The USACE will conduct risk assessments in a system context with recognition of system uncertainties about the key variables in an explicit manner and assesses them holistically. FRM model development will include sampling and solution techniques, uncertainty definitions, and system-wide component fragility and performance interactions/relationships for these complex riverine systems. It will include a systems approach, event-based sampling, the ability to do scenario analysis, and structure-by-structure, cost, non-structural, loss-of-life, and agricultural damage analysis. The new tool will accommodate many, if not all, of the recommendations that the Corps concurred with from the National Research Council report on the Corps' implementation of risk analysis for flood damage reduction (NRC, 2000), and it will also aide in implementing the Chief of Engineers' Actions for Change. FRM would be used nationwide for levee certification, levee assessment and planning and design studies.

ABSTRACT

Study of uncertainties in the design of dam diversion is of great importance due to its high economic impact on the construction cost. It is important to study the carrying capacity of the diversion systems, considering the hydrologic uncertainties due to climate change phenomenon and its impacts in decision making. In order to consider these uncertainties, the historical rainfall data of the nearest gauge stations have been analyzed, then the rainfall variations in the future have been predicted using down-scaling of the GCM (general circulation model) data. The runoff of the basin is simulated using rainfall runoff modeling. The results of uncertainties evaluation have been incorporated in an optimization model.

In this paper, a GA-based optimization model for determining the optimal sizing of a dam diversion system is developed. The proposed model minimizes the flood damages and costs based on the optimal size of the dam diversion system in a probabilistic framework. The proposed algorithm considers risk in the decision making about diversion dam height and diversion tunnel characteristics. In this model, the hydrological uncertainties and the climate change impacts in design of dam diversion system are considered in the objective function of the optimization model. The proposed methodology is applied to the Karoun-4 Dam in the south-western part of Iran. The results show the significance value of considering flood risk and climate change impact on the design of dam diversion systems.

Keywords*:* Genetic Algorithm, Optimization, Dam Diversion System, Climate Change, Hydrological Uncertainties, General Circulation Model

INTRODUCTION

In order to construct a structure on a river, it would be inevitable to use a diversion system in order to have dry construction site. As there are different types of diversion systems, the diversion system type depends on topographic conditions, site characteristics (geologically and geo-technically), river's hydrologic features, expected cost, etc. A common diversion system is using an upstream cofferdam accompanied with one or more tunnels. The dimensions of a diversion system should be constructed in a way that can safely pass the possible flood with regular return periods, and if it fails to do so, the flood damages should be minimized. Therefore there is a tradeoff between construction costs and flood damages.

The cost of diversion works depends, among other factors, on: the tunnel dimensions

and the intended tunneling support measures during and after excavation; quality and specifications of the rock through which the tunnel should be excavated. The dimensions of the upstream (and downstream) cofferdams; the characteristics of the required spillway, should be designed to divert the floods.

Yen (1985) attempted to introduce a predictable error made by project designer through definition of a risk-based design methodology. Pate-Cornell and Tagaras (1986) designed dam hydrological components considering risks and hydrological uncertainties. Following a similar approach, Afshar and Marino (1994) optimized the dam overflow capacity based on the risk concept. Tang (1975) optimized discharge of a drainage system based on risk-based design, considering hydrological uncertainties for the first time. Saeedi (2007) optimized the construction costs through selecting the dimensions of a diversion system considering tunnel covering material, type of drilling, supporters, and type of upstream cofferdam soil through mathematical solving of assumed equations.

In this paper, an uncertainty based optimization model is developed for determining the optimal characteristic of a diversion system to the proposed model which analyzes the influence of hydrologic uncertainties. SDSM (Statistical Downscaling model) is used to forecast different floods during dam construction, then a rainfall-runoff model is used to simulate the rainfall flowing to the diversion dam. The probable floods are routed to calculate the flood damages. An optimization model is developed to minimize the construction costs and the expected damages for determining the optimal diversion dam characteristics. The decision variables in the GA-based optimization model are the tunnel diameter, covering material, length, the height of upstream cofferdam and down stream cofferdam, due to floods with different return periods. The proposed model is applied for optimizing the Karoon 4 diversion system in the south-western part of Iran as a case study.

METHODOLOGY

In this case study, an optimization model is proposed to minimize costs and damages. The objective function of the optimization model includes construction costs, and the damages cost due to floods with different return periods. This model determines the best tunnel diameter and support and lining types of the tunnel according to the Manning coefficient and it also specifies level and length of the tunnel, heights of the upstream cofferdam and downstream cofferdam. It shows whether or not a Spillway for upstream cofferdam is needed. The proposed model has the three following steps:

Step 1: The recorded data as the inputs of the model is gathered and analyzed. The data consists of observed rainfall series, cross section, slope, Manning coefficient of the river and the climatic conditions of the case study.

Step2: A rainfall forecasting model is used to predict the rainfall and flood events in real time operation. In this study, SDSM (Statistical Downscaling model) which downscales General Circulation Model (GCM) output data according to climate change scenarios is used as a forecast model. Based on the obtained results of the SDSM model, the rainfall- runoff model is used to estimate the flood volumes during the construction dams. Then the flood hydrograph of different return periods are

estimated leading to calculate the probabilities of flood events.

Step 3: The objective function of the optimization model is estimated based on the construction dams for different decision variables (such as tunnel diameters, heights of cofferdams) and damages due to different floods. In order to calculate the damages, according to the decision variables, the floods are routed in the diversion system. It is a tradeoff between construction costs of spillway, tunnel with different characteristics and cofferdams. Using iterative procedure in the optimization model, the best values of decision variables to minimize the costs and damages are determined

CASE STUDY

The Karoon 4 dam is located on Karoon River in the southwestern part of Iran. The characteristics of the Karoon watershed and the Karoon 4 dam are presented in Table 1. The potential runoff inflow to the reservoir is about 4549 MCM.

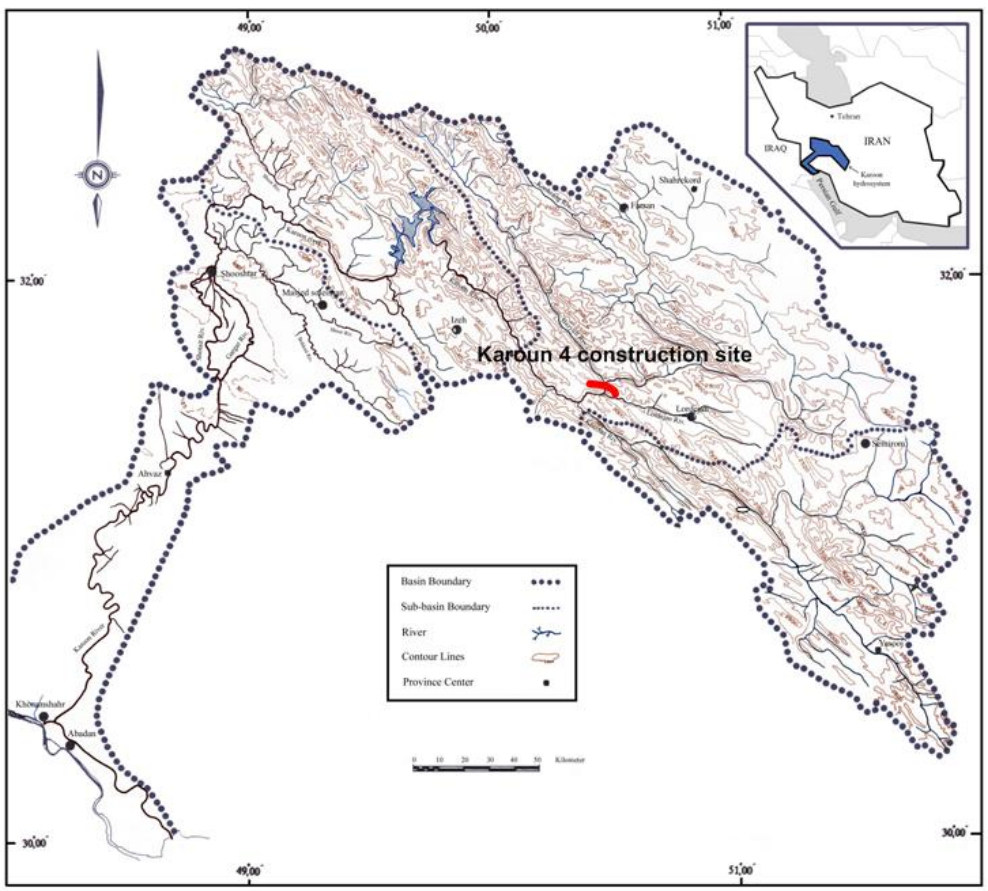

Figure 1: Karoon watershed and location of Karoon 4 construction site

During construction of dams, the river water has to be diverted away from the dam

site so that the construction of the dam can be undertaken in the dry. The usual method of river flow diversion involves construction of tunnels and cofferdams. The tunnel is excavated in either of the abutments to divert the entire river flow and both its normal and flooding condition, around the dam site. The cofferdams are watertight structures, usually earth embankments, constructed upstream and downstream of the site to isolate the construction area that is to be kept dry. The tunnel entrance is upstream of the upstream cofferdam and discharges into the river downstream of the downstream cofferdam (Saedi, 2007). Figure 1 shows the location of the Karoon 4 construction site.

Table 1: The characteristics of the Karoon watershed and the Karoon 4 dam

Area (km^2)	Average rainfall (mm)	Dam capacity (MCM)0	Length of diversion tunnels	Number of outlets	Hydropower energy (Mw)
12813	680	2192	655 , 664	3	1000

The diversion system of Karoon 4 reservoir has two tunnels, an upstream cofferdam and a downstream cofferdam. The average upstream and downstream side slopes of the cofferdams are considered 1 vertical over 2.5 horizontal. Manning roughness coefficient is about 0.014, 0.022 and 0.03 for different tunnel lining 1) rockbolts and shotecrete and reinforced concrete 2) rock bolts and shotcrete 3) little rock bolts and shotcrete. The tunnel dimensions, tunnel support types, heights cofferdams, construction of upstream cofferdams spillway, the upstream and downstream tunnel elevations (slope of the tunnel) are determined. There are some limitations on the tunnel diameter ($7.0m < D < 13.0m$) and height of the upstream cofferdam ($15m < H < 75.0m$).

METHODS AND MATERIALS

In this study SDSM is used as a forecasting rainfall model, HEC-HMS is used to estimate the runoff due to forecasted rainfall and Genetic Algorithm (GA) is used to solve the optimization model. In the following sections, brief descriptions of the models used are given.

SDSM Model

Even though global climate models in the future are run at a high resolution, the need will remain to "downscale" the results from such models to individual sites or localities for impact studies (Department of the Environment, 1996).

Downscaling techniques are divided into two main groups: Statistical and dynamical. In situations where low–cost, rapid assessments of localized climate change impacts are required, statistical downscaling (currently) are more effective. In this study, SDSM has been used for long-lead rainfall prediction for an individual site at daily time–scales, by using grid resolution GCM output.

During downscaling with SDSM, a multiple linear regression model is developed between a few selected large-scale predictors and local scale predictands such as temperature and precipitation. Figure 2 shows a schematic illustrating the general approach to downscaling.

The parameters of the regression equation are estimated using the efficient dual simplex algorithm. Large-scale relevant predictors are selected using correlation analysis, partial correlation analysis and scatter plots, and also considering physical sensitivity between selected predictors and predictand for the region. Ideally, predictor variable candidates should be physically and conceptually sensible with respect to the predictand (precipitation) and accurately modeled by GCMs. For precipitation downscaling, it is also recommended that the selected predictor should contain variables describing atmospheric circulation such as thickness, stability and moisture content. In practice, the choice of predictor variables is constrained by data availability from GCM archives.

Structure and operation of SDSM includes five distinct tasks: (1) preliminary screening of potential downscaling predictor variables; (2) assembly and calibration of SDSM(s); (3) synthesis of ensembles of current weather data using observed predictor variables; (4) generation of ensembles of future weather data using GCM-derived predictor variables; (5) diagnostic testing/analysis of observed data and climate change scenarios.

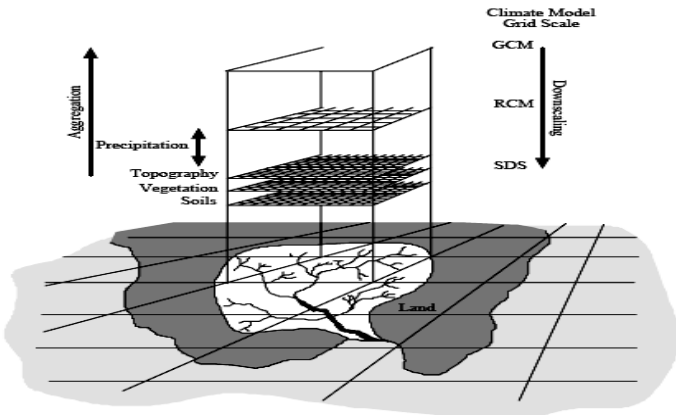

Figure 2: A schematic illustrating the general approach to downscaling. (Wilby &Dawson, 2004)

Model Formulation

The objective function of the optimization model is the total construction costs and expected damages that might occur during the project. The probabilities of flood events with different return periods are considered by the expected value of flood damages and the construction expenses of the diversion system. The objective function and the constraints of the proposed optimization model are as follows:

$$Minimize\ Z = E(damage) + Cost_C = \sum_{i=1}^{6} P(i)(D_{T_i}) + Cost_C \quad (1)$$

$$D_{T_i} = Damege_{i,UC} + Damege_{i,DC} + Damege_{i,Tunnel} + Damege_{i,Site} \quad (2)$$

$$Cost_C = (Cost_{Tunnel} + Cost_{Upstreamcofferdam} + Cost_{Downstreamcofferdam}) \quad (3)$$

$$Cost_{Tunnel} = C_e + C_l + C_S \quad (4)$$

$$C_e = V_e \times U_e = \frac{\Pi}{4} L\left[D + 2(T + 0.1)^2\right] \times U_e \tag{5}$$

$$C_l = V_l \times U_l = \Pi LT[D + T] \times U_l \tag{6}$$

$$C_S = V_S \times U_S = \Pi LT[D + 2T] \times U_S \tag{7}$$

$$Cost_{Upstreamcofferdam} = U_{UC} * V_{UC} + XU_{SP}V_{SP} \tag{8}$$

$$V_{UC} = W[(B + 0.5(z_u + z_d)(H + F)](H + F) \tag{9}$$

$$V_{SP} = W_{SP}(b + z_d k)k + 0.5W(B \times k) \tag{10}$$

$$Cost_{Downstreamcofferdam} = U_{DC} * V_{DC} \tag{11}$$

$$V_{DC} = W_{DC}[(B_{DC} + 0.5(z_{du} + z_{dd})(H_{DC} + F_{DC})](H_{DC} + F_{DC}) \tag{12}$$

$$IF(0 < h/D < 0.5) \Rightarrow Q = (\frac{D}{4}\left[\frac{\sqrt{1-a^2}a}{(Arc\cos a)}\right])^{2/3} \frac{AS^{1/2}}{n}, a = (\frac{D/2 - h}{D/2}) \tag{13}$$

$$IF(0.5 < h/D < 1.0) \Rightarrow Q = (\frac{D}{4}\left[\frac{\sqrt{1-a^2}a}{(\Pi - \arccos a)}\right])^{2/3} \frac{AS^{1/2}}{n}, a = (\frac{h - D/2}{D/2}) \tag{14}$$

$$1.0 < h/D < 1.5 \Rightarrow Q = 0.62 \sqrt{\frac{1}{1 - \left[\frac{D}{h + D/2}\right]^4}} A\sqrt{2gh} \tag{15}$$

$$1.5 < h/D \Rightarrow Q = A\sqrt{2g}\left[\frac{h + L.S_T - \xi D}{1 + Ke + \frac{2gn^2 L}{R^{4/3}}}\right]^{1/2} \tag{16}$$

$$Q_{SP} = C_0 W_{SP} h_{SP}^{1.5} \tag{17}$$

where :

i : the index of flood occurrence with given return period, $P(i)$: probability of flood occurrence with different return periods, D_{T_i} : the flood , $Cost_C$: construction, $Cost_{Tunnel}$: cost of tunnel construction, C_e : cost of tunnel excavation, U_e : unit cost of tunnel excavation, V_e : volume of tunnel excavation, C_l : cost of tunnel lining, U_l : unit cost of lining of tunnel, V_l : volume of tunnel lining, : C_S cost of tunnel support, U_S unit cost of tunnel support, V_S : volume of support, T: lining thickness, L: tunnel length, D: tunnel diameter, $Cost_{Upstreamcofferdam}$: construction cost of upstream cofferdam, W: the crest length of upstream cofferdam, B: is the cofferdam top width, z_u : the upstream side slope of upstream cofferdam section, z_d : the downstream side slope of upstream cofferdam section, H: height of upstream cofferdam , F : upstream cofferdam free board , U_{UC} : unit cost of upstream cofferdam, X : variable of spillway $(\{1,0\})$, V_{SP} : concrete volume of spillway, U_{SP} : unit cost of spillway, parameters, b: cofferdam downstream length, k: spillway

lining thickness, Wsp: width spillway $Cost_{Downstream cofferdam}$: cost of building downstream cofferdam length, V_{DC} : volume of downstream cofferdam W_{DC} : length of downstream cofferdam, B_{DC} : the downstream cofferdam top width z_{du} : the upstream side slope of downstream cofferdam section, z_{dd} : the downstream side slope downstream cofferdam, H_{DC} : height of downstream cofferdam, F_{DC} : down stream cofferdam free board, U_{DC} :: unit price of. downstream cofferdam, : C_0 variable discharge coefficient, Q : Discharge outlet of tunnel, S : The longitudinal slope of tunnel, R : Hydraulic radius, n : Manning roughness coefficient, h : the water head above tunnel intake, A : tunnel cross section, g : gravitational acceleration, Ke : the tunnel entrance loss coefficient , ξ : variable of tunnel outlet $(\{1,0.5\})$ Q_{SP} : spillway Discharge , W_{SP} : width spillway.

Equations 2-4 show the construction costs including tunnel, downstream and upstream cofferdams costs and the damages due to flood damages of tunnel, cofferdams and the working site. The construction costs are estimated using Equations 5-12, considering the volume of the materials. Equations 13-16 are used to calculate the discharge of the tunnel. Since the capacity of water transfer from diversion tunnels is limited, in large floods the spillway is constructed for increasing the passing capacity Therefore, the upstream cofferdam with a spillway is usually built. Equation 17 shows the passing discharge over the spillway.

In this study in order to find the optimal characteristic of the diversion system, the Genetic Algorithm (GA) optimization method is utilized. Genetic algorithm is an adaptive method trying to imitate the biological and genetic process and can successfully be applied to optimization problems

GA is a population of individuals, named chromosomes. Each chromosome represents a potential solution to a problem. This solution is evaluated by its fitness function. As each chromosome represents a potential solution, the fitness of each chromosome as a candidate solution, must be evaluated by a random search process to form the decision space. Additionally, fitness is a function of the problem constraints, and must be satisfied. Through successive generation, fitness should progressively be improved towards an optimum solution. The new population is generated using the genetic operators including Selection, Crossover, and Mutation.

More details of genetic algorithms can be obtained in the works of Michalewicz (1992a, b) and Gen and Cheng (2000). Genetic algorithms usually consist of the following steps:

1. Encoding of the decision variables and placing them in a chromosome.
2. Creating an initial population (first generation).
3. Determination of fitness for every chromosome in the current population (fitness
4. Setting the probability for mutation and crossover.
5. The selection of better chromosomes for matching and running a cross over operator for shuffling the selected chromosomes.
6. Performing mutation for selected chromosomes.

7. Repeat steps 3–6 to obtain the optimal or near optimal solutions.

In general, GAs start with a population of chromosomes and later modifies them through genetic operators to produce better fitting chromosomes. The main fields of application of GAs include problems with high complexity and non-linear behavior.

RESULTS

The SDSM model was calibrated for 1961-1995 with correlation factor (R^2) of 0.81 and 0.79 for HadA2 and HadB2 scenarios respectively. The validation results for 1995-2005 give a correlation factor (R^2) of 0.64 and 0.58 for HadA2 and HadB2 respectively.

The predicted monthly average precipitation of two selected scenarios (HadA2 and HadB2) and observed data are shown in Figure 3. The 10 year predicted average monthly data are from 2006- 2016 and the observed data is based on the monthly average from 1961- 2005.

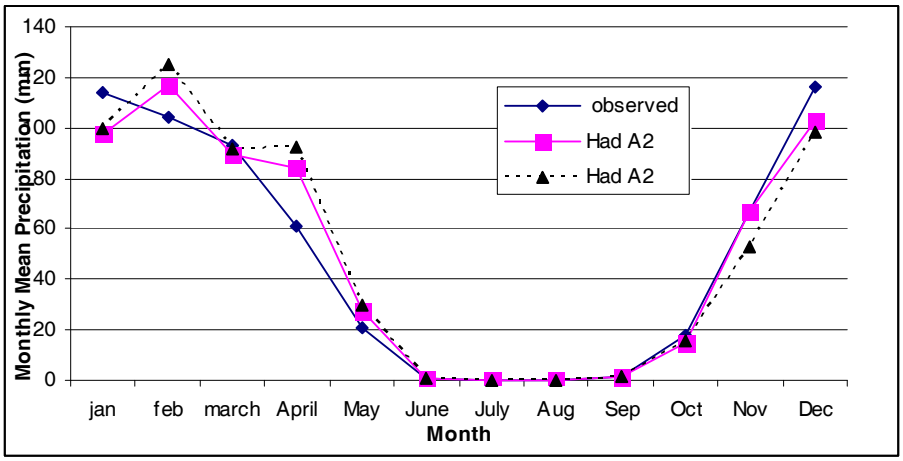

Figure 3: Comparison between precipitation Output of Had A and Had B scenarios from SDSM, and Observed Monthly precipitation.

A rainfall-runoff model has been developed using HEC-HMS software. Sub-basins of the study area have been characterized and modeled in HEC- HMS software using the SCS method. The hydrograph of March 9-12, 2004 flood has been used for model calibration. The hyetograph of rainfall has been estimated using central patterns of SCS hyetographs because of monotonous and steady intensity during the rain time in the region. The SCS curve method has been used for runoff estimation and an average curve number (CN) of 42 has been estimated for the watershed. The observed and simulated Hydrograph after rainfall-runoff model calibration for March 9-12, 2004 are shown in Figure 4. The forecasted flood hyetograph has been entered into the HEC- HMS model and the amount of flood at the construction site is estimated.

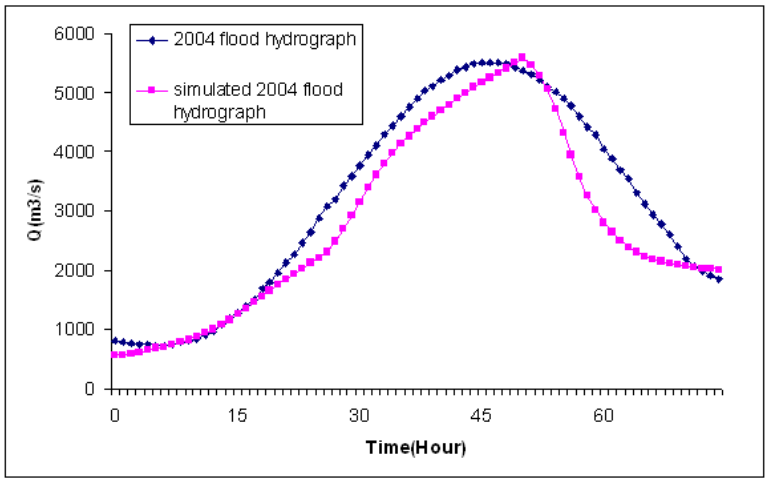

Figure 4: Comparison between simulated and observed flood hydrograph

The developed optimization model considers different alternatives for construction of the diversion system with a minimum cost that could yield low damages. According to the results, by investing about 2.4 million Dollars for the construction of a diversion system, the expected value of damages is reduced to 1.18 million Dollars. This considerable gain shows the significant value of utilizing the proposed approach.

Table 2 shows the optimal characteristics of the diversion system. The result of the optimization model maintains the construction of a cofferdam with a height of 40 meters with a spillway with the capacity of 3500 cms. The model has also proposed construction of a tunnel, 9.5 meter diameter and 655 meter length and a second tunnel with a 9.5 meter diameter and 644 meter length.

Table 2: Optimal characteristic of diversion system

Tunnel diameter(1)	Tunnel diameter(1)	Tunnel support(1)	Tunnel support(2)	Upstream tunnel elevation(1)	Upstream tunnel elevation(2)
9.5m	9.5m	Type1	Type2	850.5m	860m
Downstream Tunnel elevation(1)	Downstream Tunnel elevation(2)	Upstream cofferdam height	Downstream cofferdam height	Spillway construction	Spillway capacity
842.55m	853m	40m	20m	Yes	$3500\,m^3/s$

SUMMARY AND CONCLUSION

In this paper, an optimization model is used to design a diversion system for Karoon 4 dam site in the southern part of Iran. The proposed optimization model utilizes a Genetic algorithm model in order to select the best diversion system. The proposed optimization model minimizes the cost construction and expected value of damages. The expected values of damages are obtained based on the return period of

forecasted floods in the study area. In the proposed model, the HEC-HMS model is used for the hydrologic simulation of different precipitation events forecasted based on down scaling of GCM model results. A hydrological model is used for routing of flood in the cofferdam reservoir with and without a spillway. The innovative aspect of this study is the application of the Genetic Algorithm optimization model utilizing engineering, economic and flood probability in optimal design of a diversion system. The results include an explicit economic valuation of the cost and damages and an economical-based plan for the diversion system.

Abstract

In addition to the original design and construction information from the 2003 EWRI publication, this paper also includes follow-up regarding the Kansas River bank stabilization project condition.

The Kansas River is a major Missouri River tributary. The project site is 43 miles (70 kilometers) upstream from their confluence, with a drainage area of 58,610 square miles (151,800 square kilometers). The channel ranges from 590 to 1180 feet (180 to 360 meters) wide in an 8860-foot (2,700-meter) floodplain. The project area was a channel bulge along the left bank of the river, at an inflection point where the channel meanders from the north (left) side of the floodplain to the south side of the floodplain. A bridge is located downstream, in the middle of an east-west reach; downstream of the bridge, another meander returns the channel to the north. The sandy channel banks ranged from 20 to 30 feet (6 to 9 meters) tall, stood at slopes from 1.0 horizontal to 1.0 vertical, to nearly vertical, and tended to collapse into the channel thalweg and washed away whenever water levels receded.

During the wet decade of the 1940s the channel moved 670 feet (200 meters) eastward. The great 1951 flood resulted in an eastward shift of over 980 feet (300 meters), plus a significant channel shift southward, upstream of the bridge. At the channel bend between the project site and the bridge, three long right bank rock dike structures were built by Douglas and Leavenworth Counties in the mid 1950s; three short left bank structures were added in the late 1950s. These structures have been effective in stabilizing the reach upstream of the bridge. In the late 1970s, a Corps of Engineers demonstration project stabilized the bend upstream of the project site, mainly using windrow revetment that eventually launched and formed relatively uniform and stable bank armor. The 1993 flood initiated a left bank channel bulge between these two stabilized bends. The bulge steadily pushed eastward, progressing about 820 feet (250 meters) by 1999 and threatened existing stabilization.

Many different stabilization methods were considered, including Bendway Weirs, Bank Revetments, Rock Dikes, Longitudinal Peak Stone Toe Protection, and L-Head Dikes. The L-Head dikes were selected as a combination of the most cost effective and environmentally friendly alternative. The first four dikes were constructed in early 2002, and the fifth and sixth were installed in early 2003.

The protective works have been performing as expected, and ongoing monitoring and possible maintenance is recommended. The structures successfully moved the channel thalweg away from the bank, allowed the channel slopes to vegetate, and accretion / re-vegetation between the L-Heads and the banks.

Introduction

The site is located on the left bank of the Kansas River, 43 miles (70 kilometers) upstream of its confluence with the Missouri River. The project reach is in Douglas and Leavenworth Counties, north of Eudora, Kansas, 7 miles (11 kilometers) east of Lawrence and 20 miles (32 kilometers) west of Kansas City, Missouri. The Kansas River floodplain is 8860-feet (2,700-meters) wide at the site, and widens upstream of the site, reaching 15,100-feet (4,600 meters) in about 3 miles (5 kilometers). The Wakarusa River channel joins the Kansas River channel over 3,200 feet (one kilometer) downstream of FAS 209 Bridge (roadway: Highway 1 / extension of Main Street north of Eudora, KS).

The river channel location transitions from the extreme northern portion of the floodplain to the extreme southern portion as it flows past the site. The floodplain is heavily agricultural in the general vicinity of the site. Areas of trees and thick natural vegetation exist, mostly near the channel and generally in areas of recent accretion.

Unchecked, the left bank erosion and channel meander migration would eventually impact FAS Route 209 and its existing bridge over the Kansas River. This bridge is jointly maintained by Douglas and Leavenworth Counties, and serves as a major north-south Kansas River crossing. The nearest alternative crossing requires approximately a 20-mile (32-kilometer) detour. The eroding left bank was roughly 3,600 feet (1,100 meters) long and was migrating toward the FAS Route and the north bridge abutment. Earlier localized stabilization measures had not stabilized the entire reach.

The Soil Survey Reports indicate that the topsoil material in the erosion area consists of Sarpy-Haynie Complex and Eudora Complex. The former is described as a loamy fine sand and fine sand; the latter is defined as a silt loam and fine sand loam. Both readily erode. The bridge substructure (piers) is founded on concrete-filled sheet piling rings driven approximately 40 feet (12 meters) below the channel thalweg at the bridge.

Channel Movement and Previous Stabilization Efforts

The site history and movement of the Kansas River were investigated back to the early 1940s. The bank shifts were defined from aerials and mapping, and are superimposed on a 2001 aerial (Exhibit 1). The USGS map base contours (based on 1948 aerial photography) show the location of the channel prior to the 484,000 cubic feet per second (cfs) (13,700 cubic meters per second (cms)) 1951 flood, and its movement relative to a 1941 aerial photograph. In that period, the bank moved over 660 feet (200 meters), an average of 100 feet (30 meters) per year. USGS peak flow data at the Lecompton gage show annual peaks in 1941 through 1945 exceeded 100,000 cubic feet per second (2,830 cubic meters per second) every year. By comparison, subsequent to the 1951 flood, annual peak discharges have exceeded 100,000 cfs (2,830 cms) only five times. The 1951 flood caused a 1000 foot (300 meter) bank shift eastward, and nearly as much migration southward in the reach upstream of the FAS 209 bridge. In reaction to the 1951 channel movements, in 1953 three major dike structures were constructed from the right bank of the river into the channel upstream of the bridge to stabilize the reach, and a 600 foot (183 meter) wide channel was excavated. The dike structures from upstream to downstream, were 1500, 1260 and 1250 feet (457, 384, and 381 meters) long, respectively. The rock portions of these structures generally had a 6-foot (2-meter) top width and side slopes of 1.25

horizontal to 1.00 vertical. The structures ranged from a minimum of 4 feet (1.3 meters) tall, up to 20 feet (6 meters) in height. The channelization included a 30-foot (9-meter) base width pilot channel.

In 1959, three shorter rock dikes were constructed on the left bank, just upstream of the westernmost 1953 rock structure. These dikes, likely intended to stabilize the flow direction to the 1953 dikes, were keyed about 100 feet (30 meters) into the bank, had 12-foot (4-meter) top widths, side slopes of 1.25 horizontal to 1.00 vertical, and ranged from 170 to 330 feet (52 to 101 meters) in length. The dikes were angled downstream at about 60 degrees to the bank line. The area between the 1953 and 1959 structures and the Eudora Bridge has since been relatively stable. Some right bank erosion occurred in the 1990s, and as a result, the counties recently restored the river ends of the two right bank structures closest to the Eudora Bridge.

The left to right channel bend upstream of the 1950s protection measures and the project site moved significantly eastward in the early 1970s. A peak discharge of 140,000 cfs (4,000 cms) occurred in an October 1973 flood. A COE demonstration project was then implemented using windrow revetments at the bend upstream of the current project site, in 1979. The bank protected by the COE project appears to have been stable until the 1993 flood, which at 190,000 cfs (5,380 cms) was the second largest event since 1908.

The genesis of the current bulge at the project site may have been during a 1967 flood with a peak discharge in excess of 106,000 cfs (3,000 cms). The downstream end of the bulge was at the farthest upstream of the three left bank rock dikes constructed in 1959. The entire left bank, from the COE stabilization project to the Eudora Bend bridge, appears to have been stable from 1974 through 1990. There had been no discharges in excess of 100,000 cfs (2,830 cms) during this period. By 1992, a channel constriction had developed at the upstream end of the bulge, located between the downstream end of the left bank COE protection and heavy vegetation of a sandbar on the right. The 1993 flood resulted in floodplain flows moving eastward across the inside of the river channel loop north of the FAS 209 bridge. Significant damage occurred to the county road resulting from the flood flows. The eastward bulge between the two prior protection projects expanded significantly. Floodwater crossed the inside of the channel meander, along the north side of the floodplain, north of the current channel bulge.

The site was visited many times by the co-authors, from October 1998 through early 2003, before final construction of the protection. During that time the bank had moved approximately 160 feet (50 meters). Most of the recent bank movement occurred in late 1998 and in 1999, a period of extended above average flows with several higher peaks as well.

Site Hydrology and Hydraulics

The Kansas River has a drainage area of 58,460 square miles (151,400 square kilometers) at the USGS streamflow gage at Lecompton. That gage is at River Mile 63.8, which is 20 miles (32 kilometers) upstream of the left bank bulge site. The study site is at River Mile 43.5, with a drainage area of 58,610 square miles (151,800 square kilometers). The next USGS gage downstream is at Desoto, at River Mile 31.0, with a drainage area of 59,770 square miles (154,800 square kilometers). Approximately 60% of the drainage area lies within the State of Kansas. The hydrology at the project location is influenced by many reservoirs, located on most major tributaries to the Kansas River. The

oldest major reservoir went into service in 1948; the newest reservoirs began operating in the 1960s. Subsequent to the construction of the reservoirs, both average and peak discharges on the Kansas River have been reduced in comparison with the natural, pre-reservoir conditions. The average velocity of bank-full flows varies from 11 feet per second (3.3 meters per second) at the most constricted width to 4 feet per second (1.2 meters per second) in the widest areas, assuming that the channel is of uniform depth. It is likely that a significant scour area exists in conjunction with the constriction, reducing the actual maximum velocities somewhat.

Project Process

The justification of project need was necessary to proceed into project design. This required the project be designed in steps, each performed to determine the necessity, cost and direction of the next step. Therefore, Kansas City District Corps of Engineers retained HNTB Corporation of Kansas City, Missouri to assess, develop and design a stabilization project under the Section 14 Emergency Bank Stabilization Program. The steps of the project were as follows:

Site Assessment. The Site Assessment consisted of a site visit, acquisition of historical mapping, soils information and previous project plans. During the site visit, observations of active erosion were noted and measured against known landmark features.

The Kansas River is an active river that experiences significant and frequent movement over most of its length, and has an erodible silt and sandy floodplain which frequently lacks armoring vegetation on the banks. Previous bank stabilization measures have had mixed results; the 1953, 1959, and 1979 projects have all performed well but likely created hard points, perhaps causing the bulge at the project site. Historically, most of the major channel movements in the project area appear to be related to the occurrence of significant river flows. These high flows recede quickly, causing the saturated steep sandy banks to collapse. This material typically falls into or next to the channel thalweg adjacent to the bank, and is washed away.

The bulge erosion site at Eudora Bend changed the flow direction in a relatively short distance. The Site Assessment considered that the likely continuation of this pattern would accelerate the progression, until the bulge pushed all the way through the left bank to a short distance upstream of the FAS 209 bridge. This would adversely affect the flow alignment into the bridge opening and isolate the left bank 1959 dikes. Therefore, the Site Assessment recommended proceeding to the next step, and identified three possible stabilization measures for consideration.

Concept Design and Alternatives Analysis. The Concept Design and Alternatives Analysis involved the conceptual design of three (3) bank protection arrangements. The alternatives were selected based on the site conditions and the potential funds available for implementation. All alternatives were based on an efficient use of rock and a reasonable compromise between an ideal design and a limited construction budget. They were:

- **Rock Dikes.** A series of rock dikes projecting out from the bulge area, and a flow guiding dike at the upstream end of the bulge, would relocate the channel and cause sediment accretion downstream of the each dike. It would be used to direct flows towards the former main channel location, away from the bulge, similar to the success observed in the existing downstream right

bank dikes just upstream of the FAS 209 bridge. Due to severity of the bulge and the flow entry angle, flow would still impinge the bulge bank, and flow anomalies could result at the dike ends.

- **LPSTP**. Nearly bank aligned Longitudinal Peak Stone Toe Protection (LPSTP) would protect the toe and stabilize the bank within the bulge area. Minimal flow pattern improvements would result, versus the pre-constructed condition, allowing continual stress on the right bank from reflected flow off of the revetment.

- **L-Head Dikes.** A series of bankline re-establishing rock L-Head Dikes within the bulge, and a flow guiding dike at its upstream end, would relocate the channel, and cause sediment accretion downstream and behind the dikes. The bank paralleling portions of the L-heads would direct flows along or towards the former main channel location, away from the bulge. This was suggested by David Derrick of the U.S. Army Corps of Engineers, in lieu of a Bendway Weir alternative originally considered by the Site Assessment. David Derrick visited the site to assess the potential of Bendway Weirs, and recommended they be replaced with the L-Head Dike alternative. Bendway Weirs were dropped from consideration because of the flow entry angle into the upstream bend, the length of that bend and the relatively straight channel reach upstream, and because the various older stabilization measures were not considered compatible with Bendways.

All alternatives included rock protection / re-establishment of the upstream and downstream protection measures immediately outside of the erosion area, to inhibit erosive progression or a flanking of the proposed protective works. A comparison matrix was developed for evaluating the alternatives. The matrix assessed stability issues, potential hydraulic and environmental effects, and maintenance issues. The results of Step 2 were a report and a recommended alternative for design.

Design. The L-Head Dikes alternative was selected for design. A topographic and contour map of the river channel and the left bank throughout the bulge was necessary to obtain accurate quantities and an optimum design. To develop the map, the site was surveyed in October of 2000, but due to the rapid progression of the erosion it was necessary to resurvey the bank edge in September of 2001 and the entire southern portion in November of 2002. It was necessary to design for staged construction over two years, because of funding limitations. The locations of the proposed structures are shown on Exhibit 2, in addition to the 1953 Dikes and 1959 Dikes. The following describes the design elements:

- **Rock Blanket.** The stable upstream left bank, at the northwest extent of the erosion, is protected with a proposed 75 foot (23 meter) long full height Graded Stone blanket. The blanket has a minimum thickness of 3 feet (1 meter) and a bed surface placed rock toe, 10 feet (3 meters) wide by 5 feet (1.5 meters) thick. The revetment requires smoothly tapering 50 foot (15 meter) upstream and 80 foot (24 meter) downstream transitions.

- **Upstream Dike 1.** Downstream of the Rock Blanket, a 200 foot (60 meter) long rock dike is aligned along the pre-existing bank. Like the other project dikes, the side slopes are 1.5 horizontal to 1.0 vertical with a top crown width of 6 foot (2 meters).

- **L-Head Dikes 1 through 4.** The remaining downstream length of the erosion site is protected by four L-Head Dikes, two which were planned for construction in the first phase. The L-Head Dikes each consist of three segments: transverse (from the bank out into the river), curved (radial

direction change for construction equipment turning), and longitudinal (from the curve, downstream parallel with the river flow direction). The alignments were determined by aligning a curve from the stable bank upstream to the downstream end of the second 1959 left bank dike end, to create the desired future bank line (see Exhibit 3). The transverse portions of these dikes are perpendicular to the arc and are roughly perpendicular to the eroding bank, approximately 30, 105, 215 and 230 feet (9, 32, 66 and 70 meters) long respectively for L-Head Dikes 1 through 4. The curved portions have a 55-foot (17-meter) radius, and are approximately 80, 80, 80 and 66 feet (24, 24, 24 and 20 meters) in length along the baseline of the alignment, respectively for L-Head Dikes 1 through 4. The longitudinal portions are aligned from chords on the arc, aligned from the transverse riverward end, toward the riverward end of the next dike downstream. The longitudinal segments are roughly 40 percent of the gap distance between the transverse dikes, approximately 350, 190, 190 and 150 feet (107, 58, 58 and 46 meters) long respectively for L-Head Dikes 1 through 4.

Phase 1 Design and Construction. The L-Head Dikes were placed in two construction steps. First, the root (buried tie-back) was constructed and a full length platform was installed outward to approximately elevation 788.0 feet (240.2 meters), to relocate the thalweg and provide a work surface to nearly the elevation of the 1-year return period event 789.0 feet (240.4 meters). The platform included a riverward quantity of rock that could launch during thalweg adjustment. The deepest part of the channel was on the outside of the bend, along the eroding bank. The transverse portion of the dike blocked and redirected the existing thalweg outward. The flow was then directed along the face of the longitudinal portion of the dike, relocating the thalweg. It was presumed that this would cause the riverward stone to launch, protecting the dike toe from undercutting at the increased depth. In actuality, due to favorable flow conditions, minimal amounts of stone launched during construction. The contractor then completed (capped-off) the L-Head Dikes to the full design height of 794.0 feet (242.0 meters), starting from the river end and working back towards the bank, where the dike top slopes upward toward the bank. Additional Rock Blankets were installed along the bank adjacent to the tie-in of each L-Head Dike. Construction of Phase 1 was completed in March, 2002.

Phase 2 Design and Construction. Additional surveys were taken in November 2002 of the topography and contours at the location of proposed L-Head Dike 4, and at a possible tie-in location to the remnants of the 1959 Dike 1. The co-authors, with the assistance of Warren Mellema, a private consultant formerly with the Corps of Engineers, revisited the site, re-evaluated the un-constructed portion of the original design, and developed the Phase 2 design and construction plans.

- **L-Head Dike and Rock Blanket.** The L-Head Dike 4 was slightly relocated and re-aligned from the original design, as a result from observations of the constructed L-Head Dikes and in coordination with the newly proposed Crowned Revetment. A Rock Blanket at the bank was included at the tie-in of L-Head Dike 4.

- **Crowned Revetment.** At the time of Phase 1 design and construction, it was determined that the ground adjacent to 1959 Dike 1 was eroding too rapidly for that dike to be saved. However, drought conditions and the subsequent lack of high flows following the Phase 1 construction minimized additional erosion in that area during 2002. Therefore, it was decided to save 1959 Dike 1 and incorporate it into the project. As a result, the exposed and partially flanked east end of the existing 1959 Dike 1 was connected to the eroded bank by constructing a Crowned Revetment,

essentially converting the old dike into the streamline paralleling portion of an L-Head Dike. The new portion of the revetment has a similar section as the completed L-Head Dike 4, not including the launchable rock. It has a 6-foot (2-meter) top crown width and 1.5 horizontal to 1.0 vertical side slopes. The alignment was set parallel to the transverse portion of L-Head Dike 4.

It was determined necessary to minimize the disturbance to the existing 1959 Dike 1. Originally, lowering the top elevation of the existing dike was considered. However, it was decided to leave the dike unchanged, due to concerns regarding environmental disturbance to potential eagle perch trees, lack of construction safety for those working atop a potentially unstable steep rock structure, and the loss of hydraulic protective rock as compared to the current height.

Current Conditions

The majority of the 1970's Corps of Engineers windrow revetment upstream of Dike 1 has launched and protected the bank as expected. The transition into the project area will need regular monitoring to prevent flanking.

Accretion of material has been creating a depositional area suitable for natural re-vegetation behind the protective works (see Exhibit 4). The accretion was immediate and has decelerated through time. The depth of the accretion appears to be related to the dike height and frequency of inundation. The apparent vegetation is dictated by its survivability from inundation. As this area's deposition slowly increases in depth, it is expected to become populated with hardy maturing species.

Banks behind the protected works have slumped some, reaching stable equilibrium as evidenced by grasses and other vegetation on the banks.

The thalweg has paralleled the riverward face of the longitudinal portion of the L-Heads. The sacrificial riverward stone has only partially launched in some locations, leaving the remaining stone available for undercutting scour protection. The thalweg has also maintained an acceptable entry angle to the reach stabilized in the 1950s. The right bank upstream of the 1953 dikes was actively eroding due to flow impingement and has recently subsided. High flows that overtop the crowned revetment have been vaned between the upstream 1959 Dike (# 1) and the middle 1959 Dike (#2), causing slight erosion, debris accumulation and re-entry erosion. The channel and these structures will require monitoring and possible maintenance in the future.

The project plantings along the top of the bank, did not survive, due to dry weather, lack of sponsor maintenance, and the adjacent land owner's desire to re-cultivate the land for agricultural purposes.

The southern farm field runoff drains down the river bank into the accretion area immediately downstream of the L-Head Dike 3 tie-back, which is the best location for this slowly developing head-cut. The post-project attempts to arrest this have only been marginally successful.

The stabilization measures utilized rock blanket, dike and revetment designs in a cost effective manner, but are localized in nature, and as such are vulnerable to possible long term changes in the river that cannot be economically prevented, or to atypical flow conditions and extreme flooding that might occur.

Adverse Affects of Flood Flow at Skewed Railroad Crossings

William Yord A.M.[1], Jerry R. Richardson M., D.WRE [2], Vincent J. Zink S.M.[3]

This poster presents a case study documenting the hydraulic issues relating to skewed bridge crossings. Although Hydraulic Engineering Circular Number 20 (HEC-20) discusses these adverse affects, the illustrations and discussions of the issues relating to skewed bridges are brief. This is not a failing of HEC-20 but an acknowledgement that, given the extensive scope of the subject matter contained in HEC-20, this document can only provide a very broad treatment of the methods and process for evaluating and designing bridges in a variable morphological environment.

This study presents the hydrologic investigation of a flood event from historic, eye witness, and post flood investigation. Analysis of this data clearly indicates that due to embankment skew, the water levels on the approach embankment were as much as 1.5 m (5 ft) higher than at the bridge opening. The consequences of this are graphically illustrated by photos taken during the flood, and analysis of post-flood hydrographic survey data.

Heavy rains from June 27 through July 1, 2007, over east-central Kansas (Southern Miami and northern Linn counties) resulted in widespread flooding in the Marais des Cygnes River basin. In less than five days, this region of Kansas received approximately 44% of the mean annual precipitation for Eastern Kansas (USDA 1942). This rainfall resulted in widespread flooding on the Marais des Cygnes River and its tributaries near the towns of La Cygnes and Pleasanton, Kansas. In some areas, the resulting flood waters overtopped the embankment and rails owned and operated by the Burlington Northern Santa Fe Railway Company (BNSF), eroded embankment material and mobilized the ballast for the rails. Specifically, significant flooding occurred at various locations between Milepost (MP) 47 and 63 of the Fort Scott subdivision, and one train was derailed due to the erosion of the embankment.

The following information was obtained from the National Oceanic and Atmospheric Administration's (NOAA) website (NOAA 2007):

> "Numerous rounds of heavy rainfall affected much the lower Missouri River Valley between Wednesday June 27 and Saturday July 1, resulting in widespread flooding across the region. Some of the harder hit areas include locations along the Marais des Cygnes river including Osawatomie and La Cygne Kansas and into Bates county of Missouri...locations along the South Grand river in Missouri...including the town of Urich...and Big Creek in Missouri...including the Blairstown area."

In addition to stream gage data and NOAA resources, there were other very valuable sources of information used in this study, which include reports dated September 25, 2007, Helicopter photos taken July 2, 2007, eyewitness accounts, FEMA Flood Insurance Rate Maps (FIRMs) and Flood Insurance Studies (FISs), and data collected during our 2008 field investigation.

The first data source that was reviewed was the Hanson-Wilson report dated September 25, 2007. This report addressed some of the bridge capacity issues along MP 47 to MP 70 on the Fort Scott Subdivision. The 2007 report did not go into detail regarding actual flood elevations with respect to the elevation of the rail facilities in those areas that received damage during the June 2007 event.

Hanson-Wilson was also provided pictures taken from a helicopter on July 2, 2007 showing the areas of flooding along the Fort Scott Subdivision. The photos were invaluable in locating landmarks and water surface elevations that could be field surveyed along the route, and sections of track that were showing signs of conveyance (water moving from one side of the track to the other).

The purpose for attempting to acquire FEMA FIRMs or FISs was to compare actual water surface elevations on the July 2, 2007 event with elevations shown within the FIRMs or FISs. This could only take place if there were previous detailed studies in the area to set base flood elevations (100 year flood elevations) along the Marais Des Cygnes River or its tributaries.

Unfortunately, there have been no previous detailed studies in either Miami or Linn County. The only FIRMs that are available are the Linn County FIRMs, which show the entire Marais Des Cygnes flood plain area in FEMA Zone A.

A field investigation was conducted on June 23, 2008. The team obtained data to better map the actual extents and water surface elevations associated with the flood. This effort was greatly assisted by the photographs taken from the air on July 2, 2007, and from the recollection of BNSF lookout Mr. Rex Hall, who was an eye witness to the flood event. His recollection was invaluable in locating points on the ground which could be surveyed to establish high water mark elevations.

The flooding caused by this storm system had severe consequences to the communities in the region (most notably La Cygne, and Pleasanton, Kansas). Significant stretches of BNSF's Fort Scott Subdivision was submerged between Milepost 47 and 63.

An important and significant source of information that was critical to this study was a series of photographs taken from the air at the peak of the flood (July 2, 2007 - Figure 2). These photos allowed us to survey flood elevations along the BNSF facilities with GPS and allowed us to identify areas of low-velocity ponded water and regions along the railroad where overtopping velocities were elevated.

