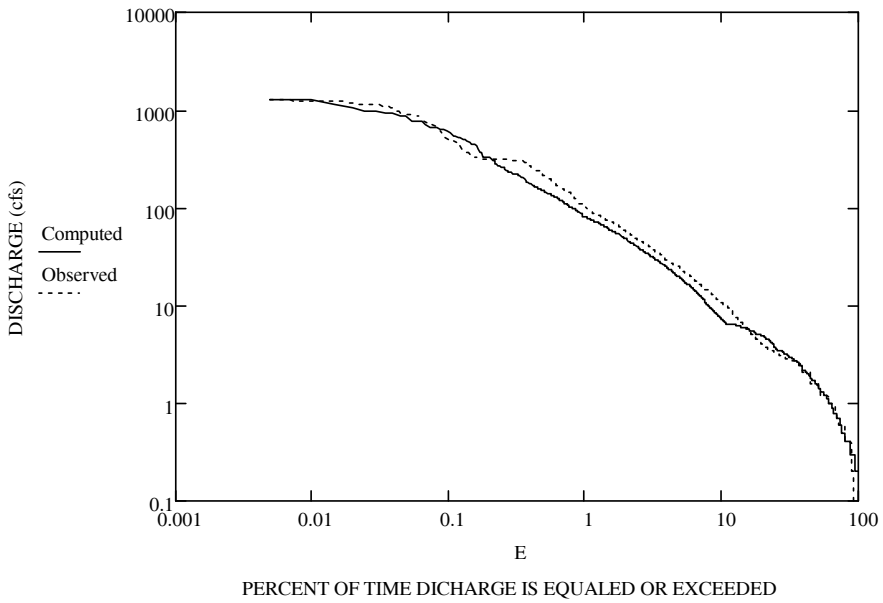

Figure 2. Flow Duration Curves

5.1 Calibration Performance

Measurement of performance allow to assess how reliable are the modeling results and therefore, the predictive power of hydrological models. The agreement between the observed and simulated runoff values may be expressed in terms of a bias or departure. The bias indicates systematic over or under prediction. The departure serves as a measure of the prediction accuracy (Vieux, 2004).

Four indexes were computed:

i) Root Mean Square Error (RMSE)
ii) Product Moment Correlation Coefficient (PMCC)
iii) Nash-Sutcliff Coefficient, NSI (Nash and Sutcliffe, 1970)
iv) Index of Agreement, IOA (Willmott, 1981)

In these indexes, the best condition is when PMC, NSI, IOA yield a value of unity and RMSE to zero. Table (5) shows these indexes for the individual storms and for the obtained flow duration curve. RMSE values depend of the size of the particular storm.

Table 5. Measurement of performance

Event	RMSE (cfs)	PMCC	NSI	IOA
Storm 1	8.44	0.91	0.83	0.95
Storm 2	90.33	0.93	0.87	0.96
Flow duration curve	6.74	0.99	0.97	0.99

6. CONCLUSIONS

The methodology showed to be effective for modeling large urban watersheds. Discretization by limiting the average size to 43 acres was appropriate. The use of DCIA instead of GIA was satisfactory since it represents better the rainfall-runoff process. However, if imperviousness maps are not available, land use covers might be used to estimate imperviousness levels by assigning imperviousness levels to each land use. In this study, field work was performed to identify main cross sections. Nevertheless, cross sections in main channels might be obtained from the DEM.

Routing channel length depends directly of the sub-watershed size, however, the relation found in this paper may not be appropriate to other watersheds, but a similar approach can be used to determine this relationship. The conversion of irregular sub-watersheds to rectangular shapes proposed by Guo (2008) showed to be perform satisfactorily and perhaps this approach may work well for even larger sub-watershed sizes. Groundwater modeling was needed to improve the estimation of low flows. Overall, the proposed hydrologic unit watersheds concept showed an exceptionally good performance.

ABSTRACT

Soil erosion of hills affects the productivity of agriculture lands and threatens our earth environment. There are several factors that trigger and sustain soil erosion. Some of the key mechanisms are believed to be: (i) climate; (ii) soil type; (iii) soil surface roughness; (iv) cropping; and (v) land management practices. This study examines the role of the rainfall-runoff on soil surface roughness and the transport/deposition of the eroded soil. Surface roughness is related to management practices and has been one of the factors that have not received considerable attention. One hindrance of previous studies was the lack of a system and robust methodology for performing adequate acquisition of the soil surface micro-topography. The required resolution in order to adequately describe the soil surface micro-topography is on the scale of a millimeter. Most of the traditional measurement techniques (e.g., roller chain, erosion pins), though, can not provide such a high spatial resolution. Thus, a state-of-the-art laser scanner technique was utilized, providing a resolution of 0.5 mm. Laser scanners use triangulation to measure surface elevation. A laser beam is projected vertically onto the surface and a line camera detects the light spot reflected from the surface. Because of the fixed camera-laser geometry, the surface height is estimated using a simple calibration procedure. The surface heights for the entire soil surface were then imported into the ArcGIS 9.2 software in order to obtain the Digital Elevation Model (DEM), while the built-in Arc Hydro tools were used next to attain the drainage networks, flow direction, flow accumulation, stream definition, and stream segmentation.

INTRODUCTION

Soil erosion on hillslopes is a complex phenomenon that involves two main processes, namely the interrill and rill erosion. Interrill erosion evolves particle detachment due to raindrop impact (splash erosion) and transport by shallow water flow (sheetwash). Rill erosion is defined as the erosion triggered by concentrated flow (surface runoff) within small channels, called rills. Interrills usually supply sediment to rills, whereas rills function as both sediment source areas and sediment conveyors in hillslopes.

Different factors affect soil erosion, such as: (i) climate; (ii) soil type; (iii) soil surface roughness; (iv) cropping; and (v) land management practices. Numerous studies have examined the effects of the aforementioned factors on interrill/rill formation. For example, Bryan (2000) observed a limited flow network development on a sealing soil influenced by subsurface moisture and seepage, while a high-intensity network was developed in a cohesive soil. Berger *et al.* (2008) showed that there is a positive non-linear relationship between soil erosion, rill development, applied rainfall intensity, and slope angle.

One of the parameters that received particular attention is the effect of soil surface roughness in runoff and erosion on hillslopes. There are opposing views concerning the effects of surface roughness and its relationship to hillslope erosion. Some researchers believe that increase roughness leads to an increase in the erosion (e.g., Helming *et al.*, 1998), whereas others think that increase roughness decreases erosion (e.g., Cogo *et al.*, 1984). Römkens *et al.* (2001) showed that the effect of roughness was most significant for high intensity storms and that smooth surfaces yielded a significant larger amount of total soil loss than the rough surface condition. Similar observations were made by Darboux and Huang (2005). Gomez and Nearing (2005) illustrated that soil surface roughness has a significant effect on runoff and sediment yield for moderate slopes, whereas it has little or no effect for steep gradients. Lastly, Helming *et al.* (1998) provided evidence that rough surfaces showed a greater soil loss than smooth surfaces, because flow concentration caused localized increase in erosion.

One hindrance of previous studies on examining soil erosion processes was the lack of technology and a robust methodology for performing adequate acquisition of the soil surface micro-topography. Stroosnijder (2005) provided a critical overview of current measurement techniques for determining the magnitude of erosion at different spatial and temporal scales. Along the same lines, Jester and Klik (2005) provided a summary of different measurement devices -such as roller chain, erosion pins, and laser scanners - which are used for determining the surface roughness. The latest studies have focused exclusively on laser scanners which can provide higher data acquisition rate than other traditional techniques (e.g., Zapp *et al.*, 2001; Darboux and Huang, 2003; Oelze *et al.*, 2003; Schmid *et al.*, 2007).

OBJECTIVES

The overarching objective of this study was to provide a preliminary assessment of the effects of rainfall/runoff in soil surface roughness and how

roughness may, in-turn, affect soil erosion. The sub-objectives of this study included the following:
1) To obtain the topography of the soil surface with a high data-acquisition rate, under different rainfall intensities, using state-of-the-art technology.
2) To use the ArcGIS 9.2 ArcHydro built-in toolset to obtain the drainage networks, flow direction, flow accumulation, stream definition, and stream segmentation.
3) To compare the sediment yield determined under different experimental scenarios (i.e., different rainfall intensity, soil stratification) and provide a quantitative assessment of the effects of surface topology on soil erosion.

METHODOLOGY

To meet the goals of this study, soil erosion laboratory experiments were carried out under simulated rainfall in the IIHR-Hydroscience and Engineering facilities located at the University of Iowa, U.S.A. The two soils used herein were TAMA surface (very dark brown silty clay loam) and TAMA subsurface soil (very dark grayish brown silty clay loam) collected from Iowa County, Iowa. TAMA is a common soil type for the state of Iowa and is considered one of the most productive soils in Iowa that are used for agricultural purposes.

A wooden box (plot) of ~ 1.0x0.3x0.07 m^3 was used for the soil erosion experiments (Figure 1). Holes were drilled at the bottom of the box to allow free drainage and limit the formation of a perched water table (Darboux *et al.*, 2001).

The rainfall simulator used in this study was mounted ~ 2.0 m above the box. Rainfall was applied by an oscillating VeeJet type nozzle. The rainfall intensity was adjusted by the frequency of the oscillating nozzle. Experiments were conducted for two rainfall intensities (60 mm/hr and 75 mm/hr) and for two arrangements of the soil (TAMA) stratification, resulting to four experimental runs. The two arrangements were the following: (1) use only one layer of surface soil ~ 0.075 m thick; and (2) use two layers of soil, a bottom layer of ~ 0.05 m sub-surface soil and a top layer of ~ 0.025 m surface soil. The soil was air dried before placed uniformly in the box. At the beginning of each experiment the soil surface was flattened and smoothed with the aid of a wooden roller (Figure 1).

Preliminary experiments were conducted under the given rainfall intensities to determine the optimal gradient (~ 14 %) to initiate erosion and cause rill development. Thus, in all four experiments the slope of the box was kept constant and equal to ~ 14 %. A funnel located at the downstream end of the plot (Figure 1) was used to quickly convey water and soil at the outlet of the erosion plot. Four moisture probes were installed in the four corners of the box to record frequently the soil moisture content during each experiment.

The micro-topography of the soil surface was determined by using a state-of-the-art instantaneous surface-profile laser scanner (0.5 mm resolution). The laser scanner used triangulation to measure surface elevation. A laser beam was projected vertically onto the surface (Figure 2) and a camera detected the light reflected from the beam. Because of the fixed camera-laser geometry, the surface height was estimated using a simple calibration procedure.

The following process was adopted to perform the individual experiments. Prior to each experiment an inclinometer validated that the surface was leveled in all directions. Next, the flat soil surface was pre-scanned using the laser system. During each experiment, soil moisture was recorded and a bucket was used to collect water and soil exiting the box. Experiments were terminated when steady state conditions were established (i.e., no visual changes in the soil surface). To verify that the experiments were terminated during steady state conditions, subsequent samples of water and sediment were collected at the plot outlet. After the experiment, data points of the bed elevation (~ 1,200,000 points) were transformed from the camera coordinates (CCD) to real (physical) coordinates through a regression-calibration equation (Darboux and Huang, 2003). The calibrated surface heights were then imported into the ArcGIS 9.2 software to obtain the Digital Elevation Model (DEM). DEM's of soil surfaces are used in soil erosion research for a better understanding of the erosion processes. By using the DEM and the Arc Hydro toolset in ArcGIS 9.2 the DEM-based stream network was generated.

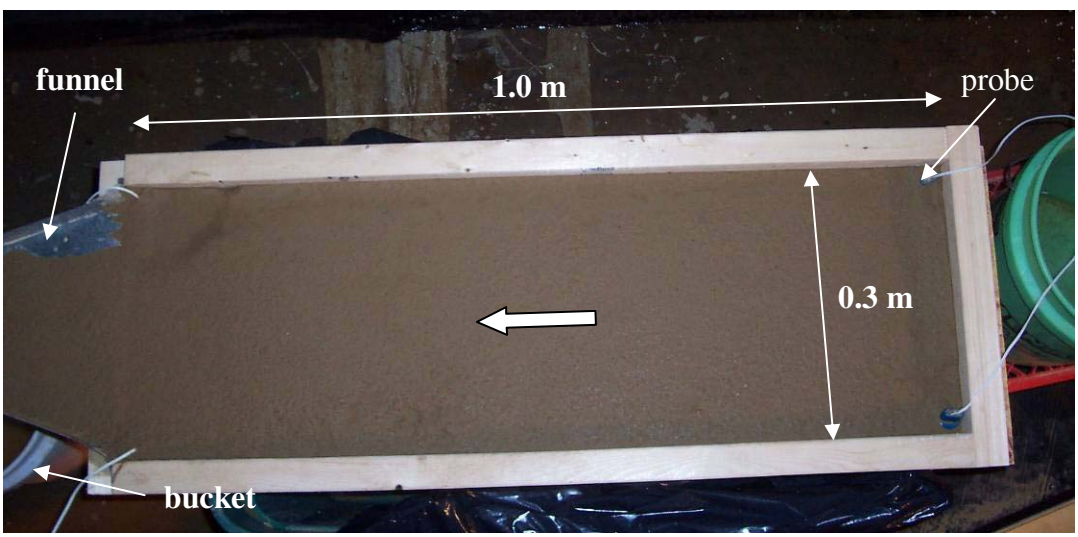

Figure 1. The experimental box used in this study filled with TAMA soil. Arrow illustrates the runoff direction.

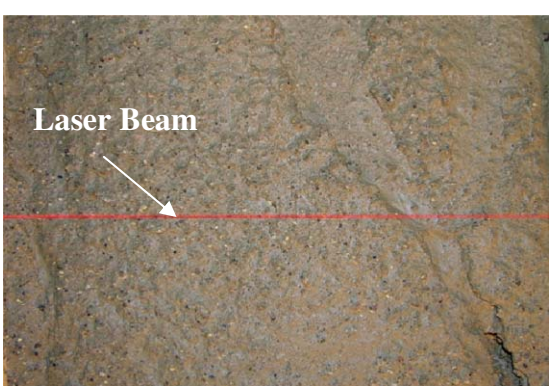

Figure 2. The laser beam over the soil surface.

RESULTS

Table 1 shows the average particle and water flux at the end of the four experimental runs, namely experiments 1-a, 1-b, 2-a, 2-b, when steady state conditions were achieved. The number denotes the soil stratification (1: one layer of soil and 2: two layers of soil, as specified in the ″Methodology″ section) and the letter denotes the applied rainfall intensity (a: 60 mm/hr and b: 75 mm/hr). As expected, higher rainfall intensity produced higher erosion rates.

Figure 3 presents a plan view of the soil surface at the end of experiment 1-b. Dye was used to visualize the eroded soil surface. Three distinct regions (regions I, II, III) were clearly observed. Region I specified the zone of splash detachment and was characterized by the formation of craters (depressions) on the soil surface, due to the impact of the rain drops (splash erosion). Region II illustrated a transition zone where the raindrop impact attenuated and runoff was generated. Additionally, region II was characterized by the initiation of rill formation. Region III depicted the zone where the rills were fully developed (rill erosion). As it can be seen in Figure 3, region I extended approximately 1/3 of the length of the box, while regions II and III together extended approximately 2/3. Similar observations were made for the other experiments.

Figures 4a-d present plan views of the soil surfaces for the four experimental runs at the end of the tests. The average duration of the tests was ~ 1 hr. It is clear that for higher rainfall intensity, more pronounced channel networks/rills were formed. Also, Figure 4b shows that the rills acquired a slightly sinuous shape with irregular width

Figure 5 displays results from the step-by-step data analysis using the ArcGIS software. Surface heights obtained by the laser were transformed from raster to point file (Figure 5a) and then interpolated using the inverse distance weighted technique (Figure 5b). Finally, the catchments and flow networks were defined using ArcHydro tools (Figure 5c).

Figure 6 provides the flow network for the four experiments and verifies the visual observations of the soil surfaces in Figure 4. In all four experiments 2-3 rills were formed (darker lines in Figure 6); distinguished rills, though, were primarily formed in experiments 1-a and 1-b. Formation of rills enhanced erosion and more eroded material was recorded in run 1-b (Table 1). Finally, the flow networks in Figure 6 failed to provide information on the rainfall induced craters formed in region I.

Table 1. The experimental conditions of each run

Experiment	Soil Stratification	Rainfall intensity (mm/hr)	Particle flux (gr/sec)	Water flux (lit/sec)
1-a	One layer	60	0.56	0.0063
1-b	One layer	75	1.23	0.0067
2-a	Two layers	60	0.19	0.0058
2-b	Two layers	75	0.61	0.0080

Figure 3. Characteristic regions formed during the experiments Arrow illustrates the runoff direction.

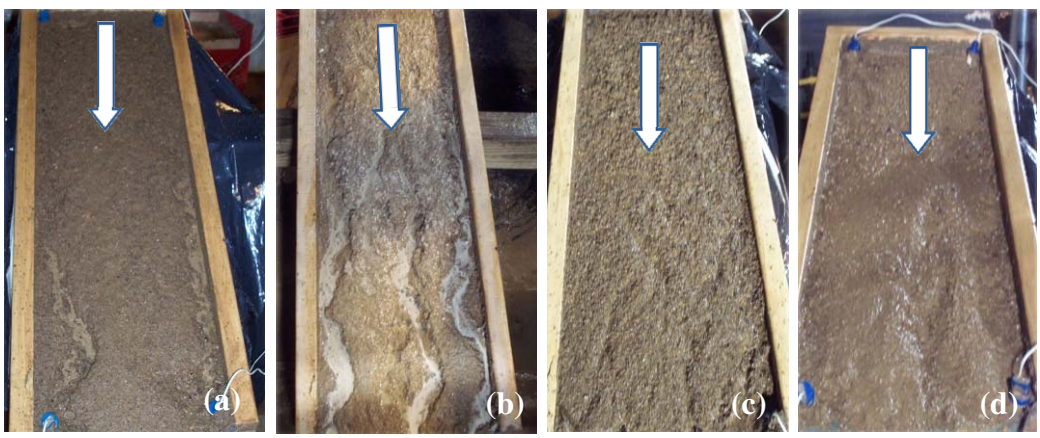

Figure 4. Soil surface at the end of the experiments. From the left to the right: Experiment 1-a, 1-b, 2-a, 2-b. Arrow illustrates the runoff direction.

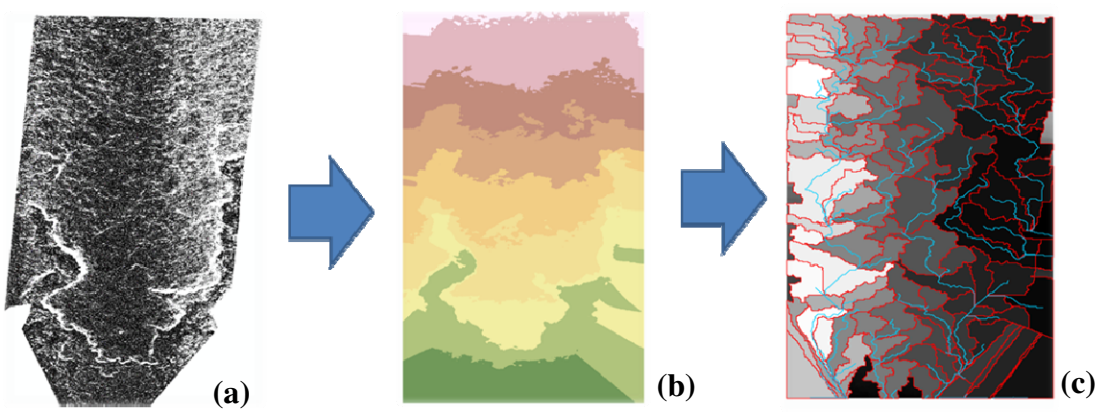

Figure 5. Procedure followed to determine the flow network.

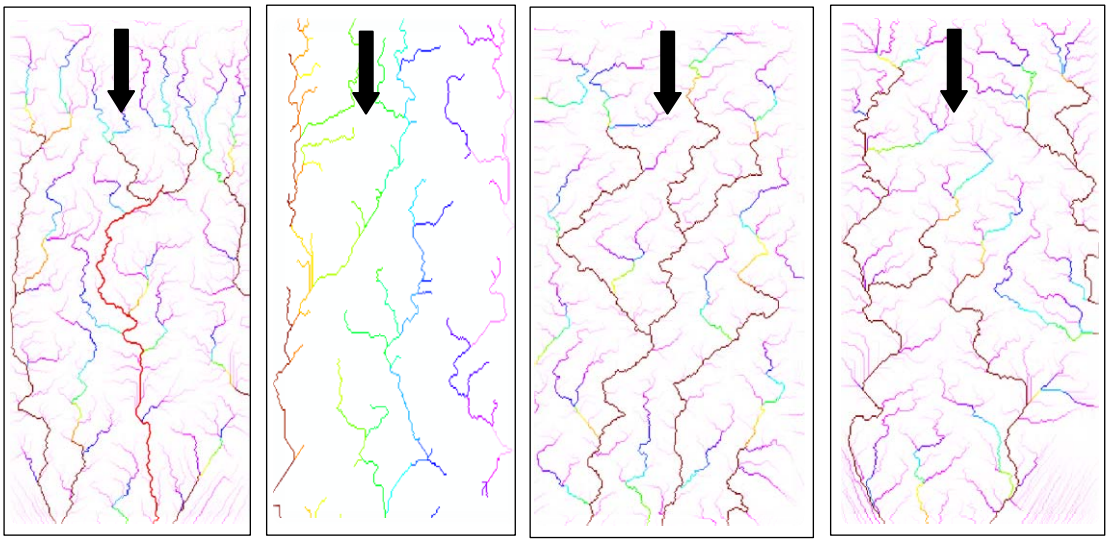

Figure 6. Flow network corresponding to the soil surfaces presented in Figure 4 (from left to right: Experiment 1-a, 1-b, 2-a, 2-b). Arrow illustrates the runoff direction.

CONCLUSIONS

The following can be concluded from this study:

(a) Rainfall and runoff affected flow network. The rainfall impact dominated at the upstream locations of the soil box (crater formation), while downstream the effect of runoff was dictated (rill formation).
(b) More complex flow networks were formed in the case of low rainfall intensity. The soil surfaces under high rainfall intensities were characterized by distinguished rills. In addition, pronounced rills were found to form only when one layer of soil was used (surface soil).
(c) Significant erosion was recorded when distinguished rills were formed. It is believed that rills delivered the material faster to the plot outlet (Bryan *et al.*, 1998).

For future studies the following should be considered:

(a) Time evolution of the bed surface by using the laser scanner multiple times during the experimental run.
(b) Address the temporal changes of the soil surface roughness, which will allow interpreting accurately the temporal variability of water and sediment fluxes.
(c) Determination of the depression storage via the calculation of different roughness indices, i.e., random roughness, tortuosity (Kamphorst *et al.*, 2000), or by using a PCRaster that finds depressions and fills them until they overflow (Van Deursen, 1995).

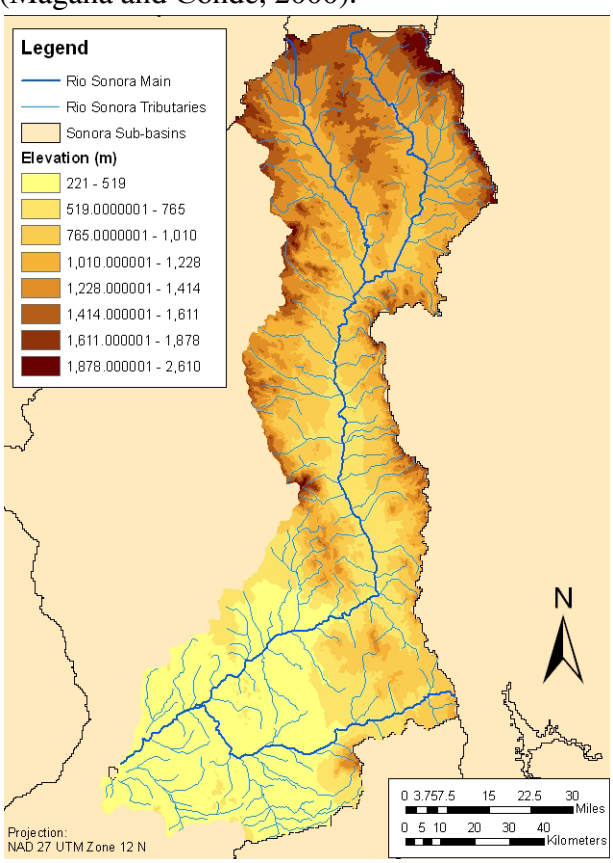
ABSTRACT

The state of Sonora is located in northwest Mexico and shares its border with the states of Arizona and New Mexico. Approximately 95% of Sonora is described as arid or semiarid. Precipitation across the state averages 437 mm per year; however, the most arid areas average less than 100 mm of rainfall annually. Sonora's climate is recognized as having a bi-seasonal rainfall pattern, characterized by frequent periods of little or no rainfall followed by periods of heavy rainfall, especially in the summer months of July and September. These periods of drought develop land cover and soil conditions that are conducive to heavy flash flooding during the rainy months, followed by quick recession of flood waters and a return to dry conditions and low streamflows. The high degree of climatic variability has presented serious challenges to water resource planning and management in Sonora. Further, recent drought conditions have led to an almost complete reliance on groundwater sources to meet the needs of the growing population.

The goals of this study are to develop an understanding of how different meteorological events impact streamflow in the study area, how changes in land use and development in the Sonora River basin might impact streamflow, and to better characterize streamflow behavior through various statistical approaches on flood flow data dating from 1942 to 2002. More specifically, a hydrologic model of the area of interest was developed and calibrated using the U.S. Army Corps of Engineers' HEC/HMS version 3.1.0 watershed modeling software, and an array of future development scenarios was simulated in order to predict the impacts to streamflow in the basin as a result of these changes. The work of this study also involved the collection and analysis of an extensive set of geographic data of the region, as well as a detailed flood frequency analysis of 58 years of peak annual flow data in order to select an extreme value distribution to model the river's behavior and predict flood quantiles.

INTRODUCTION



This project's focus is in the state of Sonora, Mexico, a region which is experiencing rapid growth and increasing water scarcity, especially in its capital city, Hermosillo. Sonora is bordered by Baja California to the northwest and the states of Sinaloa and Chihuahua to the south and east, respectively.

The Sonora River basin lies entirely within the central portion of the state and encompasses an area of approximately 26,700 km^2. The river originates in the mountainous north of the basin near the Cananea copper mining region. Historically the river's mouth met the Gulf of California at its outlet, but due to groundwater

overconsumption, the Sonora River runs dry even before it meets the city of Hermosillo. Roughly half of Sonora (260,000 km^2) is covered by the Sonoran Desert, which also includes most of the Baja peninsula, southwest Arizona, and a portion of California. The vegetation in the area of study is predominantly scrub-shrub, with areas of agriculture along stretches of the river, and pastures and forests to the north and along the perimeter of the study region. Soil cover is dominated by very coarse, deep soils with gravel at the surface. In the south of the study area there is a significant region of thin soils described as having average texture. Along the course of the river there exist three distinct regions of deep soils having average texture with areas of gravel and stone.

In examining the topographic data of the area it is noted that the greatest elevations occur in the northernmost portion of the watershed. Elevation data are provided in Figure 1. As stated previously, the lowest elevation encountered in the study area is 221 m asl and occurs at the outlet of the study area (the southwestern-most reach of the main branch of the Sonora River) near the city of Hermosillo. The maximum elevation of 2,610 m asl occurs in the northeastern-most reach of the study area.

Annual water availability in Mexico is estimated to be over 410 billion m^3; however, approximately 68% of available water is concentrated in the southeast and Gulf of Mexico regions, and only 2% in the northern states. Furthermore, approximately 53% of the soils best suited for agriculture are located in the arid and semi-arid regions (Magaña and Conde, 2000).

The climate in northwest Sonora is very arid; regular streamflows do not exist here. The main surface water flows in Sonora are in the east and the south and are dammed to provide minimal quantities of water, although they are typically insufficient to meet energy and irrigation demands and must be supplemented with groundwater (Hallack-Alegria, 2005). In the case of Sonora, approximately 95% of the state is characterized as arid or semi-arid, exhibiting year-round high temperatures and low precipitation. The Sierra Madre region of Sonora experiences the greatest rainfall and lowest temperatures. The driest region in the entirety of Mexico, el Desierto de Altar, is located in northwest Sonora (Hallack-Alegria, 2005).

Figure 1: Topographic Map of Sonora Area of Study
Map created by M. Habarth (data from INEGI), 2006

Precipitation in Sonora averages around 437 mm annually, although this is highly variable from year to year. Northwest Sonora, near its border with Baja California, receives an average of only 1 to 100 mm of rainfall each year (Magaña and Conde, 2000). Sonora experiences a bi-seasonal rainfall pattern, with most precipitation occurring during the summer months of July through September. The North American monsoon (NAM) generally determines precipitation in northwestern Mexico, although the large inter-annual variability is influenced by the El Niño/Southern Oscillation (ENSO) (Magaña and Conde, 2000).

The most dominant climate zone in terms of area is Semiseco I ("Semi-dry" I), characterized by warm, rainy summers with a mean annual temperature ranging from 12-18°C. The second most widely-occurring climate zone is Seco II ("Dry" II), characterized as having summer rains, and generally mild temperatures (mean annuals greater than 18°C) throughout the year with cooler winters. In general, the climate shows a pattern of increasing warmth and dryness as one travels from the northeastern-most portion of the study area to the southwestern-most edge near Hermosillo, following the pattern of decreasing elevation.

The study area could be delineated into five distinct sub-watersheds based on geostatistical analyses performed on the digital elevation models. Their names are: Bacanuchi and Arizpe to the north, Banamichi in the center of the study area, and Sonora-Hermosillo and Arroyo La Junta to the south. The mountainous Bacanuchi sub-watershed encompasses an area of approximately 1,600 km^2. Its even more mountainous neighbor, the Arizpe sub-basin, covers an area of roughly 2,300 km^2. To their south lies the largest of the sub-basins, Banamichi, with an area of about 5,500 km^2. In the southeast corner of the study area is Arroyo La Junta with an expanse of 2,000 km^2. Finally Sonora-Hermosillo is reached, geographically the flattest and smallest sub-watershed, covering an area of approximately 1,200 km^2.

Within the study area there exists one dam and reservoir, Rodolfo Félix Valdez, familiarly known as "El Molinito." The dam is located about 23 km upstream of the city of Hermosillo. Located slightly upstream of El Molinito is the streamflow gauging station El Orégano II, currently the only existing flow monitoring station in the area of study. The station is operated by the Mexican National Water Commission, CONAGUA (Comisión Nacional del Agua). The original station, El Orégano I, was located at the dam site and then relocated just upstream during the construction of the dam and its reservoir. Due to the dam's construction and the station's relocation, streamflow was not recorded during the period 1991-1993.

The ultimate goals of this work were to develop an understanding of how different meteorological events impact streamflow in the study area, how changes in land use and development might impact streamflow, and to better characterize streamflow behavior through various statistical approaches on flood flow data dating back to the year 1942. More specifically, the objectives included: (1) the creation of a user-friendly Geodatabase of relevant geographical information pertaining to the study area using Geographic Information Systems (GIS), (2) the development of a specific statistics-based model to adequately represent 58 years of streamflow data and estimate floods at various return intervals, (3) the creation and calibration of a hydrologic model of the study area in HEC-HMS to predict watershed behavior given an array of meteorological events, and

(4) the utilization of this model for the simulation of watershed behavior given specific changes in watershed condition. See Habarth (2008) for additional details.

FLOOD FREQUENCY ANALYSIS

The streamflow data that were utilized for the analyses in this project were obtained from CONAGUA through IMTA (Instituto Mexicano de Tecnología del Agua) via the Instituto de Ingeniería (Institute of Engineering) at UNAM and were available in their 2006 two-part report for CEA (Comisión Estatal del Agua, State Water Commission). Provided were monthly average flows from 1941-2002 (missing 1991-1998) and maximum annual instantaneous flows from 1942-2002 (missing 1991-1993), both at the station El Orégano (UNAM (I), 2006). The data gap between 1991 and 1993 occurred as a result of the construction of the dam El Molinito, during which flow measurements were not taken. Also available in the UNAM report (for CEA, Part I) were annual reported measurements of the maximum flow (m^3/s) that was sustained for 0 (instantaneous), 1, 2, 3, 4, and 5 day durations, for the period 1941-2002 (missing 1991-1993, 1995-1998). The report also published monthly drainage volumes at El Orégano (thousands of cubic meters) for the period of record 1975-2001, with values for missing years estimated by regression. These analyses were also based on the CONAGUA hydrometeorological data.

In their 2006 study, the Institute of Engineering at UNAM (for CEA) provided estimates of flood flows for return periods ranging from two to 10,000 years for durations ranging from instantaneous (maximum) to one to five days sustained.

Probability Plot Correlation Tests, L-Moment Ratio Tests, Kolmogorov-Smirnov bound tests, and other associated hypothesis tests were completed in order to rule out certain flood frequency distributions and to calculate parameters of the various distributions.began. Once the number of feasible distributions was narrowed down, the fitted quantiles for all of these remaining distributions were plotted on the same chart as the empirical cumulative distribution function (CDF) (Figure 2) with the goal of choosing a distribution to best represent the annual maximum instantaneous flow data at El Orégano

It is difficult to select the "best" distribution by only examining the graph. It appears that in the lower tail (discharges less than 250 m^3/s), the Log-normal (using Maximum Likelihood Estimators, MLE) distribution provides the best fit to the empirical data. In the middle of the data, the Gumbel, Pearson Type III (P3), and Generalized Extreme Value (GEV) distributions are closely matched. At discharges between about 650 and 1,000 m^3/s, the data appear to nearly follow a Normal distribution. And the few data points in the upper tail appear to be best represented by the GEV distribution. As one can see based on these observations, assigning a single distribution to reasonably represent a series of true flood data can be challenging. However, it appears that the P3 and Gumbel distributions are the best at following the shape of the empirical CDF, with the P3 distribution perhaps providing a slightly better fit to the data, based on visual observation alone.

Table 1 gives percentiles calculated from the fitted distributions and provides demonstrable proof of the closeness of the fit of the P3 and Gumbel distributions; they are perhaps closer to each other than any of the others, with the single exception of the GEV distribution in the 90^{th} percentile.

Based on the results of the numerous goodness-of-fit tests, hypothesis tests, graphing and diagrams, quantile calculation, and visual examination, the P3 distribution is recommended as the distribution best suited to representing the 58 years of maximum instantaneous streamflow data at El Orégano.

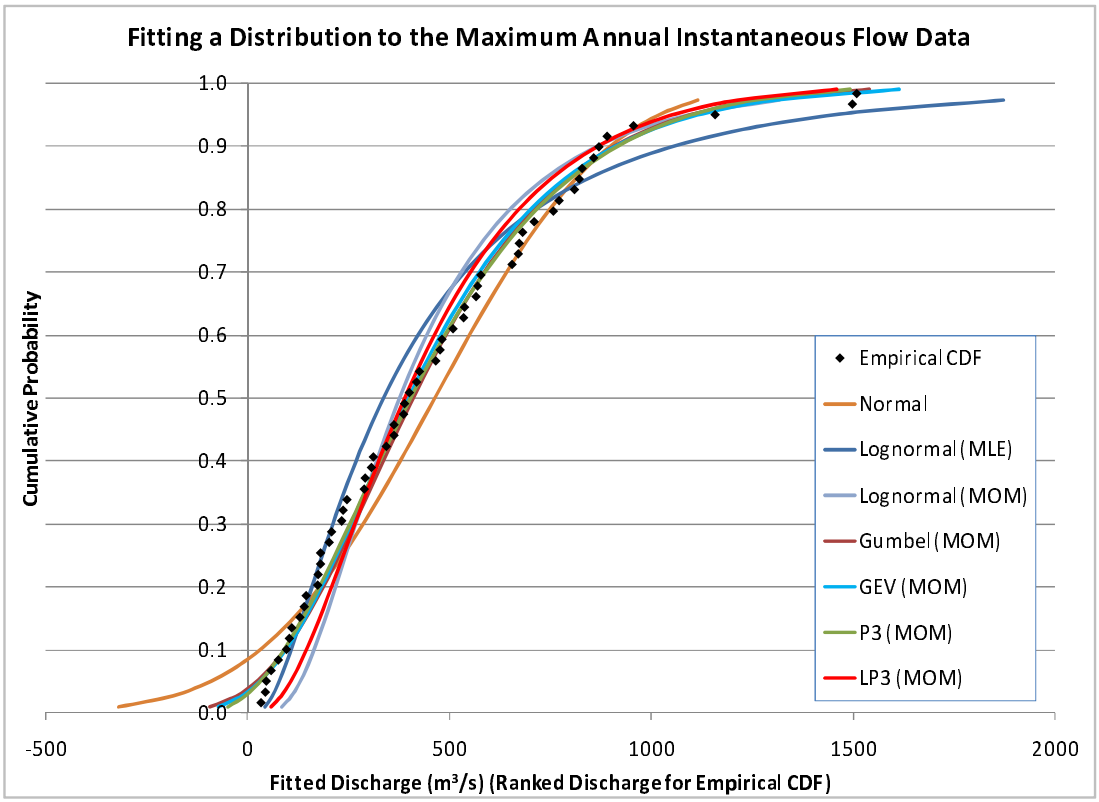


Figure 2. Plot of Fitted Distributions with Empirical CDF (based on CONAGUA data)

Table 1. Percentiles (m^3/s) Calculated (by author) from Fitted Distributions

P3 is in bold, as it was judged most appropriate to represent the data.

Distribution (Method)	10th Percentile	50th Percentile	90th Percentile	99th Percentile
EMPIRICAL	95.0	390.0	870.0	1520.0
Normal	28.8	463.5	898.3	1252.7
Lognormal (MLE)	106.7	335.7	1056.8	2691.2
Lognormal (MOM)	161.6	374.0	865.8	1716.4
Gumbel (MOM)	90.3	407.8	906.1	1527.6
P3 (MOM)	**87.5**	**402.8**	**918.4**	**1509.5**
LP3 (MOM)	143.0	387.0	868.1	1475.6
GEV (L-Moments)	93.6	397.6	911.7	1622.3

HYDROLOGIC MODELING

Figure 3 illustrates the basin model in HEC-HMS 3.1.0 for the Sonora River area of study and an inventory of all of the elements of the model. As the model illustrates, a sub-basin element has been added for each of the five sub-watersheds in the area of

study. A reservoir element indicates the presence of the El Molinito dam. There is an outlet at the watershed boundary near the city of Hermosillo, and two junctions (Arizpe station, Ures station) at the locations where the main branches of the Sonora River meet. It is important to note that the Ures station also indicates the approximate location of the El Orégano streamflow gauge.

For the five sub-basins in the Sonora River area of study, the Muskingum-Cunge Method was implemented as the most appropriate routing method given the available data and knowledge of the system. An optional loss/gain method for consideration of subsurface interactions was not implemented for this study due to the lack of infiltration data, and with the goal of minimizing the number of assumptions made.

Since fairly detailed information was known pertaining to the outlet works of the El Molinito dam and reservoir, the "Specified Release" method was chosen for the reservoir outflow modeling. Since values of the reservoir area at given water elevations were available (2006 UNAM (for CEA) part I report, Chapter 6), the Elevation-Area method was selected to model reservoir storage. Due to limited data, the "Assume None" method was selected for tailwater considerations.

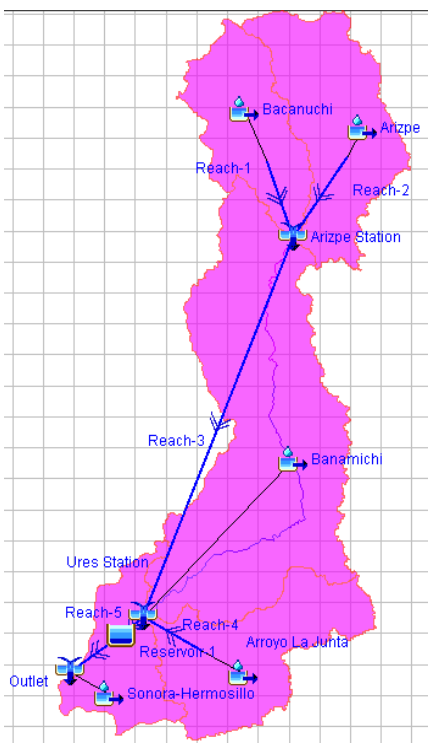

Figure 3. Screenshot of Set-up of Basin Model and Element Inventory in HEC-HMS 3.1.0

The Frequency Storm and Gage Weights methods were both considered for entering precipitation data in the Sonora Meteorologic Model. Although the Frequency Storm method was a feasible option given the available data, the gage weights option was selected to be most appropriate for calibrating the models using actual recorded rainfall data. By default the "Monthly Average" method was selected for this project because these values were available in the 2006 UNAM (for CEA) Part I report (Chapter 8); this included average monthly evaporation values (mm) at the Bacanuchi station (26007) in the north of the basin and at Hermosillo (station 26139) in the south of the basin. These data were measured for the periods 1980-2003 and 1981-2004, respectively, by CLICOM (Mexico Climatological Station Network Data). The standard evaporation pan (Class-A) was developed by the U.S. Weather Bureau, and has an average pan coefficient of 0.7 (American Meteorological Society, 2008).

The model was calibrated by adjusting the runoff curve numbers (CN) to account for dry antecedent soil conditions and resulted in a close agreement between modeled and actual streamflow with notable discrepancies in the latter months of the year. These late-year discrepancies were attributed to initial abstraction being exhausted, resulting in excessive predicted runoff.

HYDROLOGIC MODELING SIMULATION

Urbanization

The first set of scenarios that were investigated for the year 2001 were a 10, 25, 50, and 100% increase in the CN for the Sonora-Hermosillo sub-watershed, where development is occurring and is most likely to occur in the future. The results of the incremental CN increase in the Sonora-Hermosillo sub-watershed alone are shown in Figure 4. Overall, as anticipated, the greatest increase in streamflow was predicted to occur during the months of June through October, or the rainy season, with the greatest overall increase in July and September. When considering urbanization for the year 2001 in only the Sonora-Hermosillo sub-basin, a 10% CN increase resulted in an average streamflow increase of 165%; a 25% CN increase yielded in a 260% average increase, a 50% CN increase resulted in a 417% average streamflow increase, and a 100% increase in CN yielded an average 745% increase.

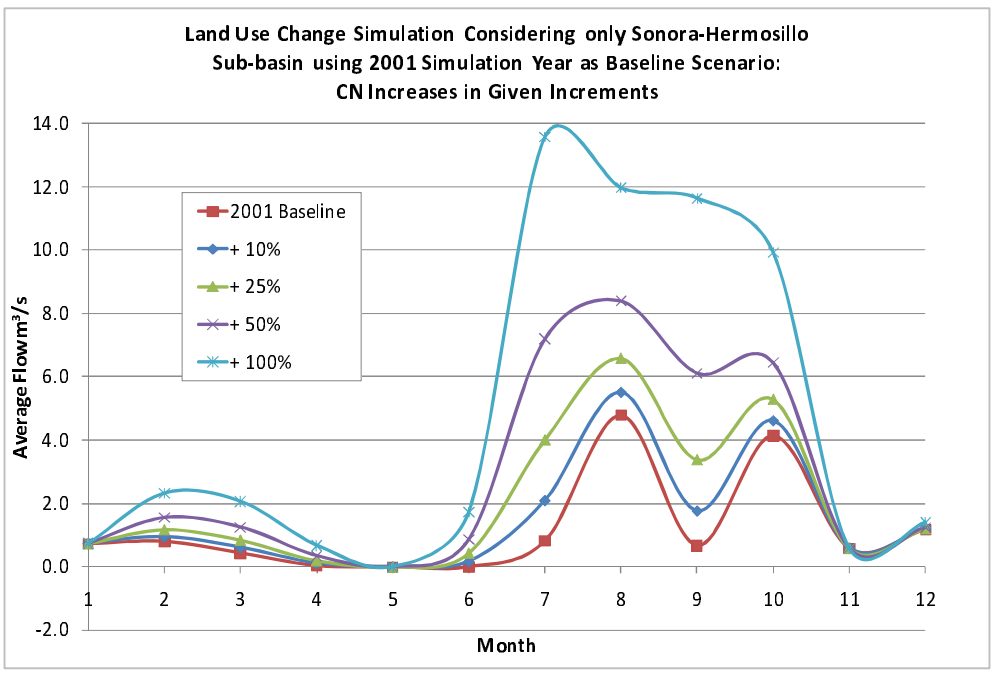

Figure 4. Graphical Results of Land Use Change Simulation, Sonora-Hermosillo
HEC-HMS model output based on year 2001 calibration

The predicted increase in peak streamflows was also examined. The peak streamflow from the 2001 baseline simulation was 15.5 m^3/s. With a 10% CN increase, the peak flow increased to 16.6 m^3/s. At a 25% CN increase, the peak flow was 18.4 m^3/s. At 50%, it was 22.8 m^3/s, and at a 100% increase in the Sonora-Hermosillo CN, the peak flow was 41.6 m^3/s, or approximately 2.7 times the baseline value.

Based on these results, it is likely that even a minimal increase in CN (or impervious surfaces) as a result of urbanization or other land use changes can result in a very significant increase in streamflow. It is important to note that the curve number

increases were applied only to represent hypothetical development scenarios; the exact correlation between population increase, urbanization, and land use change is unknown, therefore these factors should be studied in greater detail before any specific assumptions are to be made regarding increasing streamflows in the basin. Potentially, increased runoff to surface water sources could diminish the availability of groundwater due to reduced infiltration and aquifer recharge. Increased surface runoff could also cause or exacerbate flooding in vulnerable areas.

Stream Channel Modification

The first scenario that was examined for channel modification in 2001 was lining the entirety of Reaches 5 and 6 (upstream and downstream of El Molinito) in concrete, thereby changing Manning's *n* from the original value of 0.04 (for a winding natural channel rated as "fair") to a value of 0.013 for a concrete channel, with a uniform trapezoidal shape having a bottom width of 3 meters and a side slope of 1:1 (H:V). This channel shape and Manning's *n* were then uniformly applied across the entire watershed. Although not a likely scenario anytime in the near future, it is of interest to examine, hypothetically, what may be the possible impacts of heavy human modification of natural channels.

It was expected that a decrease in Manning's *n* and a uniform trapezoidal cross-section would produce, at minimal, a fluctuation in the distribution of streamflow, i.e. an earlier onset of peak flows (decreased travel time through the river reaches) due to a hydraulically smoother, more uniform channel. However, altering these parameters in HEC-HMS 3.1.0 did not produce a significant change. When the channel upstream and downstream (Reaches 5 and 6) of El Molinito (Reservoir-1) was modified, no change in streamflow quantity or shape was observed. When all six reaches in the study area were modified, the result was a nearly negligible 0.1 m^3/s increase in the average monthly flow in January and a 0.2 m^3/s increase in the monthly average flows in July and October.

These results suggest that channel modification in any or all areas of the study area may not result in a significant change in the magnitude of streamflow. However, this will depend on the magnitude of the modification; concrete lined channels with trapezoidal cross-sections were assumed, having a bottom width of 3 meters and a 1:1 side slope. Different materials and cross-sections may produce a different impact.

Additionally, HEC-HMS 3.1.0 does not report flow depth in the model results. It is likely that the depth of flow will be altered due to the change in channel morphology. Altering the flow depth could have significant impacts on flooding and erosion. Furthermore, it is very likely that such channel modification would disrupt the surface-groundwater interaction in the river basin, eliminating the infiltration of water within the streambed. The capability of HEC-HMS 3.1.0 to accurately model and account for hydraulic parameters in a watershed was not examined in detail in this study. It is highly recommended that no stream channel modifications be made without extensive hydraulic modeling in order to predict what the true impacts to streamflow in the study area might be. The effects on streamflow and the magnitude of these effects will be completely dependent on the characteristics of the channel modification.

Dam Removal

To set up the El Molinito dam removal scenario, a duplicate copy of the 2001 simulation year model was produced and the Reservoir-1 element removed. Because the dam El Molinito was located downstream of the flow gauging station (El Orégano, represented by the Ures Station), it was not expected that its removal would have any upstream impacts at the flow station, which was true. However, when the dam was in operation, no streamflow was generated downstream of the structure in any of the simulations. The most important result of the dam removal simulation was that flow occurred downstream of the original dam site after the structure was removed. The streamflow pattern observed at the Outlet is shown in Figure 8.

As El Orégano is currently the only existing flow monitoring station in the area of study (i.e. one that would have monitored flow at or near the outlet prior to the construction of El Molinito), there is no definitive way to confirm these results. However, the shape of this average monthly hydrograph seems to make physical sense. One would expect to see a relatively rapid increase in flow at the onset of the rainy season, then a larger pulse as the streamflow from the upstream elements reaches the outlet following the progression of the wet months.

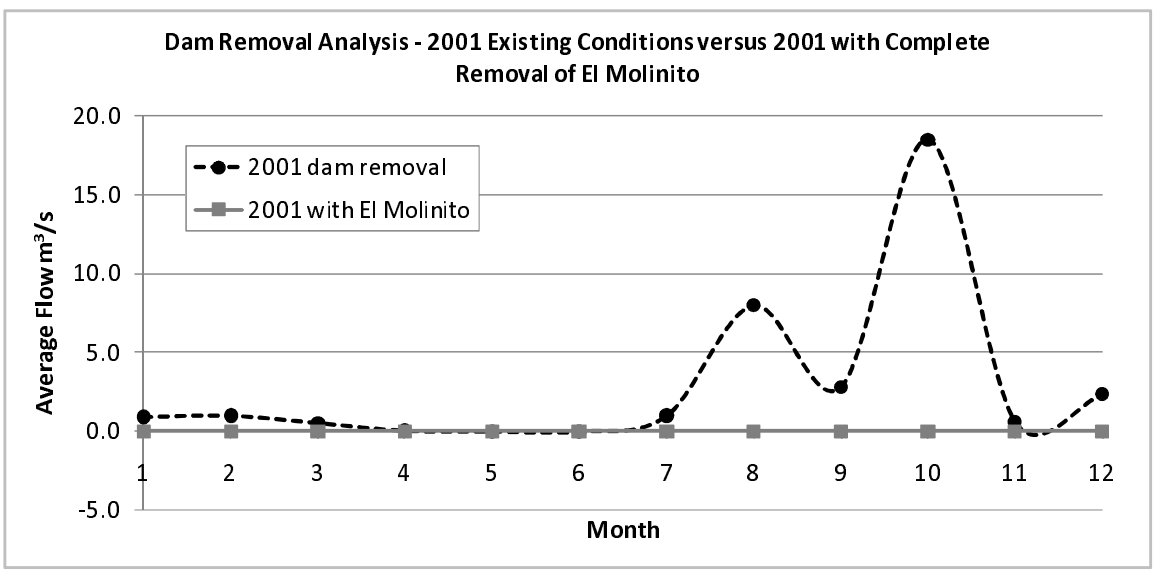

Figure 8. Graphical Results of El Molinito Removal
HEC-HMS model output based on year 2001 calibration

It may be worth considering that the value and function of El Molinito be re-examined; it may better serve the water needs of residents, farmers, businesses and municipalities downstream to remove the dam and restore natural flow to this length of the Sonora River. However, before any drastic measures are taken, the flood protection and water storage/supply benefits of the reservoir should be assessed. The original purpose of the dam's construction was to provide flood protection and water supply to the city of Hermosillo. If the dam is removed, these critical benefits could be permanently lost. If El Molinito is necessary in order to help protect the city of Hermosillo, perhaps the dam's operating procedures should be adjusted accordingly or pumps be installed upstream to assist in delivering flow to downstream users. It is highly recommended that

these many influential factors be examined before any actions involving dam removal or operating procedure modification are executed.

ACKNOWLEDGEMENTS

Agustin Robles Morua is acknowledged for allowing me to play an important role in his extensive work in the Sonora, Mexico region, for his willingness to quickly answer all of my questions and concerns, for his admirable dedication to the project, and for providing me with access to all of the data and resources without which this project could never have been a success. I wish you all the best as you continue your work in Sonora and earn your PhD.

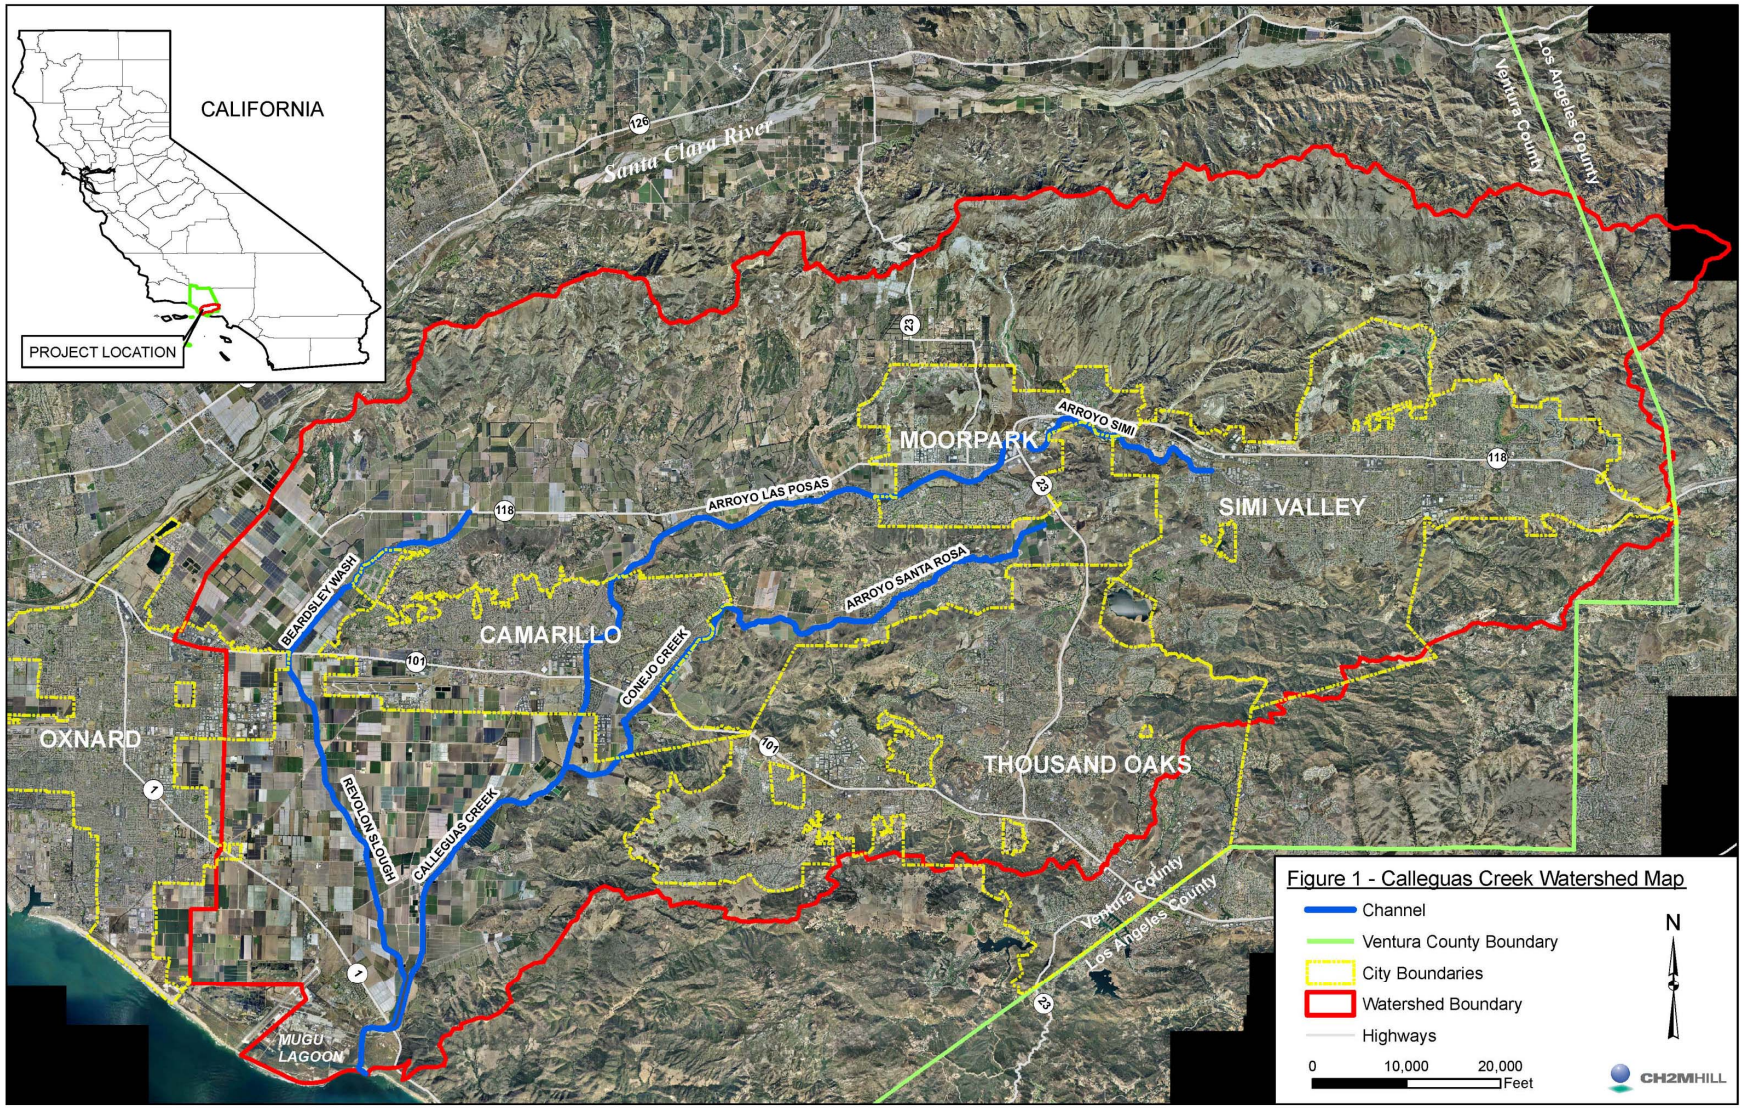
Introduction

The Ventura County Watershed Protection District (VCWPD) is preparing the Calleguas Creek IWPP Phase II Management Strategy Study as part of the development of the Calleguas Creek Integrated Watershed Protection Plan.

The 343 square mile Calleguas Creek watershed located in Ventura County, California has developed significantly over the last 50 years including the Cities of Simi Valley, Moorpark, Thousand Oaks, and Camarillo (see Figure 1). The land areas within the city limits are approximately 70 percent developed. Increased development has translated into more impervious ground cover resulting in increases in stormwater runoff volumes and peak flows into Calleguas Creek and its tributaries. These increased flows can (and do) cause erosion, sedimentation, and flooding problems. They also wash more pollutants from paved surfaces or agricultural lands into the waterways. This creates challenges and opportunities within the watershed.



There is a need to increase flood protection and provide for better sediment management in the watershed. While doing this, there is also an opportunity to accommodate or address other multi-use benefits, such as ground water recharge, water quality improvements, recreational enhancement, or habitat restoration.

The goals of the study are to provide multi-purpose conceptual projects for the watershed in order to deal with issues such as flood control, land development, erosion, sedimentation, the environment, parks and recreation, open space, and funding. Cost-effective and environmentally friendly solutions are being developed through a stakeholder driven process.

Alternative Approaches

A number of stakeholder-driven workshops have been held with stakeholders to develop and prioritize the approaches listed below and discussed in the following sections.

1. Land Management Focus
2. Watershed BMPs
3. Regional Basins

4. Protection-level
5. Channel Improvements

Alternative Approach 1 – Land Management

Land Management refers to the practice of ensuring that undeveloped land remains free of development through regulatory- or policy-based mechanisms. Maintaining land in an undeveloped state may not reduce downstream flows, but it does prevent flow increases. The goals of this approach include:

- Floodplain and agricultural preservation
- Environmental restoration
- Recreation
- Land acquisition through purchase when owners are ready to sell
- Removal of invasive plant species

Current agricultural lands may be incorporated into an Agricultural Preserve which would limit the potential for future development. This would be enacted through an ordinance or other policy mechanism.

Generally, undeveloped land in critical areas (in this case within ¼ mile each side of the main channels) is targeted. However, only 570 acres, or 4% of land use within the established ¼ mile buffer is currently identified in Ventura County's existing land use data as being undeveloped open space. The majority of other land use is agricultural (9,012 acres or 58%), residential (2,388 acres or 15%), and government/public/utilities (2,206 acres or 14%). One option is to purchase land (at market value) from willing property owners in key locations when and if they decided to sell, and then return that land to a reasonably undeveloped state.

Most Significant Issues

- Land Management can contribute to flood or sediment solutions if a significant amount of land previously excluded from the floodplain can be returned to the floodplain.
- Farmers have voiced concerns that recreational use of lands adjacent to farming operations may put recreational users at risk of contact with pesticides or other hazardous chemicals.
- Limited existing open-space undeveloped land exists within the ¼-mile buffer along the main creeks.
- Land availability and cost.
- Regulatory- or policy-based mechanisms that set aside or restrict land use within the established floodplain.

Alternative Approach 2 – Watershed Best Management Practices (BMPs)

This approach would emphasize localized Best Management Practices (BMPs) designed to reduce the volume of stormwater runoff leaving a site, such as a residential or a commercial lot. Ideally, stormwater runoff would be reduced to pre-development levels. Examples of BMPs include rain barrels and surface or underground storage tanks to capture roof runoff; pervious pavements in parking lots

and driveways, landscaping with native plants and other low impact development solutions.

Three possible implementation options are being considered:

1. **Require BMPs in Newly Developed Land –** this would maintain post-development flow rates and volumes at pre-development levels. This strategy has been carried forward for analysis and costing of combined alternative approaches.
2. **Require BMPs in All Newly Developed Land, and to Permitted Improvements –** this would reduce post-development flows to rates and volumes below pre-development levels.
3. **Retrofit BMPs to a Percentage of Existing Land –** this would have the same effect as strategy number 2.

Most Significant Issues

- Long-term effectiveness of watershed BMPs depends greatly upon proper ongoing maintenance.
- The Ventura County draft NPDES permit already incorporates a requirement that future development not increase runoff peaks or volume beyond the undeveloped flow levels for a 2-year return period event.
- Reducing peak flows beyond existing is possible with watershed BMPs, but requires retrofitting BMPs to existing developed land, or a building permit-based system.

Opportunities May Include:

1. Reduced pollutant loading, sedimentation, and erosion of natural water bodies.
2. Enhanced groundwater recharge through infiltration BMPs.
3. Promotion of storm water reuse and decrease in potable water demands.
4. Good potential for multi-use benefits (parks, trails, habitat & wetlands).

Challenges May Include:

1. A Public outreach program would be required for cistern/rain barrel programs for irrigation reuse.
2. Wide-scale implementation needed before significant benefits would be achieved (may take many years – particularly in developed areas).
3. Operation and maintenance requirements typically increase with such solutions, and long-term efficacy depends on proper regular maintenance.
4. Infiltration may not be practical for some areas due to low-permeability soil types.

Alternative Approach 3 – Regional Basins

The Regional Basin approach utilizes larger detention basins at strategic locations to capture and delay storm flow peaks in the main creek channels. Basins are considered *regional* if they are located on one of the main creek channels, or if they

receive flows from multiple significant tributaries. The basins may serve as infiltration basins, but their main purpose is to reduce downstream peak flood flows.

This approach would use regional detention basins on Arroyo Simi, Arroyo Las Posas, Calleguas Creek, at the Conejo Creek confluence with Calleguas Creek, and on Revolon Slough. Risk of flooding would be reduced from Highway 118 to the PCH along Arroyo Simi, Arroyo Las Posas, and Calleguas Creek, and would benefit the Cities of Moorpark and Camarillo, and also agricultural land along lower Calleguas Creek. Projects within creek channels would be minimized with this option.

Stakeholders ranked Regional Basins third out of the five presented approaches. It will be possible to avoid a significant amount of channel improvements downstream of the basins with their implementation.

Most Significant Issues

- Siting and acquisition of land may be a long process.
- Regional basins have a significant effect in reducing the downstream peak flows of large flows.

Opportunities May Include:

1. Significantly reduced need for channel improvements.
2. Removal of some residential and agricultural land from existing floodplain.
3. Potential for multi-use benefits in basin lands (parks, trails, habitat).
4. Reduced channel sedimentation and erosion through reduced flows.
5. Enhanced groundwater recharge.

Challenges May Include:

1. Land acquisition for basin locations (depending on basin size and siting).
2. Environmental permit restrictions.
3. Basins will not provide complete solution – some channel improvements will be required.

Alternative Approach 4 – Protection Level

This approach applies to Calleguas Creek and Revolon slough downstream of Pleasant Valley Road, and is based on channel design objectives: what flows can be contained within the channels. Land within the floodplains would continue to flood, and flood reduction via channel modifications or upstream actions would be undertaken only to restore the channel conveyance design objectives when needed. For example, if a channel was designed to convey 30,000 cfs but sedimentation has reduced the channel's capacity to 20,000 cfs, dredging or other channel modifications would be undertaken to restore the 30,000 cfs capacity of the channel.

Stakeholders ranked Protection Level as fourth out of five presented approaches. This is essentially a "do nothing" approach below Pleasant Valley Road, although a flooding inundation compensation mechanism could be implemented. Other

approaches applied upstream of Pleasant Valley Road would be responsible for reducing peak flows and minimizing the flood potential.