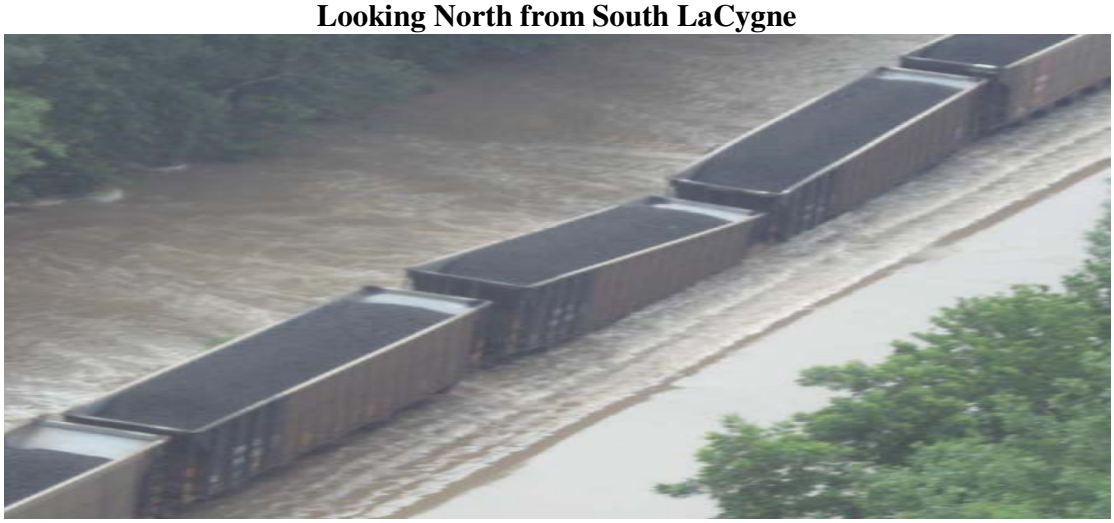

Figure 2 Air Photos of Overtopping Flow of Railroad Embankment

Although most of the railroad embankment and rail was inundated from MP 47 to 70, not all of the inundated embankments were damaged due to washout of the subgrade or ballast. Washouts were limited to locations where there was a significant cross-flow over and through the embankment.

Areas where there is a strong potential for washout is best determined from the air photos taken during the peak of the flood in early July 2007. Areas where the water surface elevations on each side of the railroad were nearly identical have minimal potential for washout. These can be easily identified because of the lack of waves or other disturbance of the water surface.

Inundated embankments without cross-flow are also subject to failure due to the potential loss of strength of the embankment material because the saturation of these soils; however, if the embankment is not loaded during saturation, and allowed to drain after the flood, the potential for embankment failure of these inundated areas is reduced.

Where the embankments were overtopped (cross-flow), the water is nearly at critical depth, and the wave action downstream is due to a weak hydraulic jump. Due to the uniqueness of the flow depth at critical depth, the overtopping flow velocity was estimated to be between 5 and 8 feet per second.

Differential water surface elevations from each side of the railroad embankments caused potential hydraulic energy and cross-flow that is available to move water through the embankment and ballast as sub-surface flow. Large differential heads result in hydrodynamic forces that can easily mobilize embankment and ballast materials. Because of this, damaged areas where the embankment has been washed out should be carefully rebuilt using standard geotechnical methods and compaction requirements.

The hydraulics and flood potential for MP 66.7-67.0 required special consideration. In this area the embankment of the railroad runs between the Marais des Cygnes River and Middle Creek (Figure 3). Since these two rivers share the same floodplain, the presence of the railroad embankment serves as a left overbank and right overbank levee for the Marais des Cygnes and Middle Creek, respectively.

If Middle Creek is flooding without the Marais des Cygnes flooding, water will flow through the relief bridges under the railroad from east to west. For very large floods on Middle Creek, water can overtop the railroad with a potential for washout of the west side of the railroad embankment. If (as in the case of the July 2007 flood) the Marais des Cygnes is flooding more than Middle Creek, the flow will be from west to east and the eastern embankments would be prone to washout. Finally if the flood on the Middle and Marais des Cygnes were nearly equal, the embankment could be inundated without washout potential.

Figure 3

As discussed previously, the flood that inundated and damaged the BNSF railroad from MP 47 to 70 had an exceedence probability of approximately 0.01 (100-year flood). However, due to the inundation and damage that occurred during this flood, the Ft. Scott Subdivision does not meet current design guidelines for hydraulic design.

We offered BNSF several options for dealing with this problem which are listed below:

1. Upgrade the line segment to meet current hydraulic design standards. This would require a comprehensive hydrologic and hydraulic study of the Marais des Cygnes River and tributaries. The design would require that most of the railroad would have to be raised between MP 47 and 70 and most of the relief structures would need to be modified or upgraded. The major river bridges would not need to be modified since they were not overtopped during the flood.
2. Stabilize the railroad embankment to mitigate/minimize washout potential. This option would accept having this line segment go out of service during a flood of similar magnitude but minimize damage and repair requirements. Service could resume soon after the flood waters recede. In this option the team of hydraulic and geotechnical engineers would assess the potential washout locations, prioritize them, and implement a plan to stabilize the embankment slopes so that the potential for washout is minimized. It is likely that areas of embankment would be required to be rebuilt and stabilized using a variety of techniques.
3. It may also be advantageous to accept that the flood was a rare event and repair only as needed. If another significant flood occurred it should be accepted that the railroad will go out of service and that washed out embankments will need to be repaired again. It should be noted that since the embankment repairs that were conducted after the 2007 event were not engineered, the extent of embankment damage may be larger the next time an event of this magnitude occurs.
4. Finally, it may be desirable to pursue a phased approach to upgrade the railroad to current design standards over a period of time. This option is a hybrid of option 1 and 3. In considering this approach it is noted that the main river bridges are sufficient to pass the 100-year flood. Furthermore, the areas that were overtopped and washed out are on sag vertical curves which would allow the rail to be raised relatively easily.

The most appropriate course of action depends on many factors such as the importance of this line segment to BNSF overall operations and the available alternative routes around this location when this line segment is flooded again.

Bridge river crossings that are skewed to a river or floodplain may require careful consideration regarding the effects to approach embankment, and abutment degradation caused by overtopping flood flows such as those that were experienced on the Fort Scott Subdivision. The data that was gathered during the flood by pictures helped provide a better understanding of what takes place and why during these events.

ABSTRACT

Rock weir and ramp structures uniquely serve a necessary role in river management: to meet water deliveries in an ecologically sound manner. Uses include functioning as low head diversion dams, permitting fish passage, creating habitat diversity, and stabilizing stream banks and profiles. Existing information on design and performance of in-stream rock structures does not provide the guidance necessary to implement repeatable and sustainable construction and retrofit techniques. As widespread use of rock structures increases, the need for reliable design methods with a broad range of applicability at individual sites grows as well.

Rigorous laboratory testing programs were implemented at the U.S. Bureau of Reclamation (Reclamation) and at Colorado State University (CSU) as part of a multifaceted research project focused on expanding the current knowledge base and developing design methods to improve the success rate of river spanning rock structures in meeting project goals. Physical modeling at Reclamation is being used to measure, predict, and reduce interstitial flow through rock ramps. CSU is using physical testing to quantify and predict scour development downstream of rock weirs and its impact on the stability of rock structures.

INTRODUCTION

River spanning rock structures can provide energy dissipation, create and enhance aquatic habitat, allow fish passage, relieve pressure on failing banks, establish grade control, and function as water diversion. Information on the design and performance of these structures is largely anecdotal based on empirical professional experience without the engineering rigor required for duplicability. Site specific design requires a

substantial design effort that in some cases can consume more resources than construction. Over the course of the past several years, the use of rock ramp and weir structures has spread from use as habitat restoration and fish passage as part of salmon recovery projects in the Pacific Northwest, to examination of alternatives to bank stabilization as part of the Middle Rio Grande River Maintenance Project in New Mexico. There is little systematic information on how well these structures meet project goals. Realizing the need for more qualitative assessment of the function of various structures, laboratory test program was designed and implemented.

Current in-stream rock structures research seeks to streamline the design process, increase understanding of the performance of river spanning rock structures, and improve the chances for successfully meeting management objectives. The laboratory physical modeling forms part of a multifaceted approach incorporating a quantitative evaluation of field data to provide empirical validation, laboratory physical modeling for controlled testing of complicated processes, and numerical simulations to expand the range of applicability and analytic capability. Field measurements, physical testing, and numerical modeling will combine to relate structure performance to interstitial flow, local hydraulics, and scour quantification processes. Laboratory tests will assist in developing tools and guidelines for more robust design or retrofits of river spanning rock structures based upon predictable engineering and hydraulic performance criteria.

Physical testing facilities in the hydraulic laboratories at the U.S. Bureau of Reclamation (Reclamation) and at Colorado State University were selected to investigate the impacts of interstitial flow and downstream scour development on the design, installation, function, and maintenance of river spanning rock structures. Current physical testing being conducted at Reclamation's Water Resources Research Laboratory at the Technical Service Center in Denver is focused on methods for quantifying and limiting interstitial flow through rock ramps. The Hydraulics Laboratory at the Colorado State University's Engineering Research Center in Fort Collins is being used to examine the downstream bed scour and structural stability in various rock weir structures. The physical modeling component will provide information for the development of sustainable construction and retrofit techniques, minimizing the structure lifecycle costs and maximizing their ability to reliably meet management objectives.

ROCK RAMP PHYSICAL MODELING

During periods of low stream flow, it is vital that rock ramps convey sufficient surface flow to meet fish passage requirements. Physical modeling facilities at the U.S. Bureau of Reclamation's Water Resources Research Laboratory at the Technical Service Center were used to determine design guidelines that identify the ratio of interstitial flow to surface flow passing down rock ramps and identify the effectiveness of adding "choke material" to the riprap to reduce permeability.

Project Need. Rock ramps are riffle like structures constructed in a stream to provide passage of aquatic species over low barriers. Ramps are typically constructed using loose riprap placed on a gravel or synthetic filter overlying a foundation of native

material. The size and gradation of the rock is based on achieving stability of the material under maximum design flow conditions. Ramp slope is generally selected based on achieving flow criteria required for aquatic specie passage. Ramps are typically constructed at slopes less than about three percent, however slopes up to five percent are used, and slopes up to ten percent have been considered.

The current state of the art does not provide the designer with sufficient guidelines to establish a low flow limit of operation for rock ramps. In many previous designs, uncertainty of interstitial flow capacity has lead to grouting to ensure sufficient water flows above the surface to support fish passage during periods of low river flow. Grouting is costly and often not favored by resource agencies. Surface grouting can also create structural problems over time by reducing the ability of the structure to adjust to foundation settlement or river degradation.

Project Objectives. This study was designed to provide the basis for selecting a rock gradation that includes estimation of the interstitial flow of the new structure. The study further investigated reducing ramp porosity by post construction choking of the ramp with selected fines and, to a limited degree, by natural sediment passage. The major objectives of the study were to:

- Conduct a literature review of flow through rock structures to develop a current basis of technology for predicting interstitial flow. The literature review also included other technologies incorporating flow through rock components. Some of these technologies are earth dam riprap overtopping protection, rock-fill dams, rock jetties, rock storm water detention levees, and water filtration.
- Develop a correlation between riprap gradation, slope, porosity and interstitial flow velocity that can be used for design of rock ramps.
- For steep rock ramps, determine the viability of post construction choking of riprap with a gradation of finer material to reduce interstitial flow.

Study Design. The framework for this study was developed as a series of tasks building on each other:

Task 1. The first task was to initiate the literature review with the goal of consolidating applicable design methods and prior research findings identified from published and gray literature sources. Current algorithms published for predicting and parameters that influence interstitial flow velocity interstitial flow velocity were documented.

Task 2. The next task was the modification of an existing physical model to obtain data on flow over and through rock ramps. The sketch in Figure 1 represents the basic conceptual design of the rock ramp test facility. The facility incorporated a 4-foot-wide by 22-foot-long by 6-foot-high Plexiglas flume in which sectional models of rock ramps were constructed. Water was supplied to the model from the laboratory sump using a 40 horsepower pump capable of discharging a maximum of about 8 ft^3/s flow. At the downstream terminus of the model, a 25 hp sediment pump provided up to an additional 8 ft^3/s flow and recirculation of sediment when required. The flume was instrumented with a vertical array of pressure piezometers and

temperature sensors located mid-channel at 5 ft stationing. Temperature probes were used to measure interstitial velocity. Hot water from a hot water heater was injected through a vertical ported pipe embedded in the rock ramp 1 ft downstream of the upstream cutoff wall. The time between injection and a rise in water temperature measured at the downstream probes equated to average interstitial flow velocity between stations. Interstitial flow was be measured at the terminus of the ramp by routing water passing through the rock to a separate channel and measuring weir. End effects in the model were avoided by adjusting a porosity plate located at the downstream end of the ramp.

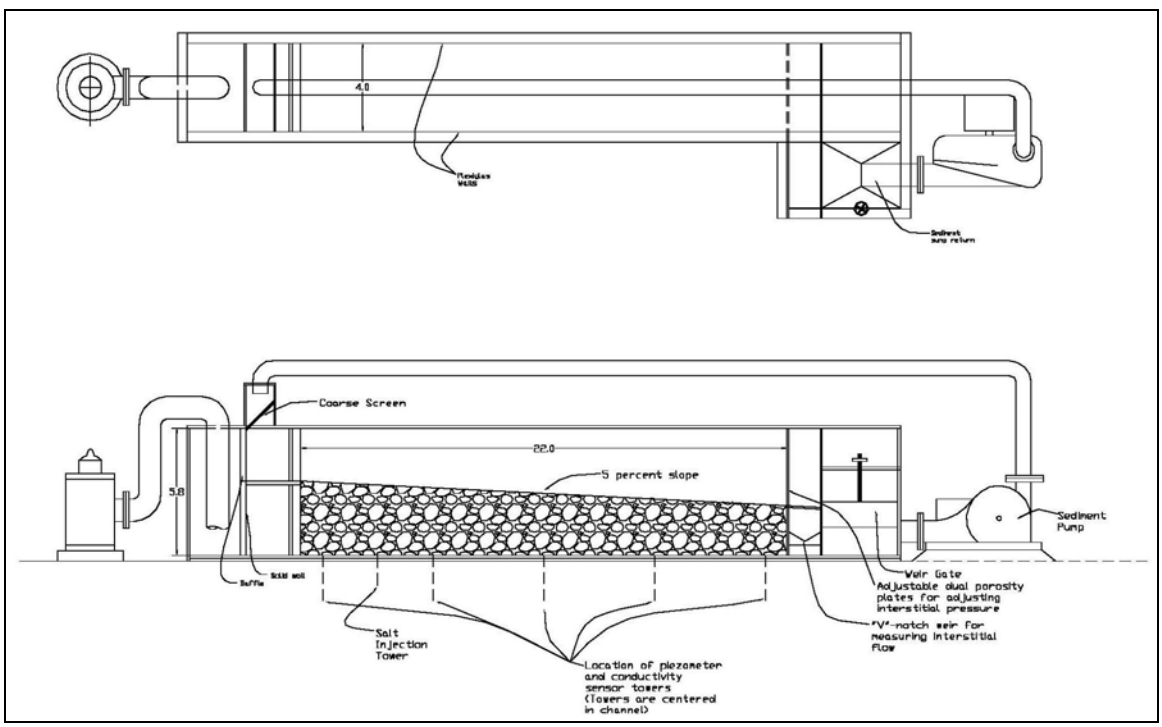

Figure 1. Plan and profile view schematics of rock ramp physical model

Originally, a saline water injection system with conductivity probes was planned for measurement of interstitial velocity. In the end, hot water injection with temperature probes was chosen instead. Figure 1 represents the proposed design before the final interstitial velocity measurement decision was made, but the basic design concept and flume configuration did not change.

Task 3. Prior studies of flow through rock for embankment overtopping protection suggest interstitial flow velocity is dependent on slope, median material size and material gradation. Frizell et al. (1998) conducted prototype studies of flow through rock on 2:1 embankment slopes using rock with medium diameters of 2.1 ft and 0.9 ft. They found interstitial velocity could be represented by the following relationship

$$\frac{V_i}{\sqrt{gd_{50}}} = 2.48 S^{0.58} C_u^{-2.22}$$

where V_i is the interstitial flow velocity, d_{50} is the median stone size, g is the acceleration of gravity, S is the embankment slope, and C_u is coefficient of uniformity, (d_{60} /d_{10}).

In similar studies with smaller material (d_{50}<0.8 ft) Abt et al. (1991) found V_i could be expressed by the empirical relation

$$V_i = 19.29\left(C_u^{-0.074} S^{0.46} n_p^{4.14}\right)^{1.064} \left(g d_{50}\right)^{0.5}$$

where n_p represents rock layer porosity.

As rock layer porosity, n_p, is often unknown for field conditions, Abt dropped n_p as a dependent variable and reanalyzed the data based on material size fractions d_{50}, d_{40}, d_{30}, d_{20}, d_{15}, and d_{10}. The correlation of the data increased with decreasing size fraction. Abt found a reasonably good relationship (correlation coefficient = 0.92) for V_i given by

$$V_i = 0.232\left(g d_{10} S\right)^{0.5}.$$

In Abt's tests the d_{10} material size ranged from about 1.5 inches to 2.0 inches.

The Frizell et al. (1998) and Abt et al. (1991) studies focused solely on defining stability of riprap exposed to flow on steep slopes. The current study expanded prior work to the design of rock ramps placing greater emphasis on control and prediction of interstitial flow.

Ongoing physical testing proposes to accomplish project objectives by constructing sectional models of rock ramps in the test facility described in Task 2. The six proposed test configurations based on two ramp slopes and three uniformity coefficients are given in the Table 1.

Table 1. Proposed rock ramp physical test matrix

Test No.			1	2	3
	Proposed Test Matrix		**Coefficient of Uniformity, C_u**		
A	**Ramp**	5 percent	1.5	2.2	3.0
B	**Slope**	10 percent	1.5	2.2	3.0

Physical testing of the rock ramps at 5 percent slope is complete for all three uniformity coefficients listed in Table 1. Based on completed tests and engineering experience with design, installation, and monitoring, physical testing at 10 percent ramp slopes has been abandoned. Data and experience indicate that 10 percent ramps may be too steep, producing turbulent, high velocity surface flows that could prevent fish passage and would present significant challenges in the design of a stable structure. Configurations for remaining rock ramp physical tests will be determined primarily based on feedback from clients currently designing and implementing these types of structures.

Task 4. Choking the voids within riprap with a material of finer gradation has been used during rock ramp construction as a method to achieve a lower porosity of the ramp. Although not well defined for rock ramps steeper than 3 percent, choke

material is typically a sandy-gravel material and standard road base material can be used. This choke material has been successfully used on ramps of slope less than about 2 percent. No data or case studies have been found on the validity of this approach for steeper slopes. For this series of tests, post construction choking was evaluated by spreading choke material on the surface after testing of the ramp stability and interstitial flow measurement without finer material was completed. The choke material was selected to meet filter criteria for the riprap. The choked ramps were tested for extended periods with clear water to evaluate the potential for loss of choke material effectiveness where a surface treatment approach is used.

Task 5. The final study task is to evaluate ramp sealing due to bed load transport for the 5 percent slope ramps. Approximately 1mm-diameter-minus sand would be introduced and allowed to re-circulate for an extended period. Sand would be added at a rate of 1.5 ft^3/day until an equilibrium transport rate is reached.

ROCK WEIR PHYSICAL MODELING

Previous testing and field investigations identified development of a downstream scour pool as the dominant failure mechanism for rock weir structures. Existing methods do not accurately predict scour or capture the hydraulic processes controlling growth of scour holes and undermining of rock weirs. Physical modeling facilities at Colorado State University's Engineering Research Center Hydraulics Laboratory were used to test a near prototype range of weir configurations and bed material sizes to determine scour magnitudes and trends, measure hydraulic conditions associated with structure type, and assess the stability of each weir configuration.

Project Need. Reclamation's Pacific Northwest Region designs and constructs numerous in-stream rock weir structures every year for fish passage and habitat restoration as part of various salmon recovery projects. In addition, the Middle Rio Grande, River Maintenance Project in New Mexico is exploring alternate means to stabilize banks by reducing flow velocity along eroding banks. Current design methods have had mixed success, primarily relying on individualized professional experience and anecdotal information. Development of design recommendations through systematic data collection, testing, and analysis is required for new structures and retro-fits to reliably meet management objectives. A scientific and mechanistic based understanding of structure behavior leads to supportable planning and management decisions and improves adaptability to new circumstances.

The rock weir physical modeling component of the river spanning rock structures research project is being conducted at the Hydraulics Laboratory located at the Engineering Research Center of Colorado State University (CSU). Physical modeling was conducted on three types of in-stream rock structures: U-weir (similar to V-weir but with a throat), W-weir, and A- weir (also called a double drop). The physical testing program was developed by CSU, in conjunction with Reclamation, to investigate the hydraulics specific to the three weir types and the associated bed scour development. For all three rock weir types, physical tests were performed using consistent methodology to document and improve understanding of how the

structures function up to a state of instability and to add to the existing data set and expand the range of applicability of rock weirs.

Project Objectives. The rock weir physical modeling component of this research will help to develop design packages to simplify the engineering of in-stream structures. There were three primary research objectives designated for the rock weirs physical testing:

- Quantify the dimensions of the bed scour downstream of rock weirs.
- Measure water surface elevations to develop water surface profiles and head-discharge relationships. Provide an empirical water surface profile for developing modeling techniques in one-dimensional numerical hydraulic model (HEC-RAS).
- Collect three-dimensional velocity measurements to analyze velocity and shear stress distributions in the physical model. Obtain calibration points for three-dimensional hydraulic modeling.
- Describe the scour failure mechanism of rock weirs.

Study Design. Physical modeling involved the construction of a scale model of each weir with a unique length scale for each selected bed material. A flume 16-ft-wide by 50-ft-long and 4-ft-deep, with a pump and head-box system capable of discharges up to 40 ft^3/s was selected for this study. A data-collection platform spanning the width of the flume was added to facilitate data collection. Conceptual design sketches of the rock weir testing facility are shown in Figure 2. Each configuration had a unique combination of weir shape, bed material, and bed slope.

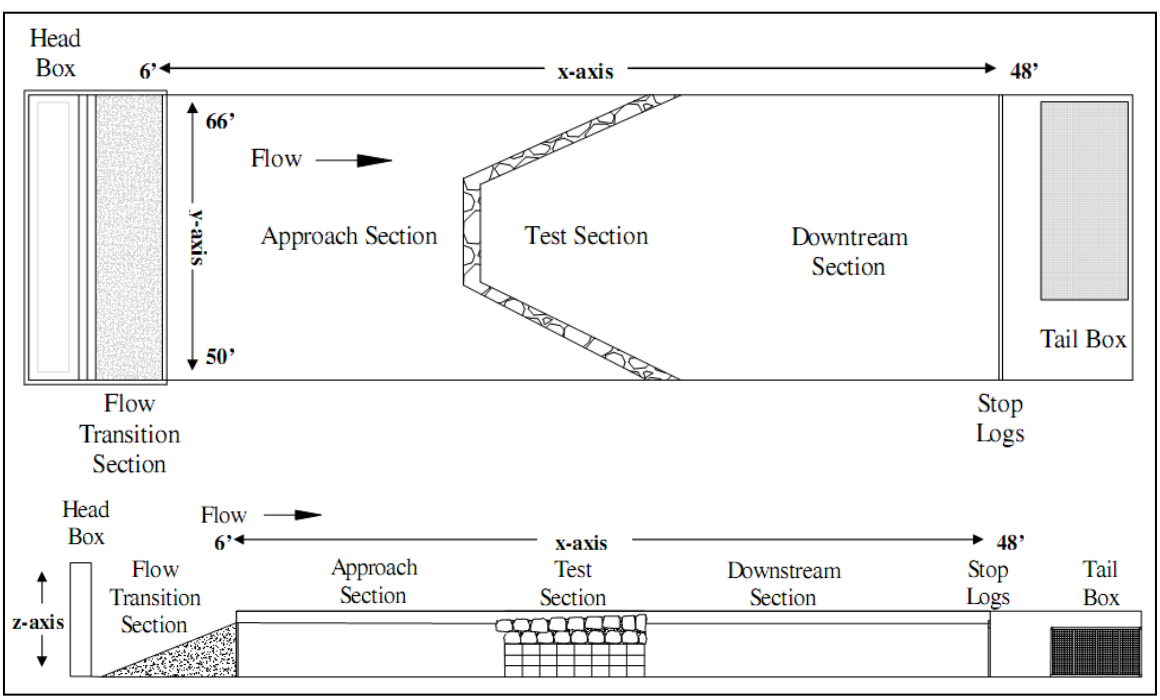

Figure 2. Plan and profile schematics of rock weir physical model

The test matrix for the rock weir physical modeling is listed in Table 2.

Table 2. Rock weir physical test matrix

Configuration	Weir Type	Weir Rock Size (in)	Drop (ft)	Bed Grain Size (mm)	Bed Slope (ft/ft)	Arm Length (ft)	Arm Slope (degrees)
1	W	6.87	None	15.0	0.0047	11.00	5.37
2	U	6.87	None	15.0	0.0047	11.44	4.08
3	U	6.87	0.14	15.0	0.0047	11.44	4.08
4	U	10.00	0.18	5.0	0.0021	11.24	1.70
5	A	10.00	0.36	5.0	0.0020	9.24	1.02
6	W	10.00	0.18	5.0	0.0020	7.97	2.38
7	U	8.80	0.17	9.8	0.0030	12.58	2.05
8	A	8.80	0.34	9.8	0.0030	9.41	1.69
9	W	8.80	0.17	9.8	0.0030	9.35	2.76
10	A	6.87	0.28	15.0	0.0050	10.69	2.40
11	W	6.87	0.14	15.0	0.0050	11.00	3.13

Three distinct of rock weirs types and three different bed gradations were tested at three separate discharges. W- and U-weirs were initially tested with the bed elevation equal to the crest elevation at the weir throat (no drop) resulting in a total of 11 unique configurations of weir shape, bed material, and bed slope that were constructed and tested.

Hydraulic Geometry. Independent variables were reduced to discharge and grain size using hydraulic geometry from Julien (2002). Three grain sizes were determined that corresponded to field conditions in areas where natural stone weirs were proposed to be built or were already in use. Using these pre-selected grain sizes and an estimated prototype discharge, regime equations from Julien (2002) were used, in an iterative process, to determine width and slope for the prototype. The design of the model was constrained by the available dimensions of the flume. Using the 16 foot width, 4 foot depth, and a maximum discharge capacity of 40 ft^3/s, scaling ratios could be adjusted to enable proper sizing of the prototype and the scale model. Prototype slope and width were calculated from the following two equations

$$S \cong 0.0124 Q^{-0.4} d_s{}^{1} \tau_*{}^{1.2}$$

$$W \cong 5.0035 Q^{0.53} d_s{}^{-0.33} \tau_*{}^{-0.27}$$

where S is the bed slope, Q is the bankfull discharge in m^3/s, d_s is the median particle diameter in mm, τ_* represents the Shields number and was assumed equal to 0.047 (Reclamation, 2006), and W is the bankfull width in meters.

Normal Depth. Normal depth, y_n, was calculated using Manning's equation

$$Q = \frac{\Phi}{n}(by_n)(S_o)^{1/2}\left(\frac{by_n}{b+2y_n}\right)^{2/3}$$

where y_n is normal depth, n is Manning's roughness coefficient, Q is discharge, b is bottom width, S_o is bed slope, and Φ is a conversion coefficient (equal to 1.486).

Manning's roughness, *n*, was calculated using Strickler's relationship (Richardson et al., 1990)

$$n = k_u \, d_s^{1/6}$$

where, k_u Strickler's constant (equal to 0.0421).

Scaling. The hydraulic testing of the model was designed to use an undistorted scale to best represent flow patterns and sediment transport. The available width of the flume in relation to the prototype width was used to determine the length scaling parameters. Length scaling ratios were prescribed as 1:4.36, 1:4.61, and 1:5.75 corresponding to the 5-mm, 9.8-mm, and 15-mm median grain diameter bed materials used in the physical testing, respectively. Since the model was considered undistorted, the slope did not require scaling. Froude similitude governs the hydraulic characteristics

$$Fr = \frac{U}{\sqrt{g \cdot Y}}$$

where *Fr* is the Froude number, *U* is the mean channel velocity, *g* is the acceleration due to gravity, and, *Y* is the characteristic depth of flow.

Froude similitude scaling requires the velocity ratio to equal the square root of the vertical scaling ratio

$$U_r = \sqrt{Y_r}$$

where U_r is the ratio of velocity in the prototype to velocity in the model and Y_r is the ratio of characteristic depth in the prototype to characteristic depth in the model.

Froude scaling results in the following relationship between flow scale and length scale:

$$Q_r = L_r^{5/2}$$

where Q_r is the ratio of discharge in the prototype to discharge in the model and L_r is the ratio of length in the prototype to length in the model.

Flow resistance was not considered to be a significant effect in this model, since local hydraulics and local scour conditions were the primary focus.

The Rouse number defines the vertical distribution of sediment in suspension. For scour testing, this parameter represents the interaction of the bed material with the water column due to turbulent hydraulic processes. The Shields parameter represents bed mobility through shear stress processes such as rolling and sliding. The Rouse numbers for the prototype conditions were expected to be relatively high suggesting bed motion processes governed and therefore the Shields parameter was the most applicable scaling condition (Reclamation, 2006). Julien (2002) reports that Shields' similitude governs the scour under clear water conditions. Therefore, Shields' scaling was used to size the model grain diameter according to the length ratio (Reclamation, 2006).

The "drop" is the distance from the crest of the weir to the surface of the bed. A prototype drop height of 0.8 feet was used in accordance with Reclamation Pacific Northwest Regional Office criteria. Model drop heights were determined by dividing the prototype drop height by the length scaling ratios. Drop heights, prescribed by Reclamation, were 0.14 ft., 0.17 ft., 0.18 ft. corresponding to the 6.87-inch, 8.8-inch, and 10-inch weir rocks, respectively. For the A-weirs, a "double-drop" design was used. The cross arm was set at the calculated drop height and the crest of the weir was set at twice the calculated drop height.

Weir-rock sizes were prescribed by Reclamation and were based on recommendations by Rosgen (2001) to use weir rocks that are three times the drop height of the weir. Rock sizes were 10 in, 8.8 in, and 6.87 in measured along the intermediate axis and corresponded to the 5-mm, 9.8-mm, and 15-mm bed material, respectively. Larger weir rocks were used with a smaller bed material to simulate field conditions.

Bed Material. Three d_{50} grain diameters for the prototype were selected to match field conditions over a range of areas where rock weir structures have been built or are proposed to be constructed. The small cobble is representative of streams in the Pacific Northwest, while course gravel is representative of Rio Grande headwater streams. The need to minimize scaling required for model testing was also a factor in grain size selection (Reclamation, 2006).

Model bed material sizes were determined using Shields scaling. The median diameters (d_{50}) of the prescribed bed materials were 5 mm, 9.8 mm, and 15 mm. The actual median diameters achieved were approximately 4.2 mm, 9.81 mm, and 12.3 mm for the U-weir tests. For the A-weir and W-weir tests, the actual median diameters achieved were approximately 4.2 mm, 9.81 mm, and 15.38 mm.

Weir Dimensions. Structures were designed to approach as close as possible the midpoint of the design ranges specified in Rosgen (2001). Recommended plan angles were between 20 to 30 degrees and profile angles between 2 to 7 percent. Target angles were 25 degrees for plan angles and 4.5 percent for profile angles. Reclamation used the solver function in Microsoft Excel® to calculate the weir arm length that minimized the relative distances on the planform and profile angles of the weir arms. No information on the importance of one angle over another could be found so the relative errors were kept equal (Reclamation, 2006). Figure 3, Figure 4, and Figure 5 show the design layout and basic dimensions for the U-, A-, and W-weirs tested.

Prototype grain size and discharge were used in an iterative process utilizing the solver function in Microsoft Excel® to determine prototype dimensions and model length scaling. The dimensional constraints of the flume influenced the design process. Froude and Shields scaling were used to determine model sizing ratios.

CONCLUDING REMARKS

In-stream rock structures are increasingly being used to serve a wide variety of aquatic habitat, fish passage, stream stabilization, and water diversion purposes. The current state of the art does not provide sufficient design and performance information for new structures and retrofits to reliably meet management objectives. Current design methods are largely based on individualized professional experience and anecdotal information with a narrow range of applicability. A clear need exists to

expand the current knowledge base and develop design procedures that would allow site specific application and improve the sustainability of rock ramps and weirs.

Physical modeling currently in progress at the U.S. Bureau of Reclamation (Reclamation) and at Colorado State University (CSU) is focused on the development of recommendations for improving the design of river spanning rock structures. Computation, measurement, and reduction of interstitial flow through steep rock ramps is being studied at Reclamation's Water Resources Research Laboratory. The Hydraulic Laboratory at CSU's Engineering Research Center is conducting physical tests to quantify and predict the development of scour downstream of rock weirs and the effects of downstream scour on structure stability. As an integral part of a multifaceted approach including collection and analysis of field data, numerical modeling, and laboratory testing, the physical modeling component will provide information for the development of improved river spanning rock structures design methods and guidelines.

Redesign and Rehabilitation of Railroad Bridges with Advanced Adverse Lateral Migration

William Yord A.M.[1], Jerry R. Richardson M., D.WRE [2], Vincent J. Zink S.M.[3]

Much of the railroad infrastructure in the United States was initially built over a century ago, whereas the highway infrastructure is roughly half as old. Consequently, the existing railroad infrastructure presents more cases with advanced stream stability issues. These include advanced lateral and vertical migration which must be addressed when assessing, mitigating, or redesigning railroad bridges for stream stability and scour. Bridge 433.3 on the Union Pacific Railroad near Chickasha, Oklahoma is used as a case study to illustrate the problems with redesigning a railroad bridge crossing which has experienced advanced long-term lateral stability issues, and to demonstrate how mitigating for stream stability and scour at railroads differs from similar work within the National Highway System.

In this case the Washita River has had extensive lateral migration over approximately the last eighty years. Two railroad bridges exist on the Washita River at this location, which are the main river bridge (Bridge 433.5) and the left bank overflow bridge (Bridge 433.3). Upstream of this location, a tortuous meander bend exists which is migrating down-valley at a rate of approximately 6 m/yr (20 ft/yr) (Figure 1). Downstream of Bridge 433.3 the west bank of the Washita River is showing signs of degradation and severe head cutting toward the bridge opening. The most likely location for this cutoff is through this relief bridge (Bridge 433.3) located 0.3 km (0.2 mi.) north of the main bridge crossing (Bridge 433.5).

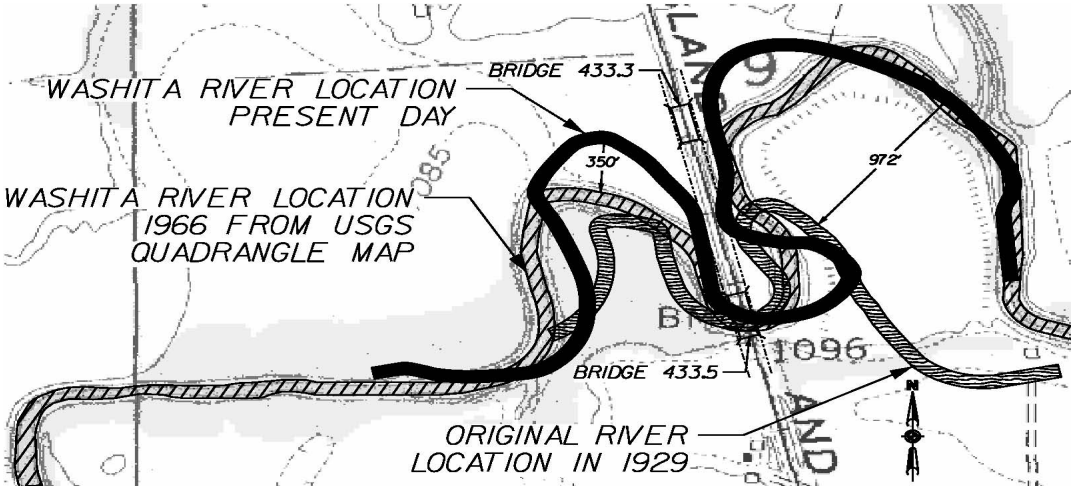

Figure 1: Stream Migration Snapshots in Time

1 Project Manager, H&H Rail Wilson & Co, 903 E. 104th street, Suite 210, Kansas City Missouri 64110

2 Associate Professor, School of Computing and Engineering, University of Missouri Kansas City, 5100 Rockhill Road, Kansas City, MO, 64110

3 Intern Engineer, Wilson & Co, 903 E. 104th street, Suite 210, Kansas City Missouri 64110

The channel length around the meander loop is nearly 5 times longer than the down valley length near Bridge 433.3, and given the rate of movement it is likely that a cutoff through the overflow bridge will occur within the next few years unless river training measures are taken.

In order to design the replacement for the relief structure (Bridge 433.3), the potential for meander cutoff had to be carefully considered. Multiple options were considered including retaining the existing channel using countermeasures, designing the replacement bridge to account for the potential cutoff, and physically cutting off the river and abandoning the main channel bridge as part of the new design. Each presented technical, geomorphic, flood control, and permitting issues.

Figure 2: Washita River Upstream of Bridge 433.3. Note Bridge 433.3 in Background and Scour on Left Bank

OPTIONS

The first option considered was to make the overflow bridge (Bridge 433.3) the main river bridge and leave the existing main river bridge in place. Do not encourage the cut-off of the Washita River through Bridge 433.3. Let the cut-off occur naturally and make adjustments to Bridge 433.3 after this cut-off occurs. This would mean that the overflow bridge would need to be sized and configured as a main river bridge (approximately 3-steel spans).

Uncertainty and extra risk to UPRR infrastructure exists regarding this option in that the Washita River may cut-off at unexpected locations (most likely between Bridge 433.3 and 433.5) and adversely affect bridge abutments or railroad fill embankments. The existing railroad embankments between Bridge 433.3 and 433.5 would need to be monitored during and after major flood events to ensure the stability of the railroad embankment, abutments of the main river bridge and the abutments and piers of the

proposed Bridge 433.5. After the Washita River cut-off through Bridge 433.3, remediation would need to take place to stabilize any areas where scour has occurred. The flow in the meander loop after this is complete would be much less problematic as most of the flow would be through Bridge 433.3 instead of the main river bridge. The existing meander bend of the Washita River through Bridge 433.5 would likely fill with sediment after a period of time.

Figure 3: Washita River Channel Showing Lateral Migration on the Left Bank

Another option was to make the overflow bridge (Bridge 433.3) the main river bridge and leave the existing main river bridge in place. Encourage the cut-off of the Washita River through Bridge 433.3 by excavating a channel from upstream of the Bridge through the structure and connect it to the main Washita River Channel downstream of Bridge 433.3. This would mean that the overflow bridge would need to be sized and configured as a main river bridge. A grade control structure could be installed upstream of Bridge 433.3 to maintain the slope of the river, help control head cutting and help maintain flow in the existing meander bend through Bridge 433.5

The Washita River cut-off would be much more predictable and controllable under this option. The flow in the meander loop after this is complete would be much less problematic as most of the flow would be through Bridge 433.3 instead of the main river bridge. The existing meander bend of the Washita River through Bridge 433.5 would likely fill with sediment after a period of time.

Figure 4: Washita River Channel Downstream of Bridge 433.5. Note Lateral Stream Migration on Outside Embankment

The final option we considered was to maintain the existing configuration of Bridge 433.3 as an overflow structure and Bridge 433.5 as the main river bridge and armor Bridge 433.3 with deep buried rip-rap and guide banks to enhance stability if the Washita River tries to cut-off through the overflow bridge. In effect, this would be a deep buried heavy rock weir (Type III Rock). The volume of the heavy rock for the weir structure beneath Bridge 433.3 is approximately 8570 cubic yards. Extra rock would be recommended for protection of bridge abutments. This rock weir is shown conceptually on the Plan & Profile Exhibit Bridge 433.3 on the following page.

CONCLUSIONS

In order to design the replacement for the UPRR Bridge 433.3, the potential for a meander cutoff had to be carefully considered. These options included retaining the existing channel using countermeasures, designing the replacement bridge to account for potential cutoff, and physically cutting off the river and abandoning the Bridge 433.5 as part of the new design. Each presented technical, economic, geomorphic, flood control and permitting issues for the crossing. Bridge 433.3 and 433.5 offer a glimpse into the future for the National Highway System as lateral migration and stream stability issues present themselves such as that experienced by infrastructure that has been in service twice as long. Scour analysis for bridges in the National Highway System should also include stream stability and geomorphologic studies upstream and downstream of the bridge crossing to properly locate bridges to account for lateral and vertical migration of existing rivers as well as general and local scour analysis.

A Direct Method for Determining Riprap Size for Erosion Protection in Rivers

Yongliang Jin[1] and Brian D. Barkdoll, F. ASCE[2]

[1]Graduate Research Assistant, Civil & Environmental Engineering Dept., Michigan Tech Univ., Houghton, MI 49931, PH: (906) 487-1981, FAX: (906) 487-2943, email: yjin@mtu.edu
[2]Associate Professor, Civil & Environmental Engineering Dept., Michigan Tech Univ., Houghton, MI 49931, PH: (906) 487-1981, FAX: (906) 487-2943, email: barkdoll@mtu.edu

Abstract: In cases where an open channel needs bed and bank protection riprap is a common lining material, of which riprap size is the main design parameter needing determination. The current solution procedure is a cumbersome iterative one. A direct solution (one not needing iteration) is proposed here that improves computation time by 98% and adds less than 8% error.

Introduction

One of the current methods for calculating riprap size is from Anderson et al. (1970) and is an extension of the tractive force concept outlined in Chow (1959). The method is summarized as follows (Sturm 2001):

1. Choose a riprap diameter and obtain φ and θ from figures of which the values are approximated by the following
$$\varphi = 1.3445\text{-}ln(d_{50}) + 34.197$$
$$\theta = 1.9366 + 0.518\,\varphi$$
in which φ is the angle of repose in degrees, θ is the side slope angle in degrees, and d_{50} is the median particle size in feet;
2. Calculate the critical bed and wall shear stresses from
$$\tau_{Oc} = 4d_{50}$$
$$K_r = \frac{\tau_{Oc}^{w}}{\tau_{Oc}} = \left[1 - \frac{\sin^2\theta}{\sin^2\varphi}\right]^{1/2}$$
in which τ_{Oc} is the critical shear stress required for initiation of motion in lbs/ft^2 and K_r is the tractive force ratio;
3. Determine Manning's n from
$$n = 0.04 d_{50}^{1/6}$$
4. For a given channel bottom width, b, discharge, Q, and slope, S, find the normal depth from Manning's equation;
5. Calculate the maximum bed ,$(\tau_O)_{max}$, and wall ,$(\tau_O{}^w)_{max}$, shear stresses from :
$$(\tau_O)_{max} = 1.5\gamma RS$$
$$(\tau_O{}^w)_{max} = 1.2\gamma RS$$

---

[1] Graduate Research Assistant, Civil & Environmental Engineering Dept., Michigan Tech University, Houghton, MI 49931
[2] Associate Professor, Civil & Environmental Engineering Dept., Michigan Tech University, Houghton, MI 49931, barkdoll@mtu.edu

where γ is the specific weight of water, R is the hydraulic radius, and S is the longitudinal bed slope; and

6. Repeat with another riprap diameter and/or bottom width until the maximum shear stresses are just smaller than the critical values.

This process is effective but time consuming with iterations not only in Steps 1 through 6 outlined above, but also within Step 4 in which iterations must be performed to obtain the normal depth from Manning's equation for a trapezoidal channel.

Procedure

To find a direct method for obtaining the minimum riprap size, one without iteration, the method outlined above was solved for over 1000 different values of the input variables Q, S, and b. A direct equation was then obtained that gave predictions of riprap size that closely matched the "true" values from the method outlined in Steps 1 through 6 above. Values of Q, S, and b were chosen to be inclusive of values found in natural channels so that the direct method acquired herein would not require extrapolation outside the range of values employed in its development (Table 1).

Table 1. Input data range

Parameter	Minimum value	Maximum value	Unit
Q	100	1,072,600	cfs
S	0.00001	0.01057	ft/ft
b	1	5,281	ft

See Jin (2006) for all of the various forms of equations tried.

Results

Of all the equations attempted, it was found that the following equation yields the most accurate results:

$$d_{50} = \frac{2.41 Q^{0.60355} S^{0.79358} b^{-0.51341}}{1 + 1.65 e^{-0.5 b/y}} \qquad 1 < \text{b/y} < 50$$

Fig. 1 shows the predictions and true values as a function of b/y. Note that for values of b/y less than 1, the error can be unacceptably high, but that otherwise the error is less than 8%.

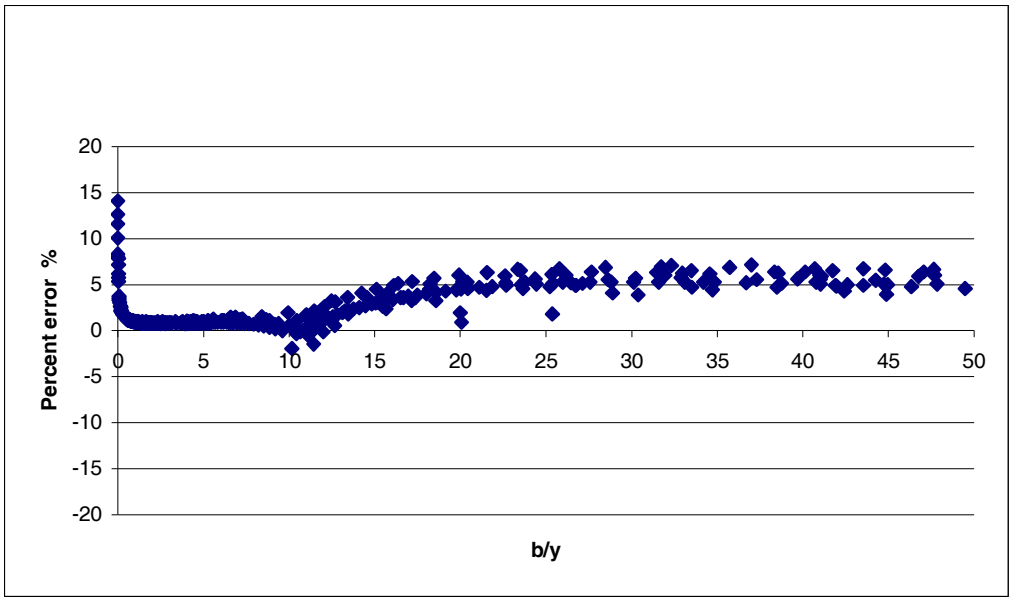

Fig. 1. Error between predicted and true values of minimum riprap size as a function of b/y.

Both the iterative and direct methods were run on the same computer for over 1000 times and it was found that there was a time savings of 98% by the direct solution.

Conclusions

The direct method found here of calculating the minimum riprap size to avoid erosion in channels improves computation time by 98% while adding an error of less than 8% and, therefore, can be used in computations of this sort. Even though the computation time of the existing iterative method may not be considered excessive, the present method does constitute a substantial time savings with not much additional error. In addition, the present solution is simpler and more pedagogically attractive.

Notation

The following symbols are used in this paper:

b	=	bottom width in ft;
d_{50}	=	median riprap diameter in ft;
K_r	=	tractive force ratio;
n	=	Mannings roughness coefficient;
Q	=	discharge in ft^3/s;
R	=	hydraulic radius in ft;
S	=	longitudinal channel bed slope;
y	=	normal flow depth in ft;
φ	=	angle of repose in degrees;
θ	=	side slope angle in degrees;
τ_{Oc}	=	critical shear stress required for initiation of motion in lbs/ft^2;

$(\tau_O)_{max}$ = maximum bed shear stress in lbs/ft^2;
$(\tau_O^w)_{max}$ = maximum wall shear stress in lbs/ft^2;
φ = angle of repose in degrees; and
γ = specific weight of water.

ABSTRACT

Although river beds generally tend to reach an asymptotic equilibrium, it may be abruptly altered by occurrences of natural extreme flow events or establishment of man-made structures. These causes lead to significant morphological changes in the bed profile through erosion and deposition processes. The change of river bed can be quantified for predicting the stability of a river channel. The status of a geomorphological equilibrium can be determined by two transport phases, i.e., water and sediment transport. In particular, the bed profile in sediment transport models can be employed as the initial condition, and the calculated movement of sediment can set a new bed profile. Herein, we propose to use the stochastic jump diffusion particle tracking model (SJD-PTM) to simulate the movement of sediment and particle deposition and resuspension processes. The stochastic diffusion jump particle tracking model is a Lagrangian particle tracking model governed by stochastic equations. When simulating the particle trajectories from the mean drift, settling velocity, diffusivity and extreme events, we can calculate the probabilities of deposition/scouring of a sediment particle by comparing the particle shear stress with the critical shear stress. As the result, we can trace particles and obtain particle trajectories and their statistical characteristics such as the ensemble mean and variance. Furthermore, we will be able to simulate particle deposition and resuspension processes.

INTRODUCTION

One of the major environmental concerns about sediment transport is the geomorphological change due to scouring and deposition. Estimating the change of river bed is beneficial to predicting the stability of a river channel. Souring / deposition processes become more significant during extreme flow events. It is of practical significance to determine whether sediment particles settle down on the bed or resuspend from the bed when simulating movement of sediment particles.

River beds generally tend to reach an asymptotic equilibrium. However, river bed may be altered by natural extreme flow events or man-made structures. These causes lead to significant morphological changes in the bed profile through erosion and deposition processes. Many of earlier models assumed equilibrium conditions in which the actual sediment transport rate is equal to the capacity of flow carrying sediment at equilibrium conditions at each computational point. In reality, alluvial river systems change continuously with respect to time and space so that absolute equilibrium states rarely exist in natural conditions. The local equilibrium assumption may not be realistic, particularly in cases of erosion and deposition during extreme events, because sediment cannot instantaneously reach a new equilibrium condition. Since extreme flow events are likely to cause strong net erosion and deposition, it is more realistic to consider non-equilibrium erosion and deposition processes when estimating the effect of extreme flow events on sediment transport. Bed shear stress is a basic shear parameter governing deposition / erosion processes. Employing the criteria of deposition / resuspension can determine if sediment particles are depositing or resuspending when the sediment particles reach the bed. The deposition / erosion processes of sediment particles also inherit the stochastic property from the stochastic instantaneous flow velocity. In other words, the stochastic flow velocity results in the randomness of bed shear stress, and such bed shear stress due to turbulence and occurrences of extreme events play a significant role in the deposition / erosion processes. Therefore, considering the stochastic bed shear stress can model more comprehensively deposition / erosion of sediment particles and then quantify the impact of extreme flow events on deposition / erosion processes.

To simulate flow and morphodynamic processes, many numerical models have been developed from theoretical equations or a combination of theoretical equations and empirical relations (Jia and Wang 1999; Molinas and Yang 1986; Lee et al. 1997). Lei et al. (1998) developed a finite-element model for rill erosion by controlling flow hydraulics and erosion processes according to altered morphology. Herein, the

proposed SJD-PTM adopts a Lagrangian particle tracking approach that traces sediment particles. Thus, it is more suitable to describe movement of particles in a probabilistic manner. Krone (1962) and Ariathurai et al. (1977) suggested the probability of cohesive sediment particles sticking to the bed based on their laboratory studies. Nagaraja (2008) attempted to simulate sediment transport with a particle tracking model using the probability of deposition / resuspension suggested by Krone (1962). However, the probability of deposition in the above studies (Nagaraja, 2008) is mainly targeting cohesive sediment particles. In the proposed study, we propose to derive the bed shear stress based on the essential stochastic characteristics of flow velocity and then use the critical shear stress to determine whether the particle would deposit or resuspend. The main objective of this study is to simulate movement of sediment particles and the particle deposition and resuspension processes.

STOCHASTIC JUMP DIFFUSION MODEL

The stochastic jump diffusion processes have been used for describing random abrupt changes of variables in time in various fields (Hanson, 2007). Movement of sediment particles in an open channel can also be controlled by an abrupt change of flow due to the passing of extreme flow events. Therefore, the stochastic jump diffusion process is pertinent to modeling movement of sediment particles in open channel flows (Oh and Tsai, 2008). The governing equations can be written as following stochastic differential equations.

$$d\mathbf{X}_t = \underbrace{\bar{\mathbf{u}}(t, \mathbf{X}_t)dt}_{\text{drift term}} + \underbrace{\boldsymbol{\sigma}(t, \mathbf{X}_t)d\mathbf{B}_t}_{\substack{\text{random term} \\ \text{due to turbulence}}} + \underbrace{\mathbf{h}(t, \mathbf{X}_t)d\mathbf{P}_t}_{\text{jump term}} \quad \text{or} \tag{1a}$$

$$\mathbf{V}_p = \frac{d\mathbf{X}_t}{dt} = \underbrace{\bar{\mathbf{u}}(t, \mathbf{X}_t)}_{\text{drift term}} + \underbrace{\boldsymbol{\sigma}(t, \mathbf{X}_t)\frac{d\mathbf{B}_t}{dt}}_{\substack{\text{random term} \\ \text{due to turbulence}}} + \underbrace{\mathbf{h}(t, \mathbf{X}_t)\frac{d\mathbf{P}_t}{dt}}_{\text{jump term}} \tag{1b}$$

where $\mathbf{X}_t$ is the position or trajectory of a particle, $\bar{\mathbf{u}}(t, X_t)$ is the drift velocity vector, $\boldsymbol{\sigma}(t, X_t)$ is the diffusion coefficient tensor (3×3 diagonal matrix in flow), $\mathbf{B}_t$ is the three-dimensional vector of the Wiener process. $\mathbf{h}(t, X_t)$ is the jump amplification factor and $\mathbf{P}_t$ denotes a Poisson process so that the inter-arrival time between extreme events is exponentially distributed. The mean drift motion of particles is represented by

$$\bar{\mathbf{u}}(t,\ X_t) = \bar{\mathbf{U}} + \nabla \mathbf{D} = \begin{cases} \bar{U}(t,x,y,z) + \partial D_x / \partial x \\ \bar{V}(t,x,y,z) + \partial D_y / \partial y \\ \bar{W}(t,x,y,z) - w_s + \partial D_z / \partial z \end{cases} \quad (2)$$

which is a deterministic component. The random turbulent motion term and jump term are stochastic components including random processes. The magnitude of extreme flow events is characterized by the jump amplification factor. The jump amplification over the extreme event duration T can then be expressed as

$$\mathbf{h}(t, \mathbf{X}_t) = \int_t^{t+T} \left(\int_0^T \frac{\mathbf{u}_f(t) - \mathbf{V}_p(t_0)}{\tau_p} d\tau \right) dt \quad (3)$$

where $\mathbf{u}_f(t)$ is the increased mean flow velocity due to an extreme event, $\mathbf{V}_p(t_0)$ is particle velocity before the extreme event and τ_p is the particle relaxation time. It is assumed that only one extreme event occurs within a time interval [t, t+dt].

DEPOSITION / EROSION PROCESSES

We set channel bottom boundaries associated with the stochastic jump diffusion particle tracking model (SJD-PTM) and simulate the movement of sediment under non-equilibrium conditions. Deposition / resuspension of a sediment particle can be determined by comparing the bed shear stress with the critical shear stress.

The bed effect in an open channel flow produces a logarithmic mean velocity profile in the longitudinal direction. The logarithmic velocity profile in the longitudinal direction is

$$\frac{\bar{u}}{u_*} = \frac{1}{\kappa} \ln\left(\frac{z_{sh}}{z_0} \right) \quad (4)$$

where $\bar{u}$ is the time-averaged streamwise velocity, u_* is the friction velocity, κ is the von Karman universal turbulence constant, z_{sh} is the elevation at which u is measured and z_o is the "virtual origin" of the profile (i.e., roughness length). Equation (4) can be used for the mean drift velocity in the longitudinal direction.

Bed shear stress is a basic shear parameter governing erosion processes. The bed shear stress can be usually calculated from the measured velocity profile. The bed shear stress, τ_o, can be estimated from the shear velocity:

$$\tau_0 = \rho u_*^2 \qquad (\rho : \text{water density}) \quad (5)$$

The shear velocity, u_*, can be estimated by the logarithmic velocity formula as

$$u_* = u\kappa \frac{1}{\ln(z_{sh} / z_0)} \tag{6}$$

where u is stochastic instantaneous flow velocity. Similar to stochastic particle velocity, the stochastic flow velocity can be estimated as

$$u = \bar{\mathbf{u}}(t, \mathbf{X}_t) + \boldsymbol{\sigma}(t, \mathbf{X}_t) \frac{d\mathbf{B}_t}{dt} + \mathbf{h}(t, \mathbf{X}_t) \frac{d\mathbf{P}_t}{dt}$$

where the jump amplification factor is expressed with the Dirac-delta function to explain abrupt change of flow velocity due to extreme flow events during a very short time period.

$$\mathbf{h}(t, \mathbf{X}_t) = \int_t^{t+T} \int_0^T (\boldsymbol{u} - \boldsymbol{V}_p) \delta(T/2) d\tau dt = \int_t^{t+T} (\boldsymbol{u} - \boldsymbol{V}_p) dt$$

Substituting equation (6) into equation (5), the bed shear stress is rewritten as equation (7).

$$\tau_0 = \rho \left[u\kappa \frac{1}{\ln(z_{sh} / z_0)} \right]^2 \tag{7}$$

Herein, the bed shear stress calculated from equation (7) can then be compared to the critical shear stress, i.e., criteria of deposition / resuspension of sediment particles. The estimated bed shear stress is inherently stochastic because of the stochastic particle velocity. The randomness originates from both flow turbulence and occurrences of extreme events.

APPLICATION AND SIMULATION RESULTS

The proposed SJD-PTM can be applied to particle movement in an enclosed domain subject to boundary deposition and erosion processes. As the result of the proposed model, we can trace particles and obtain stochastic particle trajectories, including their ensemble mean and variance.

The mean drift velocity of a regular flow in the following examples are $\bar{u} = 0.4$ m/s in the longitudinal direction and $\bar{w} = 0.0$ m/s in the vertical direction. The longitudinal diffusivity is $\sigma_x = 0.1$ m^2/s, and the vertical diffusivity is $\sigma_z = 0.008$ m^2/s. The longitudinal diffusivity is normally an order of magnitude larger than the vertical diffusivity in open channel flow. The occurrence of the extreme events can be represented by a Poisson process with a mean rate of 0.05/s, i.e., the mean frequency of occurrences with λ=180. The overall flow velocity during the extreme events is increased to 2.5 m/s in the longitudinal direction, and 1.5 m/s in the vertical direction. The total simulation time is 3600 s. The normalized total

simulation time is 1, and the normalized time step is 1/3600.

Case 1: Not considering bed shear stress

Figures 1 and 2 present sediment particle trajectories during a part of the total simulation time. Figure 1 displays the movement of sediment particles released at the center of depth. The solid line (blue) is the particle trajectory by the stochastic diffusion model. The dashed dotted line (black) is particle trajectory by the stochastic jump diffusion model. As shown in Figure 1, a sediment particle moves randomly due to flow turbulence gaining the velocity from extreme flow events occurring randomly and eventually settles down in the course of movement. The particle may be entrained or resuspended under the influence of turbulence and occurrences of extreme flow events. In other words, when the bed shear stress criteria are not being enforced, we mainly consider particle movement in response to ambient flow (both flow turbulence and extreme flows). Therefore, compared to Case 2 (where the bed shear stress criteria are established), the particle is more prone to resuspension. Figure 2 shows an ensemble mean trajectory of the 500 scenarios. The ensemble mean trajectories indicate that sediment particles move farther longitudinally and may have a higher probability for resuspension in the occurrences of extreme flow events.

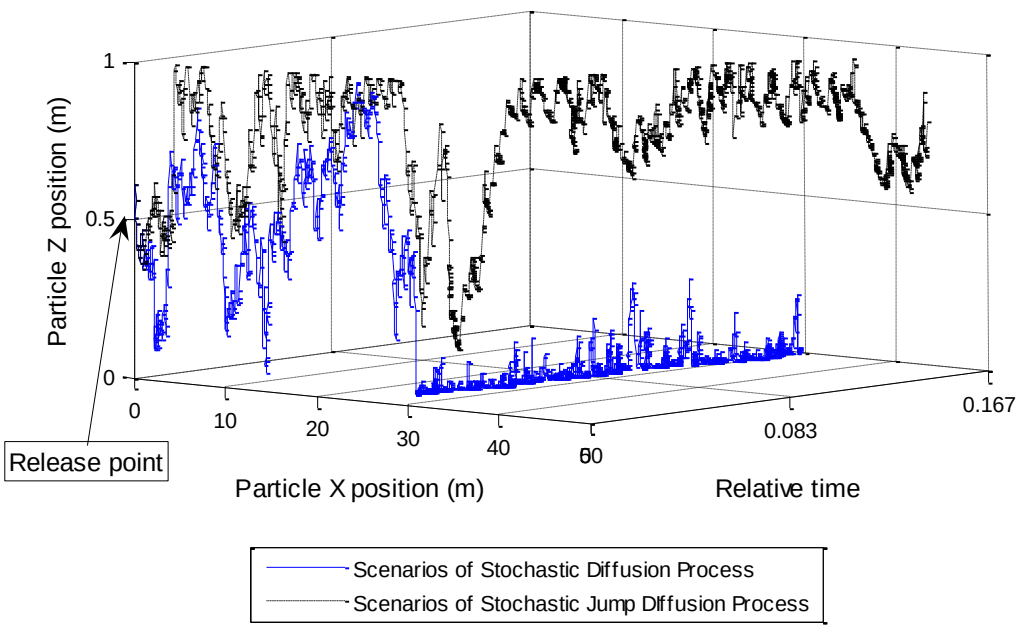

Figure 1. Sediment particle trajectories in a 2-D flow

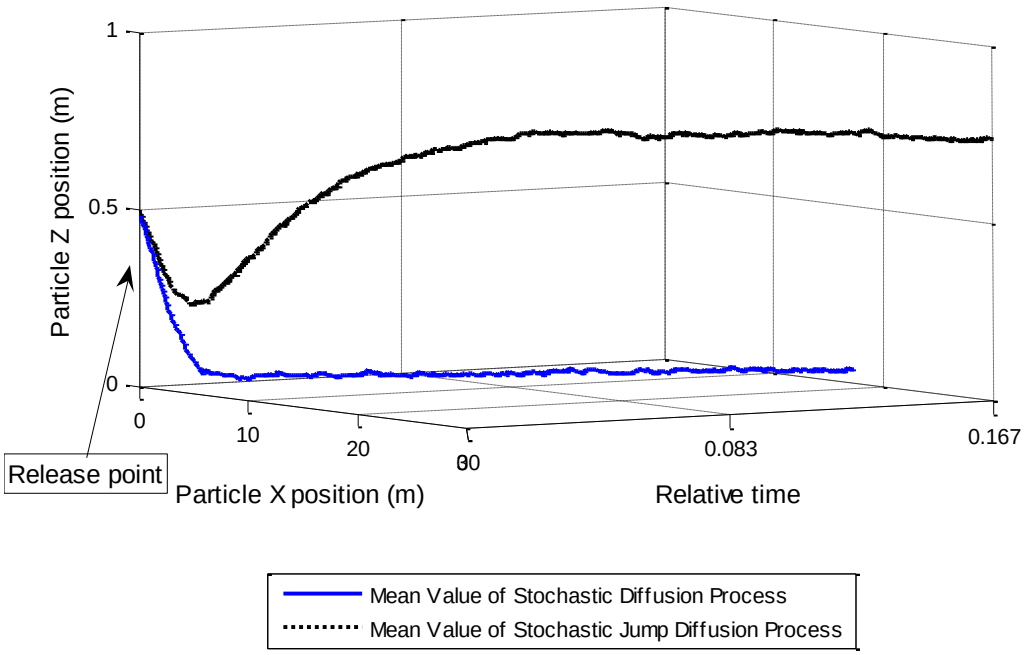

Figure 2. Ensemble mean of sediment particle trajectories in a 2-D flow

Case 2: Considering bed shear stress

Movement of sediment particles in open channel flows can be simulated including deposition / resuspension in the following examples. Herein, deposition / resuspension of sediment particles can be determined by comparing the bed shear stress with the critical shear stress. Since the bed shear stress is probabilistic attributed to stochastic particle velocity, we can obtain various realizations of particle trajectory. Figure 3 demonstrates the deposition / resuspension of sediment particles in an open channel flow. In this example, a sediment particle is also released at the center of the channel depth. Compared to Figure 1, because of the critical shear stress criterion, a particle is subject to less frequent resuspensions. The flow velocity needs to exceed the critical shear stress for particle incipient motion. The critical shear stress is 0.1 Pa for particle size 0.1 mm. Figure 4 illustrates the ensemble means of 500 simulations of the scenarios in Figure 3. From the comparison of Figures 2 and 4, it is demonstrated that the ensemble mean particle trajectory, when considering the bed shear stress criterion, travels farther longitudinally and is subject to less frequent resuspensions on the average. Also, particles in the presence of extreme events are prone to resuspensions, as can be seen in Figures 2 and 4. Overall, as shown in Figures 3 and 4, in the occurrence of extreme flow events, particles are prone to entrainment and resuspension.

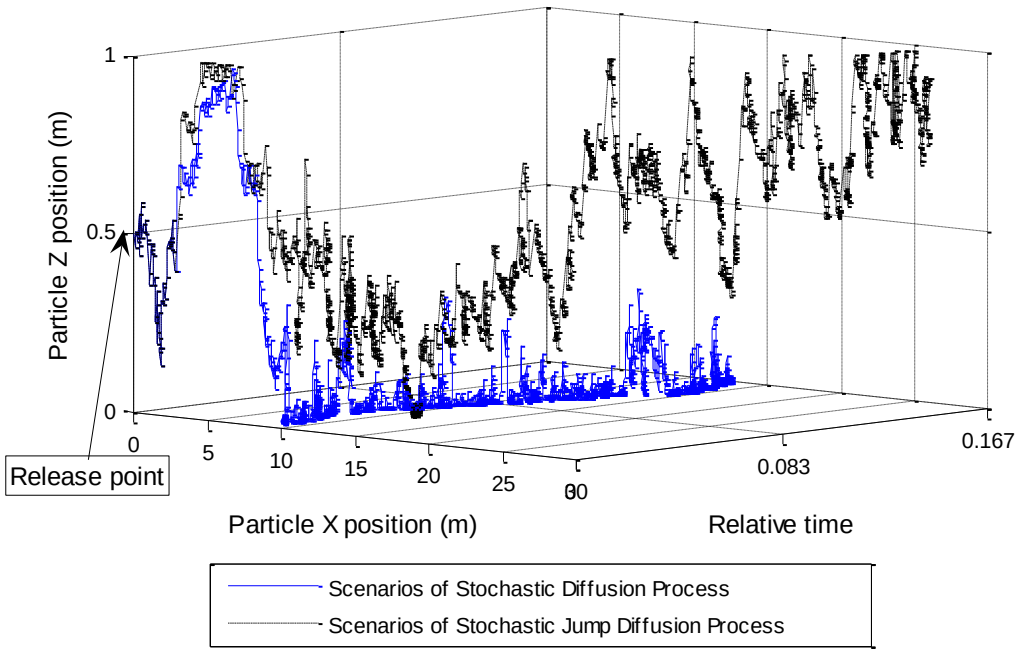

Figure 3. Sediment particle trajectories (depositing) in a 2-D flow

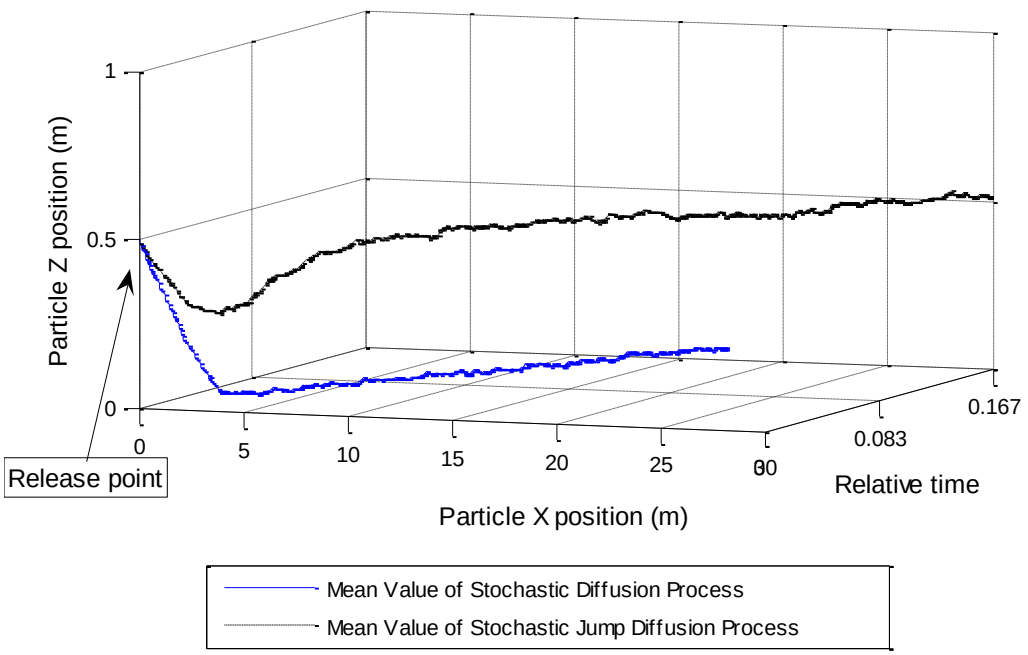

Figure 4. Ensemble mean of sediment particle trajectories in a 2-D flow

Particle Deposition and Resuspension

Figure 5 shows the position of 200 particles with respect to time after being released at the center of the channel depth. Figure 5 demonstrates diffusion, deposition and resuspension of particles. Figures 5 presents particle deposition and resuspension without any extreme flow events during total simulation time, i.e., particles move under the influence of subcritical flow (Fr = 0.13). The critical shear stress is 0.1 Pa for particle size 0.1 mm.

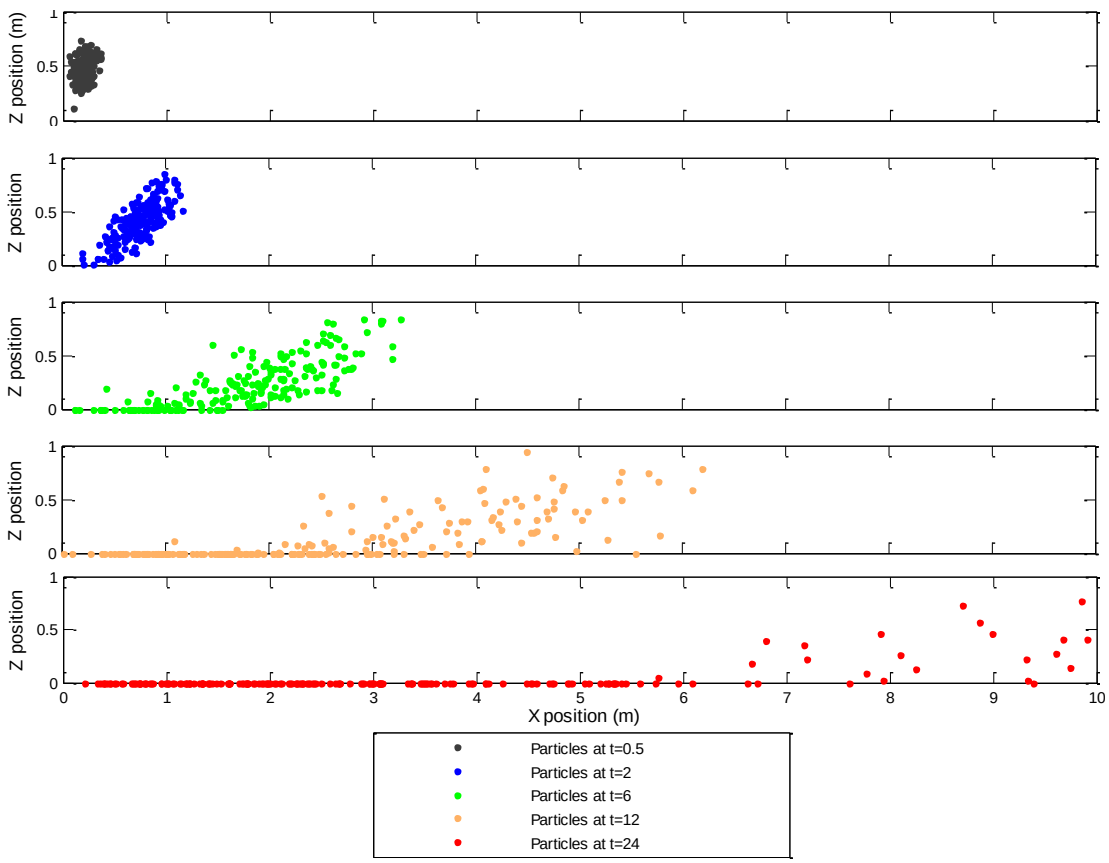

Figure 5. Snapshots of particle mass movement for each time

CONCLUSIONS

The proposed stochastic jump diffusion particle tracking model (SJD-PTM) can be developed to simulate deposition and resuspension of sediment particles in open channel flows. Movement of sediment particles in open channel flows is under the influence of the bed boundary effect. In this study, we attempt to use a logarithmic velocity profile to discuss the bed boundary effect such as deposition / resuspension processes of the particles. The channel surface and bottom are bounded and then whether sediment particles settle down on the bed or resuspend from the bed can be determined. Simulation of particle deposition and resuspension

is achieved by employing the logarithmic velocity profile formulae and the stochastic bed shear stress. As a result, the stochastic property inherently included in deposition / erosion processes is realized by the randomeness of bed shear stress from the stochastic instantaneous flow velocity. The particle trajectory in a regular flow in the previous examples presents the deposition and resuspension patterns of particles in a regular flow (Figure 5). The occurrences of extreme flow events result in net particle entrainment due to larger flow capacity carrying sediment particles (Figure 3). The proposed model is expected to predict the geomorphological changes due to scouring and deposition, which is important to channel bed and bank stability. Besides, since extreme flow events tend to result in non-equilibrium conditions, a non-equilibrium model is more realistic when estimating the effect of extreme flow events on sediment transport.

Numerical Model of Channel Meandering in the Middle Sacramento River

Jianchun Huang, Ph.D., P.E., David R. Varyu, M.S., and Blair P. Greimann, Ph.D., P.E.

Sedimentation and River Hydraulics Group, Technical Service Center, Bureau of Reclamation, Denver, CO 80225 USA (vhuang@do.usbr.gov)

Abstract

SRH-Meander was used to predict the channel migration in the Middle Sacramento River. SRH-Meander is a model developed in the Technical Service Center, Bureau of Reclamation to simulate the bed topography, flow field, and bank erosion rate in a curved channel with an erodible bed. The study area extends 101 miles from Red Bluff (RM 243) to Colusa (RM 142).

The model was first calibrated by comparing the simulated channel alignment to the actual channel alignments for the period from 1976 to 1999. The erosion coefficients and the cutoff ratio were adjusted during the calibration. The calibrated model was used to predict the channel alignment in 2019 starting from the channel alignment in 1999. The terrain elevation was updated by tracking the erosion or deposition in the channel and by exchanging information between the 1D channel and 2D terrain.

1. Introduction

Because most hydraulic and sediment transport models assume the channel position stays fixed in the horizontal plane, a channel migration model (SRH-Meander) must be used to predict future channel alignments in response to variable hydrology, upstream sediment supply, and bank material conditions. Channel migration is helpful to the colonization of cottonwoods because channel migration creates bare soil on which seedlings can establish. A channel migration model can be used to evaluate whether the channel can migrate outward and downstream in areas targeted for cottonwood establishment, or whether the channel is constrained by natural geomorphic features or human placed bank protection. If the channel cannot migrate outward and create a new bar surface, cottonwoods can have a difficult time establishing because the area of a point bar where they germinate is repeatedly reworked causing desiccation of any seedlings that do establish.

The model was first calibrated with the channel alignments in 1976 to 1999. The calibration process adjusted the erosion coefficients and the cutoff ration. After calibration the model was validated by comparison between the simulated and filed 2004 alignments. The model was used to predict the channel alignment in 1999 starting from the channel alignment in 2019. The averaged channel character values, such as mean radius of curvature, half wave length, entrance angle, sinuosity, and migration rate, were calculated for different restoration strategies. The terrain elevation was updated by tracking the erosion or deposition in the channel and by exchanging information between the 1D channel and 2D terrain.

2. Model description

SRH-Meander is a computer model that simulates the bed topography, flow field, and bank erosion rate in curved channel with an erodible bed. In each time step, SRH-Meander first calculates the flow field based on the standard step method, normal depth method, or a predefined table. It then computes the channel bank erosion rate. Finally, the channel alignment is updated with the erosion rate, followed by the channel cutoff if needed. The model can be used to predict the channel migration in meandering rivers

SRH-Meander uses the meander method proposed by Johannesson and Parker (1989). It is a re-derivation of the analysis by Engelund (1974). The basic idea behind these analyses is to write the flow variables as a sum of two parts. The first part is the solution to the case of flow in a straight channel. The second part is equal to the deviation from the straight channel solution for the case of a slightly curved channel. The deviation is assumed to be linearly related to the maximum curvature of the channel. These perturbed flow variables are substituted into the 3D flow equations. The equations are then simplified and grouped into the terms responsible for the straight channel solution and those due to the channel curvature. The equations become ordinary differential equations and can be solve analytically or through relatively simple numerical methods. The sediment transport is assumed to be a function of the local velocity and shear stress.

Sun at al. (2001a, b) improved Johannesson and Parker's (1989) linearization theory to calculate bank erosion in river meanders by incorporating multiple-size sediment transport equation. Johannesson and Parker (1989) assume the bank erosion rates are related to the near-bank depth-averaged flow velocity, which is calculated by a small perturbation approach. The near bank depth-averaged flow velocity is decomposed into two parts: the component characterized by local curvature forcing (e.g. point bars) and the component characterized by the free system (e.g. alternate bars).

SRH-Meander extends the linearization analyses of Johannesson and Parker (1989) and Sun et al. (2001a, b) to include the sediment mass balance. The incoming and exiting sediment in a reach are calculated by a non-equilibrium sediment transport model. The sediment erosion or deposition is calculated using a sediment mass balance between the incoming and outgoing sediments and sediment erosion due to bank migration. The channel width is assumed to be constant. The terrain elevation is updated by tracking the erosion or deposition in the channel and by exchanging information regarding bed elevation and bed material fractions between the 1D channel and 2D terrain.

3. Model Calibration

A calibration to historic meander rates was completed because "it is not possible to determine the erodibility coefficients a priori, based on bank properties, presence of vegetation, etc." for real rivers without "calibrating the erodibility coefficients on field observations" (Crosato, 2007). The period of record used for model calibration was from 1976 to 1999. This interval was chosen based on the availability of data and the quality of that data. Selected sub-reaches of the study reach (river mile 243 to river mile 142) were isolated to simplify the calibration process. Due to the space limit of this paper, only one sub-reach from RM 224.5 to RM 218 is presented here. The data collected and used for the calibration of the middle Sacramento River is described below, but in general, the source and quality of data will vary for each project and vary the results.

Flow data from gages operated by the State of California Department of Water Resources (CDWR) were utilized for model calibration. Mean daily flows for the period of record from 10/01/76 to 09/30/99 for CDWR gage 'VIN' were used for the selected reach.

Profile and cross-sectional geometry information was taken from a United States Corps of Engineers publication, "Sacramento and San Joaquin River Basins, Comprehensive Study" (U.S. Army Corps of Engineers, 2002). This study produced a HEC-RAS geometry model of the river that was used in this study. River planform geometry was made available by CDWR in the form of aerial photographs and GIS maps consisting of traces of the active channels.

From the 2002 USACOE publication, information on channel roughness, namely Manning's roughness coefficient values, was obtained. Also from the study, information on bed material size was gathered and used as input to the model.

No modifications were made to the flow data acquired from CDWR. However, a filter is present in SRH-Meander so that flow data that may not effect river meandering can be excluded. For instance, it is generally accepted that base flows do not cause changes in channel morphology. However, due to the linear nature of the computer model, these base flows yield a calculated meander length, however minor. Conversely, when flows of a river exceed the carrying capacity of a channel, the excess flow spills out on to the floodplain, and the excess flood waters have little affect on channel-forming processes. Without an imposed upper bound on the flow rates, the rate of bank erosion would increase as the flow rate increases even above the bank full discharge. Thus, an upper limit above which the flow is capped and lower limit below which the flows are ignored was applied to the input flow data set. Based on the flow hydrograph and the results of the RAS model, lower and upper limits of 35,000 and 90,000 cfs, respectively, were used for the Sacramento River.

The HEC-RAS model associated with the 2002 USACOE study was used to derive cross-sectional and profile geometry parameter values. Rather than assume a cross-sectional shape and associated descriptive parameters (e.g., sideslope and bottom width for a trapezoidal cross-section) to represent the river, a more generic approach was taken. The HEC-RAS model was run with a series of steady flow rates. Cross-sections were sorted by sub-reach, and average hydraulic parameters were calculated. The geometry parameters were tabulated into a format that SRH-Meander can interpret. Thus, for each sub-reach, a table was created with flow rates from 30,000 to 90,000 cfs along with associated sub-reach averaged values for velocity, friction slope, hydraulic depth, top width, and hydraulic radius. SRH-Meander linearly interpolates hydraulic parameters for flow rates between the tabulated values.

The GIS maps made available by the DWR were used for planform geometry data. The SRH-Meander meander model uses a GIS point file (which represents the centerline of the river) to compute radii of curvature and other parameters which are necessary to estimate the rate of river meander. The GIS maps provided by the DWR contained polygons which depicted the 'active' channel alignments for various years. It was necessary to digitize a polyline (representing the centerline) based on the polygons provided by CDWR, and further transform the line into a point file. A polyline was digitized in ArcGIS to represent the centerline of the 1976 channel and the 1999 channel, which are the 'starting' and 'ending' conditions to which the model was to be calibrated.

In addition, a valley axis for the 1976 channel was digitized, which is used in the computation of channel cutoffs. The cutoff ratio is a calibration parameter. When the length of the channel divided by the length of the valley exceeds the cutoff ratio, the model allows a cutoff to occur. The cutoff ratio for the sub-reach was adjusted during the calibration process.

To calibrate the model, the simulated channel alignment was compared against the actual channel alignment at the end of the time interval being modeled. An iterative approach was taken in calibrating the model to the sub-reach. Erosion coefficients were adjusted after an observed model run as necessary until the model output alignment represented the actual channel alignment sufficiently well.

Table 3-1 presents a summary of the parameters – both calibration parameters as well as those determined before calibration – used during calibration of the SRH-Meander model to the Sacramento River. All of the erosion coefficients are not listed, but rather the minimum, average, and maximum values for each sub-reach are presented.

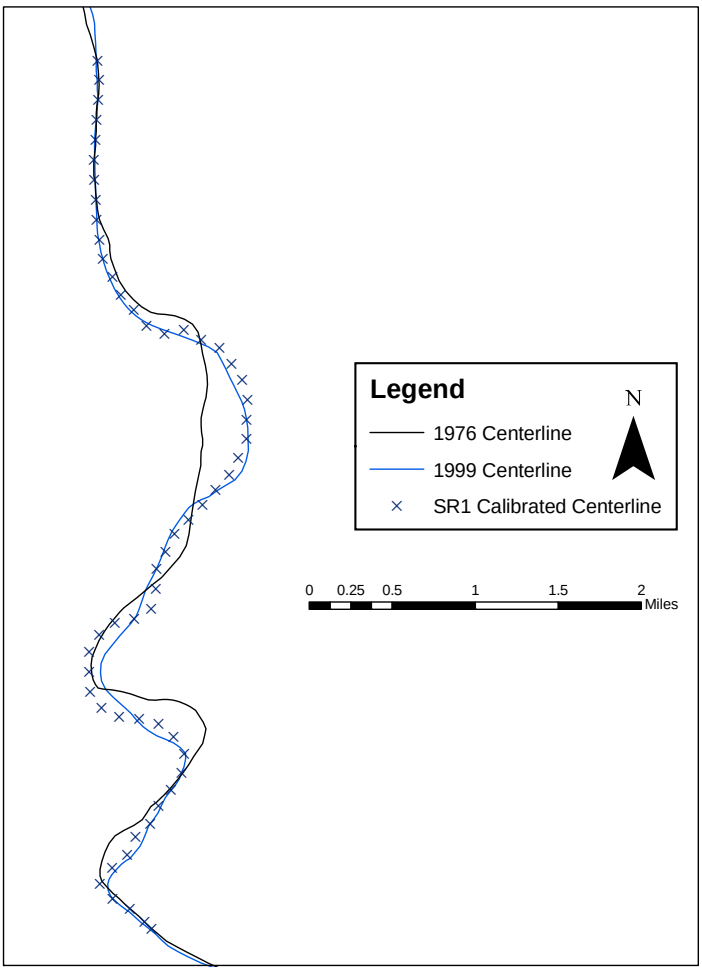

Figure 3-1. displays the centerline for the 1976 channel, the centerline for the 1999 channel, and the SRH-Meander output nodes representing the model output channel centerline.

Table 3-1. Summary of parameters used during SRH-Meander model calibration

Pre-determined parameters	**Ave. Channel Width (ft)**	1058
	Manning n (-)	0.032
	Ave. Energy Slope (ft/ft)	0.00056
	Bed Material Size (mm)	14
	Number of Polygons	18.00
Calibration parameters	**Grid Spacing (-)**	0.6
	Cutoff Ratio (-)	2.0
	Min. Erosion Coefficient (-)	9.80E-08
	Ave. Erosion Coefficient (-)	7.23E-05
	Max. Erosion Coefficient (-)	3.80E-04

The average absolute distance of the model output coordinates to the actual channel centerline was 46 feet. This value is small relative to the average channel top widths of 1,058 feet. Adjusting the grid spacing for each sub-reach yielded slightly better results, but for the sake of consistency one grid spacing value was determined for all sub-reaches. The value of 0.60 for the grid spacing agrees with the finding of Crosato for numerical meander models that the "optimal distance between successive grid points had the order of half the channel width" (Crosato, 2007).

In general, the SRH-Meander was better at modeling changes in bend amplitude than at modeling bend translation. Whether the model predicts translation versus amplification is primarily a function of the channel roughness input parameter combined with the calculated curvature of the centerline. Calibrating one bend with a given curvature may cause poor model performance in a subsequent bend of similar curvature. Another limitation of SRH-Meander lies in modeling portions of a river that migrate 'inward'; that is, when the bend amplitude decreases rather than increases and the river slightly straightens. This process is usually due to local chute cutoffs as opposed to larger scale neck cutoffs. Meander cutoffs within SRH-Meander depend on the input valley axis, and it effectively only allows for neck cutoffs. The model does not have the capability to account for straightening phenomenon, especially for two continuous bends. The only successful inward migration caused with SRH-Meander involves an over-amplification of the immediate upstream or downstream bend.

Correlating the erosion coefficients resulting from the model calibration to the existing bank properties as provided by CDWR was attempted. A meaningful correlation between existing bank properties and the calibrated erosion coefficients was not identified. It is hypothesized that the bank properties being considered reflect only at most the last couple years of a twenty-four year modeled time interval (1976-1999). In SRH-Meander, one polygon, representing one erosion coefficient, reflects the outer-bank of a bend for the entire time interval simulated. As a river meanders across its floodplain, different materials are encountered, the bank height and angle will change, geological controls may be reached, and unknown riprap may have been placed at any time during the modeled interval. Thus, the next step of the correlation process is to gather and apply more historical data to the problem to represent the conditions spanning the entire time interval and not just the last few years of the time interval. Ideal data to collect includes the time and location of riprap placement, aerial photographs for many years within the modeled time interval, and a geospatial mapping of soil types across the floodplain, which includes soil data for regions below the surface soils. When more time-dependant information becomes available, the SRH-Meander model may be re-calibrated with additional erosion coefficient polygons to reflect changes in bank properties through time.

The above limitations do not allow for future river meander prediction that would occur if bank properties were changed (e.g., riprap removed or added) due to the inability to predict an erosion coefficient based on bank properties. The model is currently capable of determining the most likely areas of future channel migration as a function of in-flow hydrographs, which would be based on release management actions occurring at Shasta and Keswick Dams. A correlation is anticipated with the collection of more historical data representing the modeled time interval.

4. Model Prediction

The calibrated model was used to predict the channel alignment in 2019 with initial channel alignment taken from 1999 photography, the CALSIM simulated hydrology at Red Bluff Diversion Dam, and lateral flows. The erosion coefficients, the channel roughness, the grid spacing, the cutoff ratios, and all other parameters were kept unchanged from the calibration model. The 2004 photography was used to verify that the predicted channel alignment was reasonable.

The future flows were taken from a water operations model (CALSIM II) that used a monthly time step. The monthly flows were downscaled to daily flows. The operations model using historical hydrologic conditions and the period from 10/1/1983 to 9/30/2003 was used to predict channel meander from 1999 to 2019. Flow data from the gage at Red Bluff Diversion Dam (RM 243.0) was used as upstream incoming flow. Three different alternative flow scenarios were simulated, corresponding to various water operations strategies. For the purposes of this paper they are designated as FNA, WQ1B, and AF1B.

The predicted channel alignment in 2019 is shown in Figure 4-1. The Sacramento River continues to meander at the same rate. Results show that a channel cutoff might happen at the largest bend in this subreach unless the channel bank is stabilized at this location.

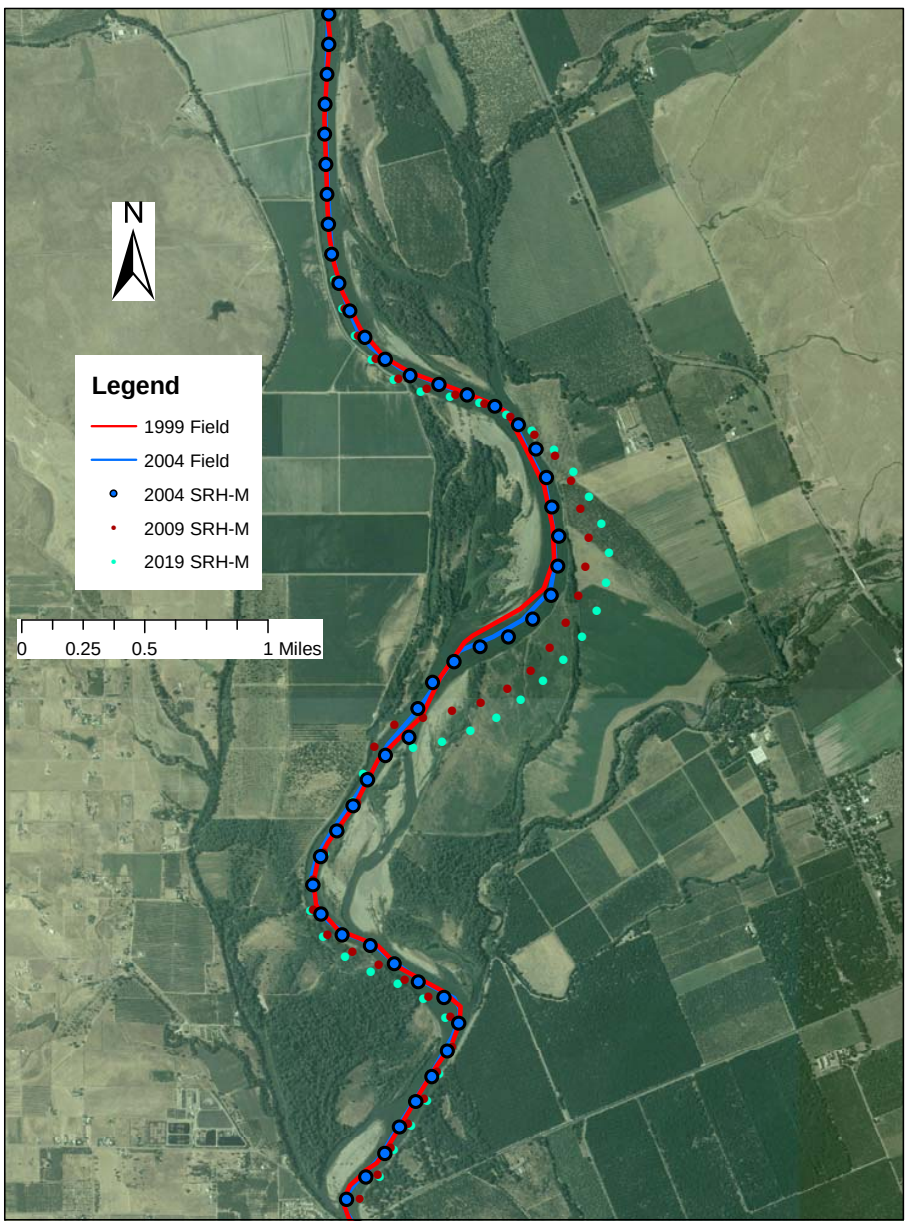

Figure 4-1. SubReach 1 prediction results

Figure 4-2 compares the channel migration rates with historical data (Larsen, 2007). Larsen mapped the channel centerlines in the middle Sacramento River from Red Bluff to Colusa from historic topographic maps (1904) and aerial photographs (in 6 time periods between 1937 and 1997). The channel migration rates are calculated for progressive migration, partial cutoff, and partial chute cutoff. Progressive migration is lateral channel adjustment that occurs via a continual and gradual process of bank erosion. Chute cutoffs occurs when overbank flows are sufficient to concentrate shear stresses to a degree capable of carving a new channel across the floodplain. "The partial cutoff category describes episodes of channel avulsion that affect only a portion of a meander bend" (Larsen, 2007). Since SRH-Meander cannot distinguish chute and partial cutoffs, the results are given for progressive migration and cutoff. Results show similar trends of migration rates with historical data. The progressive migration rate is about 4.1 m/year for FNA and AF1B, and 4.0 m/year for WQ1B. The cutoff migration rate is about 15.5 m/year for FNA and AF1B, and 15.4 m/year for WQ1B.

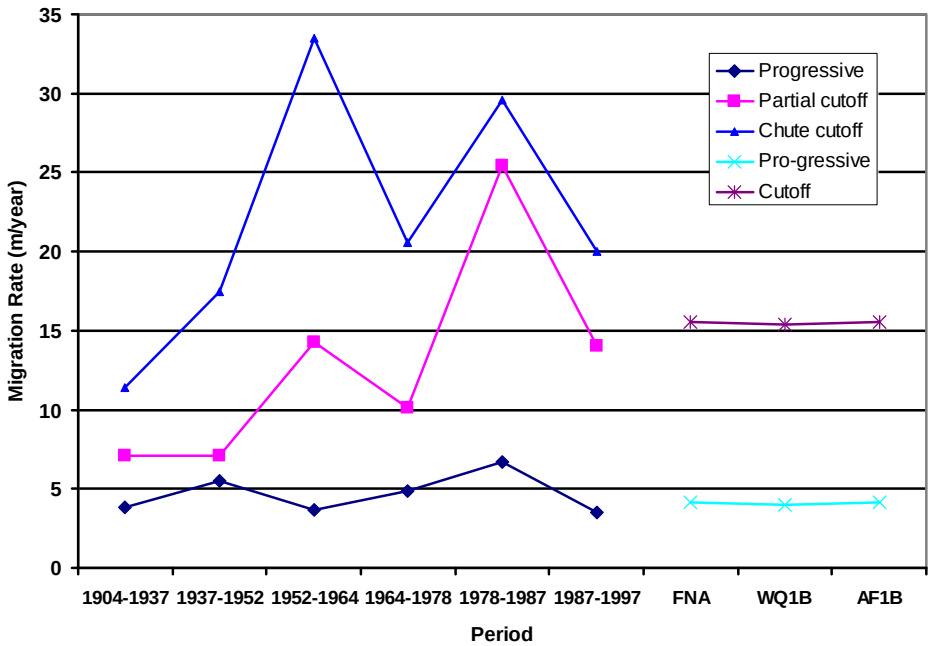

Figure 4-2. Predicted Dimensionless Migration Rates compared with historical data (Larsen, 2007)

SRH-Meander also can calculate terrain elevation changes during channel migration. The model calculates the terrain elevation by tracking the erosion or deposition in the channel and by exchanging information regarding channel elevation and bed material between the 1D channel and 2D terrain. During the simulation, the channel width was assumed constant. 2D terrain elevation was stored in a raster format generated with ARC-GIS. Since the 2D data required huge memory and the study reach covers about 100 miles, the study reach was divided into 7 sub-reaches to obtain high resolution in representing terrain elevation. Figure 4-3 shows the terrain elevation for the initial year 1999 when the field data is available. Figure 4-4 shows the predicted terrain elevation in 2019. Elevation data are only available in 1999 and no other data is available to determine the accuracy of SRH-Meander in predicting terrain elevation revision due to channel migration. Figure 4-5 shows the predicted terrain change from 1999 to 2019, which displays the erosion (red) near the outside of the bend and deposition (green) near the inside of the bend. The black polygon shows the total area that the channel would have swept in the 20-year period. Accurate prediction of terrain elevation change is helpful to determine the area targeted for cottonwood establishment.