Most Significant Issues

- Channel Improvements were ranked as the second-least desirable approach by stakeholders
- Agricultural land would remain in the 100-year floodplain.
- Agricultural land owners stated that the Protection Level approach was unacceptable if flooding at or below the 100-year level was still possible.
- Some agricultural land owners favor Q_{100} flood protection in lower Calleguas Creek, while others do not want the agricultural land removed from the floodplain because of anticipated development pressure.

Opportunities May Include:

1. Reduced flooding potential in certain areas; accepted and/or compensated flood risk in others.
2. Reduced capital cost of the final selected combined scenario.
3. Creeks remain connected with floodplain in larger flows.
4. Greater opportunity for multi-use benefits.
5. Reduced development opportunity.

Challenges May Include:

1. Flooding risk will continue to exist in agricultural lands.
2. Upper creek reaches still require the application of other approaches to reduce or manage flows.
3. Reduced development opportunity.

Alternative Approach 5 – Channel Improvements

Channel Improvements refer to in-channel projects necessary to provide flood protection and adequate sediment management within the creek channels. Projects typically include widening of channels, raising of levees, removal of sediment, altering the channel grade (slope), adding/repairing bank protection, and constructing or modifying channel grade control and drop structures.

This approach emphasizes primarily channel-based solutions to flooding and sediment issues. The objective is to contain (and to balance the sediment transport for) the 100-year flow on Calleguas Creek (and Arroyo Las Posas and a portion of Arroyo Simi), Revolon Slough and Conejo Creek. Through adjusted channel geometry, slope, and grade control structures, this approach seeks to transport as much sediment as possible to sediment basins to be constructed upstream of Highway 101.

Stakeholders ranked Channel Improvements as the least-preferred of the five presented approaches. It will not be possible to avoid all channel improvements in the final selected combined scenario of approaches, but it will be possible to

minimize the number and extent of these projects with the right mix of other approaches (such as Regional Basins and Watershed BMPs).

Most Significant Issues

- Channel Improvements were ranked as the lowest desirable approach by the stakeholders
- Some channel improvements (both flood and sediment related) will be required regardless of the final combination of approaches selected.

Opportunities May Include:

1. Proposed solutions for all critical main creek systems (Calleguas Creek, Conejo Creek, Revolon Slough).
2. Q_{100} flood protection.

Challenges May Include:

1. Uncertainty of sediment regime within (and through) Mugu Lagoon.
2. Reduced opportunities for multi-use benefits.
3. Extensive in-stream construction required.

Scenarios Being Evaluated

Each of these five approaches is being combined based on stakeholder input for the various reaches within the Calleguas Creek Watershed. One scenario is to combine all five approaches in priority order as discussed below.

Combined Scenario 1 - Regional Basins Plus Channel Improvements

This scenario combines the following Alternative Approaches:

- Land Management*
- Watershed BMPs*
- Regional Basins
- Channel Improvement

** Land Management and Watershed BMP approaches are common to all four Combined Scenarios.*

Combined Scenario 1 utilizes four of the five Alternative Approaches. Land Management will maximize the amount of land that remains in, or is added to, the floodplain over time. The Watershed BMPs will ensure that future flow peaks and volumes do not increase over current flows. The regional detention basins significantly reduce the Q_{100} peak flows in Calleguas Creek and Revolon Slough. Channel improvements will still be required, but significantly fewer will be needed than if regional basins were not implemented. This is because channel capacities have been diminished by sediment deposition over time in Calleguas Creek, and because of ongoing erosion issues in various reaches. Also there are no identified basin locations that would address flows in Conejo Creek or Beardsley Wash.

Regional Basins do not. Therefore, significantly reduce the channel improvements required in these two creeks.

This scenario provides the most significant opportunity to incorporate the multi-benefit opportunities for environmental restoration, recreation, groundwater recharge, water quality and sediment management. Many of the basins could be designed to provide these additional opportunities and trails and other recreational opportunities would be incorporated with the channel improvements where appropriate.

This scenario most closely approaches the priorities voiced by the majority of the stakeholders to date.

Most Significant Issues

- The scenario provides Q_{100} protection to the project study area.
- Significant opportunities for multi-benefit projects are available with this scenario.
- Flood-related channel improvements will be minimized.

Combined Scenario 2 - Regional Basins with Protection Level

This scenario combines the following Alternative Approaches:

- Land Management*
- Watershed BMPs*
- Regional Basins
- Protection Level
- Channel Improvement

** Land Management and Watershed BMP approaches are common to all four Combined Scenarios.*

Combined Scenario 2 applies to all five Alternative Approaches – adding Protection Level to Combined Scenario 1. Land Management will maximize the amount of land that remains in, or is added to, the floodplain over time. The Watershed BMPs will ensure that future flow peaks and volumes do not increase over current flows. The regional detention basins significantly reduce the Q_{100} peak flows in Calleguas Creek and Revolon Slough. Protection Level reduces the required channel improvements below Pleasant Valley Road, and also potentially adds cost implications related to compensation for flooded land were Q_{100} flood protection is not provided.

As in Combined Scenario 1, the Regional Basins significantly reduce the number and extent of channel improvement projects that will be needed. Channel improvements cannot be eliminated because channel capacities have been diminished by sediment deposition over time in Calleguas Creek, and because of ongoing erosion issues in various reaches. Also there are no identified basin locations that would address flows in Conejo Creek or Beardsley Wash. Regional Basins do not therefore significantly reduce the channel improvements required in these two creeks. Many of the same channel improvements noted for Combined Scenario 1 will be required, but a less-than Q_{100} flood protection level would be maintained below Pleasant Valley Road in

Calleguas Creek and Revelon Slough. Flood control projects would be eliminated or reduced (depending on the determined required flood protection level) in this area.

This scenario provides the most significant opportunity to incorporate the multi-benefit opportunities for environmental restoration, recreation, groundwater recharge, water quality and sediment management. Many of the basins could be designed to provide these additional opportunities and trails and other recreational opportunities would be incorporated with the channel improvements where appropriate.

Most Significant Issues

- The scenario provides Q_{100} protection to the project study area, with the exception of the floodplain along Revolon Slough and Calleguas Creek below Pleasant Valley Road.
- The required level of protection (Q_{100} or less) below Pleasant Valley Road has yet to be determined.
- A mechanism for compensation of landowners subject to flooding requires discussion.
- Flood-related channel improvements will be minimized.

Combined Scenario 3 – Channel Improvement Emphasis

This scenario combines the following Alternative Approaches:

- Land Management*
- Watershed BMPs*
- Channel Improvement

* Land Management and Watershed BMP approaches are common to all four Combined Scenarios.

Combined Scenario 3 applies three of the five Alternative Approaches emphasizing channel improvements. Land Management will maximize the amount of land that remains in, or is added to, the floodplain over time. The Watershed BMPs will ensure that future flow peaks and volumes do not increase over current flows. Substantial channel improvements are required to convey the existing Q_{100} flows in all of the main creeks.

Opportunities for multi-benefit improvements are limited with this Scenario. Environmental restoration and recreation opportunities could be provided with the channel improvements. However, there are limited opportunities for groundwater recharge and water quality enhancement with this scenario.

Most Significant Issues

- The scenario provides Q_{100} protection to the project study area.
- The amount of in stream channel construction is maximized with this scenario.
- Opportunities for multi-benefit improvements are limited.
- The emphasis of this Combined Scenario is the least favored approach as determined by stakeholders.

Combined Scenario 4 - Channel Improvements with Protection Level

This scenario combines the following Alternative Approaches:

- Land Management*
- Watershed BMPs*
- Protection Level
- Channel Improvement

** Land Management and Watershed BMP approaches are common to all four Combined Scenarios.*

Combined Scenario 4 applies three of the five Alternative Approaches emphasizing channel improvements, and adding Protection Level to Combined Scenario 3. Land Management will maximize the amount of land that remains in, or is added to, the floodplain over time. The Watershed BMPs will ensure that future flow peaks and volumes do not increase over current flows. Protection Level reduces the amount of required channel improvements below Pleasant Valley Road. Substantial channel improvements are required to convey the existing Q_{100} flows in all of the main creeks. Many of the same channel improvements noted for Combined Scenario 3 will be required, but a less-than Q_{100} flood protection level would be maintained below Pleasant Valley Road in Calleguas Creek and Revelon Slough. Flood control projects would be eliminated or reduced (depending on the determined required flood protection level) in this area.

Opportunities for multi-benefit improvements are limited with this Scenario. Environmental restoration and recreation opportunities could be provided with the channel improvements. However, there are limited opportunities for groundwater recharge and water quality enhancement with this scenario.

Most Significant Issues

- The scenario provides Q_{100} protection to the project study area, with the exception of the floodplain along Revolon Slough and Calleguas Creek below Pleasant Valley Road.
- The required level of protection (Q_{100} or less) below Pleasant Valley Road has yet to be determined.
- Opportunities for multi-benefit improvements are limited.
- The extent of in stream channel construction is the second highest of the four scenarios.
- The Protection Level and Channel Improvement approaches ranked as the least favored by stakeholders

Conclusion

The stakeholder driven process is being used to select a long-term management strategy for the Calleguas Creek Watershed. A combination of the above approaches and scenarios will be selected through the continuation of the stakeholder driven process as the study is completed this year.

McCormick Place West Hall Conference Center Stormwater Reclamation Tunnel and "Green Roof" helps advance Chicago's Clean Water Agenda

W. J. Weaver, PE, D.WRE

[1]AECOM, 750 Corporate Woods Parkway, Vernon Hills, Il, 60061; PH (847) 279-2494; FAX (847) 279-2510; email: bill.weaver@aecom.com

Abstract: The McCormick Place Convention Center in Chicago has undergone a dramatic expansion to remain one of the premier convention venues in this country. The new West Hall designers recognized early on that the City combined sewer system was beyond capacity resulting in periodic flooding and overflow to the Chicago River. The Metropolitan Pier and Exposition Authority (MPEA) initially considered traditional stormwater management alternatives including onsite detention and new gravity sewers to manage runoff from 70 acres of convention center rooftop.

MPEA decided to pursue a "green" approach to stormwater management to complement other environmentally sensitive design features employed at this project. AECOM devised a stormwater conveyance system that would carry clean rain water from the convention center roof to Lake Michigan thereby diverting as much as 55 million gallons of stormwater from the City's combined sewer system each year.

INTRODUCTION AND BACKGROUND

Chicago's McCormick Place Convention Center receives as many as 3 million visitors annually. Convention Center stormwater runoff from nearly 100 acres of rooftops has historically discharged to a combined sewer system. The recent Conference Center expansion for the West Hall employs an innovative stormwater management system that utilizes a "green" approach, and complements a new $1,200,000 3.5-acre green roof and garden at the recently completed West-Hall project.

The project investigated a number of options including detention storage, a traditional cut and cover or shallow tunnel sewer to Lake Michigan, and a rock tunnel to Lake Michigan. The rock tunnel option was considered most feasible. The new stormwater system manages 55 million gallons of runoff each year from 70 acres of the new West Hall and from a portion of the existing North and South Halls. This stormwater is diverted from the City of Chicago combined sewer system, and reduces combined sewer overflows to the Chicago River and Lake Michigan. The new system also reduces the potential for local flooding that has plagued this area in recent years.

The direct discharge of stormwater to Lake Michigan is normally prohibited by regulations in an effort to protect the Lake from pollutants. This policy is targeted to protect Lake water that is the primary drinking water source for the City. In this case, the policy results in rooftop runoff being treated in the City's wastewater treatment system. Rooftop stormwater runoff tests at the Convention Center indicate that the runoff exceeds Lake Michigan water quality standards. This fact and the sustainable design aspects of the proposed stormwater tunnel helped convince the regulatory authorities to allow the diversion of this runoff to Lake Michigan.

AECOM and Atkinson Construction of Broomfield, Colorado formed a design build team that completed constructed of the tunnel system during 2007. The system includes a 3,350 - foot long 12.5 - foot diameter rock tunnel constructed in bedrock approximately 160 feet below ground. The tunnel begins at the West convention center building, extends under Burnham harbor, and terminates at the south end of Northerly Island where an outlet shaft allows water to rise to Lake Michigan. First flush runoff is directed away from the tunnel to the local sewer system. Figure 1 is an aerial photograph of the site.

Figure 1. Location Map

The tunnel project fulfills the project design criteria goal to implement a design solution that supports the City of Chicago Clean Water Agenda and realizes a sustainable design approach.

PROPOSED STORMWATER RECLAMATION TUNNEL

Tunnel Structures

The proposed stormwater reclamation tunnel is a 3,350 foot long 12.5 – foot diameter unlined rock tunnel formed with a tunnel boring machine. The tunnel is 160 feet below the ground surface founded in rock and has a capacity of 500 cfs. Geological studies proved that the tunnel could be constructed without a lining; however, the stability of the tunnel roof needed rock bolts extending six feet into the rock at a horizontal spacing of about six feet and a longitudinal spacing of five feet. Figure 2 is a picture of the completed tunnel. The tunnel boring machine (tbm) cutter head is shown on Figure 3, and the installation of tunnel rock bolts is shown on Figure 4.

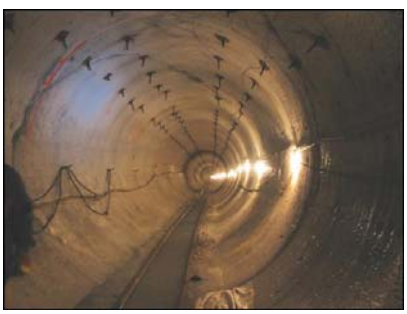

Figure 2:
Tunnel

Figure 3:
TBM cutter head

Figure 4
Rock bolt installation

The unlined tunnel resulted in significant cost savings, and promotes the infiltration of clean stormwater into the water table through rock fractures.

Stormwater from the convention center West Hall roof enters the tunnel through a 7 – foot diameter shaft. The drop shaft was constructed after the horizontal tunnel was completed. The roof downspouts are tied into the down shaft that is shown on Figure 5. The shaft is lined with concrete since it passes through 85 feet of overburden soils before hitting the rock strata that the tunnel is founded in. The tunnel has the capacity to also handle runoff from the North and South Hall roof tops. A separate drop shaft will be constructed in the future to convey runoff from this hall to the lake.

Figure 5:
West Hall Drop Shaft
Lined with Concrete

The nearly two thirds of a mile long tunnel was originally conceived to terminate on the east side of the Convention Center East Hall. AECOM recommended that the tunnel be extended nearly 600 feet under Burnham Harbor to Northerly Island to accomplish the following:

- A tunnel outfall on the east side of the east hall would require the shutdown of the lakefront trail for more than a year. This trail is an important link in the park trail system and alternative pathways would be difficult to create.
- The original outfall location would require the trucking of 20,000 cubic yards of tunnel rock spoil through the streets of Chicago. A Northerly Island outfall location allows for the beneficial reuse of the tunnel rock for the construction of landscape berms and topographic relief on the otherwise flat peninsula.
- The Northerly Island outfall location provides significant construction equipment lay down space when compared to a very restricted space on the west side of Burnham Harbor. The island also provides available nearby office space and electrical hookups for the construction team.
- The outfall location is oriented away from the harbor mouth thereby reducing any possibility of flow currents that could impact harbor operations.

As a result of the above issues, the overall cost of extending the tunnel length by 18 percent was less than the original plan for a shorter tunnel. Figure nos. 6 and 7 are photographs of the south end of Northerly Island after regrading with tunnel rock and planting of the landscape berms.

Figure 6:
Northerly Island south end after tunnel spoil placement, grading and planting.

Figure 7:
Northerly Island south end after tunnel spoil placement, grading and planting.

Tunnel Up Shaft at East End

A 22 – foot diameter vertical shaft was constructed on the east end of the tunnel to connect to the outfall surge chamber located on the south end of Northerly Island. The shaft carries stormwater from the tunnel located 160 – feet below ground back to the surface near Lake Michigan. The shaft was constructed with a reinforced concrete lining to hold back the overburden and fill soils at Northerly Island. Figure

8 shows the tunnel shaft during construction. The tunnel had not yet advanced to the level of 160 feet below grade, and the temporary liner system was still in place.

AECOM developed a grouting program for the rock exit shaft at Northerly Island that included secondary and tertiary stages to resolve leakage and solidify the limestone at the rock/tunnel interface. Groundwater pump tests were used to evaluate the effectiveness of the grouting program. This program allowed for the exit shaft to be constructed with the outside tunnel lining diameter the same dimension as the drill and shoot diameter. Thus, no over-excavation was needed to create rock shelves to accommodate the tunnel lining. This approach significantly minimized the construction cost and accelerated the schedule.

Figure 8: Outlet Shaft

The liability risk associated with the design of the 150-foot-high exit shaft support structures was placed with a specialized construction contractor who was responsible for this construction element. This approach is important since the prime design engineering team is not in a position to direct the transient structural nuances that can occur in the field for this type of construction. This portion of the construction was the most risk intense part of the design effort due to complex conditions and forces that occur during the transient construction progression. Therefore, the risk best resides with the firm responsible for this construction element. As it turned out, any issues that occurred with the shaft perimeter structures during construction that could have resulted in significant settlement of the outfall structure were addressed in real time. The specialty contractor had the appropriate contractual incentives to address these issues in a timely fashion.

Outfall Surge Chamber at Lake Michigan

The tunnel outfall at Lake Michigan includes a 500,000 gallon surge chamber that has a 3,500 square foot footprint located at the south end of Northerly Island. The outfall was located such that the discharge would be directed away from the Burnham Harbor mouth and has the following features:

- Seven 6 – foot diameter outfall orifices between the surge chamber and Lake Michigan. The reinforced concrete wall between the chamber and Lake Michigan is designed to create separation between the tunnel water and Lake Michigan storm surge. Each orifice is outfitted with a steel thimble and sleeve and backflow prevention Tideflex Check Valve by Red Valve; reportedly the largest such application on Lake Michigan. These valves held back Lake Michigan and wave action, with small leakage amounts during construction, and with a still water Lake level that was 13 feet higher than the outfall surge chamber bottom.

- A stop log notch was constructed between the outfall valve structures and the Lake to provide dewatering capability for times when the valve structures need maintenance or replacement.
- The valve structures were placed below the level of anticipated ice action to minimize the potential for ice blockage (Assel, 2004).
- A safety relief is built into the system in the unlikely case where the outfall valves become blocked. A grated opening on top of the surge chamber would allow for the release of tunnel flows on top of the structure. The top of the structure is configured to convey such emergency flows to the lake over ground surfaces that are reinforced with rock filled gabion mattresses and large armor stones. Figure 9 illustrates this structure before final grading and landscaping.
- The existing timber crib seawall was buttressed for a length of 90 feet and an armor stone protection designed to withstand the stress of tunnel flows from upstream and wave attack from downstream was placed at the outfall. The armor stones vary in weight from 1 to 3.3 tons.

Figure 9: Outfall Structure

Figure 10 illustrates a schematic profile of the tunnel outfall works. Figure 11 is a photograph of the outfall chamber and works under construction. Figure 12 is a photograph of the stop log structure downstream of the backflow prevention valves. The stop log support structures are mounted on the inside of a wall that serves as a flow and ice baffle. This wall extends down below the low level of Lake Michigan. The water level in the surge outfall chamber is approximately 13 – feet below the level of Lake Michigan in Figure12. The East Hall of the convention center can be seen in the background.

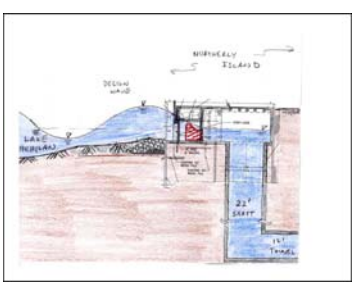

Figure 10:
Tunnel Profile Schematic

Figure 11:
Outfall Chamber

Figure 12:
Outfall Stop Log Structure

The finished outfall structure provides a lake overlook with access to the edge of the lake. This structure serves as a fishing platform and has seating walls that double as flow training works during emergency overflow or extreme wave attack conditions.

TUNNEL HYDRAULIC DESIGN

There is a 5.5 – foot drop between ground surface elevations at street level at the convention center, and the 10 – year Lake Michigan water level at the tunnel outfall. Therefore, the tunnel has to deliver a capacity of 500 cfs with 5.54 – feet of head over a tunnel distance of 3,350 feet. The design condition for the tunnel included a boundary condition that manages the combined occurrence of the following events:

- 10 – year recurrence interval Lake Michigan level (USACE, 1993).
- 100-year recurrence interval rain storm. (Huff, 1989)
- 20 – year recurrence interval Lake Michigan wave event (Hubertz, 1991).

The combined event recurrence interval for a 10 – year Lake level and a 20 – year wave event is approximately a 100 – year event (USACE, 1998). The combined event recurrence interval of the wave, lake, and rain events is estimated to be significantly in excess of a 500 – year event. Therefore, the system is designed to manage an extreme event with a significant factor of safety built in. All parties were in agreement that this design condition was reasonable given the importance of this structure.

The design runoff event for the tunnel included the following parameters:

- Drainage area equals 70 acres of rooftop.
- Rational method runoff coefficient was estimated to be 0.98 (ASCE 1992).
- 100 – year rainfall intensity for a time of concentration is 8.2 inches per hour (Huff, 1989).
- Significant tunnel system headlosses (King & Brater, 1976):
    - Bend losses at bottom of drop shafts and at bottom and top of up shaft.
    - Friction losses in unlined tunnel with Manning's roughness coefficient of 0.0165 (Pennington, 1998), and concrete lined shafts.
    - Assumed restrictions for poor rock areas that could not be determined before construction; assume a 2.5 – foot diameter tunnel reduction for a length of 100 feet of tunnel.
    - Expansion and contraction losses at blasted portion of tunnel at east end and elsewhere.
    - Backflow prevention valve losses of 0.3 – feet.
    - System exit losses.

Figure 13 is a photograph of the unlined tunnel wall and is illustrative of the tunnel roughness characteristics.

Figure 13: Unlined Tunnel

LAKE MICHIGAN STORM SURGE EVALUATION

Lake Michigan wave attack can influence the system in a number of ways. The outfall structure walls had to be designed to address static loads and internal hydraulic loads as well as wave attack loads. Furthermore, wave stresses can influence lake bed erosion potential at the outfall structure as well as stresses produced by tunnel flow conditions. Finally, wave crest attack will shut down the backflow prevention valves on the tunnel system for a portion of the time between wave crests.

A wave climate evaluation was performed to identify the characteristics and loads associated with incident wave conditions attacking from a three directions considered to be reflective of the range of wave conditions that occur at the site. A wave analysis was performed to estimate the wave heights that can attack the outfall structure after transformation from the deepwater environment considering the following effects: refraction, diffraction, shoaling, reflection and surf zone influences that evaluate the largest wave that can be supported in the near shore zone (Goda, 2000). The 5-, 10-, and 20- year wave heights that are incident to the outfall structure are 12.4 feet, 13.0 feet, and 13.6 feet respectively.

The armor stone placed on the lake bed at the outfall is sized to withstand wave attack as well as tunnel discharge currents. This stone has a weight of 1 to 3.3 tons.

LAKE MICHIGAN STORM SURGE EVALUATION

Waves that attack the outfall structure will shut down the backflow prevention valves for a portion of the approximately 8 to 12 seconds that it takes for each wave to pass (Resio and Vincent, 1976). The outfall discharge would effectively drop to zero until the wave trough begins to arrive. During the wave trough, the tunnel tailwater condition would significantly increase and the tunnel discharge would exceed the target design flows. This phenomenon of the push and pull of wave conditions at the outfall would set up a hydraulic transient.

The outfall structure is designed to harness wave action energy to help evacuate water from the tunnel outfall and to manage Lake Michigan storm surge. The seven 6-foot diameter backflow prevention valves are designed to control storm surge from Lake Michigan wave action. This is an important design item since an uncontrolled surge could cause upstream flooding. AECOM performed a hydraulic transient analysis using numerical analysis and the “Hammer” computer program (Bentley, 2005) to optimize the design of the valves and to size the outfall structure. The transient condition can be summarized as follows:

- When the crest of a wave attacks the outfall structure, the valves close automatically due to the wave crest pressure. The outfall structure is designed as a surge chamber with a capacity of 500,000 gallons and continues to accept tunnel flows into storage during periods of valve closure.

- When the wave trough arrives at the outfall structure, the water surface of the Lake drops at the valves which then open automatically. During this period, the available head across the valves allows for a greater outfall chamber discharge than the design flow rate delivered by the tunnel. The system balances the dynamics of wave action to optimize system capacity.
- As summarized by the Hammer fluid transient analysis graphs shown on Figure 14, there is a tendency for the design head in the surge chamber to drop during wave attack due to the fact that the amount of increased discharge during wave trough conditions more than makes up for the lost capacity during wave crest attack. The reality is that wave conditions in nature are anything but uniform; therefore, the analysis conclusions are assumed to indicate that the structure should perform well during the design event. No additional capacity was assumed due to the fluid transient analysis results above conditions associated with the steady flow condition.

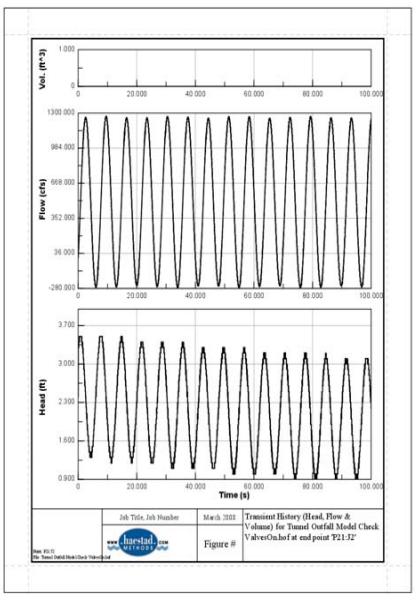

Figure 14: Hammer Analysis

- If for some reason an unusual wave condition were to occur, a safety provision is built into the outfall structure whereby flows can bypass to Lake Michigan through a large diameter grate on top of the structure.

SUMMARY AND CONCLUSIONS

The new McCormick Place convention center stormwater tunnel complements the sustainable design characteristics inherent in the new West Hall designed by Epstein. The building is LEED certified and includes the largest collection of green roof systems in the City of Chicago.

The new stormwater management system manages 55 million gallons of runoff each year from 70 acres of the new West Hall and from South and North Halls. This stormwater is diverted from the City of Chicago combined sewer system, and reduces combined sewer overflows to the Chicago River and Lake Michigan. The rock tunnel is unlined thereby enhancing groundwater infiltration.

The extension of the tunnel outfall under Burnham Harbor to Northerly Island provided tunnel rock fill that was beneficially reused for fill to create landscape berms, topographic relief, and landscaping for the southern Northerly Island edge. The ability to reuse the tunnel fill on the island eliminated the need to truck this material thereby reducing pollution, fuel consumption, and traffic. Relocation of the outfall to Northerly Island also eliminated interruptions of a critical lakefront trail during construction.

ABSTRACT

Sediment samples were collected from fifteen different locations along Athabasca River in an attempt to quantify the sediment contribution to oxygen demand. SOD rates along Athabasca River ranged from 0.09 $g/m^2 \cdot d$ to 0.71 $g/m^2 \bullet d$ near ambient temperature ($<4^0C$). SOD rates generally increased downstream, however, inter-site differences were also influenced by the physical and chemical properties of the sediment. SOD rates were also higher below wastewater discharges and tributary confluences. Variation in SOD rates along the river system were positively correlated with water column concentration of TOC, TDP, Cholorphyll-α. Sediment characteristics such as grain size was a fundamental factor in determining SOD rates. Fine grained sediment in depositional areas tended to have higher SOD. The result also highlighted the importance of inclusion of sediment diagenesis and biochemical reactions inside sediment in water quality models that seek to represent water chemistry and particularly carbon, nitrogen, phosphorus and dissolved oxygen. Results from the Athabasca River suggest that SOD rates are a primary forcing function in large high order rivers that should be determined from the complex physical and chemical factors that control it rather than from water column nutrients.

Keywords River sediment, dissolved oxygen, sediment oxygen demand, water column pollutants

1. INTRODUCTION

Acute depletion in dissolved oxygen (DO) concentration in Athabasca River was observed during record low water flow years of 2002 and 2003 (Chambers et al. 2006; NREI 2004). A one-dimensional stochastic DO model and some two dimensional water quality models were unable to predict the DO level during low flow years (Tian 2005). These models were used to calculate allowable effluent loads from five pulp mills and municipal sewage treatment plants located along the bank of the river. The high concentration of organic matter and nutrients discharged from the mills are a part of water column load that consumes DO in the river to levels that may impact aquatic life. Although improved effluent treatment processes adopted by pulp mills has led to substantial reduction in biochemical oxygen demand (BOD) load. However, nutrient load has remained unchanged or increased (NREI 2004) in part due to activated sludge treatment processes used to reduce BOD. We hypothesized

that this nutrient load may increase sediment oxygen demand (SOD) potentially offsetting the benefits of the reduction in BOD.

Significant SOD rates at different locations, even during ice-cover, were found in previous studies on the Athabasca River (Noton 1996; Moneco 1993; Casey 1990). SOD rates were compared at a site using three techniques: closed chamber, core incubation and use of microsensor; and the closed chamber method used in previous studies was shown to be unreliable (Tian 2005). Yu (2006) developed the core and microsensor method further and investigated the impact of organic carbon and nutrient load on SOD rates. The author concluded that SOD was stimulated by availability of labial carbon. Given this background, water quality management in northern Alberta Rivers required further development of processes and concepts captured in existing models to conclude a better understanding of the factors that control spatial variability and the role of nutrient loads on SOD rates.

This paper summarizes on-going research on the relationship between water column physical-chemical characteristics and SOD rates. Specifically, it examines the relationship between organic carbon, nutrients and SOD rates within the context of spatial variability along the Athabasca River. This research is a component for developing a process-based SOD model for sediment diagenesis in large sand-silt rivers.

2. MATERIALS AND METHODS

The Athabasca River originates from the Rocky Mountains of Alberta and flows in a northeast direction through the province, past the urban centers of Jasper, Hinton, Whitecourt, Athabasca and Fort McMurray prior to emptying into Lake Athabasca. The drainage area of the Athabasca River basin is about 155, 000 square kilometer and contains five pulp mills: Hinton Pulp at Hinton, Alberta News Print Co. (ANC) at Whitecourt, Millar Western Forest Products at Whitecourt, Slave Lake Pulp at Slave Lake, and Alberta Pacific Forest Industries (ALPAC) at the town of Athabasca. The Athabasca River receives discharges from these pulp mills as well as from municipal waste treatment plants situated along its bank. Major tributaries, namely: Berland River, McLeod River, Freeman River, Pembina River, Lesser Slave River, La Biche River and Calling River, drain into Athabasca River above Grand Rapids. Grand Rapids provides substantial reaeration (due to natural cascades) even during winter such that low DO is not an issue below the Rapids.

For this study, fifteen sites along the Athabasca River were selected for sediment and water sampling upstream of Grand Rapids. Fig. 1 depicts the Athabasca River basin that includes tributaries and sampling sites. The sampling sites from upstream (U/S) to downstream (D/S) were: (1) U/S of Hinton Pulp Mill (USHP), (2) Emerson Bridge (EMBG), (3)U/S of Alberta Newsprint Company (UANC), (4) U/S of McLeod River confluence (USML), (5) 2 km D/S of Millar Western Pulp Mill (DSMW), (6)Blue Ridge (BLRG), (7) Fort Assiniboine (FTAS), (8) D/S of Timeau River confluence (DSTR), (9) Chisholm (CHLM), (10) Smith (D/S of Lesser Slave River confluence)

(SMTH), (11) C-Bridge (CBRG), (12) U/S of ALPAC Pulp Mill (USAM), (13) Poacher's Landing (POLG), (14) upstream of Calling River (DSLB), and (15) D/S of Calling River (DSCR). Sediment sampling sites were located upstream and downstream of nutrient sources which either was a tributary or a pulp mill effluent discharge.

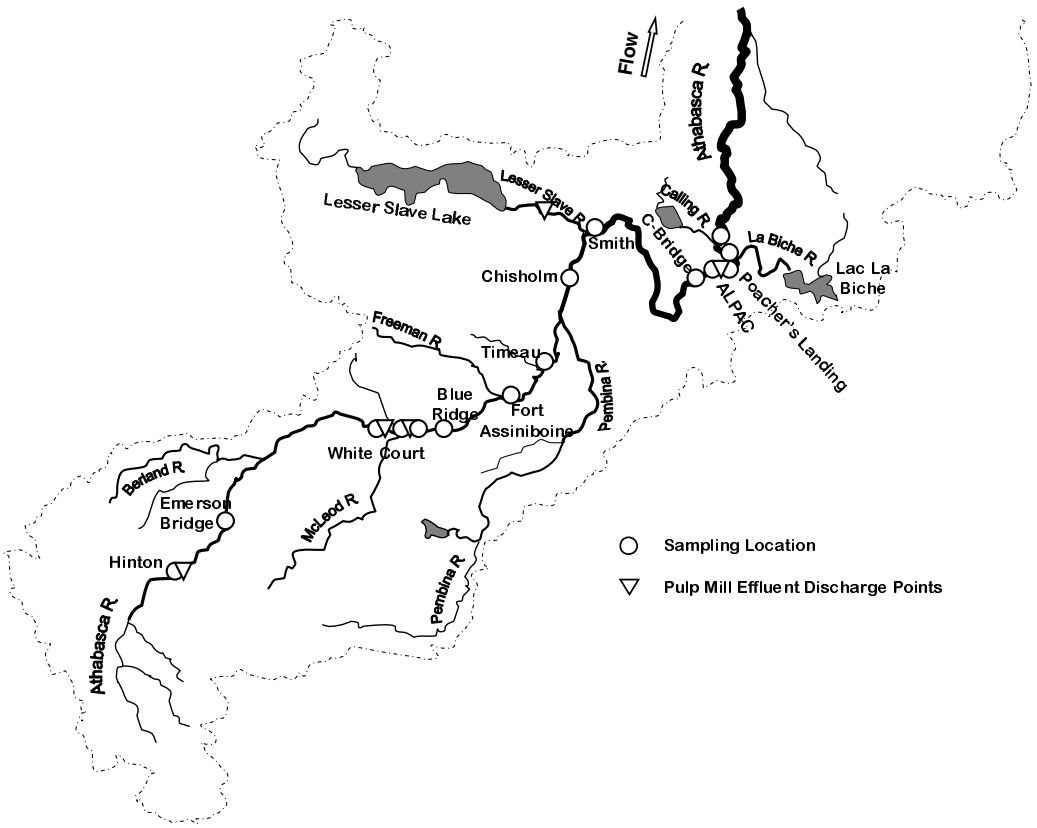

Fig. 1 Athabasca River basin, fifteen sampling sites and five pulp mill locations

Sediment cores and 20 litres of bulk river water were collected at the 15 sites between September 12, 2006 and October 16, 2006 utilizing clear polycarbonate cores to minimize disturbance (Yu 2006). The cores were sealed with no airspace, kept in ice and wrapped with dark plastic, and transported to Environmental Engineering Laboratory at the University of Alberta. SOD rate determinations commenced the following morning within 24 hours of collection. Water in the sediment core was replaced with the bulk river water which had similarly been kept in the dark at near zero condition. A core containing only bulk water served as control, resulting in two sediment cores and one control for each site. The sediment cores and control were equipped with a stirring mechanism consisting of a floating magnetic stir bar inside the core cylinder and an inverted stirrer plate at the top of the corer cylinder. Stirring speed was held constant below the threshold for sediment resuspension. The sediment cores and control were then incubated in the dark for 24 and 48 hours at 4 ± 1^{0}C. Water column DO concentrations at the start and end of the incubation period were measured by Winkler titration (Standard Methods 1998) to determine the decreased

DO concentration in the overlying water column. The replicate SOD rates were averaged for each location.

River water collected immediately after collecting sediment cores was analyzed for water quality parameters, including, total organic carbon (TOC), 5-day carbonaceous biochemical oxygen demand (BOD_5), total suspended solids (TSS), ammonia (NH_4^+), nitrate+nitrite (NO_2^- + NO_3^-), total dissolved phosphorus (TDP), chlorophyll-α (indicator of algal biomass) and iron (Fe), and alkalinity. Total inorganic nitrogen (TIN) was the sum of ammonia and nitrate+nitrite. The DO, temperature, and conductivity were recorded at each site with a polarographic oxygen probe (YSI model 85), while pH was measured in the laboratory by a pH meter.

TOC was analyzed by Shimadzu TOC-5000A carbon analyzer. Phosphorus (TDP) and nitrogen (NH_4^+ and NO_2^-+NO_3^-) were analyzed by colorimetry with Lachat 8500 FIA analyzer following Standard Methods (1998). TDP samples were filtered through pre-washed 0.70 μm Millipore filter. Samples for NH_4^+ and NO_2^-+NO_3^- analysis were treated with sulfuric acid and stored at 4^0C temperature for future analysis to be done within 14 days after sampling (Standard Methods 1998). The iron (Fe) was analyzed by atomic absorption of unfiltered samples. Chlorophyll-α was analyzed by spectroflouoro-photometer. All above parameters were analyzed at the Biogeochemcal Analytical Laboratory of University of Alberta. BOD_5 was determined after 5-days of sample incubation using a polarographic DO meter for DO measurement at Maxxam Analytics Inc., Edmonton.

SOD, or oxygen flux (J_O), is calculated from a linear regression of concentration versus time such that

$$J_0 = m\frac{V_{OLW}}{A_{chamber}} \qquad (1)$$

where $m = \Delta C/\Delta t$ or the slope of the linear regression for change in concentration per unit time, V_{OLW} is the volume of overlying water enclosed within the chamber, and $A_{chamber}$ is the surface area of sediment enclosed by the chamber (Reimer et al. 2001). The surface area of sediment in each core was 25.68 cm^2. The clay/sand composition of the sediment cores made application of a smooth surface area reasonable. With this assumption the SOD (g/m^2•d) was calculated by the following relationship (Murphy and Hicks 1986)

$$SOD = \frac{V_{OLW}}{A_{Chamber}}(O_S - O_W) = h(O_S - O_W) \qquad (2)$$

where, O_s and O_w are the changes in oxygen concentrations in sediment core and control core per unit incubation time (mg/L.h), respectively and h is the height of overlying water (m). For reporting purposes SOD values were transformed to a standard temperature (20^0C) using the following formula:

$$SOD_T = SOD_{20}\theta^{T-20} \quad (3)$$

where, SOD_{20} is the SOD value normalized to 20^0C, SOD_T is the SOD at incubation temperature, T is the incubation temperature in ^{0}C, and θ is the temperature correction coefficient, ranging from 1.04 to 1.13 at temperature range of 2-30^{0}C (Whittemore 1986). The correction coefficient of value 1.04 taken in our study is based on the reduced microbial activity and biochemical reactions at lower temperature (Stefan 1992).

The observed data on water quality parameters and SOD rates represent one point in time and space. Normality tests were conducted for all measured variables using SPSS (2007). The data were also normalized using a weighted normalization method (Bowen 2006, Mazumdar 1996).

$$\text{Normalized value of 'i' variable, } N_i = \frac{Variable_i - Variable_{i_{\min}}}{Variable_{i_{\max}} - Variable_{i_{\min}}} \quad (4)$$

where, $Variable_{imin}$ $Variable_{imax}$ are the minimum and maximum values of variable 'i', respectively.

The normalized data were analyzed by bivariate correlation (Pearson correlation, r) to examine the direction and degree of association among all variables. A principal component analysis (factor analysis) was used to reduce the normalized variables and collinearity in the multivariate analysis. Regression scores generated by SPSS were saved and normalized response variable was regressed against these individual principal components (regression scores). Since the response variable, SOD rate, was also measured as a continuous variable, we used ordinary least square technique to examine the independent effects of each principal components (composite variables) on the response variable. The significance level for these analyses was set at $P<0.05$.

4. RESULTS AND DISCUSSION

4.1 Site Water Column Pollutants

The physical and chemical water quality parameters along Athabasca River varied among the sites (Table 1). The ambient DO ranged from 9.0 mg/L to 11.8 mg/L, the temperature ranged from 3.1 ^{0}C to 11.8 ^{0}C during the field sampling period, pH was stable at 8.1 to 8.2, alkalinity ranged from 93 mg/L to 149 mg/L as $CaCO_3$ and conductivity ranged from 118 μS/cm to 247 μS/cm. In general, total and dissolved constituent concentrations increased moving downstream in the Athabasca River. For example, the lowest and highest concentration of TOC, BOD_5, TDP, Chlorophyll-α, and conductivity were at USHP (upstream site) and at DSCR (downstream site), respectively.

Table 1 Water quality parameters of Athabasca River along its reach

Parameter	USHP	EMBG	UANC	USML	DSMW	BLRG	FTAS	DSTR	CHLM	SMTH	CBRG	USAM	POLG	DSLB	DSCR

< denotes data below detection limit

The spatial variations of concentrations of water quality parameters along Athabasca River are shown in Figure 2. The concentrations of TOC revealed clear impact of pollutant discharges in the river. The TOC at EMBG, downstream of Hinton Pulp mill, was about three-fold higher than upstream of the mill. Similarly, TOC was about one and half-fold higher at downstream of DSMW, below discharge points of ANC and Millar Western pulp mills, than UANC, upstream of pulp mills. Similarly TOC

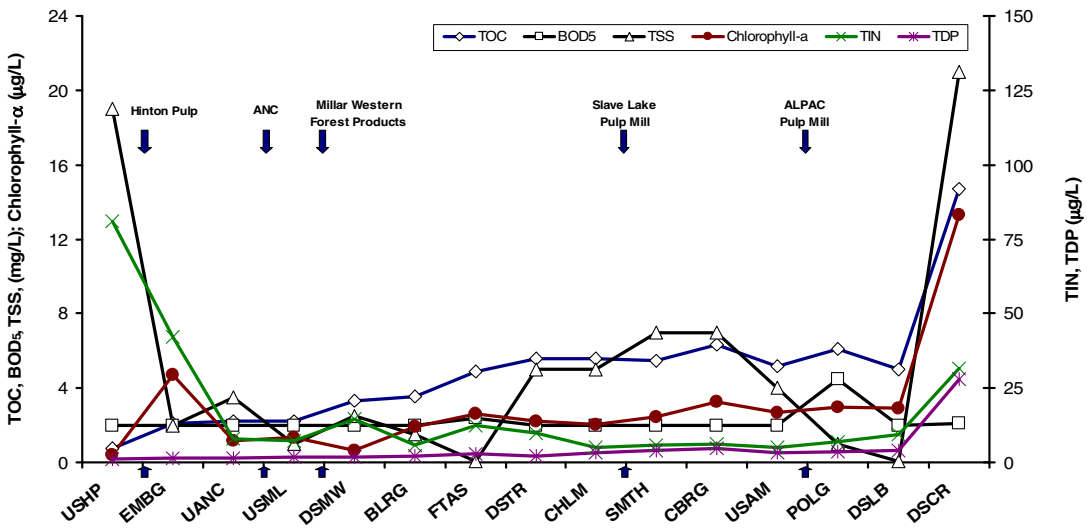

Fig. 2 Spatial variability of water quality parameters along Athabasca River. The arrows represent approximate location of Pulp Mills.

concentration upstream and downstream of the ALPAC pulp mill, at the sites USAM and POLG, was differentiated by a quarter-fold. Tributaries were also large sources of constituent load with clear increases in concentrations of TOC, TDP, and Chlorophyll-α downstream to confluence with Athabasca River. The TOC at FTAS compared to BLRG, indicated organic carbon input from Freeman River to Athabasca

River was considerable. The increase in TOC concentration at CBRG as compared to SMTH was likely due to load from the town of Athabasca wastewater treatment plant, as this is the only large contributor between SMTH and CBRG. The increased TOC concentrations at DSCR were the result of pollutant inputs from La Biche River and Calling River, respectively. The TIN and TSS concentrations were variable but correlated with each other. The TDP and Chlorophyll-α concentrations follow the trend of TOC. The BOD_5 values do not exhibit appreciable variation along the river indicating a relative steady state in oxygen consumption against pollutant load.

4.2 Spatial Variation of SOD Rates along Athabasca River

The spatial variation of SOD rates and TOC concentration are presented in Figure 3 and Table 1. The mean SOD rates determined in this study ranged from 0.09 g/m^2•d at BLRG to 0.71 g/m^2•d at DSCR, when these values are adjusted to SOD rates at 20^0C, the values ranged from 0.17 g/m^2•d to 1.33 g/m^2•d, respectively.

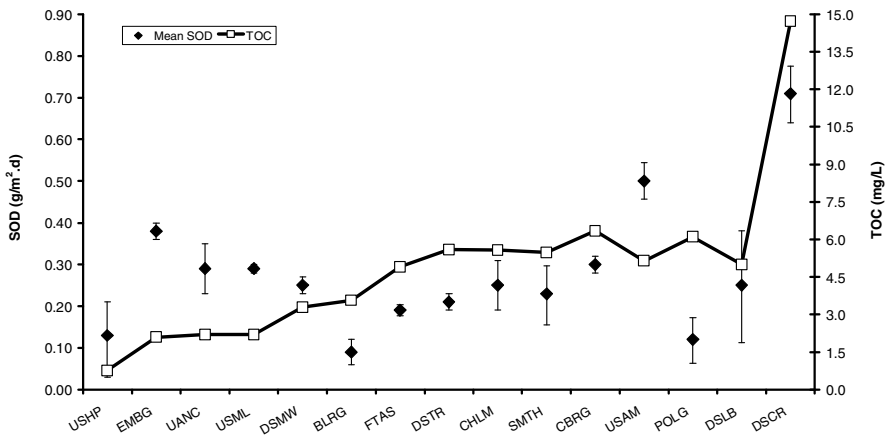

Fig. 3 Spatial variability of SOD rates and TOC concentration along Athabasca River

SOD rates were generally higher at sites downstream of pollutant discharges. The SOD value at EMBG of 0.38 g/m^2•d when compared to the 0.13 g/m^2•d at USHP highlighted the 3-fold effect Hinton Pulp and municipal effluent have on the SOD rates. Similarly, at FTAS, the SOD value of 0.2 g/m^2•d was more than 2-fold higher compared to BLRG of 0.09 g/m^2•d. TOC and SOD rates were positively correlated in the Athabasca River (Figure 3). Other studies have shown that SOD rate is influenced by the availability of organic matter (Doyle and Linch 2005, Yu 2006) and nutrient (Yu 2005). Exceptions were at DSMW and BLRG (Whitecourt area), and POLG (Athabasca) compared to upstream sites. These exceptions were attributed to differences in sediment characteristics. The sediment at USML was fine grained silty, while the sediment at DSMW was course grained silty and sediment at BLRG was sandy. Similarly, the sediment at USAM was fine grained clay/silt, the sediment at POLG was course grained sand/silt. Previous studies indicated that the grain size of sediment influences boundary layer and advective flow at the sediment water interface (SWI) and thus the SOD rate (Grenz et al. 2003).

4.3 Influence of Water Column Pollutants on SOD Rates Along Athabasca River

Historically, the Athabasca River received 5470 kg/day BOD_5, 980 kg/day total nitrogen (TN), and 400 kg/day total phosphorus (TP) load from the effluent discharges of five pulp mills (NREI 2004). In addition to this, 160 kg/day TN and 41 kg/day TP were added by municipal sewage treatment discharges during the period of 1989-1994 (Chambers 2000). Pair-wise correlation revealed strong associations among variables (conductivity, alkalinity, TOC, BOD_5, TSS, TIN, TDP, Chlorophyll–α, and Fe) and the response variable (SOD rate) in normalized dataset pooled for all 15 sites (Table 2). The pH was in very narrow range (8.0 – 8.2) that may not be able to indicate substantial chemical/microbial changes, therefore pH was not included in the correlation. The SOD rate was positively correlated with TOC, TDP and Chlorophyll-α. TOC was negatively correlated with conductivity indicating that groundwater rich water sources were depleted of organic carbon. The BOD_5 and Fe were not correlated with any other variables.

*. Correlation is significant at the 0.05 level (2-tailed).

The factor analysis identified three principal components that explained 81.5 % of the variability in SOD rate (Table 3). Principal component 1 was driven by TOC, TDP, Chlorophyll-α, and (negative) conductivity. Principal component 2 was driven by TSS, TIN and (negative) alkalinity. Principal component 3 was driven by (negative) BOD_5 and Fe.

The ANOVA result from the multivariate analysis indicated that the model best fits the data ($F = 5.86$ adjusted $R^2 = 0.61$; $P<0.012$). SOD rate was only significantly related to principal component 1 ($\beta = 0.175$; $P < 0.01$) in regression analysis (Table 4). The result of pair-wise correlation and linear regression confirmed the dependency of SOD rates on TOC, TDP and Chlorophyll-α. But at the same time, there was no strong relationship between SOD rate and TIN, (nitrogen loading). Ammonium oxidation rates may be low and therefore did not consume appreciable amounts of

DO in water column. Ammonium oxidizing bacteria are slow growing and are severely restricted by low temperature (Metcalf and Eddy 2003). Yu (2006) previously showed that SOD was influenced by organic carbon and nutrients using samples from USAM. In that study increased organic carbon loading caused increased SOD rates. Interestingly BOD_5 was not correlated with TOC or SOD rate. This could be because SOD is created by the microbially mediated degradation of

organic matter (labile or refractory) deposited on river bed over a period of time, whereas BOD_5 is only sensitive to easily biodegradable (labile) organic matter in water column. A negative correlation between SOD rate and conductivity as well as the lack of correlation with Fe suggested SOD rate is primarily determined by

carbonaceous degradation and little influenced by the hypertonic input of reduced metals and other species in ground water.

A comparison of SOD results of this study with those undertaken in the past at different time period highlighted spatial and temporal variation, as shown in Table 5. In most sites, the SOD rates found in this study were higher than previous studies. There were variations in SOD rates in the fall of 2006 and fall of 2004, indicating that SOD rates varied with time period as sediment deposition and composition varied. The temporal variations of SOD rates shown in Table 5 could be attributed to climatic condition, quantity of river flow, and to older data, inaccuracy of the chamber method (Tian 2005; Yu 2006). Results from this study suggested that models for predicting SOD rate must incorporate suites of environmental variables, particularly in river

water ecosystems. It is especially difficult to create simple models to predict SOD rates because oxygen demand both depends on and influences the concentration of many chemical parameters. It is shown that SOD can be measured relatively easily. This study was taken in the context of results by Tian (2005) and Yu (2006) that indicated organic carbon and, to a lesser extent, nitrogen and phosphorus influence SOD rates. However, more work is needed on modeling where SOD determined analytically and site specific sediment characteristics, nutrients and physical characteristics (e.g. velocity) are be used to predict temporal and spatial variability.

5. CONCLUSION

The spatial variations of SOD rates at fifteen locations along Athabasca River measured during the fall season of 2006 were presented in this study. SOD rates were

higher downstream from effluent discharges and tributaries. However, other factors such as sediment characteristics were also important. In determining relationship among SOD rates and organic matter or nutrients, it was found that SOD rates are correlated positively with TOC, TDP, and Chlorophyll-α. Observations indicate that SOD rates were also influenced by sediment types revealing that finer sediment grain had higher SOD rates compared to coarser grained sediment. The relationship among SOD rates and water quality parameters show that SOD modeling could be achieved by incorporating several key parameters.

ACKNOWLEDGEMENT

The financial support was provided by Alberta Environment, NSERC, Alberta News Print Co., Alberta Pacific Forest Industries Inc., Hinton Pulp, Millar Western Forest Products Ltd., and Slave Lake Pulp. The assistance of Nathan Findlay in field data collection, and contributions of Joanne Volk of Hinton Pulp, Dan Moore and Boyd Payne of Alberta Newsprint Co, Mark Spafford of ALPAC during site location and sample collection were instrumental. Prem Bhandari of University of Alberta is acknowledged for assistance with statistical analysis.

A comparison of a SWAT model for the Cannonsville Watershed with and without Variable Source Area Hydrology

Josh Woodbury[1], Christine A. Shoemaker[1], Dillon Cowan[1], and Zach Easton[2]

[1] School of Civil and Environmental Engineering, Cornell University, Ithaca, NY, 14853, USA
[2] Department of Biological and Environmental Engineering, Cornell University, Ithaca, NY, 14853, USA

Abstract:

In this study, two different versions of the Soil and Water Assessment Tool (SWAT) are used to simulate the Cannonsville Watershed. These versions are referred to as SWAT_TS and SWAT_VSA. The SWAT-VSA model distributes overland flow in ways that are consistent with variable source area hydrology, while the SWAT_TS model does not. Since many water quality models, such as SWAT, use some form of the curve number equation to predict storm runoff, these models may fail to accurately describe the effects of variable source areas (VSAs), which are mostly important in rural, humid areas, such as upstate New York. These two models are compared by calibrating each for flow, phosphorous and sediment against measured data.

Introduction:

The Cannonsville Reservoir is a large drinking water reservoir located in Delaware County in upstate New York. The reservoir is one of the largest of New York City's drinking water reservoirs. The Cannonsville Watershed is approximately 1200 km^2 consisting of mostly forested and agricultural lands. Due to agriculture in the area, the reservoir has often experienced water quality problems due to heavy phosphorous loading. The phosphorous has caused concerns as to whether or not New York City can continually use this water without the need for a water filtration plant.

The Soil and Water Assessment Tool (SWAT) has previously been used to accurately model the Cannonsville Watershed (Tolson and Shoemaker, 2007b). The SWAT model is a watershed scale model created to simulate long term runoff and nutrient losses in rural, agriculturally dominated watersheds. The model requires such information as soils data, elevation data and land use information. This data is then lumped together into hydrologic response units (HRUs) to direct flows and sub-basin routing. The model then requires climate data, such as temperature, precipitation and solar data in order to simulate the watershed.

In this study, two different versions of SWAT are used to model the watershed. These versions are called SWAT_TS and SWAT_VSA. The SWAT_VSA version simulates flow using variable source area hydrology, while the SWAT_TS version does not. Variable source area (VSA) hydrology is the concept that runoff generating locations vary both in time and

space, depending on time of year, rainfall, temperature and topography (Easton et al., 2008). In VSA hydrology, surface runoff is not evenly distributed over the land, but is concentrated in specific areas. This concept can have a large impact on nutrient transport, and is therefore an important consideration in management techniques. The SWAT_TS and SWAT_VSA models are calibrated against measured data in order to compare the accuracy of each.

Description:

Both of the models in this study are modified versions of the SWAT 2005 model. The first model, SWAT_TS uses a modified version of the SWAT 2005 source code. Previous work done using the SWAT 2000 model showed that the results improved with certain source code changes (Tolson and Shoemaker, 2007b). These changes include modifications of the daily manure spreading, plant growth, flow in/on frozen soils, monthly subbasin temperatures and the MUSLE equation. These modifications are described in more detail in (Tolson and Shoemaker, 2007b). The source code changes make up the difference between the SWAT_TS model and the SWAT 2005 model.

The second model, SWAT_VSA, includes the modifications in SWAT_TS as well as the variable source area hydrology (VSA). The major difference between the SWAT_VSA and the SWAT_TS models are in the way that the HRUs are created. In SWAT_TS, the HRUs are defined by the coincidence of soil type and land use. In order to incorporate VSA hydrology into SWAT, a topographic wetness index is used together with land use to define the HRUs (Easton). The soil topographic index (STI) is defined as:

$$STI = \ln\left(\frac{a}{T\tan\beta}\right)$$

where a is the upslope contributing area for the cell per unit of contour line (m), tan β is the topographic slope of the cell, and T is the transmissivity (soil depth x saturated soil hydraulic conductivity) of the uppermost layer of soil ($m^2\ d^{-1}$) (Easton et al., 2008). These index classes are then numbered from 1, the driest and least prone to saturate, to m, the most prone to saturate (Easton). For the SWAT_VSA, there are 10 different index classes.

Calibration:

The SWAT_TS and the SWAT_VSA models are calibrated using an algorithm called dynamically dimensioned search, or DDS. DDS is a simple stochastic single-solution based heuristic global search algorithm designed for automatic calibration of watershed models (Tolson and Shoemaker, 2007a). DDS performed better on a Cannonsville subbasin than a variety of other methods (Shoemaker et al., 2007). Although SWAT has many outputs, this study focuses mostly on phosphorous, so calibrations are done for flow, sediment and phosphorous. In order to get the best results, each model is calibrated in steps, with flow calibrated first, sediment second and phosphorous last. When calibrating for each constituent, only parameters that are directly related to the constituent vary, all other parameters remain constant. For example, when calibrating for phosphorous, only phosphorous parameters vary.

For the flow calibrations, the DDS algorithm is used to minimize the sum of squared errors between measured and simulated values over time.

$$SSE = \sum_{t} \left(Measured_t - Simulated_t \right)^2 \quad (1)$$

In equation (1), SSE is the sum of squared errors and t is time. Next, the models are calibrated for sediment, while keeping the optimized flow parameters constant. This is done using the DDS algorithm and a weighted objective function.

$$OF = SSE_{Flow} + \alpha_{Sed} SSE_{Sed} \quad (2)$$

Where:

$$\alpha_{Sed} \approx \frac{SSE_{Flow}}{SSE_{Sed}} \quad (3)$$

Since the SSE values for flow and sediment can vary by orders of magnitude, weighting values, the alphas, are used when calibrating for sediment. The weighting scheme normalizes the SSE values of flow and sediment. It is necessary to include flow when calibrating for sediment because many of the parameters that largely impact sediment output also impact flow output.

The final step involves calibrating for phosphorous. There are two types of phosphorous that are important in this study, total dissolved phosphorous (TDP) and particulate phosphorous (PP), each of which are outputs in the SWAT model. Using the parameters from the flow and sediment calibrations, the phosphorous is calibrated using the following objective function with DDS:

$$OF = SSE_{Flow} + \alpha_{Sed} SSE_{Sed} + \alpha_{TDP} SSE_{TDP} + \alpha_{PP} SSE_{PP} \quad (4)$$

Where:

$$\alpha_{TDP} \approx \frac{SSE_{Flow}}{SSE_{TDP}} \quad (5)$$

$$\alpha_{PP} \approx \frac{SSE_{Flow}}{SSE_{PP}} \quad (6)$$

The weighting values are necessary for the same reasons they are necessary for the sediment calibration. The weighting values normalize the SSE values so that each constituent is equally weighted. The following tables summarize the parameters used for flow, sediment and phosphorous.

Table 1: Parameters used in flow calibration.

Parameters	Description
SFTMP	Snowfall temperature
SMTMP	Snow melt base temperature
SMFMX	Maximum melt rate for snow during year where deg C refers to the air temperature
TIMP	Snow pack temperature lag factor
SURLAG	Surface runoff lag time
GW_DELAY	Groundwater delay time
ALPHA_BF	Alpha factor for groundwater recession curve
GWQMN	Threshold depth of water in shallow aquifer
LAT_TIME	Lateral flow travel time
ESCO	Soil evaporation compensation factor
CN2_f	CN multiplicative factor
DEPTH_f	Depth multiplicative factor
BD_f	Bulk Density multiplicative factor
AWC_f	Available Water Content multiplicative factor
KSAT_f	Saturated hydraulic conductivity multiplicative factor

Note: Multiplicative factors are used to linearly scale the parameters between their minimum and maximum values.

Table 2: Parameters used to calibrate sediment.

Parameters	Description
ADJ_PKR	Peak rate adjustment factor for sediment routing in the subbasin
PRF	Peak rate adjustment factor for sediment routing in the channel
SPCON	Linear parameter for calculating sediment
SPEXP	Exponent parameter for calculating sediment re-entrained in channel routing
LAT_SED	Sediment concentration in lateral flow
SLSUBBSN_f	Sverage slope length multiplicative factor
SLSOIL_f	Slope length for lateral subsurface flow multiplicative factor
CH_EROD	Channel erodibility factor
CLAY_f	Clay content multiplicative factor
ROCK_f	Rock content multiplicative factor

Note: Multiplicative factors are used to linearly scale the parameters between their minimum and maximum values.

Table 3: Parameters used in phosphorus calibration.

Parameters	Description
PPERCO	Phosphorus percolation coefficient
PHOSKD	Phosphorus soil partitioning coefficient
CMN	Rate factor for humus mineralization
P_UPDIS	Phosphorus uptake distribution parameter
ERORGP	Organic P enrichment ratio
PSP	Phosphorus availability index

Abstract

All India Co-ordinated Research Project for Dryland Agriculture, University of Agricultural Sciences, GKVK, Bangalore, conducted an experiment by adopting proven in-situ management of rainwater technologies Vetiver (khus) and Pennisitum (Nase) grass as vegetative live bunds with contour bunds. Runoff water harvesting structure such as farm ponds of 180 cubic meter capacity were dug for runoff collection from about 0.6 to 0.7 hectare area having two per cent land slope with Agro-forestry system has served as crop insurance. Lining materials were used to minimize the seepage loss from the stored water which was used for providing life saving irrigation to highly remunerative vegetable crops like chilli (sambruddi). Results of the study during the period (2000-05) clearly indicated that, the highest runoff of 93.2 mm accounting to 9.7% of the total mean annual rainfall under control plot (no inter terrace management practices) was observed. However, the runoff produced in both the inter-terrace management practices were on par with each other (65.5 to 65.9 mm). The highest mean annual soil loss of 5.66 t/ha/year under control plot and the lowest (3.151 t/ha/yr) was recorded under inter-terrace management with nase live barrier. Organic farming through application of green leaf manure (6 – 8 t/ha) enhanced the productivity of finger millet and an additional income of Rs.50,000/- with agro-forestry.

Introduction

By adopting innovative, low cost and location specific conservation measures may helps in reduced surface runoff, soil erosion and nutrient loss from the fertile top soils. Estimation of such resource degradation is much useful to design and develop suitable location specific conservation measures for different topographic features of that are. Uncertain rainfall with heavy down pour in a single storm is common in dryland situation which may cause surface runoff resulting flooding in down stream area which affect the low laying cropped area. Harvesting and effective recycling of harvested runoff through farm pond in arable lands are very effective harvesting structures increase the cropping intensity by providing life saving irrigations. Keeping this in view, a study was carried out to quantity resources (runoff, soil loss and nutrient loss) degradation under micro-watershed management at the Institute since last two decade. Conservation practices with improved techniques may adopt during the period helps to sustain the productivity of Dryland crops.

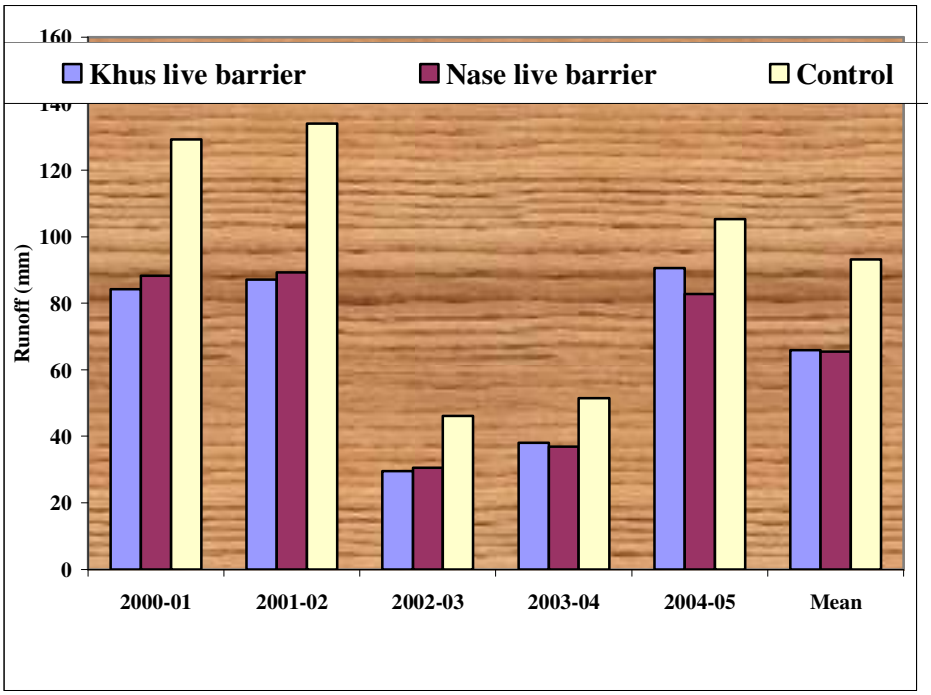
Objectives:

1. To promote in-situ soil moisture conservation through inter-terrace management practices.
2. To quantify runoff and soil loss under integrated watershed management with harvesting and recycling.

3. To study the seepage loss from water harvesting structures.
4. To accesses the tree species on the bunds and inter terrace management practices.
5. To workout the economic and sustainability of the system.

Treatments

Khus (vetiver) live barrier.
Nase (Pennisitum) live barrier
No Inter-terrace management practice.
Farm pond lined with 8:1 soil cement lining.
LDPE sheet overlaid with brick lining.
LDPE sheet over lay with brick frame work lining.



Micro-watershed catchments having 2% land slope are delineated into 0.6 to 0.7 hectare each by adopting 0.52 cross sectional contour bunds with open end with a horizontal interval of 30 – 50 mt. Each plot developed with the vegetative barriers (vetiver and penisitum) in between the two bunds and cultivation of crop across the slope. Excess rainwater (runoff) is harvested and stored in a farm pond of 180 m2 capacity which was designed by considering the highest rainfall of 160 mm for the recurring interval of 15 years. Bi-modal distribution of rainfall in the region, uncertain rain produced 6 to 14 runoff events in a year. Water harvesting structures lined with relevant materials to control the seepage loss which is high under red soil regions. Harvested water is effectively utilized through life saving irrigation to second crop may have high remunerative vegetable crops.