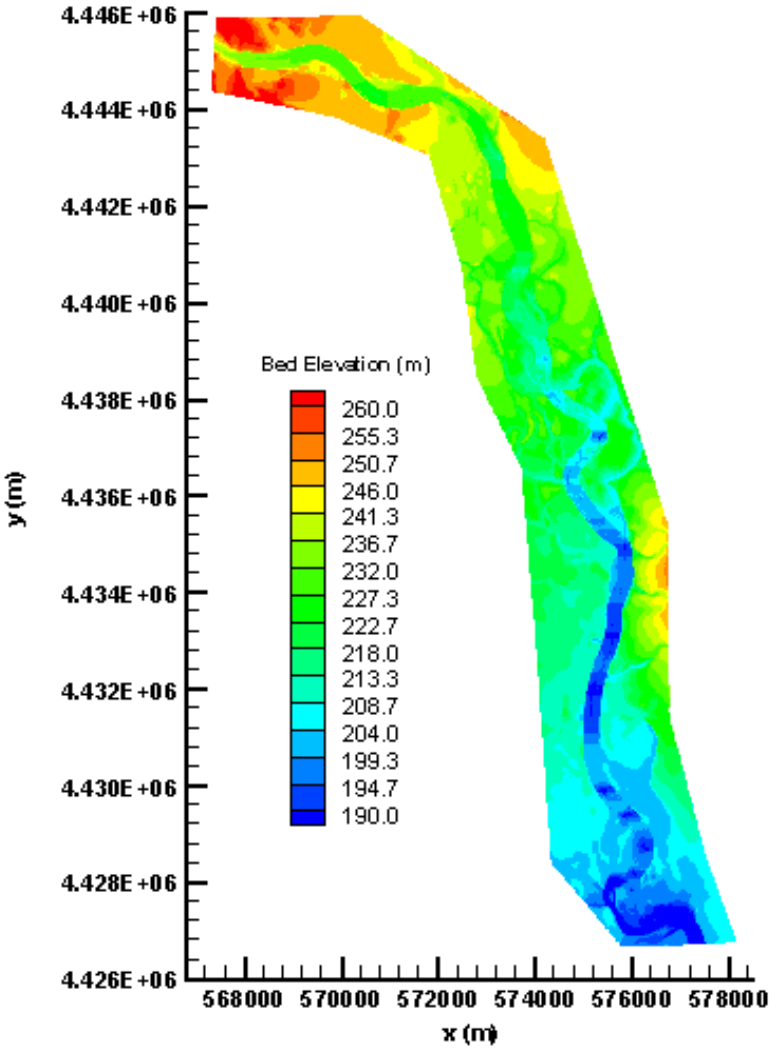

Figure 4-3. Initial terrain elevation in 1999

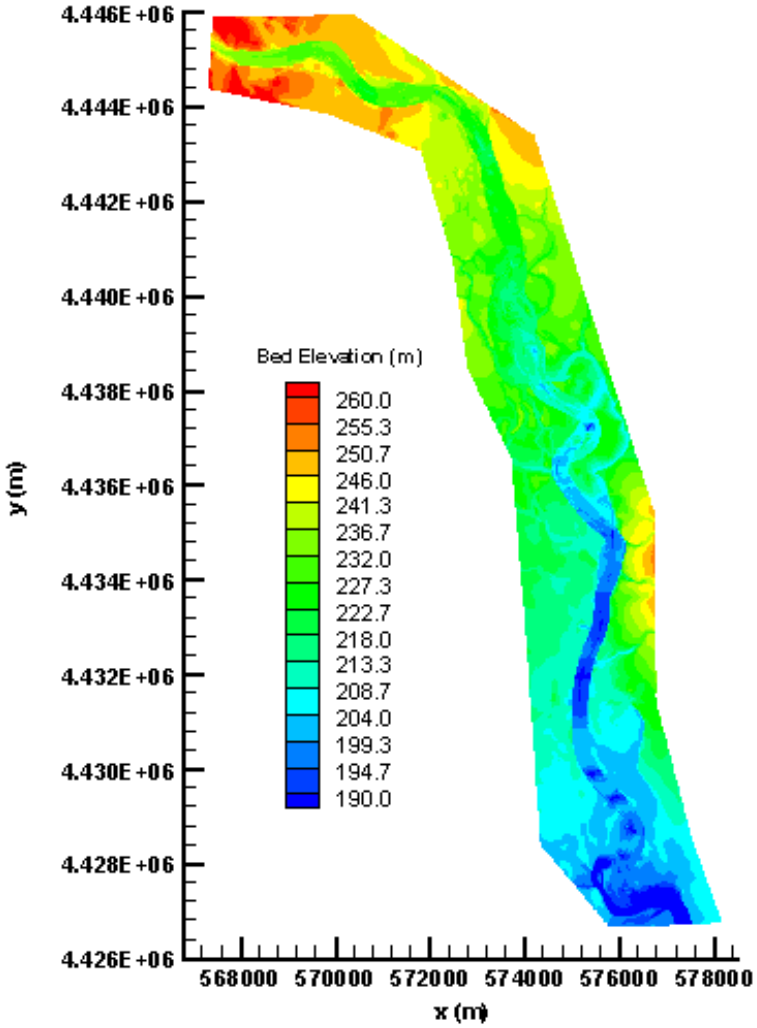

Figure 4-4. Final terrain elevation in 2019

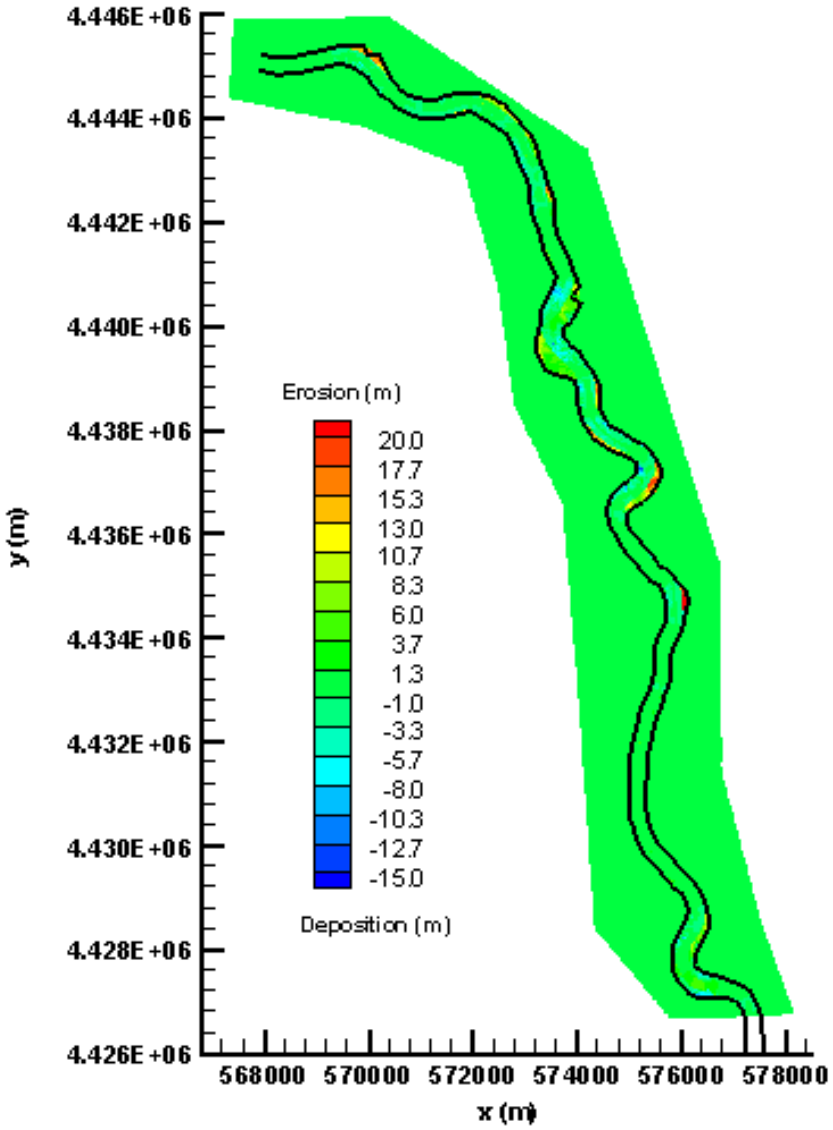

Figure 4-5. Terrain elevation change from 1999 to 2019

5. Summary

The SRH-Meander model was used in the Middle Sacramento River extending 101 miles from Red Bluff (RM243) to Colusa (RM142) to predict the channel migration. The model was first calibrated with the channel alignment from 1976 to 1999. The model reproduced the general movement of most large bends in the river. The average absolute distance of the model output coordinates to the actual channel centerline was 46 feet. This value is small relative to the average channel top widths of 1100 feet. The calibrated model was used to predict the channel alignment in 2019. The terrain elevation was also calculated and the results could be used to evaluate whether the channel can migrate outward and downstream in areas targeted for cottonwood establishment.

ABSTRACT

Impact of deep sand and gravel mining pits (with a depth of 10 meters) on flood zone coverage and riverbed change of the Rio Salado, Salt River, Phoenix, Arizona were simulated using one- and two-dimensional numerical models. Two commonly used models are applied in the study, i.e., HEC-RAS and CCHE2D. HEC-RAS is a one-dimensional hydrodynamic and sediment transport model developed by the U.S. Army Corps of Engineers, while CCHE2D is a depth-averaged two-dimensional hydrodynamic and sediment transport model developed at the University of Mississippi. The bed material was treated as three layers on the channel bed with multiple grain-sized sediment mixtures. Changes in bed elevation were calculated by solving the sediment mass conservation equation. The modeling results of CCHE2D were compared with the HEC-RAS modeling results and field observations, which showed that the 2D model was more robust in simulating flood zone coverage, non-uniform sediment sorting, and channel geomorphologic changes.

INTRODUCTION

The Salt River (Rio Salado in Spanish) drains 14,500 square miles of mountainous desert terrain in central and eastern Arizona and is the largest tributary to the Gila River in Arizona. The river originates in eastern Arizona and flows westward to its confluence with the Gila River west of downtown Phoenix (Figure 1). Prior to agricultural development and urbanization of the Phoenix metropolitan area, the Rio Salado was a perennial stream fed by snowmelt from mountains in eastern Arizona. Flow in the river had a distinct seasonal pattern, with highest flows occurring in December and January and lowest flows in October. The yearly-averaged discharge was about 570 cfs before 1938. However, perennial flows on the Salt River have ceased due to dam and diversion construction in the early 1900s. In the early part of the 20th century, major modifications to the river system occurred as part of the Salt River Project, which placed several dams along the Salt River to allow diversions of water for agricultural and urban uses. Sand and gravel

mining operations and development along the river induced additional changes to the river channel and hydrology. The materials extracted from the river have been used extensively throughout the development of the Phoenix Metropolitan area. Since 1965, the channel has carried a yearly-averaged discharge of only 400 cfs, with less than 14 cfs in almost three-fifths of the years (USACE, 2005). Now the water in the channel is dominated by the releases from upstream dams. The highest recent discharge occurred on February 13, 2005, of approximately 35,000 cfs as recorded by the USGS gauge at 51st Avenue (http://waterdata.usgs.gov/az/nwis/rt).

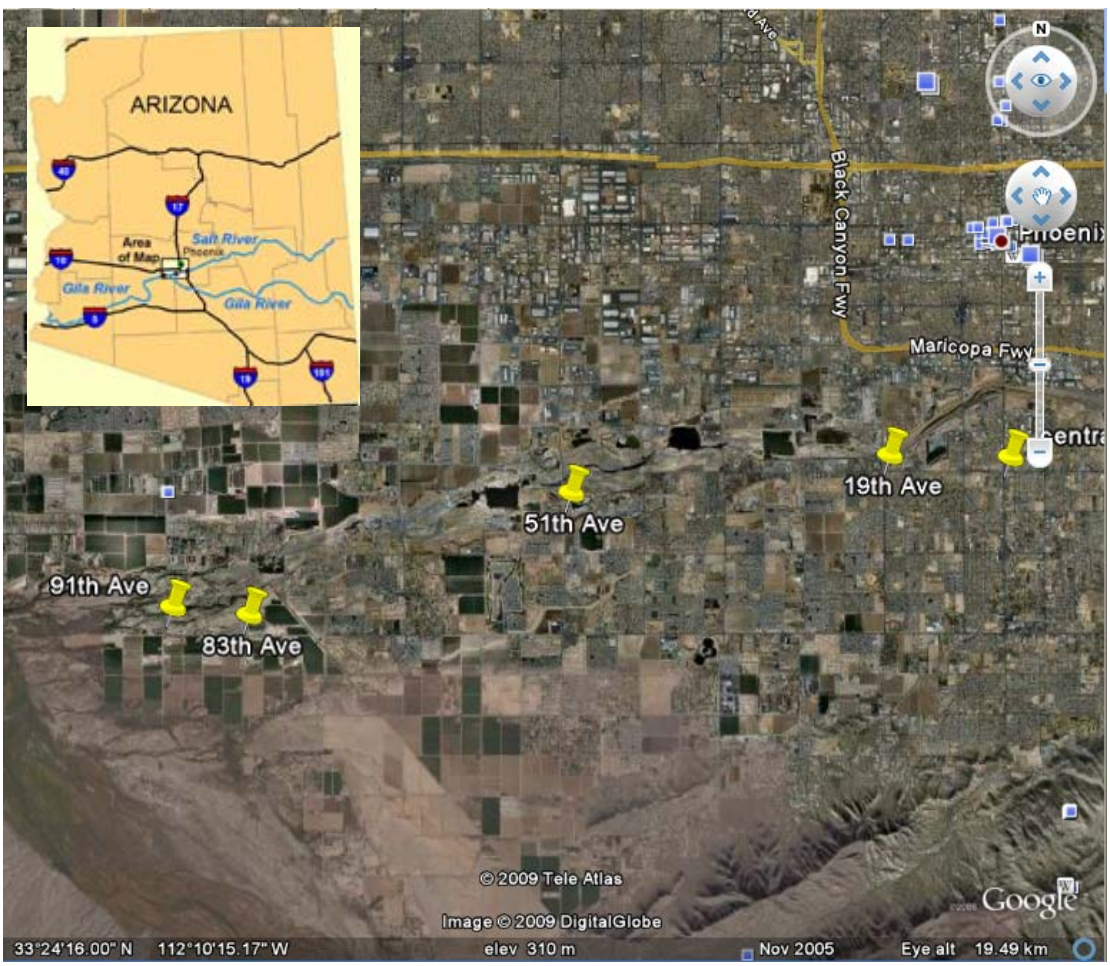

Fig. 1 Map of the Rio Salado, Salt River, Phoenix, Arizona

Sediment transport is an issue of importance in the Salt River special in the vicinity of city of Phoenix where recently unprecedented amount of growth has occurred. Previous sediment transport analyses have showed that sediment dynamics was more significant in the proximity of mining operations (USACE, 2005). Sand gravel mining has been going on in the Salt River for generations. There are numerous large mining pits in the Salt River around the city of Phoenix and the

demands of more mining pits are growing day by day (shown in Fig. 1). Sand and gravel mining operations can cause changes in channel geomorphology as well as hydrology. Therefore, it is very important to understand the sediment transport dynamics in the Salt River along with the impact of gravel mining pits along the river bed. This study was designed to understand the sediment transport dynamics due to various flood events and the impact of gravel mining operations in the Oeste reach of the Salt River. The Oeste reach (study reach) is approximately 9.5 miles of the Salt River extending from 19th Avenue on the east to 91rd Avenue on the west. The study area is within the boundaries of the City of Phoenix, Arizona.

Bed Material Gradation along the River

Bed material gradations along the channel were obtained through a combination of Pebble Count Method and Sampling Materials at five accessible locations (Chen et al, 2007). Less than 0.6% surface material consists of wash load (clay and silt) whose size is less than 0.0625 mm. About 2% bed material belonged to fine sand at 19th and 91st Avenues. Bed surface material mean size D_{50} ranges from 20mm to 40mm. More than 90% of the bed surface material consists of very coarse sand and gravels. Materials at the 51st Avenue are coarser than the bed material at other locations.

Introduction to HEC-RAS and CCHE2D

The U.S. Army Corps of Engineers' River Analysis System (HEC-RAS) is software that allows you to perform one-dimensional steady and unsteady flow river hydraulics calculations and sediment transport calculations. Both one-dimensional energy equation and momentum equation are considered in various situations including mixed flow regime calculations, i.e., hydraulic jumps, hydraulics of bridges, and evaluating profiles at river confluences. The effects of various obstructions such as bridges, culverts, weirs, spillways in the flood plain may also be considered in the computations. The sediment transport potential is computed by grain size fraction, thereby allowing the simulation of hydraulic sorting and armoring. HEC-RAS is widely used in engineering firms in U.S (USACE, 2002).

CCHE2D is an integrated package for two-dimensional simulation and analysis of river flows, non-uniform sediment transport, morphologic processes, coastal processes, pollutant transport and water quality. These processes are solved with the depth integrated Reynolds equations, transport equations, sediment sorting equation, bed load and bed deformation equations. This model is based on Efficient Element Method, a collocation approach of the Weighted Residual Method. Internal hydraulic structures, such as dams, gates and weirs, can be formulated and simulated synchronously with the flow. Dry and wet capability enables one to simulate flows with complex topography with ease. Three turbulence closure schemes, depth-averaged parabolic, mixing length eddy viscosity models and k- e model, are

available. The numerical scheme can handle subcritical, supercritical flows and their transition (NCCHE, 2005).

HYDRODYNAMIC SIMULATION

The effect of mining pits on inundated areas during different discharges was simulated in this study. Fig.2 provides an example of the calculated inundated areas with and without the mining pits at 500-year event. Based on Fig. 2, HEC-RAS and CCHE2D have similar calculated results which indicate that the inundated area has been reduced around the pits. However, this modification is minor comparing to the whole inundated area because the mining area only occupied a small part in the whole domain. Similar conclusions were drawn under other discharges which are not included in the report. However, our results suggested that mining pits altered the local flow direction and magnitude. Prior studies elsewhere have shown that over the years the Salt River around city of Phoenix has experienced severe bank erosion (USACE, 2005). The maximum riverbank shift has been as much as one-half mile in some locations through the area between 19th and 91st Avenues, Phoenix. The meander belt varies from approximately 2 miles in width at some places (19th Avenue) to approximately 4 miles in width at other places (91st Avenue; USACE, 2005). Previous sediment transport analyses have showed that sediment dynamics were more significant in the proximity of mining operations (USACE, 2005). However, the quantitative relation between bank erosion and gravel mining activities has not been formulated yet.

SIMULATION OF BED ELEVATION CHANGE

The effect of mining pits on bed elevation change was also simulated in this study. Fig. 3 and 4 show the bed topography change induced by gravel mining operation at 500-year flood event with HEC-RAS and CCHE2D models, respectively. Based on the simulation results, there was substantial erosion occurring upstream and downstream of the pits, however, the modeling results of HEC-RAS and CCHE2D model differed with each other. HEC-RAS results indicated serious head-cutting occurred upstream the pits, while CCHE2D results suggested “downstream erosion” was more noticeable. Modeling results of HEC-RAS showed the maximum bed degradation were 3.6 meters and 2.9 meters upstream of the Pit #1 and Pit #3, respectively. However, modeling results of CCHE2D exhibited the maximum bed degradation was 3.3 meters which occurred downstream the Pit #1. Besides, modeling results of CCHE2D indicated most sediment deposition was occurred in the upstream end of the mining pits. The maximum bed aggradations were 1.7 meters and 1.9 meters in the Pit #1 and Pit #2, respectively. Based on laboratorial/field observations and previous modeling study (Chen et al., 2008), the 2D model was more robust in simulating flood zone coverage, non-uniform sediment sorting, and channel geomorphologic changes.

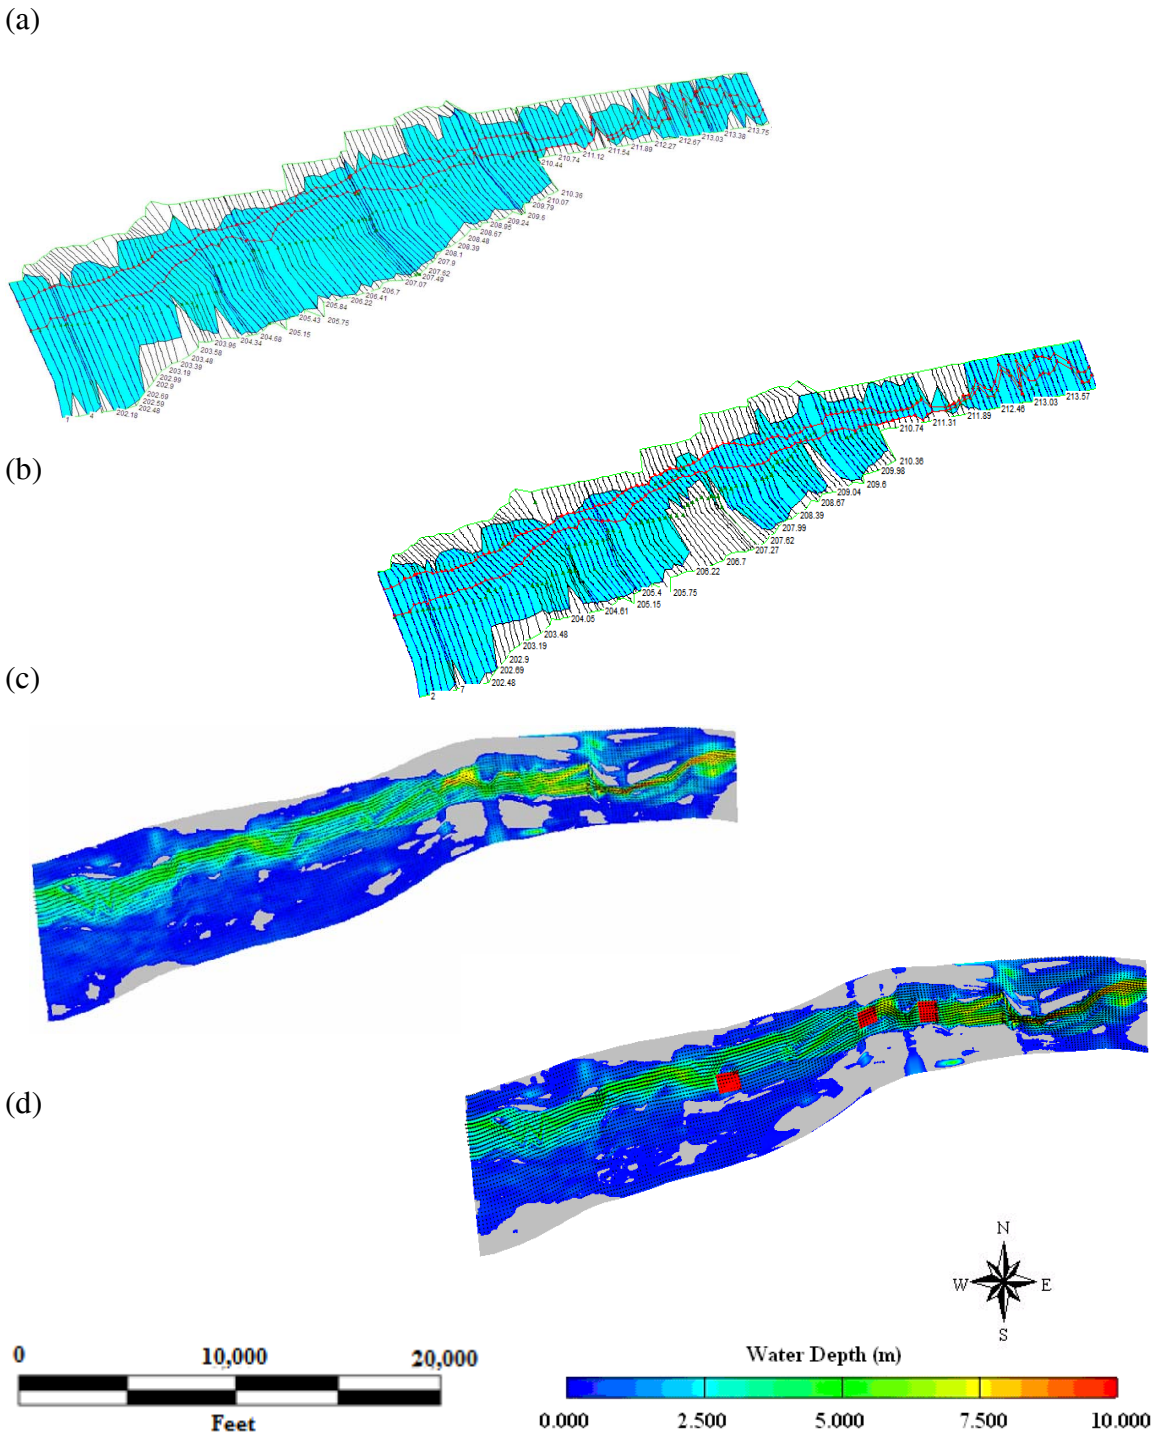

Fig.2. Calculated inundated areas at 500-year event (a) HEC-RAS without mining pits; (b) HEC-RAS with three 10m pits; (c) CCHE2D without mining pits; (d) CCHE2D with three 10m pits

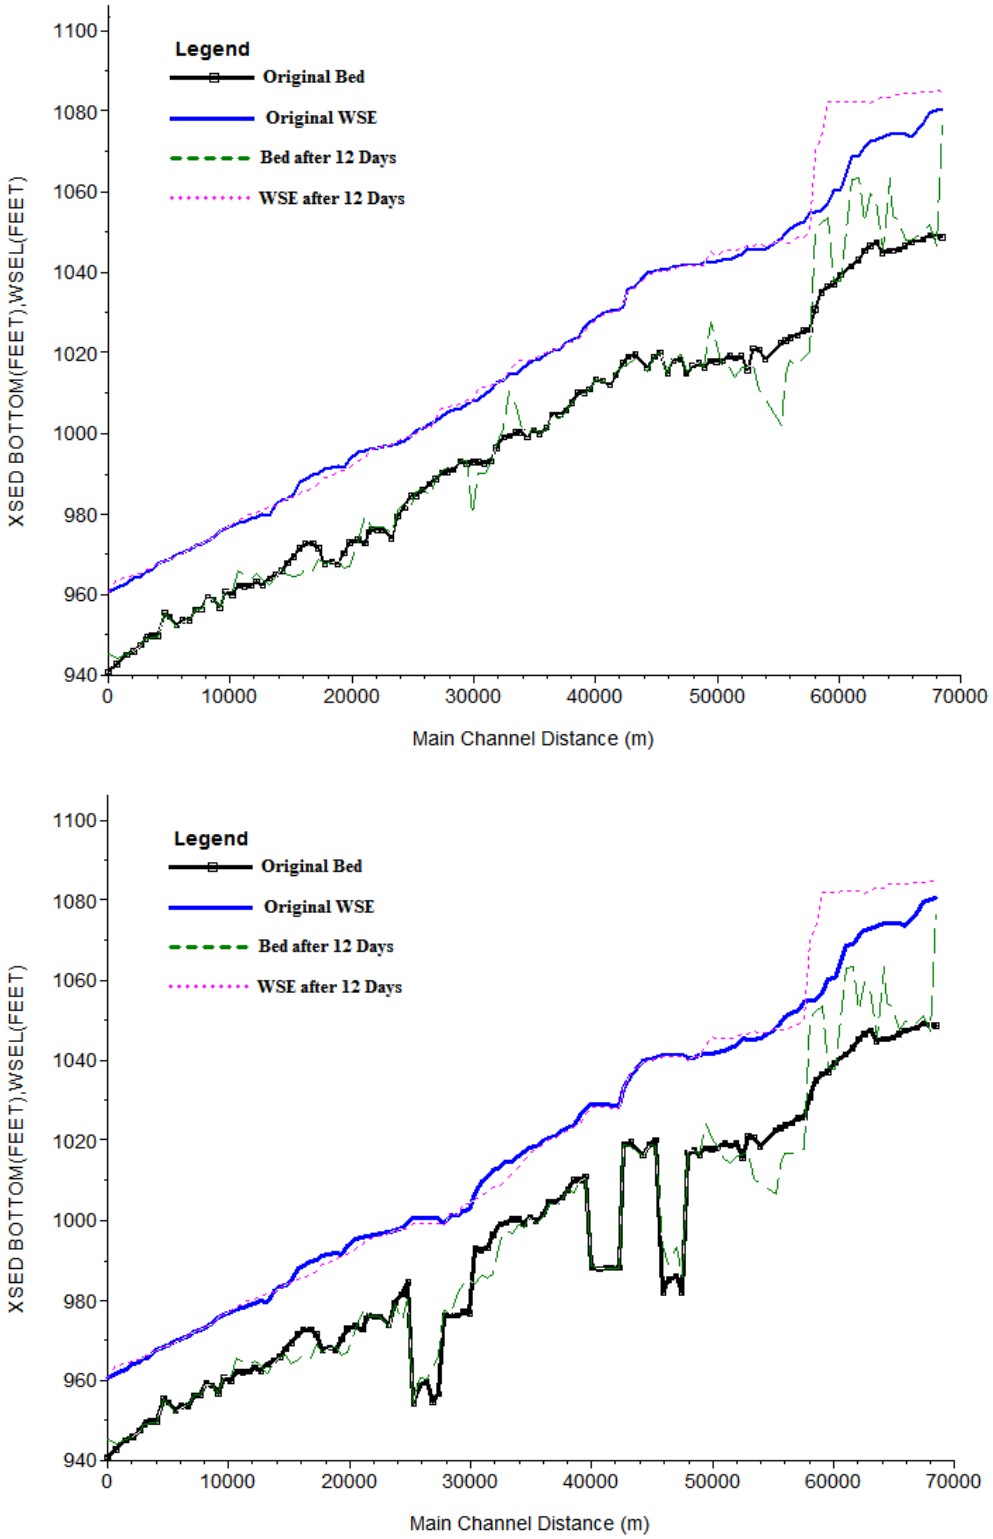

Fig. 3. Calculated bed topography change with HEC-RAS (a) without mining pits; (b) with two 10m mining pits (500-year event).

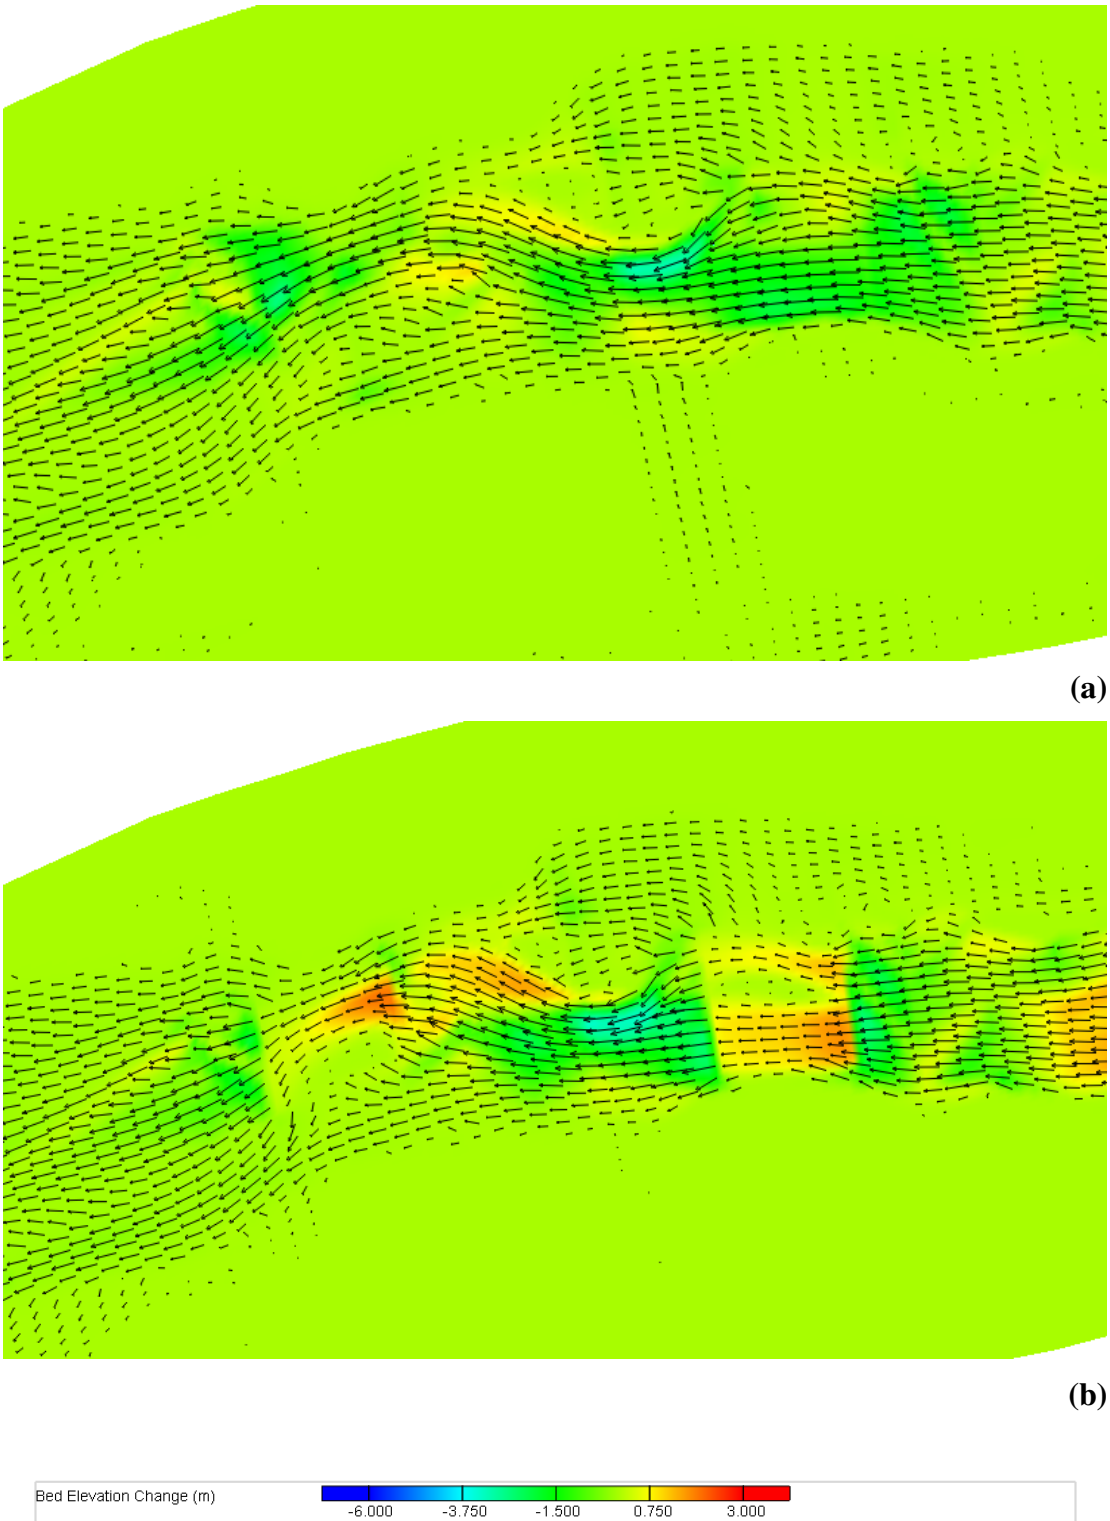

Fig. 4. Calculated bed topography change with CCHE2D (a) without mining pits; (b) with two 10m mining pits (500-year event).

CONCLUSIONS

Impact of sand and gravel mining on flood zone coverage and riverbed change of the Rio Salado, Salt River, Phoenix, Arizona were simulated using HEC-RAS and CCHE2D under 500-year frequency floods in the present study.

a) Hydrodynamic results of HEC-RAS are similar to the calculated results of CCHE2D. Presence of mining pits insignificantly reduced the inundate area, however, those pits changed the local flow directions and magnitudes which may accelerate stream bank erosion.

b) Bed Elevation calculated results of the two models differ with each other. There was substantial erosion occurring upstream and downstream of the pits, however, HEC-RAS results indicated serious head-cutting occurred upstream the pits, while CCHE2D results showed "downstream erosion" was more noticeable.

c) CCHE2D results indicated most sediment was deposited in the upstream end of the pits.

d) The 2D model was more robust in simulating flood zone coverage, non-uniform sediment sorting, and channel geomorphologic changes.

FUTURE STUDY

Flow structure around a deep mining pit (deeper than flow depth) has strong three-dimensional characteristics. The feasibility and accuracy of one- or two-dimensional models under those situations are unknown. We will look into the possibility of simulating deep mining pits in laboratories by using three-dimensional models and verified by measurements in our future studies.

ACKNOWLEDGEMENT

This study was funded by US Corps of Army Engineers (USACE), Department of Defense under Urban Flood Demonstration Program of Arid and Semi-Arid Regions (UFDP). We thank the personnel of Flood Control District of Maricopa County and Phoenix district office of the USACE for their assistance in data collection and providing over view of the sites. We would also like to acknowledge the National Center for Computational Hydro-science and Engineering at the University of Mississippi for CCHE2D model.

Effects of Gas Ebullition on Cohesive Sediment Resuspension and Cap Stability

ABSTRACT

Sediment resuspension can significantly contribute to the mass transport of sediment-bound contaminants into the overlying water column. This study considers the influence of gas ebullition (due to microbial activity) on resuspension rates as observations indicate that fine-grained sediments may be lifted into the water column in the bubble wakes. Capping aims to minimize contaminant migration to the water column by reducing sediment resuspension rates. In addition to the influence of gas fluxes on resuspension rates for uncapped cohesive sediment beds, this experimental investigation considers the effectiveness of two types of caps, sand and AquaBlok®. The investigation involved experiments conducted on sediments (d_{50}=10 μm) collected from the Anacostia River in Washington DC. Gas ebullition fluxes were selected based on values reported in the literature. The experimental results for the zero gas flux case indicated that the resuspension increases as the square of the bed shear stress level above a threshold or critical shear stress required to initiate resuspension. With regards to the ebullition experiments, it was observed that air migration occurs as a series of discrete bubbling events through semi-permanent channels in the sediment bed associated with a cyclical buildup and release of gas pressure within the sediment. A significant amount of sediment was carried in the wakes of released bubbles. When the same conditions were studied with sediment caps applied over the bed surface, no sediment resuspension was observed over the duration of the experiments with the sand cap. AquaBlok® cap heaved up and ruptured if the pressure head differential across the cap reached a level on the order of 20-25 cm.

INTRODUCTION

Resuspension process may result in increased contaminant concentrations within the water column due to the increased exposed surface area. Many factors have been demonstrated to contribute to the resuspension rates for fine-grained cohesive sediments. Hydraulic shear stress has been assumed to be the major factor leading to erosion. The theories established for the determination of the rate of erosion of cohesive sediment beds considering the bed shear stress involve different approaches to the phenomenon. More importantly, inclusion of any other mechanism such as gas

ebullition that could result in additional resuspension needs to be incorporated into the proposed framework.

Both laboratory and in-situ measurements of cohesive sediment erosion generally involve a series of stepwise increasing bed shear stress levels over fixed duration-time steps (e.g., Ravens and Gschwend, 1999; Aberle et al., 2006). The erosion rate is typically calculated using measured fluxes of suspended sediment concentration. The conclusions of these investigations vary and the most appropriate mathematical formulation to compute erosion rate from measurements is still under discussion. Interpretation of time dependent erosion rates which are typically high at the beginning of an experimental shear stress step and then decrease with time (e.g., see Parchure and Mehta, 1985; Amos et al., 2003) requires a somewhat arbitrary definition of the erosion rate. Variation in the outcomes of these investigations depend also on the types of beds considered with some experiments performed with remolded sediments with uniform properties over the bed thickness or in a form that the sediments were allowed to consolidate while suspended sediment deposits on the bed over time. The effect of consolidation on the erosion rates has been related to the bulk density by several researchers such as Jepsen et al. (1997).

A power relationship defining erosion rates has been widely used in the interpretation of experimental results in the general form of

$$E = K(z_0)(\tau - \tau_c(z_0))^m \tag{1}$$

where E is the erosion rate per unit area of bed surface [$ML^{-2}T^{-1}$], $K(z_0)$ is an empirical erosion coefficient with its dimensions depending on the exponent m, τ is the applied bed shear stress [FL^{-2}], $\tau_c(z_0)$ is the critical bed shear stress for erosion, and z_0 is the depth of erosion [L] (e.g., Maa et al., 1998; Ravens and Gschwend, 1999).

An expression expressing the time-dependency of the erosion rate over a shear stress step was given by Sanford and Maa (2001) as

$$E = \rho_d(z_0)\beta(\tau - \tau_{c0})e^{-\varphi\beta(t-t_0)} \tag{2}$$

where $\rho_d(z_0)$ is the dry bulk density at sediment depth z_0, β is a local parameter, τ_{c0} is critical bed shear stress when τ is first applied at $t = t_0$, t is time, t_0 is time at which a new shear stress is applied, and $\varphi = d\tau_c / dz_0$. For a uniform bed ($\varphi = 0$), Equation 2 reduces to $E = K(\tau - \tau_c)$ with $K = \rho_d\beta$. For a non-uniform bed ($\varphi \neq 0$), Equation 2 describes an exponential decay of erosion rate with time.

No comprehensive studies have been reported in the literature related to the effect of ebullition on bed stability or on resuspension rates. Ebullition is the result of a series of processes in which excess gases are generated by micro-organisms from organic matter. In cohesive sediment beds under organic rich conditions, ebullition leads to accumulation of gas dissolved in pore water and in bubbles. Gas bubbles are produced when the sum of the partial pressures of dissolved gases exceeds the ambient pressure (Fendinger et al., 1992). Bubbles grow until a pressure threshold is

reached as they build up sufficient buoyancy to overcome the cohesive strength of the sediment and migrate upward. Ebullition generally occurs episodically due to changes in shear stress or pressure (especially in tidal systems) that affect the gas bubble release potential (Joyce and Jewell, 2003). In fine-grained sediments, bubbles fracture the sediment and these fractures combine and form channels reaching to the water-sediment interface (Huls et al., 2003a-b). One effect of the gas bubbles is to increase sediment porosity and reduce bulk density, thus potentially decreasing the critical shear stress for resuspension (Joyce and Jewell, 2003; Jepsen et al., 2000). Bubbles rising through the sediment matrix exert an erosive force along their path, and as a result have the potential to move the sediments to the surface.

Ebullition fluxes reported in the literature vary considerably. A wide range of ebullition fluxes ranging from 0.01 cm/d to 48 cm/d was reported by Chanton and Martens (1988). These measurements were obtained from several sites under different temperature, pressure, salinity levels, water depths and sediments having variable organic contents.

Limiting the resuspension hence contaminant migration due to advective flow induced shear stresses and/or gas ebullition flux is possible using caps. However, there have been no systematic investigations on the use of sediment caps in controlling resuspension. Assessment of the effectiveness of caps as a remedial technology requires an understanding of contaminant fluxes from sediments both in the presence and absence of caps in order to understand the potential for contaminant transfer to the water column.

EXPERIMENTAL SETUP AND METHODS

Fine-grained Anacostia River cohesive sediment with d_{50} on the order of 10 μm was used in the laboratory experiments. An exploratory investigation was performed to observe various aspects of the sediment behavior when a gas ebullition flux was applied to the sediment bed with or without cap. The flume experiments were different as they involved application of an erosive force to the surface of the sediment or the cap material by creating a flow over the relevant test surface in the laboratory flume. The exploratory experiments were performed with no such flow but were conducted in glass aquaria that had a horizontal cross-section of approximately 45 cm by 90 cm. It was developed through observations that side wall effects can be avoided by using a distribution system under the sediment bed that releases gas away from the container walls. In the case of the exploratory experiments this was achieved through bubble bars and in the case of the flume experiments, perforated soaker hoses were used.

The flume experiments were conducted in a 7.5 m long, 0.6 m wide flume. The test section was approximately 2.00 m long located about 3.5 m downstream from the flume inlet. A 0.3 m wide depressed cavity was installed in a false floor in the flume bottom to be filled with the sediment and capping material. The depth of the sediment cavity in the flume was adjusted according to the specific experiment. The bed thickness was fixed to 10 cm for the Anacostia River sediment beds. For the experiments where the Anacostia River sediment together with the cap material was used, each layer was 10 cm.

The injection system consisted of a set of parallel soaker hoses connected to a common source and ran the length of the test bed. During the experiments with gas injection if an injection rate was set with a flow meter, initially the gas would flow into the sediment, increasing the internal sediment pressure which decreases gas flow rate through the meter. Increasing the control valve setting to increase the flow would only build the pressure until eventually the gas erupted from the sediment. At this point, the resistance to gas flow would suddenly decrease and the gas flow rate would dramatically increase. This inconsistent flow rate was resolved by adopting a methodology to ensure a relatively constant long term average gas flux through the sediment. It was presumed that gas release will actually occur through a series of discrete release events and a procedure was developed that would mimic this behavior. The apparatus consisted of two bottles connected in series to each other and then to the bubble bars or perforated soaker hoses. When water was supplied to the first bottle at the desired rate of the gas flux in a series of discrete additions, the air pressure in this bottle and hence in the second bottle was gradually increased to initiate bubbling through the sediment. The bubbling event then relieved pressure in the bottles and the bubbling subsided until the addition of more water increased the pressure again to a level required to initiate a new event. By this procedure, a constant long term average air injection rate was achieved. Considering the range of ebullition fluxes reported in the literature, 1.2, 12 and 48 cm/d were the initial selected rates for the resuspension experiments. A flux of 2.4 cm/d was added to the experimental schedule as 12 and 48 cm/d were observed to create continuous air bubbling which is considered to be incompatible with what would be observed in natural systems.

The flume experiments were conducted by increasing the bed shear stress in five, discrete hour long steps in the re-circulating flume starting from a low bed shear stress and increasing the shear stress each time step. The depth in the flume was approximately 0.25 m. Discharge rates were measured by an orifice meter installed in the return pipeline. Sediment concentrations in the re-circulating water were inferred by monitoring the flow with a turbidimeter connected to the return pipeline in the flume system downstream from the recirculation pump. In order to compute resuspension rates, a flow-through cell enabling continuous turbidity measurements was attached to the turbidimeter. The approach to estimate bed shear stress was to obtain local turbulence measurements close to the bed surface and to develop a procedure for converting these results to bed shear stress and to directly relate bed shear stress to flow velocity. Several sets of Acoustic Doppler Velocimeter (ADV) data were collected for this purpose (Cakir Kavcar, 2008).

All the experiments were conducted with unconsolidated sediment beds and homogenized constant bulk density. Letting each sediment bed sample to consolidate for an extended period of time (weeks) would have caused some scheduling problems in conducting the number of planned experiments. In addition, there were issues of how to treat the gas ebullition aspect of the experiments during this consolidation period. In the end, it was decided to perform the experiments by placing the sediment as a slurry and allowing it to settle for approximately 12-15 hours before each experiment.

Additional experiments were also conducted in the presence of the sand cap and the AquaBlok® cap. Other experiments were performed in glass aquaria with an AquaBlok® cap. AquaBlok® is a system prepared by placing bentonite-coated gravel as the cap; the hydration of the bentonite produces an effectively impermeable cap material.

OBSERVATIONS AND RESULTS

Similar behavior was observed in both the aquaria and flume experiments. As air was applied at the bottom of the sediments, gas pressure built up and at some point a bulge would develop on the sediment surface. Initially larger bubbles (up to 5 cm) would erupt from the bulge carrying significant amount of sediment into the water column in the bubble wake, and then followed by several smaller diameter bubbles (0.5-1 cm) with less sediment entrained (Figure 1). Typically if the air pressure applied was not excessive, bubble release would stop after a short period of time and the process would repeat itself, gas pressure build-up, bubble release, pressure drop, and cessation of bubble production. Channels at fixed locations in the sediment bed were formed by the bubbles. As the bubble diameters became smaller over time, less sediment was carried up into the flow and it is thought that some sort of armoring process on the channel walls occurs.

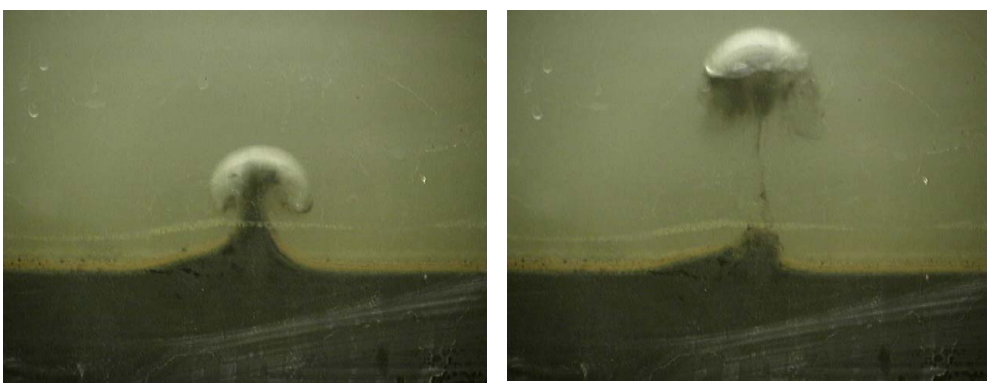

Figure 1: Air bubble is released and some sediment is entrained into the water column in its wake.

Additional exploratory experiments were performed to bubble air through sediment covered with a sand cap. The bubbles tended to be more constant diameter (0.5-1.0 cm) throughout the duration of the experiment. Again the air is observed to flow through distinct channels. Although no Anacostia River sediment was observed in the water column during the course of the experiments, the excavation after the experiment in the sand cap showed some degree of cohesive sediment migration into the cap layer indicating a potential of sediment resuspension in a longer duration experiment.

Samples of AquaBlok® aggregate obtained from the manufacturer were allowed to hydrate for at least a day in glass aquaria sub-divided to produce horizontal sections of 45 cm by 45 cm. Gas pressure was applied beneath different thicknesses of AquaBlok® layers. Sand was placed under the AquaBlok® cap as a medium to

ensure uniform pressure distribution beneath. Observations of the rupture of the AquaBlok® in the various experiments as a result of pressure built-up indicated a potential practical issue. These failures were observed at a pressure differential of 20-25 cm across the cap material. Two major rupture patterns were identified as either lifting along one wall or mounding near the center of the tank. This mound would grow until eventually the layer ruptured. Initial set of flume experiments involved shear stress applied to the bed without air injection flux (advective flow experiments). Experimental protocol dictated a five-step bed shear stress increase from 0.153-0.309 N/m^2 on average. Each flume experiment was repeated multiple times until consistent results were achieved. Suspended sediment concentration measurements collected by the turbidimeter show that there is no significant bed erosion during the first two hours of the experiment and then resuspension is apparent with increasing rates as the shear stress level is increased. The trend within each one hour interval shows that resuspension rates are usually higher initially which indicates a time dependence at a given shear stress level (see Figure 2).

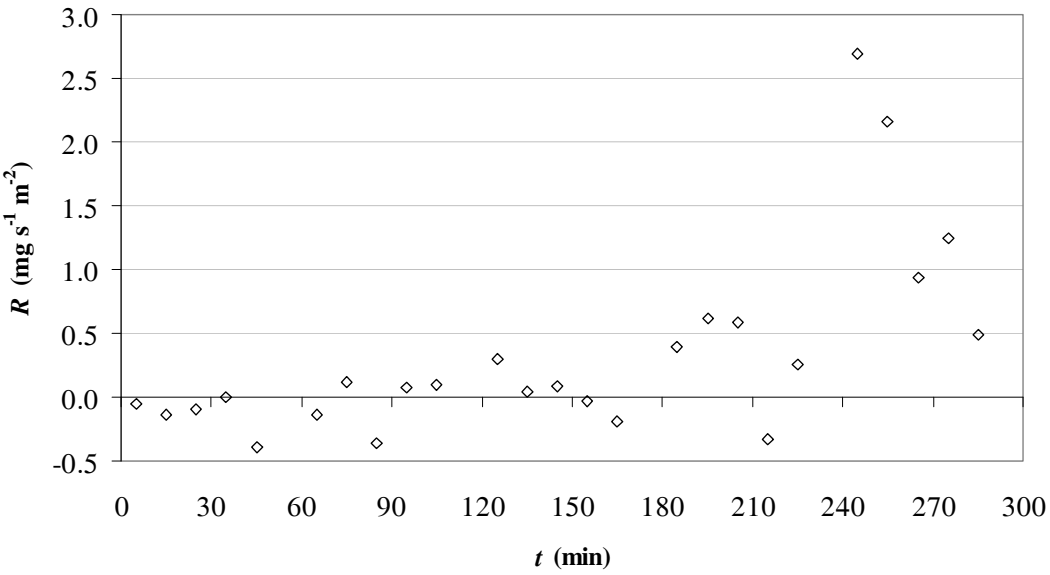

Figure 2: A resuspension rate (*R*) versus time (*t*) graph presenting time dependency of the resuspension rates during each hour of the five hour long experiment (no air injection).

Time dependency of the resuspension rates required averaging of the rates over an hour for each shear stress level for comparison purposes. This yielded relatively consistent results when the results of the repetitions of the same experiment were compared. The erosion threshold or critical shear stress was determined to be approximately 0.19 N/m^2 at which resuspension rates approach zero. An empirical relationship for the resuspension rate, R was derived as:

$$R = M(\tau - \tau_c)^2 \tag{3}$$

where M is the resuspension rate coefficient, τ is the applied bed shear stress and τ_c is the critical shear stress. For the experiments without air flux, M can be approximated to be 96.7 mg s^{-1} m^{-2} Pa^{-2} where τ_c is 0.19 N/m^2 as shown in Figure 3.

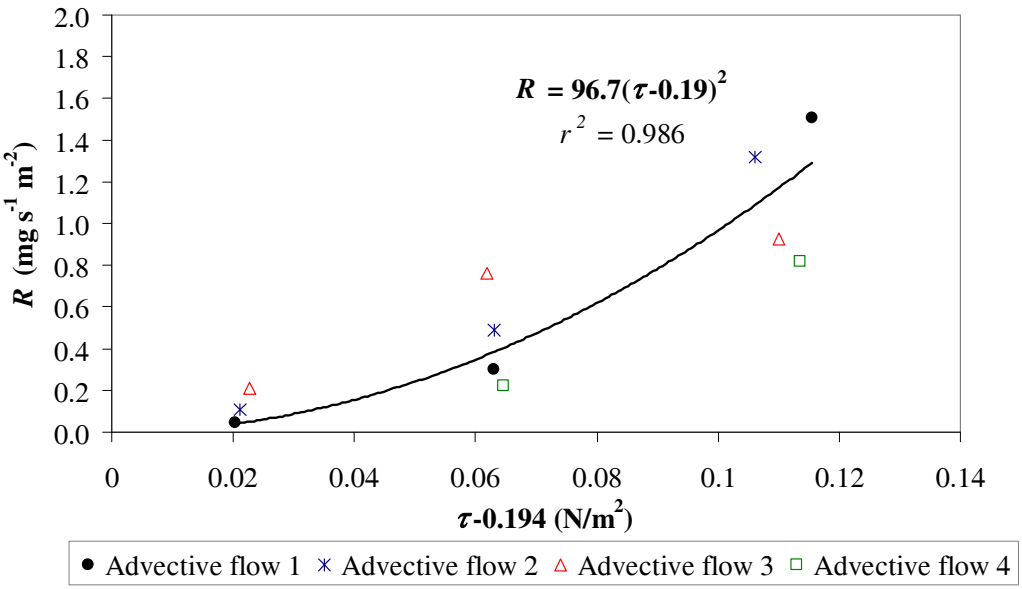

Figure 3: Quadratic relationship fit according to the "Advective flow 1" experiment and the results of all the advective flow experiments with respect to the curve fit.

When flume ebullition experiments were conducted, air migration occurred with a cyclical buildup and release of gas pressure with discrete bubbling events. This is likely to be observed in Anacostia River as the tidal fluctuations in water level will create a cyclical variation in overlying pressure that should have a strong influence on the release of gas from the sediments. The observations showed that the amount of sediment resuspended depends on several factors such as bubble size, bubbling frequency and duration of bubbling. Once a channel is well-established in the sediment bed, there appears to be a reduction in the resuspension rate. This observation is based on both visual observations as well as turbidity measurements. The size of the bubbles coming from the same channel tends to reduce over time if the bubbling is continuous. If a bubbling event from a channel stops at some point in time and restarts at a later time, the channel may heal itself to some extent. Consequently, the resuspension rates due to ebullition appear to be correlated to two time dependent processes, how long a bubbling event lasts and the time interval between successive events. It appears to be random where the channels form and at how many discrete points bubbling occurs at a given air flux rate. Therefore, considerable variation was observed among repeated experiments involving gas ebullition.

The initially selected ebullition fluxes were 1.2,12, and 48 cm/d. These rates were considered in the experiments together with the step-wise increased advective flow induced shear stress. Several experiments were conducted to investigate the effect of

each ebullition rate. The investigations showed that 12 cm/d was a very high rate creating continuous air bubbling and this is felt to not be representative of occurrences in natural systems. 48 cm/d ebullition experiments were eliminated from further consideration because of this observation. On the other hand, 1.2 cm/d ebullition fluxes usually ended up with a situation where no air bubbling events occurred during some one hour measurement periods. One or two bubbling events lasting 20 minutes during the whole 5 hours of a single experiment was not definitive for the purpose of determining the added effect of ebullition on resuspension rate. An additional ebullition flux of 2.4 cm/d was investigated in an effort to observe more ebullition events throughout the duration of an experiment.

As can be seen from a synthesis of all the data (Figure 3), ebullition results in greater sediment resuspension compared to advective flow only experiments. This effect increases with the ebullition rate. However, the data also suggest that once bubbling channels are formed in the sediment bed, the contribution of ebullition to the resuspension rates becomes minimal. It is generally observed in ebullition experiments that during the last hour of the experiment (highest shear stress level) resuspension rates closely correspond to those observed in an advective flow experiment with no ebullition. There are two possible explanations for that observation; one is that no ebullition occurs during that period of time such as often occurred for the ebullition rate of 1.2 cm/d and a second possibility is that the channels are formed in a well-defined configuration and the contribution of ebullition to the resuspension rates is minimal such as for the 2.4 and 12 cm/d ebullition rates which created sustained bubbling in most of the repetitions.

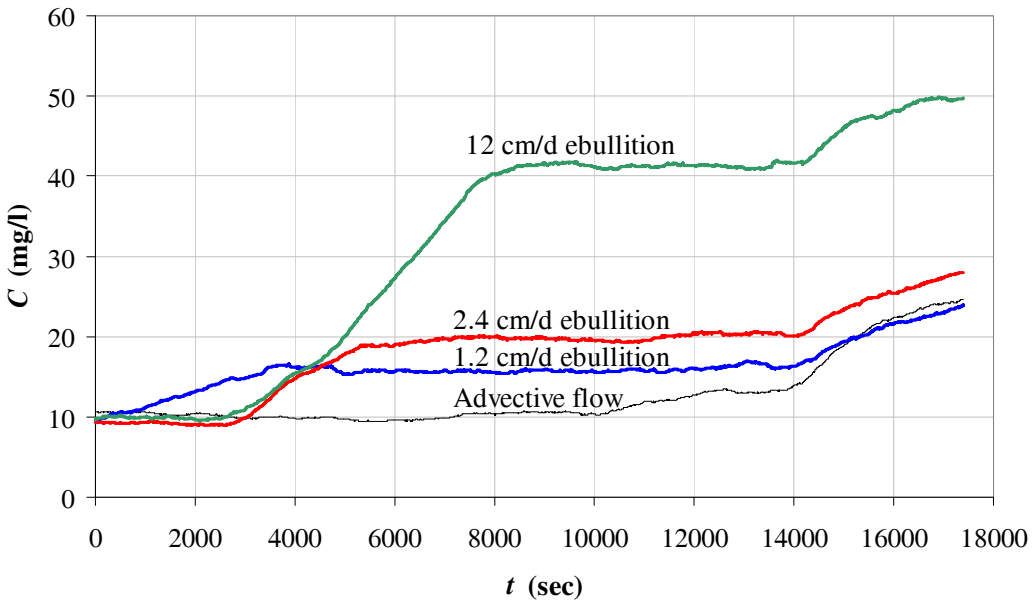

Figure 3: Comparison of suspended sediment concentration measurements (*C*) among ebullition experiments with different ebullition fluxes and an advective flow experiment.

It was noted that the computation of resuspension rates was not straightforward. The issue arises from the apparent random nature of ebullition events. As opposed to the hourly resuspension rates computed for advective flow experiments, it is not possible to compute rates in a time-averaged manner for the ebullition experiments. Each ebullition event seems to have its own resuspension potential and this potential basically depends on several parameters as explained previously. The data suggest that the amount of pressure build-up between the events affects the resuspension rates significantly. If somehow bubbling does not occur for an extended period of time, pressure builds up significantly creating very high resuspension rates when the pressure is released. However, the relationship between the pressure build-up and the resuspension rates does not seem to follow a well-defined trend.

In order to identify the contribution of ebullition to resuspension rates, the amount of sediments in suspension was calculated for three repetitions of the 2.4 cm/d ebullition experiments. The amount of sediment suspended due to bed shear stresses was approximated using Equation 3 as 40 g on average. The contribution of the ebullition to the total was calculated as 50 g on average. However, two of the ebullition experiments involving discrete ebullition events throughout the duration of the experiments resulted in 140 g on average. The one with the continuous bubbling resulted in approximately 80 g of sediment resuspension. It is apparent that resuspension rates are highly depended on on the specific nature of the ebullition process

When the sand cap (d_{50}=340 μm) was examined for its effectiveness in minimizing the resuspension rates, none of the air injection fluxes (1.2 cm/d, 2.4 cm/d, and 12 cm/d) caused any detectable suspended sediment concentration in the flume within the duration of the experiments. This result indicates that the cap material filtered all the cohesive sediment transported by bubbles from the sediment layer beneath it. However, it is not known if any resuspension would occur over extended periods of time.

As the issues related to AquaBlok® caps subjected to gas ebullition flux were identified in small scale experiments, no further experiment in the flume setup was performed on this type of cap for gas ebullition. However, advective flow induced shear stress flume experiments showed that AquaBlok® is very stable under even very high bed shear stresses. The stress values were increased up to a value of approximately 2.6 N/m^2 to indetify the limitation to the stability of the AquaBlok® bed. By looking at the surface of the bed after the experiment, it was seen that some bentonite material was eroded from the surface and some small aggregate particles were carried downstream by bed load transport. Nevertheless, the majority of the aggregate adhered to the bentonite layer underneath creating an armoring layer.

ACKNOWLEDGMENTS

This investigation was conducted as part of a comprehensive research project sponsored by the Strategic Environmental Research and Development Program. Further support was provided by the Department of Civil and Environmental Engineering and the Program of Environmental and Water Resources Engineering at the University of Michigan.

Abstract
This research studies empirical equation for abrasion of stilling basin caused by impact of the sediment. Review of previous papers shows that in previous researches, the mixture effects of erosion and impact are studied without determination of the share of impact in the mixture effect. Also in those researches, the sediment grain size is not as large as debris size in debris flow or experiments are done without tail water depth. Therefore, in this research, the impact of large grain size is determined on concrete stilling basin with tail water. One dimensional analysis is carried out. The experiment includes concrete samples with three different cement contents, five depth of tail water, three grain sizes. Abrasion of each grain impact is measured and recorded. Uni-variable and multivariable regression analysis was employed to possible relation between abrasion ratio and the dimensionless parameter of the experiment. The empirical equations are judged using mean relative error of the equations. Later a multivariable power equation is proposed for abrasion determination of the sediment impacts. The equation shows the abrasion is a function of dimensionless energy of sediment grain and the ratio of the grain velocity on stilling basin to the grain velocity on water surface. The results of the present research are used in estimating the longevity of Diversion Dams and concrete check dams in contact with debris flood.

Key words: Diversion Dams, debris flow, abrasion of stilling, Impact of Sediments

1.Introduction

Debris flow is defined as the flows with high concentrations of sediments which more than 50 % of their weight include sand stone and rock. Some reports of damaging caused by passing debris flood from different dams including Iran (Ruzbahan Diversion Dams), china, India, (Ichari and Manri dams in the mountainous areas of Himalaya), Swiss and France [3, 4, 7]. In those dams, abrasions and holes on spillway and stilling basin were seen. They have noticed the reason of all these abrasions, passing sand, stone and rocks. For solving this problem they have some methods like using metal plates, angle for the sharp edges of flip bucket and its teeth in Ichari dam, metal cover with metal halter on concrete spillway and stilling basin in Manri dam, high strength concrete and epoxy resins in china, installing granite blocks and covers for Baril stilling basin of railway in Swiss, acorn and pine woods as a protective cover in France. Eighteen dams in Swiss had the same abrasion and Reyn national company tested the resistance against impact and abrasion for various materials [1, 4, 7, 8]. Bargua and Muris has reported the damages imposed to spillways and stilling basin of reservoir and hydropower dams due to passing large grained sediment in different part of the world [4, 7, 8]. The reports and articles clarify the necessity of research in basis of the damaging effect of transitory debris flood along stilling basin and spillway. Liu et al. (2006) represented that abrasion and sediment impact on the surface are two factors for abrasion of stilling basin and spillway in dams [6]. The standards compiled for examining concrete by sediment, mainly discussed the effect of abrasion not sediment impacts' distraction. In the latest standard offered by the American Society of Testing and Materials, it is emphasized on the quality of the experimental results [9, 10]. In the research carried out by liu, jet flow containing sand is sprinkled on a concrete piece and the effect of the mentioned jet on different type of concrete with different percentages of water to cement was discussed(6). In the mentioned research the effect of abrasion and impact of fine sand sediment are combined. So a necessary knowledge of the impact effect was not detected clearly and the method and type of discussion is concentrated on comparing the effect of suggested method for concrete with different percentage of water to cement. This research shows that the percentage of abrasion on concrete samples is related to the work done per unit mass. According to the tests we can know damaging mechanism on stilling basin caused by large sized sediment of debris flood in two points. In above tests damaging mechanism is gained by modeling abrasion and impact that the share of abrasion is a lot but not distinguished. Also the grain size used as sediment (8-32 mm) compared to large sediments of debris flood mentioned in reference 5 and 2 (300, 500mm) is small. In this case a research was done by Banihabib, which in, the damaging effect of sediment impact on stilling basin of diversion dams was studied and a relation between percentage of abrasion and the potential energy of the sediments of debris flood was derived [2]. But in that research the effect of water and tail water in stilling

basin is not studied and no equation is given. Therefore the purpose of this research is to study the damaging effect of sediment impact on stilling basin and to give an equation for estimating the damages of concrete stilling basin with different depths of tail water. Also the effect of sediment impact on concrete slab of stilling basin in different water depths is studied. Then different empirical equations are evaluated.

2. Methodology

2-1- Physical Methods

Experiments are included 135 tests. The mixing plan of concrete samples are according to ACI 12 11 /1 are presented. As it is specified in these tables the ratio of water to cement was 0.5. Sand and gravel derived from river are used to make concrete.

Construction and caring of concrete samples has been in a way that after mixing materials in a mixer in a laboratory, 135 cylindrical samples with the height of 40mm and the diameter of 141mm was prepared. After 24 hours the samples were taken out from the block and till the end of the twenty eighth days was put in water. For the experiment of the impact they used 3 types of spherical object. Their weight and diameter are present in table 4. Other instruments which were used for the experiment include

- Digital scale with the accuracy of 0.01 grams for weighting
-Ruler and metal meters
-Laboratory system include water basin attended with guide pipe for hitting of bullet to the center of concrete samples.

2-2- Experiments

The main question of the research is the possibility of having an empirical relation between the percentage of damaging and the potential energy of debris sediment hitting on a concrete sample with considering the depth of tail water. Therefore the test system include water basin attended with guide pipe as in figure 1, is in dimensions 1.6 * 0.8 * 0.6. The process of the experiment begins with putting the concrete sample under and center of the guide pipe. In fact the basin was use as a model stilling basin and the impacting sediment was modeled by a metal bullet. The reason of using metal bullet instead of stone is the unchangeable weight and shape of the bullet during the test. In every test the metal bullet was dropped with the initial velocity of zero toward the concrete. Samples were placed in five depths of tail water, zero, 8, 20, 32, 40 centimeter. When the depth of water on the sample was zero, the weight of concrete sample was measured before and after impact with numerical scale but when the sample was in water the scaling of weight carried out after 3 times of impaction. Impaction and measuring weight was continued until the failure of concrete sample and dividing into some parts (figure 2).
For extracting relation and its validation three sets for each test were done. Therefore with considering 5 water depths and three concrete content the number of tests had been 45 that a number of impaction test was done till the failure of the concrete sample.

Figure 2 : concrete sample failure

3-2 - Analysis

Due to discuss on result and to study the empirical relation between damaging of the concrete and potential energy of impacting stone, the abrasion ratio is defined as follows:

$$A* = \frac{concrete weight \ \ after\ nth\ impact - superior\ concrete\ weight}{superior\ concrete\ weight} \quad (1)$$

Where $A*$ is the ratio of concrete abrasion after n time impacting to the concrete sample. Because this abrasion ratio is caused by the first impact to the impact number n. Accumulative potential energy that is spend to impact and production of this abrasion is defined as follow:

$$E = \sum_{i=1}^{n} W_{si} H \quad (2)$$

Where H_i is the height of bullet drop and W_{si} weight of bullet in the impact number i. In addition to accumulative potential E, the water depth in basin and the height of bullet drop has effect on $A*$ therefore with dimension analysis the dimensionless parameter was achieved:

$$E_* = \frac{E}{W_0 \times D} = \frac{\sum W_{si} H}{W_0 \times D} \quad (3)$$

$$P_* = \frac{P}{D} \quad (4)$$

$$Y_* - \frac{y}{D} \quad (5)$$

Where p is drop height, D is sediment diameter, W_0 is the weight of the first sample, Y is the water depth. For analysis data in each cement content, data were divided in to three individual sets that the first set was used to analysis and study of relations and the second and third sets for validation of relations gained from the first set. One-variable relation include linear, power, logarithmic and multi-variable relations include linear and power.

3-Result and discussion

According to dimension analysis we can consider cement content, dimensionless energy imposed to sample as the effective parameters on concrete abrasion ratio. Since the impaction of stones to the stilling basin is generally in a depth that is equals to that of a jumping, its essential to analysis the effect of existing water on the base of available theories and accuracy limitations should be clarify. For achieving to this goal we use the model describe in figure 3 for analyzing.

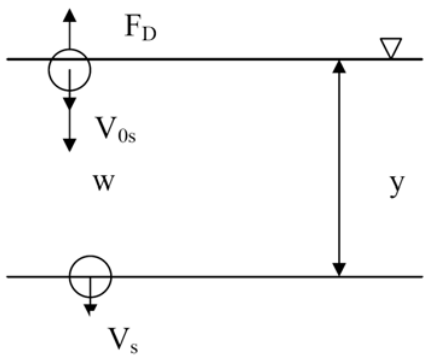

Figure 3: scheme model used for analysis

The averaged velocity of stone can be determined as follow:

$$V = \frac{V_{0s} + V_0}{2} \tag{6}$$

Sediment with the above velocity will produce a resisting force which can be determined as follow:

$$F_D = \frac{1}{2} C_D A \rho V^2 \tag{7}$$

Where in this equation FD is resisting force, CD is the shape factor, A is the stone area and p is the special mass. From dynamic balance of weight, resisting and second law of Newton forces, we can have the following relation (2):

$$C = \frac{V}{V_{0s}} = \frac{-0.056\frac{y}{D} \pm \sqrt{(0.056\frac{y}{D})^2 - [(1+0.056\frac{y}{D})(0.056\frac{y}{D} - 1 - \frac{(y/D)/(p/D)}{(1-(y/D)/(p/D))})]}}{1+0.056\frac{y}{D}} \quad (8)$$

Where Y is the water depth in stilling stone diameter, v_{0s} and v_s are respectively stone velocity when entering the water and impact to bed. This relation has been shown in a group of curves in figure 4. In this figure P_1 is the height of spillway. This figure shows that if the dimensionless depth is less than one means the flow depth is less than the sediment diameter the effect of reduction in water depth on the velocity of impaction on the bed is less than 10%.

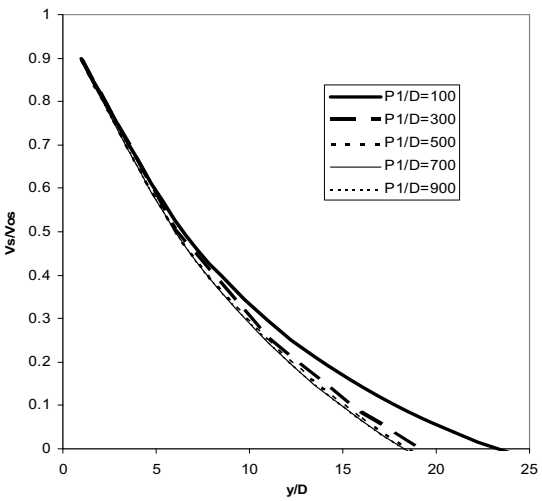

Figure 4. The ratio of velocity of sediment before entering water to after it

Water depth in stilling of dams reaches to many times as much the sediment diameter so it is necessary to consider the flow water analysis. In this research different depth water is considered on concrete samples while hitting bullet. The regression between dimensionless factors is studied. To study these relations, SPPS software was used so that the best formula which could clarify the effect of debris sediment impaction on stilling basin was derived. As mentioned before the effective parameters can be known as the value of energy imposed to the sample, P_0 and Y_*. So the value of factors of each formulas change according to the value of cement content and for different cement content individual relations was gained. Due to reduction of the number of dimensionless parameters ratio of the grain velocity on stilling basin to the grain velocity on water surface (c) was used as a dimensionless parameter. This dimensionless parameter is a function of Y_0, P_0. There for c is used instead of dimensionless parameter Y_0, P_0. Therefore, the dimensionless energy of impact will be modified and the new parameter $E_{*,m}$ named modified dimensionless energy is defined as follow:

$$E_{*m} = E_* C \quad (9)$$

By having dimensionless value of energy, 3 data groupes of empirical relations was studied.

-One variable linear, logarithmic quadratic between abrasion ratio and dimensionless parameter.

-Multi variable linear relation between abrasion ratio and dimensionless parameter.

For studying the error of above relation, averaged relative error with the following definition was used.

$$MARE = \frac{\sum_{i=1}^{n} |A_0 - A_c|}{A_0} \quad (10)$$

Where in this relative A_0 and A_c are respectively observed and calculated values. And n is the number of data in each Data group.

The data of the first data group is used for extracting relations and the data of the second and third data groups were used for comparing the results of determining A* with derived relation with this data group of data so that it was possible to validate the extracted relations

3.1. One variable Equations

The one variable relation below was derived based on the first set data and the results of determining A* was compared with relations Extracted by the use of the data of first, second and third data groups based on MARE:

$$A_* = a\,E_{*m} + b \quad (11)$$

$$A_* = a\,E_{*m}{}^{b} \quad (12)$$

$$A_* = a\,\ln(E_{*m}) + b \quad (13)$$

$$A_* = a\,E_{*,m}{}^{2} + bE_{*m} + c \quad (14)$$

$$A_* = a\,E_{*,m}{}^{3} + bE_{*,m}^{2} + cE_{*,m} + d \quad (15)$$

The parameters of 11 to 15 relations and MARE base data and validated data are present in table . This table shows that the error of one variable power relation with base data and validated data was less than the error of one variation linear, logarithmic and 8888888888.

3.3 Multi-variable linear relation based on dimensionless parameter E*, P*, Y*

Multi-variable relation between concrete abrasion ratio caused by impact and dimensionless parameters of energy, depth and the drop height are extracted for the first set of data using SPSS and averaged relative error of extracted relation was estimated with the second and third sets of data. Extracted relation is as following and the regression factor and MARE for the relation is present in the table 5.

$$A_* = a\left(\frac{y}{D}\right) + b\left(\frac{y}{D}\right) + c\left(\frac{y}{D}\right) + dE_{*,m} \quad (16)$$

Comparing MAREs of the mentioned table shows that multi variable linear relation has larger error comparing to relation 13 and using the multi variable relation can not improve the estimation of mentioned formula.

3.3. Multi-variable linear and power relation and parameter E*, C

Multi-variable relation between concrete abrasion ratio caused by impact of sediment and dimensionless parameter E*, C was derived for the first using SPSS, second and third sets are compared in tables 11 and 12.the mentioned multi variable relation are

$$A_* = a + bC + dE_* \tag{17}$$

$$A_* = a\, C^b E_*^{\,d} \tag{18}$$

Comparing the value of averaged relative error for these relations with relations 11 to 16 shows that relation number 18 has minimum error with first data set and validation data(second and third) and can be the best relation among all studied relations to determine the concrete abrasion ratio caused by impact of sediment. The parameters of this relation are different for different cement content. The result shows the effect of cement content to resist the abrasion by impact of sediment. Therefore the relation between parameters a, b, and d and cement content cc was studied and the following relation was derived as follows:

$$a = -0.0017 \times c - 4.848 \tag{19}$$

$$b = 0.0004 \times c - 1.495 \tag{20}$$

$$d = 0.0005 \times c + 1.086 \tag{21}$$

By these relations and the relation number 18, the following relation is derived.

$$A_* = (-0.0017 \times c - 4.848) \times c^{(0.0004 \times c - 1.495)} \times E_*^{(0.0005 \times c + 1.086)} \tag{22}$$

4. Conclusion

In the present research which is based on doing experiments of impacting debris sediments on submerged concrete samples and to analysis the available empirical relations between experimental results, the following results has been achieved:

-The value of abrasion caused by the impact of sediments is a function of dimensionless energy and the ratio of the grain velocity on water surface to the grain velocity on concrete stilling basin, and the cement content.

-From studied relations the multi-parameter power relation between concrete abrasion and dimensionless energy and the ratio of the grain velocity on water surface to the grain velocity on concrete stilling basin had the minimum averaged relative error and the parameters of multi-parameter power relation was a function of cement content.

ABSTRACT:

In stream erosion represents a significant portion of the watershed sediment budget for lowland watersheds, but current modeling strategies do not often include accurate methods for estimating the yield from stream bank sources or accurate representation of the stream bank erosion process at the watershed scale. This research presents a method for estimating the yield from stream bank sources using sediment carbon and nitrogen isotopic tracer results coupled with a watershed scale erosion and sediment transport model. The coupled fingerprinting-watershed modeling framework is presented in the following steps: 1) measure the sediment yield from the study watershed; 2) estimate fraction of sediment yield eroding from stream banks using sediment fingerprinting data and use this and other collected data for the watershed model calibration and verification; 3) create a conceptually simple, yet representative, model of bank erosion processes and integrate the subroutine into the watershed erosion and sediment transport model, calibrate, and verify. Land use and climate change sceneries will then be used with the calibrated model to predict the effect on the sediment transport budget.

KEYWORDS: streambank erosion, sediment transport, watershed modeling, sediment yield, isotopes, tracers.

INTRODUCTION

Sediment loss, transport, and fate are a significant environmental problem. Sediment is a pollutant that can kill fish and other aquatic life, and other potentially hazardous substances, such as fertilizers or pesticides, attach themselves onto the soil particles and eventually end up in the stream (US EPA, 1999). Turbid waters reduce

the available dissolved oxygen for aquatic life and inhibit respiration and photosynthesis (Wood and Armitage, 1997) Excess sediment deposits can smother fish eggs, reduce the storage capacity of reservoirs, and in stream sediment decomposition can contribute significant CO_2 to the atmosphere (Richardson and Jowett, 2002). Understanding sediment erosion, transport, and fate processes is a vital step toward controlling sediment pollution and creating a complete environmental model (Walling 2005).

Stream bank and stream bed erosion are watershed processes that are very difficult to model at the watershed scale due to the variability of their sediment make-up across a watershed and fluid turbulence complexity throughout a stream segment. Even small watersheds contain several miles of stream banks which can be heterogeneous and estimating erosion rates for these banks is compounded due to the varying degrees of vegetation coverage, exposure to sidewall shear stresses, mass failure, and root density which can make quantifying an erosion rate/yield very difficult. Seasonal variations in the watershed such as flow variations, microbial decomposition, pore pressure, and interflow also effect erosion rates.

Sediment yield measured at the outlet of the watershed is the sum of all watershed erosion processes, including stream banks, stream beds, and upland sediment sources (Simons and Senturuk 1992). Differentiating between these different sources is a difficult task, but much headway has been made with sediment fingerprinting toward estimating the yield from different sediment sources in the watershed (Collins and Walling, 1998). Sediment fingerprinting using natural tracers has become a feasible, acceptable method for estimating sediment yield from different sources of erosion in a watershed (Collins and Walling, 1998; Motha et al. 2004; Walling 2005; Davis 2008). The method involves collecting samples of suspended sediment using sediment traps and analyzing the collected sediment for naturally occurring tracers, e.g., inorganic elemental composition, carbon and nitrogen stable isotopic composition. Sediment samples from potential sources of suspended sediment are then collected and analyzed for the same tracers, and, using an un-mixing model, the fraction of sediment eroding from each source can be estimated (Collins and Walling, 1998; Fox and Papanicolaou, 2008).

While sediment fingerprinting provides a useful data-based tool for quantifying sediment sources in a watershed and their respective sediment loads, there is a need for performing watershed erosion and sediment transport modeling across an entire watershed in order that future land-use scenarios and climate changes can be modeled and investigated. Previous studies indicate that sediment from channel banks can be a dominant sediment source in some watersheds (Trimble, 1997; Smith and Dragovich, 2008) however, a review of recent literature suggests that hydrologically driven watershed prediction models typically do not accurately represent bank erosion processes. The modeling limitation is partially due to the fact that while empirical equations of bank erosion are available accurate process-based bank erosion models are less developed, particularly for composite watershed modeling applications where simple, computationally inexpensive subroutines with low data requirements are desirable (Borah and Bera, 2003; Merritt et al., 2003; Kalin

et al., 2003). There is a need to build erosion models that are conceptually simple, but capture all the necessary sediment processes with simple data requirements while providing some physically based structure.

The present research works towards the coupling of sediment fingerprinting with watershed erosion and sediment transport modeling in order that stream bank erosion can be more accurately modeled at the watershed scale. The long-term objective of this research works towards development and the watershed modeling tool and application for land-use change and climate change scenarios. In this paper, the goal is to present the data collection, fingerprinting, and model development components of this work. The coupled fingerprinting-watershed modeling framework is presented in the following steps: 1) traditional sediment transport data collection methods are used to measure the sediment yield from the study watershed; 2) the fraction of the sediment yield derived from the stream banks is estimated using the sediment fingerprinting approach, and the data is thereafter used for the watershed sediment transport model calibration and verification; 3) a conceptually simple yet representative model of bank erosion processes is constructed, calibrated, and integrated into a watershed erosion and sediment transport model.

STUDY AREA

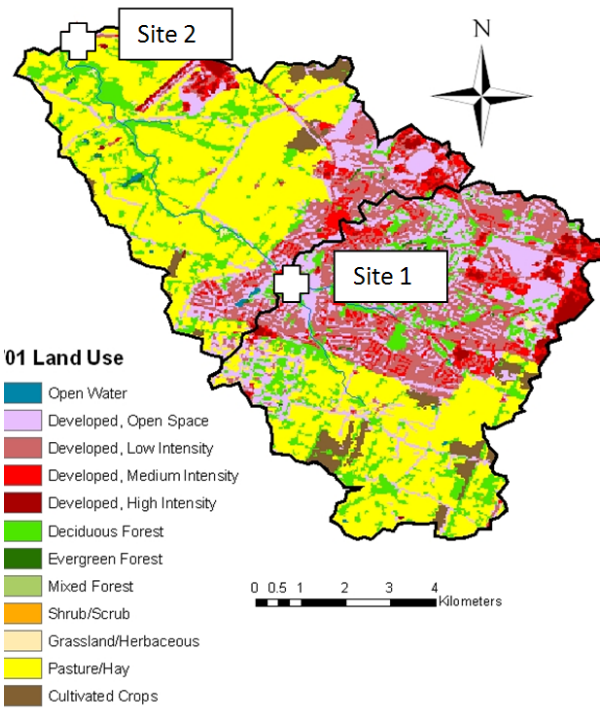

Figure (1) Map of the South Elkhorn Watershed, Lexington Ky.

The study area for this research is the South Elkhorn watershed located near the University of Kentucky in Lexington, Kentucky (see Figure 1). The South Elkhorn is approximately 61 km^2. The South Elkhorn was chosen for the coupled model development due to the fallowing reasons. (1) The South Elkhorn experiences stream bank erosion as its dominant source of transported sediments. (2) Overland erosion processes such as rill and inter-rill erosion are only a small contribution to sediment loads in the South Elkhorn watershed, thus model development can be achieved under fairly controlled conditions. (3) The South Elkhorn has been an experimental watershed where tracer development and sediment fingerprinting methodologies have been improved over the past four years. Tracer data has been previously collected for the watershed (Davis 2008) thus making it ideal for development of coupled modeling strategy. (4) Stream flow and precipitation data is available for the watershed. Weather data is readily available from NOAA. The Lexington Airport is located inside the study watershed and hourly precipitation, temperature, and wind speed data are easily accessible. Flow and water depth data is also easily accessible from USGS gage 03289000 located at the outlet of the watershed. (5) The South Elkhorn is very close to the University of Kentucky and is easily accessible to the researchers on a daily basis. (6) The South Elkhorn is a multi land use lowland watershed with urban and non-urban land cover, and is representative of other small scale basins in the bluegrass region of Kentucky. At this time, the region has pronounced sedimentation problems in its streams primarily as the result of bank erosion processes, thus making the model development a regional environmental need.

In general, the banks of the South Elkhorn have low erodibility and are stable in the watershed upstream of Site 1 in Figure 1. . From Site 1 to the outlet of the watershed at site 2 the banks become progressively more incised with less vegetation. Stream bank, stream bed erosion and deposition are the dominant sediment processes within this reach of the watershed.

In development of the coupled modeling tool for the South Elkhorn, emphasis was placed upon data collection and performing sediment fingerprinting using data from sites 1 and 2 in Figure 1. Thereafter, the watershed model was further developed for the problem reach.

(1) Measure Sediment Yield

In order to provide data for calculation of suspended sediment yield in the watershed, suspended sediment was collect and thereafter the Einstein approach was used to estimate sediment yield.

Suspended sediment was collected from the South Elkhorn watershed using a Teledyne ISCO water sampler. 500ml samples were collected on a storm by storm basis on either a one hour or two hour time step. The samplers were then transported to the University of Kentucky Hydrosystems Laboratory where they were individually run through a pre-weighed dry filter, and then dried for an additional twenty four hours, and the sediment was measured. A total of 5 storm events were used for estimation of sediment yield. The yield for the storm events were evaluated

using Einsteins approach (1950) which is described in (Chang, 1988). The suspended sediment discharge was obtained by integrating

$$q_{ss} = \int_a^D Cudz \qquad \text{Eq(1)}$$

where q_{ss} is the discharge of suspended sediment per unit channel width, a is the lower limit where suspension begins, C is the sediment concentration, and D is the depth. The Einstein integration yields the equation

$$q_{ss} = 11.6 C_a U_*^{'} \left[2.303 \log\left(\frac{30.2D}{\Delta} \right) I_1 + I_2 \right] \qquad \text{Eq(2)}$$

where

$$I_1 = 0.216 \frac{A^{z_*-1}}{(1-A)^{z_*}} \int_A^1 \left(\frac{1-\eta}{\eta} \right)^{z_*} d\eta \qquad \text{Eq(3)}$$

$$I_1 = 0.216 \frac{A^{z_*-1}}{(1-A)^{z_*}} \int_A^1 \left(\frac{1-\eta}{\eta} \right)^{z_*} \ln(\eta) d\eta \qquad \text{Eq(4)}$$

I_1 and I_2 are function of A and z^* and were integrated numerically using (Nakato, 1984). The sediment concentration, C, can be calculated at any time instant with the equation

$$C(y) = C_a \left[\left(\frac{D-y}{y} \right) \left(\frac{a}{D-a} \right) \right]^{z^*} \qquad \text{Eq(5)}$$

where C_a is a reference concentration and a is a reference level. z^* is the Rouse number defined as

$$z_* = \frac{\omega_s}{\kappa U_*} \qquad \text{Eq(6)}$$

where w_s is sediment fall velocity in m/s, κ is the dimensionless von Karman constant equal to approximately 0.40, and U^* is the shear velocity in m/s. U^* is defined as

$$U_* = (gHS)^{1/2} \qquad \text{Eq(7)}$$

The reference level a is treated as the transition from bed load to suspended load and occurs on the order of 5% of the flow depth (Chang 1988). C_a typically corresponds to this reference level, however, here C_a will be calculated using concentration at the ISCO sampler inlet depth, C_Y, which can be used in Equation (5) and rearranged as

$$C_a = \frac{C_Y}{\left[\left(\frac{H-Y}{Y}\right)\left(\frac{a}{H-a}\right)\right]^{z^*}} \qquad \text{Eq(8)}$$

where Y is the depth of the depth at the inlet as defined before.

The yields for an individual storm event were determined by integrating the sediment rate function Equation (2) over the entire storm hydrograph.

$$S_y = \int_0^T Q_s dt \qquad \text{Eq (9)}$$

Where 0 is the onset of the storm event, T is the end of the event, and Q_s is the sediment flow rate (q_{ss}) integrated over the width of the channel.

A storm hydrograph is defined as the flow period between the onset of the hydrograph until the point in time when significant flow acceleration ceases and the flow regime returns to base flow conditions. This base flow separation method was taken from (Chow, 1988). The onset of acceleration of the flow over time was defined as the point when flow acceleration begins, and the end of the flow acceleration was determined as a function of the peak flow (Q_p)

$$N = 4.094e^{0.004Q_p} \qquad \text{Eq(10)}$$

where N is the length of time from the time of peak flow to the time when storm acceleration ends and the flow regime returns to base flow conditions.

Using the Einstein method, the sediment yields were calculated. Thereafter, a power law was used to fit the relationship of sediment yield to peak flow rate. Figure (2) show the yields and peak flow rates for the sediment transporting storm events in the South Elkhorn.

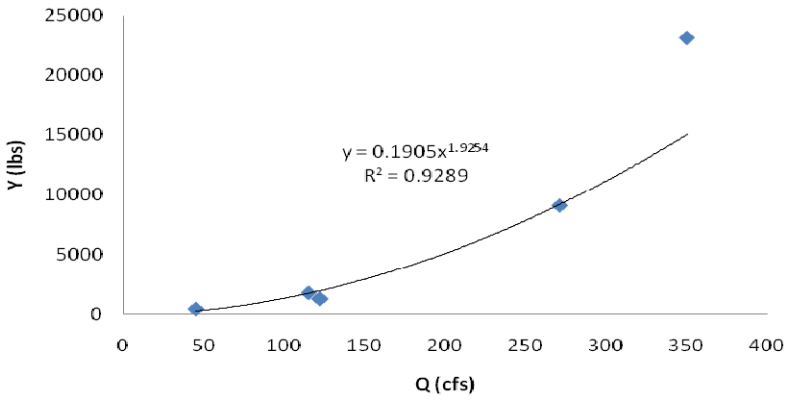

Figure (2) Sediment Yield and Peak Flow Rate for the Sampling Period

(2) Sediment Yield Estimation Using Tracer Data and Sediment Fingerprinting

The contribution of the sediment yield derived from bank erosion was estimated using sediment fingerprinting with carbon and nitrogen isotope (δ^{13}C and δ^{15}N) natural tracers.

The isotopic tracers are a signature of the sediment and a result of carbon and nitrogen cycling. δ^{13}C and δ^{15}N are dependent upon environmental variabiles including the spatial properties of the land cover (e.g.,. vegetation type) and land management (e.g., tillage, biostabilzation methods) making the tracers ideal for comparison of different spatial sources of erosion in a watershed. In other words, two different tracks of land will have two different isotopic signatures, and sediment can be traced back to its source by analyzing its isotopic signature. This method can be applied to the watershed by collecting and analyzing suspended sediment captures at an outlet. The sediment at the outlet is a mixture of all sediment sources in the watershed, and by comparing the signature of the sediment at the outlet with the signature of the sediment sources a fraction of total sediment yield can be derived for each sediment source.

Sediment tracer samples were collected using *in situ* sediment trapping devices (Walling and Amos 1999; Phillips et al. 2000; Russell et al. 2000; Gruszowski et al. 2003; Fox 2005; Walling et al. 2006; Fox and Papanicolaou 2007). The sediment traps were collected and replaced weekly. The traps were emptied and the contents centrifuged to remove as much water as possible without losing sediment. The samples were then freeze dried, weighed, and wet sieved to separated the d<53 μm, where d is particle size diameter, fine fraction. The fine fraction was then freeze dried and weighed again to determine the mass of suspended sediment captured inside the trap for the sampling time.

A characteristic of the South Elkhorn is the predominance of bank erosion in the lower reach of the watershed between sites 1 and 2 (see Figure 1) and the lack of overland (rill and inter rill) erosion in the uplands. The majority of sediment collected at the outlet is either from the stream banks or streambed of the ephemeral and perennial streams throughout the basin and the bed of the main channel. Past research has shown that the δ^{15}N signature of the stream banks is statistically unique in comparison with the in-stream sediments of the streambeds (Davis 2008). The differences are due to the in-stream biochemical processes that the sediments undergo, e.g., microbial processesing, once deposited in the stream of the channel. The fingerprinting study collected samples at two locations, site one near the uplands before the incised stream banks and site two at the outlet of the watershed. The sediment collected at each sampling site was analyzed for their N^{15} isotopic signature.

Because of the small contribution from sediment sources other than the stream banks and streambed, the isotopic signature of the sampling site before the bank erosion reach (site 1) was assumed to be the signature of the stream banks and all other sediment sources except the stream banks, and the signature of the sediment at the outlet (site 2) was assumed to be the signature of the all sediment sources plus the stream banks in the lower reach where bank erosion was a severe problem.

$$\delta_{outlet}^{15} = X_{banks}\delta_{banks}^{15} + X_{other}\delta_{other}^{15} \quad \text{(Eq 11)}$$

where X_{Banks} is fraction of material coming from the banks, X_{Other} is the fraction of material coming from all sources except the banks, and δ^{15} is the isotopic signature from its respective source. By definition

$$X_{banks} + X_{other} = 1 \quad \text{(Eq 12)}$$

and by substitution.

$$X_{banks} = \frac{\delta_{outlet}^{15} - \delta_{other}^{15}}{\delta_{bank}^{15} - \delta_{other}^{15}} \quad \text{(Eq 13)}$$

Using this method a fraction of sediment yield from stream bank erosion is determined. Figure 3 shows the yield of sediment for each source for weekly samples collected during the sampling period. The stream banks show higher sediment yield with discharge but also show variability. The streambed erosion shows a consistent trend with increasing peak flow that erodes a greater load of streambed sediments.

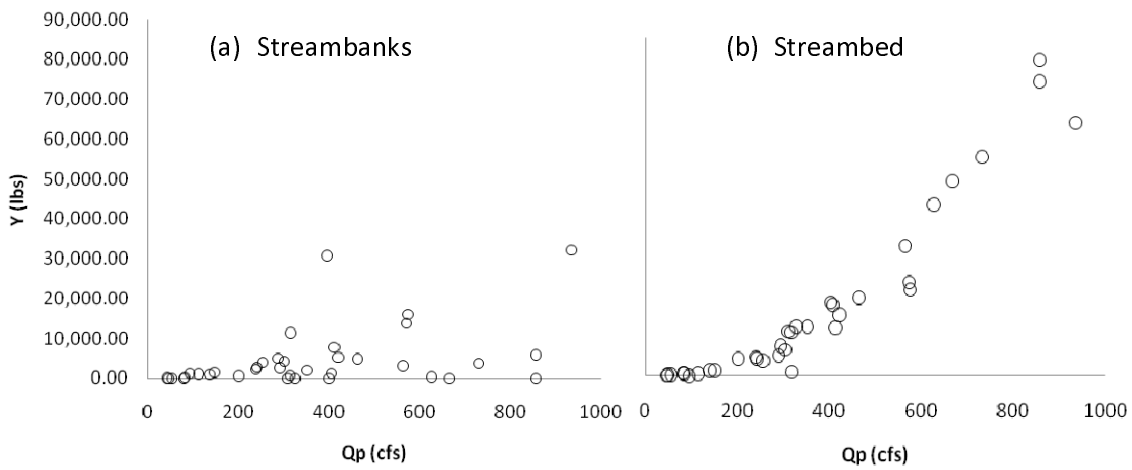

Figure (3) Yield from streambank and streambed sediments

(3) Watershed Bank Erosion Model

The sediment fingerprinting results were used in a coupled modeling framework to calibrate bank erosion at the watershed scale. The watershed model Hydrological Simulation Program – FORTRAN (HSPF) (Bicknell et al., 1997) was chosen to be used as the watershed model for the South Elkhorn. HSPF was chosen for the hydrological model for the South Elkhorn because 1) HSPF has the ability to model on a variety of time steps including hourly and daily, 2) HSPF is a very comprehensive watershed model that includes a multitude of overland and in-stream processes, 3) HSPF is easily available via download from the EPA.

HSPF is a deterministic lumped parameter model that has been used successfully on large (Bergman et al., 2002; Ackerman et al., 2005; Ribarava et al,

2008) and small (Mishra et al., 2006) watersheds. HSPF can also be used as a semi-distributed parameter model as it divides the watershed into different hydrological homogeneous land segments (i.e. forest cover, urban cover, est.), and calculates runoff and pollutant values for these land segments independently. HSPF considers three types of modeling segments, permeable land, impermeable land, and reaches. These modeling segments have several components that calculate runoff and pollutant values for each land segment. The flow and pollutants are routed through the reaches, and the resulting hydrograph and pollutant graphs can be exported for any reach/land segment desired. HSPF requires time series data of precipitation and potential evapotranspiration as a minimum data requirements, although certain pollutants require additional time series including daily temperature, percent cloud cover, dew point temperature, wind speed, and solar radiation.

HSPF simulates sediment detachment and transport for upland sources as a function of runoff shear stress and of raindrop detachment. Sediment detachment, transport, and entrainment are modeled in the bed of the channel as a function of reach mean velocity, particle settling velocity, and entrainment/transport/scour velocity thresholds. HSPF models three sizes of sediment (sand, silt, and gravel). HSPF does not include a bank erosion component and therefore a bank erosion component was developed as a separate subroutine that was input to the model.

Flow calibration and verification was performed by first performing a simple sensitivity analysis to determine which parameters the model is most sensitive too by adjusting routing, permeable land, and impermeable land parameters from their maximum to their minimum value and analyzing the resulting hydrograph. Once sensitive parameters were determined, the sensitive parameters were adjusted until the outflow from the model matched the observed values for the calibration period (2006 to 2008). The was calibrated as a two step process: 1) Routing parameters were adjusted until yearly volumes of water and were matched with observed data as well as possible, 2) cross sectional geometry parameters were adjusted using cross sectional data to match average stream velocities with observed values as well as possible 3) permeable land and impermeable land parameters such as interflow and soil storage capacities were adjusted until the base flow and hydrograph shape were as closely matching observed data as possible. Figure 4 shows the observed and simulated flows for a six month period, and figure 5 shows the verification period.

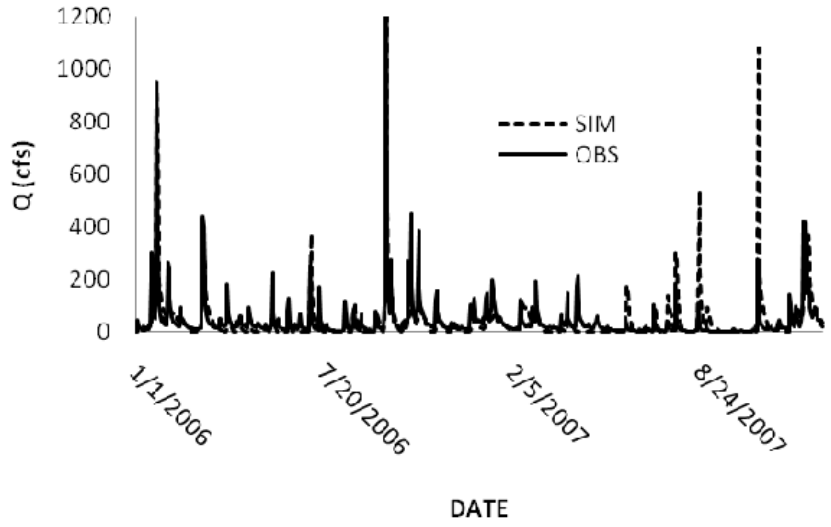

Figure (4) Observed and Simulated flow for the Calibration Period

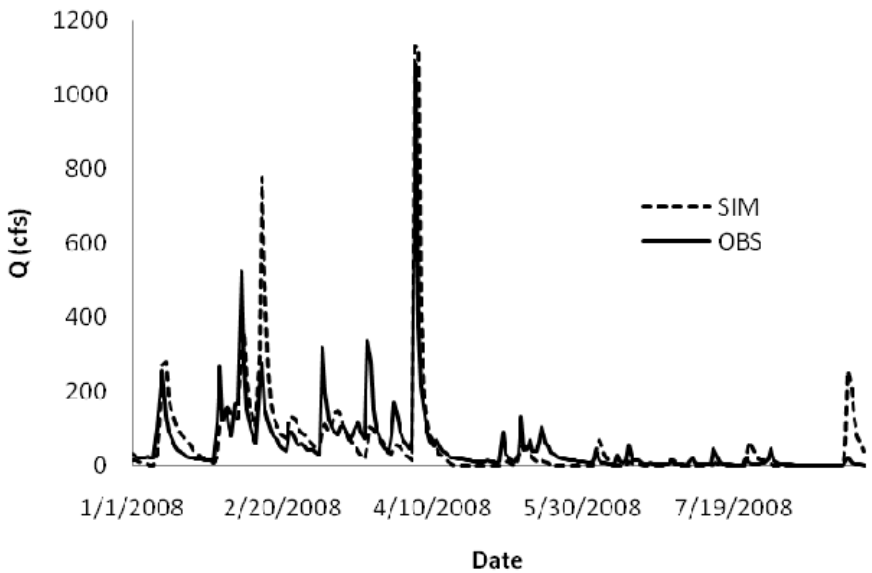

Figure (5) Observed and Simulated flow for the Validation Period

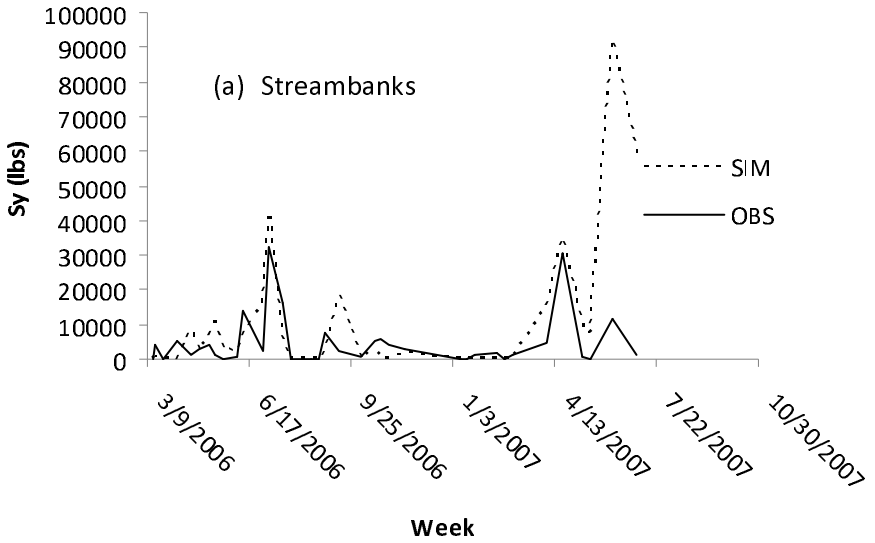
After calibrating for flow, the sediment component, including the bank erosion component, were added to HSPF. For the time being, the bank erosion model used was a conceptually simple model that relates sediment yield from the banks in the reach as a function of the excess shear stress as

$$S_y = m\left(\frac{\tau}{\tau_c} - 1\right)^n \qquad \text{Eq (14)}$$



where τ is the shear stress at the banks and τ_c is the critical shear stress for the reach, and m and n are calibration coefficients. The sediment fingerprinting results were used to calibrate the bank erosion model. Common values for the critical shear stress were used based on the published literature and were varied from 2 to 5 Pa. Values

were iterated through the bank erosion model until reasonable values of sediment yield were calculated. The coefficients m and n were also calibrated and equaled 2211 and 1.44, respectively.