Results:

The inter-terrace management practices may help in conserving rainwater and soil which reduced the erosion of these resources. Adoption of inter-terrace management practices like khus and Nase live barriers for the individual land holdings resulted that the maximum mean runoff of 93.2 mm under plot without inter-terrace management practices as compared to khus and Nase live vegetative barriers (65.7 mm). The results clearing indicated that by adopting inter-terrace management practices which may conserve more rain (40 to 46 mm) besides reduce the runoff by 28 per cent compared to control. However, both inter-terrace management practices are on par with each other irrespective of the rainfall amount, intensity and duration and which may helps in enhancing the crop yield as shown below;

Table.1: Inter-Terrace Management Practices produced runoff under Individual Land Holdings

Treatments	Run off (mm)					Mean
	2000	2001	2002	2003	2004	
Khus inter-terrace management	84.1 (6.83)	87.08 (8.7)	29.5 (4.7)	38.1 (5.9)	90.6 (9.1)	65.9 (7.1)
Nase inter-terrace management	88.3 (7.2)	89.2 (8.9)	30.6 (4.9)	36.8 (5.7)	82.8 (8.3)	65.5 (7.0)
Control	129.2 (10.5)	134.0 (12.1)	46.1 (7.4)	51.4 (7.9)	105.3 (10.6)	93.2 (9.7)
Mean	100.5 (8.2)	103.4 (9.9)	35.4 (5.6)	42.1 (6.5)	92.9 (9.3)	74.9 (7.9)

Incorporation of organic (GLM) and inorganic (fertilizers) manures gave highest grain yield of finger millet (2121 kg/ha) under GLM + Nase live barrier followed GLM + khus live barrier (1924 kg/ha) and 1647 kg/ha under with out any GLM and inter-terrace management practices. However, the marginal increase in finger millet grain yield from 1379 kg/ha with 50 % RDF to 1647 kg/ha under 100 % RDF as presented in Table below;

Table.2: Effect of Integrated Micro-Watershed Management Practices and Fertility Management on productivity of Dryland crops

Treatments	**Finger millet grain yield (kg/ha)**		
	100 % RDF	**50 % RDF**	**Mean**
GLM + Khus inter-terrace management	1924	1788	1856
GLM + Nase inter-terrace management	2121	1687	1904
Only GLM	1844	1644	1744
Control (No inter-terrace management)	1647	1379	1513
Mean	1884	1624	-

Horsegram grown as green manure crop for in-situ incorporation gave higher bio-mass yield under khus live barrier plot (8.97 t/ha) followed by nase live barrier plot (8.3 t/ha) compared to control (6.0 t/ha) which influence on grain yield of finger millet under both inter-terrace management practices (2121 kg/ha and 2103 kg/ha) as compared to control (1961 kg/ha) during 2005-06 as presented below;

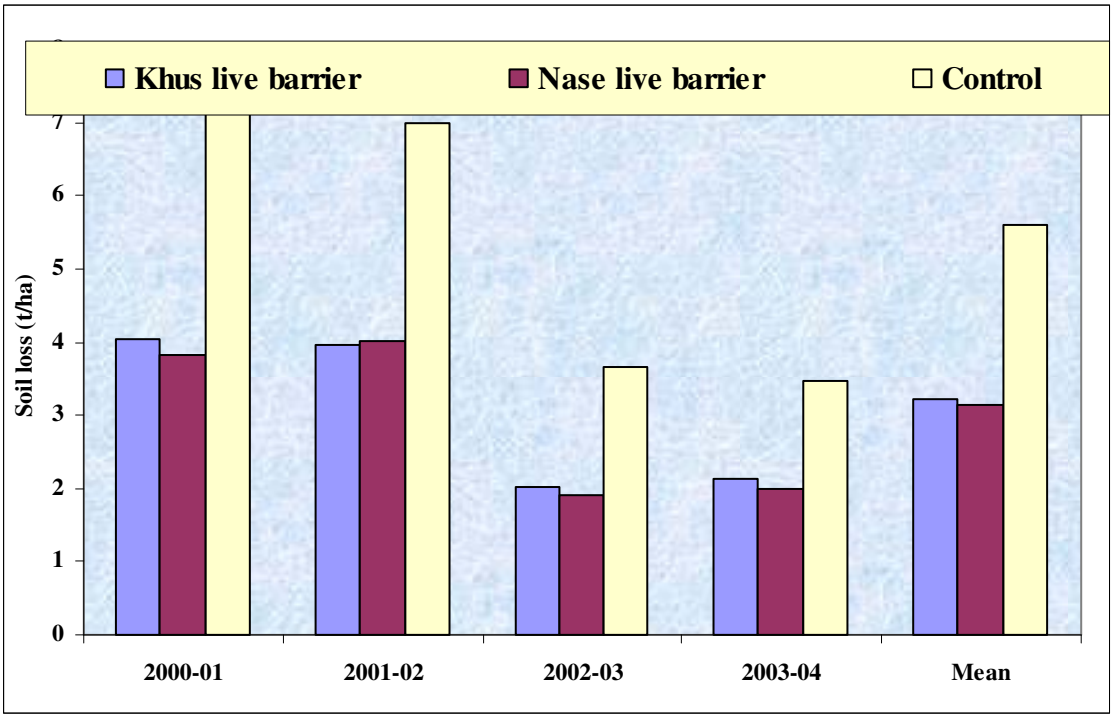


Table.3: Crop Yield as influence by green manure application Under Dryland condition

Treatments	**In-situ green bio-mass with Horsegram (t/ha)**		**Grain yield (kg/ha)**	
			FB (2004)	**FM (2005)**
Khus inter-terrace management	7.4	8.97	269	2121
Nase inter-terrace management	7.9	8.3	536	2103
Control	5.6	6.0	106	1961

Soil loss of 7.139 t/ha/yr under control plot as compared to 4.036 t/ha/yr and 3.812/ha/year in khus and Nase inter-terrace management practices during 2000-01. However, the mean annual soil loss under both the inter-terrace management practices was on par with each other and which helps in reducing 44 percent (3.15 t/h) and 3.231 t/ha) as compared to 5.6 t/ha under control (without any inter-terrace management practices). More rainfall coupled with higher intensity of rain may cause more soil erosion (ranging from 3.812 to 7.139 t/ha/yr) during the year 2000 and 2001. The result indicate that the amount and intensity of rainfall directly proportional and duration of rainfall indirectly proportional to the soil erosion as presented in table and figure below;

Table.4: Soil Loss as influence by Inter-terrace Management Practices under Individual Land Holding.

Treatments	Soil loss (T/ha)				Mean
	2000-01	2001-02	2002-03	2003-04	
Khus inter-terrace management	4.036	3.971	2.015	2.135	3.210
Nase inter-terrace management	3.812	4.013	1.917	1.986	3.151
Control	7.139	6.981	3.651	3.472	5.6
Mean	4.99	4.98	2.528	2.531	3.99

In khus live barrier treatment, Finger millet produced highest yield of 2605 kg/ha as compared to Nase live barrier (2575 kg/ha) and control (2315 kg/ha). By adopting the khus /Nase inter-terrace management practices, the grain yield of finger millet enhanced by 10-15 per cent as compared to the control as presented in table below;

Table-5: Grain Yield of Finger Millet as influence by Inter-terrace Management Practices.

Treatments	Finger millet Grain yield (Kg/ha)				B.C. ratio
	2000	2001	2003	Mean	
Khus inter-terrace management	1924	2892	3480	2605	1.98
Nase inter-terrace management	2121	2815	3260	2575	1.95
Control	1844	2775	2680	2315	1.74
Mean	1963	2827	3140	2498	

Khus and Nase live barriers as inter-terrace management practices for individual land holdings of less than 2 to 3% land slope at an interval of 15 to 30 m horizontal distance are the effective low cost inter-terrace management practices.

ABSTRACT

Estimation of watershed nutrient loads into the reservoir through a simulation model is a vital step in eutrophication management of reservoirs. The analysis of uncertainty associated with the utility of simulation models is an important consideration in the development of Total Maximum Daily Load plans in the control of watershed nutrient loading. When using models during the development of the TMDL, either to predict loadings or to simulate water quality, managers should address the inherent uncertainty in the predictions. In this paper, a Monte Carlo based probabilistic approach namely Generalized Likelihood Uncertainty Estimation (GLUE) is utilized to develop a computational procedure for analysis of the model uncertainties on prediction of phosphorous loads of a distributed watershed model, Soil and Water Assessment Tools (SWAT). In the GLUE method a cumulative likelihood for nutrient outputs of the SWAT model is generated. Quantile analysis of the cumulative likelihoods yields expected nutrient loads as well as their corresponding uncertainty limits. Uncertainty bounds could be used to obtain a Margin of Safety (MOS) for such evaluations in the TMDL formula. The analysis is demonstrated for the Aharchai watershed in the North –Western part of Iran.

Keywords: Nutrient load, uncertainty, SWAT model, GLUE method

INTRODUCTION

Eutrophication is the enrichment of waters with plant nutrients which results in an array of symptomatic changes, namely increased production of algae and aquatic macrophytes, deterioration of water quality and other undesirable changes that interfere with water uses. In many regions around the world, eutrophication has been recognized as a priority water quality problem. The main cause of this phenomenon is the excessive nutrient load from the watershed upstream of the reservoir. Thus control and reduction of watershed nutrient loads is a key step in reservoir water quality remediation.

USEPA (1999) has established the Total Maximum Daily Load (TMDL) process for impaired waterbodies especially eutrophied lakes and reservoirs. This process determines the allowable nutrient loading to a reservoir to preserve the water quality standards. In this process, margin of safety should be taken into account to consider the uncertainty about the relationship between pollutant loads and receiving water quality.

When using models during the development of the TMDL, either to predict loadings or to simulate water quality, managers should address the inherent uncertainty in the predictions. Various techniques for doing so include sensitivity analysis, first-order analysis, and Monte Carlo analysis. Implications of uncertainty associated with model predictions have not been widely endorsed in the decision making process mainly as a result of large uncertainty estimates. The magnitude of uncertainty itself is a key factor in the acceptance of the implementation cost of management actions such as the Total Maximum Daily Load (TMDL) program. The larger uncertainty estimates cause a significant increase in the cost.

Arabi 2007, developed a computational framework to investigate the uncertainty in the evaluation of watershed management practices. The Generalized Likelihood Uncertainty Estimation (GLUE) method was employed to generate a cumulative likelihood for sediment and nutrient outputs of the Soil and Water Assessment Tool (SWAT) for two scenarios with and without implementation of BMPs. The analysis focused specifically on the ranges of some model parameters that require site-specific adjustments with available data and the uncertainty associated with estimated effectiveness of BMPs.

Shirmohammadi et al. (2006) described the experience of scientists and engineers in the assessment of uncertainty associated with TMDL models. They reviewed sources and methods of uncertainty including Monte Carlo simulation (MCS), Latin hypercube sampling (LHS), and generalized likelihood uncertainty estimation (GLUE). It also presented strategies for communicating uncertainty in TMDL models to users. Four case studies were presented to highlight uncertainty quantification in TMDL models. It concluded that uncertainty in TMDL models was a real issue and should be taken into consideration during both the TMDL assessment and implementation phases.

Sohrabi et al. (2003) provided appropriate probability distributions for each of the most sensitive input parameters of SWAT2000 and showed the combined effect of such variability on model output in the form of cumulative probability distribution curves. They concluded that variability in model output caused by inaccurate input estimates can be reduced by decreasing the uncertainty in the inputs through increasing the number of measurements of the parameter and improving the methods used to measure the parameter.

Vogel et al. 2008 showed how the choice of a likelihood function in the GLUE methodology is critical and when properly implemented with a statistically valid function can provide credible regions for model prediction.

In this study, GLUE methodology is applied to estimate the uncertainties embedded in the SWAT model for prediction of total phosphorous load input to the Satarkhan dam reservoir at Aharchai river watershed in the north-western part of Iran. In the following sections first the case study is introduced then the methodology and tools

for uncertainty estimation is described and finally the results and conclusion are discussed.

CASE STUDY

The Study area is Aharchai river watershed in north-western Iran in East Azerbaijan province and is one of the sub-basins of the Aras River. The watershed is located between 38° 24' and 38° 41'N and 46° 20' and 46° 55' E as shown in Figure 1. The Satarkhan dam was constructed in 1998 to provide water for drinking, irrigation, mining and industrial use in the region. Therefore, water quality of the reservoir is of great concern which has been deteriorated during recent years due to excessive nutrient loads which have resulted in reservoir eutrophication.
Satarkhan reservoir watershed encompasses 93000 ha with land use distributions of 36.5% dry farming, 1.4% irrigated farming, 5.3% combination of irrigated farming and orchard land use, 12% bared land, 16.6% combination of dry farming and range, 27.3% range, 0.5% urban area, and 0.4% water. The average flow at the outlet of the basin is 2.9m^3/s. The water quality data at Orang station at the intake of the reservoir is available from August 2002 to December 2005 for a 41 month period.

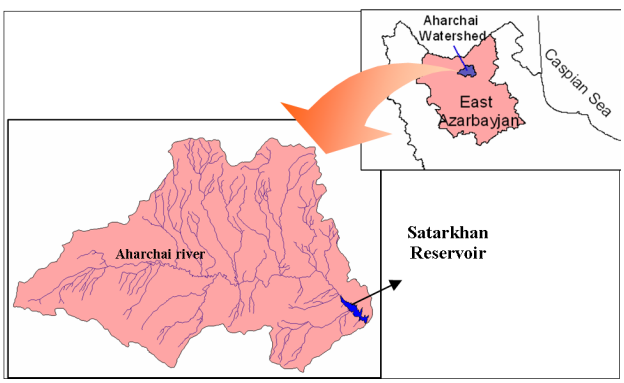

Figure 1 **Aharchai River and Satarkhan reservoir watershed in east Azerbaijan – North-western Iran**

SWAT MODEL

SWAT (Soil and Water assessment Tools) is a physically-based, time continuous simulation model that operates on a daily time step. It is designed to evaluate management effects on water quality, sediment production and yields of agricultural chemicals. The major components of SWAT include hydrology, weather, erosion, pesticide and nutrients. (Neitsch et al. 2000). The SWAT model divides the watershed into sub-basins to represent the large scale spatial heterogeneity of the studied area. Each sub-watershed is parameterized using a series of HRUs (hydrologic response units) which are a particular combination of land cover, soil and management. All model calculations are performed at the HRU level. The EPA currently supports this model for developing TMDLs in agricultural watersheds. SWAT consists of three major components: (1) sub-basin, (2) reservoir routing, and (3) channel routing. GIS interfaces have been developed to facilitate the aggregation

of input data. This interface requires a land cover map, soils map, and DEM. A detailed description of the model can be found at the SWAT website (www.brc.tamus.edu/swat/index.html). In this study the watershed of Aharchai River was subdivided into 20 sub-basins (HRUs) as shown in Figure 2.

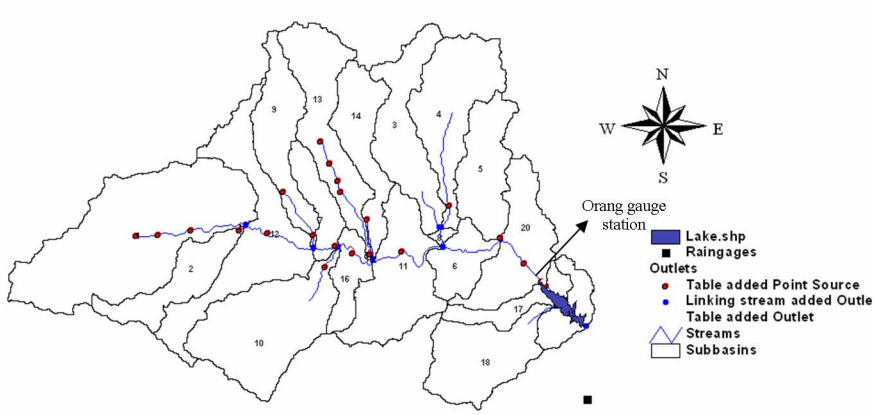

Figure 2 Aharchai Watershed with 20 sub-basins (HRUs)

UNCERTAINTY ANALYSIS TECHNIQUE

Here, the techniques of uncertainty analysis consisting of sensitivity analysis and generalized likelihood uncertainty estimation (GLUE) used in this study will be explained. The total procedure includes a combination of two techniques discussed here.

SENSITIVITY ANALYSIS

Sensitivity analysis is the simplest method in uncertainty analysis and is used to identify the model parameters that have the most influence on predicted outputs. In this process, each model run involves perturbation of only one parameter in turn. Therefore, the variation of model output can be clearly ascribed to the variation of the corresponding input parameter. For each input parameter, local sensitivities are computed at different points of the parameter range, and then the global effect is obtained by calculating their average.

Sensitivity analyses may not be needed when the model contains only a few parameters. However, in a complicated model like SWAT when the number of parameters is large, and as more than one output is affected by the same parameter, sensitivity analysis is needed to identify the model parameters that have the greatest impact on model outputs. A relative sensitivity coefficient can be calculated according to Eq. (1) and used to rank model parameters (Shirmohammadi et al. 2007)

$$S_r = \frac{\partial O}{\partial P} \times \frac{P}{O} \qquad (1)$$

Where *O* is output of interest, and *P* is the input parameter under analysis. The S_r calculated using this method is dimensionless and can be used to compare all parameters. One of the limitations of using S_r to identify the most sensitive model parameters is that it does not account for covariance among parameters. (Shirmohammadi et al. 2007)

GENERALIZED LIKELIHOOD UNCERTAINTY ESTIMATION

The Generalized Likelihood Uncertainty Estimation (GLUE) technique introduced by Beven and Binley (1992) is an innovative uncertainty method that is often employed with environmental simulation models. It is a sampling method that uses the behavior and non-behavior classification concept to distinguish between the fraction of Monte Carlo simulations that matches the system behavior and the complement fraction that does not. The main argument that led to the development of GLUE is that for a selected model structure, several combinations of model parameters (in contrast to a unique optimum) may exist that are equally good for reproducing the system behavior. Beven and Binley (1992) suggested that uncertainties due to errors in model structure and effects of correlation structure in the parameter space are implicitly handled within the GLUE procedure. In the GLUE method, the relative importance of model parameters is not evaluated individually and independently but as a set of parameters. Each set of model parameters within a given model structure is evaluated as a single unit. In other words, it is the parameter set that is important to produce system behavior, not the individual parameters. First, retained behavior-giving Monte Carlo simulations are given weights based on a likelihood function. A likelihood measure based on the Nash-Sutcliffe efficiency criterion with shaping factor *N* is defined as (Freer and Beven, 1996),

$$L(\alpha|y) = (1 - \frac{\sigma_\varepsilon^2}{\sigma_o^2})^N \qquad (2)$$

where $L(\alpha|y)$ is the likelihood of parameter set(α), given the observed data (y); σ_ε^2 refers to the error variance between model simulations and observed data, and σ_o^2 is the variance of the observed data. Beven and Binley (1992) used N=1 but suggested that the shape factor can be chosen by the user. For N = 1, $L(\alpha|y)$ in Eq. (2) is the Nash–Sutcliff efficiency coefficient (E_{N-S}) which is often used as the calibration criteria of hydrologic and water quality models like SWAT.

This coefficient is considered as a qualitative criterion to group the generated model parameters into two sets: (1) *behavioural* sets of model parameters that produced results consistent with the observations, and (2) *nonbehavioural* sets of model parameters that produced results that contradict the observations.

A negative E_{N-S} value indicates that the corresponding model output is unlike the behavior of the system under study, and the likelihood of such simulation in mimicking the system behavior is zero. Therefore, the likelihood function is defined as follows (Arabi,et al, 2007) :

$$L(\alpha|y) = \max\left[(1-\frac{\sigma_\varepsilon^2}{\sigma_o^2}),0\right]; \quad (3)$$

Then, the likelihood estimates associated with model simulations are rescaled such that they sum up to 1.0 and are used as likelihood weights to form a cumulative weighted distribution for the output of interest which can be used for estimation of uncertainty bounds associated with the output by computing its quantiles. The GLUE method is dependent not only on the choice of likelihood function, but also to the cutoff criterion used for classification of Monte Carlo simulations to behavior and non-behavior sets. (Arabi et al. 2007)

METHODOLOGY

The methodology structure utilized in this study consists of the watershed model (SWAT) applied for simulating the fate and transport of phosphorous load input to the reservoir and an uncertainty analysis methodology based on two sampling based methods: sensitivity analysis and Generalized Likelihood Uncertainty Estimation (GLUE; Beven and Binely, 1992).

A computational method was developed to limit the range of input parameters to adjusted ranges corresponding to the observed data, used in the GLUE analysis. The methodology was tested on Aharchai watersheds located in northwest Iran. This shows the usefulness of the developed computational analysis to quantify modeling uncertainties associated with estimated phosphorous load.

A schematic of the uncertainty analysis process used for phosphorous load estimation through SWAT model is presented in Figure 3.

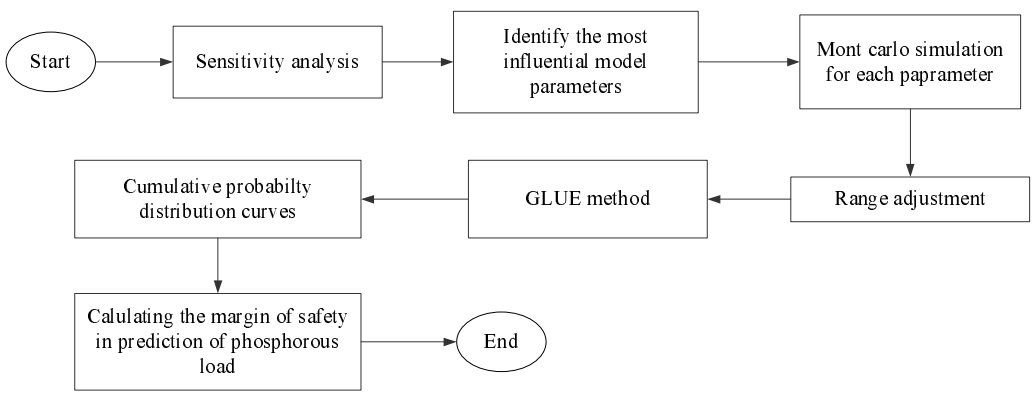

Figure 3. Flowchart of uncertainty estimation process

RESULTS AND DISCUSSION

SENSITIVITY ANALYSIS

Figure 4 presents the results of the sensitivity analysis calculated for the SWAT model parameters. The target output of the SWAT model is the phosphorous load at sub-basin 20 located just upstream of the reservoir.

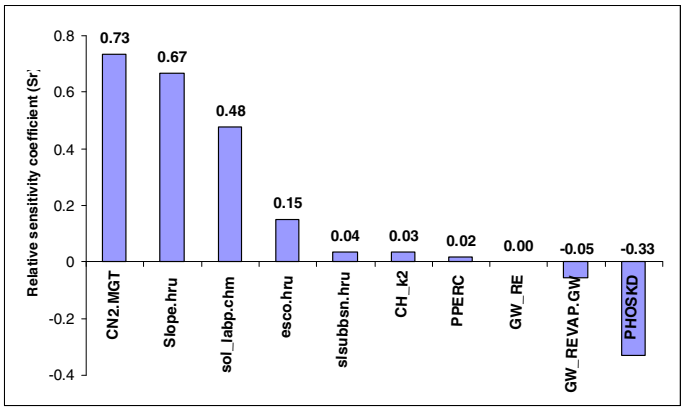

Figure 4. Results of sensitivity analysis

According to results of sensitivity analysis the most sensitive parameters were selected in the GLUE analysis as shown in Table 1.

Table 1 – Top five sensitive SWAT parameters for watershed phosphorous load

No	Parameter	Description	*Sr*
1	CN2.mgt	SCS runoff curve number	0.73
2	Slope.hru	Average slope steepness (m/m).	0.67
3	Sol_labp.chm	Initial soluble P concentration in soil layer	0.48
4	Phoskd.bsn	Phosphorus soil partitioning coefficient (m3/Mg).	-0.33
5	Esco.hru	Soil evaporation compensation factor	0.15

BEHAVIORAL RANGE ADJUSTMENT

Using the entire parameter ranges in the uncertainty analysis may result in a large number of simulations with negative likelihoods ($L(\alpha|y)$) that make the GLUE analysis ineffective and time consuming. Therefore, adjustment of ranges of sensitive input parameters is an essential step before quantifying the uncertainty of model outputs.

To adjust the behavioral range of the parameters for each individual parameter, 60 random value based on the uniform distribution is generated and for each run the phosphorus load and the likelihood measure is calculated. The behavioral range of each parameter is identified according to the positive value of the likelihood function which is depicted in Figure 5 for all 5 sensitive parameters selected in this study. The base case value of the input parameters was selected from a calibrated and validated model for a 41 month data of phosphorous load. The data was measured just upstream of the reservoir at sub-basin 20 from August 2002 to December 2005.

The FORTRAN source code of the SWAT model was developed to derive the probability distribution according to the set of parameter variations.

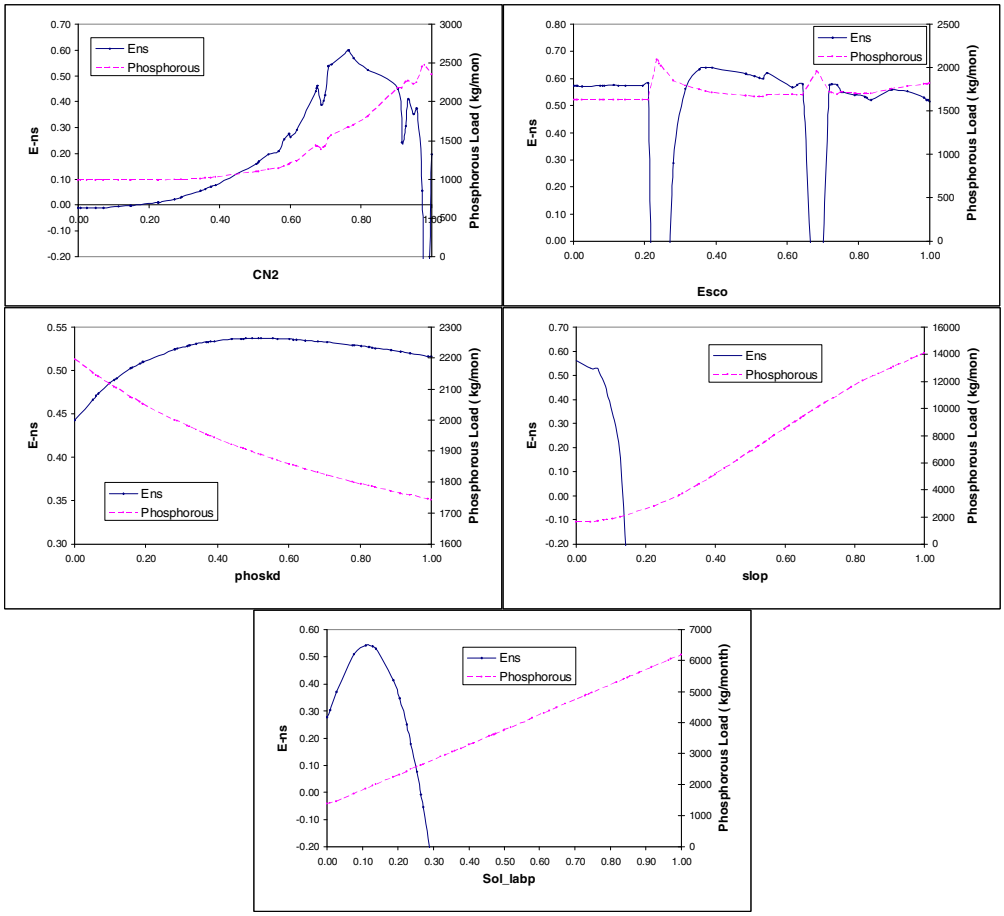

Figure 5- Plots for the top five sensitive SWAT input parameters related to average monthly phosphorous load

Table 2 – Behavioural parameter ranges for the study watersheds

No	Parameter	Suggested range	Behavioral range
1	CN2.mgt	35-96	44-96
2	Slope.hru	0.013- 0.594	0.013-0.09
3	Sol_labp.chm	0.38-94	0.38-25
4	Phoskd.bsn	100- 198	100- 198
5	Esco.hru	0.017-0.971	0-0.22, 0.27-0.65 , 0.68-0.97

THE UNCERTAINTY ANALYSIS

Adjusted parameter ranges from previous step were used to probabilistically determine the margin of safety in the load estimation. In this study, 1000 model simulations using Monte Carlo method were performed for the 2002–2005 period. Five sensitive model parameters in Table 1 were included in the analysis using the behavioral range. For each realization of the parameter space, the uncertainty analysis requires the following steps:

1. Select parameter values from the adjusted ranges randomly.

2. Perform model simulation with the selected values to compute model outputs
3. Compute likelihood of the simulation for monthly output variables based on Nash-Sutcliff equation.
4. Using GLUE-likelihood weights computed at previous step, generate a cumulative density function for phosphorous load

Figure 6 presents the cumulative likelihood distribution of average monthly phosphorous load at inlet of Satarkhan dam reservoir. This figure is very important in determining the margin of safety in total maximum daily load (TMDL) process. Uncertainty bounds could be used to obtain a Margin of Safety (MOS) for such evaluations in the TMDL formula. As shown in Fig. 6, lower and upper bounds are obtained according to 10^{th} and 90^{th} percentiles of the cumulative likelihoods, respectively. Therefore, the uncertainty bounds of phosphorous load simulation model equals to [1140, 1980] kg/month.

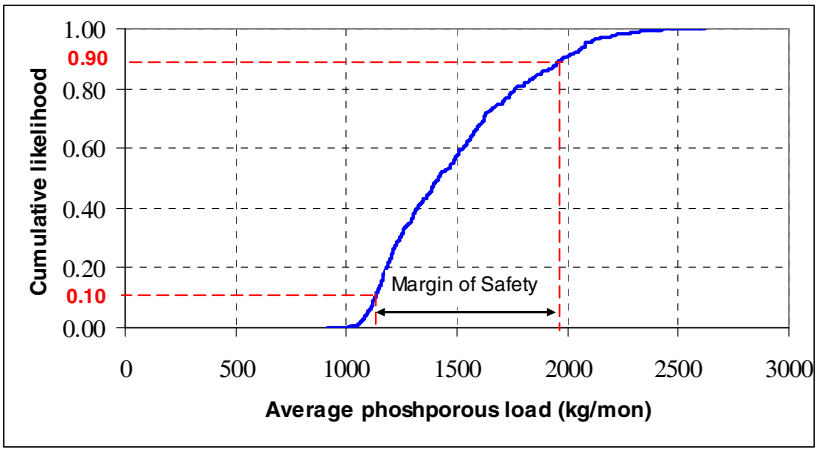

Figure 6. Cumulative GLUE-likelihood for phosphorous load simulated at the Satarkhan reservoir inlet

SUMMARY AND CONCLUSION

An uncertainty analysis process was developed, in which investigation of uncertainty provides complementary quantitative and qualitative information to support management and decision making. The analysis focused specifically on two issues. First, ranges of some model parameters that may require site-specific adjustments with observed data. This was particularly evident for parameters that are not determined from landscape characteristics. The computational procedure for the analysis of uncertainty was performed for Aharchai watershed just upstream of Satarkhan reservoir. It was demonstrated that the computational procedure is able to quantify the uncertainty of phosphorous load of the watershed. The main focus was on investigation of the utility of the developed methodology in the TMDL process. Especially, the means for coping with the margin of safety (MOS) in the TMDL formula.

Once the level of protection is provided by the margin of safety (MOS) by decision makers, the uncertainty analysis presented in this study could be applied to verify the success of a particular management action in achieving its designated goals.

Implementation of the estimated MOS is more feasible in this context, as opposed to the MOS computed from uncertainty analysis of absolute model predictions where the additional cost of implementation may render its consideration impractical. Finally, the methodology can be easily incorporated in other watershed and water quality models that are commonly used for TMDL development.

ABSTRACT

The Environmental Protection Agency (EPA) has promulgated a water quality trading policy. (WQT). The discharge of pollutants may be traded within/between locations in a watershed as long as nowhere along the applicable stream are water quality criteria exceeded. The tradable discharges may be of a point or a nonpoint nature. While the trading of point source pollutants has progressed, nonpoint source pollution (NPS) trading has not made as much progress. As the EPA stated in the policy statement, the development of appropriate trading units will be a considerable difficulty for nonpoint trades. The specification of trading units for nonpoint source trading may be difficult because of uncertainty for a number of reasons. The first of these is that trading must be initiated and executed legally in the present in order to trade with/for pollutants generated in the future. Nonpoint source pollutants, by their nature, can be generated by a number of different sources in different locations; the greater the number of sources and locations, the greater the uncertainty in their quantification. In addition, the generation of nonpoint source pollutants is driven, in part, by precipitation. Even as precipitation patterns are understood, there is considerable variability in the precipitation intensity and total volumes at specific locations at specific times. To meet these challenges, a research effort has been undertaken. As a start, a modeling system has been set up/established in a rapidly developing location southwest of St. Louis, Missouri. The test location is the Brush Creek watershed, where the area of the outlet of the watershed intersects the community in and around Pacific, Missouri. Because of its location 30 miles southwest of St. Louis, Missouri, the Pacific region expects to see considerable development that could increase the generation of nonpoint source pollutants. In addition, because Pacific is located in the lower portion of the watershed, nonpoint source pollution expected to be generated in the city could be traded with upstream locations and not cause decreases in water quality anywhere along Brush Creek. Because of the uncertainties associated with NPS trading, it can only be addressed via modeling. For this initial effort, the modeling is being limited to discharges and the generation of sediment. U.S. Geological Survey data for discharges and sediment concentrations in the Meramec River have been used to calibrate EPA's HSPF model for the Brush Creek watershed. Alternative development scenarios have been developed to represent potential conditions in the upstream and downstream locations that may be associated with a trade. Multiple precipitation patterns allow the modeling to represent the variability that may occur in the precipitation that drives the generation of sediment loads. Altogether, the modeling framework is appropriate to investigate and offer insights into the development of NPS trading units. Because Brush Creek is not currently impaired, and is not associated with any regulatory actions, it is an excellent location within which to test the modeling framework.

BACKGROUND

Water Quality Trading

In 2003, the U.S. Environmental Protection Agency (EPA) promulgated a policy regarding water quality trading (WQT). The policy states that WQT could be a means to address water pollution problems in an innovative fashion by trading between various pollutant dischargers that have varying capacities to control pollutant discharges. Those that have excess ability to control pollutant discharges can sell that ability to dischargers that cannot easily control discharges or would like to expand operations that would normally increase discharges. The ultimate goal of the policy is to promote an improvement in water quality.

Trades are theoretically possible two point sources, between a point source and a nonpoint sources, and between two nonpoint sources. Trades involving nonpoint source pollutants would be the most difficult to establish because of the distributed nature of the source and because of the variability associated with nonpoint sources initiated by precipitation rather than irrigation water. This difficulty in characterizing nonpoint source pollutants can be identified as the difficulty in establishing trading units—that is, what exactly is to be traded between pollutant dischargers. With nonpoint source pollutants, one could consider trading actual pollution (e.g., pollutant concentrations or quantities over time). Because nonpoint source pollution is impacted by land use, trading units could theoretically be acres of land with varying characteristics and with varying land uses/land covers. In addition, trading units could be modified based on the implementation best management practices (BMPs) that are intended to improve the quality of storm water runoff. Property owners may have the ability to control nonpoint pollutant discharges from land surfaces either by not developing the land and/or implementing BMPs. Another difficulty with nonpoint sources is that they may simultaneously include multiple pollutants in the runoff water.

Any water quality trades would have to maintain compliance with water quality criteria everywhere along a stream of interest. This means that donating sites (sites that are not developed as might be expected and thus produce less pollution) must always be upstream of receiving sites (sites that might be developed more intensely than might ordinarily be allowed, thus generating additional pollution).

HSPF

There are multiple computation tools available to model water quality associated with nonpoint source pollutants. Once such tool is EPA's HSPF. HSPF simulates water quality incorporating many parameters that arose out of agricultural investigations—land use/land cover, soil type and conditions/performance, as well as the precipitation that provides for the transport of materials from the land surface to a body of water.

OBJECTIVE

The objective of this research effort is to propose and test out a water quality modeling framework that would assist in the establishment of trading units for water quality trades between two nonpoint pollutant sources.

METHODOLOGY

Study Area

The study area is the Brush Creek watershed, as indicated in Figure 1. This watershed is part of the larger Meramec River watershed that has its outlet at the Mississippi River south of St. Louis, Missouri. Brush Creek is located in what is called the Pacific Ring, an area of land within a 7-mile radius of the city of Pacific, MO. Residents of this area are interested in maintaining the environmental quality of their surroundings, even as they are experiencing more and more growth coming from the direction of St. Louis toward their undeveloped agricultural and forested land. The fact that this location contains many undeveloped areas, and is experiencing increasing development pressure, makes this area a perfect one in which to begin to investigate water quality trading. In addition, the lower portions of the Brush Creek watershed coincide with the limits of the City of Pacific. This is shown in Figure 2, where the outline of the City of Pacific is shown in purple. Locations already within the city limits might experience additional pressures to develop where there is already infrastructure and where there is existing economic activity. These lower portions might be considered as receiving sites under a water quality trading proposal. Many upper portions of the watershed are covered in forest or are used for agriculture. If these sites are not developed and/or agricultural areas are taken out of production or operated with conservation practices, they might be considered to function as donating sites.

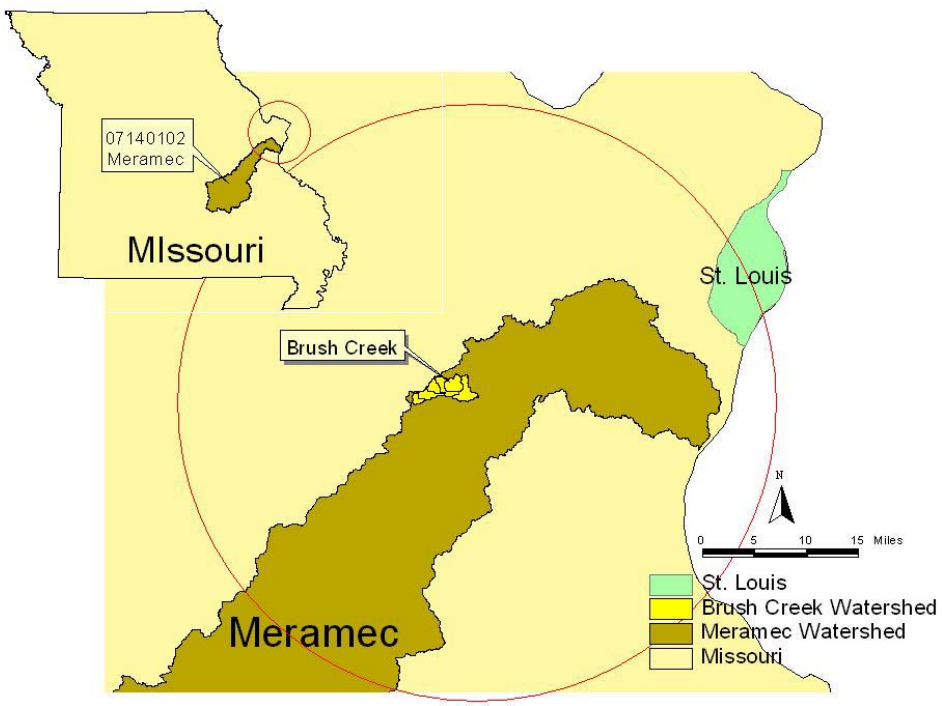

Figure 1. Location of Brush Creek watershed within the Meramec River watershed.

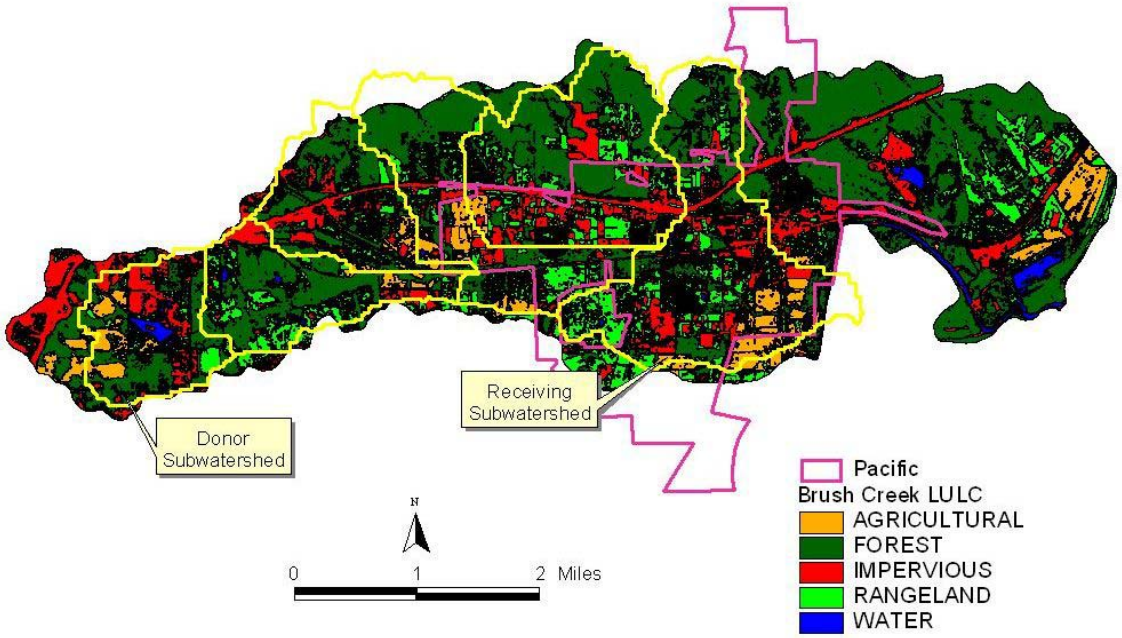

Figure 2. Brush Creek watershed with subbasins superimposed upon a land cover map.

Data Sources

U.S. Geological Survey (USGS) stream flow and sediment concentration data were used to calibrate the HSPF model for the Brush Creek watershed. Data are available for the Meramec River below the confluence with Brush Creek, so it was necessary to calibrate the model for the overall Meramec basin and utilize that model for the trading calculations. The calibration and validation plots for discharge are shown in Figures 3 and 4. The observed and simulated sediment concentrations for the period of USGS data are shown in Figure 5.

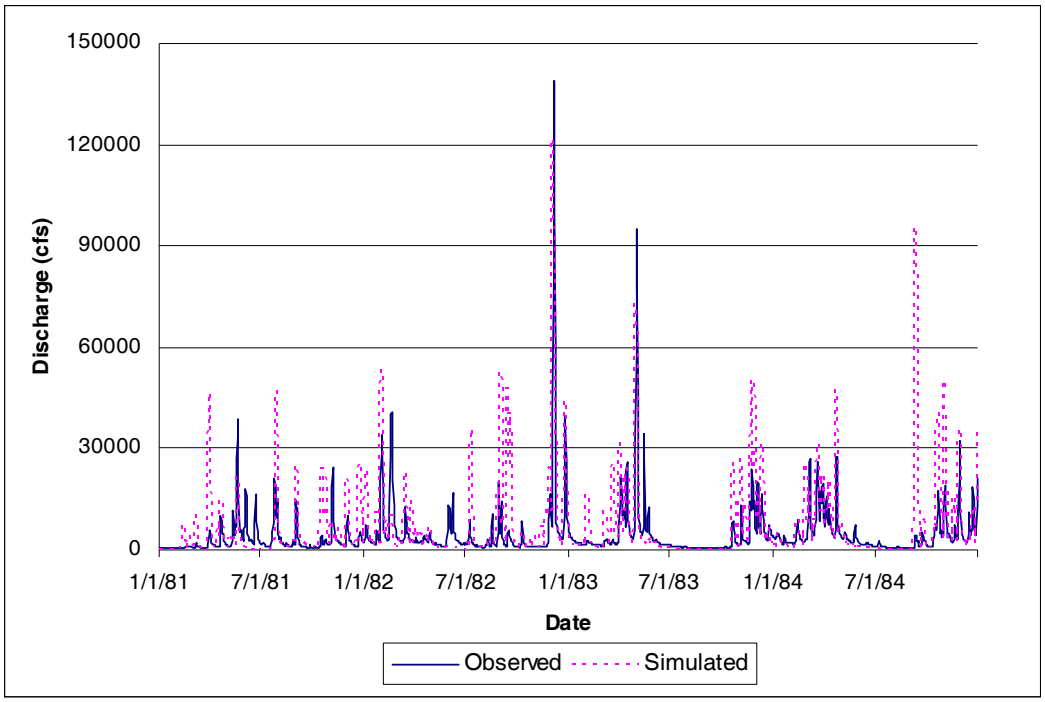

Figure 3.Scatterplot of simulated versus observed runoff for model calibration.

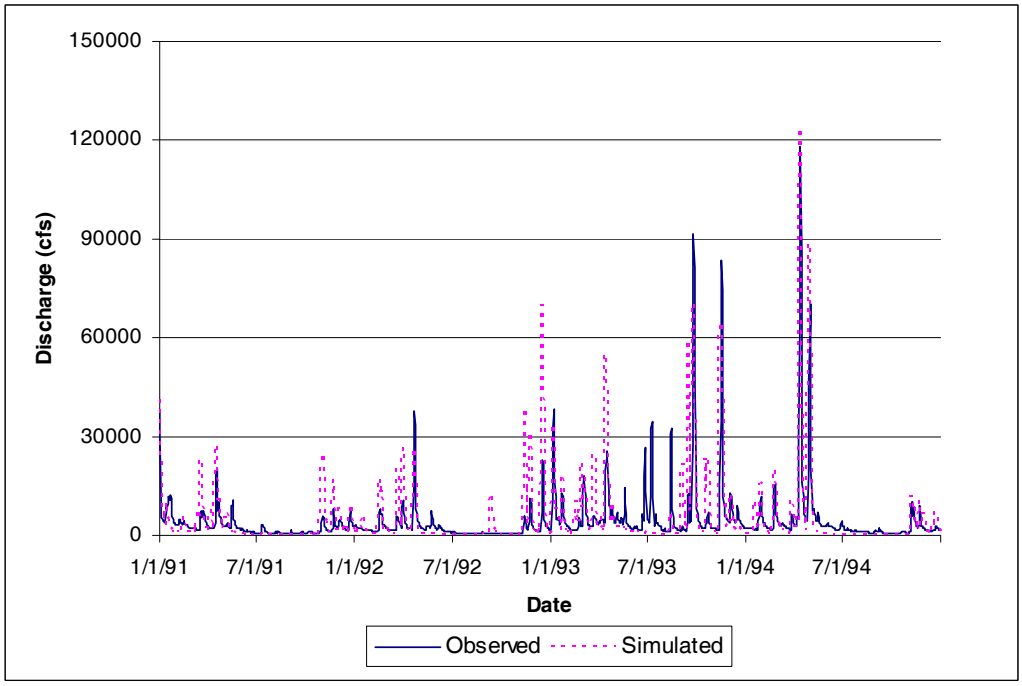

Figure 4. Scatterplot of simulated versus observed runoff for model validation.

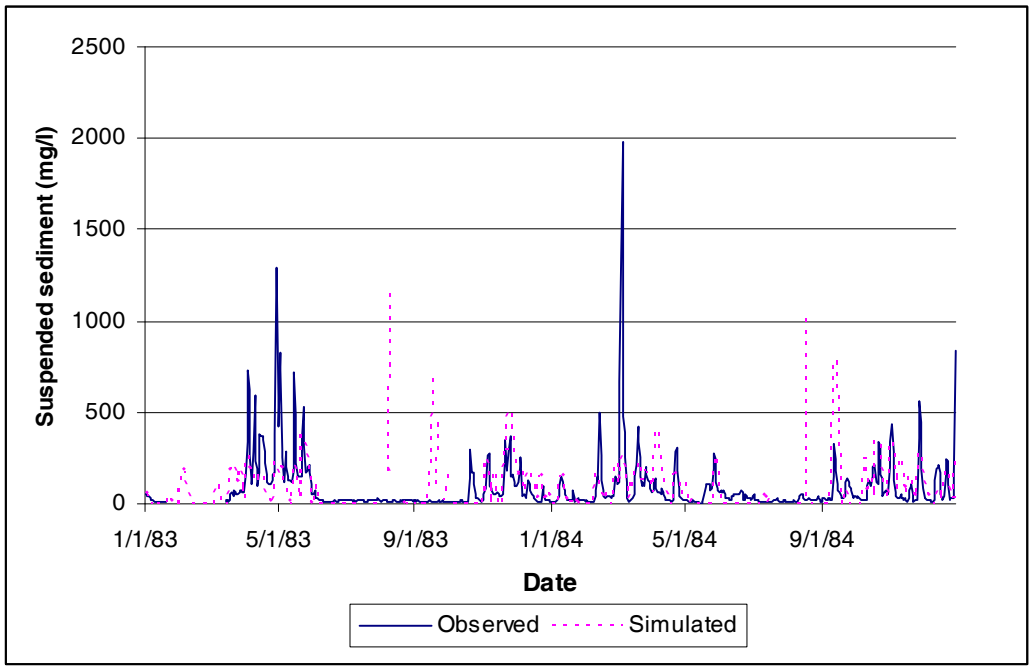

Figure 5. Scatterplot of simulated versus observed suspended sediment concentration.

A land cover classification map was developed for another project within the Pacific Ring. This classification can be seen in Figure 2.

Scenario Development

Nonpoint source water quality trades would be associated with land use patterns that are different than what normally be expected or allowed in a given location. The trade might be implemented through a mechanism such as a transfer of development rights. A trade would be based on understanding how different development scenarios would impact water quality. Such an understanding would allow for the establishment of a trade requirement. Such a requirement could specify how many acres of land at a given level of development and with what, if any BMPs, would be needed to be traded in order to provide a reduction in pollutant discharges equivalent to the increase associated with a more intense development scenario. In the development of this modeling framework, several development scenarios were established. These include the development of agricultural lands and forested lands and range land with varying percents of impervious surface.

RESULTS

Figure 6 shows the average discharges at the Brush Creek watershed outlet associated with Scenario 1, current land cover conditions for both up-watershed donor and down-watershed receiver locations. Scenarios 2-10 have no change to the donor locations, but do incorporate changes to the receiver locations. This graphic shows the trend of increasing discharges with increasing levels of impervious surface, as would be expected. The yellow markers represent changes associated with the development of agricultural land. “Agri 70” indicates that agricultural land was developed to a level of 70% impervious surface. “Agri 50” represents the

discharge associated with development to only 50% impervious surface that is lower than that of "Agri 70." Similar trends are seen for the development of forest land and range land. The exact values are a function of the amount of acreage developed as well as the soil and topographic characteristics of the developed land. The variation in the values shows that the specification of trading units will be site specific in nature.

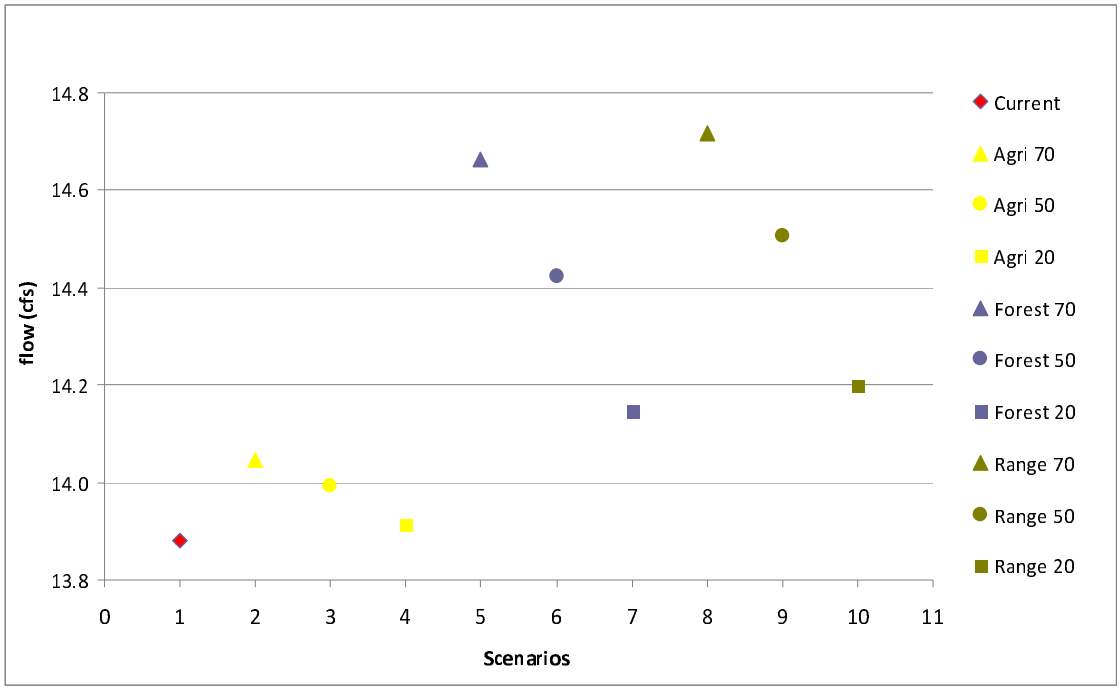

Figure 6. Average annual flow associated with land use changes.

Figure 7 shows the variation in suspended sediment concentration associated with a single storm across the various scenarios. As with Figure 6, comparisons are difficult between agricultural, forest and range lands, but trends within each original land cover are apparent. Within any of the three original land covers, one can see that greater levels of development are associated with a reduction in the sediment concentration when compared to current land cover conditions as represented as Scenario 1. These levels represent some combination of transport of materials from the land surface to the stream and suspension of bed materials. This figure highlights that land covers where there is exposed soil can result in greater sediment concentrations than impervious surface alone. Conditions are complex and the solution is not to cover everything with impervious surface. The results do suggest, however, that serious consideration be given to the specification of land uses in a trade, perhaps including conservation practices.

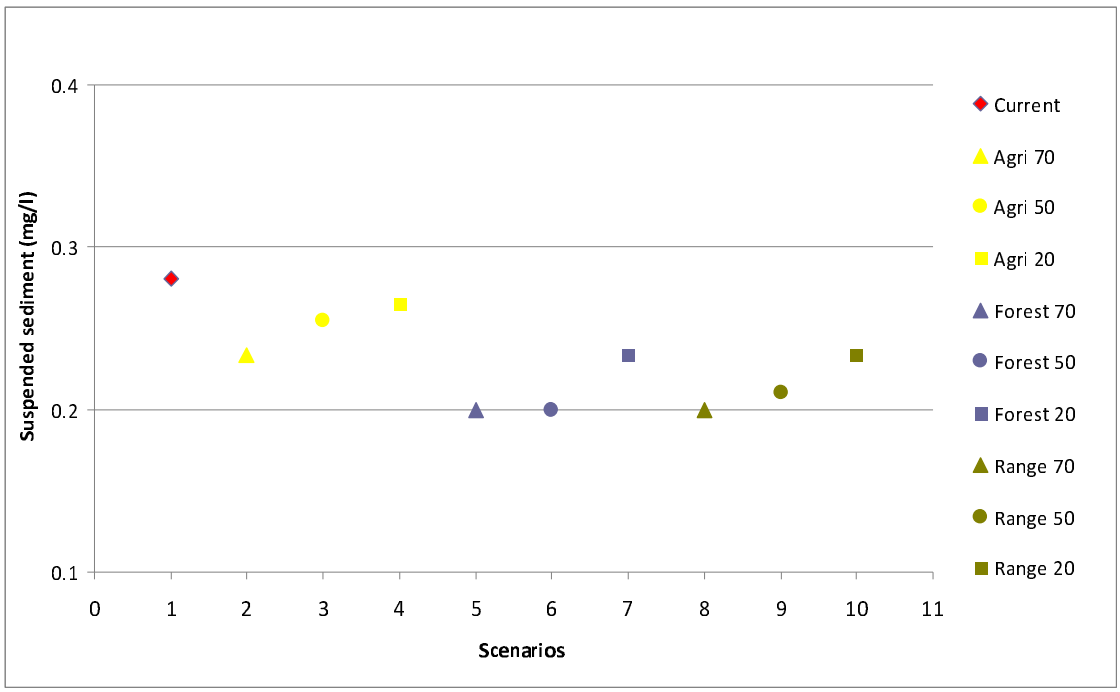

Figure 7. Suspended sediment concentrations (single storm) associated with land use changes.

CONCLUSIONS AND RECOMMENDATIONS

The HSPF model has been calibrated for flow and sediment load. The effort was undertaken with sediment as the only pollutant because the transport mechanisms are well understood and incorporated into freely available software. In addition, an extensive database of measured sediment loads is available from the USGS.

In order for actual trades to take place, they will need to encompass the entire suite of nonpoint source pollutants associated with agricultural, forest and urban land uses. Agricultural land covers may result in sediment loss, but development land covers may be associated with fertilizers, pesticides, heavy metals and petroleum products. A trade must encompass and balance out all of the applicable pollutants.

For complete specification of the water quality impacts of various development scenarios, the calculations must be performed under a full range of precipitation sequences that cover the expected climatic conditions.

The modeling framework has been established within which to evaluate multiple scenarios in order to match donor and receiver locations. Expansion of the precipitation conditions, scenarios, and comparison measures will help to build a robust process upon which to implement nonpoint source water quality trades.

ABSTRACT

The Mermentau and Vermilion-Teche River Basins consisting of 11 watersheds are located in the southwestern part of Louisiana and encompass a drainage area of approximately 17,431 km^2, 52% of which is cropland, primarily rice (34%) and soybeans (17%). Stormwater runoff and rice field discharges from January through May result in high pollutant and nutrient loadings containing nitrogen, phosphorous, and TOC (total organic carbon). As a result, the Louisiana 1998 305(b) Report indicates that 95% of the waterbodies within the basins are not fully supporting their designated uses. Since 1990, a variety of Best Management Practices (BMPs) has been implemented in the Mermentau and Vermilion-Teche River Basins. However, effectiveness of the BMPs in improving water quality and particularly in reducing nutrient impairment is largely unknown due to the lack of source information and to the spatio-temporal variability in hydrological and hydrometeorological parameters controlling nonpoint source pollution. This paper presents a statistical method for evaluating the effectiveness of Best Management Practices (BMPs) in reducing nutrient impairment using water quality data monitored from 1980 – 2006 in the Mermentau and Vermilion-Teche River Basins. The statistical method mainly involves (1) determination of seasonal variations in nutrient (NO_2+NO_3, TKN, total phosphorous, TOC) loading rates in order to identify critical months of nutrient impairment, (2) mapping of mean annual nutrient loads for pre-BMPs and post-BMPs, and (3) evaluation of the effectiveness of BMPs in reducing nutrient impairment based on the trend analysis. Results of the statistical evaluation show that (1) nutrient loading rates vary both seasonally and spatially. Nutrient loading rates become high in winter and spring (January – May) and low in summer and fall. The main impairment in January – March is caused by wet weather runoff. The severe impairment in April and May is related to the releases of muddy rice_field water. High nutrient loading rates are concentrated in the three watersheds: Bayou Queue de Tortue, Bayou Nezpique, and Vermilion River; (2) Since the implementation of BMPs in 1990, water quality in the two river basins has shown an improving trend in terms of nutrient impairment while it was worsening from 1980 – 1990; and (3) BMPs need to be enhanced in the two river basins.

INTRODUCTION

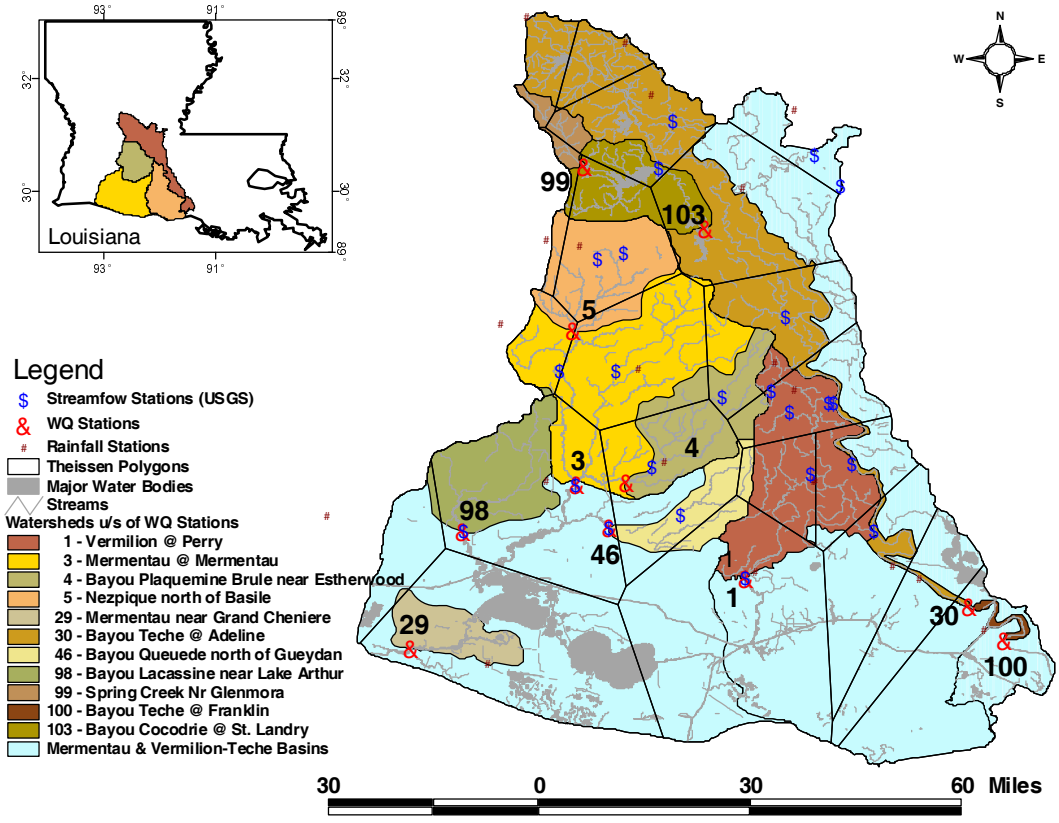

Figure 1. Station network and 11 watersheds in Mermentau and Vermilion-Teche River Basins.

The Mermentau and Vermilion-Teche River Basins are located in the southwestern part of Louisiana and encompasses a drainage area of approximately 17,431 km^2. The Mermentau River Basin has a drainage area of approximately 12,400 km^2. The Mermentau River and its five major tributaries divide the basin into a series of broad, flat areas which are separated by bottomland hardwood riparian corridors, as shown in Figure 1. The Vermilion/Teche Basin on the north and east of the Mermentau basin drains about 5031 km^2 and includes about 1000 km^2 of wetlands. Both river basins are characterized by a dendritic river network, low gradient, and a heavy clay soil. In addition, a dense system of canals for rice irrigation modifies historical overland flow and connects many bayous together such that there may be inter-basin drainage during heavy rainfall events. The two basins are ideal for agriculture and 52% of which was cropland in 2001, primarily rice (34%) and soybeans (17%), as shown in Figure 2. A comparison among the land use maps for the years of 1986, 1991, and 2001 shows that land use change over the period of 1986 – 2001 is less than 3%. Traditional rice-cultivation practices include precision-leveling during water impoundment and releases of rice field water shortly after seeding in the spring months, especially April. The leveling practice increases the erosion of soil. Releases of impounded rice_field water (called “tailwater”) into nearby drainage ditches and bayous can bring large amounts of sediments and agrichemicals (including nutrients) directly into these water bodies. The most significant source of sediment and nutrients in the basins is

suspended solids in wet weather runoff from upland areas. These short pulses of high sediment and nutrient loading in streams can lead to a high biochemical oxygen demand and high turbidity. As a result, the Louisiana 1998 305(b) Report indicates that 95% of the waterbodies within the basins are not fully supporting their designated uses (US EPA 2001, LDEQ 1999). Since 1990, a variety of BMPs, including no-till rice planting, mudding-in with a 15-day setting period, dry cultivation with clear water planting, and mudding-in with a vegetative filter strip, have been implemented in the Mermentau and Vermilion-Teche River Basins through the cost-share assistance provided by various federal, state, and local agencies (Deng et al. 2007). However, the effectiveness of the BMPs in improving water quality has not yet been fully assessed due to the lack of an efficient methodology and significant spatio-temporal variability in hydrological and hydrometeorological parameters controlling water quality.

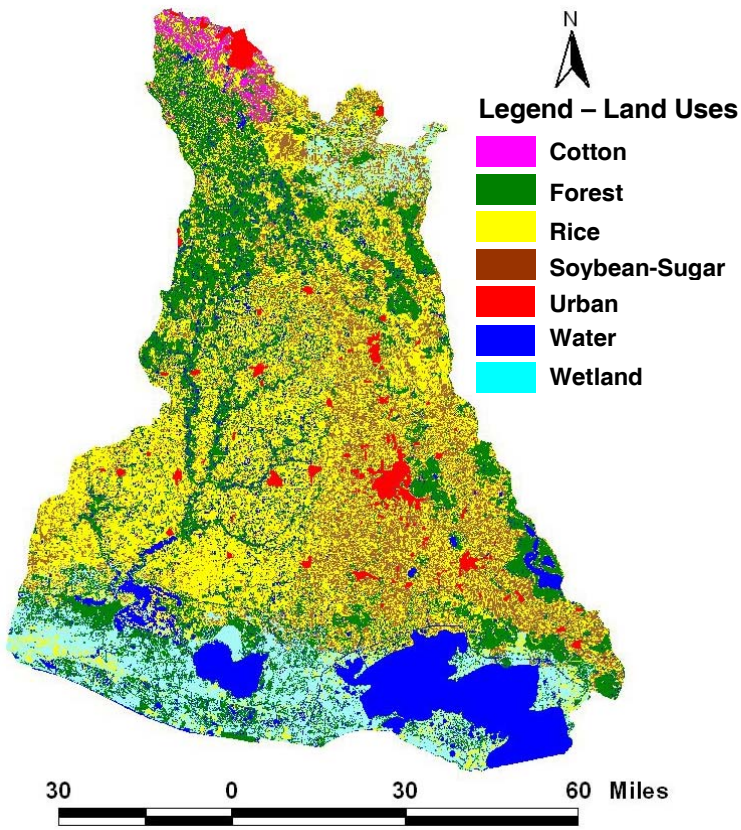

Figure 2. Land use map of Mermentau and Vermilion-Teche River Basins.