Using the calibrated flow data from the model, the daily sediment yield was predicted using Equation 14 and a time series was built. Bank erosion was modeled as a point source in the affected reach, and this time series was used as the daily load of sediment delivered from the banks into the reach. The sediment was then routed to the outlet of the watershed and the final fine sediment time series was compared with the observed sediment yield. The calibration procedure was as follows: 1) Predict sediment yield from the banks using the simulated flow data and Equation 14 and create a time series of sediment load delivered into the reach from the banks, 2) Use the bank sediment load time series as the loading data for a point source in the affected reach, 3) compare the sediment yield at the outlet with the observed values of sediment yield, and 4) adjust model parameters and repeat steps one through four until simulated values match observed values.

Figure 6 shows the comparison between simulated and obverted sediment yield at the outlet that is derived from the stream banks and the total sediment yield.

The model shows reasonable results for the stream bank estimates with the exception of the last event, however the total sediment yield comparisons need additional refinement, which is on-going. While flow is modeled reasonable well, velocity and total yield estimates have considerable error. Table (1) contains the correlation and error of observed velocity, flow, and yield measurements with the simulated values.

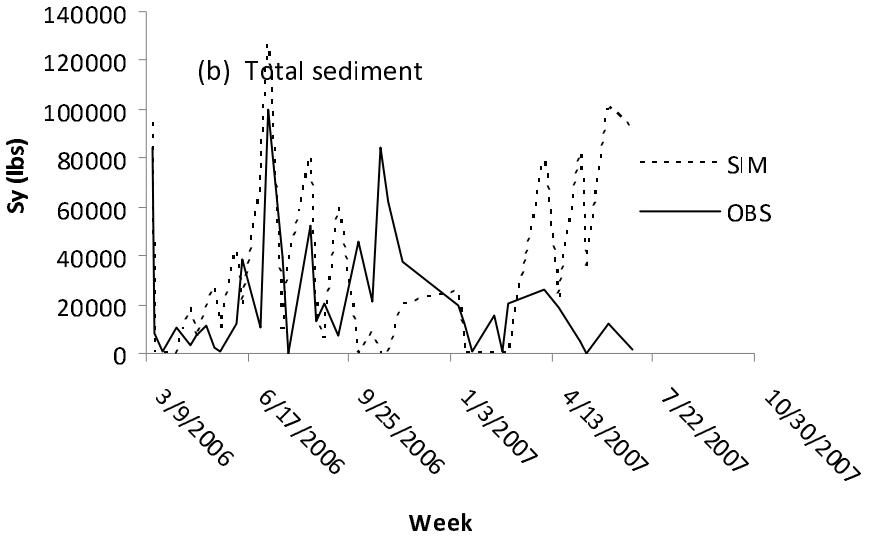


Figure (6) Bank and total Sediment Yield SIM and OBS VS Date

Table (1) Table Statistical Observations

	Correlation With Observed Data	Percent Error
Flow Calibration Period (06-07)	0.80	-1.10
Flow Verification Period (08)	0.77	-6.79
Velocity Calibration Period (06-07)	0.68	-28.48
Velocity Verification Period (08)	0.81	-34.16
Bank Sediment Yield (06-07)	0.46	57.25
Total Sediment Yield (06-07)	0.47	36.73

The percent error is the difference between the simulated and the observed values while the correlation coefficient is a measure of how well the trends of the simulated data match the trends of the observed data.

DISCUSSION

This paper presents a new coupled methodology for estimating and modeling stream bank erosion yields using sediment fingerprinting and watershed erosion and sediment transport modeling. This research is ongoing and areas of ongoing improvement include the following:

- Further refine the stream bank model component to account for spatial distribution laterally and vertically in the reach. The sediment yield estimation for the bank estimation shows a low correlation with the peak flow for the sampling period (0.43). Other processes are occurring that are affecting stream bank erosion besides the peak flow rate, and these processes must be investigated.
- Refine the sediment yield and the tube mass relationship. The sediment yield data represents the mass of sediment transported out of the reach for the entire sampling period, which is about one week. The current relationship between flow and yield is based on the peak flow for that sampling period. This data needs to be refined so that we can draw a relationship between a single storm event, and the peak flow for that event.
- Increase the resolution of the model. Stream banks are currently modeled as a point source in one reach of the model. The next step needs to be to differentiate the different sections of stream bank erosion, estimate erosion yield for each of these sections, and increase the resolution of the model by simulating stream bank erosion in each of these sections.
- Further calibration of the flow, velocity, and sediment models. The most important parameter for the HSPF stream bed erosion model is the velocity of the flow in the reach. Velocity and sediment yield all show a low correlation with observed values and large percent errors. Further calibration is needed to enhance the models predictive capacities.

After refining the coupled model, the model will be used for performing watershed erosion and sediment transport modeling across the watershed in order that future land-use scenarios and climate changes can be modeled and investigated for the Bluegrass.

Retrofitting Stormwater BMPs in a Supercritical Flow Regime
A Hydraulic Perspective

ABSTRACT

A computational hydraulic model toolkit was required to facilitate designs that would permit retrofitting stormwater Best Management Practices (BMPs) and flow diversion structures on covered and open channels flowing under supercritical flow conditions:

- Without exacerbating flooding, and
- Maximizing the capture of suspended solids.

This paper outlines the development of the computational hydraulic model toolkit.

The paper addresses:

- The computational hydraulic modeling of the base case – pre installation of the BMP,
- The use of a Diversion Channel to divert the treatable flow from the Main Channel to the BMP via a weir or gate,
- The transitioning of the flow regime from supercritical to subcritical immediately upstream of the BMP and wholly within the Inlet Diversion Channel to optimize the settlement of sediments in the BMP and limit sediment drop out in the Inlet Diversion Channel,
- The transitioning of the flow regime from subcritical to supercritical immediately downstream of the BMP and wholly within the Outlet Diversion Channel to minimize flow depths,
- The strategic positioning of the hydraulic jump outside of the Main Channel to prevent overtopping and the likely flooding of adjacent residences,
- The design of flood mitigation works and the mitigation of sediment drop out upstream of the weir in the Main Channel, and
- Retaining Main Channel capacity.

A physical model was constructed of a proposed BMP retrofit and tested for a range of flows. The physical model was used to check and refine the computational model as well as for determining the optimum angle for flow diversion and the total force on weirs. The latter was used in the design of collapsible weirs.

The computational hydraulic model has been successfully used to design the diversion channel bed slopes and the lengths and dimensions of inlet and outlet Diversion Channels to optimize pollutant capture and to manage potential flooding.

1. INTRODUCTION

Many of the stormwater channels that were constructed in our cities and towns pre-1980 were typically constructed from concrete or brickwork (Refer to Photographs 1, 2 and 3). Hydraulic analyses indicate that the majority of these channels flow under supercritical flow conditions, thus the ability to settle out suspended sediments within a stormwater best management practice (BMP) is made more difficult by the fast moving water. Attempts to slow the water down to enhance settlement generally lead to a raising of the flood level and in some instances the flooding of private property and the deposit of sediment in the Main Channel instead of in the BMP (Refer to Photograph 4). This paper sets out the techniques that were developed to overcome these issues.

Photo 1 - Typical concrete lined stormwater channel

Photo 2 - Typical brick lined stormwater channel

Photograph 4 illustrates an example of a BMP and weir retrofitted in the 1990's. This method is still commonly used and creates the following hydraulic issues:

- Establishment of a hydraulic jump at the diversion weir which results in floodwaters overtopping the channel wall, and
- Establishment of a slow moving body of water immediately upstream of the weir resulting in sediment dropping out from the water column in the Main Channel. The drawback is that during the next flood event the sediment can become re-suspended and then carried over the weir instead of to the BMP. Other negative issues; include unsightliness, provision of a habitat for mosquitoes and vermin and public complaints.

Photo 3 - Typical covered concrete channel.

Photo 4 – A weir retrofitted to divert stormwater towards a BMP for treatment.

2. HYDROLOGY

In hydrologic terms the channels generally had capacities of the order of a 1 in 10 year to a 1 in 20 year storm event. In most instances the flow rate that was adopted for diversion to the BMP for treatment was the 1 in 3 month peak flow. The 1 in 3 month storm event was selected as it represents in excess of 90% of the total yearly volume of runoff.

3. HYDRAULICS

The computational hydraulic modeling toolkit developed for this project was to be later used by a number of sub-consultants to carry out the detailed hydraulic modeling and design work and it was thus necessary to find a program that was readily available, within target budget and reasonable straight forward to use. Computational Fluid Dynamic Models and other complex hydraulic models were not considered due to cost and the need for experienced hydraulic modelers.

The public domain hydraulic program HEC-RAS was selected as it was readily available and there were reasonable number of modelers who were familiar or experienced users of that particular model.

3.1 Current Practice

Prior to this project, the practice was to retrofit the BMP as economically as possible and often in locations with limited space. Thus a Diversion Weir was placed across the Main Channel and the Inlet Diversion and Outlet Diversion Channels were kept as short as possible (refer to Figure 1) and their hydraulic impacts were not fully appreciated. Often a hydraulic jump would occur in the Inlet Diversion Channel and it would extend into the Main Channel resulting in a slow moving body of water at the weir and subsequent settling out of sediments and debris immediately upstream of the weir (Photo 4). Additionally, early overtopping of the weir would occur, resulting in a lesser quantity of suspended sediment being diverted to the BMP.

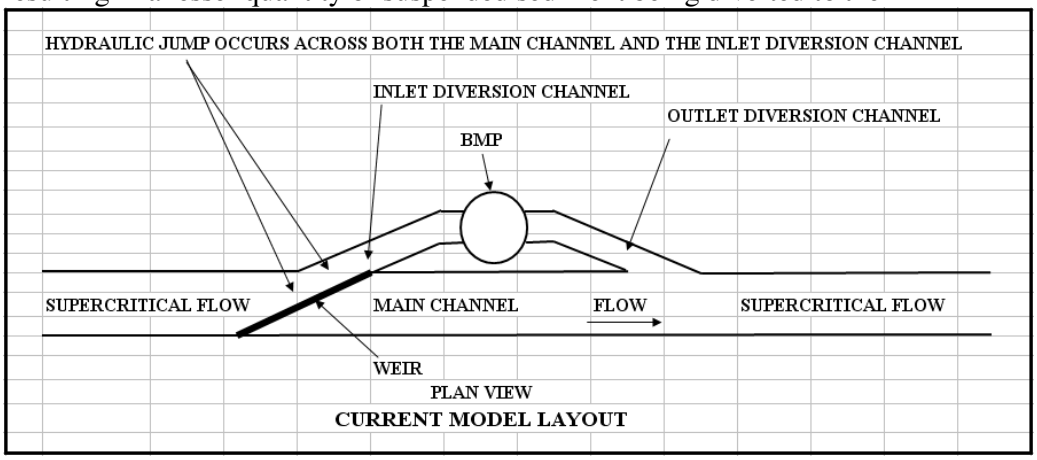

Figure 1 – Current Practice BMP Retrofit Layout

3.2 Conceptual Model

A conceptual model (Figure 2) was developed which laid out all the requirements of the hypothesis and which if achieved would significantly enhance the capture of pollutants, in particularly sediments and also manage flooding which is typically associated with placing obstructions within channels flowing under supercritical conditions.

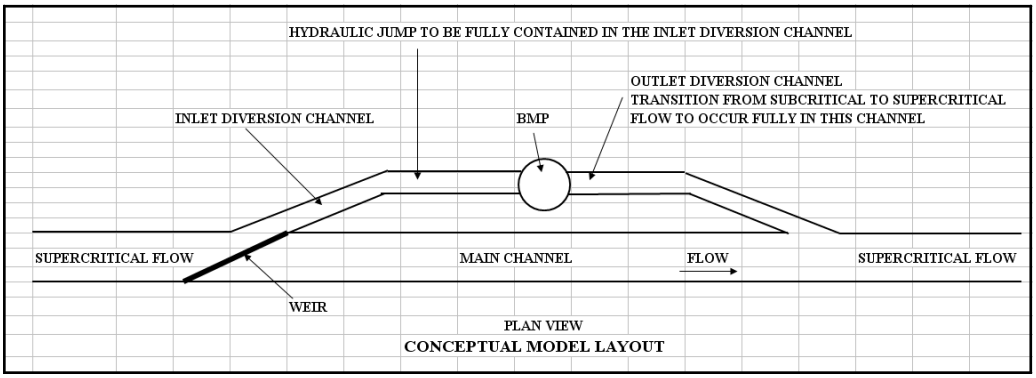

Figure 2 – Conceptual Model Layout

3.3 Computational Model Components

To simplify the modeling and to provide ease of review the computational hydraulic model was broken up into three (3) separate models.

Model 1 (Figure 3) was developed to determine the base case. That is, to determine the capacity (Q_c) of the existing channel just before overtopping occurred and to determine the flow depth for the treatable flow rate. In HEC-RAS, the channel is constructed from a number of channel cross sections (also known as River Stations). For our project, cross sections were surveyed at typically 20 meter intervals and at least 200 meters upstream and downstream of the selected BMP location. Where other hydraulic control structures, such as culverts, existed within the 200 meter limit then the survey and the model was extended a further 200m beyond the hydraulic control structure.

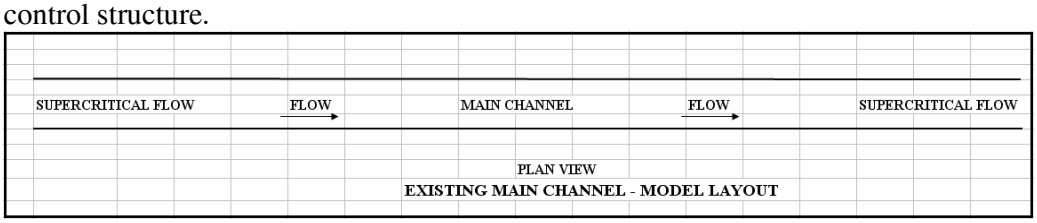

Figure 3 – Existing Main Channel Layout – Model 1

Model 2 (Figure 4) was developed to model the treatable flow rate only and to determine the lengths, grades and dimensions of the Inlet Diversion Channel and the Outlet Diversion Channel such that:

- The flow immediately upstream of the BMP was subcritical in order to optimize settlement of sediments in the BMP,

- The hydraulic jump is fully contained within the Inlet Diversion Channel in order to provide the minimum allowable weir height (preferable equal to the supercritical depth of the treatable flow in the Main Channel for the base case plus the estimated super-elevation),
- The hydraulic jump does not overtop the walls of the Inlet Diversion Channel,
- The flow when it departs the BMP is subcritical, and
- The flow transitions from subcritical back to supercritical within the Outlet Diversion Channel and before it reaches the Main Channel.

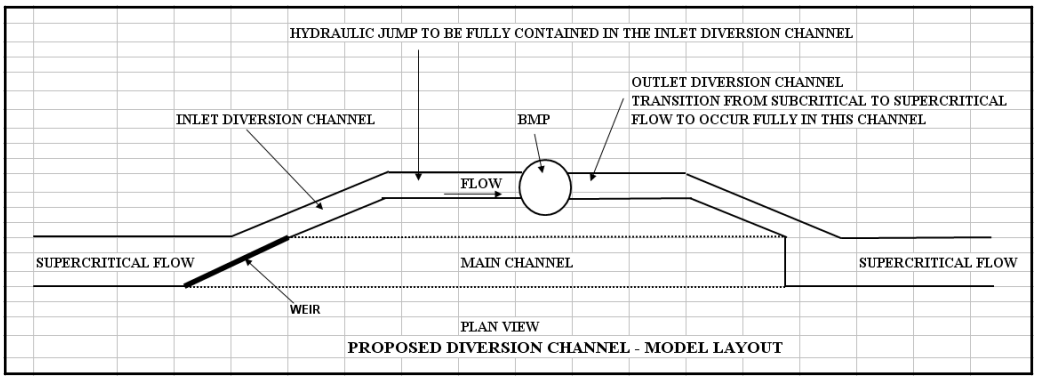

Figure 4 – Proposed Diversion Channel Layout – Model 2

Model 3 (Figure 5) was developed after the location of the start of the Inlet Diversion Channel and the end of the Outlet Diversion Channel had been determined in Model 2 above. This model was necessary to determine the impact of including a fixed weir and sudden expansion and contraction sections in the Main Channel and assuming that the BMP is fully blocked. The model was then amended to include flood mitigation works to prevent over topping of the channel for the previously determined full capacity flow (Q_c).

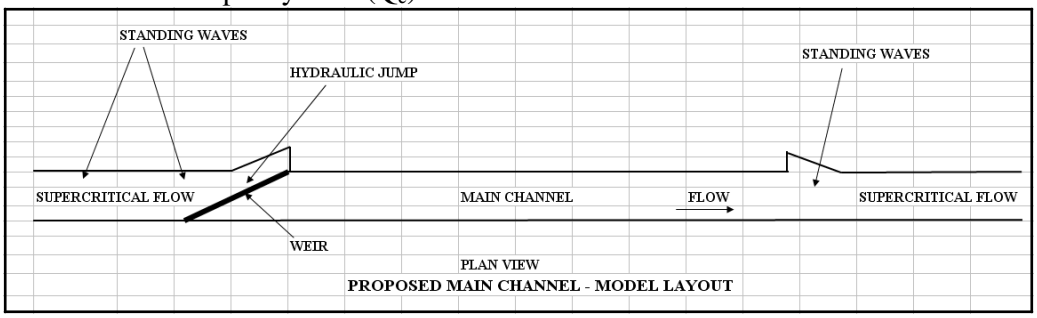

Figure 5 – Proposed Main Channel Layout – Model 3

3.4 Physical Model

A physical model of an actual design was constructed at the University of Technology - Sydney, hydraulics laboratory. The physical model was used to check the conceptual model, the hydraulic behavior predicted by the computational model,

determine where the computational model required refining and what assumed computational model parameters required adjustment.

Photograph 5 illustrates the 1 in 20 scale model which was constructed from Perspex. The BMP was represented by a section with a dropped invert and removable vertical plates with different sized holes. The different size holes represented the percentage blockage of the BMP.

The model shown in Photograph 5 included a collapsible weir (and not a skewed weir as shown in Figure 4). A strain gauge was used to measure the force on the weir at the design flow. This was later used to design the counter-weight for the collapsible and self righting weir.

Fourteen Piezometers (Photograph 7) were used to record the hydraulic head at various locations within the Main Channel and the Diversion Channel. This data was used to compare the computational model results against the physical model results. Key areas of difference between the physical model and the computer model were the predicted behavior at weirs that were located at right angles to the Main Channel and the magnitude of the disturbances at the confluence of the Diversion Channel with the Main Channel. The physical model showed the water profile super-elevating at bends but also banking up at the downstream end of the weir (Photograph 8).

Photo 5 - 1 in 20 scale model of actual design to determine overall system behavior. (Flow direction is from top to bottom of photo.)

Photo 6 - 1 in 10 scale model to obtain better details at the confluences and at the weir. (Flow direction is from top to bottom of photo.)

Photograph 6 illustrates a 1 in 10 scale model but with geometrically simplified Main and Diversion Channels. The larger model was used to obtain better definition of the behavior of the water surface at the weir and the confluence of the Diversion Channel and the Main Channel as well at the hydraulic forces on the collapsible weir.

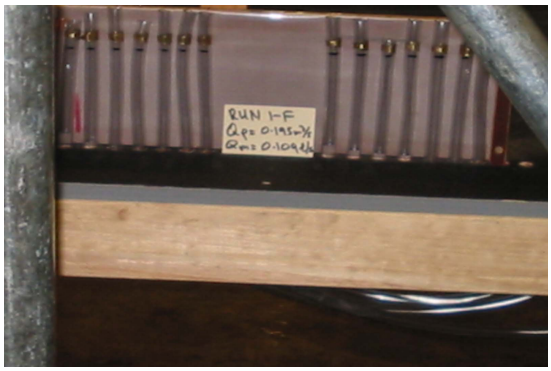

Photo 7 - Piezometers indicating the hydraulic head at various locations in the Main Channel and in the Diversion Channels.

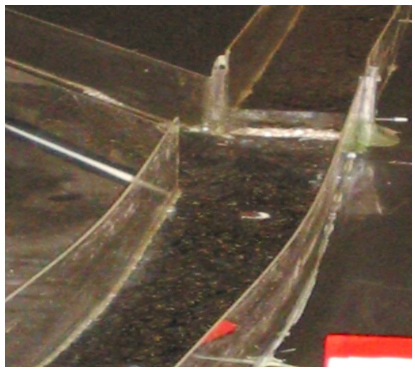

Photo 8 - Close up of the weir, positioned at right angles to the main Channel. (Flow direction is from bottom left to top of photo.)

The physical model was invaluable in identifying hydraulic behavior that was not evident in the computer model results and in providing the computational modelers with the:

- Data to permit model calibration, and
- The confidence that the computer model was providing realistic results.

3.5 Computer Model Calibration

The computer model that was initially developed for the concept design, and which was later used in the construction of the physical model, was revisited and some model parameters amended to reproduce flow profiles that more closely matched the physical model profiles.

Typically Manning's n value is adjusted in computer models to produce profiles to match recorded levels, however in this instance, the flow profiles between the physical and computer models were a good match except at the confluence of the Diversion Channel and the Main Channel and at the weir. Thus the Manning's n value of 0.013 for both concrete and brick channels was retained. The default contraction and expansion values at the River Stations that represented the confluences were increased, from 0.1 to 0.3 and 0.3 to 0.5 respectively. The "ineffective flow area" facility in the HEC-RAS Model was also used to exclude non active flow areas.

3.6 Computer Model

The HEC-RAS Model was developed with three separate geometry files. The geometry files represented:

- Main Channel (Refer to Figure 3),
- Diversion Channel with Diversion Weir and BMP (Refer to Figure 4), and
- Main Channel with Diversion Weir and confluences of Diversion Channels (Refer to Figure 5).

The geometric data file and model and the hydraulic profile in the Diversion Channel with BMP for the treatable flow are shown in Figure 6. Note, in the example in Figure 6, the hydraulic jump commences at River Station 25.8, thus the section of channel between RS 25.8 and RS 46.5 was not necessary from a hydraulic perspective. That section of channel was provided to allow the channel to be located around a large tree that was of significant value to the local community.

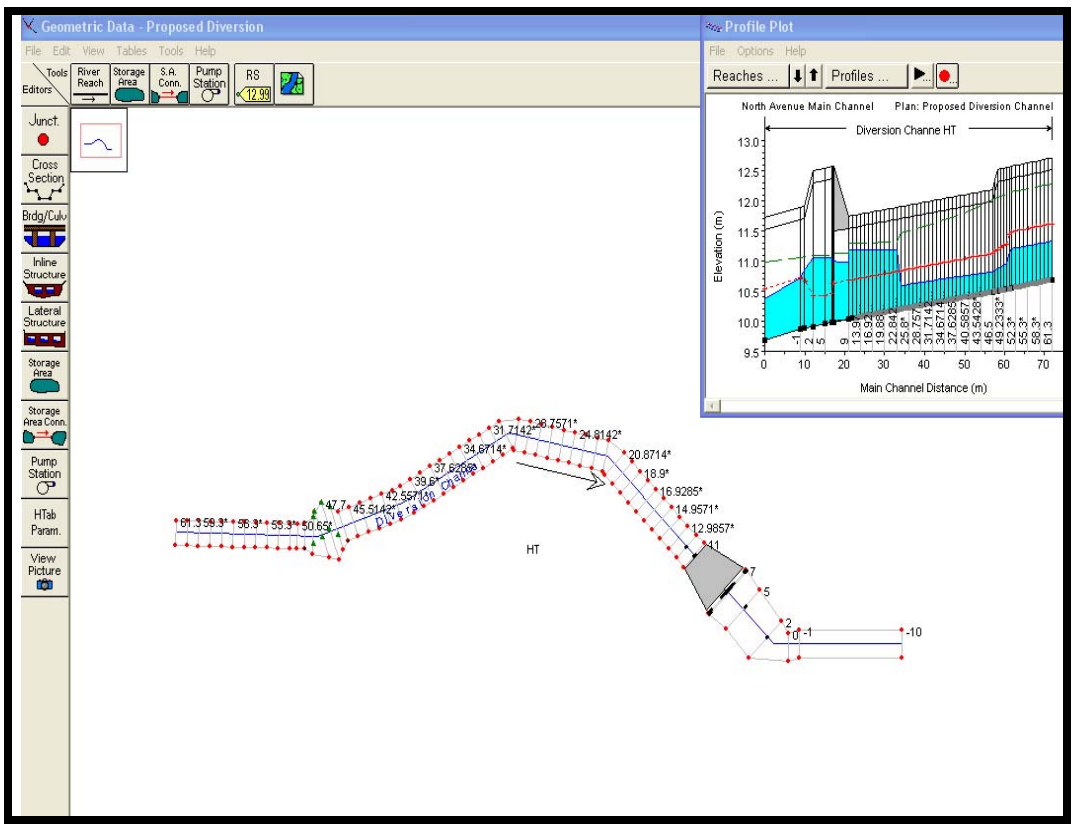

Figure 6 – Plan showing HEC – RAS Geometric Layout and inset the Hydraulic Profile for the treatable flow rate

4. LESSONS LEARNT

During the design of the computational model, the main lesson learnt when working with super critical flow, was the need to avoid abrupt changes to the channel geometry. Abrupt changes to the channel geometry, whether to the invert or the side walls resulted in short sharp spikes in the hydraulic profile.

The effect of placing fixed weirs in the Main Channel resulted in the development of a hydraulic jump and overtopping of the channel walls. Thus flood mitigation works included raising of the channel walls. To reduce the height of hydraulic jumps, the employment of hydraulically efficient ogee and half-circle weirs was determined to be an effective strategy.

5. EARLIER EXAMPLE

Initial designs were trialled on smaller channels with small treatable flow rates and an example is illustrated by Photographs 9, 10 and 11.

Photo 9 – Shows the Main Channel (looking downstream) with a broad curved weir and with the Inlet Diversion Channel on the left.

Photo 10 – Shows the Inlet Diversion Channel and the entrance to the BMP.

Photo 11 – Shows the outlet from the BMP and the Outlet Diversion Channel

Note that the walls of the Diversion Channel are much higher than the walls of the Main Channel. The flow in the Main Channel is supercritical whereas the flow in the Diversion Channels is both supercritical and subcritical.

Also of interest is that the Main Channel can be observed to be free of settled sediment.

For the earlier designs, a separate physical model was developed to investigate the optimum angle for the Diversion Channel (and the diversion weir). The physical model was trialled with diversion channels set at angles of 45^0, 30^0 and 15^0 to the main channel. An angle of 30 degrees was adopted for the designs as:

- The disturbance to the hydraulic profile in the Main Channel remained manageable, and
- It was shown to be optimal in matching the length required for the Inlet and Outlet Diversion Channels and the space for the BMP. (The flatter the angle, the greater the length of the diversion channels to provide sufficient separation from the Main Channel to fit the BMP.)

6. CONCLUSIONS

The decision to invest in a physical model to verify the computational model was invaluable.

The conceptual hydraulic model toolkit developed for the purpose of analyzing the retro-fitting of BMPs on channels that flowed under supercritical conditions was successful. The HEC-RAS computer model performed very well when run under mixed flow (sub-critical and super-critical) conditions and it proved to be a robust and reliable hydraulic modeling tool.

The computational hydraulic model toolkit was used at 15 sites that flowed under supercritical flow conditions and all 15 designs have been successfully constructed, withstood the rigors of a number of actual storm events and have to date not received adverse feedback from adjoining residents.

7. ACKNOWLEDGEMENTS

The author wishes to thank all those who assisted on the project, but in particular: Thilaka Mampitiyarachchi, Sydney Water's Senior Hydraulic Modeler, for her invaluable contribution and the many hours spent reviewing computer model runs and providing guidance in the development of the toolkit, Neil Davis, Azzurra Consulting, for his many useful tips in computational hydraulic modeling, and to Rudi van Drie, Balance R&D Consulting, for constructing and running the physical models.

ABSTRACT

JiJi Weir was built across a mountain river, Chuoshui Creek, Taiwan. Because of deep slope, abundant sediment supply and tropical Typhoon climate, channel changes are very fast and occur in Typhoon seasons. Since its normal operation in 2002, the shallow reservoir of the JiJi Weir had a serious sediment problem: it could be filled up in just one strong typhoon event. Sediment will be completely carried through the reservoir and the spillway of the Weir. In this paper, a computational model, CCHE2D, was used to simulate the sediment transport of the JiJi Weir Reservoir. Transport of both suspended load and bedload sediments with multiple grain-sizes was simulated, and the geomorphology changes were studied within the reservoir during nine typhoon events. Simulation results were compared with the measurements of morphological change, and it shows that the CCHE2D model is capable of producing reasonable and realistic morphological changes.

INTRODUCTION

The JiJi Weir was built in the Chuoshui Creek, a mountain river with a large amount of sediment and affected strongly by floods due to Typhoon. Since the reservoir is shallow and the sediment transport rate is high, the sediment could fill up the reservoir quickly; then once the reservoir is full, the sediment will be completely carried through the reservoir to the downstream. Since its operation in 2002, the JiJi Weir reservoir had serious sediment depositions. Sediments are mainly carried by large flood events in typhoon seasons.

Figure 1. shows the study area from JiJi Weir to JiLu Bridge; the reservoir is about 2 km long. The delta of sedimentation is separated by the main channel into two large areas A and B. According to the measurements in 2003, the total amount of sediment from upstream is about 14.77 million m^3, but only about 13% was transported downstream of the spillway, so the reservoir lost about 1.92 million m^3 in

that year.

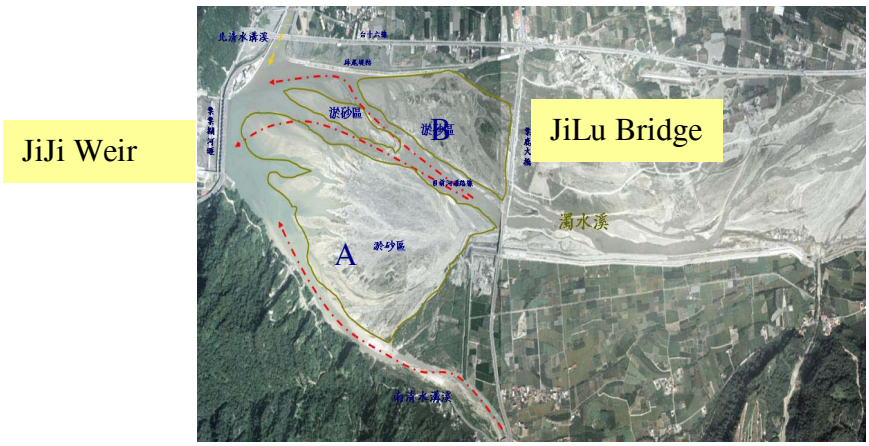

Figure 1. Study Area

In this study, the CCHE2D model was used to simulate the sediment transport and bed morphological changes in this reservoir during nine typhoon events in three years from 2004 to 2007. Simulation results were compared to the measurements of morphological changes.

*C*CHE2D Hydrodynamic and Sediment Transport Model

The CCHE2D model is a state-of-the-art numerical modeling system for two-dimensional, unsteady, turbulent river flow, sediment transport, and water quality prediction. The model is also designed for applications to multiple-process simulations in surface waters with complex geometry such as river bed and bank erosion with both uniform and non-uniform sediment and meander river migration. The model can be used for designing and evaluating the effects of the hydraulic structures, such as grade control structures, dikes, etc. The CCHE2D model uses a hybrid numerical method, the Efficient Element Method (EEM), which takes the advantages of both the Finite Element Method (FEM) and the Finite Volume Method (FVM). Depth-integrated two-dimensional equations (the continuity equation, the momentum equations, the k-ε turbulent equations, the sediment transport equations, etc) are solved with multiple capabilities such as turbulent flow, wind-driven flow, tidal flow, and flow with vegetation effects (Jia and Wang, 1999, 2001a, and 2001b).

The CCHE2D model can simulate the transport of non-uniform sediment mixtures of multiple size classes with bed slope effects, secondary flow effect in curved channels, and avalanche effects. The capability of simulating the non-equilibrium sediment transport process is achieved by solving the following equations (Wu et al., 2000):

Suspended Load:

$$\frac{\partial(hC_k)}{\partial t}+\frac{\partial(UhC_k)}{\partial x}+\frac{\partial(VhC_k)}{\partial y}=\frac{\partial}{\partial x}\left(\varepsilon_s h\frac{\partial C_k}{\partial x}\right)+\frac{\partial}{\partial y}\left(\varepsilon_s h\frac{\partial C_k}{\partial y}\right)+\alpha\omega_{sk}\left(C_{*k}-C_k\right) \quad (1)$$

Bed Load:

$$\frac{\partial(\delta_b\bar{c}_{bk})}{\partial t}+\frac{\partial(\alpha_{bx}q_{bkx})}{\partial x}+\frac{\partial(\alpha_{by}q_{bky})}{\partial y}+\frac{1}{L_t}\left(q_{bk}-q_{b*k}\right)=0 \quad (2)$$

Bed Change:

$$(1-p')\frac{\partial z_{bk}}{\partial t}=\alpha\omega_{sk}\left(C_k-C_{*k}\right)+\left(q_{bk}-q_{b*k}\right)/L_t \quad (3)$$

where h is the local water depth, U and V are the depth-integrated velocity components in the x and y directions, respectively; ε_s is the eddy diffusivity of sediment; C_k is the concentration of the k-th size class, and C_{*k} is the corresponding transport capacity; α is the adaptation coefficient for suspended load; ω_{sk} is the sediment settling velocity; q_{b*k}, q_{bk}, q_{bkx} and q_{bky} are the bed load transport capacity, the bed load transport rate, and transport rate components in x and y directions, respectively; L_t is the adaptation length for bed load; p' is the porosity of bed material, and z_{bk} is the bed change.

The non-equilibrium adaptation length L_t characterizes the distance for a sediment process adjusting from a non-equilibrium state to an equilibrium state, which is related to the scales of sediment transport processes, bed forms and channel geometry.

CURRENT STUDY

Mesh Generation

The study area in the JiJi reservoir is about 2km long. Mesh generation is based on the topographic data measured along cross sections in the reservoir in October, 2004 and January, 2007. A computational mesh (40 x 161) was generated by the 2D structured mesh generator---CCHE-MESH (Zhang, 2006), as shown in Figure 2.

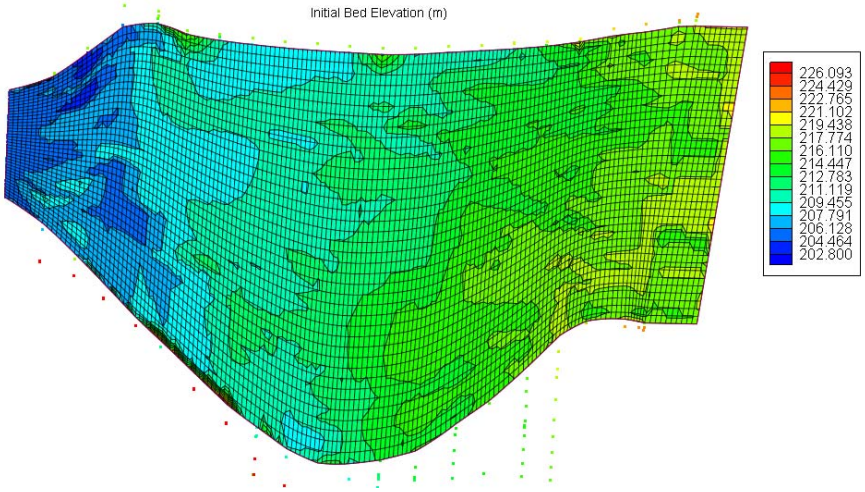

Figure 2. Computational Mesh

Bed Material and Grain Size

Bed material samples obtained in July 2004 were used as initial bed composition within the reservoir. Figures 3. and 4. show the locations of the bed material samples and the representative grain sizes of these samples, respectively. As one can see, within the area about 1000m to the weir, the bed material is very fine, while beyond this area the bed material becomes coarser.

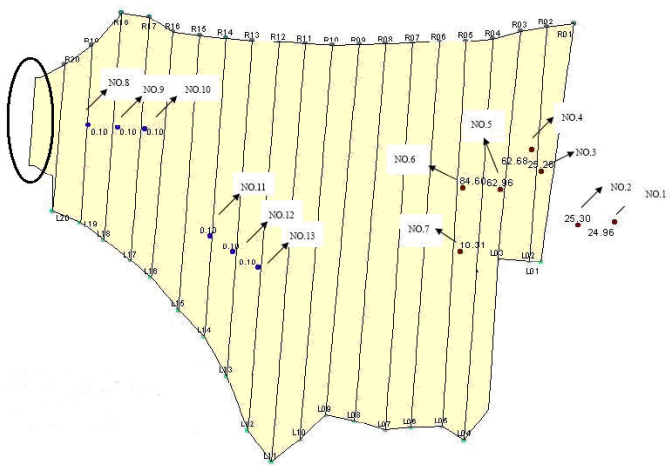

Figure 3. Bed Samples

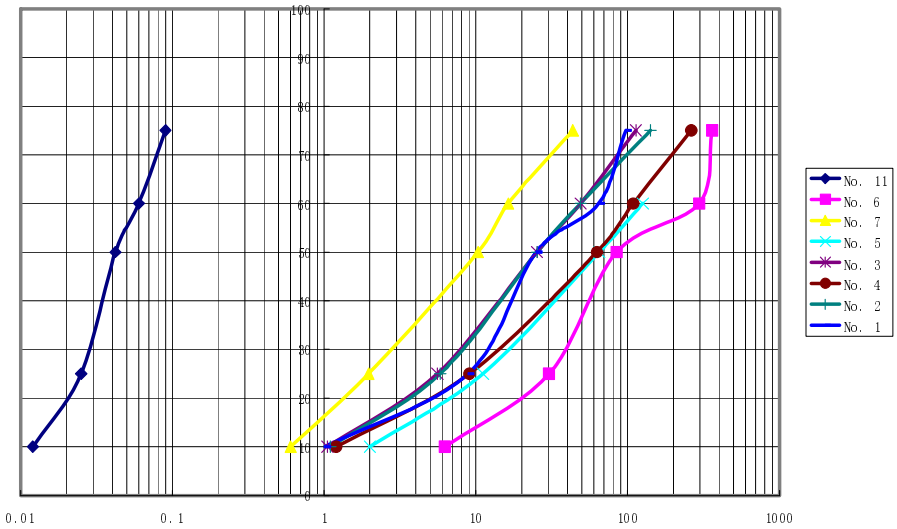

Figure 4. Grain Sizes in JiJi Reservoir

In this study, 6 size classes were defined to simulate the sediment transport in the JiJi reservoir (Table 1).

Table 1 Sediment Size Classes

Classes (mm)	Lower Limit (mm)	Upper Limit (mm)
0.0272	0.001	0.074
0.297	0.074	0.59
2.38	0.59	4.76
9.52	4.76	19.1
152	19.1	305
457	305	610

Boundary Conditions

Table 2 indicates the typhoon events from July 2004 to June 2006 used to calibrate the model, and those events June 2007 to October 2007 were used to validate the model. The sediment hydrograph data was obtained according to the observed relationship between the flow discharge and the sediment concentration. The flow hydrograph and the sediment hydrograph at JiLu bridge, and the stage hydrograph at JiJi weir are plotted in Figs. 5 and 6, respectively.

Table 2 Typhoon Events

Time	Peak Flow at JiLu Bridge (cms)	Time	Peak Flow at JiLu Bridge (cms)
2004/07/01	8,343	2005/08/12	1,201
2004/08/24	4,841	2005/09/01	1,333

Simulation Results

The bed elevation was interpolated onto the computational mesh using the topographic data of October 2004 and January 2007, respectively. Figure 7. shows the comparisons of the bed elevation change in this period (from 2004 to 2007). A big erosion area (A) was observed on the delta where deposition usually occurs, which was caused by extensive dredging in the simulation period. The delta with fine sediment extended further downstream toward the Weir Site and formed two big depositions (B and C) which stopped a few hundred meters from the weir. A scour hole (D) appeared immediately behind the weir, which could be caused by three dimensionality of the flow and associated sediment transport.

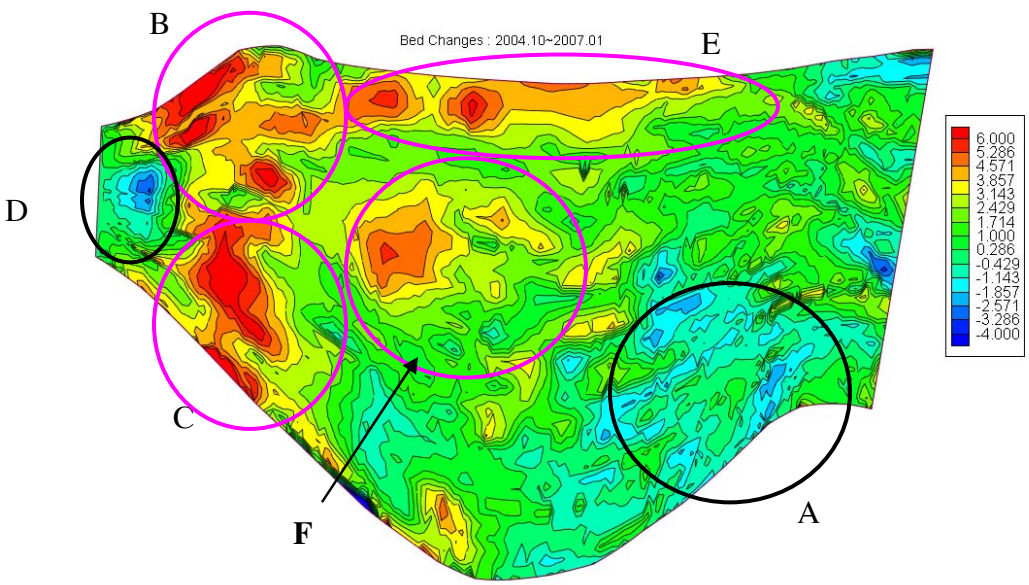

Figure 7. Measured Bed Changes

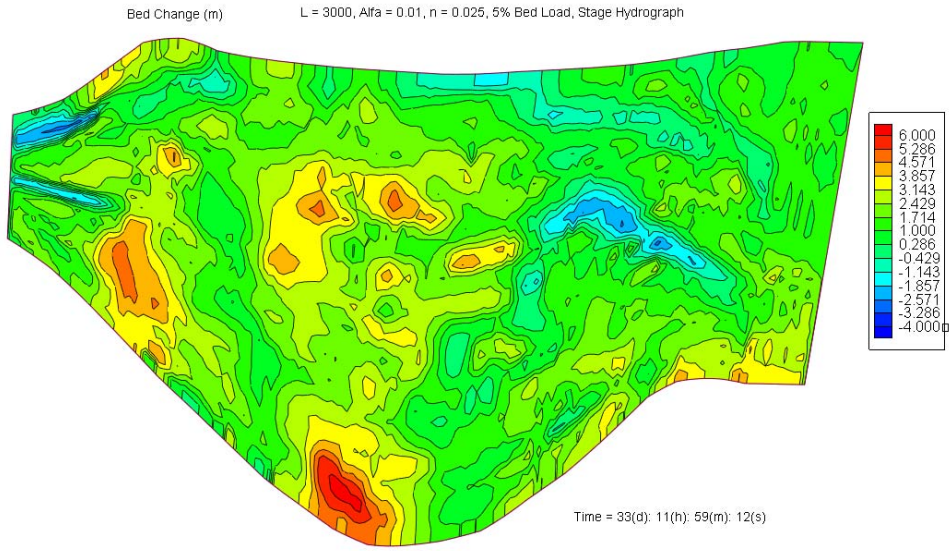
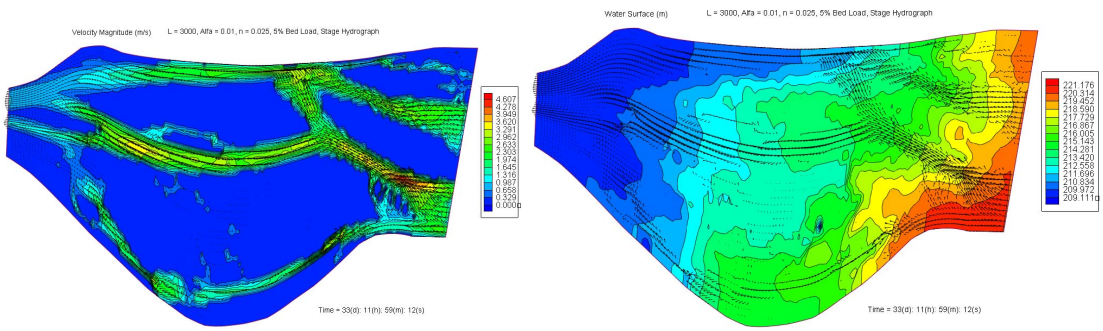
The model was calibrated using the bed topography of October of 2004, the flow and sediment hydrograph from July 2004 to June 2006. Sensitivity studies were performed on the following main model parameters: (1) Ratio of bed load and suspended load (90% suspended sediment, 10% bed load; 95% suspended sediment, 5% bed load; and, 99% suspended sediment, 1% bed load); (2) Bed load adaptation length $\boldsymbol{L_t}$ (= 1000m, 1500m, 2000m, and 3000m); (3) Suspended load adaptation coefficient $\boldsymbol{\alpha}$(= 0.01, 0.015, and 0.02); and, (4) Bed roughness $\boldsymbol{n}$ (= 0.04, 0.032, and 0.025). According to the simulation tests, 95% suspended load and 5% bed load produced more reasonable results, and the combination of bed roughness, bed load adaptation length and suspended load adaptation coefficient ($\boldsymbol{L_t}$ = 3000m, $\boldsymbol{\alpha}$=0.010, and n = 0.025) produced the best results.

Figure 8. shows the simulated bed changes, Figure 9 (a) and (b) show the final

flow field and the water surface level, and Figure 10 (a) and (b) show the peak flow field and water surface level. When the flow discharge was low, large dry areas over the Delta appeared. In the erosion zone A, the simulated results show slight depositions; in the deposition zones B and C, the model under-estimated the depositions; in the deposition zone E, under-estimated results were observed as well; the model predicted two scour holes instead of one in zone D; and, in deposition zone F, the simulation agrees well with the measurements.





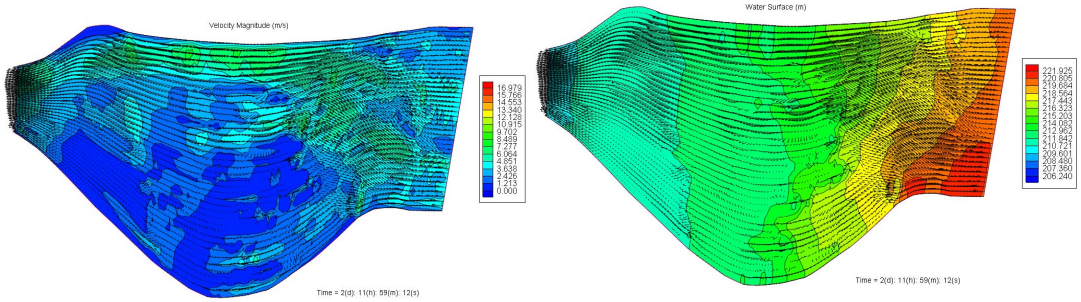


Figure 8. Simulated Bed Changes

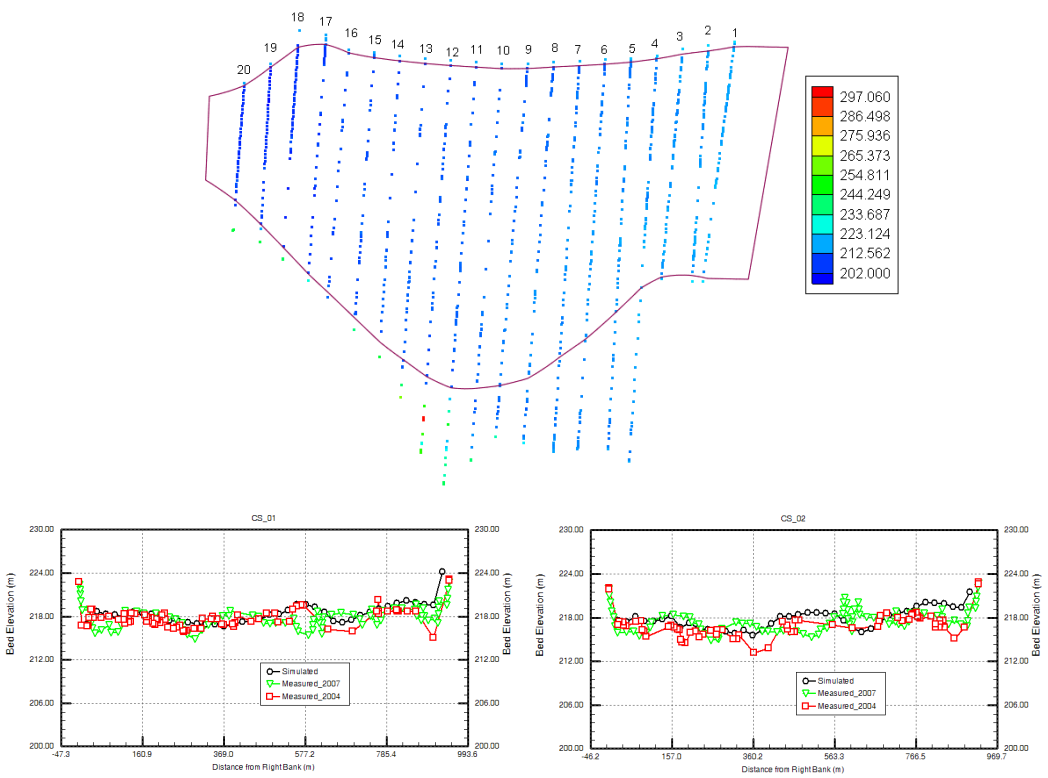

Figure 9. Simulated Flow Field and Water Surface Level

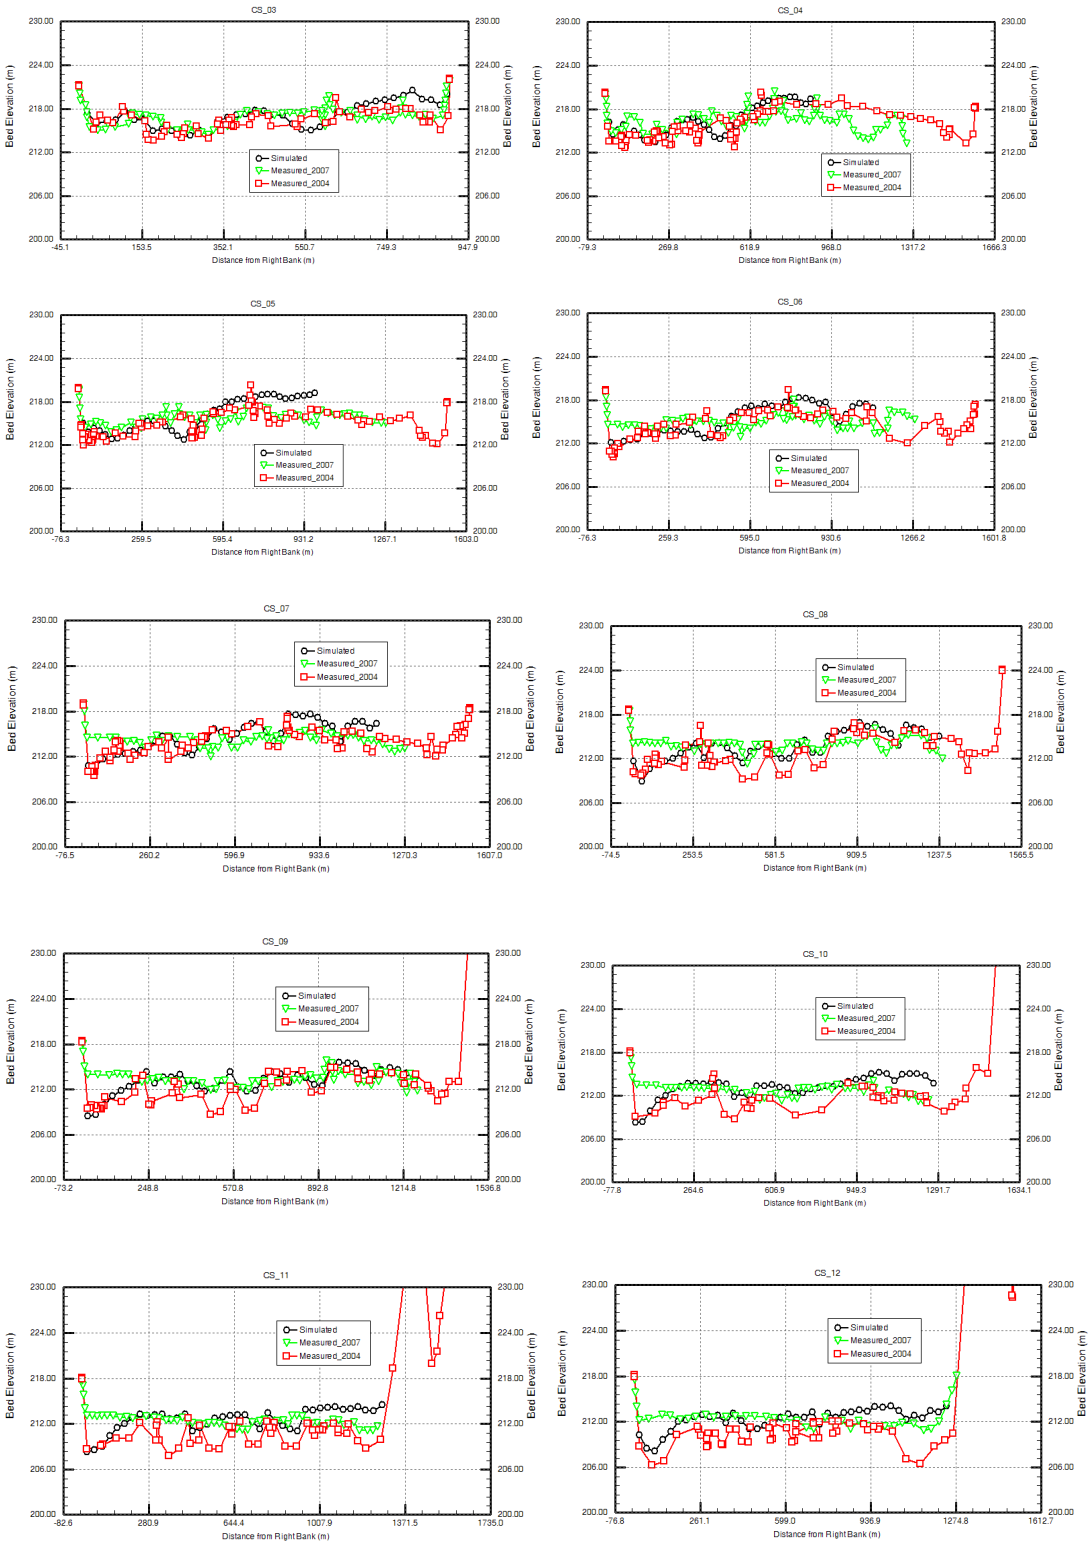

(a) (b)

Figure 10. Peak Flow Field and Water Surface Level

Figure 11. shows the cross sections where the simulated bed elevations are compared with those measured in October 2004 and January 2007. For CS 1~4, the simulated results basically showed good agreements with the measurements except some small scour holes; for CS 5~10, the simulated results under predicted the big erosions over the delta dredging area (zone A, Figure 7.); for CS 11~15, the simulation correctly predicted depositions, but underestimated near the right bank and over-estimated near the left bank; for CS 16~19, the simulated results under-estimated the depositions; and, for CS 20, the big scour hole in front of the Weir was not predicted well.

CONCLUSIONS

The CCHE2D model was used to simulate the sediment transport and the bed morphological changes in the JiJi Reservoir. The followings conclusions are made according to the analysis of simulated results and measurements:

(1) Morphological changes occurred mainly during big flood events. Erosions are near the inlet and in the Weir front. More depositions are distributed in

the lower part of the reservoir, and near the right (North) bank.

(2) The suspended sediment is dominant, which contributes most of the depositions. 95% of suspended load and 5% of bed load are found to be an appropriate sediment combination. The adaptation length of bed load L = 3000 and the adaptation coefficient of the suspended load Alfa = 0.01 produced the best results.

(3) Generally, the trend of the simulated bed change agreed with the observed pattern, but differences remain obvious. The model under-predicted a big scour hole close to the weir and large erosions over the delta which are partially affected by the unknown amount of dredging. The scour hole in front of the weir could be due to the three dimensionality of the flow and sediment transport, which could be resolved better with a 3D model.

(4) The CCHE2D model is capable of simulating sediment transport and morphological changes within the JiJi Weir reservoir with unsteady boundary conditions for the flow and sediment. The dry-wet capability makes simulations with complex morphology very efficient.

(5) The uncertainty of the data such as sediment load, its composition and bed material composition may affect the accuracy of the numerical model prediction.

Abstract

This paper presents the results of a sedimentation study using the one-dimensional sediment transport capabilities of HEC-RAS 4.0 to quantify sedimentation processes in the lower Puyallup River, WA. The HEC-RAS 4.0 model used in this study was calibrated using USGS measured sediment transport rates and verified by reproducing the observed deposition of the reach between 2001 and 2007. Historical USGS flow data observed on the lower Puyallup River was used to create average annual flow-duration curves used as hydraulic input into the model, while averaged NOAA observed tidal elevations for the mean high tide, mean sea level, and mean low tide within Commencement Bay were used as downstream hydraulic boundary conditions. Depositional trends in the model results were compared with existing trends noted in historical cross-section comparison and gage adjustments to a nearby USGS streamflow gage. Results of the model show the bed elevations are expected to increase by as much as 5 feet over the next 50 years. The overall trap efficiency of the reach is expected to decrease as tidal influences begin to control the sedimentation processes over time.

Introduction

Located in Western Washington, the Puyallup River along with its major tributaries, the White and Carbon Rivers, convey the majority of flood flows from the slopes of Mount Rainier into Commencement Bay. Recent hydrological and hydraulic analyses associated with updating Federal Emergency Management Agency (FEMA) floodplain maps on the Puyallup River have shown that predicted flood elevations are higher than estimated in previous flood hazard mapping efforts (**nhc** 2007). This increase in flood profile elevations is hypothesized to be caused by ongoing sediment deposition within the river channel as the Puyallup River carries a significant sediment load. To quantify the changes in the hydraulic characteristics of the river channel, a sedimentation study was completed to characterize the sediment conditions of the lower Puyallup River. As part of this study, the numerical sediment transport model provided in HEC-RAS 4.0 (Hydrologic Engineering Center, 2006) was utilized to predict the sediment movement through the study reach; specifically the location, volume, and depth of sediment deposition or erosion.

The HEC-RAS 4.0 sediment transport module incorporates much of the HEC-6 "Scour and Deposition in Rivers and Reservoirs" code (Hydrologic Engineering Center, 1993) into the graphical HEC-RAS interface. This one-dimensional, movable boundary, open channel flow model simulates streambed profile changes resulting from varying river flow and tailwater conditions. The model was developed to assess spatial and temporal variations in non-equilibrium sediment transport conditions due to an imbalance of sediment inflow, existing bed material characteristics and sediment transport capacity on alluvial channels. The model is based on one-dimensional, gradually varied flow hydraulics and sediment transport theory and is capable of calculating sedimentation in dendritic, closed loop and distributary networks of river systems.

Such one-dimensional sediment transport models are dependant upon both hydraulic and sediment transport computations. Hydraulic inflows into the sediment module are inputted as a flow hydrograph segmented into a series of steady flow events of variable duration. For each flow sequence, the one-dimensional conservation of energy equation is solved to determine the water surface profile and pertinent hydraulic parameters such as energy slope, velocity, depth, hydraulic roughness, and width at each cross-section. Sedimentation process (i.e. erosion, entrainment, transportation, deposition, and compaction of sediment particles) are then computed at each cross-section by solving the sediment continuity equation (i.e. the Exner equation) and a user defined sediment transport function.

The proper application of the HEC-RAS 4.0 sediment transport model requires the calibration of both hydraulic and sediment transport parameters. Hydraulic calibration includes the adjustment of effective conveyance limits, Manning's n values, and expansion and contraction energy loss coefficients. Calibration to the sediment transport computations includes the selection of the proper transport relationship (i.e. Ackers-White, Laursen-Copeland, etc.), as well as the adjustment of sediment inflows to obtain reasonable agreement between measured and modeled sediment deposition and erosion. This paper provides the methods and results of the calibration of the HEC-RAS 4.0 model for simulating sedimentation processes on the lower Puyallup River.

Study Site

The modeled study reach includes the lower 37,800 feet (7.15 miles) of the Puyallup River from Commencement Bay to a few miles upstream of the Puyallup River USGS Stream Gage (Station 12101500). Streambed elevations in the study reach range from -10 feet (NAVD88) near the mouth of the Puyallup River at Commencement Bay to about 25 feet (NAVD88) near the confluence with the White River (River Mile 10.1). Slopes range from approximately 0.00035 ft/ft near the mouth of the Puyallup River to approximately 0.0006 ft/ft near the confluence with the White River (River Mile 10.1) with a break in gradient near River Mile 3.75. Sediment samples indicate that bed materials are primarily medium and fine sand, with gravel. Field observations show that the median particle size decreases in the downstream direction.

Objective

The primary objective of this sediment modeling investigation is to provide a 50-year forecast of bed adjustments as it pertains to the locations and characteristics of sediment deposits that may affect channel flood carrying capacities. To meet this objective, information from surveyed channel cross sections, site specific measurements of sediment transport rates, measurements of existing bed material characteristics, and analysis of hydrologic conditions were used to calibrate the sedimentation model. The model was then used to estimate future channel aggradation occurring throughout the model reach. The results provide estimates of future channel geometry, which when input into the HEC-RAS hydraulic model will reveal how flood profiles are likely to be affected by sediment deposition 50-years in the future.

Methodology

The following major steps were incorporated into the methodological design to achieve the study objectives:

1. Calibration of hydraulic parameters to match existing hydraulic conditions in the lower Puyallup River.
2. Choice of proper sediment transport function to best simulate the flow and sediment capacity relationship of the lower Puyallup River.
3. Calibration of sediment inflow rating curves to match sediment loading characteristics in the lower Puyallup River.
4. Model Verification.
5. Model Application.

Hydraulic Calibration

Sediment transport capacities calculated in the HEC-RAS 4.0 sediment module are based on locally computed hydraulics (i.e. depth, velocity, hydraulic radius, friction slope). (Hydrologic Engineering Center,2008). Based on this dependence, inaccuracies in the hydraulic computations can be reflected in the results of the sedimentation computations. To ensure the most accurate representation of overall sedimentation processes, user-defined parameters in the hydraulic computations must be adjusted to best match the computed and measured hydraulic results. In the HEC-RAS 4.0 model, these user-defined parameters primarily consists of adjusting effective conveyance limits, Manning's n values, and expansion and contraction energy loss coefficients to obtain reasonable agreement between measured and computed hydraulic characteristics.

A previously calibrated unsteady HEC-RAS model from the **nhc** (2007) floodplain study was used as a basis for this sedimentation modeling study. The calibrated unsteady HEC-RAS model included 67 cross-sections over the lower 8.2 miles of the Puyallup River cut from recent topographic and bathymetric surveys. Levees along the Puyallup River were modeled as lateral weirs connecting the river to large floodplain storage areas. Hydraulic roughness and energy loss coefficients were

calibrated to match computed water surface elevations to observed water surface elevations observed in a February 1996 flood (**nhc,** 2007).

For this study, the geometry was adjusted to incorporate only the lower 7.15 miles, from the mouth of the Puyallup River at Commencement Bay to a point approximately 4 miles upstream of upstream of the Puyallup River USGS Gage (Station 12101500) near the confluence of the White and Puyallup Rivers. Floodplain storage areas and lateral weirs utilized for defining floodplain inundation limits in HEC-RAS can not be utilized in the sediment transport algorithms within HEC-RAS, and were removed from the geometric representation of the reach. Bridge sections were modified as needed to properly simulate hydraulic losses and sediment transport through the bridge sub-sections for sedimentation modeling. To account for the hydraulic affects of bridges, blocked obstructions replaced bridge piers and the Manning's n coefficient was adjusted to obtain similar hydraulic characteristics as the original model. The last adjustment was the addition of a simplified "inflow" reach from River Mile 7.15 (STA 377+50) to River Mile 10.18 (STA 537+50), which was adjusted to maintain a constant cross-sectional shape and bed slope, typical of the uppermost sections in the vicinity of STA 377+50. This inflow reach provides sufficient distance for developing a sediment inflow in equilibrium with the bed material and hydraulic conditions at the upstream boundary of the study area.

Choice of Transport Equation

HEC-RAS 4.0 provides the user with a choice of the following seven published sediment transport functions to be used to compute potential sediment transport capacity:

1. Ackers-White (1973)
2. England and Hansen (1967)
3. Laursen-Copeland (1968/1989)
4. Meyer-Peter and Muller (1948)
5. Toffaleti (1968)
6. Yang (1973/1984)
7. Wilcock (2001)

Although each of these functions is well-founded and widely accepted, the assumptions and empirical data used to create each do vary. This variance may result in the results of equations varying by orders of magnitude for equivalent flow conditions. Appendix E of the HEC-RAS reference manual provides insight on selecting the most applicable function for the project conditions.

For this study, the Laursen-Copeland transport function was used to compute bed material sediment transport capacity on the Puyallup River. The Laursen-Copeland transport function is a total load formula developed for computing sediment transport of coarse silt to gravel sized sediments. This particular transport function was chosen based on our experience in sedimentation modeling studies and on the formula's

ability to most accurately replicate the sediment load rating curve derived from USGS measured data from the Puyallup River gage (Station 12101500) shown in Figure 1.

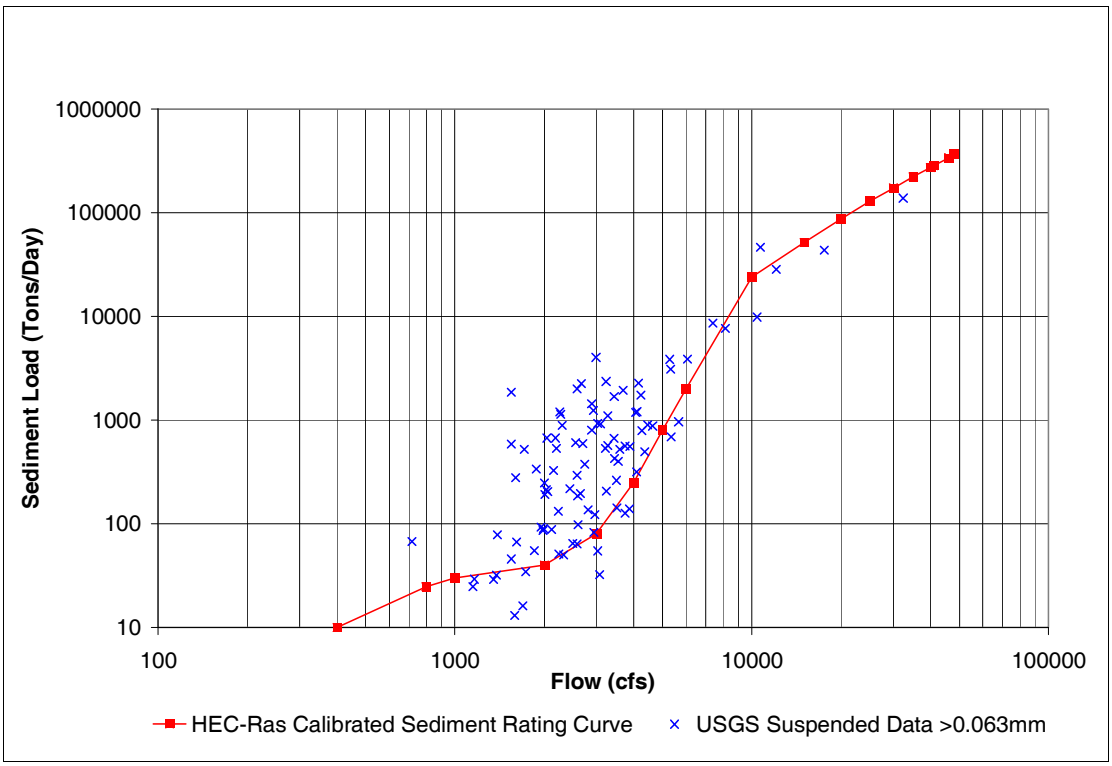

Figure 1: Sediment Inflow Rating Curve With USGS Suspended Sediment Data

Sediment Inflows

The HEC-RAS 4.0 model requires the user to specify a sediment inflow as an upstream boundary condition. This boundary condition can be set as an equilibrium load based on model calculations, a sediment load series defined by the user, or based on a user-defined rating curve. For this study, historical measured suspended sediment loads measured by the USGS at the Puyallup River Gage near Puyallup, WA (Station 12101500) were used as an initial assumption to create a rating curve for the sediment inflow boundary condition.

Figure 1 shows a sediment rating plot created from suspended sediment discharges (tons/day) and stream flow (cfs) both recorded by the USGS in the Puyallup River at USGS Gage 12101500 from January 1978 through July 1994. Only the fraction coarser than 0.063mm (very fine sand) is plotted, because this closely matches the minimum size of the sampled bed material. It is assumed that the finer silts and clays do not deposit but are carried downstream to Commencement Bay. The final HEC-RAS calibrated rating curve shown in Figure 1 was originally developed from the USGS suspended data and adjusted to match historic depositional patterns in the modeled reach as discussed below in the *Model Verification* section.

Model Verification

To determine the locations and quantities of sediment deposition and erosion for model adjustment and verification, an analysis of historic cross-sectional survey data and a field reconnaissance was performed. In all, twenty-nine cross-sections ranging from River Mile 0.20 (STA 10+75) to River Mile 9.63 (STA 508+25) were compared using data from a 2002 **nhc** survey and a 2007 Minister and Glaeser survey. Changes in average bed elevation from erosion and deposition were calculated for each cross-section. Depositional volumes were computed using the end area approach, and bed level surveys were extrapolated to channel banklines if bed coverage was incomplete

The HEC-RAS 4.0 model was then run using historical flow rates reported at the Puyallup River USGS Gage (Station 12101500) for the same time period as the surveyed cross sections (i.e. April 2002 to March 2007). By slightly adjusting the sediment rating curve developed from the USGS field measurements, a close agreement between the measured and modeled changes in bed elevation caused by sediment deposition were obtained. The final sediment rating curve is shown in Figure 1. Figure 2 shows the comparison of measured deposition to modeled deposition for each modeled cross section. Figure 2 shows reasonable agreement between measured and computed sediment deposition locations and magnitudes over the entire study reach.

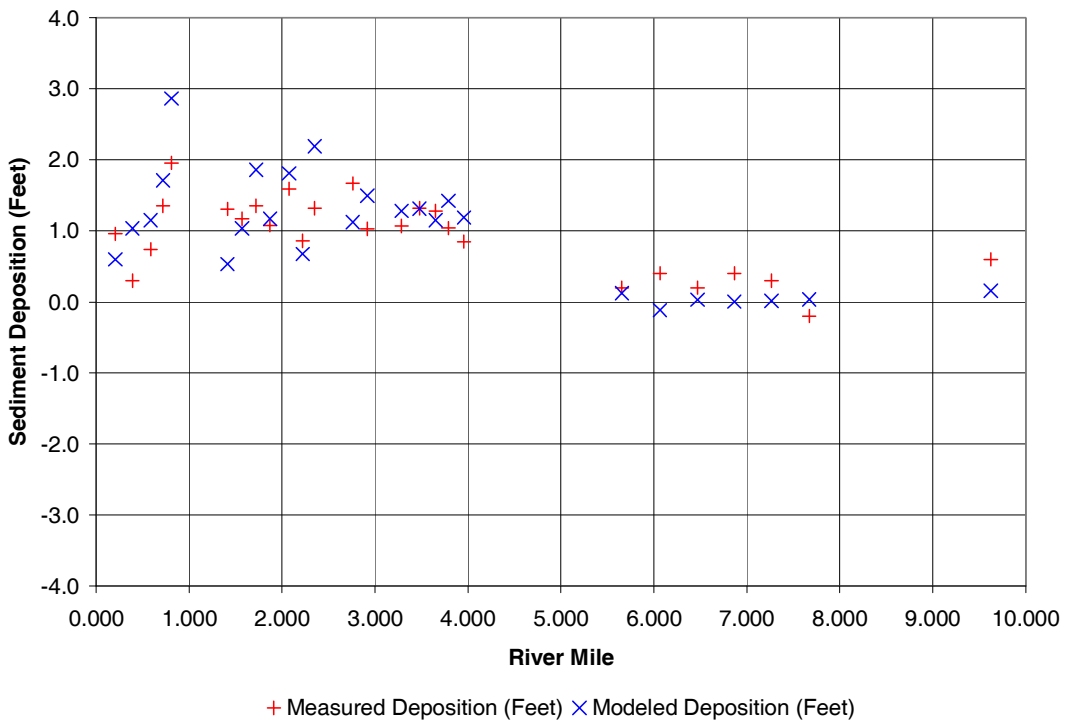

Figure 2: Comparison of Measured Deposition to Modeled Deposition

Model Application

Once the HEC-RAS 4.0 sediment model was calibrated, it was applied to forecast future sedimentation processes on the lower Puyallup River. A cumulative frequency curve, also known as a flow duration curve was developed based on historic flow-duration statistics of the lower Puyallup River. The Puyallup River USGS Stream Gage (Station 12101500) mean daily flow record from WY 1945 through WY 2006 was used for this analysis. The mean daily flows were sorted by magnitude and the number of days or fractions of days that the flow exceeded a given range of flows was determined. Dividing the number of days a given flow rate is exceeded by the total number of days in the streamflow record provides the expected value of the percent time that a given flow is exceeded. This relationship can be scaled to any time period of interest for assessing net water and sediment discharge for numerical modeling purposes.

The downstream water surface elevations in the Puyallup River are controlled by the tidal elevation at the river's mouth in Commencement Bay. Time variant water surface elevations can be specified as a function of time in the HEC-RAS 4.0. Tidal stage elevations for the sedimentation assessment were based on tidal records at the National Oceanic and Atmospheric Administration gage in Tacoma, WA (Station 9446484). The tidal elevations recorded at this gage yield the approximate tidal stage elevations (NAVD 88) for the mouth of the Puyallup River:

- Mean High Water 8.27 ft
- Mean Sea Level 4.22 ft
- Mean Low Water 0.17 ft

These mean tidal elevations were specified to occur within each flow increment in the sedimentation model simulations. To simulate the effects of the varying tidal elevations in the quasi-unsteady hydraulic simulations of the HEC-RAS 4.0 model, the Mean High Water and Mean Low Water elevations were specified for 25% of the duration for a given flow as determined in the flow duration analysis described above. The Mean Sea Level was specified for the remaining 50 % of the flow duration

Results

A useful way to assess the sedimentation dynamics of a stream is to plot the "total accumulated load" of sediment as a function of stream distance. The total accumulated load is the total mass (or weight) of sediment that passes a given section of the river for the total time period of the analysis. A reduction in total accumulated load in the downstream direction can be interpreted as sediment deposition in the reach, as the total load has decreased, and the decreased sediment load manifests itself as channel aggradation in the intervening reach. Conversely, an increase in total accumulated load in the downstream direction can be interpreted as sediment erosion in the reach, as the total load has increased, and the increased sediment load manifests itself as channel incision in the intervening reach.

The total accumulated load on the modeled reach of the Puyallup River for 10- and 50-year simulation periods is shown in Figures 3 and 4, respectively. The computed total load is fairly horizontal for entire upper reach to approximately River Mile 5, indicating sediment passes through this reach without significant erosion or

deposition of sands in the bed material. This is consistent with the small amounts of sediment deposition observed from the field measurements upstream of River Mile 5. The computed accumulated load then decreases as the river approaches Commencement Bay, consistent with observations of significant deposition on these lowermost reaches of the Puyallup River. The modeled reach trap efficiency, or the percentage of sediment inflow which deposits in the reach, decreased over time. Over the initial ten years of simulation, the reach traps around 13% of all inputted bed material sediment whereas over the last ten years of simulation time the reach traps less than 5% of bed material sediment transported into the reach. This trend suggests that without any major changes to the bed configuration (i.e. dredging) the channel will progress towards higher bed elevation, steeper profile, and quasi-equilibrium state where the long-term deposition in the reach will be nearly equivalent to the long-term erosion of the reach.

Figures 3 and 4 also include the load composition throughout the reach. The transported sediment is primarily sands with trace amounts of gravel. This is consistent with field observations, where bed material sampling in the lower reach found no appreciable amounts of gravel. During the first two decades of simulation, the deposition in the downstream portion of the modeled reach is primarily composed of coarse sands. During the final three decades of the simulation, the composition of the load remains fairly constant throughout all of the cross-sections suggesting that equal amounts of each inflowing grain size are being deposited.

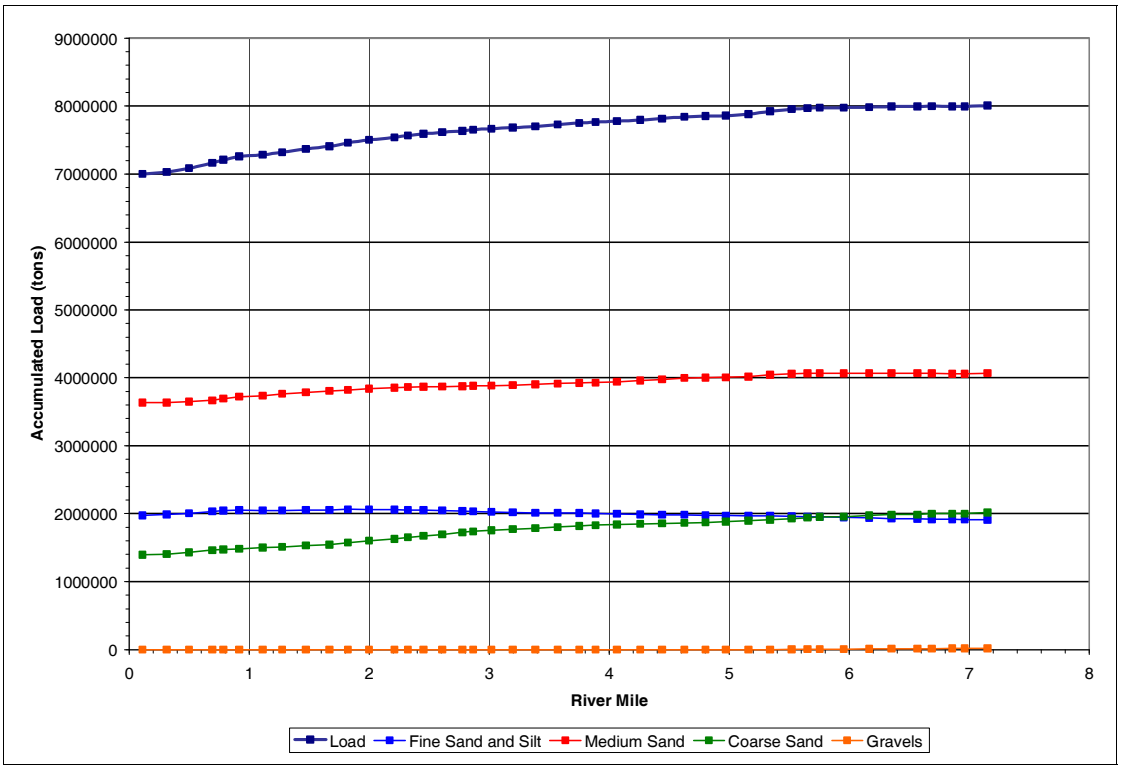

Figure 3: Total Accumulated Load Over Ten Years of Simulation

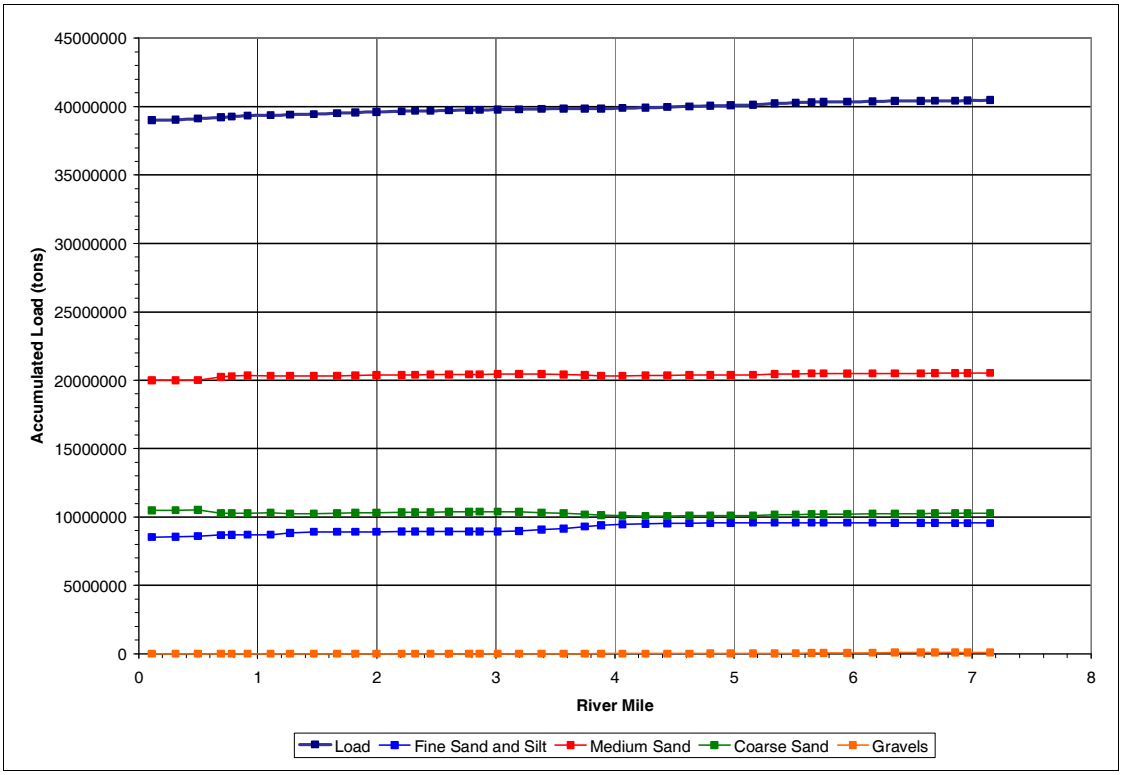

Figure 4: Total Accumulated Load Over Fifty Years of Simulation

Conclusions

As discussed in the previous sections, significant increases in bed elevation are expected to occur in the Lower Puyallup River. These estimates of sediment deposition over a 50 year time period into the future are developed from application of the calibrated sediment transport model using observed values for flow duration characteristics, tidal elevations, and sediment loads. A detailed analysis of the stationarity (i.e. invariance of statistical properties over time) of hydrologic and sediment data has not been completed, however obvious trends in peak discharge magnitude or flow duration are not evident in the review and incorporation of this data into the sedimentation model. Rates and locations of aggradation and subsequent increases in flood elevation profile over the next 50 years are reasonably presented by this analysis.

Examination of both the accumulated load curves and specific gage analysis (**nhc,** 2008) suggest that the Puyallup River is tending towards a state of quasi-equilibrium. The accumulated load curves show a trend of decreasing trap efficiency in the study reach. As the trap efficiency approaches zero, the downstream reach would achieve a steady state condition with nearly equivalent amounts of sediment leaving and entering the system over a period of time. The specific gage analysis shows an overall increase in peak flood water surface elevations during the first ten years of simulation and a much smaller increase throughout the remainder of the 50 year simulation. The actual time needed for the system to reach a quasi-equilibrium state is dependant upon the flow events and sediment loading. Variability of the

hydrologic conditions may affect the time required to reach the quasi-equilibrium state, but should not affect the final bed changes.

The primary control on the reduction over time in the rate in sediment deposition and trap efficiency on the lower Puyallup River is a result of the control of the bed and water surface elevation on the Puyallup River Delta from Commencement Bay. Although the size of the Delta appears to be significant from aerial photos, this tidal sand flat is worked by currents resulting from diurnal tides of approximately a 10 foot tide range, and additionally worked from wind waves during periods of inundation and high winds, a not uncommon occurrence in the Puget Sound. Commencement Bay beyond the limits of the delta is a significant sink for additional sediment deposition, given adjacent depths of the bay are on the order of 100 or more feet and worked by the relatively strong tidal currents of the region. Transects were surveyed over the sand flat delta surface in 1997, and a bathymetric survey of the same area completed by the Corps of Engineers in 2001. These transects indicate that both erosion and deposition have occurred over this time period, but the average elevation of the delta is approximately equivalent between the two surveys.

ABSTRACT

The sediment removal capacity in catchbasin sumps and other hydrodynamic separators does not necessarily imply the ability to prevent the sediment from being scoured, especially when the remaining sediment capacity volume of the device is small and the flow rates are high. The sediment removal ability of catchbasin sumps and hydrodynamic separators must be balanced with their ability to retain the captured material by preventing scour. Therefore, understanding and quantifying scour processes in catchbasin devices is an important need when considering these devices as part of a stormwater management plan. This study investigated the sediment scour from a conventional catchbasin sump for different particle sizes, sediment depths, and flow rates. Full-scale physical experimentation and Computational Fluid Dynamics (CFD) modeling were conducted to determine a wide range of conditions at which different particles sizes are scoured.

METHODOLOGY

The methodology includes two main parts: full-scale physical modeling and computational fluid dynamic (CFD) modeling.

Physical modeling. The geometry of the catchbasin sump used for the experiments was based on the optimal geometry recommended by Lager et al. (1977) and tested by Pitt et al. (1979, 1985, 1998). For this geometry, if the outlet diameter is d, the total height of the catchbasin sump is $6.5d$, and the inside diameter is $4d$; the outlet has to be located $4d$ above the bottom and $1.5d$ below the top of the catchbasin. The outlet diameter (d) was selected as 300 mm (approximately 12 inches) (see Figure 1).

The scour tests consisted of the measurement of the suspended sediment concentration (SSC) at the effluent of the catchbasin sump to determine the sediment mass loss. Turbidity and particle size distribution (PSD) were also measured. A 50-cm wide rectangular inlet was used as the inlet.

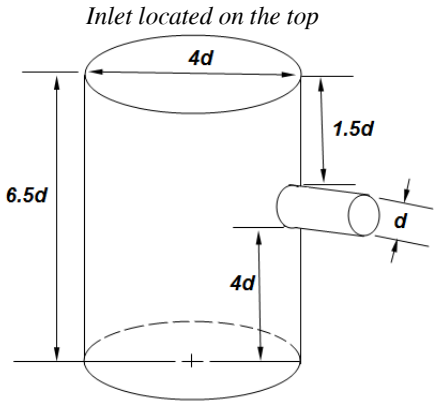

Figure 1. Optimal catchbasin geometry (Larger et al. 1977) used to build the full-scale physical model.

Two types of scour tests were performed. The first series of scour tests were performed with a sediment mixture at Lake Lureen State Park, Northport, AL, as once-through tests using the lake water. The second scour tests were performed with sediment with a homogeneous particle size at the facilities of the University of Alabama. The first PSD mixture was a prepared sediment mixture having a PSD similar to the measured values from deposited sediment sampled from catchbasin sumps observed by Valiron and Tabuchi (1992) and Pitt and Khambhammettu (2006). The characteristic diameters of this sediment mixture are D_{10} = 90 μm, D_{50} = 500 μm, and D_{90} = 2000 μm. Figure 2 shows the PSD of the sediment mixtures and also the particle size distributions for the separate components used to make the mixture. Four overlaying water depths were evaluated: 10, 25, 46, and 106 cm. Each overlaying water depth was tested with five consecutive flow rates, each lasting 25 min; the flow rates were: 0.3, 1.3, 3.0, 6.3, and 10 L/s. Composite samples (1.0 L) were collected for the first 5 min and for the last 20 min of test.

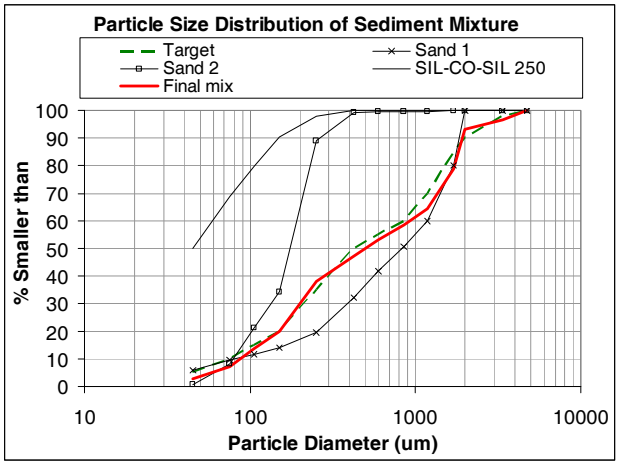

Figure 2. Particle Size Distribution (PSD) of sediment mixture prepared for scour test.

The wide range of this PSD in the sump contributes to the formation of bed armoring, which is the development of an erosion-resistant layer of relatively large particles created by the preferential washing of fine particles from the surface layers due to the velocity field acting on the sediment surface.

The second PSD mixture corresponded to a sediment material with a fairly homogeneous PSD, with D_{10} = 80 μm, D_{50} = 180 μm, and D_{90} = 250 μm (the PSD corresponds to Sand 2 in Figure 2). The sediment scour results obtained with this homogeneous PSD were used for calibration and validation of the CFD model.

CFD modeling. Sediment scour evaluation was conducted for homogeneous sediment materials by using a scour model customized for a 2D-CFD model implemented in *Flow-3D v.9.2*. The simulations were performed assuming a 50-cm wide rectangular inlet. A new scour model code was written and implemented that considered the specific conditions of the phenomenon as well as the limitations of the CFD software package. A total of 40 scenarios, including the calibration and validation cases, were simulated. The scenarios included combinations of three flow rates, five overlaying water depths, and four sediment particle sizes. Figure 3 shows a CFD output from a series of scour simulations.

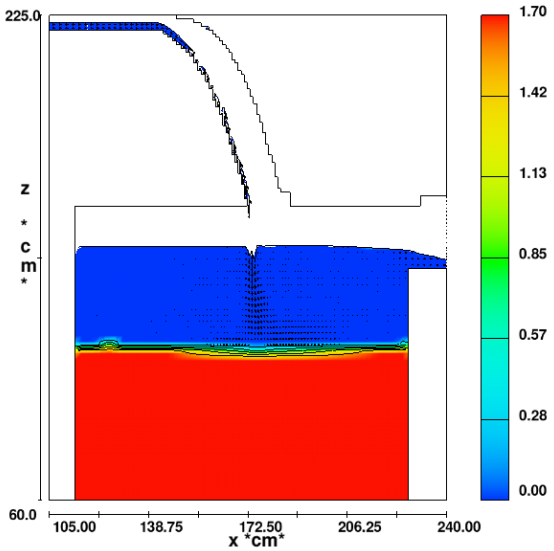

Figure 3. Total sediment concentration (g/cm^3) at 20 min of continuous flow. Flow rate: 10 L/s, overlaying water depth: 24 cm, particle size: 180 μm.

The sediment scour simulations were performed assuming clear water as the influent. The use of clear water is conservative when determining the scour rate. Clear water has a larger sediment-carrying capacity and therefore a larger scour potential compared to heavily silt-laden water. However, this assumption does not greatly differ from typical conditions of stormwater runoff in urban areas. The scour tests with the full-scale physical model were performed with lake water having a maximum SSC of 6 mg/L. The National Stormwater Quality Database reported median suspended solid concentrations of 50 to 100 mg/L for different land uses for data collected throughout the U.S. (Pitt and Maestre 2008); however, concentrations

as high as several thousand mg/L were also reported. Stormwater runoff with high suspended sediment concentrations has a somewhat lower carrying capacity and therefore less scour potential than clear water. The list of case scenarios simulated is presented in Table 1.

Table 1. List of Case Scenarios Simulated with the 2D-CFD Model

RESULTS OBTAINED WITH A SEDIMENT MIXTURE

The turbidity time series showed that with this specific PSD, the scour had an exponential decay pattern under steady flow conditions, having a maximum turbidity value at the beginning of the flow when the plunging impact of the incoming water had its greatest effect and decreasing exponentially over time. This pattern was more evident when the sediment was located relatively close to the outlet (with shallow water layers over the sediment), where it is more exposed to scour (Figure 4).

The turbidity time series tests showed that an armoring layer of large sediment particles is formed on the sediment surface during steady flow conditions. This finding reveals that if relatively large particles (D_{75}=1500 μm, D_{90}=3350 μm, and D_{max}=4750 μm for this experiment) are present in the pre-deposited sediment in a catchbasin sump, the scour potential of underlying smaller particles is rapidly decreased as an armoring of the larger particles rapidly form on the sediment surface. Therefore, only a few centimeters of the surface sediment will be exposed to scour. However, the effectiveness of the armoring is relative to the fraction or proportion of large particles in the pre-deposited sediment and their proximity to the sediment surface.

The SSC for different flow rates and overlaying water depths for the 0-5 min composite samples is shown in Table 2. SSC increases as a fractional power function of the flow rate. A maximum SSC of 1139 mg/L was measured when the overlaying water depth was 10 cm during the 10 L/s flow rate. The difference between the flux rate at 6.5 L/s (1045 mg/L) and at 10 L/s (1139 mg/L) is not large, considering that an armoring layer had already been formed after 100 min of continuous flow at the lower rate before the 10 L/s flow rate was applied. The pattern for SSC for the 5-25-min composite samples is similar to the pattern seen for the 0-5-min composite samples; however, the SSC values were between 40 and 80% lower (see Table 2).

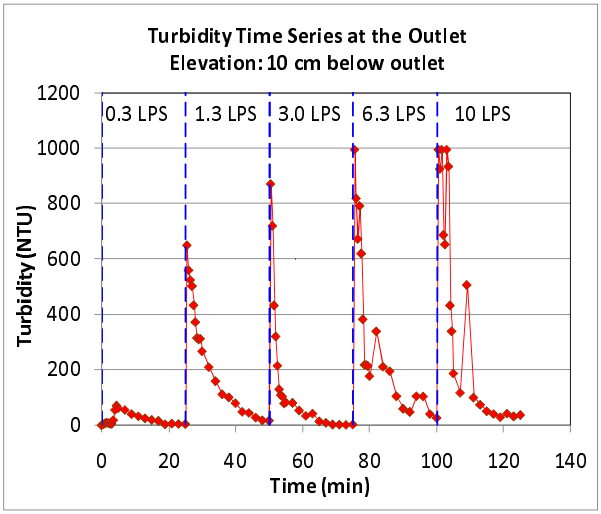

Figure 4. Turbidity time series at the outlet for scour tests: 10 cm (left) and 46 cm (right).

Table 2. Total SSC (mg/L) of Scoured Sediment for the Composite Samples

Depth below the outlet (cm)	Flow rate (L/s)									
	0.3	1.3	3.0	6.3	10.0	0.3	1.3	3.0	6.3	10.0
	SSC (mg/L) 0-5 min composite sample					SSC (mg/L) 5-25 min composite sample				
10	55.6	392	427	1045	1139	13	55	102	244	684
25	7.0	8.0	42	108	46.4	1.6	5.5	20	22	44
46	4.9	4.1	6.5	12.0	10.6	2.0	1.5	4.8	10.8	11.2
106	1.7	2.6	3.3	2.9	1.7	0.6	1.1	2.0	2.1	4.0

The total scour-mass time series presented in Figure 4 shows that with an overlaying water depth of 10 cm, the maximum scoured mass, after 125 min, was about 16 Kg. The scoured particles were all smaller than 4750 μm. This scoured mass is equivalent to a scour depth of about 0.9 cm in the catchbasin. In contrast, with an overlying water depth of 25 cm, the total scoured mass, after 125 min, was reduced to less than 1 kg (930 g), which is about 17 times less than that observed with the 10 cm water depth. With an overlaying water depth of 46 cm, the total scoured mass was further reduced to only 360 g in the 120 min period of flow. With a 106 cm water depth, the total scoured mass was reduced even further to only 90 g during the 125 min test. At 106 cm below the outlet, only particles smaller than 45 μm were detected in the effluent water.

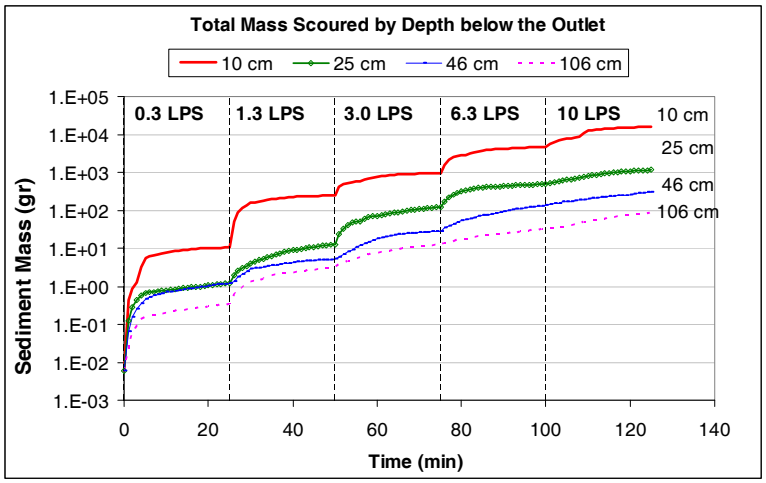

Figure 5. Total sediment mass scoured by water depth over the sediment for all scour tests.

Regression analyses were conducted to examine the effects of overlaying water depth and the scoured sediment mass. The depth of the water was found to be a significant factor, with a highly significant p-value of 0.006. A similar conclusion was also found by Avila et al. (2007) with CFD modeling. These results show that the overlaying water depth over the sediment significantly contributes to a reduction in scour potential. As the overlaying water depth increases, the armoring formation decreases, because the sediment is less exposed to scour. However, at shallow overlaying water depths, the armoring layer plays an important role in reducing the scour potential. If no armoring mechanism is present at shallow overlaying water depths, the sediment scour will be considerably higher. Figures 6 and 7 show the experimental response surfaces of suspended sediment concentrations obtained with the sediment mixture for the 0 -5 and 5 – 25 min composite samples, respectively.

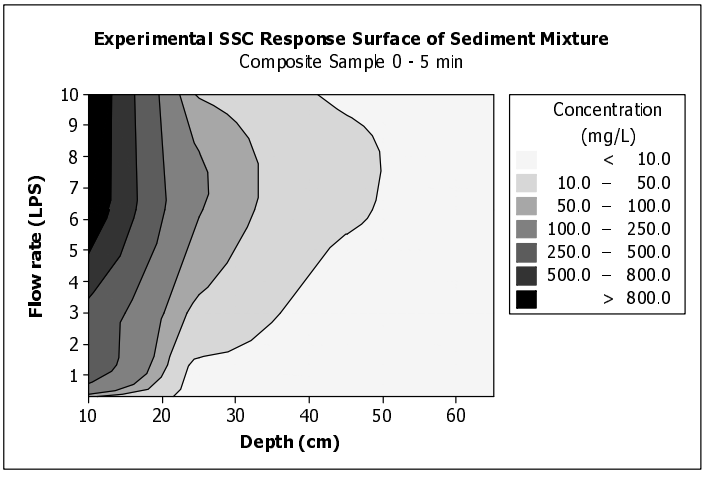

Figure 6. Response surface plots of experimental suspended sediment concentration (SSC), mg/L as a function of flow rate (L/s) and overlaying water depth (cm). 0 – 5 min composite sample.

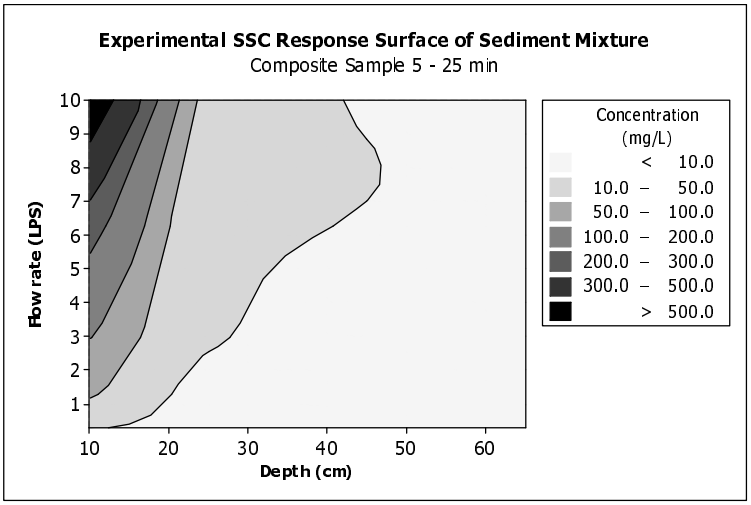

Figure 7. Response surface plots of experimental suspended sediment concentration (SSC), mg/L as a function of flow rate (L/s) and overlaying water depth (cm). 5 – 25 min composite sample.