The overall goal of this study was to evaluate the effectiveness of BMPs in improving water quality within the Mermentau and Vermilion-Teche River Basins in terms of nutrient impairment. Monthly nutrient data for NO_2+NO_3, TKN, total phosphorous, and TOC) at the outlet of these watersheds, are obtained from Louisiana Department of Environmental Quality for the period of 1980 to 2006. Daily rainfall data for 21 stations for the same period are gathered from the National Climatic Data Center (NCDC). Daily flow data for 22 river gauging stations are available from the National Water Information System (NWIS) of the USGS. Locations of these water quality, rainfall and streamflow stations are shown in Figure 1. Also shown are the Theissen polygons that are used for obtaining daily areal rainfall for each of these watersheds.

Due to the temporal and spatial variability of controlling water quality parameters, a statistical approach is utilized. Nutrient loading rates in the two river basins are computed at various temporal scales including daily, monthly, seasonal, yearly, pre-BMPs, and post-BMPs scales for the nutrient parameters NO_2 + NO_3, TKN, TOC, Phosphorous, and NH_3. Based on results of the loading computations maps showing loading rates in the watersheds of the two river basins are also created for the nutrient parameters on a seasonal basis to see seasonal variations and on the pre-BMP versus post-BMP basis to see the effectiveness of BMPs.

MAPPING OF MEAN SEASONAL NUTRIENT LOADS

Maps for mean seasonal nutrient loading rates are created and shown in Figures 3 and 4. Figure 3 shows that high total phosphorous loading rates mainly occur in the watersheds # 1, 5, and 46, especially in spring and winter. Figure 4 indicates that high TKN loading rates mainly occur in the watersheds # 1, 5, and 46, especially in winter. The TOC loading rate distributions over the river basins are similar to TKN and phosphorous. High TOC loading rates also occur in the watersheds # 1, 5, and 46 in spring and winter. High NO_2NO_3 loading rates mainly occur in the watersheds # 1 and 5, especially in spring. Overall, nutrient loading rates vary seasonally and become high in winter and spring and low in summer and fall. The main impairment in winter (January – March) is caused by wet weather runoff (Deng and Chowdhary 2008). The severe impairment in April and May is related to the releases of muddy rice_field water.

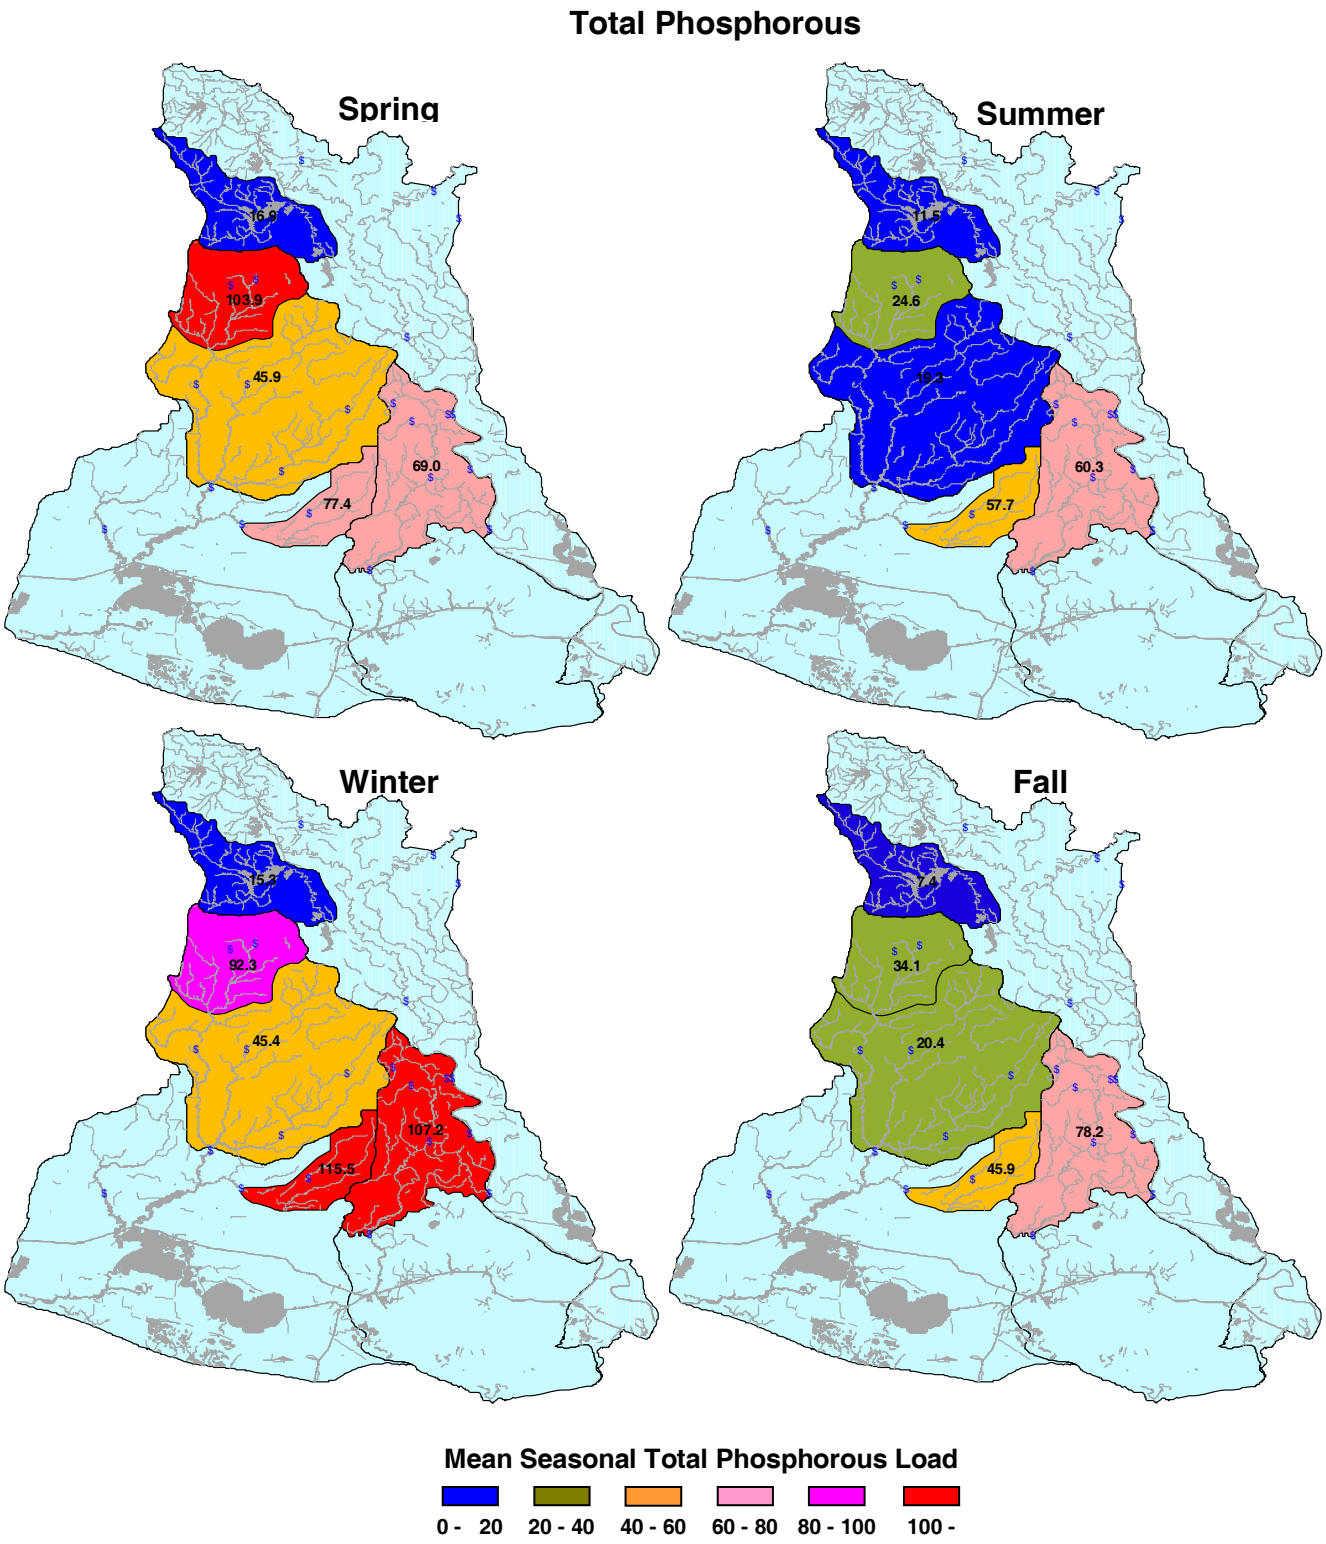

Figure 3. Mean seasonal total phosphorous loading rates (Kg/km^2) in the Mermentau and Vermilion-Teche River Basins.

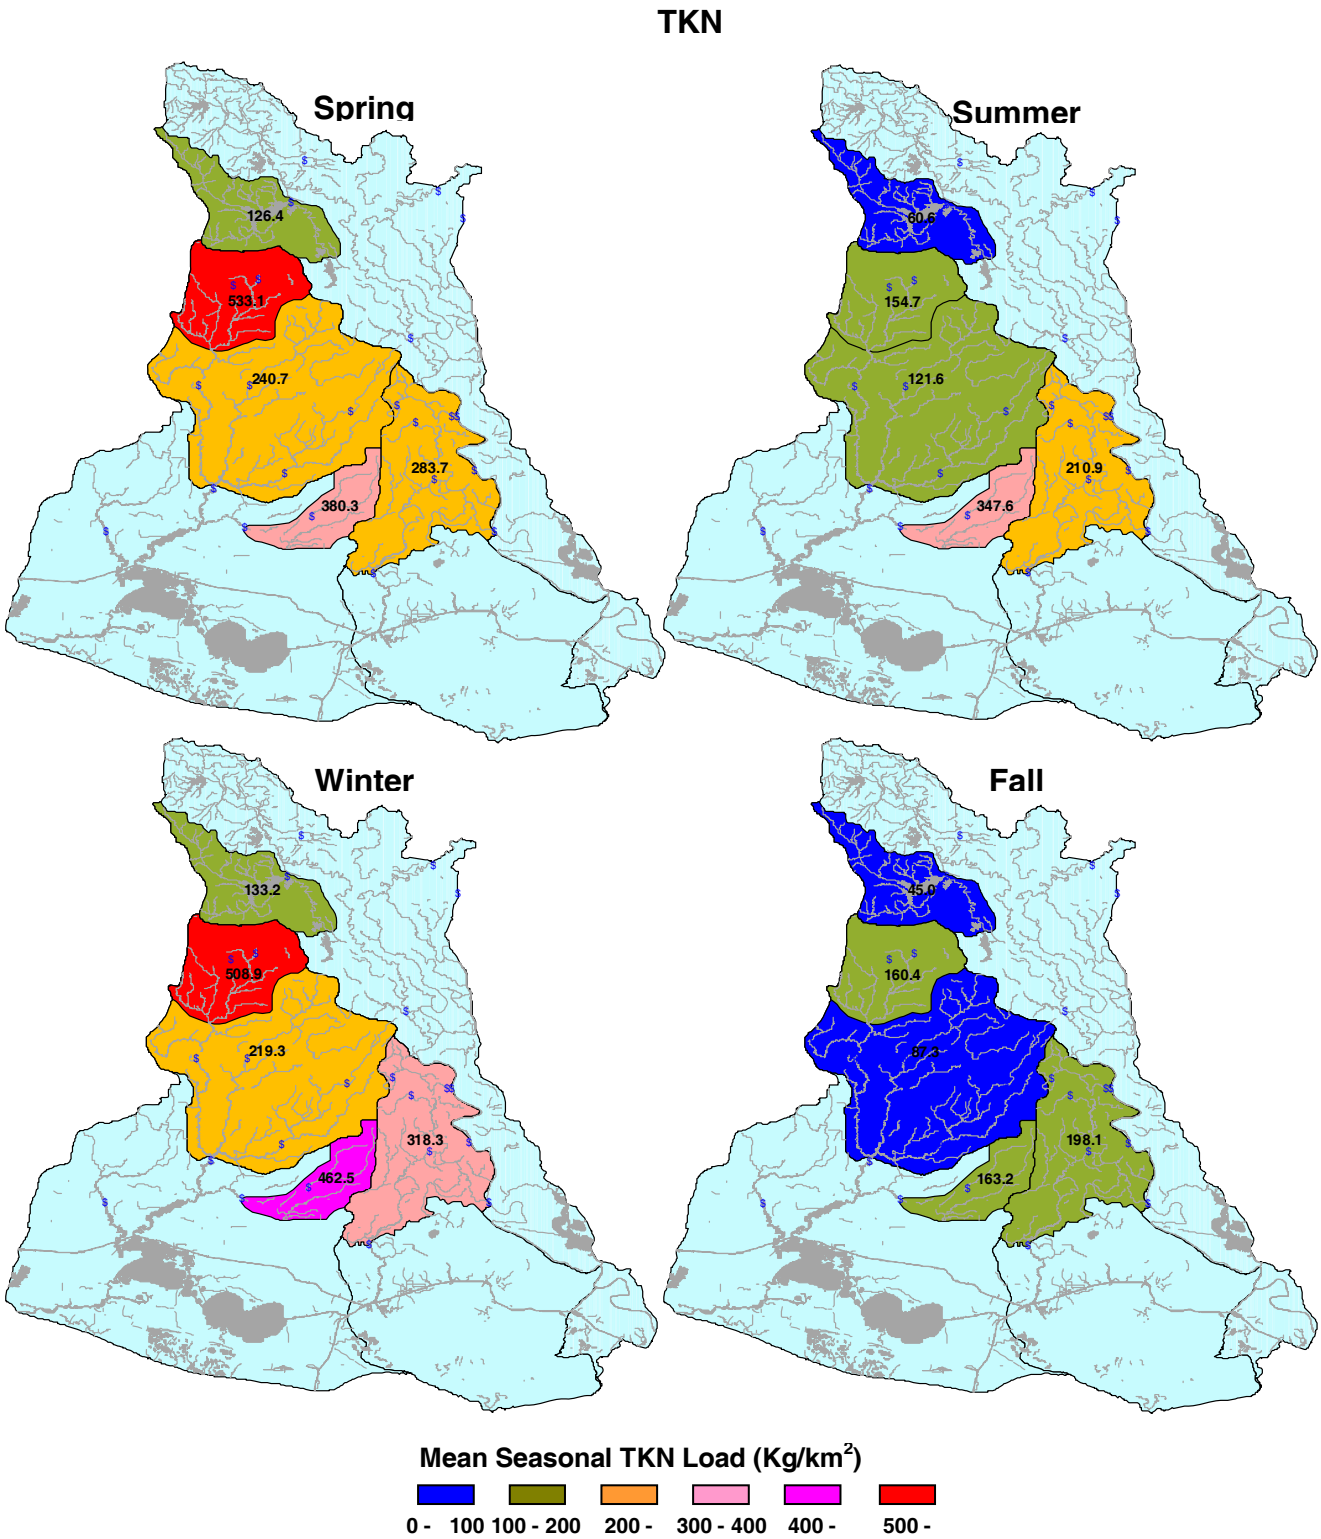

Figure 4. Mean seasonal TKN loading rates in the Mermentau and Vermilion-Teche River Basins.

MAPPING OF MEAN ANNUAL NUTRIENT LOADS FOR PRE-BMP AND POST-BMP

Maps for yearly mean nutrient loading rates are shown in Figures 5 – 7. Figure 5 shows that high TKN loading rates mainly occur in the watersheds # 1, 5, and 46. The TKN loading rate in the watershed #1 has decreased but it increased in the watershed #3 since the implementation of BMPs. The mean yearly loading rates (Kg/km^2) of TKN in the watersheds #1, 3, 5, 46, and 103 are 977.39, 646.79, 1414.65, 1470.12, and 383.04, respectively. Figure 6 shows that high total phosphorous loading rates mainly occur in the watersheds # 1, 5, and 46, especially before the implementation of BMPs. The mean yearly loading rates (Kg/km^2) of total phosphorous in the watersheds #1, 3, 5, 46, and 103 are 296.425, 126.281, 251.072, 317.793, and 52.332, respectively. The TOC loading rate distribution over the river basins is similar to TKN. High TOC loading rates also occur in the watersheds # 1, 5, and 46, as shown in Figure 7. The TOC loading rate in the watershed #1 has decreased but it increased in the watershed #3 since the implementation of BMPs. The mean yearly loading rates (Kg/km^2) of TOC in the watersheds #1, 3, 5, 46, and 103 are 7149.33, 5524.48, 11968.99, 8865.70, and 4633.61, respectively. High NO_2NO_3 loading rates mainly occur in the watersheds # 1 and 5, especially before the implementation of BMPs. The mean yearly loading rates (Kg/km^2) of NO_2+NO_3 in the watersheds #1, 3, 5, 46, and 103 are 302.712, 111.994, 317.757, 141.446, and 22.357, respectively. The mean yearly loading rates (Kg/km^2) of NH_3 in the watersheds #1, 3, 46, and 103 are 138.268, 95.467, 29.174, and 83.794, respectively. Overall, there are no significant variation trends in the nutrient loading rates at the river basin scale although some loading rates decrease but others may increase in some watersheds.

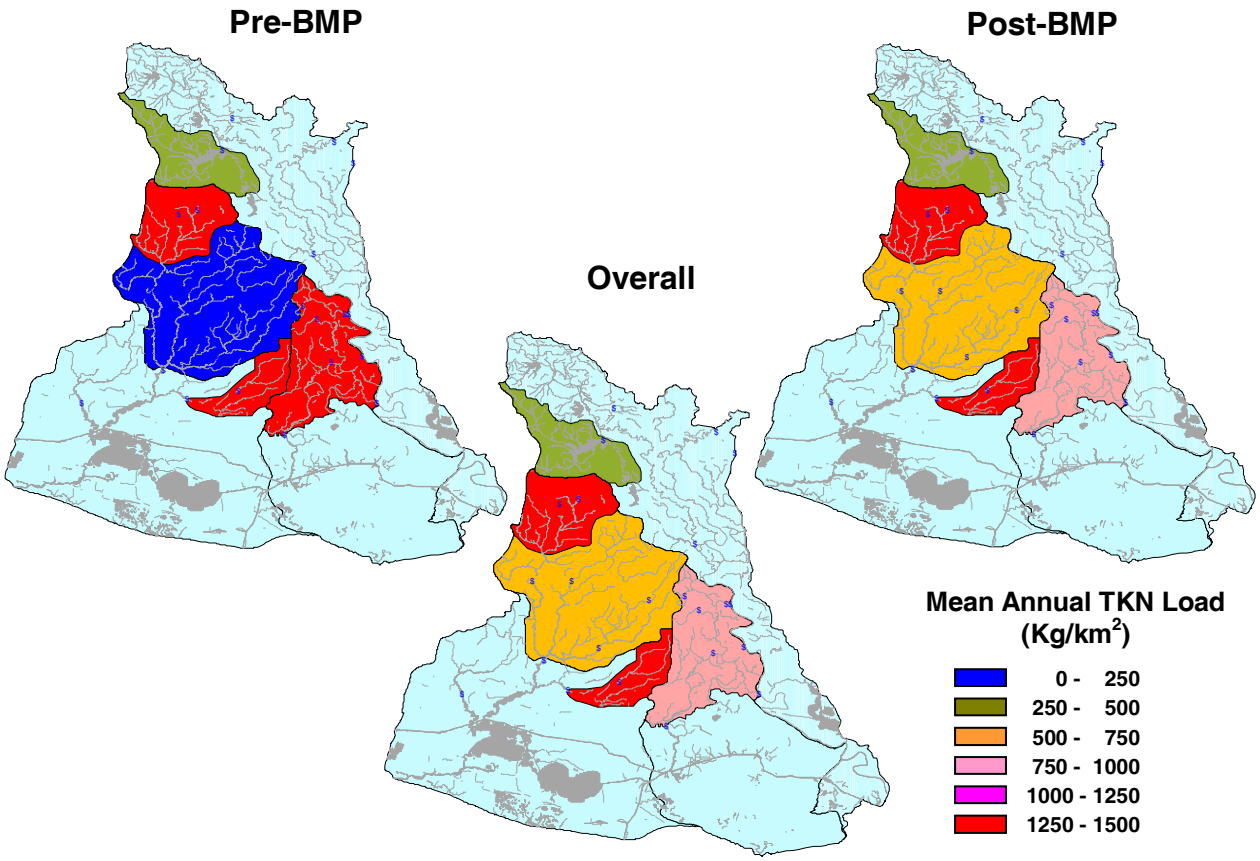

Figure 5. Yearly mean TKN loading rates before and after the implementation of BMPs.

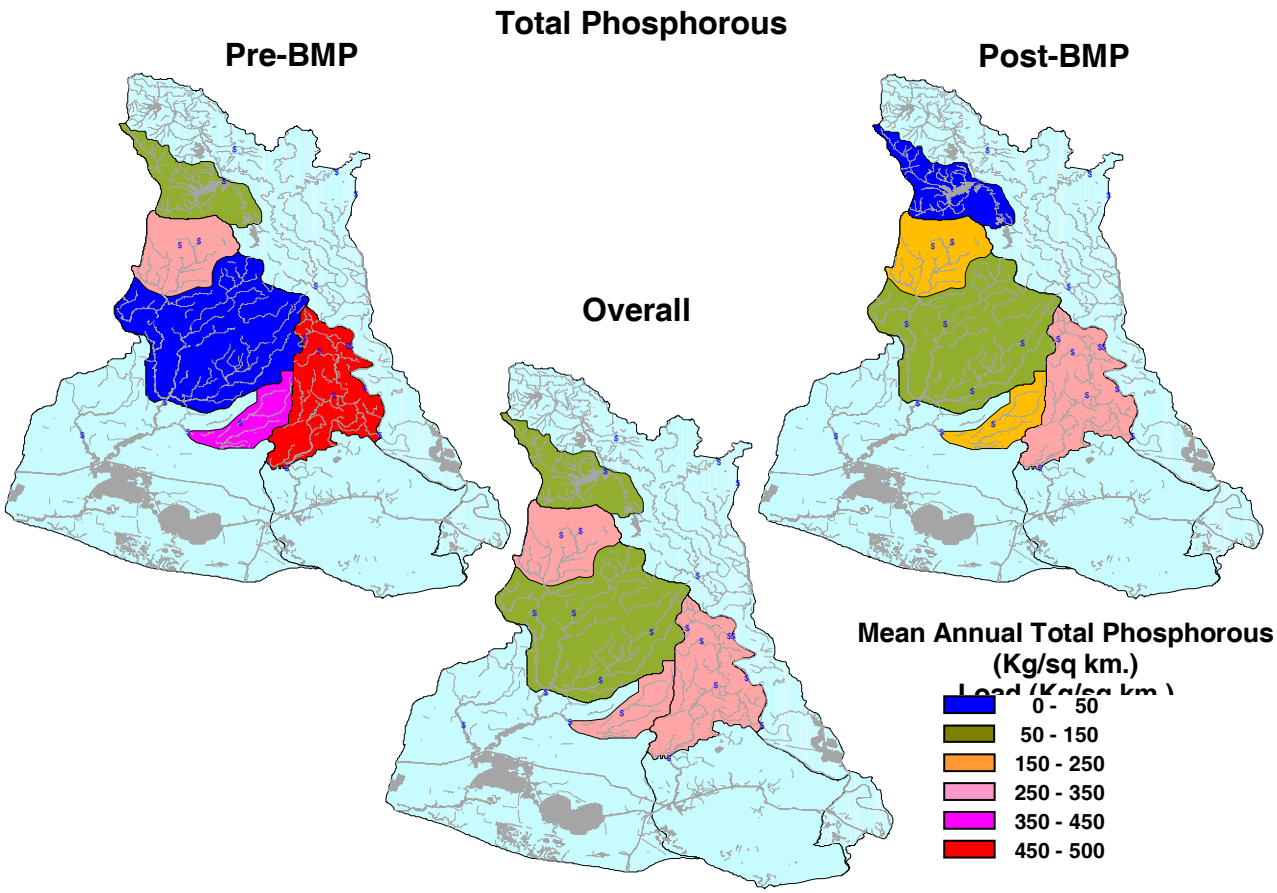

Figure 6. Mean yearly Total Phosphorous loading rates before and after the implementation of BMPs in the Mermentau and Vermilion-Teche River Basins.

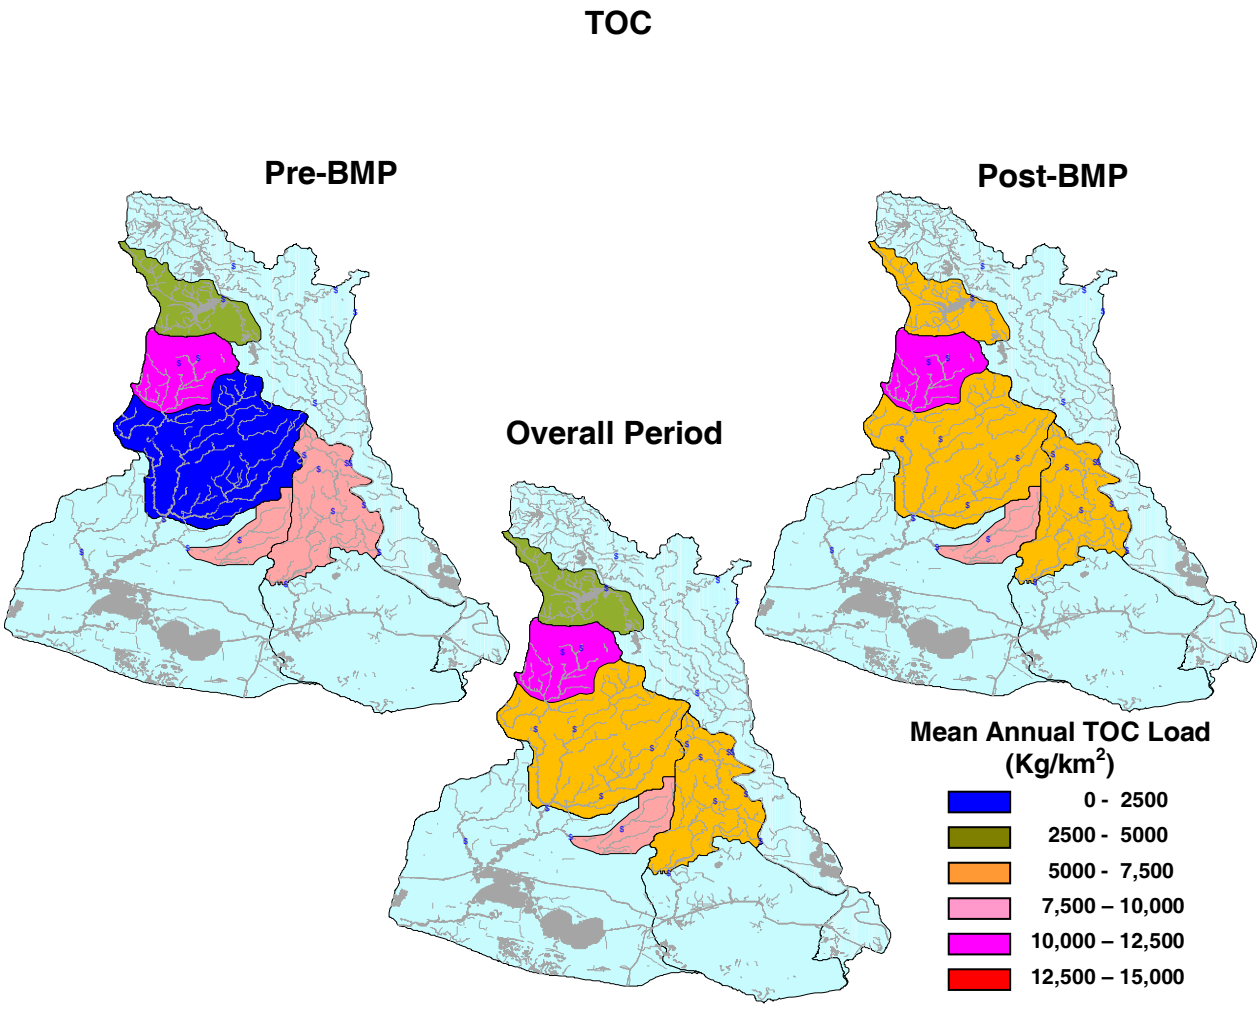

Figure 7. Mean yearly TOC loading rates before and after the implementation of BMPs in the Mermentau and Vermilion-Teche River Basins.

CONCLUSIONS

Based on the results of this study the following conclusions can be drawn:

(1) Nutrient loading rates vary seasonally and become high in winter and spring and low in summer and fall generally.

(2) There are no significant variation trends in the loading rates at the river basin scale although some loading rates decrease but others may increase in some watersheds

(3) The nutrient impairment in winter is primarily caused by wet weather runoff.

(4) The severe pollution in spring is mainly caused by releases of muddy rice_field water, but wet weather runoff makes the water quality even worse.

(5) Since the implementation of BMPs, the water quality in the Mermentau and Vermilion-Teche River Basins has shown some improvements. The most polluted areas in the basin are the two watersheds Bayou Queue de Tortue and Bayou Nezpique, followed by the watersheds Bayou Plaquemine Brule and Bayou Lacassine.

(6) BMPs in the basins need to be enhanced to meet water quality standards.

ABSTRACT

Data mining has been described as "the search for valuable information in large volumes of data", with its defining characteristic being large datasets, or "big data". In every domain, including the environmental sciences, big data's ubiquitous, massive databases comprise millions and even billions of records, and are the consequence of the powerful, low cost monitoring and computing technology that has evolved over the last three decades. The state-of-the-art models now used for natural resource management and control, such as finite-difference hydrologic and land use models, are time consuming and expensive to develop, and are based on approaches that predate the availability of big data and data-mining technology. The representations of process physics in these types of models can be inherently too simplistic for some applications, which is underscored by their limited ability to incorporate all available data types, including hydrologic, water-quality, and meteorological time series from many sites; and categorical parameters that describe site-to-site differences such as basin characteristics and land uses. Reducing large numbers of parameters to a select subset to accommodate model limitations can lead to model uncertainty, subjective decision-making, and delayed formulation and implementation of management decisions and plans.

This paper describes a new divide and conquer approach that leverages big environmental data, utilizing all available categorical and time-series data without subjectivity, to empirically model hydrologic and water-quality behaviors across expansive regions. The approach decomposes large, intractable problems into smaller ones that are optimally solved; decomposes complex signals into behavioral components that are easier to model with "sub-models"; and employs a sequence of numerically optimizing algorithms that include time-series clustering, nonlinear, multivariate sensitivity analysis and predictive modeling using multi-layer perceptron artificial neural networks, and classification for selecting the best sub-models to make predictions at new sites. This approach has many advantages over traditional modeling approaches, including being faster and less expensive, more comprehensive in its use of available data, and more accurate in representing a system's physical processes. This paper describes the application of the approach to model ground-water levels in Florida, stream temperatures across Western Oregon and Wisconsin, and water depths in the Florida Everglades.

INTRODUCTION

Managers of expansive natural systems often use predictive models to help them make decisions. Models typically are developed from existing or newly collected data. The data used to develop the models should fully represent the diversity of behaviors exhibited across the natural system and may consist of categorical parameters, such as land use or geology, or represent dynamics with time series, also know as signals. The mechanics of integrating multiple data types and reducing large numbers of parameters to a select set often leads to subjective decision-making, which may have important ramifications when applying state-of-the-art multi-step modeling approaches, for example, land-use models driving streamflow models. These models often fail to accurately reproduce observed behaviors because their representations of complex process physics can be too simplistic for some applications, which is underscored by their limited ability to incorporate all available data types, including hydrologic, water-quality, and meteorological time series from many sites; and categorical parameters that describe site-to-site differences such as basin characteristics and land uses.

Weiss and Indurkhya (1998) describe the emerging field of data mining as "the search for valuable information in large volumes of data", with its defining characteristic being large datasets, or "big data". In every field big data's ubiquitous, massive databases comprise millions and even billions of records, and are the consequence of the powerful, low cost monitoring and computing technology that has evolved over the last three decades. While large databases for environmental systems are common, they are usually under interpreted and utilized. Data-mining methods come from different technical fields such as signal processing, statistics, and artificial intelligence (AI), and are used extensively in financial services, banking, advertising, manufacturing, and e-commerce. Data mining employs methods for maximizing the information content of data, determining which parameters have the strongest relations to problems of interest, and developing models that predict future outcomes. This knowledge encompasses both understanding cause-effect relations and predicting the consequences of alternative actions.

This paper describes a new approach for modeling expansive natural systems directly from big data. It employs a number of data-mining algorithms that address the full complexity of these systems in a numerically optimized way. This paper also describes how this powerful technology has been successfully applied to modeling ground-water levels in a Florida aquifer, stream water temperatures in Oregon and Wisconsin, and water depths in the Florida Everglades.

NEW APPROACH

Given that environmental systems can appear intractably complex from the data in hand, a "divide and conquer" approach is needed for developing numerically optimized models by employing multivariate, numerically optimizing methods such as clustering, classification, and nonlinear empirical modeling.

Sub- and Super- Models. At the top level, the new approach uses the concept that a process model of a system is a "super-model" composed of multiple "sub-models". Sub-models are numerically optimized to compute output signals that can be combined to predict complex output behaviors resulting from multiple, interacting physical forces.

Time-Series Clustering. Time-series clustering is used when uncertainty exists about whether a region to be modeled should be sub-divided because of spatial differences in the underlying physical processes. For example, localized pumping can cause gradual or dramatic differences in ground-water behaviors between monitoring sites. Time-series clustering optimally groups (segments) monitoring sites or populations of signals into behavioral classes without subjectivity, allowing different classes to be optimally sub-modeled. The signals that comprise a class are called class "members". To perform time-series clustering, a cross-correlation matrix created for signals of interest is clustered using a clustering algorithm such as the k-means algorithm or others (Goddard and Martinez, 2000). The optimal number of classes "k" to be used is estimated by evaluating the sensitivity of the clustering algorithm's error to k.

Signal Decomposition. Signals can have multiply periodic behavioral components, for example tides are modulated by the attraction between the earth, moon, and sun. Periodicity is by definition highly predictable; however, signals can also display dramatic spatial and temporal variability due to chaotic forcing by humans and weather. Chaotic behaviors are by definition only somewhat predictable, yet it is these behaviors that modelers strive to reproduce. Techniques such as spectral band-pass and moving window average difference filtering can "decompose" a signal to separate the periodic components, leaving behind chaotic components.

Signal decomposition reduces the difficulty of modeling signals with individual sub-models. Subsequently, a super-model combines the outputs from multiple, individually optimized sub-models. This approach can greatly improve the representativeness and accuracy of an empirical process model. Roehl and Conrads (2006) detail the use of "multivariate state space reconstruction" as a method to decompose and model estuary salinity intrusion events using flow and water-level signal component as inputs to artificial neural network sub-models, which were combined into a super-model. For the study area's most inland monitoring site, the determination coefficient R^2, calculated from the Pearson coefficient of the field measurements and super-model predictions for a 6-month drought period, was 0.90 versus an R^2=0.10 for predictions made by a three-dimensional (3D) state-of-the-practice finite-difference hydrodynamic model of the same system (Conrads and Greenfield, 2008).

Spatially Interpolating ANN Models. Environmental systems usually exhibit complexities such as chaotic behaviors and nonlinear relations among parameters, and it is important for modeling methods to accommodate them. The field of Artificial Intelligence offers machine learning algorithms such as artificial neural networks (ANN) for different purposes (Hinton, 1992). An ANN is a flexible mathematical structure based on the biological nervous system. The multi-layer

perceptron (MLP) ANN, as described Jensen (1994) and used here, is "trained" on a database organized into multivariate vectors of input-output data. The training of ANNs synthesizes complex, continuously differentiable, nonlinear functions to near-optimally fit example populations of input-output vectors. In comparison, the ubiquitous ordinary least-squares curve-fitting algorithm only fits prescribed functions, such as planes or hyper-planes, whether the prescribed function describes the actual parameter relations or not.

A study by Conrads and Roehl (1999) found that ANNs offered a number of advantages over finite-difference physics-based models in reproducing the dynamic flow and water-quality behaviors in an estuary. Most importantly, the ANNs gave much better prediction accuracy when using the same input and output parameters and data. Coppola and others (2005) made some of the same observations after applying ANNs to forecast water levels at two monitoring wells in an aquifer affected by climatic parameters and pumping. ANNs can provide near optimal multivariate nonlinear curve fitting for dynamic, nonlinear environmental processes when: the data are well distributed throughout the historical range of conditions of interest; and the input parameters selected by the modeler share significant “mutual information” about the output parameters.

A benefit of finite-difference and finite-element models is their ability to provide spatially semi-continuous predictions from mesh nodes. Similarly, Dowla and Rogers (1996) used a "radial basis function" ANN to provide spatially continuous but temporally static 3D land elevations. This paper's new approach employs ANN models that are configured to simultaneously predict spatial and temporal variability, made possible by using spatial coordinate input parameters with a "stacked" training database. The input coordinates represent the sites where the training output values were measured. For run-time application, the coordinates are for a "new site" where the user wants the model to make a prediction. It is left to the super-model's machinery to "classify" the user's new site coordinates to select the most appropriate sub-model(s) to execute. The outputs of two or more class's sub-models can be averaged for sites that lie on or near class boundaries. A stacked database is used to train ANNs to interpolate between values of spatial coordinates and other categorical parameters. In flat file format, each monitoring site is represented by a block of rows denoting time stamps and columns denoting candidate input and output parameters.

New Site Classification. Some modeling applications must make predictions at new sites where no data of the type being predicted has been collected. A new site can be described by categorical parameters such as spatial coordinates and land uses. For a new site's categorical input values, the super-model application determines which behavioral class's sub-model(s) should make the prediction. This can be handled by programmed logic and/or use of a classification algorithm such as the linear k-nearest neighbor classifier or a nonlinear MLP ANN classifier (Holmstrom and others, 1997).

APPLICATIONS

Four applications of the new approach are provided to illustrate its efficacy on a range of problems having interesting conceptual differences. They predict ground-water

levels in Florida, stream temperatures across Western Oregon and Wisconsin, and water depths in the Florida Everglades.

Upper Floridan Aquifer water levels in the Suwannee River Valley. This model was a development test bed for the new approach, and was first described by Roehl and others (2006). Here, the big data were provided by the study area's (Figure 1) water-resource managers, who were interested in determining how to defensibly reduce the size of their extensive network of approximately 200 wells monitoring the Upper Florida Aquifer.

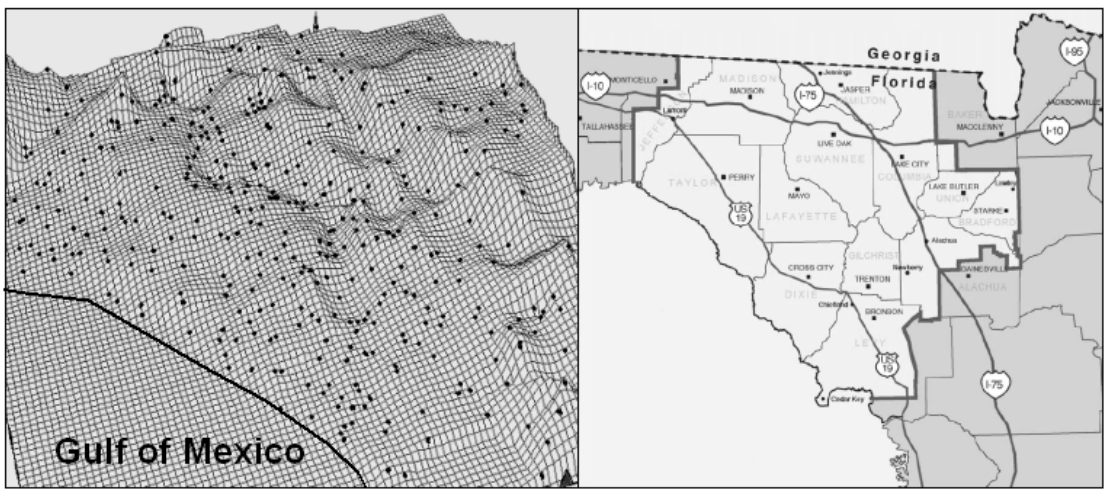

Figure 1. Monitoring well locations on 1x1 km^2 grid (left) on approximate 160x160 km^2 study area (right).

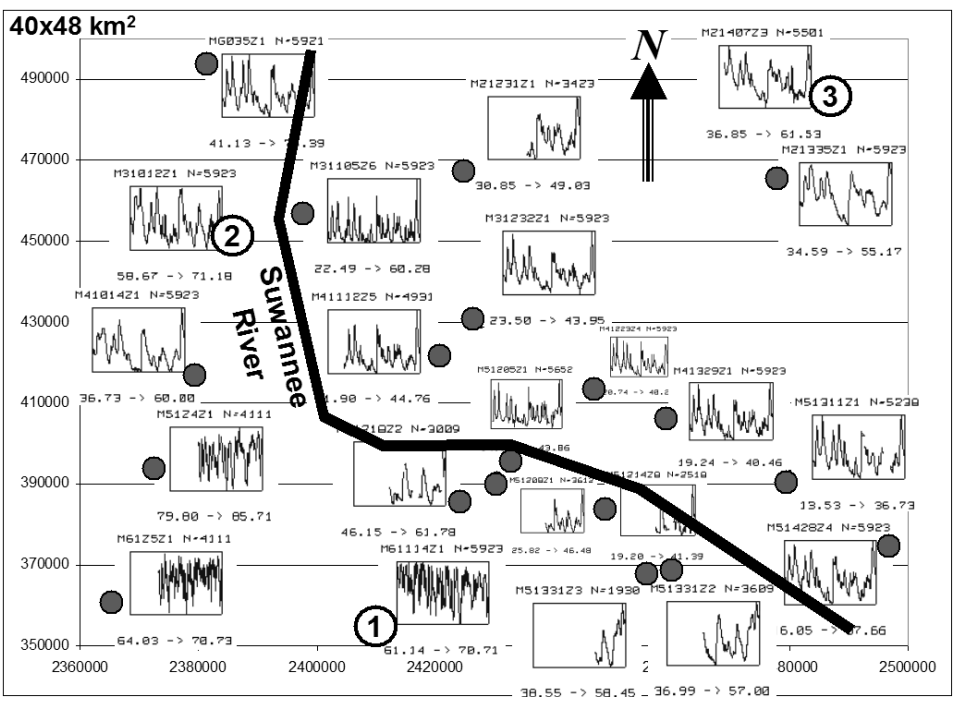

Figure 2. Well locations and daily water levels from 1982 to 1998 in an approximate 40x48 km^2 sub-region of the Suwannee River Valley.

Figure 2 shows an approximate 40x48 km^2 sub-region of the study area with daily measured water-level signals from 1982 to 1998 superimposed next to their well locations. Note that the signals of the three numbered wells are dissimilar, especially well 1, which is completely different from its neighbors to the northeast. This infers a spatial discontinuity in the process physics that would be problematic for both physics-based and empirical model approaches. The new approach segments the signals into different behavioral classes using time-series clustering. Figure 3 shows normalized signals for 2 of 12 classes. It is apparent that the members of each class are similar, and dissimilar to those in the other class.

A side benefit of time-series clustering is that it answers the question, *"Which monitoring site's signals are redundant and possibly unneeded?"* Time-series clustering offers a defensible pathway to optimizing data collection networks with respect to the quality of the information gathered for a given cost.

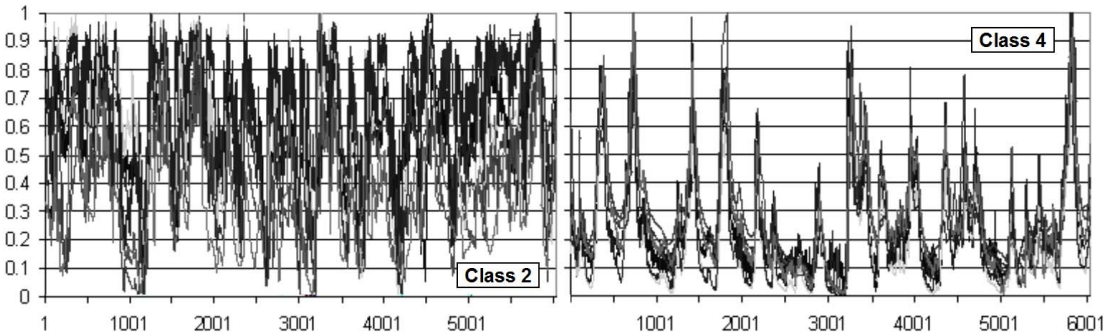

Figure 3. Normalized water-level signals for Classes 2 and 4. The x-axis is in days from April 1982 to October 1998.

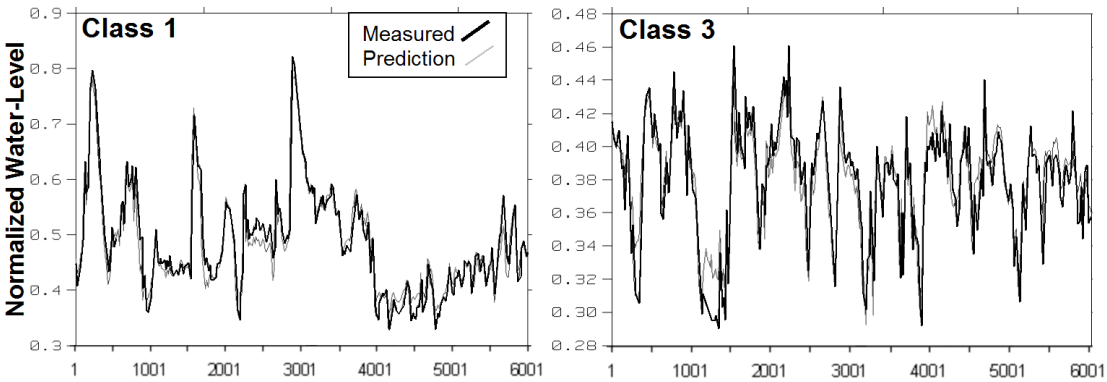

Figure 4. Measured (black) and predicted (gray) normalized water levels for example Class 1 and 3 wells. Here, each signal was normalized using the historical minimum and maximum water levels of all signals in its class.

A divide and conquer approach was also used to model each class's members by cascading sub-models that predict the historical mean and then the dynamic signal components. Sub-models model-1i (i = 1 to k, k=12) were trained for each class to predict the historical mean water levels of its members. These models were quasi-autoregressive, using inputs representing the signals of each class's members plus the spatial coordinates of each output value. A second, autoregressive, sub-model

(model-2i) was trained to predict the dynamic components of the members of each class. The inputs to model-2i were the outputs from model-1i plus the signals of the constituent class members and their spatial coordinates. Figure 4 shows that the sub-model pairs achieved good accuracy in predicting the water levels for typical examples of Class 1 and Class 3 signals.

The next step was to classify regions of the study area so that the most appropriate model class would be applied to a new site. As shown at left in Figure 5, the study area was divided into 1-km^2 cells. All of the cells were assigned to a class by kriging the class assignments of the cells having wells. The kriging method used 12 identical grids, one for each class, on which cells having wells were assigned a 1 or a 0 depending on whether the well was a member of the map's represented class. Each map was kriged and those cells having a value of 0.5 or greater were assigned to the map's class. The kriged maps were then superposed to compile the class assignments. Few cells were found to have been assigned to multiple classes.

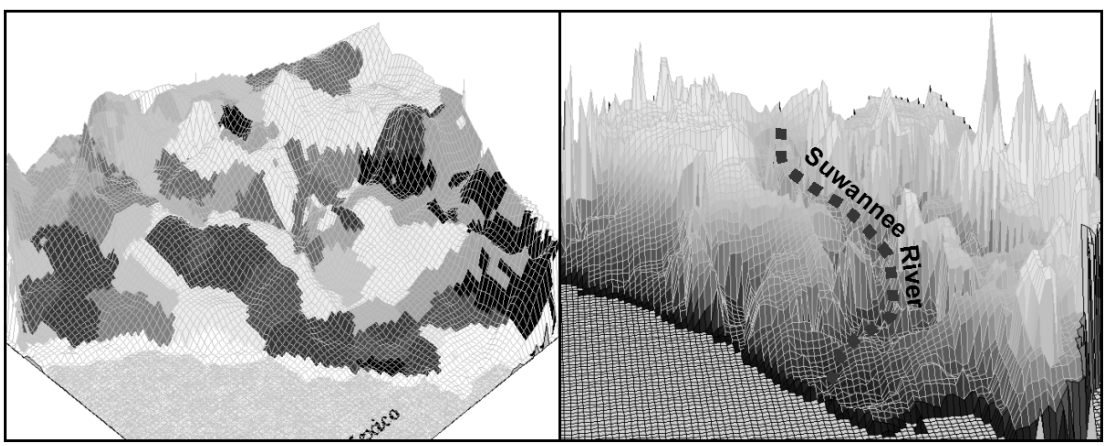

Figure 5. Grid with color-coded class assignments (left) and an aquifer water-level surface (right) predicted by the super-model.

The super-model comprised 12 cascaded sub-model pairs, one pair for each class, for a total of 24 separate ANNs. It was assembled in a spreadsheet program that could run simulations to predict spatially-continuous aquifer surfaces at each time step (Figure 5 right). Long-term simulations revealed highly asynchronous spatial and temporal water-level variability that are caused by rainfall, pumping, and flow.

Western Oregon Stream Temperatures. This model predicts "unimpaired" water temperatures (no anthropogenic influences) in 1st, 2nd, and 3rd order streams in the western third of Oregon, and was first described by Risley and others (2003). Stream temperature is an important parameter for assessing the ecological status of stream segments. The model was developed to support the implementation of the Total Maximum Daily Load requirement under section 303(d) of the Clean Water Act.

Here, the big data was composed of stream temperature, climate, stream habitat, and basin parameters. The stream temperatures were hourly signals collected at 148 unimpaired sites from June to September 1999 (Figure 6). The sites were located on streams that drained basins ranging from 0.3 to over 300 km^2. Site elevations ranged from 7 to 1,445 meters above mean sea level. Six of the 148 sites

were randomly withheld from model development for validating results. The climate parameters were 65 hourly signals of air temperature, dew-point, solar radiation, barometric pressure, snowpack, and precipitation from 25 sites. The stream habitat and basin attributes comprised 34 categorical parameters that included stream bearing, gradient, canopy cover, wetted widths, depth, and bed substrate; and basin topographic and vegetation characteristics such as size and forest cover.

Relative to the Upper Floridan Aquifer model, this problem had a more complex and varied database, and model development was further complicated by a requirement to predict hourly rather than daily output values from which summarizing statistics could be calculated. This indicated a need for three cascaded sub-models for each behavioral class to predict in succession historical mean, daily, and hourly stream temperatures. A second issue was the large list of candidate categorical and dynamic inputs whose interrelations and predictive performance were unknown. Many of the potential input parameters were multicollinear. A third issue was that new site classification could not be based solely on spatial coordinates because of the strong influences of habitat and basin parameters.

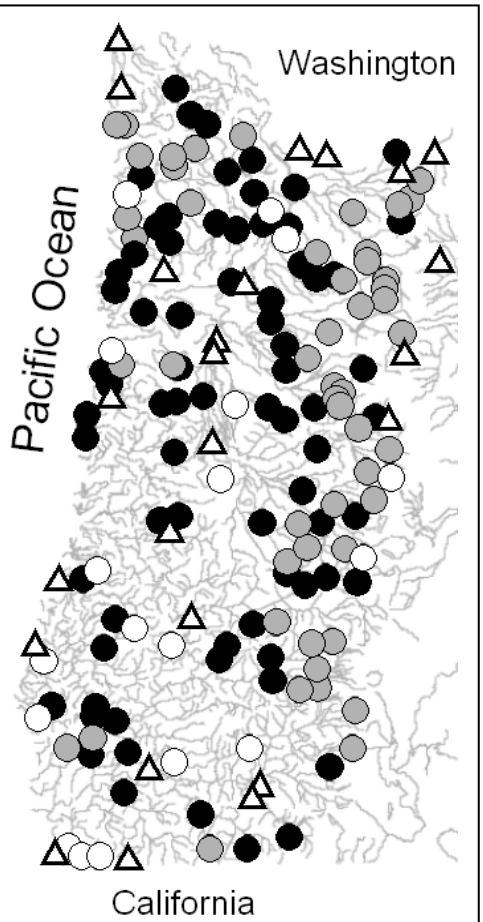

Figure 6. Western Oregon study area. Class 1, 2, and 3 sites are white, gray, and black circles respectively. Triangles mark climatic and snowpack sites.

Signal processing consisted of computing a historical mean and 24-hour (1-day) moving window averages for each hourly signal. The 1-day stream temperatures signals were normalized relative to their individual ranges and time series clustering segmented them into three classes (Figure 6). The Class 1 sites were found to be generally located in warmer sub-regions at lower elevations and in the southern portion of the study area. This includes the Klamath Mountains ecoregion and the Willamette River valley lowlands. The Class 2 sites were more predominant at higher elevations, particularly in the Cascade Mountains. The Class 3 sites were widely distributed at middle elevations. The climatic signals tended to be highly correlated site-to-site, so they were decorrelated by setting one site to be a "standard" for each parameter type and calculating differences from the standard at the other site.

The divide and conquer approach cascaded three sub-models that predict the historical mean, 1-day, and hourly stream temperature signal components. For modeling, the 1-day stream temperature signals were normalized by subtraction from

their means, and the hourly signals were normalized by subtraction from their 24-hour moving window averages. A single ANN sub-model (model-1) was trained to predict the historical mean stream temperatures for all three classes from only categorical input parameters. To predict the normalized 1-day stream temperature components, sub-models model-2i (i = 1 to k, k=3), were trained for each class. Their inputs were selected categorical parameters and 1-day climatic time-series parameters. To predict the normalized hourly components, sub-models model-3i were trained for each class. Their inputs were selected categorical parameters and hourly climatic parameters. The outputs of model-1 and model-2i are summed to predict 1-day stream temperatures, and the outputs of all three sub-models are summed to predict hourly stream temperatures. For each sub-model, the final sets of categorical parameters and climatic time series inputs were arrived at experimentally according to their predictive performance and lack of collinearity. The most important input parameters included air temperature, riparian shade, site elevation, and basin percent forested area.

The new site classifier was developed using ANNs, making it a nonlinear classifier. It was composed of three ANNs, one for each class. Each class's ANN was trained to predict a binary 0 or 1 depending on if a new site's habitat and basin attributes matched those of its member sites. Generally, the class whose classification ANN predicts the highest output indicates the new site's class, with programmed logic being used to resolve ambiguous cases.

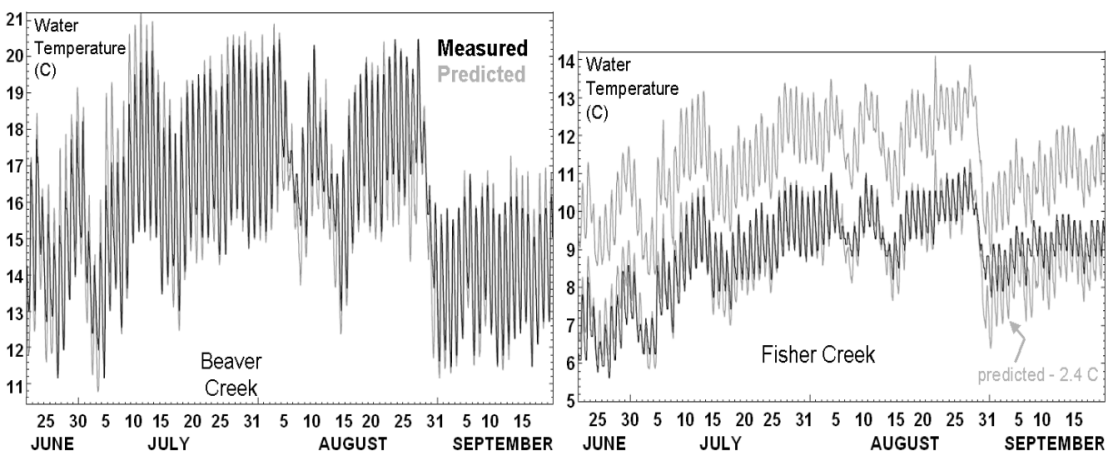

Figure 7. Measured (black) and predicted (gray) hourly stream temperatures at two validation sites.

The super-model is composed of one historical mean sub-model, 1-day and hourly sub-models for each of the three stream temperature classes, and three classification models for a total of 10 separate ANN models. It was assembled in a spreadsheet program that runs simulations using the historical climate input data with categorical input values set for new sites. The simulations predict stream temperature signals that are characterized statistically. Figure 7 shows measured and predicted hourly stream temperatures at the "best" and "worst" of the six validation sites. Both predictions track the climatically-forced dynamic behaviors; however, the Fisher Creek predictions are offset from the measurements by an average of 2.4 C. The offset is

due largely to the error in the predicted historical mean stream temperature caused by the process used to characterize and collect habitat and basin information. A contributing factor is how the validation sites were selected. Here, random selection was used. These results indicate that the Fisher Creek site possesses attributes that are substantively different from the training sites, and unlearned and poorly represented by the empirical model.

Wisconsin Stream Temperatures. This project sought to develop an ANN-based model using landscape and climatic time series data to predict stream temperature signals for stream segments throughout Wisconsin, and was first described by Stewart and others (2006). It was believed that the state-of-the-practice linear modeling approach is not applicable to larger regions where climate factors are heterogeneous. Here, the big data was similar to that used on the Western Oregon model. The stream temperatures were half-hourly signals recorded from June 1 to August 31 in 254 wadeable streams during a 13 year period from 1990 to 2002. No site was measured for more than two years, and most were measured only one year. Daily mean water temperatures were calculated and served as the output parameter of interest. The climate signals were from sites across Wisconsin and consisted of 7 air pressure, 156 air temperature, 13 dew point, 164 precipitation, and 13 solar radiation signals for a total of 353 signals. Forty-two categorical parameters described the basin and stream network characteristics for the watersheds, 60-meter buffers, and the stream network associated with each stream segment. These were culled to 20 parameters using a cross correlation matrix that identified collinear pairs.

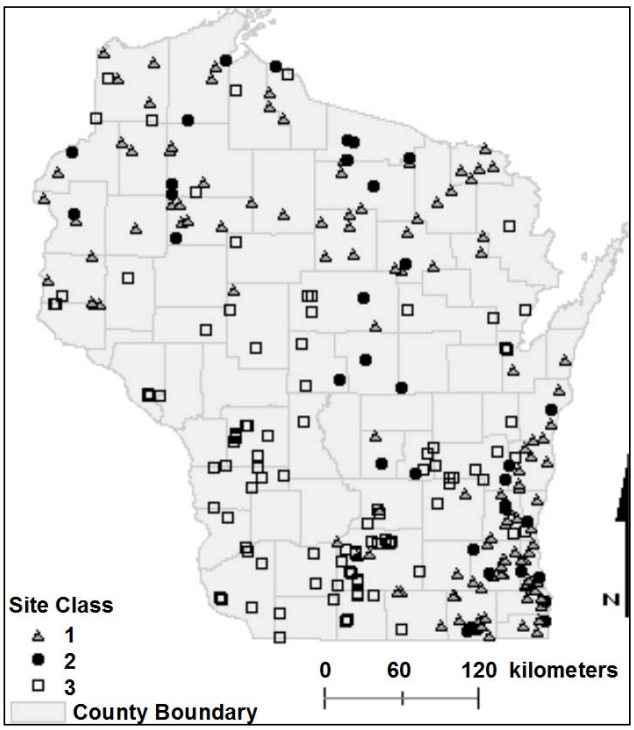

Figure 8. Distribution of 254 stream sample sites identified by class (right).

A few issues made this model more complicated to develop than the Western Oregon model. The large number of climatic signals was too unwieldy to be used directly and required a method for reducing them that would retain potentially important information about stream temperature variability. This was accomplished by clustering the climatic signals using the times-series clustering method. Mean signals for each class were synthesized by computing the daily means of the class members. The mean signals were then decorrelated by assigning one to be a standard signal and calculating differences for the others. This greatly reduced the number of climate parameters to 20 while preserving a semblance of spatial variability.

A second issue is that climate behavior drives stream temperature temporal variability, and daily variability changes greatly year-to-year for any specific calendar period. Here, the population of stream temperature signals were scattered over 13 years, preventing the use of the time-series clustering method and the modeling of the response of all the sites to coincident climatic forcing. An "alternate" time-series clustering algorithm was developed to accommodate the lack of coincident stream temperature signals, consisting of the following steps.

a. Where possible, populations of overlapping signals are compiled.
b. Using time-series clustering, estimate how many classes should be created for each population, then select a single number of classes to be used for all of them.
c. Reapply time-series clustering algorithm to each population using the number of classes determined in (b).
d. Determine which categorical parameters best discriminate between population classes using sensitivities determined from prototype ANN classification models.
e. Use a scoring method to determine which categorical parameters are consistently the best at discriminating between classes for all of the populations.
f. Re-cluster all sites using the important categorical parameters identified in (e).

The alternate algorithm was employed as follows. Streams sampled during the summers of 1998 to 2002 made up 241 of the 254 total sites. They provided five populations in step (a). In step (b) the number of classes was determined by the sensitivity of the mean square error computed by the k-means algorithm. The number chosen was three, which corresponded to low, medium, and high correlations between stream temperatures and climatic forcing. After steps (c) and (d), the scoring method used in (e) was based on how frequently a parameter survived culling in the development of the prototypes classification ANN models, and the sensitivity of the prototype's prediction R^2 to having the parameter included. The top categorical parameters for class discrimination were those that describe land use, upstream drainage area, bedrock depth, and surficial texture. While step (f) produces a linear segmentation of sites, it does so using parameters that were found in step (d) to be the best at discriminating site-to-site behavior by a reliable nonlinear ANN-based method. Site classification results are shown in Figure 8.

Results from the alternate algorithm were used to develop a separate sub-model for each class. Cascaded models were not needed because of the daily time step and the limited dynamic range of the June-August recording periods. Of the 254 sites, 223 were used for training and 31 were set aside for independent validation. The sub-models were trained to predict daily mean stream temperature signals for the June-August periods from 1990–2002. The inputs were selected categorical parameters and mean climate time series parameters. The six decorrelated air temperatures were found to be the best predictor climate parameters, and were included in the models for all three classes. The best categorical parameters, which were also included in all models, were drainage area, Darcy values for watershed and buffer areas, and watershed water and wetland land cover percentages.

A nonlinear classifier for new sites was developed in the same manner as that for the Oregon model. The super-model is composed of one sub-model per class and three classification models for a total of 6 separate ANN models. It was assembled in a spreadsheet program that runs simulations using the historical climate input data and categorical input values set for new sites. The simulations predict June to August stream temperature signals for the years 1990–2002 that are then characterized

statistically. Figure 9 shows measured and predicted hourly stream temperatures at 14 Class 1 validation sites. The sites' signals have been concatenated together. These results are typical of the other models. It is apparent that the prediction tracks the dynamic variability in the measurements, but generally runs either high or low for each site. As was the case for the Western Oregon stream temperature model, this indicates that the primary sources of error are the categorical parameters that predict the mean behavioral component for each site.

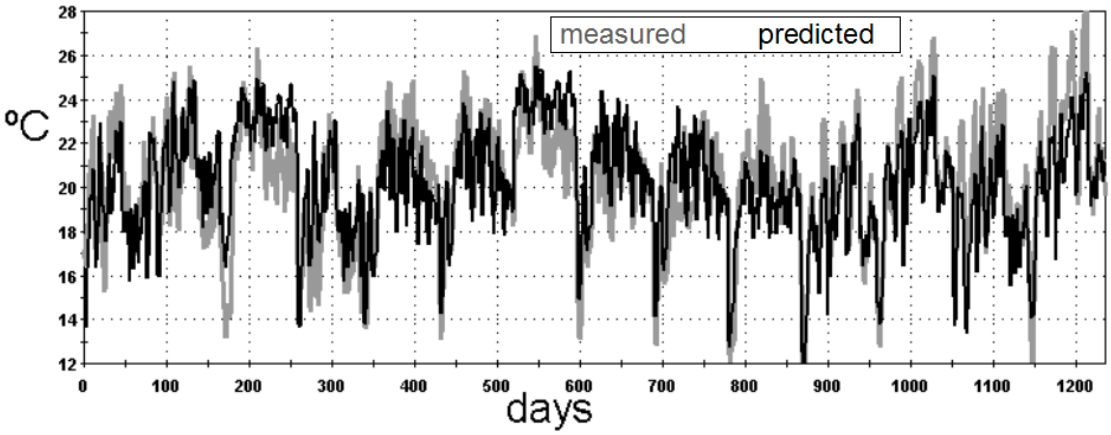

Figure 9. Measured (gray) and predicted (black) Class 1 stream temperatures at 14 validation sites. The 14 time-series are concatenated and show the rise and fall of stream temperature for June–August in the years when they were recorded.

Water Depths in Water Conservation Area 3A in the Florida Everglades. The real-time Everglades Depth Estimation Network (EDEN) supports a variety of scientific and water-management purposes, including the estimation of water depths throughout the greater Everglades from a limited number of reference "gaging" sites. Accurately predicting the water depths at ungaged sites is made difficult by the limited gaging and imperfect knowledge about the complex interactions of topology and vegetation. Linear regression and interpolation techniques are often used to estimate water depths at ungaged locations, however, the dynamic relations between hydrology, topography, and vegetation are nonlinear.

As first reported by Conrads and Roehl (2006), the purpose of this model is to provide better water-depth predictions at ungaged sites in the Water Conservation Area 3A (WCA3A, Figure 10). Note the overlain 400x400 meter^2 grid. This model is similar to the Upper Floridan Aquifer model, but in addition to spatial coordinates, its inputs include categorical parameters that describe each cell's distribution of vegetation types.

Here, the big data comprised water-level and water-depth signals, and categorical parameters representing cell coordinates and vegetation types in percentages of slough, prairie, sawgrass, or upland. The signals were 15-minute time series of water depths from 16 sites (W# in Figure 10) and water levels from 3 sites (Sites 64, 65, and 69 in Figure 10) for the period December 2002 to May 2005. These were reduced to daily values using moving window averages. Note that Figure 10 indicates that 14 of the sites are used for model training - 5 for inputs and 9 for

output. The 5 validation sites were selecting using a filter that identified them to be the least unique according to their categorical parameter values.

A preliminary analysis indicated that good prediction accuracy could be obtained using a single class of water-depth signals. The signals were processed by using the Site 64 water level as a standard and computing the differences between the other water-level and water-depth signals, called the difference-from-the-standard. This effectively set all the water-depth and water-level data to the same datum and decorrelated the signals.

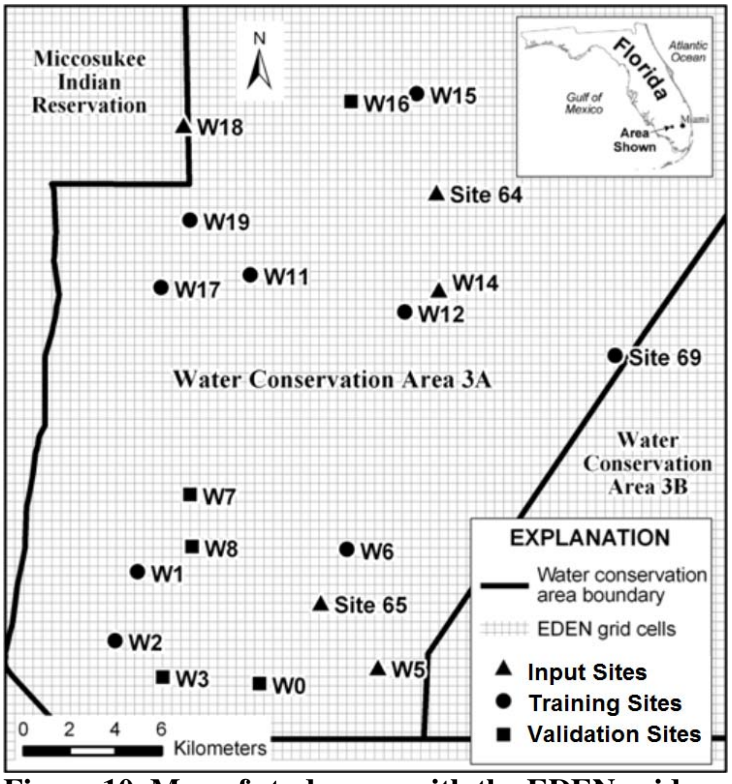

Figure 10. Map of study area with the EDEN grid and input, output, and validation sites.

The divide and conquer approach used two ANN sub-models. Model-1 was trained to predict the difference-from-the-standard signals using only categorical input parameters. Model-2 was trained to predict model-1's prediction error, which exhibits the training site's daily variability, using the categorical inputs, the Site 64 water level, and difference-from-the-standard signals for the input sites. For a given cell, the predicted water depth is the sum of the Site 64 water level and the predictions made by model-1 and model-2.

The super-model is composed of model-1 and model-2, and was assembled in a spreadsheet program that runs simulations to the predict water depth at a specified cell at each time step. Figure 11 shows measured and predicted water depths at the W8 validation site. While the prediction accuracy is good, the model slightly under-predicts the water depths for the majority of the simulation. Like the Western Oregon and Wisconsin stream temperature models, the primary sources of error are the categorical parameter inputs that predict the mean behavioral component for each site.

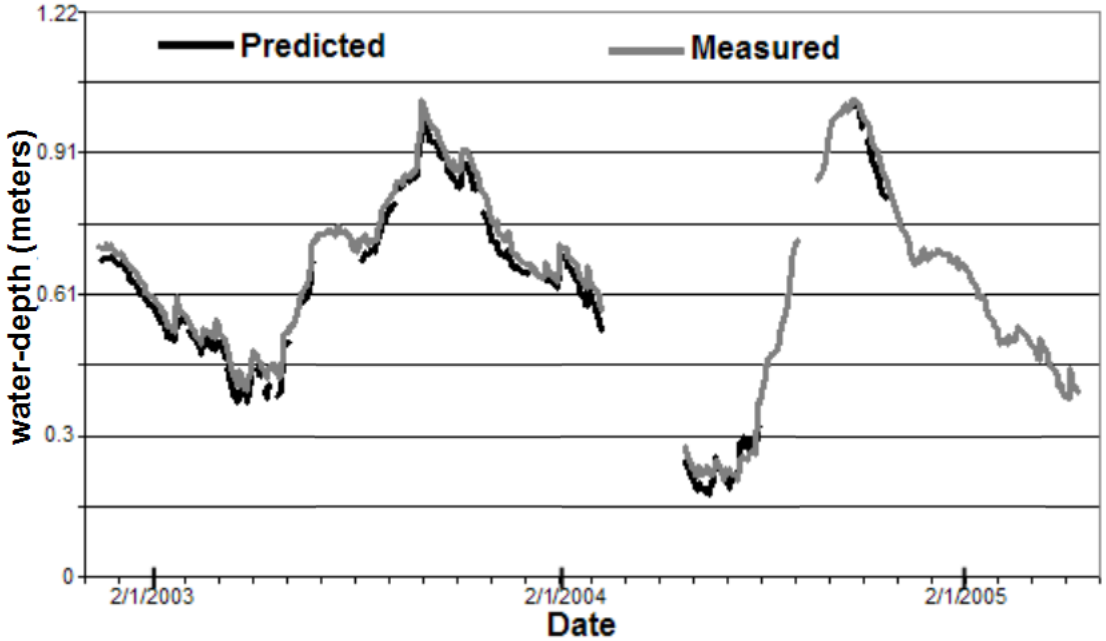

Figure 11. Plot showing measured (gray) and predicted (black) water depths for Site W8. The gaps are caused by periods of missing data.

CONCLUSIONS

This paper describes a new technical approach that leverages big data to provide several advantages over traditional modeling approaches, including being faster and less expensive, more comprehensive in its use of available data, and more accurate in representing complex physical processes. Many problems that confront resource managers and environmental scientists are already described by data that is ready and available. For example, of the four applications described in this paper, only the Western Oregon stream temperature model relied on data that was specifically collected for the problem solved.

The new approach readily solves problems of a scale and complexity that confound other approaches because it employs a divide and conquer approach that breaks large complex problems into smaller, tractable sub-problems, and then solves them using signal processing and numerically optimizing algorithms such as clustering, classification, and nonlinear empirical modeling. For example, the development of the Wisconsin stream temperatures model ensued after state and federal agencies concluded that there was no other way to proceed; and the Everglades water-depth model was developed because of perceived inadequacies of other state-of-the-practice solutions that had already been tried.

ABSTRACT

There has been much discussion regarding global climate change and potential impacts to the environment. One suggested impact of climate change is increasing storm intensity. Changes in rainfall intensity could significantly alter the accuracy of current stormwater management designs.

Civil engineers and community planners use historical precipitation data and statistically generated models to design stormwater management facilities. It is not uncommon for civil engineers to design stormwater management facilities using models that are based on precipitation data published more than 50 years ago.

The design of stormwater facilities is largely based on the amount of runoff generated from a design storm event. Rainfall intensities and depths for various storm frequencies are determined using local Intensity-Duration-Frequency (IDF) curves and isohyetal maps, respectively. The IDF curves currently in use in Rochester, New York were originally published in 1955 and generated using approximately 40 years of data. Approximately 55 years of additional precipitation data is now available.

The purpose of this paper is to: 1) evaluate and report trends in precipitation observed at the Greater Rochester International Airport; and 2) Generate updated Intensity-Duration-Frequency (IDF) curves and compare these to existing IDF curves. This paper will use Rochester, New York as a case study.

Data sources for this paper include daily precipitation depths collected at the Greater Rochester International Airport and published research by the Northeast Regional Climate Center (NRCC) at Cornell.

The methodology used in this study can be applied to any municipality in the United States. However, some comparisons presented herein make use of research limited to the north eastern US.

INTRODUCTION

There has been much discussion regarding global climate change and potential impacts to the environment. Climate models have long predicted that global warming will increase the intensity of extreme precipitation events. Of utmost concern is that heavy rainstorms will become more common and more intense in a warmer climate due to the increased moisture available for condensation. More intense rain events increase the risk of flooding and can have substantial societal and economic impacts (esciencenews, 2008). Changes in rainfall intensity could significantly alter the accuracy of current stormwater management designs.

Stormwater management systems include exceptional projects such the Mississippi River levee system in the US and the Zuiderzee Works in the Netherlands. These are large installations that require consideration of marine weather impacts as well as land based runoff from rainfall. Smaller scale stormwater management devices such as culverts, detention ponds, erosion control methods, and storm sewer networks are common in any community, frequently replaced or constructed and are designed based on rainfall/runoff relationships. This paper will focus on the latter.

The purpose of this paper is to determine if there is significant evidence from precipitation data in the Rochester, New York area to warrant generation of updated stormwater management design tools.

Current Stormwater Management Design Tools

The design of stormwater management devices is largely based on the amount of runoff generated from a design storm event. Rainfall intensities and depths for various storm frequencies are determined using local Intensity-Duration-Frequency (IDF) curves and isohyetal maps, respectively. The rainfall amount is then applied, together with watershed characteristics, to determine the volume or rate of stormwater runoff.

The IDF curves and isohyetal maps are statistically generated and published for use by governmental agencies and engineering firms. In fact, the use of IDF curves and/or isohyetal maps are often required in local regulations. Stormwater management facilities in Rochester, New York are currently designed based on IDF curves (See Figure 1) published in December 1962 (MCPC, 1962).

The 1962 curves were redrawn for engineering application from a 1955 US Weather Bureau publication – Technical Paper No. 25 (TP-25) (USWB, 1955). Precipitation records, tabulated since circa 1910 at the Greater Rochester Area International Airport, provided the basic data from which the TP-25 IDF curves were derived. A Type I Gumbel Distribution was used to generate the recurrence intervals. More recent hydrological research suggests that TP-25 and a later US Weather Bureau publication – TP-40 (USWB, 1961), which also used Gumbel Distribution; underestimate the largest extreme precipitation events (NRCC 1993).

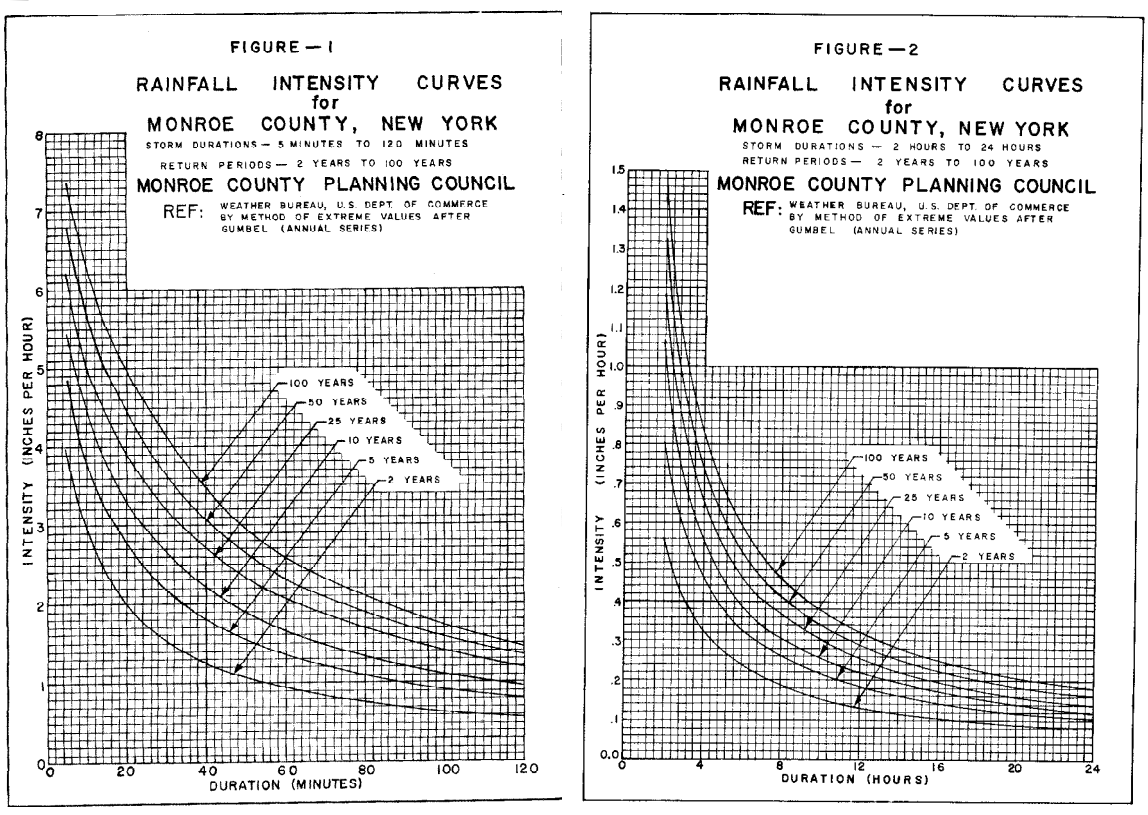

Figure 1. Existing IDF curves for Rochester, New York

Updated isohyetal maps (See Figure 2) have been developed by the Northeast Regional Climate Center (NCRR, 1993). Isohyetal maps describe the expected precipitation over an area based on a given return frequency. Each line represents a line of equal precipitation. By identifying the location on a map and determining the magnitude of the adjacent isohyetal lines, the magnitude of rainfall expected to occur during a specific return frequency can be determined.

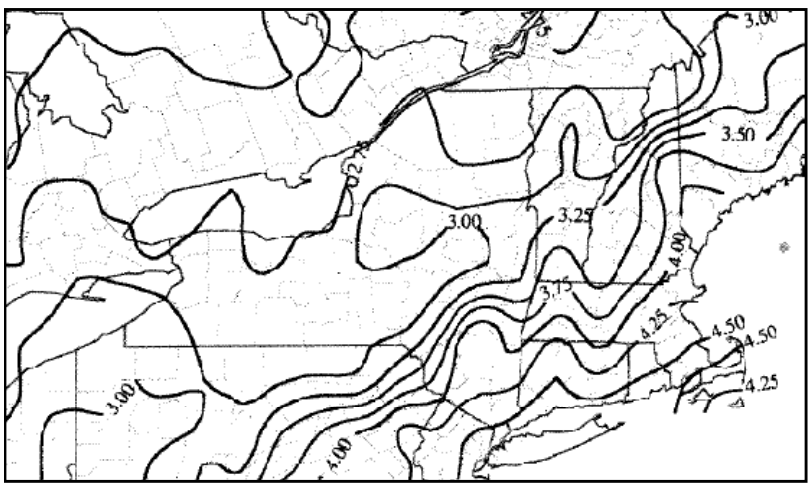

Figure 2. 1-day precipitation, 10-year return period (NCRR 1993)

The *Atlas of Precipitation Extremes for the Northeastern United States and Southeastern Canada* (NCRR 1993) is the most current and comprehensive extreme precipitation study in the region. Isohyetal maps presented in the study will be used to determine one day precipitation depths for 2-year, 5-year, 10-year, 25-year, 50-year, and 100-year return periods for Rochester, New York.

PRECIPITATION TRENDS

Daily precipitation data, collected from the Greater Rochester Area International Airport between 1926 through 2005, has been analyzed to see what trends exist. A simple linear trendline was generated for each parameter evaluated: annual maximum daily precipitation; annual standard deviation; annual precipitation; and the number of days with precipitation.

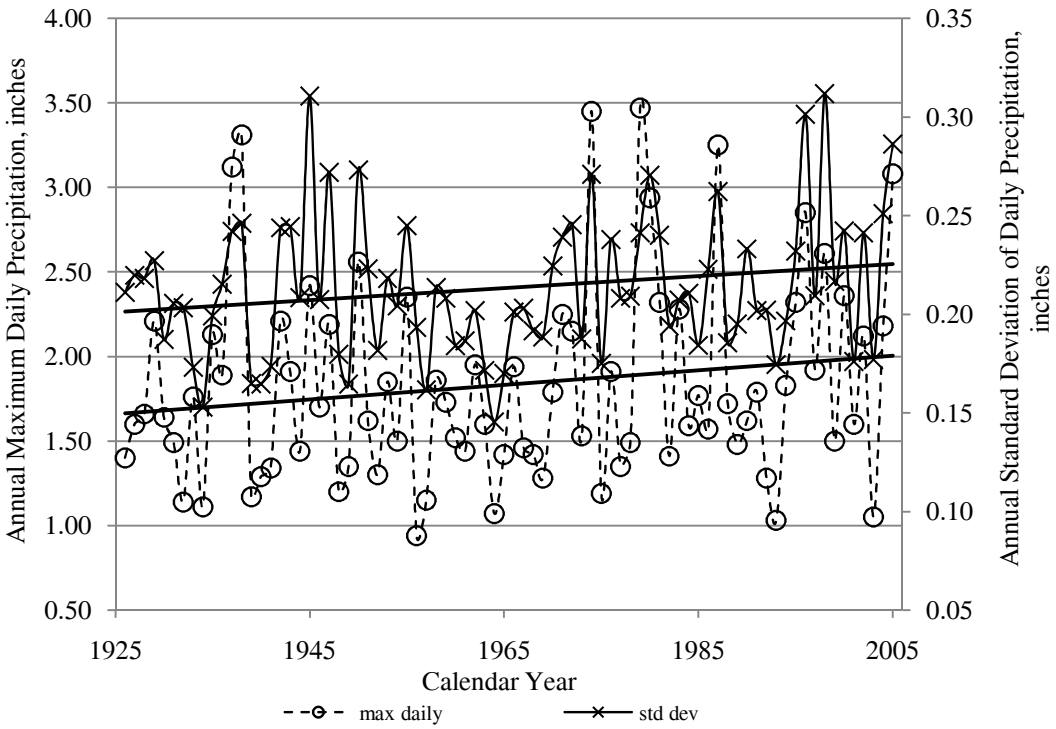

Figure 3. Annual Maximum Daily Precipitation and Standard Deviation

Increasing trends are observed in the four parameters investigated (See Figures 3 and 4). The value of each trend in terms of inches or days per year seems relatively small.

However, if the incremental increase over a 100 year period is divided by the mean of the 80 year period of record the trends seem less trivial (See Table 1). The values of annual maximum daily precipitation, annual standard deviation of daily precipitation and the annual total precipitation increase at least by 14 percent over a 100 year period. However, the number of days of precipitation increases by only 5 percent. This indicates that the intensity, variability and volume of precipitation are increasing at a faster rate than the number of precipitation days. In other words, it won't rain more days in a given year, but it will rain harder (i.e. intensity).

Table 1. Linear Trends of Precipitation Data (1926 – 2005)

Parameter	Mean	Trend	Increase per 100 yrs	% increase
Annual Max Daily Precip.	1.83 in	0.0043 in/yr	0.43 in	+23
Annual Standard Deviation	0.21 in	0.0003 in/yr	0.03 in	+14
Annual Precipitation	32.16 in	0.0532 in/yr	5.3 in	+16
Number of Precip. Days	161.4 days	0.0789 d/yr	8.9 d/yr	+5

The 80 year period of record data supports the hypothesis that storm events are increasing in intensity. IDF curves will be generated and evaluated in this paper because of the following reasons:

1) existing IDF curves were developed using a statistical method (Gumbel distribution) that might underestimate the largest extreme precipitation events (i.e. 100 year storms) (NRCC 1993);
2) existing IDF curves were developed using a relatively short period of data, estimated to be approximately 35 years (~1915 - ~1950); and
3) Analysis of precipitation trends using 80 years of data (1926 – 2005) indicate that precipitation is increasing in intensity.

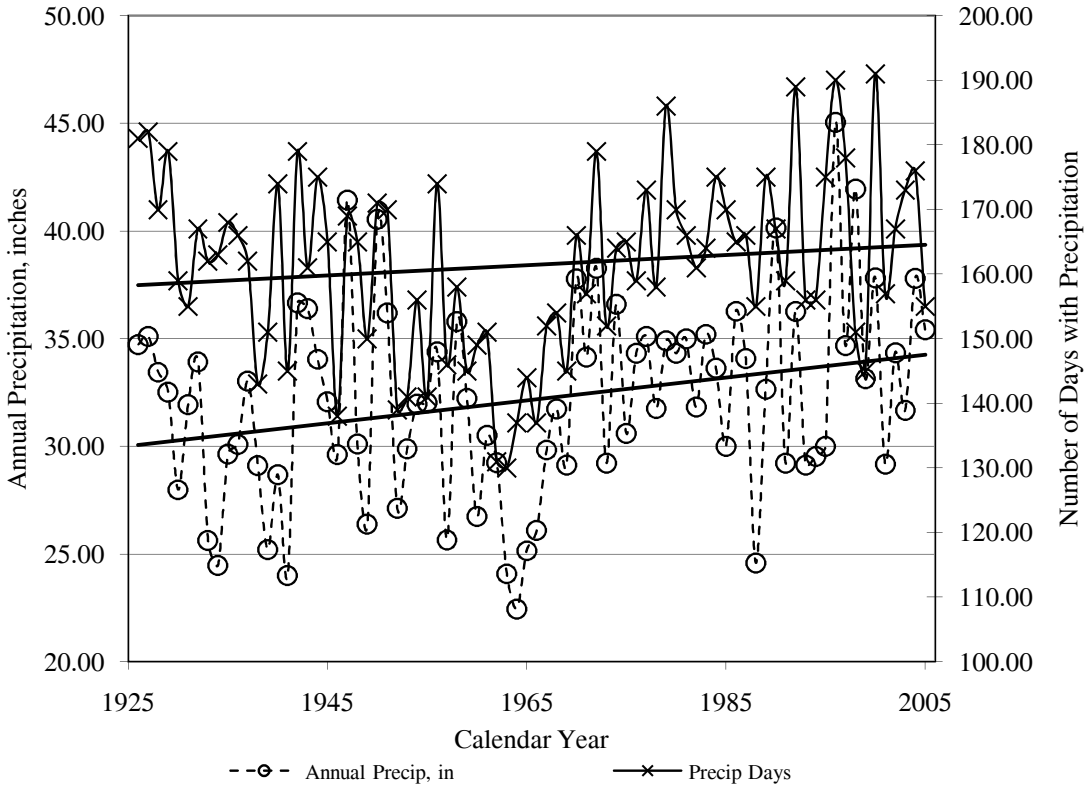

Figure 4. Annual Precipitation and Number of Precipitation Days

GENERATION OF NEW IDF CURVES

The generation of new IDF curves follows a procedure presented by NRCC. One day precipitation depths are selected for the Rochester, New York area from isohyetal maps (NRCC, 1993). One day precipitation depths were selected from maps with return periods (i.e. frequencies) of 2-yr, 5-yr, 10-yr, 25-yr, 50-yr, and 100-yr to correspond with the frequencies on the IDF curves (See Table 2). For comparison purposes, one day precipitation depths from the existing IDF curves and the results of a LOG Person III analysis of the 80 year period of record are also provided. Data selected from the NRCC isohyetal maps are generally higher than the other two sources. Interesting, the return period precipitation depths from existing IDF curves and the Rochester airport are relatively close. The depths generated from data collected from the Rochester airport are within 2% and 6% of the depths estimated from the existing IDF curves. The Rochester data is slightly higher than the return period depths from the existing IDF curves

Table 2. One Day Precipitation Depths, Rochester New York area.

	Precipitation, inches					
	2-yr	5-yr	10-yr	25-yr	50-yr	100-yr
NRCC, 1993	1.90	2.37	2.74	3.45	4.00	4.85
Rochester Precipitation Data	1.71	2.25	2.62	3.10	3.48	3.88
Existing IDF curves*	1.68	2.17	2.53	2.93	3.40	3.80

*24 hour depths estimated from the existing IDF curves were divided by 1.13 (Huff & Angel empirical adjustment factor) to obtain the 1 day depth presented in Table 2.

The one day precipitation depths are multiplied by empirical adjustment factors to modify one day precipitation depths to 24 hour precipitation depths. The one day time frame corresponds to a calendar date and is used during collection of precipitation data. An extreme precipitation event is unlikely to follow a calendar date and can occur over multiple days. Two different multipliers were applied in this analysis (See Table 3) to convert one day depths from isohyetal maps to 24-hour depths used in IDF curves.

Huff & Angel factors were reported in the 1993 NRCC report were based on analysis of data from the Midwestern U.S. NRCC determined that the Huff & Angel factors overestimated precipitation depths for shorter durations. Empirical adjustment factors for the northeast were presented in *Atlas of Short-Duration Precipitation Extremes for the Northeastern United States and Southeastern Canada* (NRCC 1995).

Northeast empirical adjustment factors for durations of less than one hour were not presented. Therefore, short duration values, developed by the World Meteorological Organization (Prodanovic 2007) supplemented the Northeast factors.

Table 3. Empirical Adjustment Factors

	Durations										
	5 min	10 min	15 min	30 min	60 min	2 hr	3 hr	6 hr	12 hr	18 hr	24 hr
Huff & Angel (1992)	0.14	0.24	0.31	0.42	0.53	0.66	0.72	0.85	0.98	1.06	1.13
Northeast & *WMO*	*0.125*	*0.194*	*0.245*	*0.340*	0.43	0.54	0.65	0.79	0.97	1.07	1.13

Several IDF curves have been generated to determine if adopting new IDF curves for the Rochester, New York area are necessary. Only the 10-year return period is presented in these illustrations for clarity.

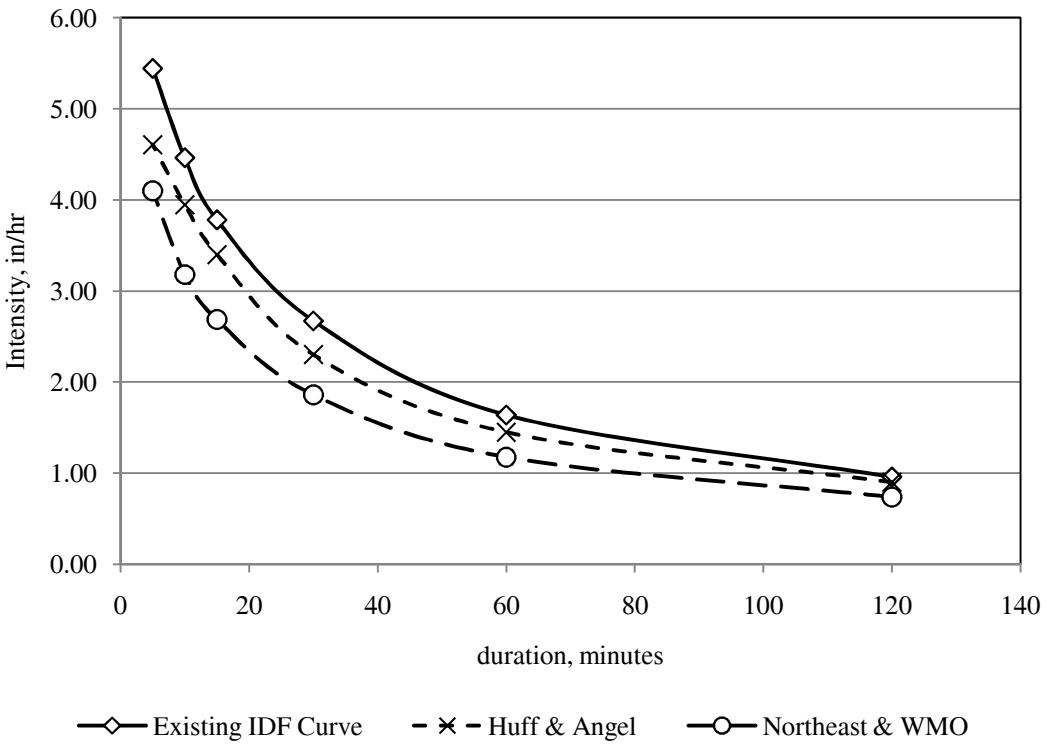

Figure 5. IDF Curve (5 min to 120 min) using NRCC 1993 return period depths

Figures 5 and 6 show that newly generated IDF curves provide lower intensities than the existing IDF curves for a given duration. This is true regardless of which empirical adjustment factor is used. In fact, the Huff & Angel IDF curve is closer to the existing IDF curve than the curve produced using empirical adjustment factors specifically developed for the northeast. The three IDF curves produce nearly identical intensities when the duration is greater than 10 hours (See Figure 6).

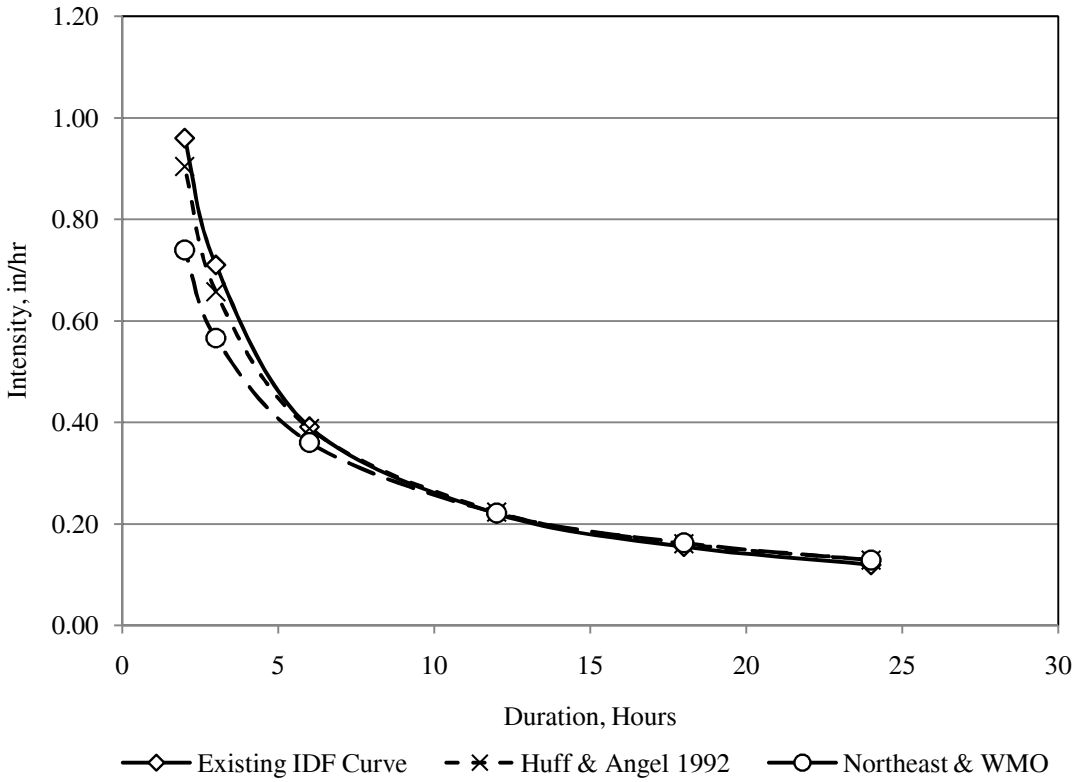

Figure 6. IDF Curve (2 hr to 24 hr) using NRCC 1993 return period depths

Very similar sets of IDF curves are produced if the curves are generated using the return period precipitation depths from the Rochester Airport precipitation data.

CONCLUSIONS

There is no need to replace the existing IDF curves for the Rochester, New York area. Even though precipitation trends indicate increasing intensity of storm events, IDF curves generated with new hydrologic methods and updated precipitation data sets consistently produce lower intensities for a given duration than the existing IDF curves. Stormwater management designs, based on existing IDF curves, will continue to offer some level of conservativeness.

In light of the estimated increasing trends in precipitation intensities, the results of this study were somewhat surprising. It is very possible that the authors of the existing IDF curves purposely used conservative methodologies and assumptions. They may have done so to provide a safety factor comparable to the inherent risk of predicting rainfall depths for 50 or 100 year return periods using a period of record of approximately 35 years.

Assessment of Flood Risk due to Storm Surge in Costal Bayous Using Dynamic Hydraulic Modeling

T. Ray[1], Z. Feng[2], P.B. Bedient[3]

[1,2,3]Department of Civil and Environmental Engineering, Rice University, 6100 Main St. MS 312, Houston, TX 77005; PH (713) 348-3798; FAX (713) 348-5239; email: jtray41@gmail.com

Abstract

The purpose of this study is to analyze the combined effects of storm surge and inland rainfall on the floodplain of a coastal bayou in the Houston area using dynamic hydraulic modeling.

The hydrologic and hydraulic models that were utilized in the study were created by the Tropical Storm Allison Recovery Project (TSARP). The TSARP HEC-RAS model was run for both the steady and unsteady states. In steady mode, storm surge was introduced by changing the downstream boundary conditions to match that of the measured and predicted peak stage of the surge. HEC-RAS was then used to run a backwater calculation in order to provide a worst case floodplain.

Upon completion of the steady state study, the model was then evaluated in the unsteady state. Running HEC-RAS in the unsteady state allowed both rainfall and storm surge to be introduced dynamically. This allowed for a more accurate representation of the flooding characteristics of this channel, but more work is needed to refine hydrographs.

Introduction

In coastal areas like the Gulf Coast, hurricanes and tropical storms often bring storm surge and inland flooding. The surge threat in these areas is real as was evidenced by Hurricanes Katrina and Ike in 2005 and 2008. The focus area for this study was chosen because of it's proximity to the storm surge impacts of the Texas Gulf Coast.

Clear Lake City is located approximately 25 miles southeast of Houston proper and 5 miles west of Galveston Bay. Because of its proximity to Houston and the industry located in the Galveston Bay area, Clear Lake has been rapidly developing. As it has developed, areas within the city boundary have experienced frequent flooding, primarily in the vicinity of Horsepen Bayou and its tributaries. The Horsepen Bayou watershed is a 2.7 square mile watershed that drains into the downstream portion of Armand Bayou which discharges through Clear Lake and into Galveston Bay. An area map can be seen in Figure 1.

Many of the characteristics of the Horsepen Bayou watershed are typical of a watershed situated on the Texas coast and, in particular, Galveston Bay. There is very little relief in the area and this flat topography results in poor overland drainage

and very low channel slopes. In Horsepen, the overall watershed slope is 0.06 percent, a very low slope. Clay soils are typical in the area and the predominate soil in Horsepen Bayou is Lake Charles clay. This is a somewhat poorly drained soil with very slow permeability and internal drainage. This leads to a very slow surface runoff. It has a high available water capacity and when it is dry its forms deep, wide cracks that will rapidly allow water to enter. During the rainy hurricane season, however, these cracks will disappear, which means that any rainfall will generate large runoff and will do so very slowly. (USDA-SCS, 1976).

In the Houston/Galveston area, there has been a noticeable rise in high intensity rainfall events over the past few decades. There have been two storms larger than the 500 year event and six storms larger than the 100 year event since 1960. This large amount of rainfall coupled with rapid urban development has led to frequent flooding due to an under designed storm water management infrastructure. Horsepen Bayou has risen up to flood Clear Lake City four times in the past 30 years. (Dunbar 2005).

Hurricane Katrina and the damages that it caused have brought a new respect and understanding to the threat that storm surge poses. The National Hurricane Center reported that a 19 ft storm surge was measured in New Orleans during Katrina. In 2008, Hurricane Ike hit the Texas coast and a storm surge that ranged from 12-20 ft leveled the Bolivar Peninsula and caused major damages throughout Galveston Bay. (NHC, 2006) (NWS, 2008).

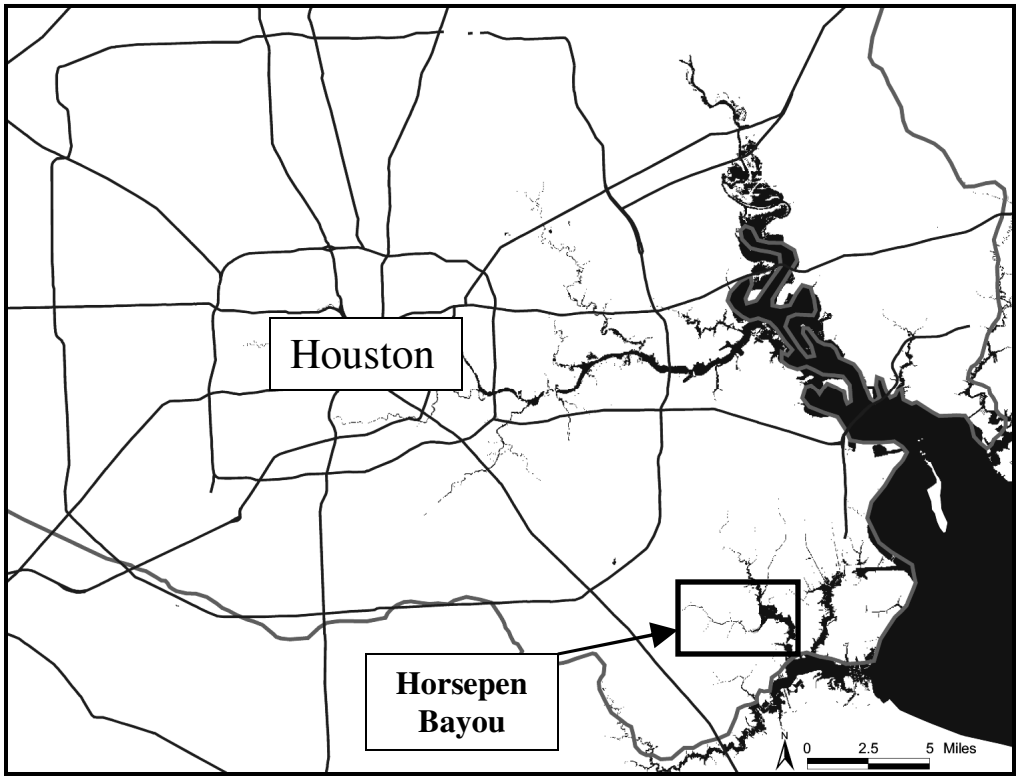

Figure 1: Location Map

Problem Statement

Areas that are frequented by hurricanes and tropical storms are consequentially faced with the threat of storm surge. Because of this, current modeling practices may be insufficient and lead to a false sense of security and safety. For example, when evaluating risk, inland rainfall and coastal storm surge are treated as separate and unrelated events. However, history has shown that this is not practical. The problem with studying these two events separately is that storm surge rarely occurs without inland rainfall. Storm surge is usually associated with tropical storms and hurricanes which are both accompanied by heavy rainfall. Storm surge, when acting alone, presents a problem because it is water moving through a channel and stream network that was only designed to carry the run-off from rainfall. If rainfall and storm surge are combined in the same channel, water flowing in opposite directions meets and any flooding that would normally occur is exacerbated by the combination of the two.

The scope of this study is to determine what affect the convergence of surge and rainfall/runoff will have on the floodplain. Many coastal areas such as Horsepen Bayou are inhabited by residential areas, commercial areas, chemical and power plants, schools, and hospitals. While many of these entities are geographically protected from the direct effects of storm surge, they are not protected by its rarely considered backwater effects. The Clear Lake City Water Authority (CLCWA) has expressed concern regarding the effects of storm surge because of the frequency at which they currently experience flooding without the presence of a storm surge.

With this information, surge-induced floodplains, or scenarios associated with coastal storm surge, could be created to better inform emergency managers, city officials, home owners, and citizens of the potential escalated flood risk. This study will also later investigate the timing of important events such as out of banks flooding, maximum flood depth, maximum floodplain extent, and flood subsidence. Armed with this information, emergency groups will be equipped with the information needed to make informed decisions regarding flooding due to storm surge.

Model Description

A number of models are being utilized in this study and the following is a brief description of each. Hydrologic, hydraulic and shallow water models are all incorporated.

HEC-HMS

This a Hydrologic Modeling Software (HMS) designed by the Hydrologic Engineering Center (HEC) for the Army Corp of Engineers. This software is designed to simulate the precipitation-runoff process of a watershed. Precipitation is entered as a hyetograph (precipitation per time) for each sub-basin in the watershed. By changing parameters such as infiltration, soil type, land use, and overland slope, the model can be calibrated to accurately simulate the amount of runoff that will

occur after a particular storm event. HMS also has basic flood routing abilities. (HEC, 2008)

Vflo

Vflo is a physics-based distributed hydrologic model that allows for spatial variability to be considered within a watershed when calculating runoff. It uses input from a Geographical Information System (GIS) which provides gridded watershed data. Within Vflo, each grid cell can be assigned different properties which allow a watershed with highly diverse characteristics to be modeled more precisely than can be done using HEC-HMS. HMS assigns physical properties to an entire sub-basin whereas Vflo is able to assign it to each individual cell within a sub-basin. Vflo also allows precipitation to vary from cell to cell. Because of this, radar rainfall data that has been calibrated against rain gages can be used in the model. By assigning each grid cell different physical properties and different rainfall amounts, Vflo is able to very precisely model the behavior of a watershed. (Vieux, 2004)

HEC-RAS

Both HMS and Vflo are hydrologic models that predict runoff. HEC-RAS (River Analysis System) is a hydraulic model that aids in channel flow analysis and floodplain delineation. RAS can be directly linked to HMS which makes if very easy to go from a hydrologic model to a hydraulic model. HEC-RAS can be run for steady flow which assumes flow rates are constant, or for unsteady flow which allows flow which assumes that flow rates are dynamic, or vary with time. Cross-sectional data that describe the channel can be imported or user defined and channel properties can then be assigned and modified to make the model an accurate representation of the actual channel. For steady flow, peak flow values are input at each cross-section and HEC- RAS uses the one-dimensional energy equation to make a backwater calculation. From this calculation a floodplain is produced. For unsteady flow, a hydrograph is input at each cross-section and HEC-RAS solves the full, dynamic, Saint-Venant equation using an implicit, finite difference method. As with the steady flow analysis a floodplain is created and a variety of output data is made available. (HEC, 2008) (Bedient et al., 2008)

ADCIRC

This is the Coastal Circulation and Storm Surge Model whose output will be used to provide the storm surge data that will be entered in HEC-RAS. ADCIRC is a system of computer programs for solving time dependent, free surface circulation and transport problems in two and three dimensions (ADCIRC.org). Although this model is capable of providing a variety of outputs, the only data that will be used in this application are simulated stage hydrographs that will act as a downstream boundary condition. This data will be provided by Dr. Clint Dawson at the University of Texas at Austin. Figure 2 is the surge that ADCIRC predicted for Hurricane Ike (Courtesy of Dr. Clint Dawson).

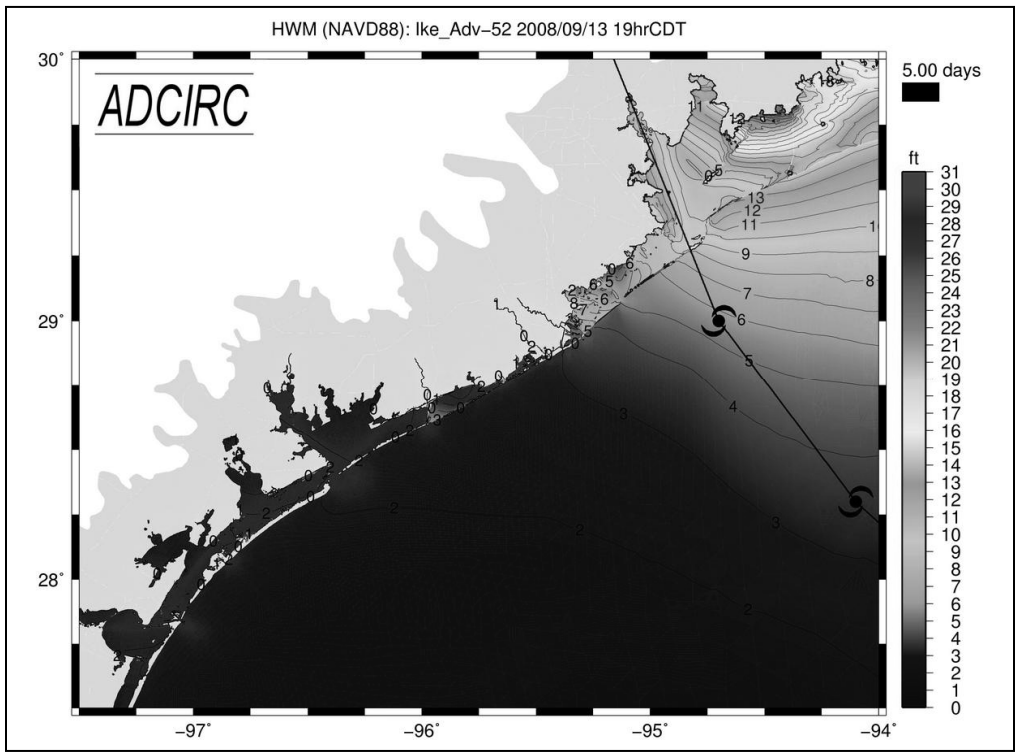

Figure 2: ADCIRC Storm Surge Prediction for Hurricane Ike

Model Application and Setup

Tropical Storm Allison Recovery Project (TSARP) created both hydrologic and hydraulic models. These models were calibrated and used to create new floodplain maps for the Houston-Galveston area. Because these models were available, they were chosen for use in this study. However, to test the accuracy and validity of the TSARP HMS model, a Vflo study was also performed. Model inputs were obtained from a variety of sources. A digital elevation map (DEM) created from the LIDAR data collected by TSARP was input along with soil information (USGS soil survey), land use data (land use classification from remote sensing images), and rainfall data collected during Tropical Storm Allison (June 2001) and a large storm event from October 1994. After running Vflo, the results were compared with TSARP data and observed data and can be seen in Figures 3a and 3b. It can be seen that the TSARP model under predicts on the October storm and over predicts on the Allison storm but the timing on both events is very accurate. The Vflo model almost matches the peak for Allison but the timing is about three hours early. Both models performed similarly in the October 1994 storm. After studying these results it was concluded that, for the purpose of this study, the TSARP model was satisfactory.

The TSARP hydraulic model, which was created using HEC-RAS, was used to obtain preliminary results that will later be compared to unsteady results. However, TSARP only studied the steady state case so an unsteady model did not

exist. The geometry from the steady model was taken and an unsteady model was created from it.

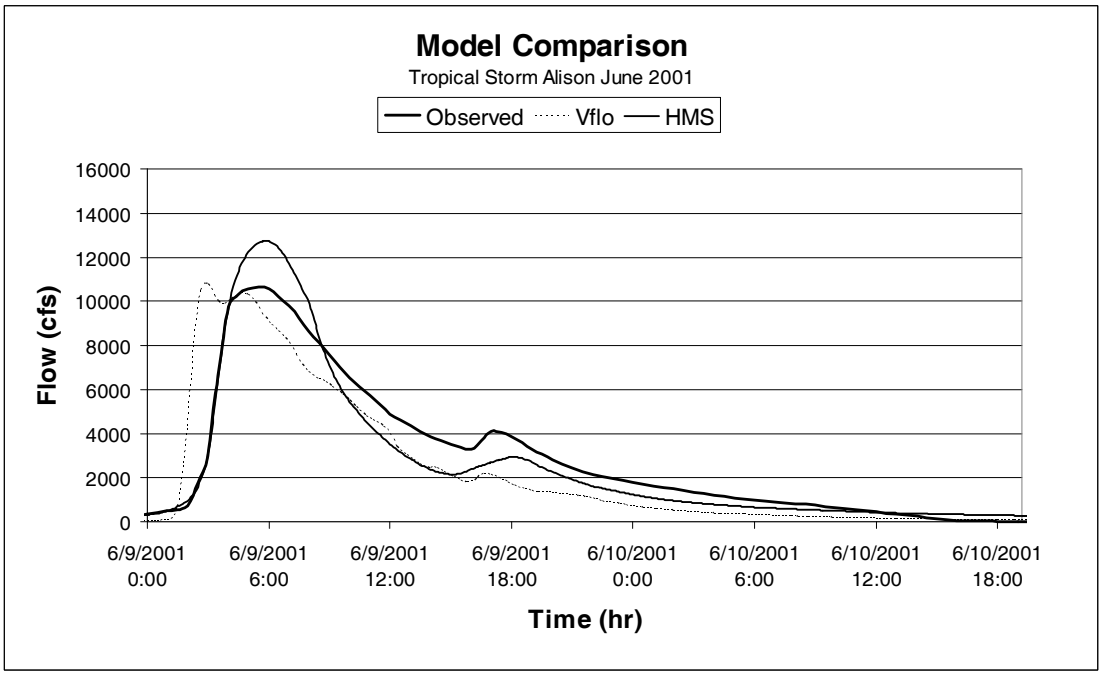

Figure 3a: Model Comparison – June 2001

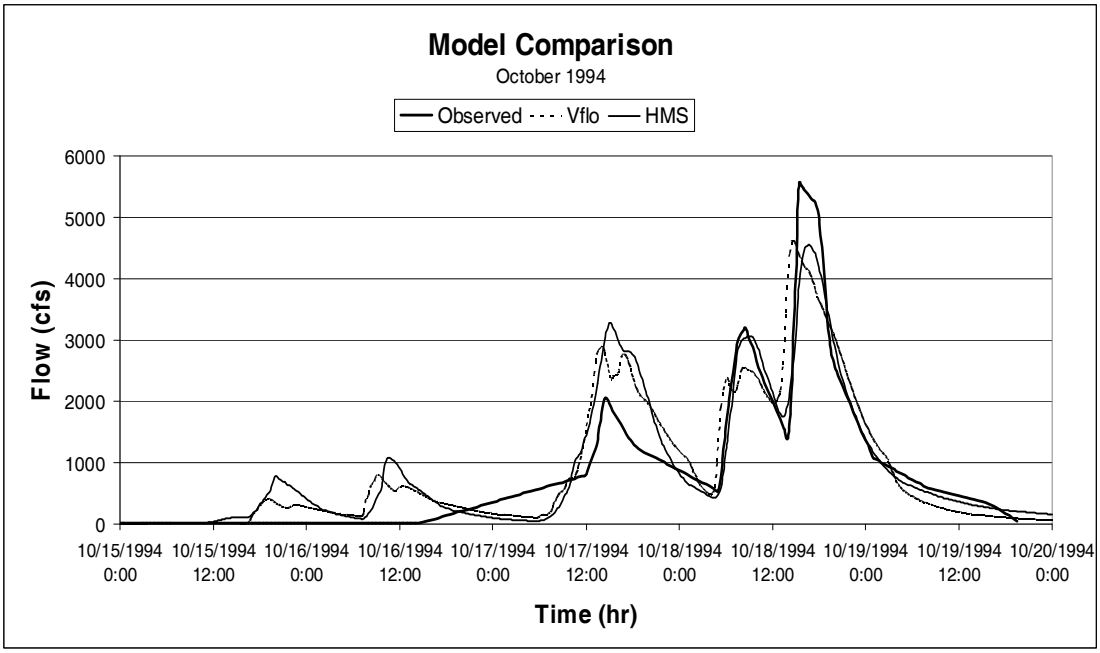

Figure 3b: Model Comparison – October 1994

Results

Initial work began by utilizing the existing steady state model created by TSARP. Storm surge was input in the steady model as a downstream boundary condition. The surge values that were input represent peak stage in Armand Bayou at the outfall of Horsepen Bayou. For the purpose of this study, the 10, 50, 100, and 500-year design storms were selected. Each of these storms was run in HEC-HMS and the data was input into HEC-RAS. All four of these storms were run for each downstream condition (0, 3.5, 6.5, 10, and 15 ft theoretical surge). This was decided to be a reasonable range based on USGS data collected during Hurricane Ike. The information from HEC-RAS was exported to HEC-GeoRAS, a program that works with ArcMap to delineate a floodplain by overlaying the information from HEC-RAS on a digital elevation map. Using these images, the floodplains for different rainfall-surge scenarios were mapped and compared.

Figures 4a and 4b show the floodplains caused by the 10-year and 100-year storm events combined with the effects of no surge and a 15 ft surge. For the 10-year event, storm surge effects can be seen at two locations. At the downstream end there is a significant difference in the two floodplains which is to be expected due to its proximity to the actual surge. In the middle portion of the watershed there is a noticeable difference in the two floodplains which can most likely be attributed to the flat topography in the area. In the case of the 100-year event similar effects can be seen at the downstream end but it is evident that there is a much larger impact throughout the rest of the watershed. The similarities at the downstream end may be attributed to cross-sections that are not wide enough to sufficiently cover the extent of the floodplain. This could be remedied by extending these cross-sections, but, as watershed overflows could result, they were left unchanged. Similar effects can also be seen in other portions of the watershed.

The results from the steady state modeling were produced assuming a peak on peak scenario. In other words, the peak discharge from the Horsepen Bayou happens at the exact same time as the peak stage in Armand Bayou. This is a worst case scenario and one that has a low probability of occurring. To more realistically model the interaction between rainfall-runoff and storm surge, an unsteady model must be employed.

TSARP only looked at the steady state scenario therefore no unsteady model currently exists. The geometry from the steady model was taken and adapted to create an unsteady model. After the unsteady model was created, a few simple runs were made to test the model. For the downstream boundary condition a theoretical surge was introduced. This data is actual surge data collected by the USGS during Hurricane Ike measured at the Clear Lake-Kemah gage. This data was scaled down by 20 percent because Horsepen Bayou is more inland than this gage. With this stage in place, two different scenarios were run.

In the first scenario, a constant 50 cfs (low flow) was input at the upstream most cross-section. This was done to very simply represent the effects of storm surge only. Horsepen Bayou is approximately 5.9 miles long and impacts of this surge were noticeable as far up the channel as 4.9 miles. It caused a 1.4 ft increase in water surface elevation at this point. At the downstream end of the bayou there was

significant out of banks flooding. The bayou got out of banks as far up the channel as 2 miles.

In the second scenario, a constant 1000 cfs (higher flow) was input at the upstream most cross-section. This 1000 cfs was intended to represent a small rainfall event occurring inland. Under this scenario, the surge had an effect the entire way up the bayou with a 1 ft increase in water surface elevation at the upstream most cross-section. Out of banks flooding stopped around the same point but the floodplain was noticeably larger at the downstream end than in the previous scenario.

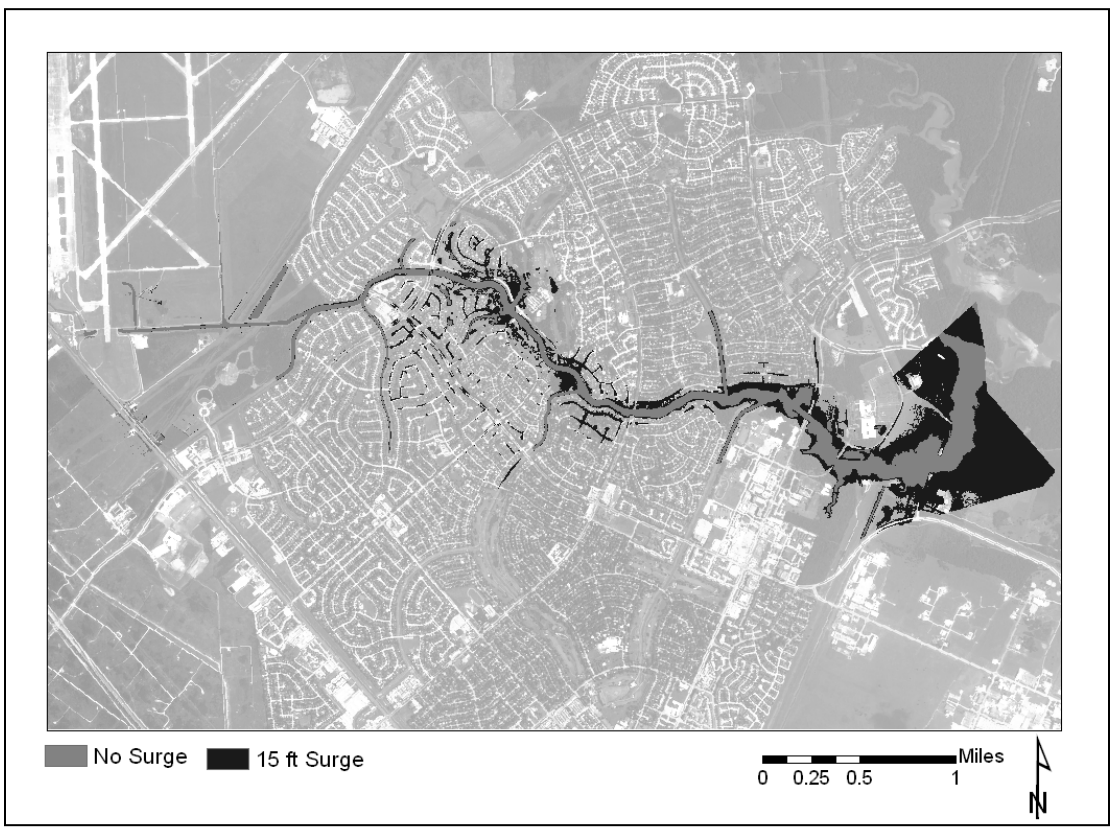

Figure 4a: 10-yr Storm Under Varied Surge Conditions

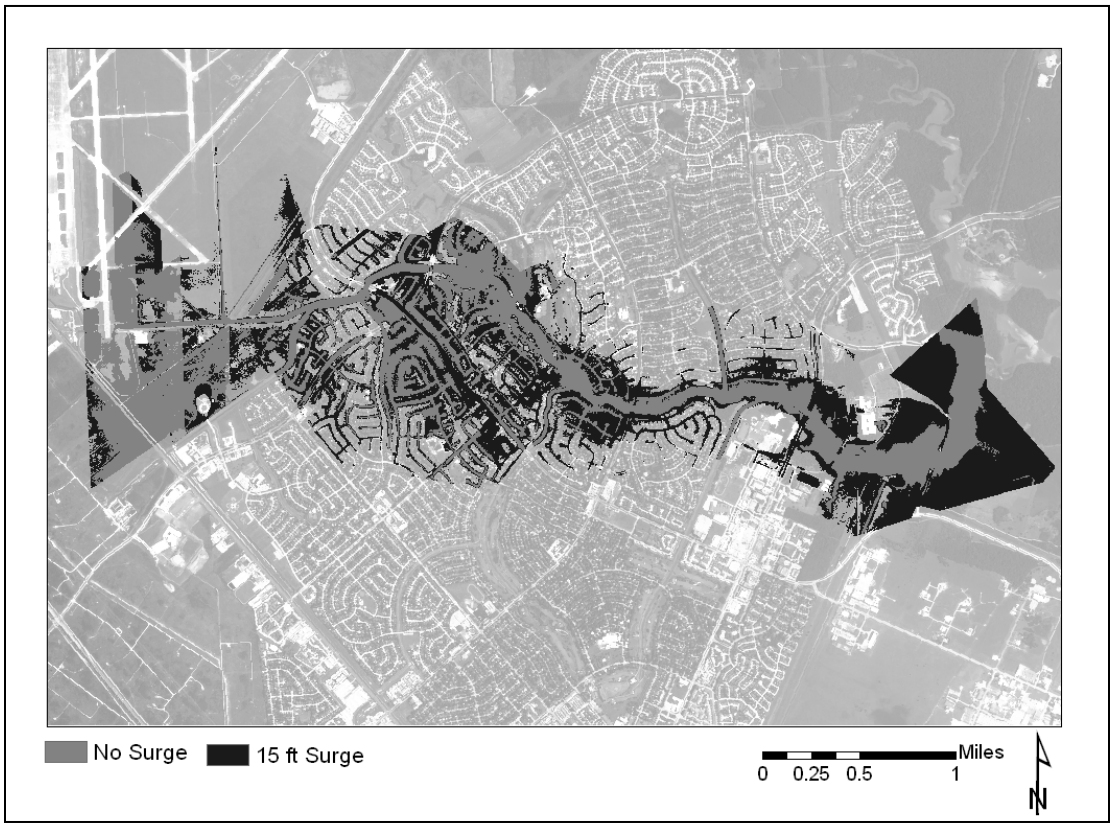

Figure 4b: 100-yr Storm Under Varied Surge Conditions

Future Research

Future research will use the unsteady flow model to model the 100-year design storm event. Flow hydrographs from HEC-HMS will be applied at corresponding cross-sections in HEC-RAS. Running the unsteady model with a varying downstream boundary condition and a varying inflow will allow for the investigation into different timing issues such as out of banks flooding and flood subsidence time. Future work will also vary the beginning times of the surge and rainfall in an attempt to better understand the behavior of this bayou under various scenarios.

Abstract

The majority of scour-related studies in rivers and streams in Iowa and the Midwest indicate that bridge pier protection is strongly interrelated to bank stability. Findings from a recent survey conducted as part of a project performed for the IHRB (Iowa Highway Research Board) and HCA (Hungry Canyon Alliance) suggest that accelerated riverbank degradation has resulted in an estimated $1.1 billion in damages to bridge infrastructure and the loss of agriculture lands since the turn of the century in parts of the western United States, including western Iowa.
Yet, a robust technique that systematically quantifies bank erosion on a continuous basis is lacking. This is because conventional, manual, field monitoring methods, typically erosion pins, cross-section resurveys or terrestrial photogrammetry, merely reveal net change in the position of a bank surface since the previous measurement. They do not quantify the precise temporal distribution of that change. This means that erosion event timing, and the precise bank response to individual flow or flow hydrograph changes, is generally uncertain. Because of the limitations of existing measurement methods, little knowledge has yet emerged of the dynamics of bank erosion and deposition events at a time resolution comparable to that available for flow discharges.
Clearly, bank erosion monitoring will be more securely based when (a) the full episodicity of bank change is detected, including event timings and (b) magnitude/timing information for specific erosion and deposition events can be related to continuous information on the temporal fluctuations in the suspected hydraulic forces.

1. Introduction

Relatively few papers (e.g. Raudkivi & Hutchison, 1974; Millar et al., 1998; Julian &Torres, 2005; Papanicolaou et al., 2002, 2007) have investigated erosion of banks comprised of cohesive materials. Thorne (1982) states that erosion of a cohesive river bank is mainly dominated by mass failures and fluvial erosion processes. The former is driven by gravity. This phenomenon occurs as blocks of materials collapse when the critical height and angle of the bank are exceeded. The latter, which is the focus of this paper, occurs when hydraulic shear forces break the bond between particles and provoke the entrainment of aggregates (Millar, 1998; Papanicolaou, 2007).

Previous papers report that fluvial erosion processes occur when the applied side-wall shear stress τ is greater than the critical erosional or simply soil strength τ_c ($\tau > \tau_c$). Hence, accurately predicting the critical shear stress τ_c can lead to a better understanding of fluvial erosion. Unfortunately, this control variable, together with the shear-stress, depends on many factors and it cannot be directly estimated. For instance, to predict the side-wall fluid shear-stress τ, river engineers use a uniform flow approximation to conduct their experiments (Leutheusser, 1963; Simons and Senturk, 1992; Knight et al., 1984; Flintham and Carling, 1988; Millar and Quick, 1998) (as cited in Papanicolaou, 2007). Those studies do not consider the effects of secondary currents which cannot be neglected in natural open-channels. Nevertheless, Guo & Julien (2005) analyze the effect of secondary currents on the side-wall shear stress. By neglecting the secondary currents, observations were made that the near-wall shear stress was underestimated while the bed-shear stress was overestimated. They verified that it was not adequate to make the approximation of the uniform flow for natural rivers.

Another limitation is the little knowledge of the complex electrochemical forces between cohesive particles and the water flow. In 1966, Grissinger found that the erosion rate depends on bulk density and moisture content even though those variables are not correlated to the critical shear stress (as cited in Raudkivi, 1976). Millar (1998) found that vegetation has a significant effect on cohesive river banks that are subject to fluvial erosion. Papanicolaou et al. (2007) developed an experimental method to estimate the critical shear-stress. Although these papers contribute to the overall understanding of hydraulic erosion of cohesive materials, continuous monitoring of bank fluvial erosion for a wide range of discharges is needed. Instruments have been developed to measure erosion and techniques have been created to study bank erosion. Thorne (1981) reviews the methods used to measure the rate of bank erosion and displacement of banks due to erosion. Such techniques require the use of erosion pins for detailed measurements of the site and aerial photography and remote sensing for erosion in a larger scale. The erosion pins allow researchers to measure erosion spatially. This device also permits to measure the degradation of the banks from the last time the measurement was recorded. However, it does not allow automated monitoring of the rate of bank erosion over frequent periods. A consequence of this limitation is a lack of available data for bank change over a period of time, especially during critical flow events, which shape the bank shape. A new technique is needed to address this limitation.

This work is part of a pilot project, and proposes measurement of bank erosion using Photo-Electronic Erosion Pin (PEEP) sensors developed by Lawler (1991, 1994). This will permit researchers to study fluvial erosion on a continuous basis including the effects of flow and of freezing and thawing processes on bank stability. A real analysis of the behavior of the banks under different flow conditions will be possible with the proposed set-up.

2. *Objectives*

The goal of this paper is to demonstrate the use of the PEEP sensors to perform a real-time monitoring system in terms of timing and magnitude of the erosion events. The study will firstly calibrate the PEEPs to automatically monitor fluvial erosion of cohesive banks. The PEEP, together with other instruments, will possibly provide researchers with the opportunity to simulate interactions between the flow peaks and the magnitude of bank erosion. Secondly, this study will demonstrate the PEEP potential to establish more clearly the timing of individual bank erosion events through a pilot study in Clear Creek, Iowa.

3. *Methodology*

3.1. Instrumentation

The PEEP system proposed in this paper is composed mainly of a sensor model 200, a Data Logger, a solar panel, and a computer. The PEEP sensor is designed by Lawler (1991) and consists of an assemblage in series of 20 diodes, so called photovoltaic cells. It is protected by a transparent waterproofed acrylic tube (Lawler 1992). This 20 cm long section constitutes the active length of the sensor; the outer diameter of the acrylic tube is 16 mm. Two reference cells at the beginning and the end of the row of diodes are present. The other 18 diodes will be used to automatically monitor the position of the bank. When the diode is exposed to light, it produces a voltage which is equivalent to the length of tube exposed (Lawler 1992). This means that the more diodes exposed, the higher the voltage. The whole instrument is 66 cm long and is terminated by a cable, which is connected to a Data Logger. This model is a revision of the original sensor and is designed to be more suitable for dynamic erosion sites (Lawler, 2004). A unique feature of this model is that two Thermistors are attached. These Thermistors permit researchers to monitor the soil temperature during an experiment. The first Thermistor is located at the beginning of the sensor and the second one is 68 mm away. This feature allows for the study of soil temperature and

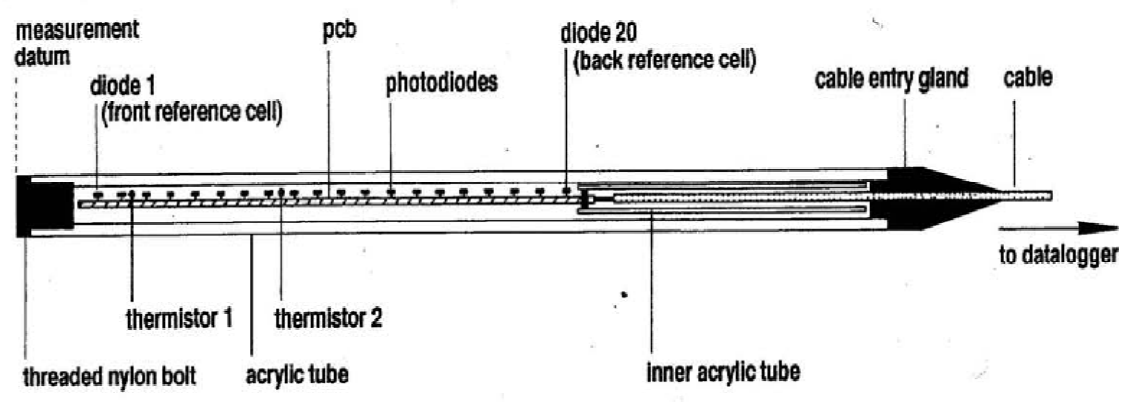

Figure 1. Typical PEEP 200 (PEEP System: User Guide 2004)

soil freeze-thaw processes. Data loggers in the range of 0-225 mV are suitable for the PEEP 200 (Lawler, 2004). For this experiment, a Campbell CR800 Data Logger is used, and with the appropriate computer program, the data is downloaded. As designed by Lawler, the PEEP sensor does not require any power supply. A solar panel is connected to the system and recharges the battery automatically. The system can be easily installed and operated in the field.

3.2. Calibration

The amount of voltage produced can be converted to reveal the amount of exposed active length (Lawler, 1991). The calibration procedure will permit researchers to obtain the relationship between voltage and exposed active length. This step is done outdoors using natural light. To simulate the retreat of the bank, a dark tube is placed around the PEEP sensor to cover all the diodes. The tube represents insertion of the sensor into the bank. Then, the tube is gradually moved to expose the diodes to the sunlight. The interval between the movements is chosen to be three minutes. Once the sensor is completely exposed, the data can be downloaded and analyzed. To calculate the exposed length, the ratio between the voltage output of cell series and reference cell is needed. It is given by the following equation:

$$Rpp = \left(\frac{Vcs}{Vrc} \right) \times 100 \quad (1)$$

where V_{cs} is the voltage output of the cell series in mV and V_{rc} is the voltage output of the reference cell in mV.

Equation (1) allows calculation of the exposed length L using the following relation:

$$L = c + d \times Rpp \quad (2)$$

where L is the exposed length and
c and d are constants (respectively equal to 17.83 and 2.1743)

3.3. Proposed experiment

The calibration of the sensors has been completed in a range of temperatures, ranging from 45°F - 65°F. The purpose is to use the sensors in a pilot project in Clear Creek, a tributary of the Mississippi River, located in Eastern Iowa. The site was chosen because of the cohesiveness of its bank materials and the large amounts of sediment. The Iowa Department of Natural Resources (2006) reports that 239,559 tons of soil were eroded due to a rainfall event in 2004, making this site ideal to study fluvial erosion of cohesive banks.

The PEEP sensors, together with a pressure transducer, are the key instruments. Two cross-sections have been chosen at the site, and four sensors will be installed in each cross section (two on each side of the creek). Eight sensors will be installed in total. One sensor will be as close as possible to the bank toe (See *Figure 2*). Although the installation of the sensors is straightforward, it should be done with extreme caution to avoid breaking of the acrylic tube. The PEEPs will be installed in pre-drilled horizontal holes 16 mm in diameter. It is recommended that the reference cell (1st diode) and that the second diode to be initially exposed. Hence, the first Thermistor

will give the temperature of the air while the second one provides the soil temperature. When the two Thermistors are uncovered they should indicate the same temperature. This feature can be exploited to study the effect of the climate on bank change (e.g., freeze-thaw cycle, flow increase or secondary currents). In order to do so, this paper proposes to exploit the capabilities of the PEEP sensors to create a system which can monitor rate of erosion and permits more secure analysis of the controlling factors (flow peak, weather, and secondary currents).

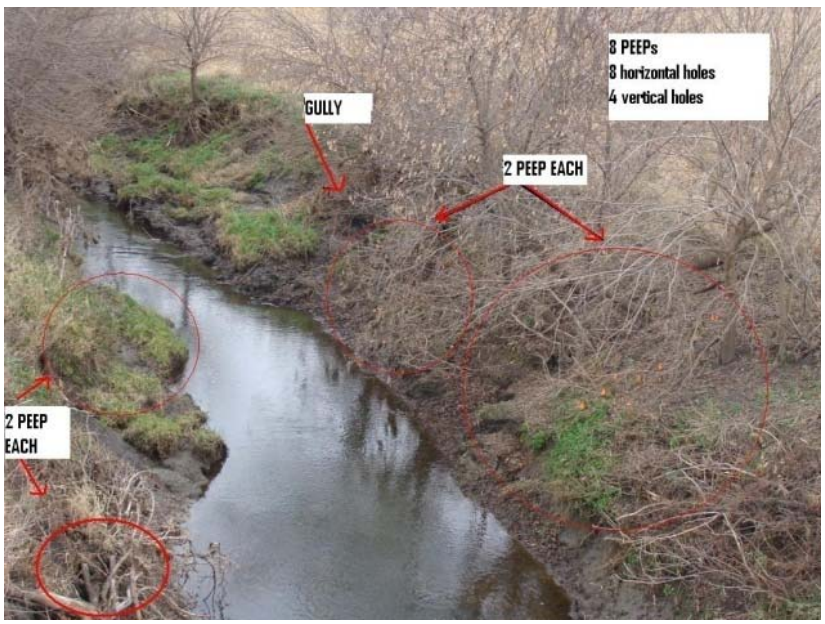

Figure 2: Side view of Clear Creek

The sensors will permit the researchers to monitor temporal changes of the banks. Simultaneously a pressure transducer, model WL400, which is a water level sensor, will be used to measure the stage (H) of the flow. As a consequence, the discharge (Q) can be computed using a log-law relationship between Q and H. The resulted hydrograph and the erosion graph will be plotted together and the data will be analyzed. The correlation of the soil temperature, flow peaks, and real-time erosion will be investigated.

Additionally, to measure the net change of the bank from previous field visits, erosion pins will be used. They can spatially measure the retreat of the bank. A camera may permit a visualization of the phenomenon during the night and show when and if mass failure has occurred. Therefore, it can be distinguished from fluvial erosion when doing the analysis. An Acoustic Doppler Velocity (ADV) will be used to obtain the velocity profile and study the effects of the secondary currents of the flow on the cohesive banks. It is important to state that the PEEP sensors cannot record erosion events during the night. However, more than two Thermistors may be placed and distributed along the sensors. They can be used to monitor the soil erosion during night-time periods along with measuring the soil temperature (Lawler, 2004). Differences between the soil temperature and soil-air interface temperature can indicate whether erosion takes place or not.

4. *Preliminary results*

The calibration procedure has been conducted during the months of September and October 2008. While moving the dark tube around the sensor to simulate erosion, the data logger has been set up to record the data every 15 seconds. At the beginning of the test, the first diode is exposed. Three minutes later, the second diode is exposed, with an additional diode being exposed every three minutes. All 20 diodes are uncovered after 1 hour.

Table 1 gives a summary of the condition of the days when the simulations have been conducted and the number of scans recorded. These tests have been conducted on a bright day using the natural light. The number of scans is for the whole simulation period.

Table 1: Weather Condition of the Simulation

Date	Temp. (°F)	Weather	Number of scans
09/30/2008	54	Sunny	240
10/06/2008	65	Sunny	240
10/14/2008	55	Sunny	240

As indicated in *Table 1*, 240 data points have been recorded for each simulation. The data logger records in mV the voltage of the first diode and the series cells. To make the calibration graph clearer and easily readable for this experiment, the average of the data between two consecutive diodes have been taken. Thus, after applying *equation (1)* to the averaged data, the ratio (in %) is reported in columns 2 and 5 of *Table 2*. The length (in mm) is calculated using *equation (2)* and it is displayed in columns 3 and 6. *Table 2* represents the automated measurements of the active sensor being gradually exposed. For instance, Record Number # 1 (RN 1),means that diode 1 is exposed while all the others are covered and RN 20 means that all the diodes are uncovered which means that the sensor is completely showed.

Table 2: Data for the erosion simulation of a PEEP on September 30th, 2008

RN	Rpp (%)	L (mm)	RN	Rpp (%)	L (mm)
1	24.64451854	71.41	11	78.96284285	189.52
2	56.00633651	139.60	12	81.46560495	194.96
3	55.9436448	139.47	13	85.59561991	203.94
4	59.07246651	146.27	14	86.67546954	206.29
5	62.41851725	153.55	15	89.50065044	212.43
6	66.03480067	161.41	16	92.34980561	218.63
7	68.31858965	166.38	17	94.98888923	224.36
8	70.4561907	171.02	18	97.66384358	230.18
9	73.28275935	177.17	19	99.81462409	234.82
10	75.94637012	182.96	20	101.2659425	238.01

Figure 3 plots a typical calibration graph for the PEEP sensor. For better accuracy in the field, one can measure the distance exposed from the bank and verify the calibration graph.

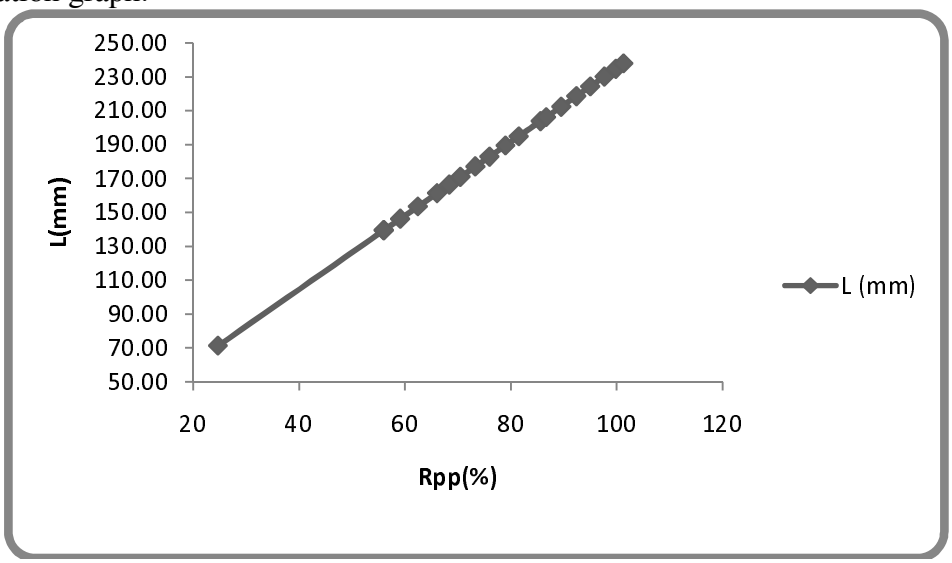

Figure 3: Typical calibration graph for test conducted in 09/30/2008

Another way to present the results is shown in *Figure 4*. Note that a correlation between the exposed cells and the protrude sensor from the bank can be made. As the dark tube is removed, the diodes are exposed to light, simulating erosion.

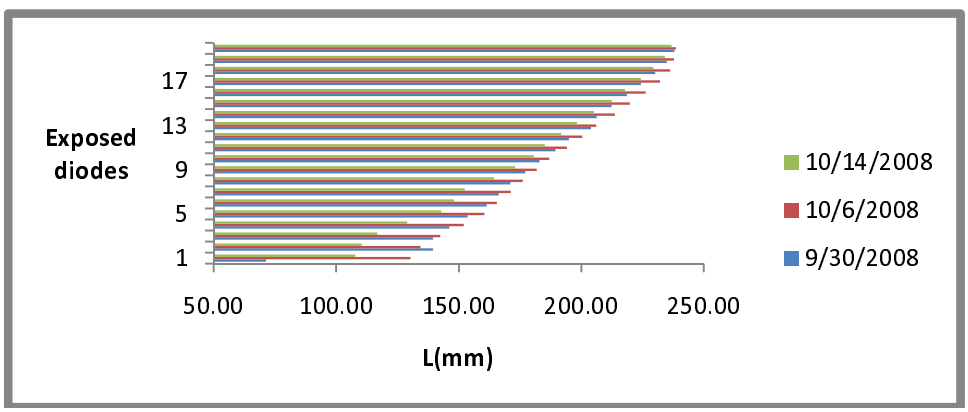

Figure 4: Erosion simulation for the PEEP sensors

The tests conducted September 30th and October 6th have been completed with the PEEP model 200 labeled S-230-30. The calibration graph converged from exposed diodes 2 to diodes 20. The divergence in diode 1 may be explained by a shadow or a cloud in the sky while conducting the experiment. Therefore enough light does not reach the 1st diode to output the necessary voltage. This is one of the apparent weaknesses of the instrument. On October 14th, another PEEP, which is the same model, labeled S-231-30 is utilized. Although a divergence with the data recorded can be observed, the data are close when diode 10 is exposed. Indeed for accuracy of the results, it is required to calibrate each sensor before using it in the field. It is not a

discrepancy because it is required to calibrate each sensor for more accuracy. The calibration graph of each sensor may show some differences.
This system not only will introduce a new technique to automatically monitor bank retreat but also permits a comparison between flow peaks and erosion events. Also, investigation of the effect of the freeze-thaw process on these erosion events is possible.

5. *Conclusion*

This paper demonstrates that the Photo Electronic Erosion Pin is indeed a system which can easily be installed and operated. The capability of the instrument can be exploited to obtain real-time and more secure data in terms of magnitude and frequency. Also, the freeze-thaw induced erosion will be investigated using the features provided by the instrument. Combined with other instruments (e.g.: a pressure transducer), a correlation can be completed comparing flow peaks and erosion events. However, the sensor depends on daylight to output a voltage. It cannot record erosion during the night and when it is submerged in turbid water. This limitation is being considered. The PEEP model 200 gives the soil temperature. Therefore, erosion can be detected by the existing temperature difference and other devices such as a camera, which gives a clear visualization of the event occurring. Although this paper does not study the complex electro-chemical forces existing between particles of cohesive banks, this system, if exploited, can lead to more secure analysis of critical shear stress but most importantly a better analysis of the impact of the freeze-thaw processes on bank stability.

Integrated Surface water and Groundwater modeling of Orange River Basin in Southwest Florida for Flood Mitigation/Ecosystem Restoration

E. Zia Hosseinipour
Advance Planning Section, Ventura County Watershed Protection District, 800 S. Victoria Avenue, Ventura, CA 93009; email: Zia.Hosseinipour@Ventura.org

ABSTRACT

MIKE SHE/MIKE 11 water modeling software was applied to develop a comprehensive water resources plan for the East County Water Control District (ECWCD) in southwest Florida. The main objectives of the comprehensive plan were, (1) to reduce the extent, magnitude, and duration of flooding in the upper region of Orange River basin, (2) increase groundwater recharge within the ECWCD to augment water supply, and (3) improve water quality of the waters leaving ECWCD boundaries.

It was envisioned that the comprehensive plan would result in modification of a number of existing structures on canals in the areas covered by the ECWCD jurisdiction. As part of this modeling project, a number of flow diversions and water storage options are being reconsidered. This paper describes calibration of the integrated model and modeling results for a set of potential hydraulic network upgrades and diversion alternatives. The alternatives proposed and fully evaluated were either quick-action projects that can be implemented in the near future or are more long-term projects that have a high potential to meet project objectives and require land acquisition that could be initiated in the near future. Additional alternatives were also evaluated based on the results of the alternatives described here. All of the hydraulic network modifications were evaluated to consider downstream impacts so that problems are not simply transferred from one area to another. The modeling work was performed using the ECWCD version of the Tidal Caloosahatchee River Basin (TCRB) integrated surface-ground water model developed for SFWMD and ECWCD.

INTRODUCTION

The scope of this study included performing integrated modeling in support of hydraulic/hydrologic analysis of existing conditions, and for potential storage and/or diversion of water from the Orange River/Able Canal Basin to a number of other basins during high flows for the purpose of mitigating flooding in the headwaters of Orange River. The initial phase of the work included refinement of the TCRB model to incorporate a more detailed representation of ECWCD canals and water control structures. During the initial phase, the model was used to determine the dimensions of various structures (e.g., S-HC-1 and S-HC-2) on Hickey Creek Canal in support of the re-design of those structures. The model was calibrated using 2004 and 2005 rainfall and landuse data provided by ECWCD. The project's main goal was to provide a basis for better management of runoff during intense storms in ECWCD domain as the area further develops by looking at a number of diversion alternatives that would mitigate flooding while being protective of the fragile ecosystem.

PLANNED LANDUSE AND THE PROJECTED RUNOFF INCREASES

The alternative analyses that provide the foundation for the Comprehensive Water Resources Plan are described below. Undeveloped lands in ECWCD are platted and subdivided into many small ¼-acre parcels. Currently, new development in ECWCD is constructed on a lot-by-lot basis without any stormwater management. Because ECWCD does not provide wastewater collection and seasonal high water tables can be close to the land surface for a portion of the year, all new houses and septic systems are constructed on a pad that is typically 2-4 feet above natural ground. Compaction of the elevated pad and the higher elevation results in lower infiltration and elevated rates of runoff. Figure 1 below shows the domain of the model and conveyance features. Figure 2 presents a comparison of simulated flows at full build-out to existing flows for the 2004 period. Peak flows (summed for all canals that drain ECWCD) in the future will be 50% higher than current flows.

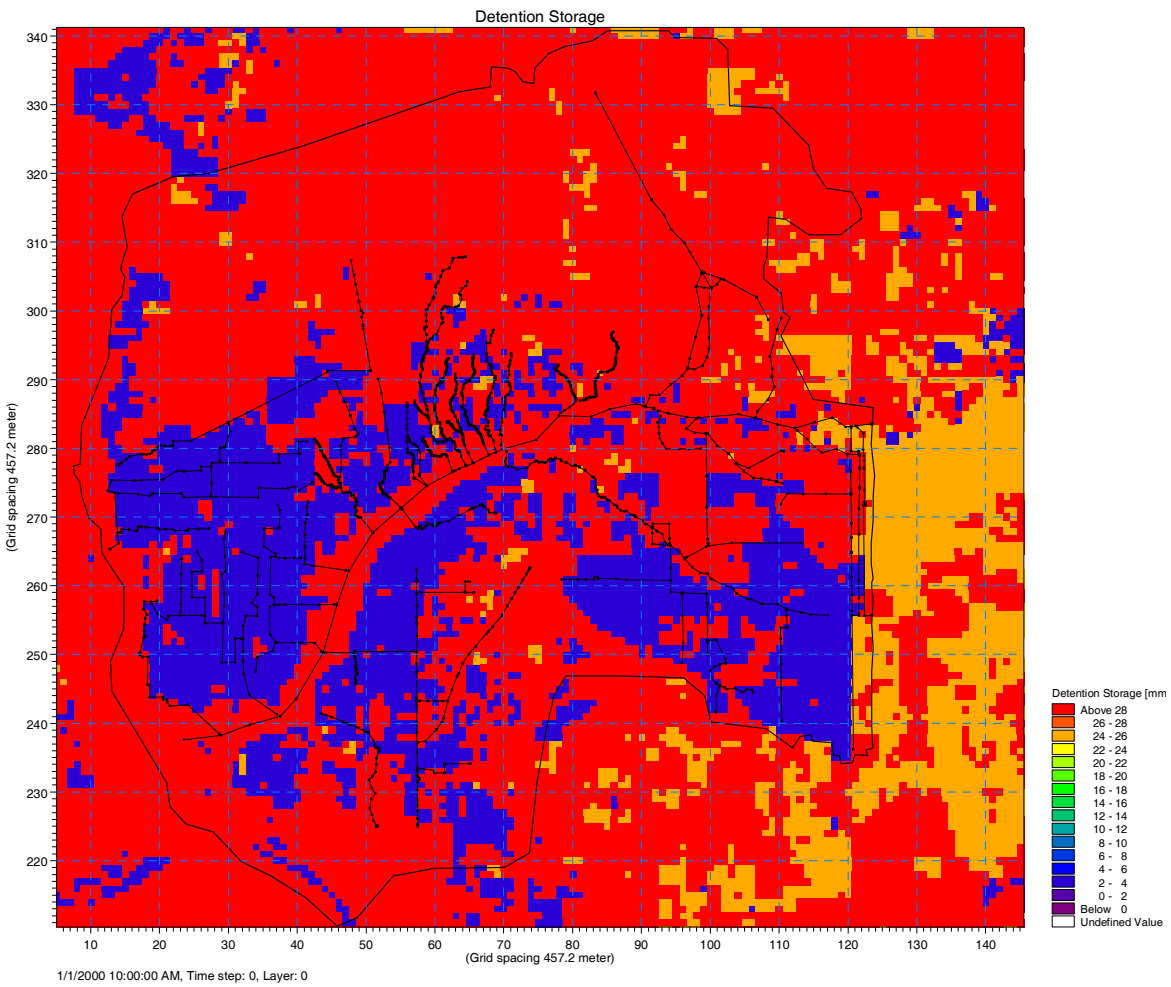

Figure 1- Integrated model domain and major drainage networks

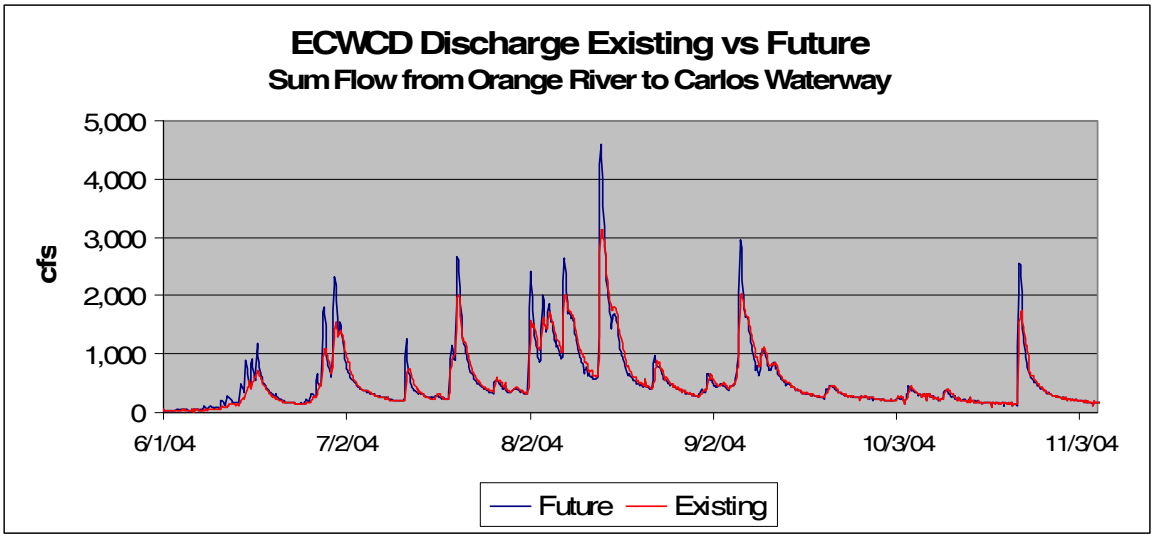

Figure 2 – Total Flow from ECWCD for Existing and Future Conditions

Below we provide initial modeling results for a sub-set of a larger set of possible alternatives. The alternatives considered and simulated using the integrated model is summarized below:

- Modify existing South Harns Marsh hydraulic control structures to provide more storage and detain a larger portion of ECWCD runoff. Increase the area of the marsh system if appropriate.
- Modify weir control elevations to maintain higher canal levels in ECWCD that will reduce peak discharge rates and increase groundwater recharge.
- Divert runoff from the Able Canal/Orange River basin through Charlie Diversion to Hickey Creek to alleviate flooding during high flows in the Orange River catchment. Enlarge Hickey Creek Canal and divert some Hickey Creek Canal flows for water quality treatment.
- Retain runoff from the southeast portion of ECWCD to re-hydrate drained wetlands east of Hendry Canal Extension.
- Route water from Mirror Lakes into the Estero Watershed to alleviate groundwater impacts associated with public water supply well-fields.

The ECWCD canal system has re-distributed runoff from historic watersheds. Figure 3 shows the original and current watershed boundaries. The figure clearly indicates that the current drainage area for Hickey Creek (yellow line polygon) is significantly smaller than the original drainage area (black line polygon).

DESCRIPTION OF ALTERNATIVES

The alternatives that have been evaluated with respect to peak flow reduction, base flow enhancement, and ground water recharge are described here. A simulation of a major storm event was conducted that assumed implementation of a combination of improvements to Hickey Creek, Harns Marsh, and ECWCD groundwater recharge weirs.

The purpose of this combination simulation was to determine if a combination of quick-action features can be implemented to reduce flood impacts in the Orange River basin during the 2006 wet season while maintaining adequate flood protection in Hickey Creek.

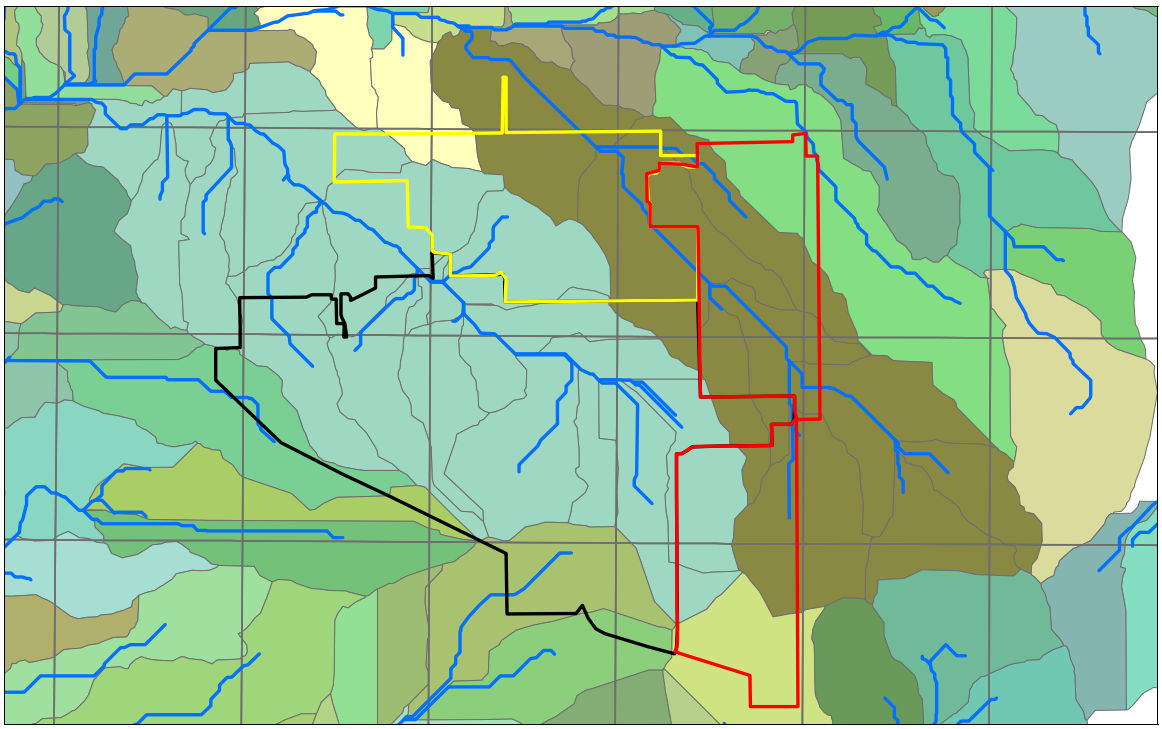

Figure 3 – Historic and Current Drainage Area Boundaries for ECWCD

Harns Marsh Improvements: This alternative, shown in Figure 4, includes improvements to the South Harns Marsh inflow, North and South Harns Marsh outflow gates, and considers the benefits of adding a third treatment cell (referred to as the West Marsh). Simulations were conducted with and without the West Marsh to quantify the benefit of adding additional treatment area. Additional modifications to evaluate in the future may include the realignment of North and South Marsh levees to restore the original Orange River flow pathway.

Groundwater Recharge: The southwest portion of ECWCD has numerous canals that are maintained at relatively low elevations. Figure 4 also shows the layout of typical drainage canals; water levels in these canals are maintained approximately 8 feet below natural ground elevation. Houses and septic systems are typically built on pads approximately 2-3 feet above natural ground elevation. Water levels in these canals are maintained by either S-SF-1 or S-SF-2 weirs. If additional weirs were installed with bleed-down orifices, runoff could be detained in this area to promote more groundwater recharge.

Hickey Creek Improvements: The purpose of this alternative was to restore flows to Hickey Creek that were diverted during initial construction of ECWCD Canals. The diversion of flows will be limited to the conveyance capacity of Hickey Creek so that

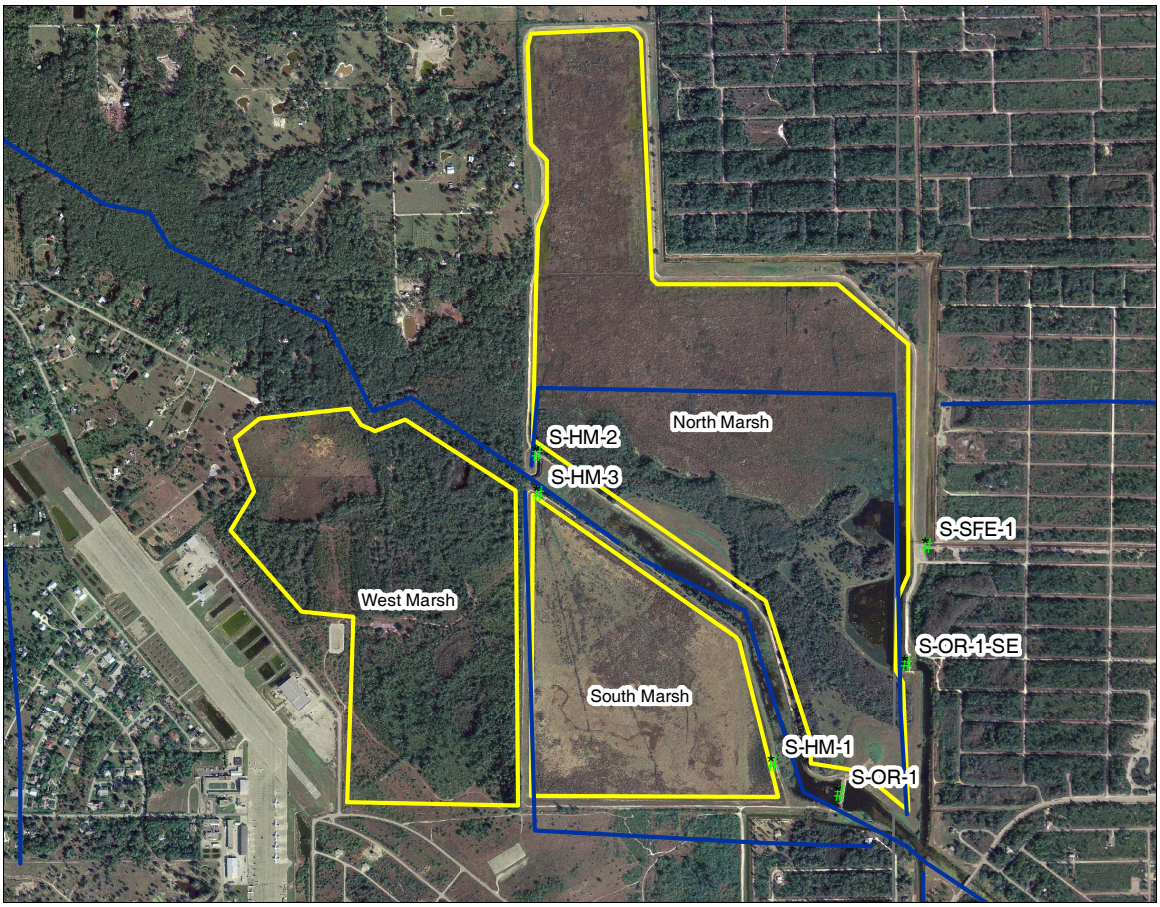

Figure 4 – Features of the Harns Marsh Improvement Alternatives

flooding problems in the Orange River are not transferred to Hickey Creek. The features of this alternative are shown in Figure 5 and are summarized below:

- Widening of Hickey Creek Canal south of S-HC-2 from a 40-foot bottom width to a 200-ft bottom width
- Operation of the gates at S-HC-3, S-HC-2, and S-HC-1 to divert a portion of Orange River flood flows (limited to that amount that can be safely conveyed down Hickey Creek)
- Treatment of a portion of the Hickey Creek Canal flows in a network of canals north of Fox Canal, east of Hickey Creek Canal, and southwest of Greenbriar Swamp
- Drawdown of Greenbriar Swamp prior to storm events so that the Swamp can detain runoff during large events

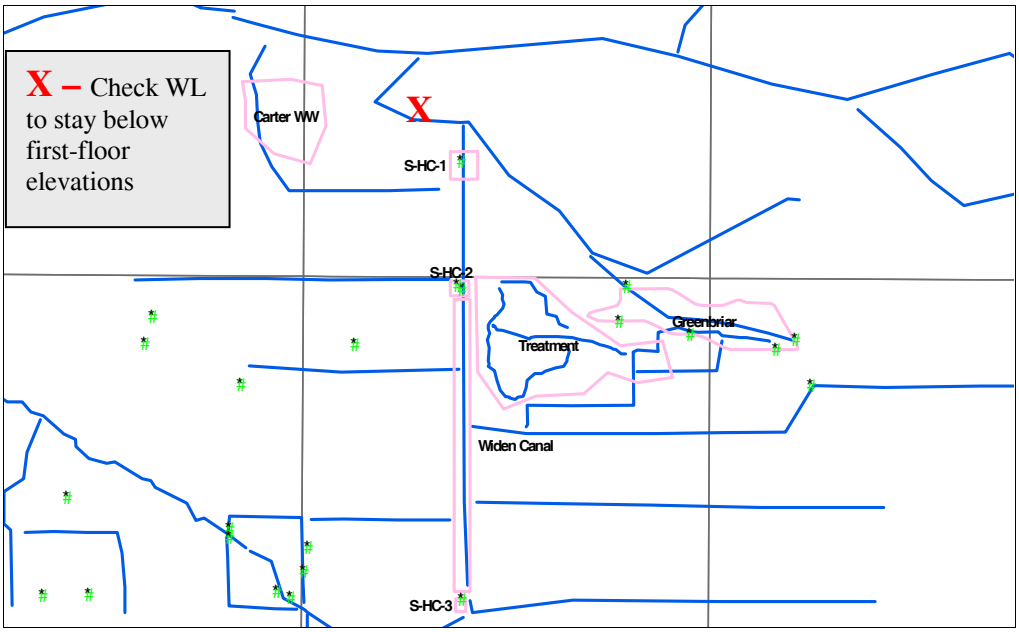

Figure 5 – Features of the Hickey Creek Improvement Alternative

Wetlands Re-hydration East of Hendry Canal Extension: The southeast headwaters of Able Canal and Hendry Canal Extension were part of a broad expanse of wetlands that contributed flows to Hickey Creek and the Orange River to the north, and to the Estero and Imperial Rivers to the south. This alternative involves connection of Nine Mile Canal, Branch 84 (Canal 57-11-3), and Hendry Canal Extension and a pump station to route storm water runoff to drained wetlands east of Hendry Canal Extension. Water would be held in the restored wetlands and then used to augment base flows in the downstream watersheds via hydraulic control structures.

Diversion of Mirror Lakes flow to Re-hydrate Drained Wetlands: Mirror Lakes was originally part of another watershed (Estero River). There are well-fields in the Estero River watershed northeast of the junction of Corkscrew and Alico Roads that have caused lower wetland water elevations in Estero River headwater wetlands north of the well field. This alternative would pump runoff from the Mirror Lakes watershed to a flow-way south of SR 82. Flows would be delivered to these wetlands only during periods when the Estero headwater wetland water levels were below their normal hydro-period elevations. Modeling of Estero headwater wetlands is required to determine an optimum regulation schedule and diversions that would be allowed when these wetlands were below the regulation schedule. This would allow for diversion of Mirror Lakes flow to off-set wetland impacts due to well field operation without causing flooding problems in the Estero River and Imperial River basins.

ALTERNATIVE ANALYSIS

Modeling analysis was conducted for the Harns Marsh expansion, ground water recharge, Hickey Creek Improvements, and Hendry Canal Wetland Re-hydration Alternatives. Analysis of existing conditions was conducted to evaluate the Mirror Lakes

Diversion Alternative. Simulation was also conducted of a merged quick-action alternative to determine the degree of flood control that could have been achieved in the wet season of 2006.

Harns Marsh Alternative: Peak flow reduction was good for small storms, and peak flow reduction can also be significant if the wetland treatment areas can be drained prior to a major storm. Figure 6 presents the results for relatively small storms using rainfall during the early part of the 2004 wet season. Peak flow reduction is improved with the inclusion of west marsh.

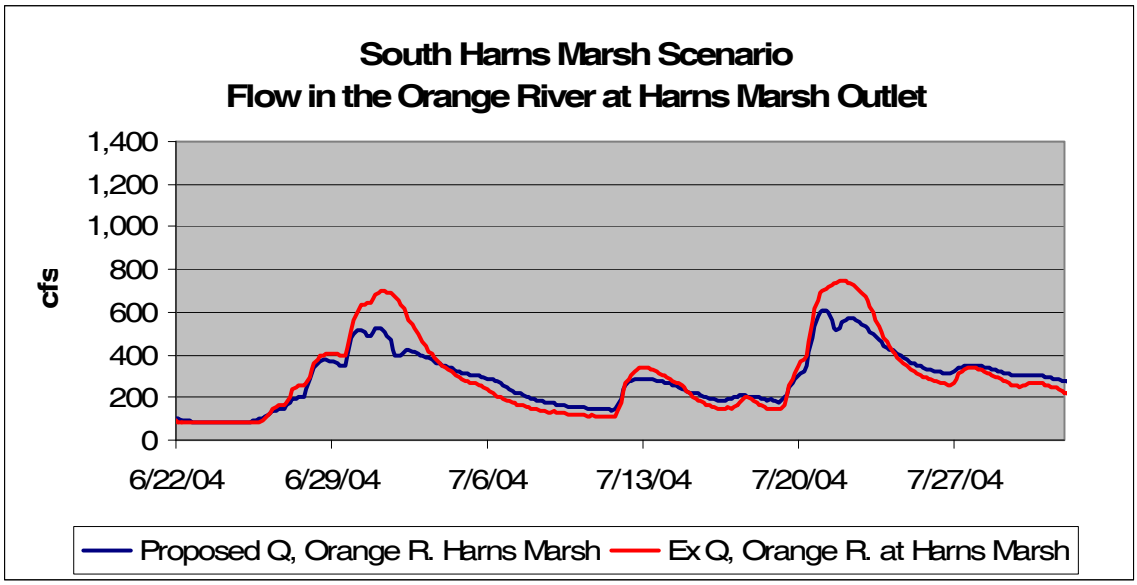

Figure 6 – Peak Flow Reduction for Harns Marsh Improvements Including the West Marsh for the Early Portion of summer 2004

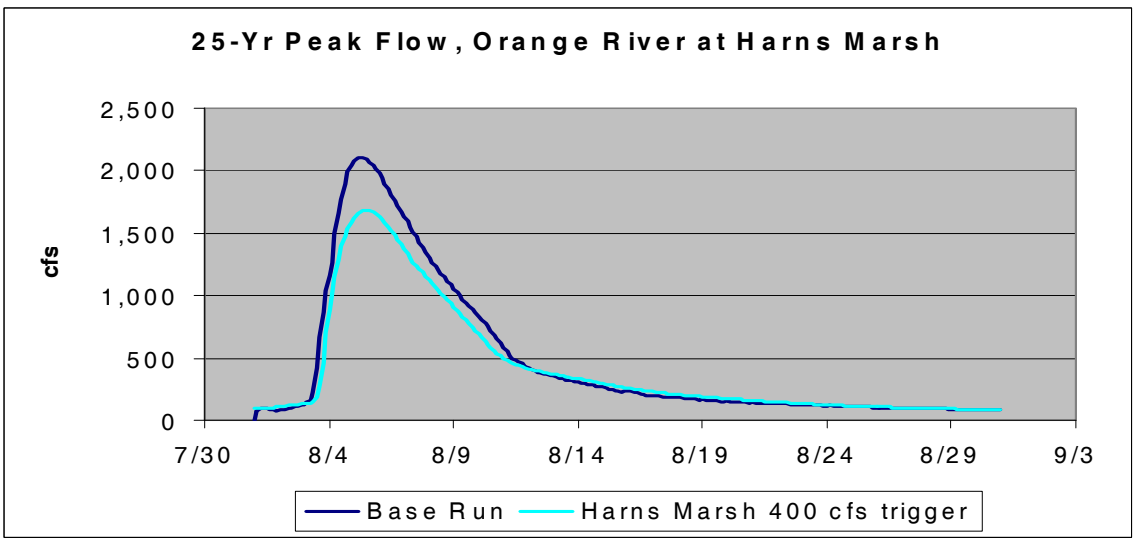

Figure 7 – Peak Flow Reduction for Harns Marsh Improvements Including the West Marsh for a 25-Year Design Storm

Figure 7 above shows results for a 25-year storm when additional capacity is included by expansion of the marsh on the western side (West Marsh addition).

Groundwater Recharge Alternative: Initial runs presented in Figure 8 with high weir elevations do not reduce peak flows for the 25-year storm but are effective in reducing both the peak flow and the volume of runoff for the 10-year storm.

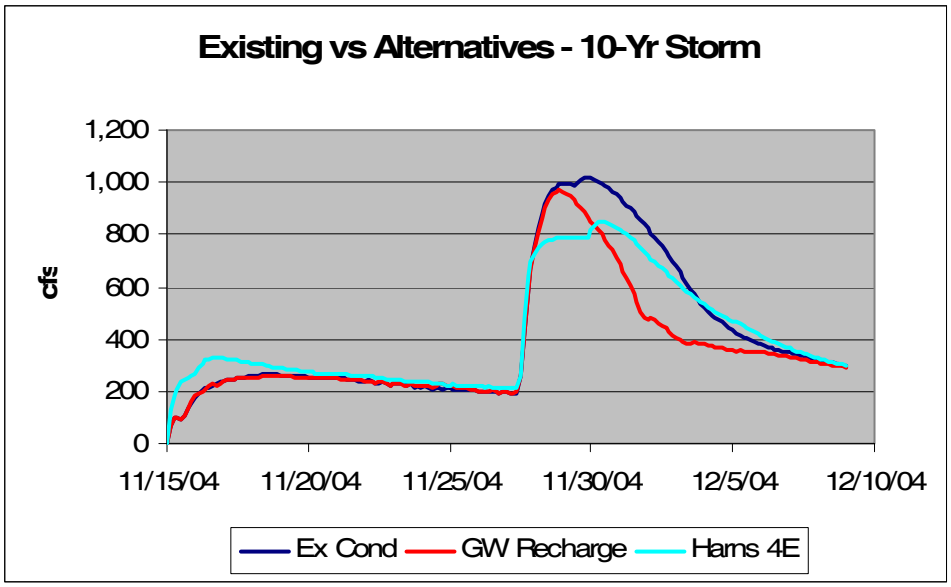

Figure 8 – Orange River at Harns Marsh 2004 Flow with and without Recharge

Hickey Creek Improvements Alternative: The Hickey Creek alternative results presented below do not include improvements to allow flows to enter the canals east of Hickey Creek Canal. The results are presented below in Figures 9 and 10 for design flow and stage.

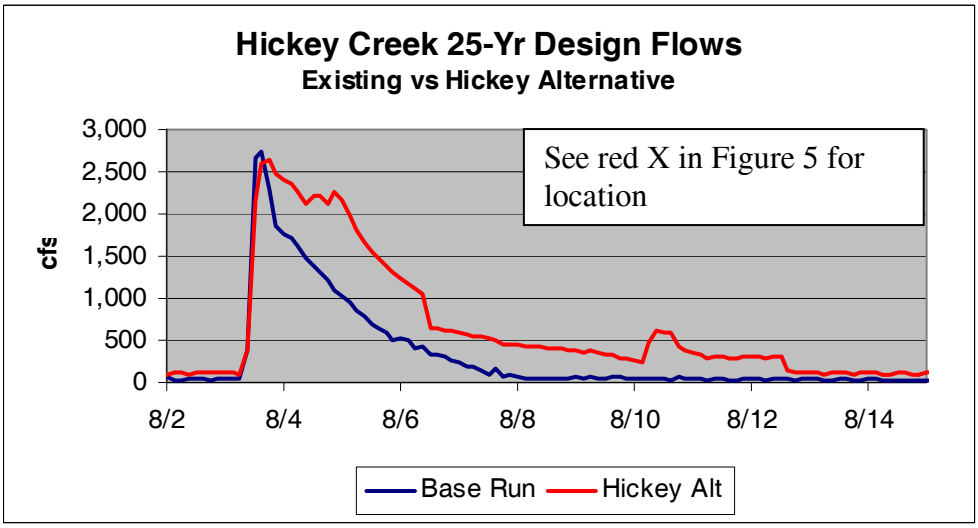

Figure 9– Flow in Hickey Creek with and Without the Diversion

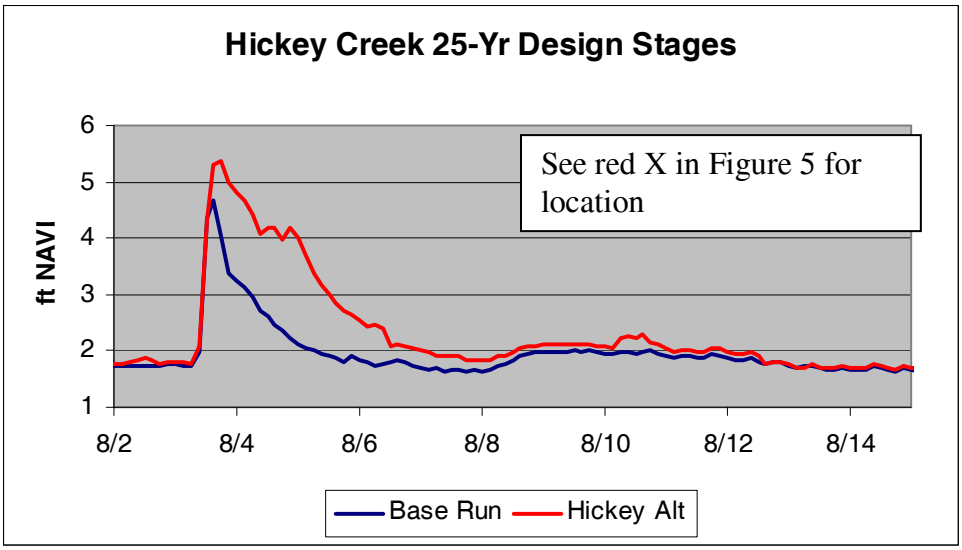

Figure 10 – Stage in Hickey Creek with and Without the Diversion

Hendry Canal Wetland Re-hydration Alternative: This alternative has been tested as a stand-alone alternative and also in combination with South Harns Marsh Improvements. Flow in the Orange River at the Harns Marsh outlet is presented in Figure 11. This wetland re-hydration alternative provides peak flow reductions, however the combination of this alternative and South Harms Marsh Improvements provides increased peak flow reductions. Average dry and wet season ground water elevation difference maps were produced. When the difference values are positive, it indicates higher ground water levels, and the impact of the re-hydration is evident. A number of groundwater difference maps were produced to evaluate the efficacy of rehydration scenarios. Simulation results indicated that if all of the water stored in this wetland area were released to Able Canal during the dry season, the release rate could be as high as 17 cfs over a 180-day period. Thus the wetland alternative provides both ecosystem benefits and groundwater augmentation via enhanced recharge by maintaining optimum wetland hydro-period.

Mirror Lakes Diversion Alternative: An 80 cfs pump station on Canal 57-19-5 could divert approximately 9,200 acre-feet in 2004 and 9,000 acre-feet for June through December (the rainy season) if water levels in Mirror Lakes were maintained above 27 ft-NAVD (28.3 ft-NGVD). Some expansion of canal 57-19-5 would probably be required to accomplish this diversion. There are approximately 6,200 acres of wetland recharge area south of SR 82, therefore it is expected that this diversion would have a negligible effect on water depths within the wetland recharge area.

The diversion rate for this alternative is limited by the small drainage area of Mirror Lakes. This diversion rate is approximately 10% of the 2004 peak flow for the Orange River at Harns Marsh. Accordingly, as shown in Figure 11, this alternative

would not be able to reduce peak flows in the Orange River sufficiently by itself however it could be one component of the comprehensive plan.

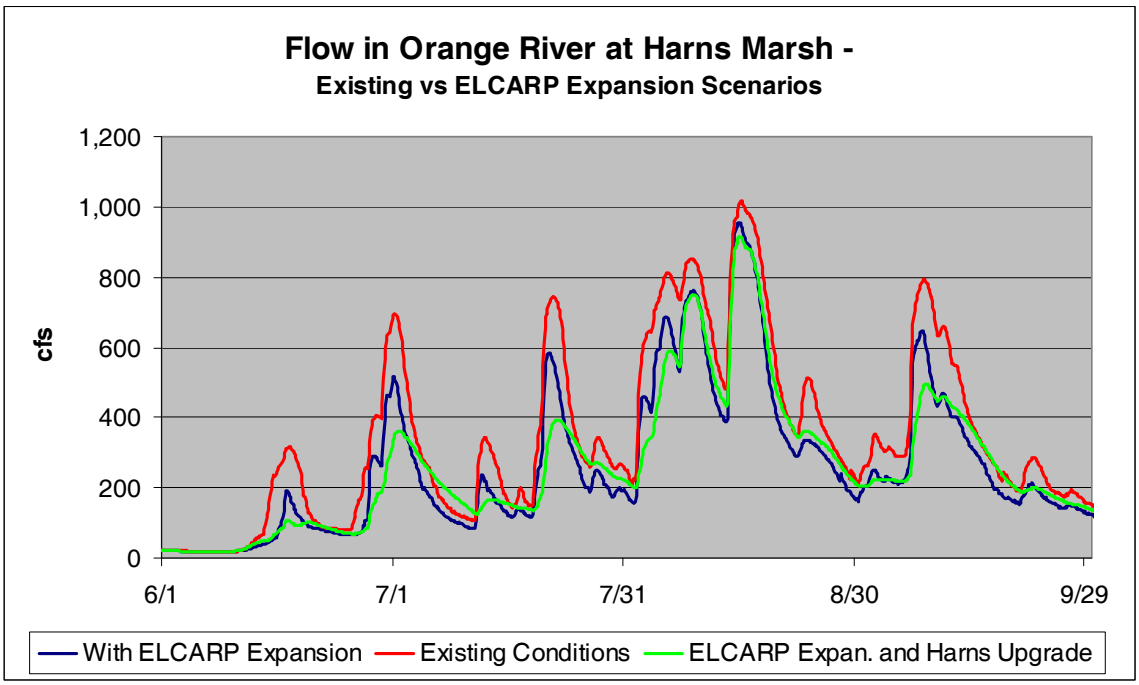

Figure 11 – Flow for the Orange River at Harns Marsh for the Re-hydration Alternative, Re-hydration and Harns Marsh Improvements, and Existing Conditions

CONCLUSIONS

The integrated modeling of the project area using the MIKE SHE/MIKE11 package was very effective because of high ground water table conditions and close interactions of surface and ground waters. Modeling of quick action scenarios as possible components of the comprehensive plan for the ECWCD showed acceptable results and are listed here:

1. Harns Marsh Improvements including addition of the West Marsh
2. Hickey Creek Improvements to divert Orange River flows
3. Ground water recharge in southwest ECWCD
4. Hendry County wetland re-hydration
5. Mirror Lakes Diversion to re-hydrate wetlands near the Corkscrew well field
6. Drawdown of canal water levels prior to major rainfall events

Future modeling is recommended to determine the best mix of effective solutions for: (a) Reducing flooding in the Orange River, (b) Enhancing ground water recharge in ECWCD to reduce Lehigh Estates private residential well failures, (c) Minimizing potential project(s) costs, (d) Augmenting flows in Able Canal and the Orange River during the dry season , and (e) Increasing water levels in drained wetlands near the Corkscrew well-field in the Estero River watershed.

The optimum mix of solutions will likely involve one or more of the scenarios described here along with additional measures based on ecosystem requirements.

Spatially distributed modeling of soil erosion and sediment transport at watershed scale

H. Zeinivand[1&2] and F. De Smedt[1]

[1]Department of Hydrology and Hydraulic Engineering, Vrije Universiteit Brussel, Pleinlaan 2, 1050 Brussels, Belgium; email: Hossein.Zeinivand@vub.ac.be, fdesmedt@vub.ac.be

Abstract
A distributed, physical and GIS-based modeling approach is developed to estimate runoff, soil erosion by water and sediment transport within a watershed at a daily time step. The approach relies on the use of GIS data for deriving major model parameters that show distinct spatial variability over the catchment. Surface runoff is calculated by a modified rational method, which depends upon rainfall intensity, soil moisture status, slope, land-use, and soil characteristics. The erosion model simulates soil erosion by raindrop impact and shear erosion in overland and channel flow using equations with a physical basis. A diffusive approximation method is used for routing runoff and sediment transport to the basin outlet. The model uses as few parameters as possible while retaining its physical basics. The model was applied on the Latyan dam catchment in Alborz mountain range in the northern part of Iran. Simulated river discharge and sediment concentration are compared to daily measured data from September 2005 to September 2006. The results indicate that there is a good agreement between simulated and measured discharge and sediment concentration at the basin outlet, though more efforts regarding soil erosion and sediment transport need to be clarified by further research.

Introduction
Soil erosion and transport is a complex process that is influenced by soil type, topography, climate, land use, and antropogenic activities such as tillage systems and soil conservation measures (Kuznetsov et al., 1998). The three main phases of soil erosion are detachment, transport and deposition. Soil detachment and transport by impacting rain drops is an important first step in soil erosion. Physical understanding of the processes causing detachment and transport by falling rain drops has improved considerably over the last two decades, mainly by laboratory experiments (Poesen and Savat, 1981; Ghadiri and Payne 1988; Poesen and Torri, 1988; Sharma and Gupta, 1989; Salles and Poesen, 2000; Van Dijk, et al., 2003). The erosion of soil caused by the raindrop splash and the overland flow is known as sheet erosion or interrill erosion. Models differ in terms of complexity, processes considered, and the data required for model calibration and model use. Sediment transport is sensitive to the flow hydraulics. Therefore, when applying physically based models, detailed and accurate simulation of the velocity and depth of flow is more important than an accurate calibration of rainfall erosion and runoff erosion parameters although, in

some cases, erosion can be sensitive to those parameters (Smith et al., 1999; Aksoy and Kavvas, 2005). In this model water and sediment are routed over the land surface with WetSpa, a GIS-based distributed hydrological model for flood prediction and watershed management on catchment scale. The erosion model simulates soil erosion by raindrop impact and leaf drip impact, shear erosion in overland flow and channel flow, and sediment transport by overland flow and channel flow using physically based equations.

Erosion and sediment transport processes and modeling

Soil detachment by raindrop impact

Modeling soil detachment by raindrop impact is based on relationships between detachment and the kinetic energy of rainfall. In this model, equations for splash detachment by rain drops have been largely taken from the EUROSEM model (Morgan et al., 1998; Koo et al., 2005). Soil particle detachment by raindrop can be predicted as (Morgan et al., 1998; Koo et al., 2005):

$$DR = k\left(KE_r + KE_l\right)\exp\left(-Z_s h\right) \quad (1)$$

where DR is the rate of soil particle detachment by raindrop impact [$gm^{-2}s^{-1}$], k is an index of the detachability of the soil [gJ^{-1}] for which values must be obtained experimentally, KE_r is the kinetic energy rate of direct rainfall [$Jm^{-2}s^{-1}$] which reaches the soil surface, KE_l is the kinetic energy rate of leaf drainage from the canopy [$Jm^{-2}s^{-1}$], and Z_s is a parameter varying between 0.9 and 3.1 [mm^{-1}], depending on soil texture but for which a value of 2.0 [mm^{-1}] can be used for a wide range of conditions (Torri et al., 1987), and h is the mean depth of the surface water layer [mm].

Soil detachment by overland flow

Overland flow detaches soil particles by exerting a shear stress which breaks the inter particle bonds. Soil particle detachment by overland flow [$kgm^{-2}s^{-1}$] is calculated as (Ariathurai and Arulanandan, 1978; Wicks and Bathurst, 1996; Adams and Elliott, 2006):

$$DF = K_f\left(\frac{\tau}{\tau_c} - 1\right) \qquad \text{for } \tau > \tau_c \quad (2)$$

$$DF = 0 \qquad \text{for } \tau \le \tau_c$$

where DF is the rate of soil particle detachment by the flow [$gm^{-2}s^{-1}$], K_f is the overland flow erodibility [$gm^{-2}s^{-1}$], τ is the shear stress [Nm^{-2}], and τ_c is the critical shear stress [Nm^{-2}] which is calculated by the modified Shields diagram (Madsen et al., 1976).

Runoff simulation

A distributed hydrological model WetSpa is applied for simulation of the hydrological processes including precipitation, interception, depression storage, surface runoff, infiltration, evapotranspiration, percolation, interflow, ground water flow, and water balance in each layer. Hydrological processes in each grid cell are set in a cascading way, starting from a precipitation event. Incident rainfall first encounters the plant canopy, which intercepts all or part of the rainfall until the interception storage capacity is reached. Excess water reaches the soil surface and can infiltrate the soil zone, or is diverted as surface runoff. The runoff is subsequently routed through the basin along flow paths determined by the topography using a diffusive wave transfer model that leads to response functions between any start and end point, depending upon slope, flow velocity and dissipation characteristics along the flow lines (De Smedt et al., 2000).

Basic equation for sediment transport

Overland flow is routed prior to implementation of the erosion algorithm, so the depth and velocity of flow are available for sediment calculations. The transport of sediment in a stream commonly can be approximated using the kinematic wave and first-order kinetics for the settling. In one dimension, the partial differential equation describing solute transport in streams is given by:

$$\frac{\partial C}{\partial t} = D(x)\frac{\partial^2 C}{\partial x^2} - v(x)\frac{\partial C}{\partial x} - \lambda(x)C \tag{3}$$

where C is sediment concentration [gm^{-3}], x is the distance along the flow path [m], D(x) is the longitudinal dispersion coefficient at location x [m^2s^{-1}], v(x) is the transport velocity at location x [ms^{-1}], and λ(x) is the settling coefficient at location x [s^{-1}].

For convenience of analysis, the dependent variable of concentration C can be transformed into the rate of transport by multiplying Equation (3) by the rate of water discharge, i.e. (Liu et al., 2005)

$$\frac{\partial q_c}{\partial t} = D(x)\frac{\partial^2 q_c}{\partial x^2} - v(x)\frac{\partial q_c}{\partial x} - \lambda(x)q_c \tag{4}$$

where $q_c = CQ$, denotes the mass rate of sediment transport [gs^{-1}].

The total transport rate at the catchment outlet can be obtained by a convolution integral of the responses from all grid cells, i.e.

$$Q_{sh}(t) = \int_A \int_0^t L(x,t')U(x,t-t')dt'dA \tag{5}$$

where $Q_{sh}(t)$ is the sediment outflow transport rate [gs^{-1}], $L(x,t')$ is the loading rate at a certain location in the catchment [$gm^{-2}s^{-1}$], t' is the delay time [s], U is a unit flow path response function [s^{-1}], and A is the catchment area [m^2]. The loadings can be calculated as:

$$L(x,t) = DF(x,t) + DR_r(x,t) \quad (6)$$

Application

Study area and model simulation

The erosion and sediment module was applied and tested for the Latyan dam watershed located in Alborz mountain range in the northern part of Iran. The drainage area is 435.3 km^2 up to Roodak hydrometric station at the entrance of the Latyan dam reservoir, as shown on the location map in Figure 1. The basin is mountainous with elevations ranging from 1700 to 4212 m. The mean elevation is 2830 m and the mean basin slope is about 45.6%. Land use is composed of 5 different types of land cover: 91% of the basin is covered by deciduous shrubs, 6.2 % by deciduous broad trees, 1.8% by short grass, and about 1.0% by agriculture and impervious areas, mainly villages (Zeinivand and De Smedt, 2008). There are 3 different soil textures in the catchment. The dominant soil texture is clay loam, which covers about 89.4% of the basin, and silt loam and sandy loam about 5.6% and 4.8% respectively (Zeinivand and De Smedt, 2008). Hydrologic data for this study were obtained from Tehran Regional Water Organization and Iranian Water Resources Research Organization (TAMAB Co). The data set include, daily precipitation in 8 stations, temperature and evapotranspiration in 3 stations, and daily discharge and suspended sediment concentration data at Roodak station. All data are available for a one year from September 2005 to September 2006, except for sediment concentrations for which only 13 samples have been collected. The catchment is a mountainous and about 50% of the precipitation is snowfall. The annual precipitation in the study area and for this period is 676 mm; the temperature varies from -11.73 to 23.6 ºC with 8.57 ºC on average.

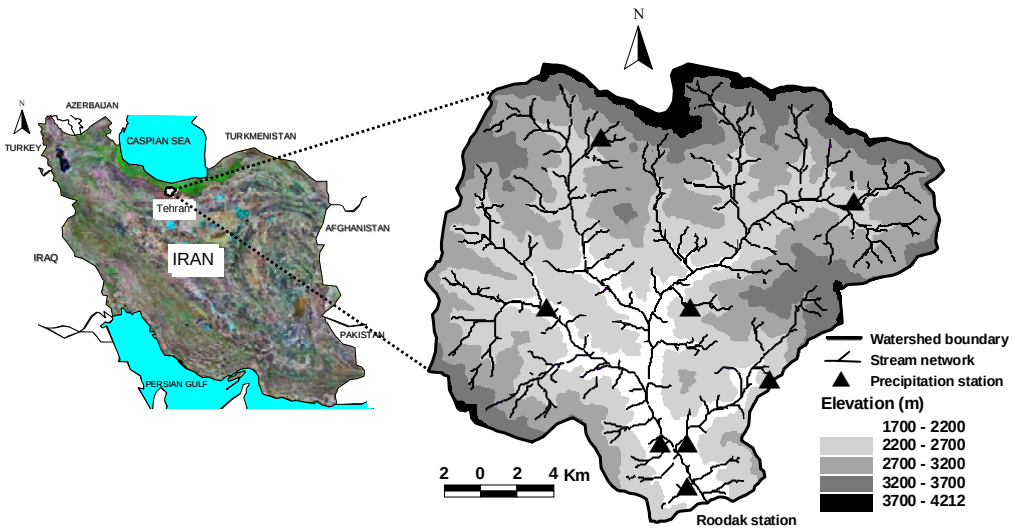

Figure 1. Location of the Latyan dam watershed in Iran and detailed map of the subbasin upstream of Roodak station, showing stream network, topography and location of precipitation stations.

The one year daily discharge data and the 13 sediment concentrations observed at the catchment outlet is used for model simulation and evaluation.
All parameters of the model that are related to the basin are derived from a combination of a digital elevation model, a soil map, and a land use map. For the simulation of hydrographs and suspended sediment concentration at the basin outlet, the catchment was divided into 193 subcatchments. First, model calibration is implemented by comparing the simulated hydrograph with the observed hydrograph graphically and statistically. Then measured suspended sediment concentrations are compared with the simulated sediment concentrations at Roodak station. The calibrated detachability of the soil k is 0.005 gJ^{-1} and the overland flow erodibility K_f is 8.75×10^{-7} $gm^{-2}s^{-1}$ in this catchment. The soil detachability k parameter seems to be lower than in other studies. The reason could be snow cover, because k is the detachability of the soil by raindrops, and when there is a snow cover raindrops no have effect on the soil.

Results and discussion

Three statistical evaluation criteria for the model performance for discharge, suspended sediment concentration, and sediment yield are given in Table 1. The statistical results presented in Table 1 show that the model is able to predict runoff and sediment yield reasonably. The Mean Error (ME) for discharge is -0.33 m^3s^{-1}, which shows that the simulated discharge is a little underestimated compared to the measurements, while for the suspended sediment concentration and sediment yield this is 0.04 gl^{-1} and 1.52 kg s^{-1} respectively, which shows that the suspended sediment concentration and sediment yield are a little overestimated. The Nash-Sutcliffe model efficiency (NS) for discharge is 0.85, which shows that the model can simulate the hydrograph very well. The efficiency for suspended sediment concentration is 0.63 which indicates a reasonable agreement between simulation and observation, which the efficiency for sediment yield is only 0.14 indicating that the model can not simulate sediment yield accurately. The Correlation coefficient (R) for discharge, suspended sediment concentration, and sediment yield is 0.91, 0.93 and 0.95.

Table 1. Evaluation criteria for simulated flow, suspended sediment concentration, and sediment yield.

	Discharge ($m^3 s^{-1}$)	Suspended sediment concentration ($g l^{-1}$)	Sediment yield ($kg s^{-1}$)
ME	-0.33	0.04	1.52
NS	0.85	0.63	0.14
R	0.92	0.90	0.86

ME: Mean Error, NS: Nash-Sutcliffe model efficiency, R: correlation coefficient

The observed precipitation, temperature, and graphical comparison between observed and simulated discharge is shown in Figure 2a. As can be seen, the precipitation occurs mostly in January and February 2006 when temperatures are below zero. Hence, this precipitation falls as snow, and remains in the soil surface.

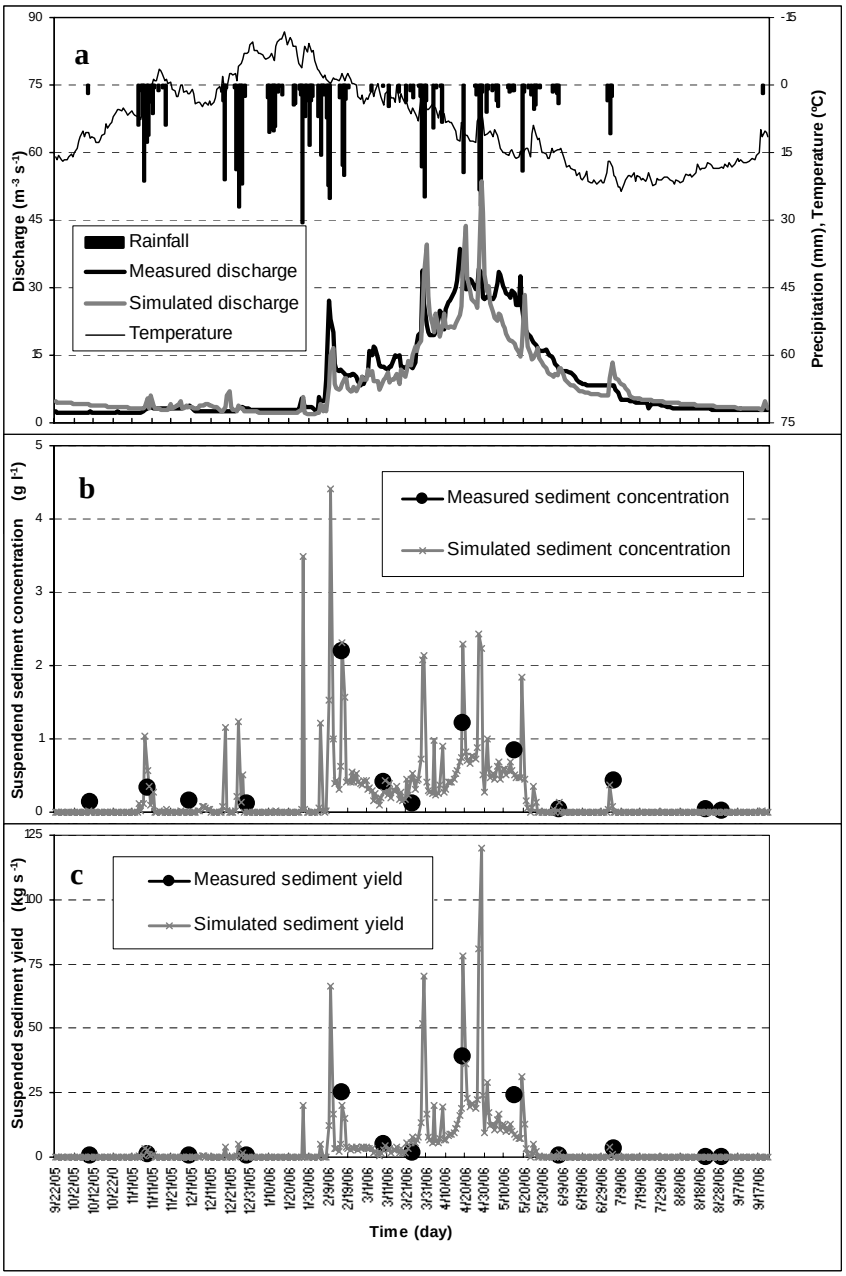

Figure 2. Measured precipitation, temperature, and observed and simulated discharge (a), sediment concentration (b), and suspended sediment yield (c) for September 2005-Septembet 2006 for Latyan dam watershed.

The snow cover melts at the end of April and during May when the weather becomes warmer. The discharge from September '05 till middle of February '06 is very small and almost constant, but from the middle of February increases because of snowmelt and rainfall. The model simulations compare reasonably to the observations. The graphical comparison between measured and simulated suspended sediment

concentration for is shown in Figure 2b. The suspended sediment concentration increases when discharge because of rainfall or snowmelt increases. And there is good agreement between measured and simulated suspended sediment concentration for the days which sediment concentration has been measured. For example measured sediment concentration on 16th of February '06 is 2.19 gl^{-1} which is the highest measured sediment concentration among all measurements and the model simulation is 2.3 gl^{-1}. The graphical comparison between measured and simulated suspended sediment yield for this event is shown in Figure 2c. The general trend of simulated and observed sediment yield is acceptable and model prediction for sediment yield is satisfactory.

For discuss and more details of processes in erosion and sediment transport processes we select 16th February '06 which maximum suspended sediment concentration has been measured among measurements. Figure 3 (left) shows distributed snow water equivalent in the Latyan dam watershed. This figure shows that except small part of catchment in downstream which has no snow, most part of the catchment is covered by snow in this day and snow depth in the upstream of the basin is more than downstream. The reason is obvious and that is because of elevation difference e.g. elevation in the upstream is higher than 4200 m while in the outlet of the basin is around 1700 m.

Snowmelt in mountainous area has a big impact in surface runoff generation. And surface runoff can erode soil and generate and transport sediment. Figure 3 (right) shows distributed snowmelt in the Latyan dam watershed on 16th February '06. This figure shows that snowmelt occurs only in small part of catchment in downstream which has higher temperature than upstream. There is no snowmelt in the upstream of the catchment during that day. The maximum snowmelt is 4.7 mm.

Figure 4 (left) shows distributed surface runoff in the Latyan dam watershed on 16th February '06. This figure shows that there is surface runoff only in the lower part of the basin and compare to snowmelt in Figure 3 (right) it can be concluded that almost all of this runoff is due to snowmelt in this day.

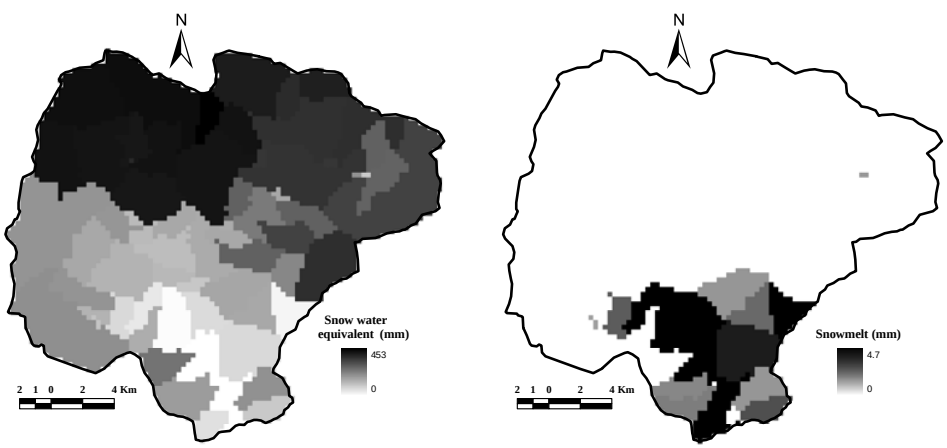

Figure 3. Distributed snow water equivalent (left) and (right) distributed snowmelt in the Latyan dam watershed on 16th February 2006.

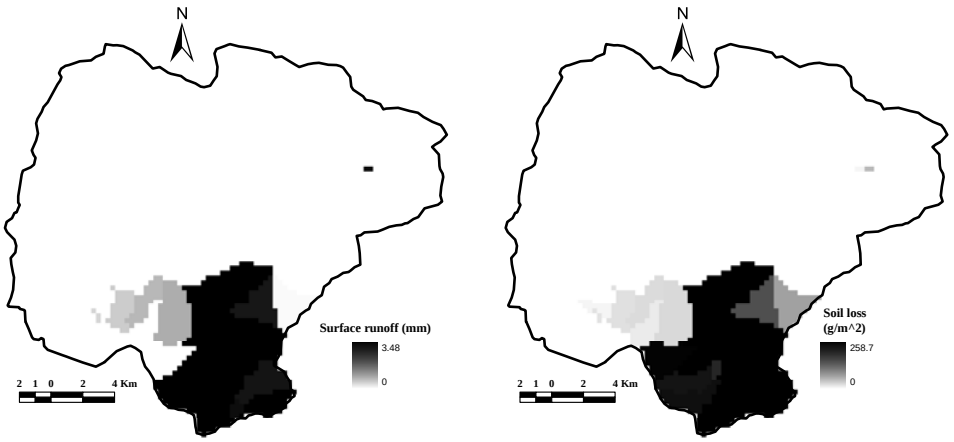

Figure 4. Distributed surface runoff (left) and distributed soil loss (right) in the Latyan dam watershed on 16th February 2006.

Figure 4 (right) shows distributed soil loss in the Latyan dam watershed on 16th February '06. As discussed above there is no snowmelt and surface runoff in upper part of the basin so it can be predicted there is no erosion and sediment in those parts of the catchment. But in lower part of the basin there is snowmelt and surface runoff which resulting erosion and soil loss that has shown in this figure. During this day there are snowmelt and surface runoff only in the area close to the outlet, and there is no long distance to the catchment outlet so there is no high opportunity for deposition, that can be a reason for high sediment concentration measured in this day. Regarding to above explanations it can be concluded that model are able to predict erosion and sediment in the basins with snowfall prominent.

Conclusion

A physically based, spatially distributed model was developed to simulate erosion, sediment transport and deposition, within the framework of the hydrological WetSpa model. Soil detachment by raindrop impact is calculated based on relationships between detachment and the kinetic energy of rainfall. Soil particle detachment by overland flow is calculated based on actual and critical shear stress. Water and sediment are routed over the land surface along topographically determined flow paths with travel times and flow rates determined by the WetSpa model. The applications of this model to the Latyan dam watershed catchment with outlet at Roodak station in Alborz mountain, Iran, shows good overall results for the flow hydrographs and suspended sediment concentration at the catchment outlet.

Further future works and applications are required to demonstrate the usefulness of this model on improve the model's efficiency, validity, and accuracy.

Abstract

Desert pavement is a surficial feature widespread throughout arid lands in the world. Whenever found, it can play an important dynamic role in geomorphic, hydrologic, and ecologic processes in desert environments. The hydrological properties, especially the clast layer impact on hydrological processes, are still not clear to the academic community. Anecdotal evidences and empirical observations have reported rapid runoff generation process which implied low permeability of the pavement with the clast layer. Quantitative result, however, has not yet been reported. An experimental study has been carried out in Mojave National Preserve near Providence Mountain to investigate the hydraulic properties of the clast layer. Rainfall simulations were conducted with a pair of portable rainfall simulators. Each group of experiment includes two parallel runs on two adjacent plots, one with intact clast layer and one with clast layer removed. Soil moistures time series were measured with Water Content Reflectometers (WCR). Runoff was collected at the downstream side of each plot. Experimental results of both runoff and soil moisture did not show significant difference between two types of plots, which implied the clast layer at the experiment site is not a restrictive layer for infiltration and rainfall-runoff processes. In addition, the measured soil moisture curves were used to develop an optimization method for Green-Ampt infiltration parameters, which can produce a useful tool of direct estimation of G-A parameters for practical applications.

1. Introduction

Desert Pavement is a common feature of surfaces in arid and semi-arid regions around the world. Evenari et al. (1985) showed that about half of arid land in North America covered by pavement. The structure of desert pavement consists of a clast layer overlying a sand-poor AV horizon. Due to the high occurrence of desert pavement in arid and semi-arid areas, it is expected that the pavement surface plays an important role in the desert hydrological and ecological system. Significant research has been conducted regarding to the mechanism of pavement formation and the geomorphic features. However, the hydrological properties of such surface have not been thoroughly investigated. Among many questions that are not fully understood on desert pavement, the hydrological properties and functions of the clast layer has not been addressed previously. There are anecdotal evidences that tightly packed clast layer reduces the water infiltration rate. Wood et al (2005) showed indirect qualitative evidences for the same trend. This implies that the clast layer can significantly influence the hydrological cycle and ecological processes. Quantitative studies are still void for this topic. It is our purpose to conduct field measurements to quantitatively examine the hydrological properties of the clast layer.

2. Methodology

The method of rainfall simulation was adopted in this study. The rainfall simulation test was conducted on a desert alluvial fan at the Mojave National Preserve, CA (between 115.61 and 115.39ºW and 35.31 and 34.83ºN)) close to the Providence Mountain. The test site is characterized by a layer of desert pavement with the age of ~100 ka (Young et. al., 2004) dated by McDonald, et al. (2003). An early field survey showed that the site is sparsely vegetated by *L. trendentata* and *A. domosa*. In each experimental run, rainfall simulation was simultaneously conducted on two adjacent plots, one intact surface and one surface with clast layer removed, so that we can make comparison directly.

Two portable rainfall simulators (Fig. 1a) were used to conduct rainfall simulation on a selected pavement surface. The rainfall simulator consists of a flat, two-foot-square (61 cm x 61 cm) Plexiglas reservoir for water, with hypodermic needles on the under side (Mutchler and Moldenhauer, 1963; Munn and Huntington, 1976). Water drops were produced on the needles and the rainfall intensity was artificially maintained to a constant rate through a Marriot system. The rainfall intensity was calibrated three times before and after each test to assure that the rainfall intensity was well produced and maintained. At the lower slope of each plot, a trench was dug and a plastic trough was placed into the trench to collect surface runoff. The gap between the trough and the plot was connected by a 900 bend aluminum flashing and sealed using expandable insulating foam to prevent leakage (Fig 1b).

Soil moisture was measured continuously during the rainfall experiment. A Water Content Reflectometry (WCR) was placed under each rainfall simulator to measure the soil moisture of the top 6.5 cm soil at the frequency of 1Hz.

There are several advantages of using the rainfall simulation method. The rainfall simulation approximates the natural rainfall-infiltration process, while most other permeameters test the infiltration at certain constant head. The rainfall simulator can be used for complex surface conditions without intrusion to the soil, whereas application of many other permeameters interfere the surface of soil at various extent. With the direct measurement of the soil moisture, we can observe the whole rainfall-infiltration-runoff process. It may also generate a new parameter estimation approach for infiltration models.

Fig. 1 (a) rainfall simulator ; (b) Probe of water reflectometer

3. Observation of runoff generation

In total, 7 pairs (14 runs) of rainfall experiment were conducted. Runoff time series at down slope side of each plot were recorded and the results are plotted in Fig.2. Total runoff volumes for different surfaces are compared in Fig.3.

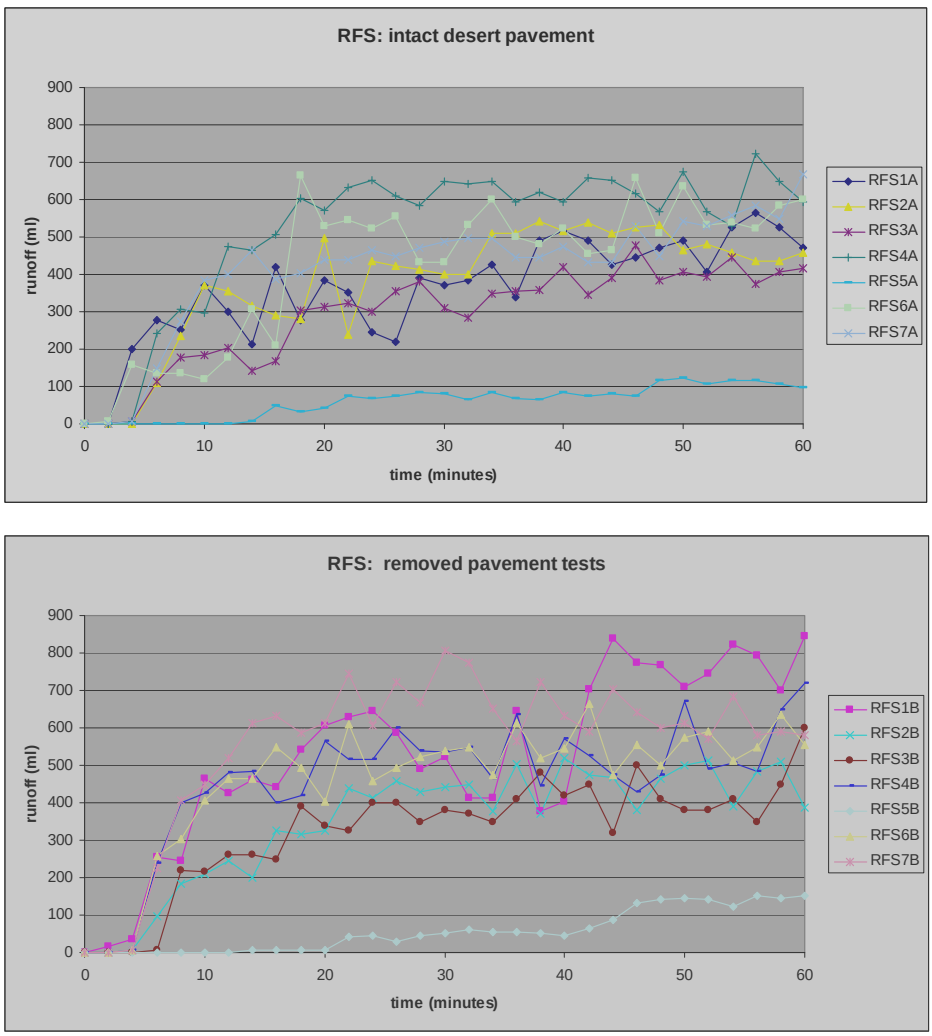

Fig.2 Observed runoff generation processes

Table 1 summarizes the surface runoff characteristics on both paved and unpaved plots. In terms of the averaged timings, observed runoff on clast removed plots (B) is a little delayed than the observed runoff on intact plots (A). However, t-test (for normal distributions) or Mann-Whitney Rank Sum Test (for non-normal distributions) showed that there is not a statistically significant difference between two types of plots in any of the runoff characteristics, showing that statistically desert pavement has very little affect on the runoff generation in the first few minutes after the precipitation started. Fig. 3 shows the comparison of total runoff volumes for the two types of plots. The result indicates that the clast layers generally leads to slightly less runoff or more infiltration,

which may be caused by the micro storage and larger roughness of the clast layer that impede water flowing downstream and thus promote the infiltration process.

Table 1 Characteristic times of runoff generation process

RFS#	Ponding (s)	Initial runoff on surface (s)	Runoff in all quadrants (s)	Flow connection back to front (s)	Flow to trough (s)
2A	68	114	218	340	194
2B	60	90	145	270	225

4. Green-Ampt Parameters

Green-Ampt (Green and Ampt, 1911) model is the simplest physically based infiltration model. It is widely used in practices for rainfall runoff analyses. We can also use Green-Ampt parameters to examine the physically properties of the clast layer. Previous studies for Green-Ampt parameters (e.g., Rawls et al, 1983) do not determine parameter values directly from the infiltration process. In this study, we propose a method of parameterizing the Green-Ampt model using soil moisture data measured during the infiltration process and apply them to examine the role of the clast layer.

A numerical optimization approach is adopted for the parameterization. The objective function is defined as

$$OF = \sum_{i=1}^{m} \left[y_i - f\left(x_i, \beta\right) \right]^2 = \sum_{i=1}^{m} r_j^2(x) \tag{1}$$

where y_i is the observed value and $f\left(x_i, \beta\right)$ is the optimized function using the optimized parameters β, r is the residual of f. Note that $f\left(x_i, \beta\right)$ in this study is solved implicitly from the Green-Ampt equation. The Levenberg-Marquardt method (Marquardt, 1963) was employed to obtain the minimum of equation (1). The method can be described with the following equations:

$$\min_p \frac{1}{2} \| J_k p + r_k \|_2^2, \text{ s.t. } \| p \| \leq \Delta_k \tag{2}$$

$$\left(J\left(x_k\right)^T J\left(x_k\right) + \mu_k I \right) s = -J\left(x_k\right)^T r\left(x_k\right) \tag{3}$$

where J is Jacobian of r, $p = x\text{-}x_k$ for step k, Δ_k is the trust region radius. For Green-Ampt model, we have the following equations for the objective function and Jacobian J:

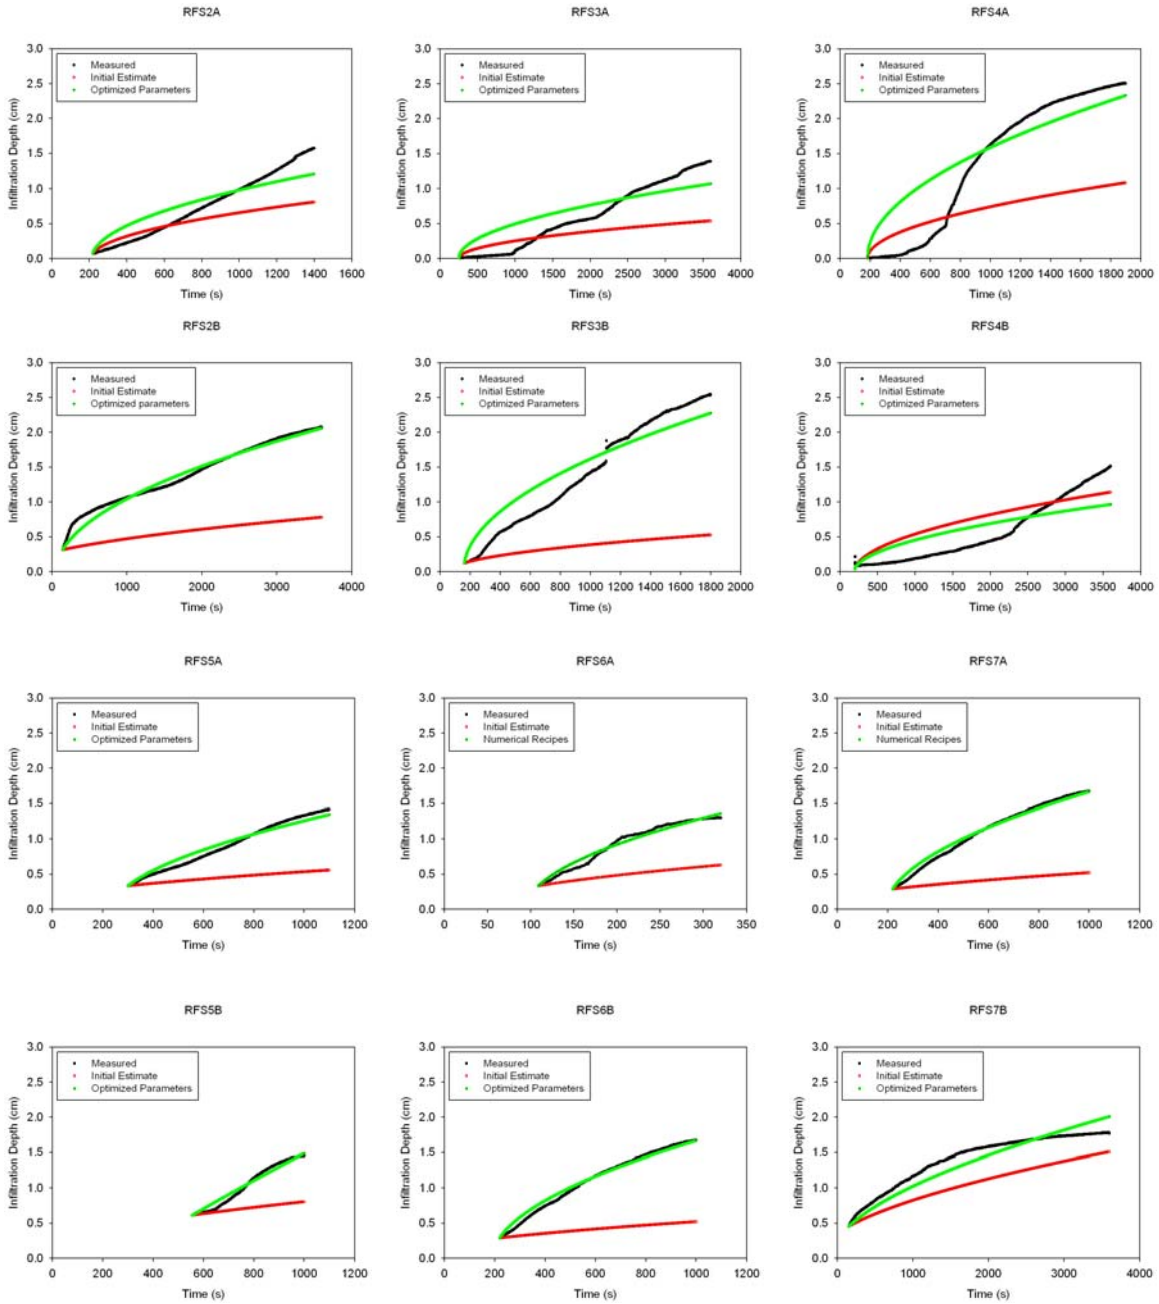
$$f(K, MS) = I - MS \ln\left(1 + \frac{I}{MS}\right) - K\left[t - \left(t_p - t_s\right)\right] \tag{4}$$

$$\frac{\partial f}{\partial K} = -(t - (t_p - t_s)) \tag{5}$$

$$\frac{\partial f}{\partial MS} = -(\ln(1 + \frac{I}{MS}) - \frac{I}{(1 + I / MS)MS}) \tag{6}$$

where K is soil hydraulic conductivity, M is moisture deficit, S is suction head, M and S are combined as one parameter, t_p is ponding time and t_s is a virtual time to convert rainfall-infiltration to ponded infiltration. In this study, we only optimize K and MS, and the optimization covers the soil moisture curve after ponding time.

In 6 out of 7 pairs of experimental runs we obtained valid soil moisture curves and optimization was conducted for these 12 cases. Fig.4 shows the results of optimization. It is found that if the actual infiltration curve has a similar shape to the theoretical Green-Ampt curve, the optimized infiltration curve can approximate the real curve fairly well. However, if abnormal curves were observed, for examples, in case 4A and 4B a point of inflection exists which is different from the theory, the optimized curve will not accurately approach the actual curve. The reason for such abnormal curves can be complex. Layered soil, preferential flow, anisotropic soil or vegetation effect may all cause the infiltration deviates from the standard curve. The theory will not be able to well represent highly complex natural conditions.



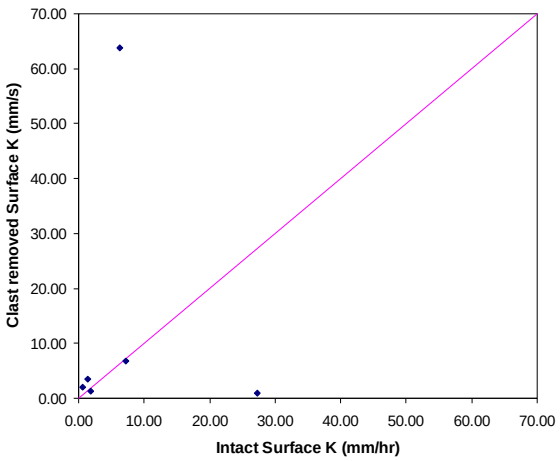


Fig. 4 Optimized Green-Ampt infiltration curves

The results of the optimized Green-Ampt parameters for two types of plots are shown in Fig. 5. Comparison does not show significant difference for the conductivities, whereas it demonstrates the intact surfaces have larger suction head than clast removed surfaces. This implies that the clast layer does not change the soil hydraulic conductivity but may affect the capillary force. Such a trend may be explained by the rain drop influences on the soil. Clast layer may protect the soil structure and prevent the potential surface sealing during rainfall events and thus maintains the capillary effect.

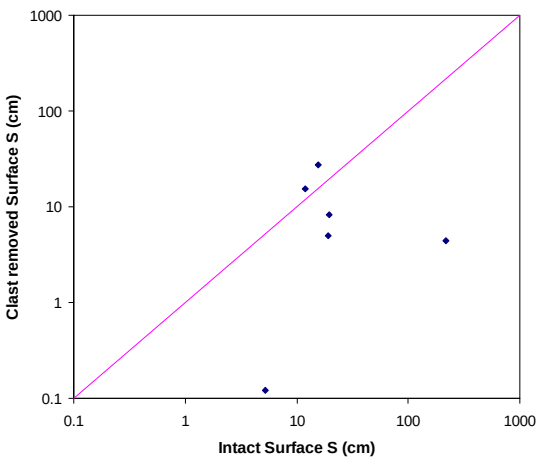

Fig. 5 Comparison of optimized *K* and *S*.

6. Concluding remarks

The role of clast layer within desert pavement in hydrological processes has not been fully understood because quantitative observations on the rainfall-runoff events occurring on such surfaces are largely absent. In this pilot study, we investigated the clast layer function using rainfall simulation method. The rainfall simulation tests described herein provided the in-situ runoff and infiltration measurements. Based on these data the runoff and infiltration characteristics of intact and clast removed plots were analyzed. Although slight differences were observed between two types of plots in terms of total infiltration and timing of surface runoff generation, t-test and Mann-Whitney Rank Sum Test indicated that the difference is not statistically significant. Total runoff volumes on intact surfaces are slightly smaller, implying the clast layer may increase the surface storage and runoff routing time and promote infiltration.

Green-Ampt infiltration parameters were derived from the observed moisture curves through a parameter optimization approach. Results show that the soil hydraulic conductivity values for two types of plots do not have significant difference, but the suction head values for intact surfaces are larger. This may be explained again by the surface storage and the larger roughness of the clast layer. In addition, it implies that the infiltration rate with or without the clast layer will be the same for large time when the gravity dominates the infiltration process. This study also presented a new method to calibrate Green-Ampt or other infiltration model parameters using the observed data and will show application in hydrological analyses.

From this study we found that the clast layer of desert pavement does not act as a restrictive layer for infiltration. Rather, it may provide extra surface storage and increase runoff routing time to allow more infiltration to occur. The results we found in this pilot study may not disclose all truth for the clast layer effect. For some very tightly interlocked clast layer with macro pores fill by fine particles, the clast layer may form a crust for the underneath soil and impede the infiltration process. However, such surface was not observed in our study site.

Abstract: Many different watershed models are available today that have various complexities, strengths, and weaknesses. Selecting the most appropriate model to achieve the most accurate and efficient solution possible is a challenging task. Despite the fact that all models are mathematical engines, their basic mathematical foundation is often overlooked due to high demands on model applications such as the ease of the graphical user interfaces and the incorporation of geographic information systems. This often leads to modelers' and managers' making decisions based on model marketers' potentially non-objective pitch. The objective of this investigation is to provide a mathematical-based review of available watershed models used for storm water management and provide insightful facts for the end users, particularly water resource managers, so that an informed decision can be made when selecting a model. Fourteen watershed models simulating storm event runoff were reviewed and evaluated resulting in the development of six summary tables which compile, rank, and compare the models. The dominant hydrologic and hydraulic procedures used in the models are compiled, including rainfall excess or infiltration (most rainfall loss), subbasin or overland (land surface) runoff routing, channel flow routing, and subsurface flow simulation. The rankings are based on the formulations and their relative complexities and accuracies for routing overland runoff and channel flows which provide some base for comparing the models because these procedures are backbones of any watershed simulation model, and ultimate performance of a model depends largely on accuracies and speed of these procedures. The compilations and the rankings would be helpful to managers and modelers in understanding and comparing the models, selecting the most suitable model for a project or an application, and using it to its full potential. The comparison approach and the tools (tables) presented would be useful to conduct objective comparisons of other watershed models as well.

Introduction

Many watershed models are available today most of which were developed during the 1960s-1980s. The most widely used models are the ones having a graphical user interface (GUI). Experiences applying these commonly used models have received mixed results (Borah and Bera, 2004). A question often asked is "was the right model selected?" Selecting the most suitable model to accomplish a project most accurately and efficiently as possible is a challenging task.

The available models are diverse. They are based on a variety of concepts, principles, and equations that mathematically simulate the natural processes of a stormwater drainage system resulting in various complexities, strengths, and weaknesses. Recent reviews of existing watershed models (e.g., Borah and Bera, 2003, 2004; Shoemaker et al., 2005; Muñoz-Carpena et al., 2006; Obropta and Kardos, 2007) acknowledged and addressed some of these modeling issues. However, none are in-depth investigations or compilations of the basic model formulations and relative complexities and accuracies. Without this information, it is almost impossible to select the most suitable model and use it to its fullest potential. Such a detailed investigation is also critical to advancing the fundamental knowledge of model formulations currently being used, most of which are over half-a-century old. It is also vitally important to consider the needs and expectations of the managers who are responsible for the modeling studies. They are simultaneously the user of the results in decision making, and the interpreter of

those results to stakeholders and policy makers. Therefore, managers' understanding of the models is critical as well.

The objective of this paper is to advance the understanding of watershed models among the water resources managers through the summary of available models and providing insightful information, specifically on theoretical (mathematical) basis, sophistication levels (complexities), and relative accuracies. Fourteen models that simulate storm event runoff were reviewed and critically evaluated. Some models were commonly used, and others had applications documented in the literature. Only models having capabilities to simulate single storm events, as opposed to continuous simulation models, were selected.

Review and evaluation of the 14 models resulted in the development of six summary tables compiling, ranking, and comparing the models. The dominant hydrologic and hydraulic procedures used in the models are compiled, including rainfall excess or infiltration, subbasin or overland (land surface) runoff routing, channel flow routing, and subsurface flow simulation. The rankings are based on the formulations and their relative complexities and accuracies for routing the overland runoff and channel flows. These procedures are backbones of any watershed simulation model, and ultimate performance of a model depends largely on accuracies and speed of these procedures. The compilations and rankings would be helpful to managers and modelers, who often rely on model marketers subject to non-objective opinions about other models, to understand and compare the models, select the most suitable model for a project or an application, and use it to its full potential. The comparison approach and the tools (tables) presented would be useful to conduct objective comparisons of other watershed models as well.

Watershed Models

The fourteen watershed models reviewed are listed here in alphabetical order along with their sources, brief backgrounds and key facts are given in a full-length paper (Borah et al., 2009). The models are: (1) ***AGNPS*****:** The Agricultural NonPoint Source pollution model of the U.S. Department of Agriculture – Agricultural Research Service (USDA-ARS) (Young et al., 1987); (2) ***ANSWERS*****:** The Areal Nonpoint Source Watershed Environment Response Simulation model of the Purdue University, West Lafayette, Indiana (Beasley et al., 1980); (3) ***DR3M/DR3M-QUAL*****:** The Distributed Routing Rainfall Runoff Model and water quality extension (DR3M-QUAL) of the United States Geological Survey (USGS) (Alley and Smith, 1982a, 1982b); (4) ***DWSM*****:** The Dynamic Watershed Simulation Model of Woolpert, Inc. (Borah et al., 2002); (5) ***GSSHA*****:** The Gridded Surface/Subsurface Hydrologic Analysis model of the U.S. Army Corps of Engineers' (USACE) (Downer et al., 2006); (6) ***HEC-HMS*****:** The Hydrologic Engineering Center – Hydrologic Modeling System (HEC-HMS) of the USACE (USACE-HEC, 2002); (7) ***HSPF*****:** The Hydrological Simulation Program – Fortran of the U.S. Environmental Protection Agency (USEPA) (Bicknell et al., 2001); (8) ***KINEROS*****:** The Kinematic Runoff and Erosion model of the USDA-ARS (Woolhiser et al., 1990); (9) ***MIKE SHE*****:** MIKE Système Hydrologique Européen of Danish Hydraulic Institute (DHI) (Refsgaard and Storm, 1995); (10) ***MIKE URBAN*****:** MIKE URBAN of DHI (2008); (11) ***PRMS*****:** The Precipitation-Runoff Modeling System of the USGS (Leavesley and Stannard, 1995); (12) ***SEDIMOT III*****:** The Sedimentology by Distributed Modeling Techniques – Version III of Barfield et al. (2006); (13) ***SWMM*****:** The Storm Water Management Model of the USEPA (Rossman, 2007); and (14) ***TR-55*****:** Technical Release 55: Urban Hydrology for Small Watersheds of the USDA-Natural Resources Conservation Service (USDA-SCS, 1986).

Hydrologic and Hydraulic Procedures

Modeling of a watershed involves mainly dividing the watershed into manageable modeling units; computing rainfall excess on each of the units; routing the excess rainfall (runoff)

over the land surfaces and through the stream channels beginning at the uppermost unit and ending at the lowermost (outlet); and parallel computations of subsurface flow contributions to stream flows. The models use various hydrologic and hydraulic methods to compute or simulate rainfall excess, flow routing, and subsurface flow. Each of the models has its unique way of applying the procedures into its source code, sometime through simplification or modification of the original formulation or method. Such details are beyond the scope of this paper. Only the procedure names are listed here, details and mathematical expressions are available in the literature and also in a full-length paper of the authors (Borah et al., 2009).

Rainfall Excess

Computing rainfall excess or runoff volume is the first step in watershed modeling. This involves computing rainfall losses due to interceptions at tree canopy and ground cover, depression storage, and infiltration through the soil layer, then computing the excess rainfall available for runoff. Various procedures are used by the models for computing rainfall excess, directly, or through the above losses, among which infiltration is the major. Below are the rainfall excess or infiltration procedures. Table 1 compiles the models using these procedures.

- SCS Runoff Curve Number
- Richards infiltration equation
- Philip's infiltration equation
- Smith and Parlange infiltration method
- Green and Ampt infiltration equation
- Horton's Infiltration equation
- Modified Holton-Overton infiltration equation
- Initial loss and constant rate

Table 1. Models using different rainfall excess (infiltration) simulation procedures

HEC-HMS				HEC-HMS (optional)			
SEDIMOT III				PRMS			
SWMM (optional)				SWMM (optional)			
TR-55							

The curve number is a rainfall excess procedure, lumps all the factors (soil, land cover, and initial moisture) responsible for rainfall losses and, therefore, is the simplest, most efficient, and more popular method, and has been for more than half a century. Use of infiltration equations

involves estimating losses due to interception at canopy and ground covers and depression storages separately in addition to estimating empirical parameters present in most of these equations.

The initial loss and constant rate infiltration is a rough method of computing rainfall losses, infiltration, and excess rainfall. With the exception of this method, the remaining methods are physically based and practically result in almost the same or similar infiltration and rainfall excess values. For example, Borah et al. (2002) found similar results from SCS runoff curve number and Smith and Parlange procedure on a 100-km^2 watershed in Illinois, and King et al. (1999) found no significantly different results from curve number and Green and Ampt equation on a 21-km^2 watershed in Mississippi.

Flow Routing

Once the rainfall excess is determined, a hydrograph is developed by routing the excess rainfall (runoff) to a common point in the watershed. Flow routing is primarily responsible for accounting the dynamics of a watershed (i.e., the dynamic movement of water) in a model. A model's performance and applicability are largely dependent on speed and accuracy of the flow routing procedure used.

Different levels of flow routing procedures and formulations are used in the models for overland and channel flows, which are all listed below. Table 2 compiles the models with procedures or equations for routing overland runoff and Table 3 ranks those based on relative complexities and accuracies of the equations and/or their solutions. Similarly, Tables 4 and 5, respectively, compile and rank the procedures or equations for channel flow routing.

- Dynamic Wave Equations: Numerical solution
- Diffusive Wave Equations: Numerical solution
- Kinematic Wave Equations: Analytical, shock-fitting, and numerical solutions
- Nonlinear Reservoir Equations
- Muskingum Method
- Unit Hydrograph Method
- Synthetic Unit Hydrograph Methods:
    - Snyder Unit Hydrograph
    - SCS Unit Hydrograph: TR-55 Method
    - Clark's Unit Hydrograph
- Time-Area Histogram
- The Rational Method: Peak Flow Formula

The basic flow-governing equations are the dynamic wave equations, also known as the St. Venant equations, consisting of the continuity and momentum equations for shallow water flows. These are the most physically-based flow routing equations available. However, there is no analytical solution to these equations which require the use of approximate numerical solutions. This requirement causes complexities and challenges with numerical instabilities and errors. Only a few of the models use these equations for routing flows in channels or pipes (Table 4). In order to obtain relief from the solution complexities, approximations are used to eliminate some of the terms and simplify the dynamic wave equations.

The next simplified flow governing equations are the diffusive wave equations derived by ignoring the local and convective acceleration terms of the momentum equations. These equations do not have analytical solutions and must be solved using approximate numerical procedures. A few of the models use these equations to route overland and channel flows (Tables 2 and 4).

The most simplified form of the dynamic wave equations are the kinematic wave equations derived by ignoring the pressure term as well from the momentum equation. Quite a few models use these equations (Tables 2 and 4). The kinematic wave equations have the advantage of having an analytical solution by the method of characteristics, although limited by shocks under shock-forming conditions, where the solution is no longer valid. Therefore, some models (Tables 2 and 4) use approximate numerical solution to solve the equations, where the shock is not an issue. These models do not get the benefits of the analytical solution in terms of accuracy and speed. DR3M uses the analytical solution where shocks are not present, generally on overland surfaces, but use approximate numerical solution to other conditions, mostly channels. DWSM is the only model that uses the analytical solution in both overland and channel flow routings by introducing an approximate shock-fitting solution to simulate under shock-forming conditions, which occurs when there is a sudden change of channel grade from steeper to flatter and only during a narrow sharp rising part of the hydrograph.

The next level of physically-based flow routing equations are the nonlinear reservoir equations where the spatial variation is ignored assuming leveled water surface. A number of models use these to route overland flows (Table 2) and a few for channel flows (Table 4). The Muskingum method, used only for channels by a few of the models (Table 4), is also based on mass conservation and uses empirical factors determined from observed flows.

The remaining methods (unit hydrographs, time-area histogram, and the rational formula) are empirical based on historical events. These methods have been traditionally useful for predicting flow hydrographs in rural watersheds with limited data and practically no change in hydrologic or land use characteristics, however, have limited use in modern watersheds undergoing rapid land use changes or urbanization.

Based on the physical basis of the equations and relative complexities and expected accuracies of the solutions or methods used, the models are ranked in two 2-dimensional matrices, one for the overland runoff routing (Table 3) and the other for channel flow routing (Table 5). These two matrices provide comparisons of some basic but critical facts about the models in relative orders (scale of 1-7 for overland and 1-9 for channel) and should be useful to modelers and managers. These show strengths and weaknesses of the models in these two critical operations. For example, watersheds having large-sized overland units, the comparisons in Table 3 would be useful to determine expected performance of a model relative to the others. Similarly, watersheds having long channel units or segments, the comparisons in Table 5 would be useful to determine expected performance of a model relative to the others.

Subsurface Flow

Only half of the models reviewed have a subsurface flow simulation component. The procedures or equations used by the models are listed below. Table 6 compiles the models using these procedures. It also lists the models having no subsurface flow component.

- 3-D Groundwater Flow Equation
- 2-D Groundwater Flow Equation
- Kinematic Storage Equation
- Huggins and Monke Drainage Equation

- Baseflow Recession Curve

Table 6. Models using different subsurface flow simulation procedures

3-D groundwater flow	*2-D groundwater flow*	*Kinematic storage equation*	*Huggins and Monke drainage*	*Baseflow recession curve*	*Other methods*	*None*
MIKE SHE	GSSHA	DWSM	ANSWERS	HEC-HMS	HSPF (empirical relations)	AGNPS
					MIKE URBAN (MOUSE RDI license: linear reservoir)	DR3M
					SWMM (mass balance and empirical fluxes)	KINEROS
						PRMS
						SEDIMOT III
						TR-55

There are vast differences between these procedures from 3-D groundwater flow equation to baseflow recession curve. However, the procedures go along with the respective models and accuracies of their other hydrologic and hydraulic simulation procedures. A model having one of these procedures has a distinct advantage over the models not having one in capturing the subsurface flows or base flows into the total stream flow, which are critical, and also by better representing the hydrologic cycle.

Summary and Conclusions

The rainfall excess (runoff), flow routing, and baseflow components of fourteen watershed models were evaluated resulting in the development of six summary tables which compiled the modeling procedures, and ranked and compared the models based on accuracies and complexities of the model equations and the solution methods used.

With the exception of the approximate initial loss and constant rate infiltration procedure, the remaining methods for determining rainfall excess are physically based. If properly used, they will generate similar results.

The flow routing procedures are the backbones of any watershed simulation model, and ultimate performance of a model depends largely on accuracies and speed of these procedures. Therefore, the models were ranked based on the formulations, their solution procedures, relative complexities, and accuracies used in routing overland runoff and channel flows.

Only half of the models reviewed have a subsurface flow simulation component. There are large differences between procedures used in subsurface flow simulation although a model having one of the procedures has a distinct advantage over any model not having one. Capturing the subsurface or base flows into the total stream flow allows better representation of the hydrologic cycle, a natural process.

The compilations and the rankings shown in the above sections will be helpful to managers and modelers for understanding the models, comparing those, selecting the most suitable model for a project or an application, and using it to its fullest potential.

The model comparison approach and the tools (tables) introduced would be useful to allow objective comparison of other models simply by placing those into the respective tables. Such an approach has been adopted by the Watershed Assessment Model (WAM) peer review panel by adding WAM into Borah and Bera's (2003) comparison table (T. Donigian, personal communication, December 30, 2008).

Water Subdivision for Modeling

Theodore G. Cleveland[1], Thuy Luong[2], , and David B. Thompson[3]

1. ABSTRACT

Rainfall-Runoff models, such as Hydrologic Modeling System (HEC-HMS), Stormwater Management Model (SWMM), etc., are used for predicting the hydrologic response of watersheds. An issue that to be addressed by users of these models is the estimate of an appropriate level of watershed subdivision for simulating runoff. The size and number of subwatersheds can affect a watershed modeling process and subsequent results.

The research reported herein is exploration to evaluate the effect of various levels of watershed subdivision on simulated runoff hydrographs. The HEC-HMS program was applied to five watersheds in Central Texas with drainage areas that varied from 12.3 to 166 square miles. Each of the five watersheds is near one of the following urban areas: Austin, Dallas (the rural watershed studied is close to Dallas), Fort Worth, San Antonio.

In this study, the models were intentionally left uncalibrated, thus the subdivision specification is the result of application of engineering hydrologic modeling practice, as would occur when modeling ungaged watersheds. Watershed subdivision was performed using an iso-area arrpoach where each contributing subdivision contained roughly the same area. The results of the HEC-HMS analysis indicated that the number of subwatersheds had little effect on computed runoff hydrographs.

No consistent pattern emerged as to whether lumped or multiple subbasins produce superior results; thus, the appropriate level of subdividing a watershed is still unanswered by this study.

2. INTRODUCTION

One routine task associated with hydraulic design is the delineation of the watersheds and subsequent computation of the watershed characteristics such as drainage area, main channel length, main channel slope, and etc. After this task is completed, the engineer must decide if the watershed should be further subdivided into smaller components, referred to as subwatershed or sub-basins. The sub-basin parameters are then input into a hydrologic model to develop runoff hydrographs.

The ability of a model to simulate the watershed systems depends on how well the watershed system is described by model input parameters. In a lumped hydrologic model, the watershed is assumed homogeneous with representative parameters. However, the size of the watershed affects the homogeneity assumption, because larger watersheds are more likely to have variable conditions within the watershed. Subdividing a watershed into smaller sub-watersheds would certainly increase the input data preparation effort. In practice, subdividing watershed into smaller components might or might not produce more accurate model results compared to measured, that is observed, streamflow from the watershed. On the other hand, modeling a large watershed as a single lumped model might lead to poor simulation results. Thus, the art of watershed subdivision remains an unsolved problem facing hydrologists wood1988and civil engineers.

Hromadka (1986) developed an application manual for hydrologic design for San Bernardino County. In that manual, mechanics were developed based on the Los Angeles hydrograph method. The manual states:

> Arbitrary subdivision of the watershed into subareas should generally be avoided. The fact is that an increase in watershed subdivision does not necessarily increase the modelling accuracy but rather transfers the models reliability from the valiated unit hydrograph and lag relationships to the unknown reliability of the subsequent flow routing submodels used to link together the divided subareas.

Hromadka (1986) further suggests that subdivisions should be about the same size[4].

Wood et al. (1988) examined the relation between watershed scale and watershed runoff on the 6.5 mi2 Coweeta River experimental watershed located in North Carolina. Their study was to determine the representative elemental area (REA) for the Coweeta River watershed. They divided the Coweeta River watershed into 3, 19, 39, and 87 subwatersheds. They reported that for a drainage area less than 0.4 mi^2, subwatershed response was highly variable. However, at scales greater than about 0.4 mi^2, further aggregation of subwatersheds had little impact of simulated results.

Norris and Haan (1993) studied the impact of watershed subdivision on hydrographs estimated using the Natural Resources Conservation Service (NRCS) unit hydrograph procedure, as implemented in HEC-1. The Little Washita watershed near Chickasha, Oklahoma, was subdivided into 2, 5, 10, and 15 sub-watersheds, as well as treating the watershed as a whole. Results were that watershed subdivision had a pronounced impact on the estimate of peak flow from the watershed. The change from a single watershed to 5 sub-basins resulted in a net increase in peak discharge of about 30 percent. Use of 15 sub-basins increased the difference from a single watershed to about 40 percent. However, the impact of subdivision

[4]The manual states a desirable area ratio of subdivisions — not iso-area, but suggestive of that classification.

diminished with further increase of sub-basins. They concluded that the number of sub-basins for simulating watershed response should not vary through the course of a hydrologic study. Guidance as to how many subdivisions to use was left unanswered.

Michaud and Sorooshian (1994) applied three different model formulations to simulate the rainfall-runoff process for Walnut Creek Gulch in Arizona. They concluded that simpler models[5] appear to perform better than more complex approaches.

Mamillapalli et al. (1996) conducted a study of the impact of watershed scale on hydrologic output. They concluded that, in general, increase of the level of discretization and the number of soil and land use combinations resulted in an increase of the level of accuracy. There is a level of discretization beyond which the accuracy cannot be further improved. Their work suggests that more detailed simulation may not always lead to better results.

Bingner et al. (1997) attempted to determine the degree of watershed subdivision required to achieve reasonable results in predicting watershed runoff and sediment yield of the Goodwin Creek Watershed. A suite of subdivisions was generated with elemental areas that ranged from a maximum of 60 acres to a minimum of 4 acres to model runoff and sediment yield. The authors concluded that model predicted runoff volume was not heavily dependent on the degree of watershed subdivision, however, the model predicted sediment yield did depend on the degree of watershed subdivision.

Fitzhugh and Mackay (2000) conducted a similar study and reported that model predicted watershed runoff was not heavily dependent on the degree of subdivision , but the predicted sediment yield dependened on the degree of subdivision.

Jha et al. (2002) examined the relation between watershed subdivision and water- quality model results. He applied the SWAT model to four Iowa watersheds. Jha (2002) reported that streamflow was not significantly affected by a decrease in sub-watershed scale, where model predicted results stabilized with about ten subdivisions. However, model predicted sediment yields were more dependent on sub-watershed scale, requiring 40-50 divisions to stabilize model predicted sediment yield.

Tripathi et al. (2006) studied the Nagwan watershed in eastern India. The watershed was subdivided into 12 and 22 sub-watersheds, as well as treating the entire watershed as a whole. They found little difference in watershed runoff for different number of sub-watersheds used, however, they did observe variations in other components of the hydrologic cycle.

Nearly all these prior efforts suggests an insensitivity of runoff volume to the level of watershed subdivision. The principal input to the watershed, precipitation, is typically measured at point gages, which measure the rainfall field over an eight-inch diameter (if a standard rain gauge is used) region. In contrast, measurements from a stream gage reflect the integrated

[5]Few subdivisions

response of the watershed to the rainfall field and all of the processes that act as rainfall become runoff. The two phenomena and their measurements are inherently different in magnitude, method, and meaning, so the insensitivity is not completely unanticipated.

Synthesis of these and other references suggests the following approaches to as ways to model watershed subdivision (in the absence of obvious natural features and flow regulation structures):

(1) An iso-characteristic approach, where each sub-basin has about the same physical characteristic (area, length, etc.). Drainage area ratios would fall into this approach. The characteristics may be subtlesome authors have used contiguous areas of similar slope to define watershed subareas. The San Bernardino (1986) manual seems to imply a range of area ratios that are acceptable for preserving sufficient model believability, again a spatial characteristic based concept.

(2) An iso-temporal approach, where each sub-watershed is selected to have about the same characteristic response time, that is, tc. This particular approach may have great value in concurrent flooding (concurrent arrival times of flood waves). A challenge of this conceptualization is that lumped systems will necessarily be replaced by routed systems and any gain in certainty by using smaller sub-basins may be more than offset by increased uncertainty caused by routing.

(3) A scoring approach: Scoring is similar to the above concepts, except a set of characteristicsis assigned a score; similar scores that are geographically connected are selected as watersheds. The scoring approach could admit descriptors not easily quantified numerically.

(4) A gage-defined approach where the locations of existing gages are used to subdivide a watershed not necessarily a modeling tool, but a good comparative tool. An extension would be to locate good gage locations based on measuring requirements and use these locations to divide a watershed.

(5) Stream-order/bifurcation approach. Watersheds are subdivided based on branches in the dendritic drainage network. This approach is arguably a scoring approach.

(6) The ad hoc approach is a research-only approach where basins would be defined at random subareas, perhaps preserving some minimum measure.

3. METHODOLOGY

This research examined an iso-characteristic approach based on sub-basin areas. Area is the principal scale measure common in all hydrologic studies; it is usually always computable. The report by Roussel et al. (2006) illustrated that different analysts, and diferrent methods (manual, automated) compute areas to within 10% of one another; thus, area represents a reasonably consistent metric regardless of analysts involved.

Five sets of watersheds in Central Texas with USGS streamflow-gaging stations were selected for this study: Onion Creek, South Mesquite, Little Fossil, Olmos Creek, and Trinity Basin North. The supporting data include 30-meter DEM information, and a database of incremental cumulative rainfall and runoff values for storms that occurred during the period from 1961 to 1986.

Paper-based USGS quadrangle maps (1:24000 scale) containing the watershed were used for watershed delineation. To subdivide the selected watersheds into 3, 5, and 7 sub-basins, locations of the sub-basin outlets were chosen. The drainage area upstream of the outlet was measured by planimeter. The outlet locations were adjusted until the individual sub-basin areas are about the same[6].

Figure 1 is one example of the subdivision approach applied to the Trinity-North watershed. Similar subdivisions were produced for the other study watersheds. In all the study watersheds, there was an actual configuration where gages were "nested" — this configuration was one of two "validation" configurations used in the study[7].

A discussion of "about the same" is in order. The subdivision process was manual, using paper maps and a mechanical planimeter. Iso-area subdivision is non-trivial and small movements of subdivision outlets on the map, required re-delineation. A particular challenge was the treatment of tributaries to the main channel. In many cases inclusion of a tributary in one sub-basin contributed too much area to that sub-basin and made exact equal area delineation practically impossible. This experience alone suggests that prior works that used stream bifurcation rules encountered similar issues and the author speculates that this division challenge is in-part why these [bifurcation] schemes exist.

Models of the watersheds, with varying degrees of subdivision (lumped, 3, 5, and 7 sub-basin models) were built using HEC-HMS. The runoff generation component used the NRCS CN procedure because CN values were available for these watersheds from prior studies. The routing component, where used, was lag routing chosen for (1) simplicity and (2) because the length of the sub-reaches for the study sub-basins are small enough that routing tends towards pure translation. The routing times were estimated using the Kirpich method reported in Roussel et al. (2006), where the distance is the Euclidean distance from the sub-basin outlet to the next element (into which the flow is routed). The translation method (time redistribution of runoff from the runoff generation procedure) used the Dimensionless Unit Hydrograph (NRCS-DUH) parameterized by the Kerby-Kirpich method reported in Roussel et al. (2006).

[6]The use of manual methods was intentional — automated technology certainly can accelerate the process, however the manual effort teaches the analyst a lot about the watershed in the process of preparing the input data.

[7]Lumped was the other validation configuration.

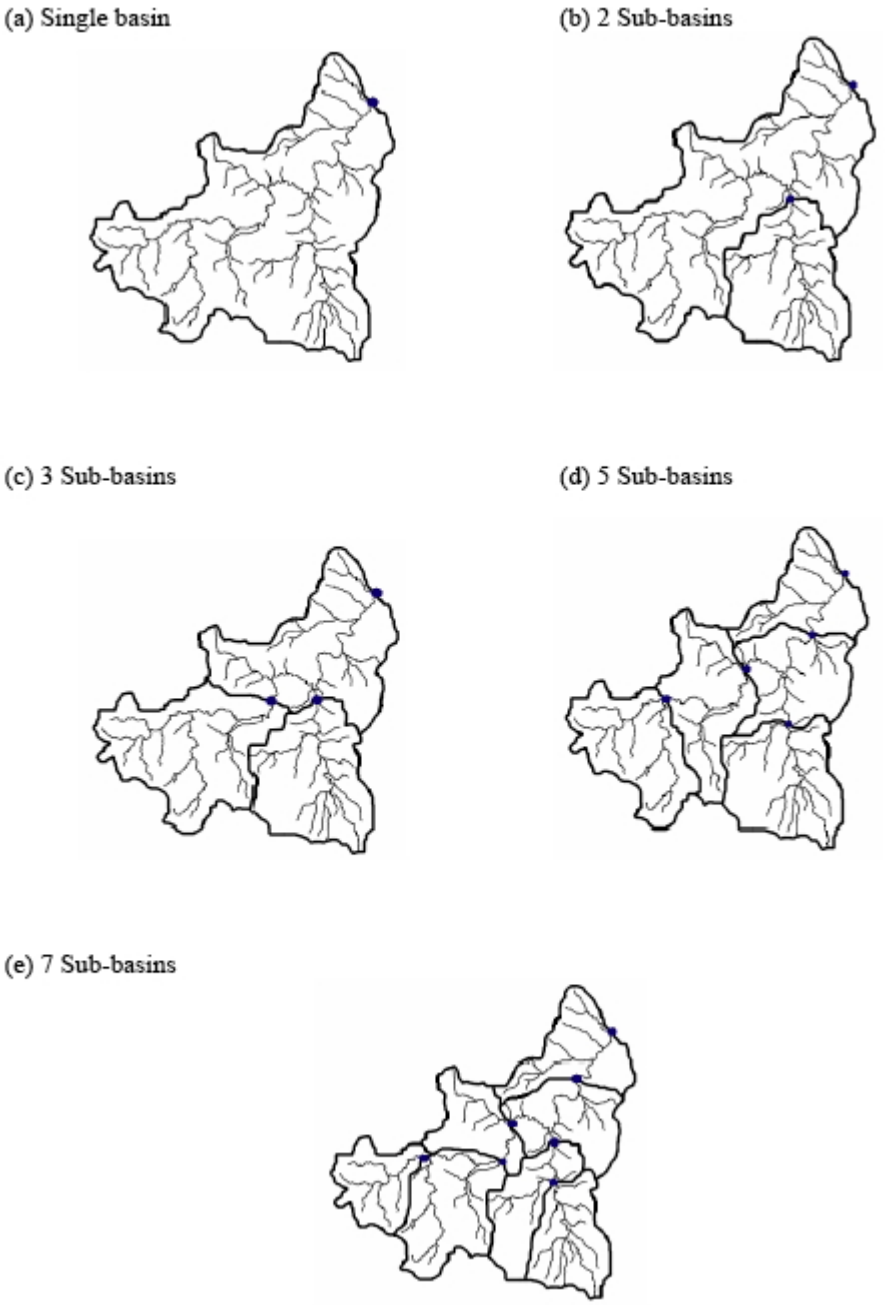

FIGURE 1. Representative basin subdivisions for Trinity-North watershed. The 2-Basin representation is not iso-area; gage locations are "actual" locations for this configuration on the watershed. Remaining subdivisions are approximately iso-area. Adapted from Luong (2008).

4. RESULTS AND INTERPRETATION

The various watershed models were operated and discharges computed by the model were compared to observations and evaluated using selected measures of error. The arithmetic mean relative error, relative root-mean-square error, and an acceptance criteria measure(Cleveland et al., 2006) were used to evaluate the different subdivision scheme performance. Figures 2, 3, and 4 are tabulations of these various metrics as applied to the results from the study watersheds.

Watershed	Peak Discharge	No. Subdivisions					Selected No. Subdivisions
		1	2	3	5	7	
Onion	*AVG (%)*	200.06	285.30	324.68	281.96	331.20	1
	RRMSE (%)	233.08	294.30	366.57	313.13	367.94	1
	MIN_COUNT	2	0	0	0	0	1
South Mesquite	*AVG (%)*	9.67	5.00	16.04	27.63	9.13	2
	RRMSE (%)	16.47	12.09	20.78	32.53	14.50	2
	MIN_COUNT	2	3	1	0	0	2
Little Fossil	*AVG (%)*	78.52	98.97	85.48	123.41	97.63	1

	MIN_COUNT	2	0	0	3	4	7

FIGURE 2. Tabulation of metrics for peak discharge comparisons. Adapted from Luong (2008).

These tabular results of the various measures of model performance indicate that there is no single watershed division scheme that performed well for all observed storms on a particular watershed. The authors interpret this result as typical, and an implication is that there is no consistent pattern on whether lumped or multiple subbasins produce superior results using this quasi-iso area scheme. The models were not calibrated, however even when we calibrated one watershed to observations there was only a marginal change in results.

Watershed	Runoff Volume	No. Subdivisions					Selected No. Subdivisions
		1	2	3	5	7

FIGURE 3. Tabulation of metrics for watershed runoff (volume) comparisons. Adapted from Luong (2008).

5. CONCLUSIONS

Runoff hydrographs that were developed for the Onion Creek, South Mesquite, Little Fossil, Olmos Creek, and Trinity Basin-North watersheds were used to determine the affects that number of sub-watersheds had on the runoff hydrographs. It was found that the increase in the number of sub-watersheds does not significantly affect the simulated runoff hydrograph (volume). This study also shows that none of the subdivision schemes were able to accurately simulate peak flows or runoff volumes from all individual events for each watershed.

In general, this study, as performed, indicates that unless the engineer needs internal flows, subdivision simply to gain accuracy does not justify the additional modeling effort.

Continued research is needed to ascertain if the results obtained in this study will change using a runoff generation model that is less sensitive to hyetograph behavior than the CN loss model, and with distributed rainfall observations.

Abstract

In the past 30 years, lumped-parameter watershed models have been employed for integrated surface water and groundwater modeling to calculate surface and base runoffs. Physics-based, process-level models that employ consistent sets of governing equations for integrated overland, river, vadose, and groundwater flow have been practically nonexistent until early 1990s. This paper presents the development of an integrated media, physics-based watershed model. Complete coupling simulations among system components of land surfaces, river networks, vadose zones, and groundwater or partial couplings between any two components can be conducted with the model. Various rigorous coupling strategies based on physics and numerics for interactions among these components are described. Two examples were employed to discuss the issues of coupling. One was used to demonstrate differences and implications between continuity and linkage approaches when the surface water and groundwater are in direct connection. Another one, a watershed modeling in Florida, was used to illustrate that complete and partial couplings yield quite different simulations.

1. Introduction

The design of watershed simulators for fluid flows and scalar (e.g., thermal, turbulent energy, dissipation energy, salinity, sediment, water quality, et cetera) transport to analyze response and behavior of a watershed is probably the classic problem in watershed modeling. An extensive review on available simulators and their applications to watershed modeling by practitioners was made in late 1990s (EPA, 1997). These simulators can be classified into two broad groups: parametric-based approaches and physics-based approaches. There are numerous advantages in a physics-based approach. The parameters of the governing equations are the properties of the system media and can be independently determined from physics. As a result, the scaling up or down of a problem is not an issue and extrapolation can be made with confidence as long as the continuum treatment is valid. Repeated calibration of physics-parameters is not necessary although some kinds of

fine-tuning may be required. On the other hand, for the parametric-based approaches, parameters in the working equations are non-physics and they must be repeatedly calibrated for each individual application. The scaling up or down of a problem is problematic and involves numerous types of parameters. The single greatest advantage of parametric-based approaches is their ability to generate numerical results regardless if they are correct or not. This is perhaps the major reason why such approaches, for example HSPF (Bicknell et al., 1993), have dominated watershed modeling in the past four decades since the development of Stanford Watershed Model IV (Crawford and Linsley, 1966).

A watershed includes multiple system-components of river/stream networks, land surface, reservoirs/lakes, and subsurface media of vadose and saturated zones. It encompasses multiple processes of fluid flows and transport of thermal energy, salinity, sediment, and water quality, et cetera. From the EPA compilation (EPA, 1997), only the Hydrologic Smulation Program Fortran (HSPF) or similar parametric-based (lumped parameter) simulators have the design capabilities to deal with the complete system-components in a watershed. Also, only these types of simulators have encompassed the complete suite of fluid flow and scalar transport processes.

There have been tremendous progresses in first principle, physics-based modeling of flow and transport processes in partial system-components. Subsurface flow codes based on Richards' equations have been developed and applied to the prediction of various types of subsurface runoffs. Many overland computer codes based on two-dimensional St Venant equations have been developed for the computation of overland flow and surface runoff. Numerous stream flow codes based on one-dimensional St Venant equations have been developed for the prediction of stage and discharge as functions of time and distance along the stream-river networks.

It is widely recognized that the coupling of system components among subsurface media, overland regime, stream/river networks, and reservoirs/lakes into a complete watershed simulator would be desirable. The development of first principle, physics-based watershed simulators that have the same design capabilities as parametric-based simulators has intensified since the middle of 1990s (Abbott, et al.,1986; Wigmosta and Perkins, 1997; Yeh et al., 1998; VanderKwaak, 1999; Ewen et al., 2000; HydroGeoLogic In., 2001; SFWMD,https://my.sfwmd.gov/portal/page?_pageid=1314,2556300&_dad=portal&_schema=PORTAL&navpage=home; Downer and Ogden, 2002; Swain, Langevin and wolfert, http://sofia.usgs.gov/projects/coupling/comptechnique_03geerab.html; SOBEK: http://delftsoftware.wldelft.nl/; Yeh et al., 2003, 2005, 2006). While these new generation watershed simulators have the potential to further the understanding of the fundamental biological, chemical and physical factors that take place in nature watersheds, and give mechanistic predictions, three key issues remain to be resolved: (1) Coupling among media, (2) applicability of kinematic, diffusive, and fully dynamic wave models, and (3) select of wave directions in multi-dimensional dynamic wave models. This paper focuses on addressing the first issue. From a physical point of view, the surface water and subsurface water can be considered in direct or indirect connection. Form a numerical point of view, the coupling can be conducted with fully coupling, alternatively iterative coupling, or time-lagged decoupling.

The consideration of surface water/subsurface water interactions consists of two parts: stream-aquifer interaction and overland-subsurface interaction. The stream-aquifer interaction has been extensively studied by coupling saturated groundwater flow with

one-dimensional channel flow (for example, Pinder and Sauer 1971; Swain and Wexler 1996; Hunt 1990, among others). The role of unsaturated zone on stream-aquifer interaction is rarely considered. The overland-subsurface interaction is usually studied in the context of runoff generation at the watershed scales (for example, Freeze 1972; Smith and Woolhiser 1971; Akan and Yen 1981; Abbott et al. 1986).

Recently, the physics-based coupling of surface and subsurface flows has been an active research topic. Panday and Huyakorn (2004) discussed the utility of different coupling schemes in a new watershed model and seemed to favor the conductance-type, linkage term approach. Favoring the continuity-of-pressure approach, Morita and Yen (2002) classified coupling approaches, from the numerical point of view, as fully coupled (simultaneous solution), alternating iterative coupling and externally coupling (decoupled). In their model, the concept of infiltrability was introduced. This term refers to the variable boundary conditions in numerical solution of Richards equation; however, a leakage term was used in the coupling process.

2. Coupling among Media

In the core of an integrated, physics-based watershed model is a study of coupling among surface water and subsurface water flows. In this study, we focus on physics-based coupling approaches that utilize partial differential equations both in surface water flow (Saint Venant equations) and variably saturated subsurface flow models (Richards equation). For simpler watershed models, the infiltration term is treated with an empirical algebraic equation; accordingly, the surface water/groundwater interaction computation is straightforward and independent of water flow solutions. Although the numerical solution of the Richards equation is computationally intensive and difficult at watershed scales, it is essential for a complete, physics-based representation of the subsurface flow.

The interaction between the surface water (SW) in river network, overland water (OW) in the land surface, and groundwater (GW) in subsurface media occurs at the interface between these domains. Depending on the mesh resolution and distribution of material properties, there are two types of connections on the SW-GW interface, as schematically displayed by Figure 1. If the distribution of soil property near the SW-GW interface can be fully resolved by the GW mesh, then the interface is termed a direct SW-GW connection. While, an indirect SW-GW connection refers to the situation where the soil property can not be resolved by the mesh, e.g. the GW mesh size is much larger then the thickness of a skin layer of clay/sediment. The direct and indirect connection can also be defined similarly on the OW-GW interface, see also Figure 1.

Mathematically, the continuity of flux and pressure are imposed at the interface for the direct connection. At the SW-GW interface, this condition is mathematically expressed as

$$h^r = h^s \quad and \quad q^r = \int_P \left[-\mathbf{n} \cdot \mathbf{K} \cdot \left(\nabla h^s + \nabla z \right) \right] dP \tag{1}$$

where h^r is the depth of the river [L], h^s is the pressure head of subsurface water [L], q^r is the seepage of groundwater to the river per unit river length [L^2/T], P is the wet perimeter of the river cross-section [L], $\mathbf{n}$ is the outward unit vector of the interface in the direction from groundwater to surface water, and $\mathbf{K}$ is the hydraulic conductivity of the

subsurface media [L/T]. At the OW-GW interface, it is expressed as

$$h^o = h^s \quad and \quad F^o = \mathbf{-n} \cdot \mathbf{K} \cdot \left(\nabla h^s + \nabla z \right) \tag{2}$$

where h^o is the depth of overland water [L] and F^o is the flux from groundwater to overland water [L/T].

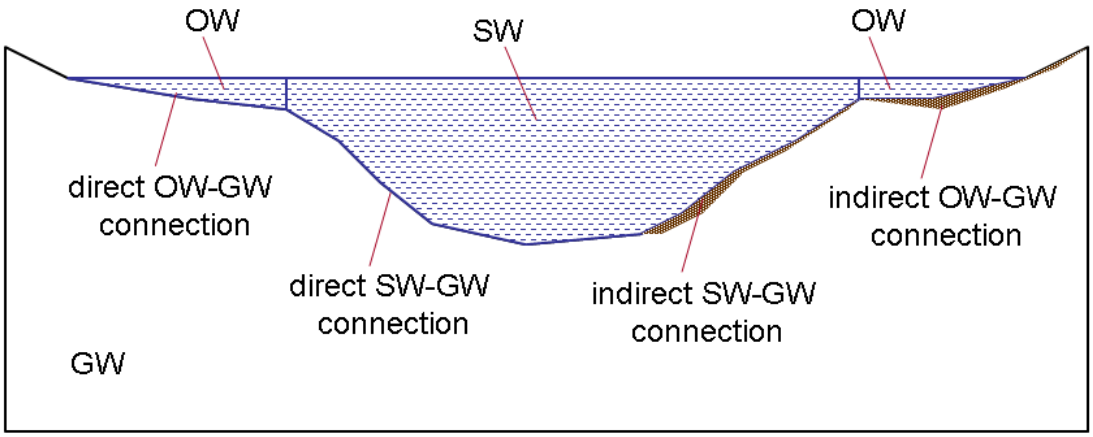

Figure 1 Direct and Indirect Connections on SW-GW and OW-GW interfaces

At the interface of an indirect connection, the mass exchanges between surface water and groundwater and between overland water and groundwater are formulated in terms of the differences of pressure between two media. At the SW-GW interface, the formulation is given as

$$\mathbf{-n} \cdot \mathbf{K} \cdot \left(\nabla h^s + \nabla z \right) = k(h^s - h^r) \quad and \quad q^r = \int_P k(h^s - h^r) dP \tag{3}$$

where k is the exchange coefficient [1/T]. It represents the hydraulic conductivity divided by the thickness of the layer that separate the surface water and groundwater but not included as part of the media. This is the coupling by the linkage term. Even when the media are in direct connection, many models (e.g., Panday and Huyakorn, 2004) still use this linkage approach to coupling. Under such circumstances, k is simply a non-physics fitting parameter. At the OW-GW interface, the formulation is similarly given as

$$\mathbf{-n} \cdot \mathbf{K} \cdot \left(\nabla h^s + \nabla z \right) = k(h^s - h^o) = F^o \tag{4}$$

Even in the case of indirect connection, it is still more rigorous to use the continuity approach than the linkage approach by including thin layer of the material as part of the non-heterogeneous subsurface media. However, computer demands and numerical convergence may be at issues (Huang and Yeh, 2009).

A different classification of coupling strategies is based on numerical schemes rather than physical-connection based mathematical formulation. A simple overland/subsurface flow-coupling example is used to illustrate the classification. As shown in Figure 2, in this simple example, there are 12 overland nodes and six elements in the two-dimensional

overland domain. The three-dimensional subsurface medium consists of 36 subsurface nodes and 12 elements. Finite element discretization of the continuity equation governing the overland flow would result in the following algebraic equations

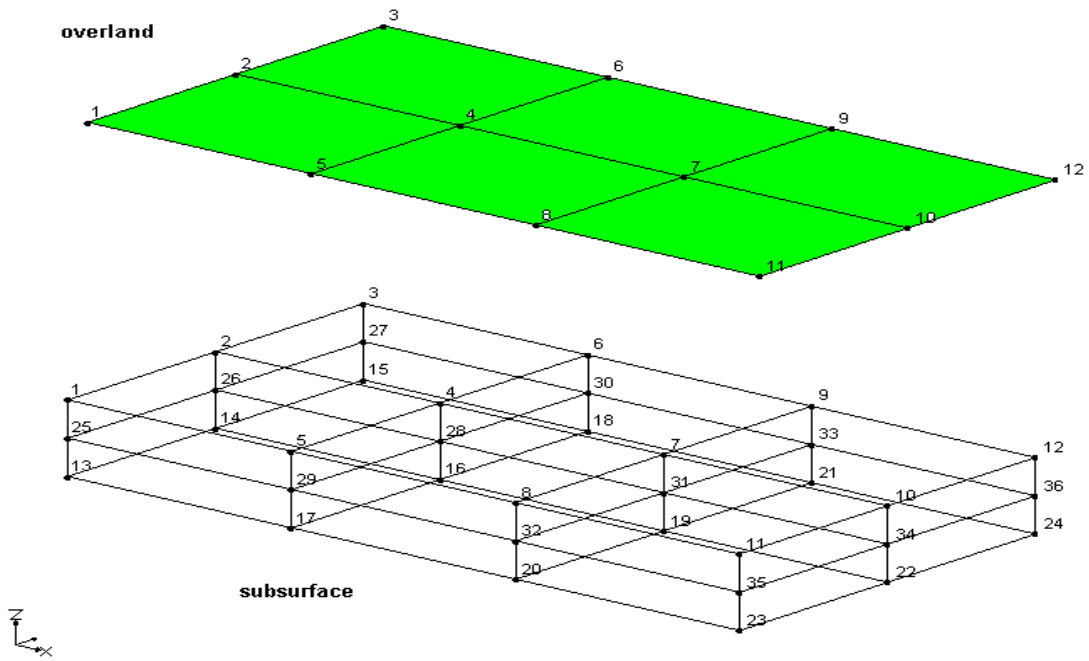

Figure 2: 2D Overland and 3D Subsurface Finite Element Mesh

$$\sum_{j}^{12} a_{ij}^{o} h_{j}^{o} = R_{i}^{o} + Q_{i}^{o},\ i = 1,2,..,12 \tag{5}$$

where a_{ij}^{o} is the coefficient matrix resulting from the discretization of the overland-flow equation; h_{j}^{o} is the water depth at the *j-th* overland node; R_{i}^{o} is the load of the *i-th* overland node resulting from initial condition, external source/sink, and global boundary conditions; and Q_{i}^{o} is the source at *i-th* overland node resulting from groundwater flux. Finite element discretization of Richards equation for subsurface flow would result in the following algebraic equations

$$\sum_{j=1}^{36} a_{ij}^{s} h_{j}^{s} = R_{i}^{s} - B_{i}^{s},\ i = 1,2,..,36 \tag{6}$$

where a_{ij}^{s} is the coefficient matrix resulting from the discretization of the subsurface-flow equation; h_{j}^{s} is the hydraulic head at the *j-th* subsurface node; R_{i}^{s} is the load of the *i-th* subsurface node resulting from initial condition, external source/sink, and global boundary conditions; and B_{i}^{s} is the boundary flux at the *i-th* subsurface node. It should be noted B_{i}^{s}

is zero for node that is not belong to the subsurface-overland overlapping nodes. In other word, the *i-th* nodal flux is zero ($B_i^s = 0$) when *i* is greater than 12 ($i > 12$) in this case.

For decoupled flow simulations, there are 12 overland-flow equations for 12 overland unknowns ($h_j^o,\ j = 1,2,..,12$) with 12 external sources ($Q_i^o,\ i = 1,2,..,12$) considered given; and 36 subsurface-flow equations for 36 subsurface unknowns ($h_j^s,\ j = 1,2,..,36$) with 12 boundary fluxes ($B_i^s,\ \mathrm{i} = 1,2,..,12$) considered prescribed. However, for a coupled flow simulation, the 12 overland external sources and 12 subsurface boundary fluxes, which result from the interaction between overland and subsurface flows, must also be considered unknowns. These 24 unknowns require 24 additional equations to close the system. These 24 equations are obtained from the interface conditions. Obviously, the continuity of interface fluxes provide 12 equations as follows

$$Q_i^o = B_i^s,\ i = 1,2,..,12 \tag{7}$$

The additional 12 equations can be obtained based on the physical condition of the interface. For a direct connection interface, the continuity of pressure at the interface would yield

$$h_i^o = h_i^s,\ i = 1,2,..,12 \tag{8}$$

For an indirect connection, the overland external source or the subsurface boundary fluxes must be formulated in terms of the properties of the material between two flow regimes. Incorporation of the boundary condition given by Equation (4) in the finite element approximation of flow equations would result in

$$Q_i = B_i^s = \mathrm{K}\left(h_i^s - h_i^o\right),\ \ i = 1,2,..,12 \tag{9}$$

In summary, there are 72 equations [12 in Eq. (5), 36 in Eq. (6), 12 in Eq. (7), and 12 in Eq. (8) or in Eq. (9)] for 72 unknowns [12 overland water depths, 36 subsurface pressure heads, and 24 exchange fluxes which compose of 12 overland source/sink terms, Q^o's and 12 subsurface boundary fluxes B^s's].

Nominally, solving the coupled flow problem can be considered as the simultaneous solution of these 72 algebraic equations. Three strategies have been employed in the literature: fully implicit scheme, iteratively implicit scheme, and time-lagged explicit scheme. Take the case of direct connection as an example, the fully implicit scheme solves 72 equations for 72 unknowns simultaneously as

$$\begin{gathered}\sum_j^{12} a_{ij}^o h_j^o = R_i^o + Q_i^o,\ i = 1,2,..,12;\ \ Q_i^o = B_i^s,\ i = 1,2,..,12 \\ h_i^s = h_i^o,\ i = 1,2,..,12;\ \ \sum_{j=1}^{36} a_{ij}^s h_j^s = R_i^s - B_i^s,\ i = 1,2,..,36\end{gathered} \tag{10}$$

The iteratively implicit scheme solves the overland flow unknowns and subsurface unknowns iteratively as

$$\sum_{j}^{12} a_{ij}^{o}(h_j^o)^{(k+1)} = R_i^o + Q_i^o,\ i = 1,2,..,12 \ \text{ with } \ Q_i^o = (B_i^s)^{(k)},\ i = 1,2,..,12 \qquad (11)$$

and

$$(h_i^s)^{(k+1)} = (h_i^o)^{(k+1)},\ i = 1,2,..,12;\ \sum_{j=1}^{36} a_{ij}^{s}(h_j^s)^{(k+1)} = R_i^s - \left(B_i^s\right)^{(k+1)},\ i = 1,2,..,36 \qquad (12)$$

where the superscript $(k+1)$ and (k), respectively, indicate the present iteration and previous iteration, respectively. The time lagged explicit schemes first solve the overland flow equation using subsurface flow information of previous time step, then solve the subsurface flow equations using the newly obtained overland flow water depth as the boundary conditions as

$$\sum_{j}^{12} a_{ij}^{o}(h_j^o)^{(n+1)} = R_i^o + Q_i^o,\ i = 1,2,..,12 \ \text{ with } \ Q_i^o = (B_i^s)^{(n)},\ i = 1,2,..,12 \qquad (13)$$

and

$$(h_i^s)^{(n+1)} = (h_i^o)^{(n+1)},\ i = 1,2,..,12;\ \sum_{j=1}^{36} a_{ij}^{s}(h_j^s)^{(n+1)} = R_i^s - \left(B_i^s\right)^{(n+1)},\ i = 1,2,..,36 \qquad (14)$$

where the superscript $(n+1)$ and (n), respectively, indicate the present time step and previous time step, respectively.

3. Demonstration Examples

Example 1: This example is a simple case of rainfall-runoff process on a horizontal surface of 500 m x 400 m. The closed boundary was applied except a 100 m-outlet is located at the center of a 500 m-side (critical flow) (Figure 3). The Manning's n value is 0.02. A rainfall intensity of 4.0E-5 m/s was applied for 600 minutes. The underlying porous medium has a vertical saturated hydraulic conductivity of 5.5E-5 m/s and an effective porosity of 0.41. There is no physical discontinuity of subsurface media at the interface, that is, the two flow regimes are in direct connection. Initially, the water table is 10 m below the land surface. No flow boundary was applied to subsurface domain except the top boundary, which is the interface between overland and subsurface domains. Constant time steps of 20 s and 180 s were applied for two-dimensional overland flow and three-dimensional subsurface flow, respectively. The 900-minute simulations were performed with the continuity coupling approach and the linkage-term coupling approach. The outflow discharge hydrographs were compared (Figure 4).

The computed outflow discharge hydrograph represents the integrated results of rainfall, surface runoff and infiltration processes. It can be seen from Figure 4 that the linkage-term and continuity coupling approaches resulted in different rising part of the flow hydrograph. After the subsurface domain is fully saturated and the runoff became steady, the simulation results are essentially the same. Since physically, there is no discontinuous interface, the conductance values (k) were tested for three cases (k = 5.5E-6, 5.5E-4 and 3.0E-3). A small k value constrains exchange fluxes; therefore, land surface

saturation leads to surface runoff, at which point the whole unsaturated zone gradually becomes saturated. As for enough big k values, the simulation results are very close to those of continuous coupling.

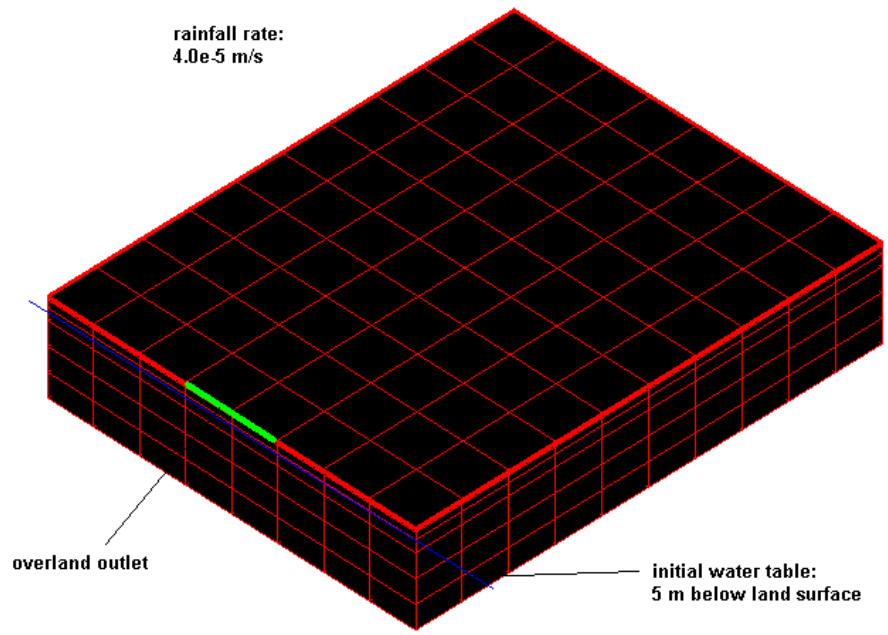

Figure 3: Problem Description and Finite Element Discretization for Example 1

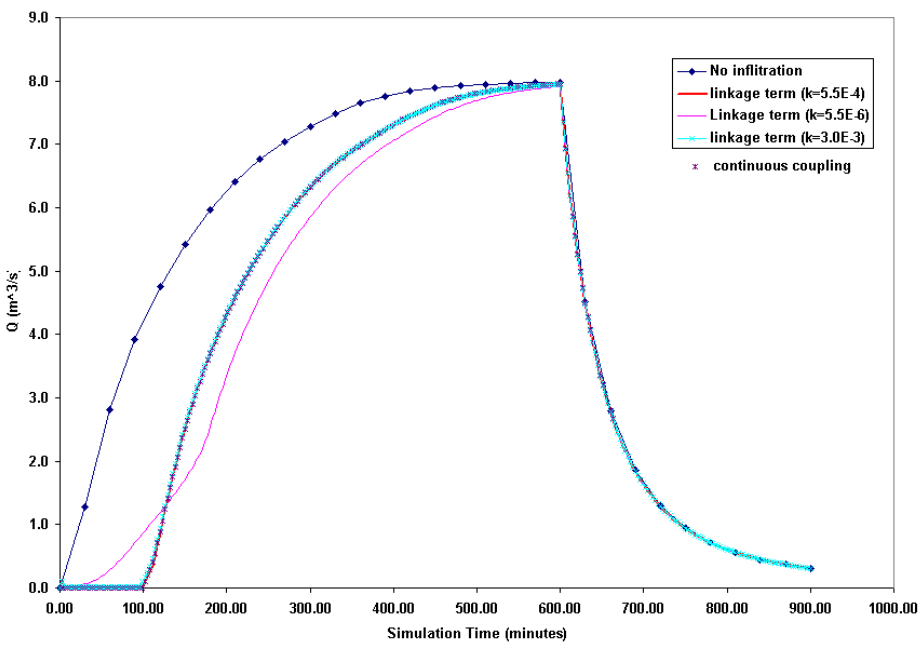

Figure 4: Comparison of Outflow Hydrographs using Continuity and Linkage Approaches

This example demonstrates that the use of linkage-term coupling can produce different results depending on the chosen k values. In Figure 5, the computed time series of total

exchange fluxes were compared for all simulation cases; this is consistent with the pattern shown in the discharge hydrograph.

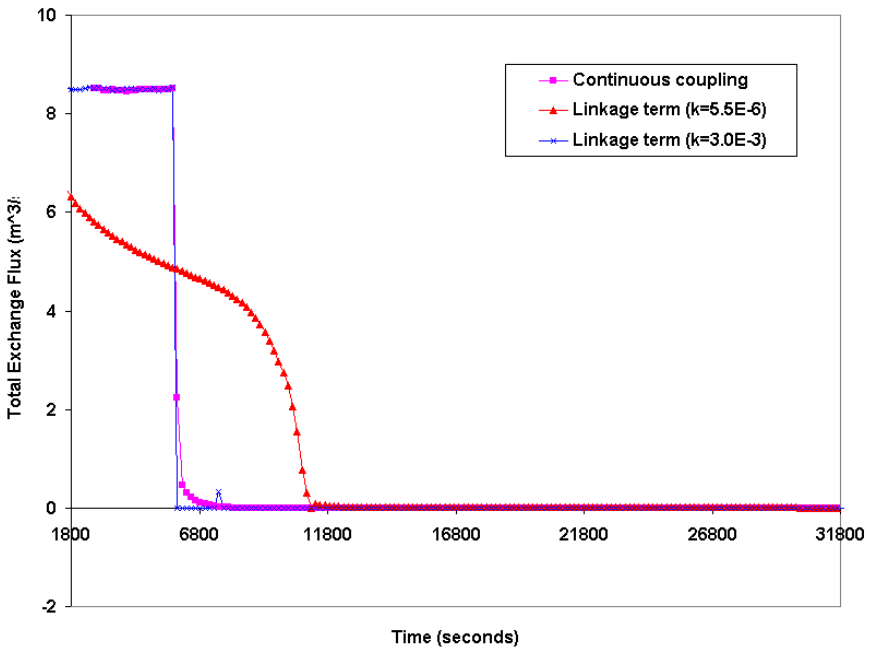

Figure 5 Comparison of Exchange Fluxes using Continuity and Linkage Approaches

Example 2: This is a regional scale modeling effort for the South Florida wetlands. The Dade model domain extends from four miles west of the L-67 Extension dike to the western shore of Biscayne bay and from one mile north of the Tamiami canal south to Florida bay. Vertically, it extends from the land surface to the bottom of the surficial aquifer. Some characteristics of this model are: (1) Strong interaction of overland flow/groundwater flow and canal flow in south Florida; (2) Complex hydraulic structure operations.

The 3-D finite element mesh for subsurface media (as shown in Figure 6) is complex: there are 37,760 global nodes, and 65,429 elements. There are 7 layers in the vertical direction. And levees are incorporated as part of subsurface media. The boundary conditions for subsurface flow were determined from the SFWMM 2x2 model output for the northern boundary, and from structure operation records for the other sides of boundaries. The 2-D overland flow domain consists of 4,720 nodes, and 9,347 triangular elements. Levees are included in the computation domain (Figure 7). Boundary conditions were determined from structure operation records along the boundary. The canal network as simplified in this simulation includes: Canal nodes: 560; Canal elements: 506; River reaches: 55; there are 20 canal junctions, and 11 interior Gates (Figure 8).

Two numerical modeling were conducted. One was a coupled 2-D overland flow and 3-D subsurface flow simulation. A steady state 3-D subsurface flow simulation was run first. The pressure heads from the steady state are then used as the initial pressure heads for the coupled 2-D overland and 3-D subsurface flow. Another one was a coupled 1-D canal flow, 2-D overland flow, and 3-D subsurface flow simulation. Initial conditions were provided from the results of 2D-3D simulations,

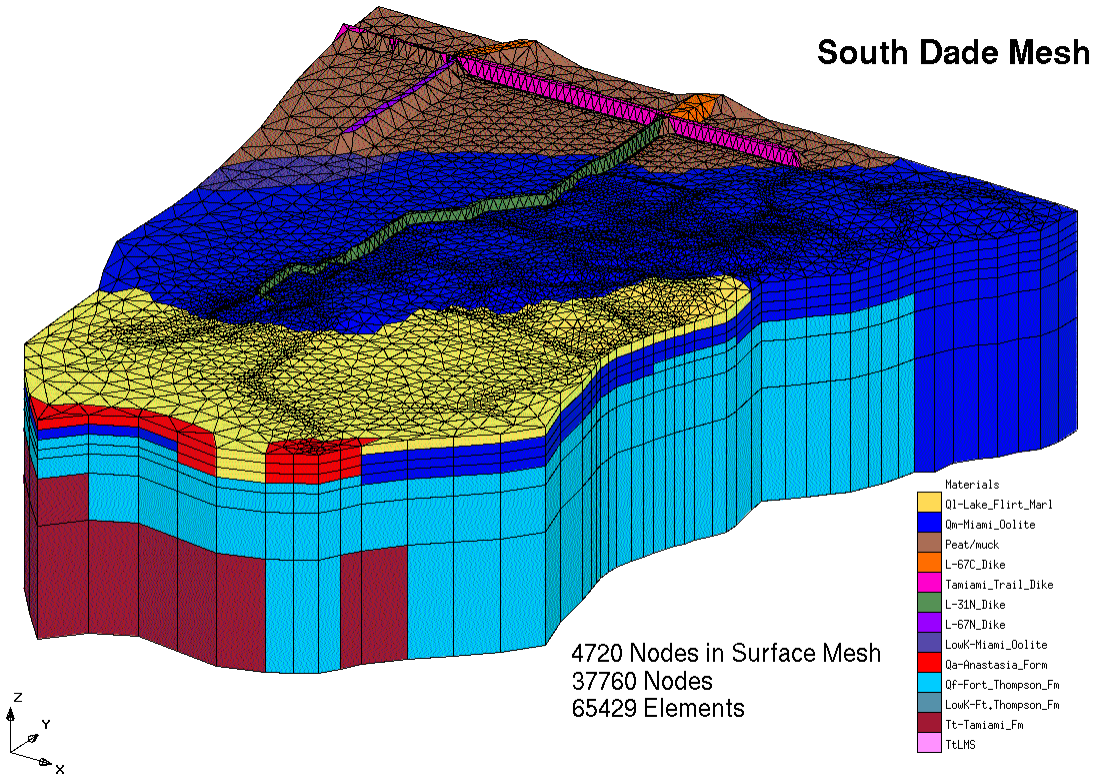

Figure 6 3-D Subsurface Media Finite Element Mesh

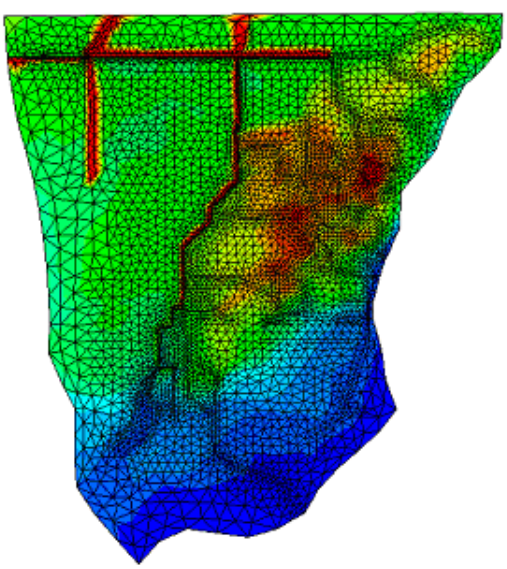

Figure 7 2-D Overland Regime Finite Element Mesh

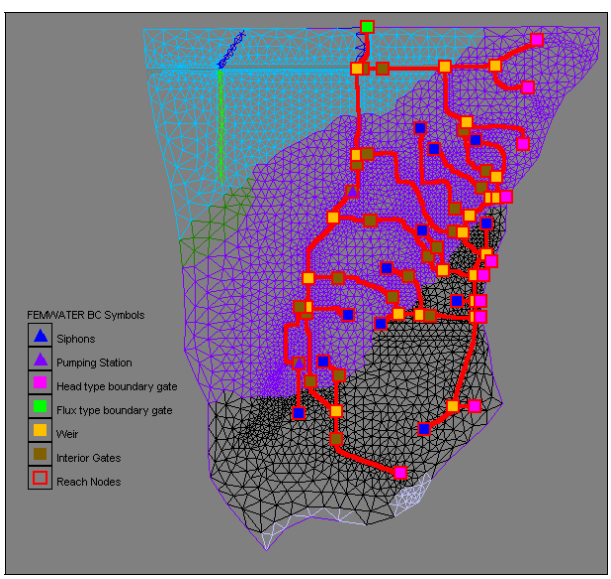

Figure. 8. Canal Network

The combined processes of 1D canals, 2D overland flow, and 3D subsurface flow are complex and require a systematic modeling approach of adding computational complexity until all of the important processes are simulated. This is primarily because the physical processes being simulated cannot all be turned on at the same time due to numerical initial

condition issues. It is important to start with consistent boundary and initial conditions and to run the model first in steady state 3D-only mode followed by 2D/3D overland and groundwater flow, followed by fully coupled 1D/2D/3D mode. In each step of the process, increasingly complicated but accurate initial conditions are provided to the next stage of the simulation until all physical processes are simulated.

Results from the coupled 2D overland flow and 3D subsurface flow simulations are voluminous due to the large mesh and the two-hourly time steps made over the one year time period. Given the temporal and spatial choices for a written paper, only spatial distributions of model output at a discrete time is presented. Figure 9 through Figure 11 show spatial distributions of simulation results for an early point in the yearlong simulation. Figure 9 shows overland flow depths, Figure 10 shows overland flow vectors, and Figure 11 shows coupled 2D/3D total head elevations.

After the model produced reasonable responses based on the coupled 2D overland and 3D subsurface flow simulation, initial conditions were saved and used as input to simulations of coupled 1D canal flow, 2D overland flow, and 3D subsurface flow. These simulations are the most rigorous of the coupled simulations. Figure 12 and Figure 13 show spatial distributions of model output for an early point in the yearlong simulation. Figure 12 shows overland flow depths and Figure 13 shows coupled 1D/2D/3D total head elevations.

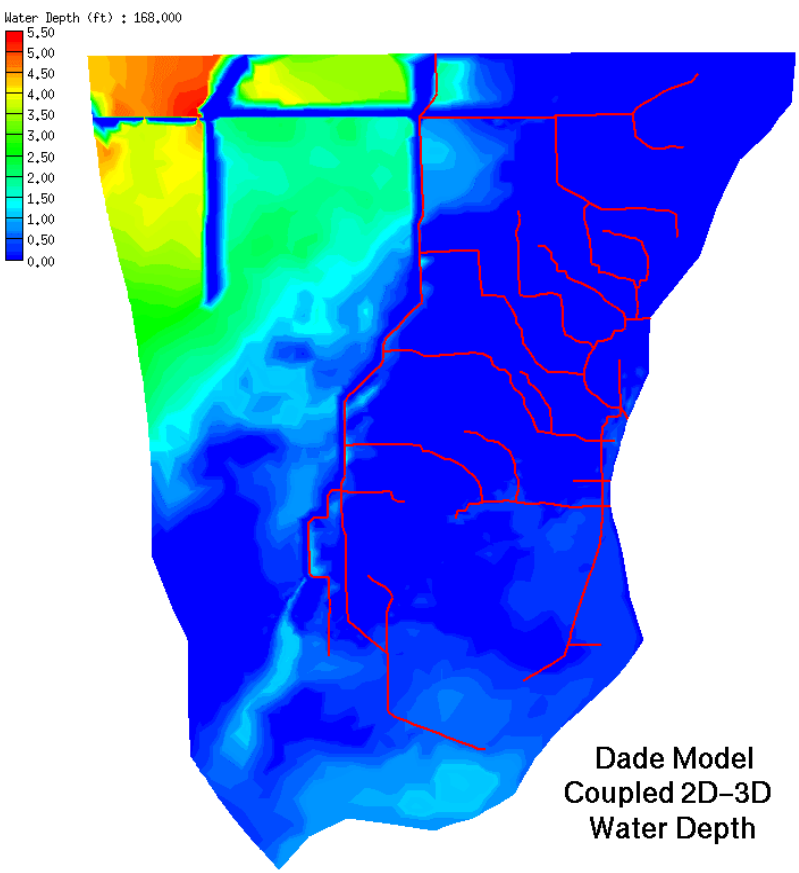

Figure 9 Dade Model Coupled 2D-3D Overland Flow Water Depth Contours

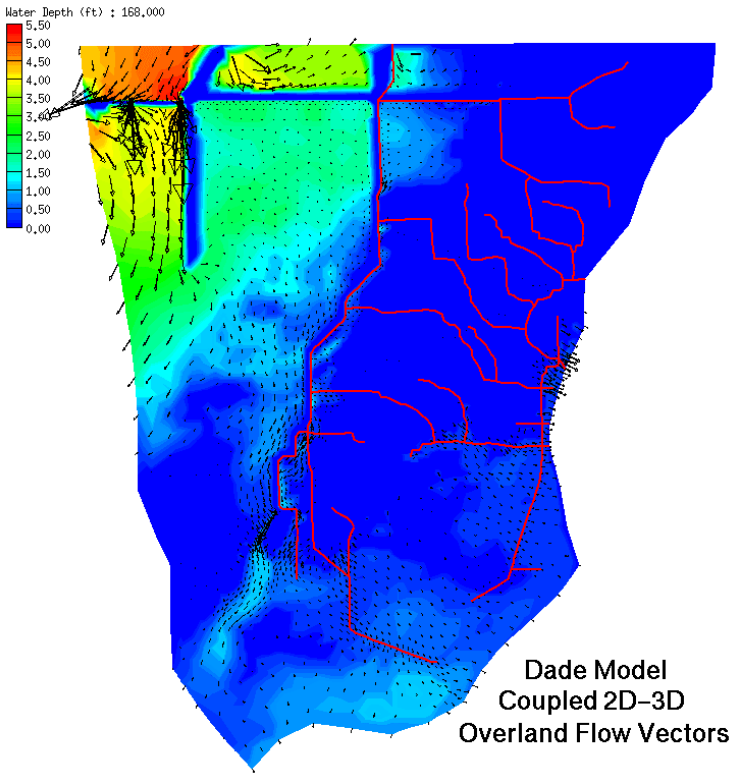

Figure 10 Dade Model Coupled 2D-3D Overland Flow Vectors

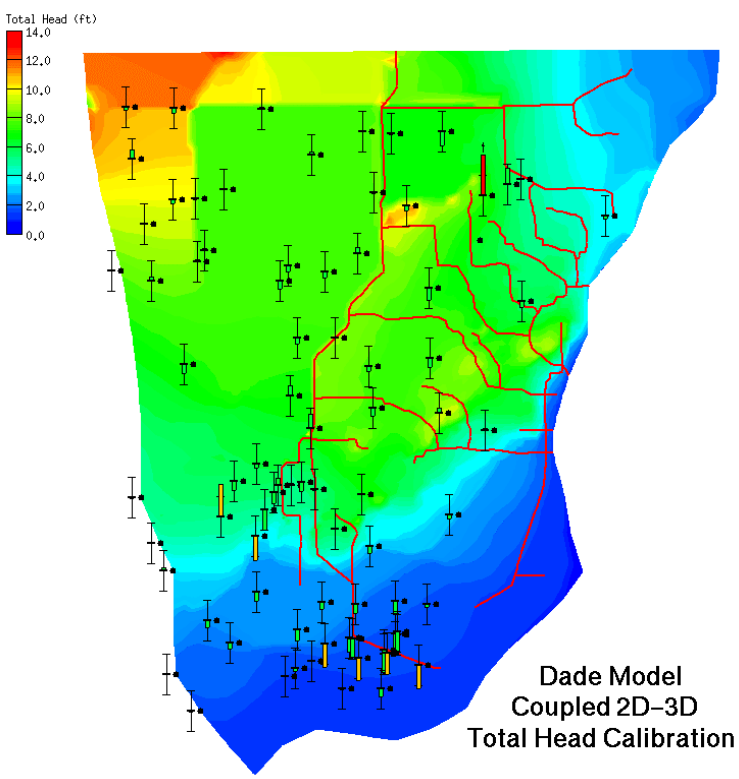

Figure 11 Dade Model Coupled 2D-3D Total Head Calibration

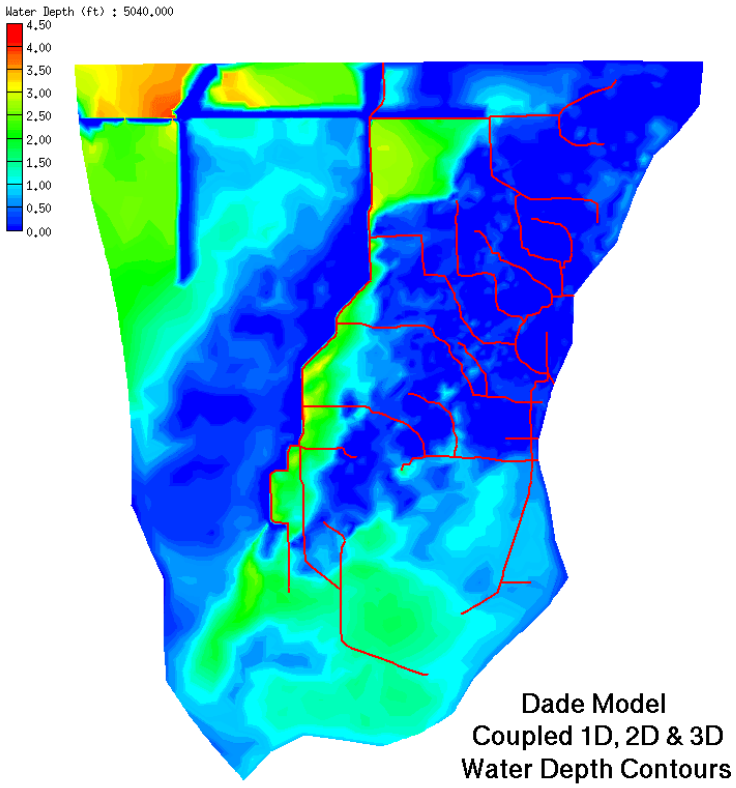

Figure 12 Dade Model Coupled 1D-2D-3D Overland Flow Water Depth Contours

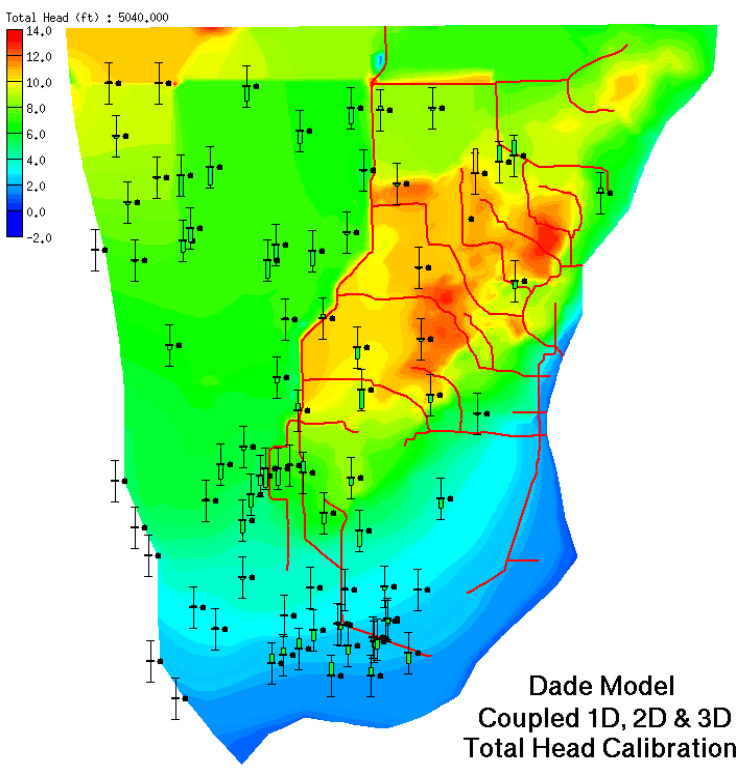

Figure 13 Dade Model Coupled 1D-2D-3D Total Head Calibration

Comparing Figure 9 and Figure 12, it is clearly seen that there is a significant difference between 2D-3D and 1D-2D-3D simulations. It is thus important to consider interactions among all system components.

4. Summary and Conclusion

An integrated media, physics-based watershed model has been developed. Three key issues have to be addressed in a complete watershed model: (1) Coupling among media, (2) applicability of kinematic, diffusive, and fully dynamic wave models, and (3) select of wave directions in multi-dimensional dynamic wave models. The coupling issue is the focus of this paper. From a physical point of view, the surface water and subsurface water can be considered in direct or indirect connection. For the case of direction connection, the continuity of pressure and flux can be mathematically stated. However, many models have used the linkage formulation, which introduces non-physics fitting parameters. For the case of indirect connection, most models have employed the linkage approach. Although the continuity approach can still be taken by including the thin layer separating surface water and groundwater as part of the heterogeneous subsurface media, it may cause numerically convergent problem or demand excessive computational time. Once the mathematical problem is reduced to a set of algebraic equations, there schemes have been widely used to solve the matrix equation: fully implicit scheme, iteratively implicit scheme, and time-lagged explicit scheme. Two examples were employed to discuss the issues of coupling. One was used to demonstrate differences and implications between continuity and linkage approaches in a physically direct connection problem. Another one, a watershed modeling in Florida, was used to illustrate that complete and partial couplings yield quite different simulations.

ABSTRACT

Temporal water budget assessments are necessary for short- and long-term water resources management and operational planning. However, these estimates are subject to a variety of potential sources of error, some of which are not easily quantifiable. Several past water budget studies have focused on quantifying residual errors and improving the water budget balance using statistical methods. In the current study, a weighted mass balance equation, solvable by using mathematical programming models at different time scales, is proposed and investigated. The mathematical programming models employ mixed-integer, non-linear programming formulations and binary variables to estimate weights that can improve the water budget by reducing residual errors. The formulations developed were tested and evaluated for a large constructed wetland operated and managed by the South Florida Water Management District for nutrient control. Hydraulic and hydrologic data from the wetland were used to test the methodology proposed in the current study. Results suggest reduction in residual errors and identify variables that need improvement in measurements and estimation for accurate water budgeting.

INTRODUCTION

Managing water resources and operations requires accurate water budget assessments. These assessments are normally carried out using traditional mass balance equations based on a simple water budget model at different temporal scales. Hydro-meteorological components play a major role in developing accurate water budget assessments, but are subject to systematic and random errors. In addition, various

empirical relationships are used to estimate values for some of these parameters and they have associated uncertainties in their estimation. While some of the errors are easily quantifiable, others are not. In the current study, a weighted mass balance equation, solvable by using mathematical programming models, is proposed and investigated using data from a large constructed wetland in South Florida.

Stormwater Treatment Area 2 (STA-2) is one of six wetland treatment areas operated by the South Florida Water Management District. Its purpose is to reduce water-column phosphorus concentrations in runoff from the Everglades Agricultural Area prior to discharge to Water Conservation Area 2A (WCA-2A), part of the remnant Everglades (**Figure 1**). Nutrient removal is accomplished by sedimentation and uptake by emergent and submerged aquatic vegetation in each treatment cell.

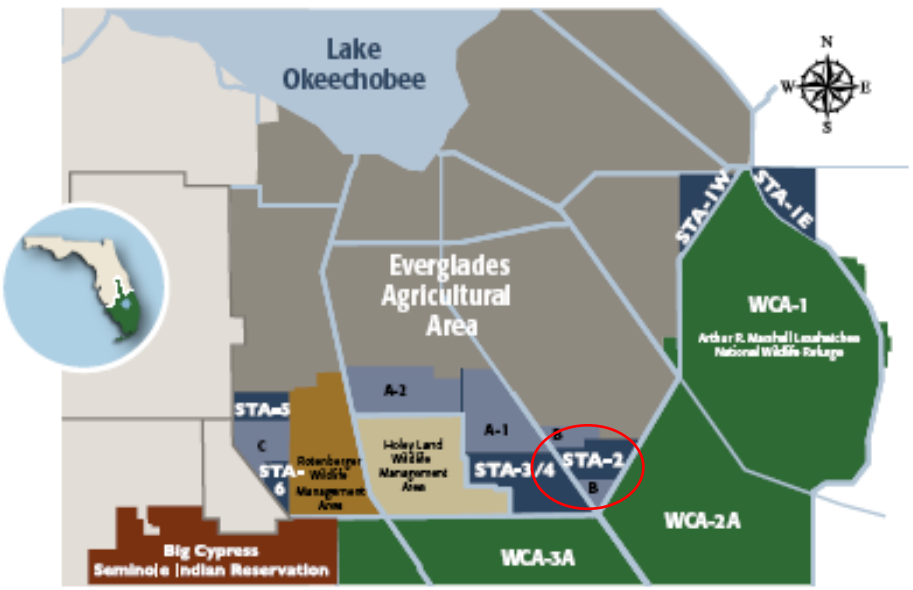

Figure 1. Location of STA-2.

STA-2 has four parallel treatment cells (**Figure 2**) with a total effective treatment area of 3,418 hectares (8,445 acres) (SFWMD, 2008). Cell 4 began operations in 2007 (Hall et al., 2007); the analysis discussed here used data pre-dating flow-through operations in Cell 4.

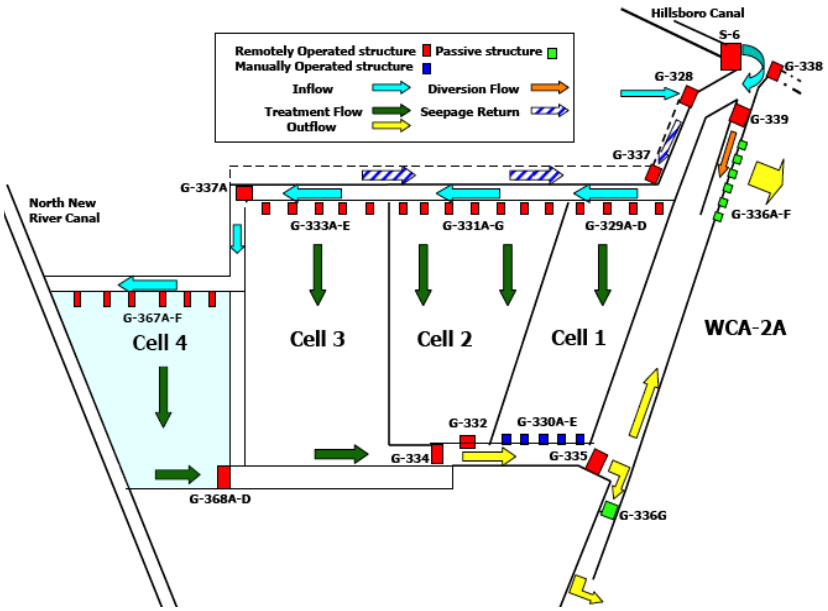

Figure 2. Schematic of STA-2 treatment cells and direction of water flow.

Water budget analysis is critical to understanding and optimizing STA operations. This analysis is mandated and is performed annually. STA-2 water budgets have been produced since the STA began permitted discharges in 2001 and are based on daily mean stages and flows, estimated daily seepage, rainfall, and evapotranspiration (ET). Errors in the water budget can be attributed to uncertainties associated with hydrologic measurements, such as flow and stage, and physical properties of the STA (e.g., ground surface elevation, surface area). A previous study (Huebner et al., 2007) examined the effect of using spatially distributed rainfall data (gauge-adjusted NEXRAD rainfall estimates) versus point data from a raingage network. Although limited in scope, the study indicated that water budget residuals were reduced when using NEXRAD data for larger STAs. Nevertheless, rainfall measurement probably exhibits the least random error with respect to all of the terms used in water budget analysis.

In all STA water budget analyses performed to date (Hall, et al, 2007), daily water budget residuals have demonstrated a trend to increase during significant runoff (flow) and draw-down events (**Figure 3**) suggesting that flows and change of storage responses may be better captured using a time increment smaller than one day. Parrish and Huebner (2004) examined water budget error for another STA, STA-5, using 15-minute increments and found that for the two-week period examined, daily water budget error was reduced on the order of 50 percent.

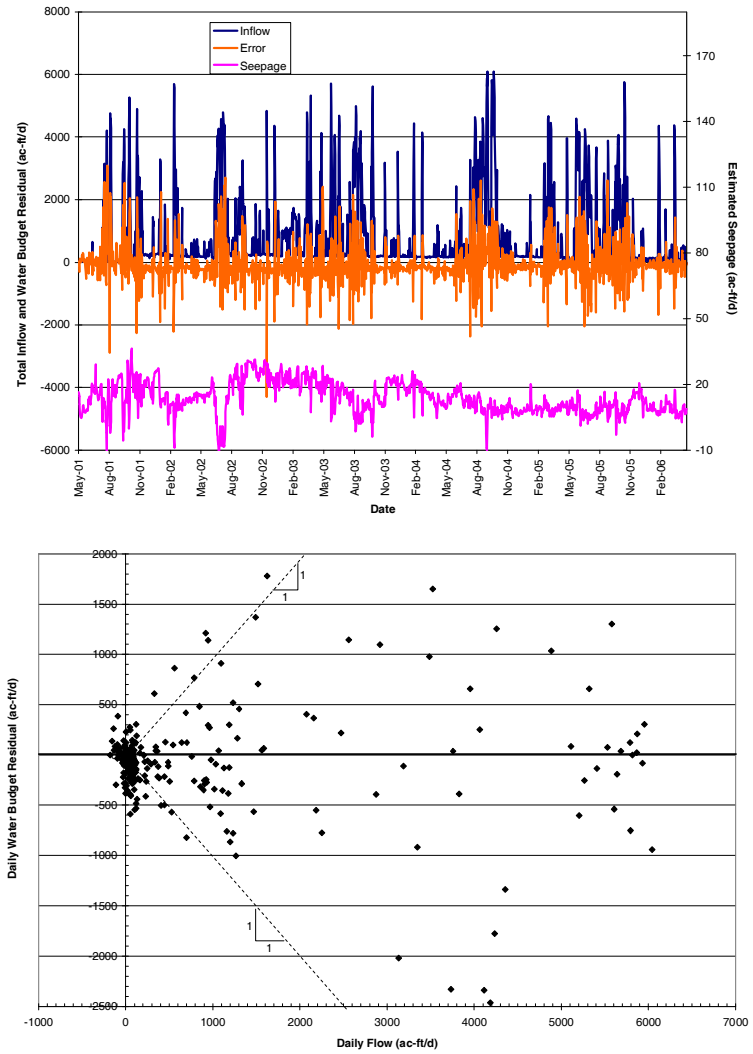

Figure 3. STA-2 water budget residual versus flow.

METHODOLOGY

The main objective was to identify and assess systematic errors in the STA water budget. Methods used by Teegavarapu and Pathak (2009) were repeated in this study to examine the effect of various time-steps on weights applied to independent variables as determined by two models that minimized the mean absolute error (MAE) and the mean squared-error (MSE) in the water budget (**Equation 1**). Time periods used in this study were 15 minutes, 1 hour, 3 hours, 6 hours, and 1 day. The analysis focused on wet season water budgets and results are presented by water year for South Florida (May 1 to April 30). The wet season in this area typically extends from June to October and flow through the STAs is greatest during these months. Similar to the analysis used by Teegavarapu and Pathak (2009), the period of record was divided into calibration and validation sets; the calibration data period was from June 2001 to October 2005 and the validation set contained data from June 2006 to October 2006.

$$\frac{\Delta S}{\Delta t} = I - O + R - ET \pm G + \varepsilon \quad (1)$$

Where, ΔS = change in storage over the time period
Δt = time period
I = average inflow over the time period
O = average outflow over the time period
R = rainfall over the time period
ET = evapotranspiration over the time period
G = levee and deep seepage over the time period
ε = water budget error over the time period

Optimization Formulations

The first model used a "simple" weighting method using the following formulation:

$$Minimize \quad \sum_{i=1}^{N} |\varepsilon_i| \quad (2)$$

$$\varepsilon_i = (\Delta S)_i - (P + w_1 I - w_2 O - w_3 G - w_4 ET)_i \quad (3)$$

$$w_j \geq w_j^l \quad (4)$$

$$w_j \leq w_j^u \quad (5)$$

The weights for inflow, outflow, estimated seepage, and evapotranspiration are w_1, w_2, w_3, and w_4 respectively. Inflow, outflow, seepage, and evapotranspiration are the parameters that tend to have the greatest uncertainty associated with their measurement and therefore were the parameters weighted in the optimization. The upper and lower limits are w_j^l and w_j^u respectively. The optimization used the solver available in Microsoft Excel 2007. The Newton search, tangent estimate, and forward derivation techniques were used in the solver. N is the number of time periods; i and j are indices for time increments and weights.

The second model (binary method) weighted the same variables in the water budget equation as described above and used binary variables (Teegavarapu and Pathak, 2009). **Equations 6** through **12** apply:

$$Minimize \quad \sum_{i=1}^{N} |\varepsilon_i| \quad (6)$$

$$\sum_{i=1}^{4} \lambda_i \leq n_k \quad (7)$$

$$\sum_{i=1}^{4} \lambda_i = n_k \tag{8}$$

$$if\ \lambda_i = 0, then\ \ w_i = 1, else\ w_i = w_i^0 \tag{9}$$

$$\varepsilon_i = (\Delta S)_i - (P + w_1 I - w_2 O - w_3 G - w_4 ET)_i \tag{10}$$

$$w_j^0 \le w_j^u \tag{11}$$

$$w_j^0 \ge w_j^l \tag{12}$$

λ_1, λ_2, λ_3, and λ_4 are binary variables. Only **Equation 7** or **8** is used for the solution of the formulation to constrain the number of binary variables; in this study, **Equation 8** was used to determine the number of binary variables used in the analysis. The term n_k represents the upper limit on the number of binary variables used in the formulation.

RESULTS AND DISCUSSION

This study substantially confirmed the results observed by Parrish and Huebner (2004) concerning 15-minute data and its ability to reduce water budget error during wet season operations as shown in **Table 1**. Water year 2006 is the exception. The results (wet season water budget errors presented by water year) did not use the optimization methods described above. Unfortunately, data for the 1-hour, 3-hour and 6-hour water budgets were aggregated from the 15-minute data so that the water budget tables developed for those time steps simply replicate the water year results for the 15-minute time step. Therefore, they could not be used to verify the results shown in **Table 1**.

Table 1. 15-minute vs. Daily Wet Season Water Budget Residuals (not optimized)

Water Year	Daily Time Step		15-minute Time Step	
	Residual (ac-ft)	Percent Error	Residual (ac-ft)	Percent Error
2002	33,888	18.83%	18,640	10.03%
2003	4,270	2.02%	1,031	0.51%
2004	-16,811	-7.44%	-7,121	-3.23%
2005	2,647	0.90%	-2,153	-0.75%
2006	-1,310	-0.47%	-8,213	-2.93%
2007	-17,403	-7.97%	-16,420	-7.45%
Total	-15,219	-1.10%	6,264	0.45%

The validation data set confirmed the results of optimization using the calibration data for both the MAE and MSE targets although the improvement in the respective targets appears to be insignificant. Results are shown in **Table 2**.

Table 2. Water Year 2007 Wet Season, 15-minute Data Validation Optimization Results

Objective Function	Without Optimization	With Optimization	Percent Improvement
MAE (ac-ft/d)	15.99	15.64	2.21%
MSE (ac^2-ft^2/d^2)	1,585	1,578	0.41%

An unintended result was that using MAE and MSE for objective function targets did not ensure that the total water budget error would be minimized. **Table 3** shows wet season water budget residuals by water year using the 15-minute water budgets and the results of applying method 1 optimization coefficients to the appropriate terms in the water budget. Although counterintuitive, the optimization based on either MAE or MSE relies in minimizing positive measures of error. The un-adjusted water budget residuals for each time step can be either positive or negative and appear to cancel each other when aggregated over a period like a water year wet season. The results shown in **Table 3** show this anomaly. On a wet season, water year basis using the 15-minute data, the MSE target appears to reduce residuals better than the MAE target except for water year 2005 and for the entire period of record. However, since the differences are so small, this may be of little consequence.

Table 3. Effect of Optimization Results on Water Budget Residuals (Wet Season, 15-minute Data)

Wet Season Water Year	Without Optimization		MAE		MSE	
	Residual (ac-ft)	Percent Error	Residual (ac-ft)	Percent Error	Residual (ac-ft)	Percent Error
2002	18,640	10.03%	16,259	12.77%	18,530	11.11%
2003	1,031	0.51%	9,337	6.75%	4,890	2.69%
2004	-7,121	-3.23%	-10,024	-7.07%	-11,793	-6.12%
2005	-2,153	-0.75%	-6,217	-3.35%	-9,551	-3.80%
2006	-8,213	-2.93%	-16,854	-9.48%	-18,891	-7.80%
2007	-16,420	-7.45%	-18,673	-13.19%	-23,854	-12.42%
Total	6,264	0.45%	-26,172	-2.92%	-40,669	-3.36%

The seepage term in the water budget equation (**Equation 1**) was the parameter that was consistently weighted most heavily in the analyses regardless of optimization target, model, or time step. In STA water budgets, the seepage term is typically at least an order of magnitude smaller than the flow terms in the equations for STA-2. The relative magnitude of the weight also suggests that the seepage term has the greatest uncertainty associated with it. **Table 4** shows the weights determined during the optimization runs. In **Table 4**, as the weight approaches 1.00 with increasing time increments the parameter itself appears to became more reliable at reducing water

budget error. Nevertheless, there is no consistent pattern in the data over all time steps and this trend which occurs for several of the parameters is probably caused by the canceling of negative and positive errors as the time increment increases.

Table 4. Parameter Weights from Optimization Runs – Simple Method (Wet Season, 15-minute Data WY2002- WY 2006)

Time Increment	Objective Function	Inflow	Outflow	Seepage	ET
15-minute	MAE	0.63	0.61	8.05	0.06
1-hour	MAE	0.64	0.63	8.46	0.38
3-hour	MAE	0.65	0.64	9.61	0.29
6-hour	MAE	0.69	0.66	9.12	0.47
1-day	MAE	0.59	0.50	5.11	1.67
15-minute	MSE	0.88	0.84	7.82	0.23
1-hour	MSE	0.84	0.84	11.10	0.00
3-hour	MSE	0.80	0.78	11.55	0.00
6-hour	MSE	0.75	0.74	10.08	0.00
1-day	MSE	0.62	0.51	4.82	1.76

The binary optimization scheme (**Equations 6-12**) effectively selects the parameter(s) that most significantly contribute to achieving the optimization goal (minimization of the target, either MAE or MSE). **Table 5** shows the parameter weights resulting from optimization of the 15-minute water budget using the binary method. ET is the first parameter to drop out of the analysis as the number of optimized parameters is reduced from four to three. This is consistent with the results shown in **Table 4** where the weight for the ET term in the water budget equation becomes negligible as the time step increases.

Table 5. Parameter Weights from Optimization Runs – Binary Method (Wet Season, 15-minute Data WY2002- WY 2006)

Number of Weighted Optimized Parameters	Objective Function	Inflow	Outflow	Seepage	ET
4	MAE	0.63	0.61	8.05	0.06
3	MAE	0.61	0.59	8.04	1.00
2	MAE	1.00	0.92	10.29	1.00
1	MAE	1.00	1.00	1.00	0.04
4	MSE	0.88	0.84	7.82	0.23
3	MSE	0.86	0.84	7.82	1.00
2	MSE	0.85	0.84	1.00	1.00
1	MSE	0.99	1.00	1.00	1.00

As the number of variables used to seek the target was reduced, results varied with respect to parameters selected for optimization. The most consistent results resulted from using MSE in the objective function. ET was dropped first, followed by

seepage and then inflow. Using MAE as the optimization target, ET was dropped first. This was consistent with the MSE results. However, inflow was the second parameter dropped from the MAE optimization when only two parameters were used in the optimization. When only one parameter was used in the optimization, outflow was the parameter that is selected using the binary method as the variable that has the greatest effect on achieving the optimization goal of minimizing MAE. ET is brought back into the equation but with a very small coefficient. In both cases when one parameter is selected for optimization, the weight is nearly 1 indicating that the optimization has a minimal effect on the water budget residual values.

Admittedly, the solver in MS Excel 2007 is limited as were the objective functions used (minimizing MAE or MSE). However, the optimization results consistently confirmed that seepage estimation should be an area of focus in reducing the uncertainty associated with STA water budgets. Estimating seepage not only has implications for water budget calculations but also mass balance equations for constituents like soluble phosphorus (Huebner, 2003).

Using MAE or MSE as the optimization target did not result in the water budget with the lowest water budget error (**Table 1**). However, these targets did narrow the range of water budget residuals. Using MSE as an optimization target reduced the variability of the largest errors; using the MAE optimization target results in the reducing the range of all residuals. Again, these are reflected in the optimization function target improvements shown in **Table 2**. However, these improvements are not practically significant and, in fact, imply reductions in parameter uncertainties that may not be necessary. For instance, the MSE result using 15-minute data implies that there may be a 12 percent overestimation of inflow and 16 percent overestimation of outflow. Stream gauging data at those inflow and outflow sites indicate that the error is less than these values.

Some would argue that improving water budget error by half (i.e., from typically less than 10 percent to less than 5 percent) is an exercise without much payoff for STA management and operations. However, few would argue that the cost of resources necessary to perform water budget calculations at time steps smaller than one day has decreased substantially. In addition, water budget computations can be automated so that time step size is effectively inconsequential

CONCLUSIONS

A weighted mass balance equation, optimized using mathematical programming models at different time scales was used to identify independent water budget variables that need improvement in measurement and estimation. The mathematical programming models employed mixed-integer, non-linear programming formulations and binary variables to estimate parameter weights. The formulations were applied to a large constructed wetland operated and managed by the South Florida Water Management District for nutrient control. Results suggested that residual errors could be reduced by improving the measurement of variables associated with estimating seepage. However, there are tradeoffs between cost and benefit that need to be

considered in this context. Further work might include randomizing data over the period of record to develop more robust weights, partitioning flows to examine systematic errors in the parameters and developing a method for quantifying benefits of reduced water budget uncertainty to justify data acquisition expenses.