The regression model for SSC (mg/L) of the 0-5 min composite samples with a R^2 = 0.92 is given as:

$$SSC = (670)^2 \cdot H^{-3.32} \cdot Q^{(0.92H^{-0.15})}.$$

The regression model for the 5-25 min composite samples with a R^2 = 0.93 is given as:

$$SSC = (115)^2 \cdot H^{3} \cdot [\ln(H)]^{-15} Q^{(1.6H^{-0.19})},$$

where *SSC* is the Suspended Sediment Concentration (mg/L), *H* is the overlaying water depth, or depth below the outlet (cm), and *Q* is the flow rate (L/s or L/s).

Both regression models fitted the experimental data very well and the residuals achieved the assumptions of normality.

RESULTS OBTAINED WITH A HOMOGENEOUS SEDIMENT MATERIAL

Initially, it was expected that the SSC values in the effluent with homogeneous sediment material would have an exponential pattern similar to the one obtained with the sediment mixture. However, the results showed that the SSC was approximately constant during the 30 min of continuous flow. This finding is attributed to the absence of an armoring layer formed by large particles which protect smaller particles from scour within minutes after the water jet impact. In the case of sediment with a homogeneous particle size, all particles on the sediment surface were exposed continuously to scour during 30 min of continuous flow. However, the scoured mass was not large enough to increase the overlaying water depth to the point where sediment scour would decrease. Nevertheless, it is expected that after longer periods of time with continuous flow, the scour rate would decrease as the overlaying water

depth increased, especially below the plunging water jet, where a hole is created in the sediment surface. Table 3 shows the experimental SSC values obtained for tests with sediment at 24 and 35 cm below the outlet, 10 L/s flow rates, and with a 50-cm wide rectangular inlet.

Table 3. Experimental SSC of 3-min Composite Samples (Scour Tests with Sediment Material with Homogeneous Particle Size, Flow rate: 10 L/s, Overlaying Water Depth: 24 and 35 cm)

Composite Samples - Time Interval (min)	SSC (mg/L) at 24 cm below the outlet	SSC (mg/L) at 35 cm below the outlet
0 – 3	600	170
3 – 6	479	161
6 – 9	491	203
9 – 12	556	182
12 – 15	521	153
15 – 18	425	179
18 – 21	574	172
21 – 24	562	206
24 – 27	569	182
27 – 30	557	178

Table 4 shows the computed SSC obtained with the CFD model. These results show that in the absence of armoring, SSC decreases exponentially as a function of the homogeneous sediment particle size (Figure 8) and approximately linearly as a function of the overlaying water depth above the sediment (Figure 9).

Table 4. Mean SSC obtained with a calibrated CFD modeling for different flow rates, overlaying water depth and sediment particle size. Homogeneous sediment particle size.

Flow rate (L/s)		SSC (mg/L)											
		50			180			500			1000		
		Particle size (mm)											
		5	10	20	5	10	20	5	10	20	5	10	20

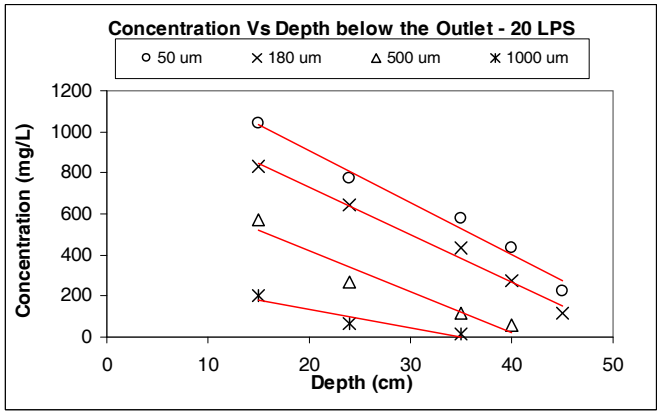

Figure 9. Suspended sediment concentration (mg/L) versus overlaying water depth (cm) plotted by sediment particle size (μm) (20 L/s flow rate.)

CONCLUSIONS

Two protection mechanisms occurred when conducting the tests with the sediment mixture: the overlaying water depth and an armoring layer. In this case, the overlaying water depth protected the sediment surface from the first impact of the plunging water jet. However, the plunging water jet still had enough energy to scour the sediment material directly below it. Then, due to the high shear stresses generated by the first water impact, all particle sizes (large and small) are suspended. Consequently, a *"washing machine effect"* occurs with the suspended sediment while the plunging water jet retreats upward because of the air buoyancy. The washing machine effect consists of the preferential removal of fine material from the suspension of the whole mixture, leaving a layer of large particles on the sediment surface which forms the armoring layer. Only the overlaying water will serve as a protection mechanism against scour if armoring is not present.

In contrast, the variation of SSC over time using sediment having a homogeneous particle size showed that SSC has a magnitude that was statistically constant during the 30 min period of evaluation. Initially, it was expected that the SSC magnitudes with homogeneous sediment material would have an exponential decay pattern similar to the one obtained with the sediment mixture, with high concentrations within the first minutes of flow and then undergoing a substantial decrease for the remaining flow duration. However, the results showed that the SSC maintained an approximate constant magnitude. This phenomenon is attributed to the absence of an armoring layer that protects the sediment from being scoured. SSC will decrease only when the overlaying water depth is high enough to dissipate the eroding energy of the velocity field and therefore reduces the acting shear stress on the sediment surface.

Abstract

The Nakdong River Estuary Barrage (NREB) was constructed in 1987 to prevent saltwater intrusion and to provide the sustainable water supply in the upstream channel of the NREB. The upstream channel of the NREB has experienced sedimentation problems requiring annual dredging operation after the construction. The main purpose of sediment dredging is to prevent flooding during late summer. According to the past records, the annual average dredging volume is about 524,170 m^3 in the upstream channel of the NREB. Fluvial changes and sedimentation problems have been continued due to urbanization and development in the watershed as well as construction and management (sediment dredging) of the NREB. However, the sufficient field monitoring and researches for sedimentation characteristics and bed changes have not been performed after construction of the NREB. Therefore, bed elevation changes for 14 years (1990-2003) after construction of the NREB were analyzed using the Hec-6 model and relatively short term changes of bed elevation were simulated using RMA2 and SED2D programs with field data to review the superficial changes. Field survey before and after sediment dredging was conducted at various points of time to examine the natural flushing effect of sediment by moderate and high discharge before flood season (late July to early September) during low tide.

Introduction

The Nakdong River flows 510 km through the southeastern region of South Korea from the Taebaek Mountains to the East Sea (Park et al, 2008). The Nakdong River is the second largest river in Korea and flows through the major cities such as Daegu and Busan. The Nakdong River has a drainage area of about 23,384 km^2 with frequent typhoons and floods from June to September. Among the annual typhoons, Typhoon Maemi of September 12, 2003 was the worst typhoon to hit South Korea for more than a decade and the old Gupo Bridge partially collapsed with the loss of a pier due to high velocities by the large flood and bridge pier scour by Typhoon Maemi (Ji and Julien, 2005).

Near the Nakdong Estuary, there are wetlands, sand islands and deltas, which provide an ideal habitat for migratory birds and waterfowls. The Nakdong River Estuary Barrage (NREB) was built in 1983-87 near the Eulsuk Island to prevent salt-water intrusion in the estuary. The 2.3-km-long barrage includes 510 m of 10 gates section and 1,720 m of a closed dam section with a navigation lock, fish ladder, and other related structures. The NREB provides the control of the upstream water level and the local road for auto-traffic, and prevents salt-water intrusion into the Lower Nakdong River.

Since the construction of the barrage, the Lower Nakdong River has experienced sedimentation problems requiring dredging. The main purpose of dredging sediments is to maintain the flood conveyance capacity of the upstream channel on the Lower Nakdong River during typhoons and floods, which are coupled with high water levels. Historical records (1990 to 2007) indicate an average of 524,170 m^3 per year of dredging with an annual cost estimated at $2 million. The material dredged is primarily non-cohesive fine sand. Most of the sedimentation occurs after floods and during low flows. The gates cause a backwater effects upstream of the barrage, which results in sediment deposition.

The objectives of this study are to perform historical data collection, numerical simulation, and field surveying for the Lower Nakdong River and to analyze sedimentation characteristics. Therefore, outcomes in this study should be used to improve the present method to control sediment deposition and to propose a new approach to solve sedimentation problem upstream of the Nakdong River Estuary Barrage.

Site Description of the Lower Nakdong River

The Lower Nakdong River has a drainage area of about 23,384 km^2 and spans 510 km from the north across South Korea. The average width of the Nakdong River is approximately 45 m and reaches 250 m in the Lower Nakdong River. Based on the Mulgeum station, the average water depth is 2 – 3 m on the Lower Nakdong River (from the NREB to Samryangjin). The Lower Nakdong River has a very mild bed slope of approximately 0.0001 to 0.0002 m/m and has one tributary, the Yangsan River. The mean annual precipitation of the Nakdong River basin is 1,186 mm and the mean annual temperature ranges from 12 to 16 $°C$. The median grain size of bed material at the Gupo Bridge is 0.25 mm and the bed is mainly fine sand.

The Nakdong River Maintenance General Planning Report (KMOCT, 1991) presented the roughness factor of 0.023 for Manning's n which was determined for the Lower Nakdong River using the field data of historic floods, bed materials, and bedforms. Also, a Darcy-Weisbach friction factor (f) of 0.03 was used to compute the backwater profile of the Lower Nakdong River in the NREB maintenance manual (ISWACO-NEDECO, 1987). If the averaged depth 3m of the Lower Nakdong River is applied to their relations between different friction factors, Manning's n of 0.023 produced the Darcy-Weisbach friction factor of 0.03.

Because resistance to flow depends largely on bedform configurations, three methods (Simons and Richardson (1963, 1966), Bogardi (1974), and van Rijn (1984)) to predict bedform configurations are selected to verify the feasibility of given roughness factors. The backwater profile was calculated based on the mean daily flow of the Lower Nakdong River, and then the bedform configurations were determined by three methods. The calculation results show that the bedform configurations of the Lower Nakdong River consist of ripples and dunes and the results are described in Figure 1 and Figure 2 is the field observations in 2006 using the sound navigation ranging, which is in good agreement with the bedform calculation results. For the roughness factor, the Darcy-Weisbach friction factor of 0.03 was used for numerical modeling.

Korea Water Resources Corporation (KOWACO) collected sediment field data in 1995 at the Jindong Station, which is located in 80 km upstream of the NREB, and presented calculated total sediment load of Jindong Station. Measured sediment field data and the Modified Einstein Procedure (Colby and Hembree, 1995) were used to estimate the total sediment load at Jindong Station (KOWACO, 1995).

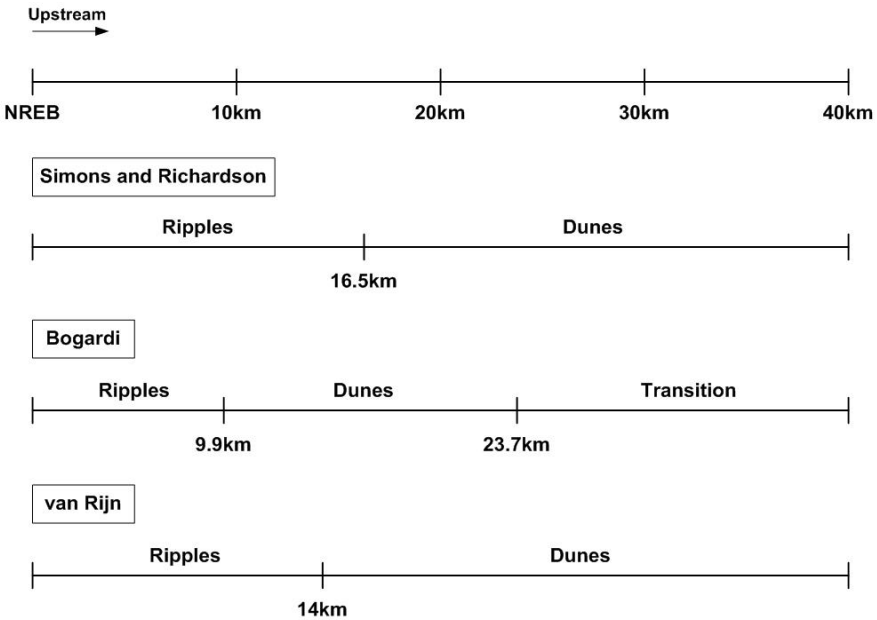

Figure 1. Bedform calculation results on the Lower Nakdong River

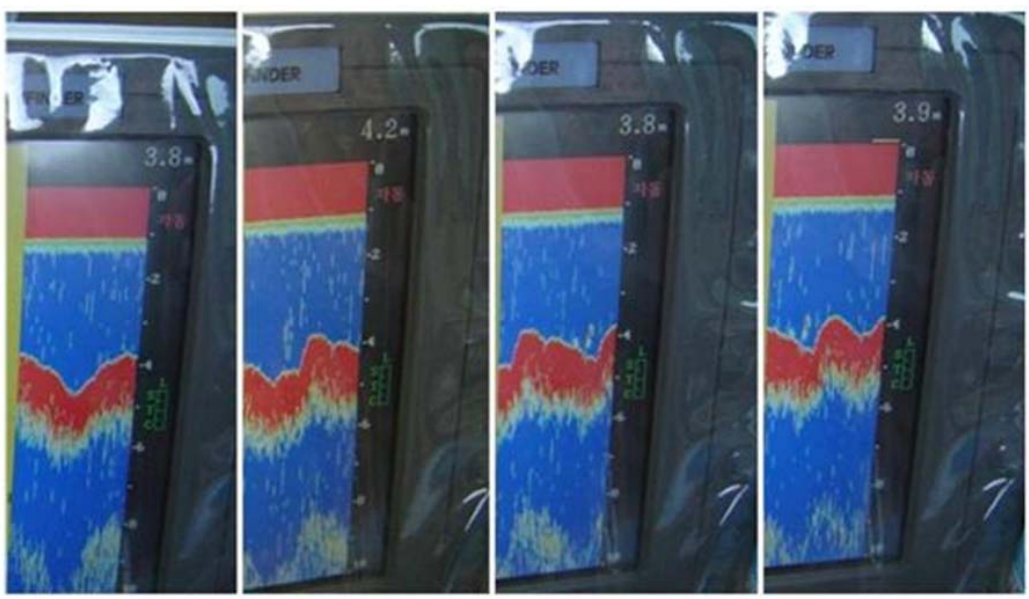

Figure 2. Field observation of bedform configuration in 2006

Because presently used suspended sediment sampler such as point and depth integrated samplers cannot collect the sediments for the entire water column, the unmeasured load must be estimated and added to the measured load to estimate the

total load using the Modified Einstein Procedure. Sediment field data include suspended sediment concentrations, and particle size distributions of suspended sediment and bed material. Calculated sediment discharge data of Jindong Station by KOWACO were compared with several total sediment load equations in Figure 3. The total sediment load calculated by the Modified Einstein Procedure is referred to as field data in this study. The Engelund and Hansen (1967) method overestimated the total load at Jindong Station. Shen and Hung (1972), Ackers and White (1973), Yang (1979), and Brownlie (1981) equations show relatively good agreement with the field data.

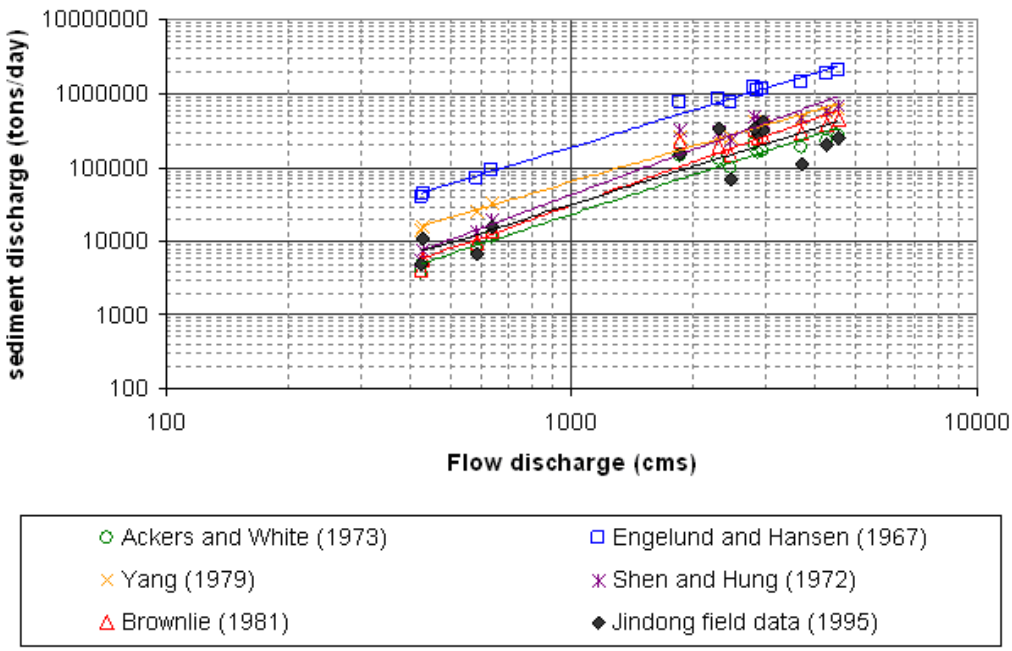

Figure 3. Sediment transport equations comparison of Jindong Station

Numerical Simulation

1D Simulation of Bed Elevation Changes Using the Hec-6 model

Bed elevation changes from the NREB and 50 km upstream of the NREB were simulated using the Hec-6 model for one month with Typhoon Maemi in 2003. Yang's method for sediment transport equation, which was relatively consistent with field measurement of Jindong Station as shown in Figure 3, was adopted in the

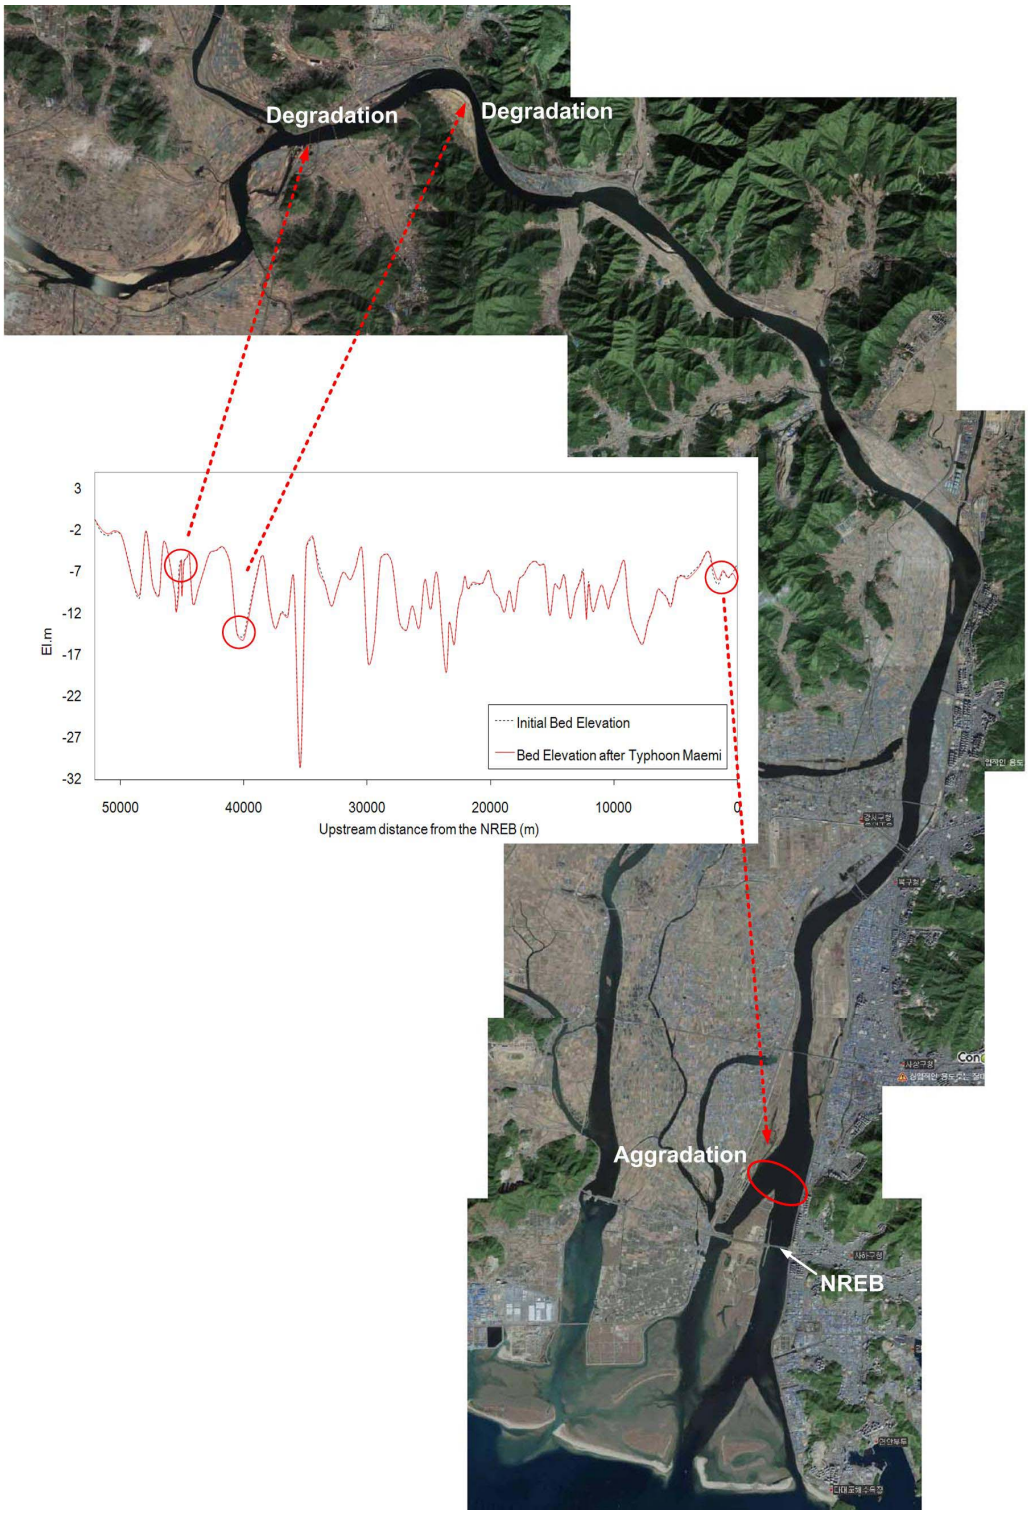

Figure 4. Hec-6 result for bed elevation changes for 30 days in Sept. 2003

Figure 5. Hec-6 result for bed elevation changes for 14 years (1990-2003)

model. Typhoon Maemi hit the Lower Nakdong River on September 12, 2003 and simulation time in the model was one month of September 2003. The simulation result is shown in Figure 4. The maximum degradation of 1.59 m occurred near the 4.5 km upstream of the NREB and bed elevation at the 4 km upstream of the NREB was decreased 70 cm. Also, the downstream area near the NREB had sediment deposition of 80 cm because the expanded channel width resulted in the velocity decrease.

To analyze the long-term changes of bed elevation in the upstream approached channel (3 km upstream form the NREB) after construction of the NREB, the gauging data for flow discharge and water stage form 1990 to 2003 was used. Bed changes from NREB to Jindong Station (80 km upstream of the NREB) were calculated for 14 years after construction of the NREB and the result is plotted in Figure 4. Bed elevation from Samrangjin (40 km upstream of NREB) to Jindong was degraded after the placement of NREB. Also, it was represented in the simulation results that bed elevations near the NREB, 20 km, and 35 km were increased. The results of the Hec-6 model to analyze the characteristics of bed changes in the Lower Nakdong River show typical features of sediment deposition near the estuary barrage or dam due to the decreased velocity.

2D Simulation of Flow and Bed Elevation Changes

RMA2 and SED2D models were used for 2-dimensional numerical simulations of flow and bed changes for 3 km area in the approached channel of NREB in this study. Field data surveyed by KOWACO in April 3rd 2008 were

utilized to construct topographical data for numerical modeling. Finite element and node numbers of constructed geometry were corresponding to 2,831 and 8,830. Daily mean discharge in Sanrangjin and water surface elevation in NREB from April 1st to July 15th 2008 were collected as shown in Figure 6 and used for boundary conditions. Discharge and water surface elevation data were classified to three groups and representative values of each groups are summarized in Table 1.

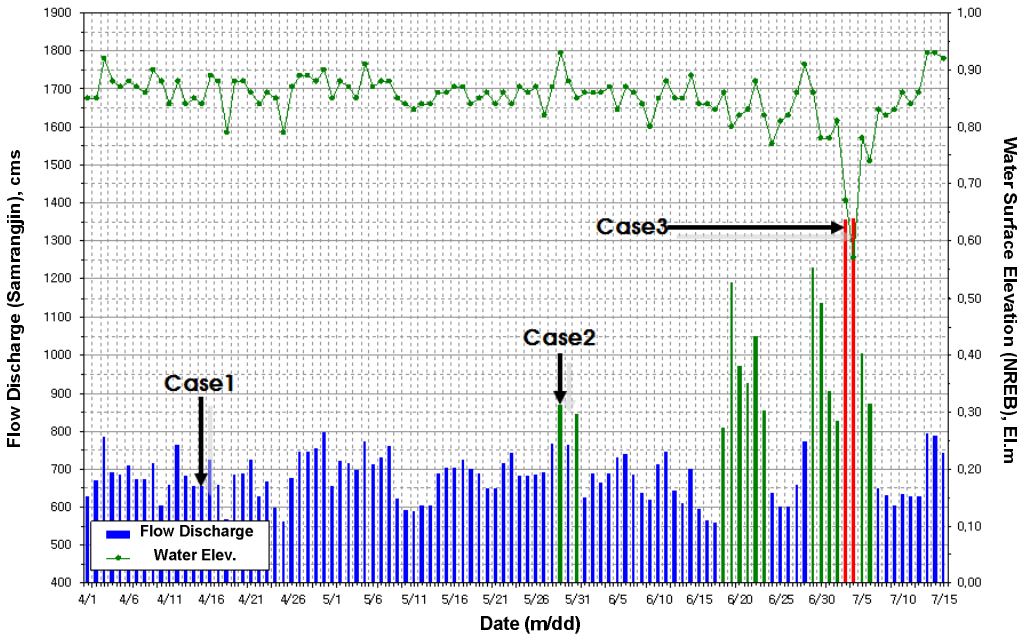

Figure 6. Discharge and water surface elevation from April 1st to July 15th 2008

Table 1. Boundary conditions of simulation cases

Groups	Discharge range [m³/s]	Averaged discharge [m³/s]	Averaged water elevation [m]	Corresponding time [day]	Sediment discharge [tons/day]	Initial sed. [kg/m³]
Case1	0 ~ 800	678.30	0.86	90	16204.20	0.27650
Case2	800 ~ 1250	963.75	0.82	14	29602.58	0.35551
Case3	1250 ~ 1400	1359.28	0.62	2	53399.13	0.45469

RMA2 and SED2D models were used for 2-dimensional numerical

simulations of flow and bed changes for 3 km area in the approached channel of NREB in this study. Field data surveyed by KOWACO in April 3rd 2008 were utilized to construct topographical data for numerical modeling. Finite element and node numbers of constructed geometry were corresponding to 2,831 and 8,830. Daily mean discharge in Samrangjin and water surface elevation in NREB from April 1st to July 15th 2008 were collected as shown in Figure 6 and used for boundary conditions. Discharge and water surface elevation data were classified to three groups and representative values of each groups are summarized in Table 1.

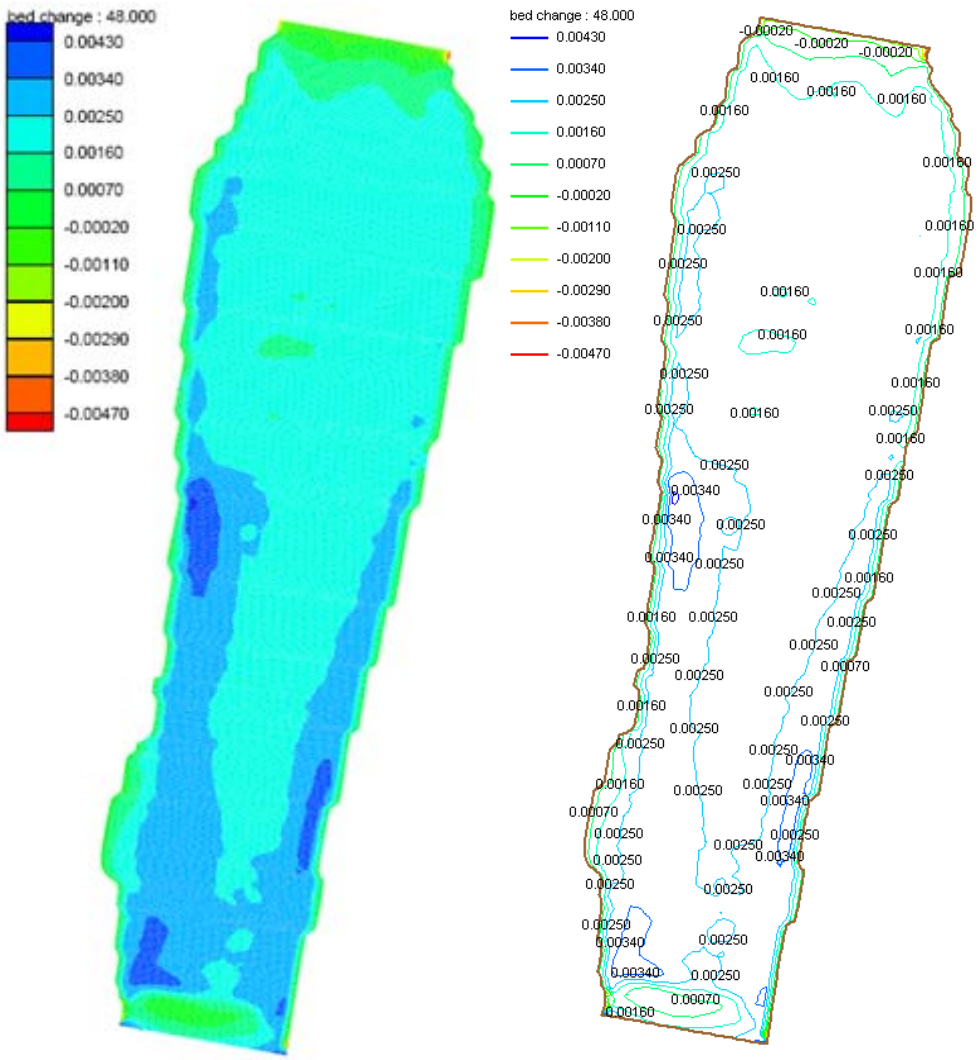

Figure 7. Bed change results of Case 3 (Flow direction from upside to downside)

According to the results of RMA2, maximum velocities for Cases 1 and 2 wer 0.2 m/s and 0.3 m/s in the vicinity (100 m) of the NREB. The water depth was ranged from 4 m to 10 m and the deepest point was 1.5 km upstream of the NREB. The calculation results of the SED2D model represented that most of the simulated area had sediment deposition and the aggradation was increased in the direction of the NREB for Cases 1 and 2. The velocity distribution of Case 3 was 0.02 m/s to 0.47 m/s and maximum velocity occurred in the similar location of Cases 1 and 2. Superficial bed changes for Case 3 are shown in Figure 7. Sediments were deposited in the main channel and bed was scoured in the edge of the river bank and upstream and downstream boundaries. There was no sediment deposition near the NREB because of the lower water stage by gate opening.

Field Surveying Results for Bed Changes before and after Floods

Volumetric analysis of bed changes was performed using field surveying data of 3km in the upstream direction from the NREB. Addition field surveying for volumetric analysis of bed changes was executed three times except two regular annual surveying in April and September (Figure 8). Sediment dredging was

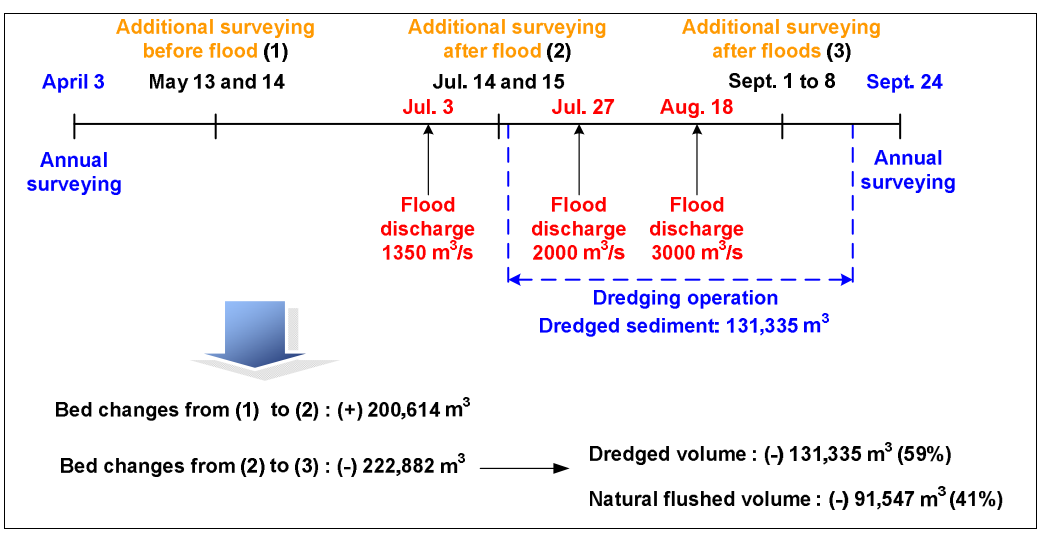

Figure 8. Volumetric analysis of bed changes using field surveying data (2008)

operated from July 16th to September 19th 2008 and dredged sediment volume was corresponding to 131,335 m^3. The sediment volume of bed change between

additional surveying before and after first flood is (+) 200,614 m^3 as shown in Figure 8 and the sign of (+) represents deposition. It is similar results of 2D numerical simulation from April 1st to July 15th 2008. Also, the volumetric bed change between additional surveying (2) and (3) was (-) 200,614 m^3. The sediment volume of (-) 91,547 m^3 was flushed by natural flow because sediment dredging of (-) 131,335 m^3 was operated in this period

Conclusion

Historical data collection, numerical simulation, and field surveying for the Lower Nakdong River were conducted to analyze sedimentation characteristics near the NREB. The bedform calculation results show that the bedform of the Lower Nakdong River consist of ripples and dunes and the field observations in 2006 using the sound navigation ranging shows good agreement with this results. The results of Hec-6 modeling to analyze the characteristics of bed changes in the Lower Nakdong River show typical features of sediment deposition near the estuary barrage or dam due to the decreased velocity. As a result of 2D numerical modeling, sediments were deposited in the main channel and bed was scoured in the edge of the river bank and upstream and downstream boundaries. There was no sediment deposition near the NREB because of the lower water stage by gate opening. Lastly, volumetric analysis of bed changes was performed using field surveying data of 3km in the upstream direction from the NREB and analysis results were similar to the 2D numerical simulation conducted in this study.

ABSTRACT

Due to conflicting conclusions in the literature, this study considers the influence of vertical pore water flux on the initiation of motion criterion for noncohesive bed sediments subject to an applied shear stress. A key issue with respect to interpretation of experimental results may be associated with the determination of bed shear stress, a quantity that cannot be measured directly and thus relies on indirect methods to estimate. Another issue is the determination of the key variable characterizing the bed seepage as many studies characterize seepage in terms of the velocity while others account for the piezometric head gradient.

A modification of the traditional Shields' parameters to account for the effects of bed seepage was developed suggesting that the bed hydraulic gradient is the key parameter in characterizing initiation of sediment motion. Experiments were performed for three different sand sizes subject to both vertically upward and downward bed flow to test the validity of the formulation over a wide range on the Shields curve. Experimental results interpreted using the modified dimensionless shear stress are shown to be consistent with the conventional Shields curve.

INTRODUCTION

Lu, et al (2008) present an excellent review of the existing literature related to the effects of bed seepage on turbulence intensity, bed shear stress, and sediment transport rates. In their Table 1 which is a summary of existing studies, they indicate that each of these variables have been reported to decrease, increase, or remain unchanged. The current study is concerned with the effect of bed seepage on initiation of sediment motion which is clearly related to these same variables. Both conditions of injection (vertically upward pore water flow) and suction (downward flux) are considered. Simons and Richardson (1966) suggested that seepage of water into the bed would increase the effective weight of the bed particles and, therefore, increase the stability of the bed. Cheng and Chiew (1999)

reported a tendency for lowered critical shear stress as injection velocities were increased for median grain sizes ranging from 0.63 mm to 1.95 mm. On the other hand, Martin (1970) reported that inflow seepage does not enhance incipient motion of the sediment particles even up to a quick bed condition. However, Rao and Sitaram (1999) investigated bed stability using seven different sizes of sand (0.32-3.0 mm) under the effect of either injection or suction. They concluded that suction reduces the stability of the bed particles and increases mobility whereas injection does the opposite.

A review of the specifics of previous experimental studies indicates a number of potential explanations for these conflicting conclusions. One critical issue is that the initiation of motion is generally characterized by the bed shear stress such as through the Shields' curve which relates sediment stability to two dimensionless parameters:

$$\tau_* = \frac{\tau}{(\gamma_s - \gamma)d} \text{ and } \mathrm{Re}_* = \frac{u_* d}{\upsilon} \quad (1)$$

in which τ is the bed shear stress, γ_s and γ are the unit weight of sediment and water, respectively, d is the effective sediment diameter, u_* is the shear velocity defined by $\tau = \rho u_*^2$ and υ is the kinematic viscosity of the fluid. bed shear stress cannot generally be measured directly and must be inferred from the measurement of other flow variables. Another issue is the definition of the key variable characterizing the bed seepage. Most previous studies have used the seepage velocity to establish a relationship to bed stability. The development by Cakir and Wright (2006) of a modified Shields' parameters to account for the effect of bed seepage suggests that the piezometric head gradient is the more relevant parameter. Since seepage velocity and gradient are related related to grain size, the possibility exists that previous studies did not choose a relevant range of flow variables in order to observe an effect. In order to address these issues, an experimental study was performed using sands with different diameters selected to span a wide range on the Shields' curve. Experiments with both injection and suction were performed. The results of these experiments are presented in this study.

MODIFIED SHIELDS PARAMETERS

The conventional Shields parameters in Equation 1 may be derived by several different approaches, all of which involve a consideration of forces acting on the bed material; Cakir and Wright (2006) chose an approach using a moment balance considering three principal forces acting on an idealized (spherical) non-cohesive sand particle: a drag force F_D, the submerged weight of the particle F_W and a lift force F_L. Flow through the bed may be included as a seepage force F_J in this balance. The seepage force is assumed to be produced by a linear vertical pressure gradient deviation from hydrostatic conditions and this gradient i produces a force similar to the buoyant force (included in the submerged weight term in Equation 2) and in the same direction in the case of injection. Suction conditions are described

with a negative value of i. Since these forces are both due to linear pressure variations acting through the center of volume of the sediment particle, regardless of actual shape, the effect of the seepage force can be directly incorporated into a modified definition of τ_* although possibly with a correction factor to account for the local variation of the head gradient at the sediment/water interface as suggested by Martin and Aral (1971). Their approach assumes that a constant correction of the piezometric head gradient within the sand bed can be used to estimate the local gradient at the sediment/water interface. The moment balance yields the scaling that $\rho u_*^2 \propto (\gamma_s - (1+Si)\gamma)d$ at incipient instability and there suggests that the dimensionless shear stress in the conventional Shields; parameters can be replace with

$$\tau_{*m} = \frac{\tau}{(\gamma_s - \gamma(1 + Si))\, d} \qquad (2)$$

where S represents an adjustment to the internal hydraulic gradient within the sediment bed representing the effect of the altered flow pattern at the sediment/water interface as proposed by Martin (1970), and Martin and Aral (1971). The value of S value was estimated as 0.85 from an arithmetic average of the individual experimental values reported in Martin and Aral (1971). It is noted that minor changes of this coefficient does not have a significant effect on the current results as demonstrated by Kavcar (2008). From Equation 2, it can be seen that i must be fairly large, at least greater than about 0.1, in order to have at least a five percent effect on τ_{*m}. Many previous studies were conducted with hydraulic gradients considerably less than this value.

EXPERIMENTAL INVESTIGATION

Experiments were conducted in a 7.5 m long, 0.6 m wide flume with the front of the test section located 3.5 m downstream from the flume inlet. The test section was approximately 2.00 m long, with a 0.3 m wide sediment filled cavity installed in a false floor in the bottom of the flume. A platform covered with geotextile was installed within the cavity to support approximately 10 cm of sediment while allowing free migration of pore water into or out of the sediment depending on the applied pressure beneath. The hydraulic head at the bottom in the cavity beneath the sand bed was measured with a piezometer and the head difference between the cavity and the water flowing above the sand bed was measured. The injection or suction discharge was also metered.

There are various definitions for initiation of motion criterion in the literature (Buffington, 1999). Initiation of motion was observed visually in this study. Specifically, it was observed that if each flow rate was run for an extended period of time (20-30 minutes), bed ripples would be initiated at a given flow and then spread over the entire bed. This approach provided a more repeatable methodology for defining initiation of motion than other approaches investigated. All the sands were commercially produced and referred to as *beach/lake sand* and have a fairly rounded shape. Three sizes of sands, d_{50}=160 μm, 500 μm and 1200 μm were used.

As mentioned previously, there is no direct way to measure bed shear stress in experiments with injection or suction. It was considered unacceptable to achieve a fully developed boundary layer by performing experiments at depths of only a few cm since the resulting bulk flow Reynolds Numbers would only nominally be above the transition from laminar to turbulent flow and therefore not representative of typical field conditions. Flow depths were held in the range of 25-30 cm for all experiments and a typical value for the local boundary layer thickness over the sediment bed was on the order of 5 cm. The bed shear stress was estimated by measuring local turbulence measurements close to the bed surface and developing a procedure for converting these to bed shear stress. An Acoustic Doppler Velocimeter (Sontek MicroADV, down-looking probe) is capable of measuring the instantaneous velocity components of the flow in all three dimensions. Vertical velocity profiles were measured at the center of the flume width over the sediment bed as well as on a rigid boundary that temporarily covered the test bed. The ADV measurements also provided statistics on the velocity fluctuations, and consequently the Reynolds Stress term which is proportional to the local turbulent shear stress. The details of the procedure for determination of bed shear stress are provided in Kavcar (2008). Although this approach has its own limitations, it was considered to be preferable to experiments with water depth of a few cm (Rao and Sitaram, 1999) in order to ensure a fully developed boundary layer that changes considerably with distance along the test bed due to the requirements for a significant inflow or outflow.

For each sand size, a baseline experiment without pore water flux was conducted to define a critical bed shear stress at which incipient motion was observed. After a critical bed shear stress induced by the no bed seepage case was determined for each sand size, positive (injection) or negative (suction) hydraulic gradients were applied to the bed to investigate the effect of pore water gradients on the bed stability. In theory, the range for the applied injection hydraulic gradients would have an upper limit of 1 which implies a quick sand condition. The applied hydraulic gradients were selected to be sufficiently large that an effect on sediment stability could be observed and they would cover as wide a range of values as possible. Overall, three injection and two suction cases with different pressure gradients were investigated. The flow rate through the bed was metered in both injection and suction experiments while the piezometric gradient was determined by measuring the head difference across the bed. An injection or suction experiment was conducted by first setting the hydraulic gradient to a predetermined value and increasing the flume discharge until incipient motion was observed.

RESULTS

It is useful to explore the effect of suction and injection on velocity and Reynolds stress profiles. ADV measurements were made for flows with and without vertical flux through the sand bed. The results of typical experiments are provided in Figures 1 and 2. The measured velocity profiles demonstrate the intuitive result

that when the pore water flow is upwards into the free stream flow, the lower velocities near the bed are displaced further away from the boundary. Similarly,

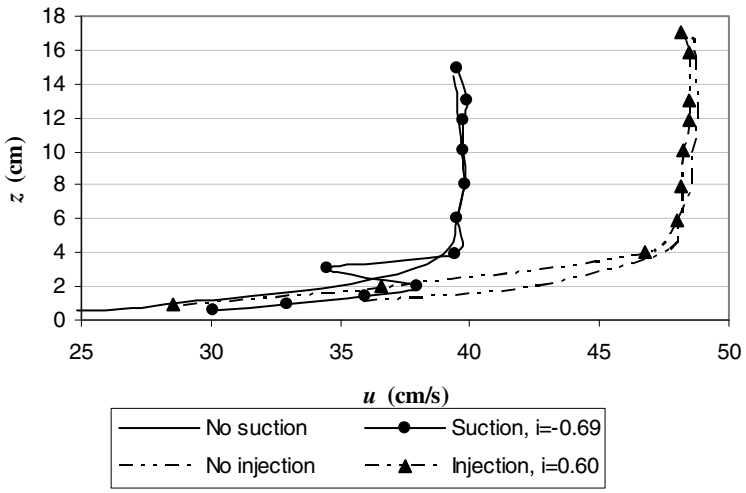

Figure 1. Comparison of mean velocity profiles of experiments with strong injection (hydraulic gradient=0.60)and strong suction (hydraulic gradient=-0.69) with experiments at same free stream velocities and no suction or injection (d_{50}=1200 μm).

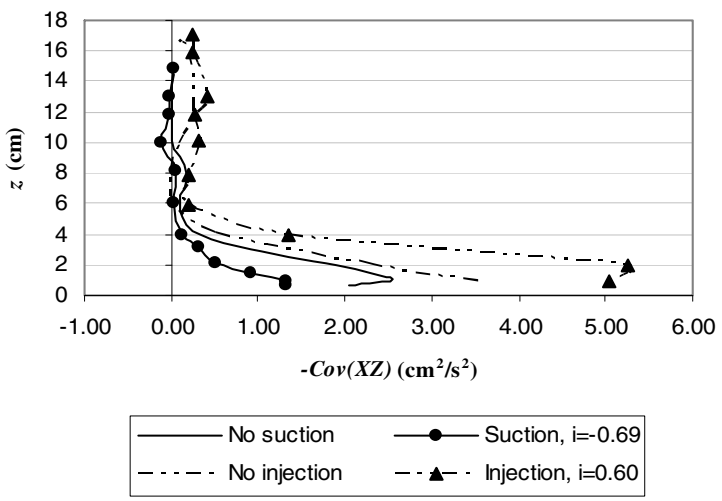

Figure 2. Comparison of covariance profiles of experiments with strong injection (hydraulic gradient=0.60) and strong suction (hydraulic gradient=-0.69) with experiments at same free stream velocities and no suction or injection (d_{50}=1200 μm).

when there is suction into the bed, higher velocities persist closer to the bed surface as the lower momentum flow near the boundary is removed from the main flow.

The two sets of measurements contain velocity profiles where the free stream velocity is similar in a case without suction or injection and in experiments with high injection or suction rates. These results imply that if one used the surface velocity or the cross-sectional averaged velocity to characterize the flow (e.g., to estimate the bed shear stress from the Manning equation), each set of measurements would experience the same bed shear stress. It is believed that this situation has led to confusion to some previous discussions on the influence of bed injection or suction on sediment stability. Since most accepted bed stability criteria are shear-stress based, it is irrelevant how the velocity or discharge required to initiate sediment transport varies with injection or suction; the only thing that is important is how the shear stress varies. Thus it was observed during this experimental investigation that sometimes a greater discharge was required to initiate sediment motion but at the same time, a lower estimated bed shear stress was experienced and therefore by shear stress-based criteria, the bed is less stable

Considering the covariance profiles, the results indicate that at the same free stream velocity, injection increases the local turbulent shear stress while suction decreases it. The effects are more pronounced the larger the hydraulic gradient. Prinos (1995) studied numerically the effects of bed suction on the structure of turbulent flow by solving the Reynolds-averaged Navier-Stokes equations for the experimental data by Maclean (1991) and reported the same behavior of decreased turbulent shear stress in case of bed suction.

These results are counter to some of the qualitative behavior discussed in the literature (e.g, Cheng and Chiew, 1998a) on the role of suction or injection on bed shear stress and this may have led to some of the contradictions in the literature on bed stability in experiments with pore water seepage. One could argue that in the case of injection the smaller local velocity gradient due to the displacement of a given velocity further out into the flow would indicate a smaller bed shear stress; nevertheless this would only be valid for a laminar flow where the shear stress is directly proportional to the local velocity gradient. In this study, the flow was turbulent over the test section, implying that the bed shear stress was dominated by the turbulent characteristics of the flow.

The bed shear stresses corresponding to the conditions when incipient motion was observed were computed employing the procedure explained above in cases of suction, injection and in the absence of injection or suction; results are given in Table 1. The suction experiments for 500 μm are not included here since no ADV measurements were available for determination of bed shear stress. The results are consistent with a greater bed shear stress required to initiate sediment motion when bed suction is applied and a reduced shear stress with injection. Figure 3 shows the Shields curve defined by the van Rijn (1984) functional relationships. When the data measured in this study are plotted but without the modified shear stress defined in Equation 2 the results indicate scatter that is somewhat greater than traditionally observed in experiments without suction or injection. However the trends for individual grain sizes, especially the 160 and 1200 μm sizes don't follow the general trends of the Shields' curve. When the dimensionless shear stress is

modified to account for the effects of suction and injection, Figure 4 demonstrates the results using a value of 0.85 for the S coefficient suggested by Martin and Aral (1971). The data for d_{50}=1200 μm lie below the Shields curve but basically parallel to it. This may be due to the fact that the grain size distribution is fairly broad for that particular sand and smaller grain sizes in the distribution are responsible for the observed initiation of motion, but it is also noted that many researchers suggest that the limiting value of τ_* for large R_* should be around 0.03 (e.g. Garcia, 2008, Chapter 3) and thus consistent with the current results. The main issue is that Figure 4 presents a more consistent presentation than Figure 3.

There are a number of assumptions that were employed in the determination of the bed shear stress used in the computation of the modified dimensionless shear stress and the grain Reynolds number. It is likely that a more rigorous procedure to determine the bed shear stress would result in better agreement with the traditional Shields curve, but there is a fair disagreement in the literature regarding even what the Shields curve is supposed to be. The presented results are considered

satisfactory in verifying the methodology for incorporating the effects of suction or injection on bed stability with a straightforward and simple modification of the dimensionless shear stress used in the conventional Shields curve.

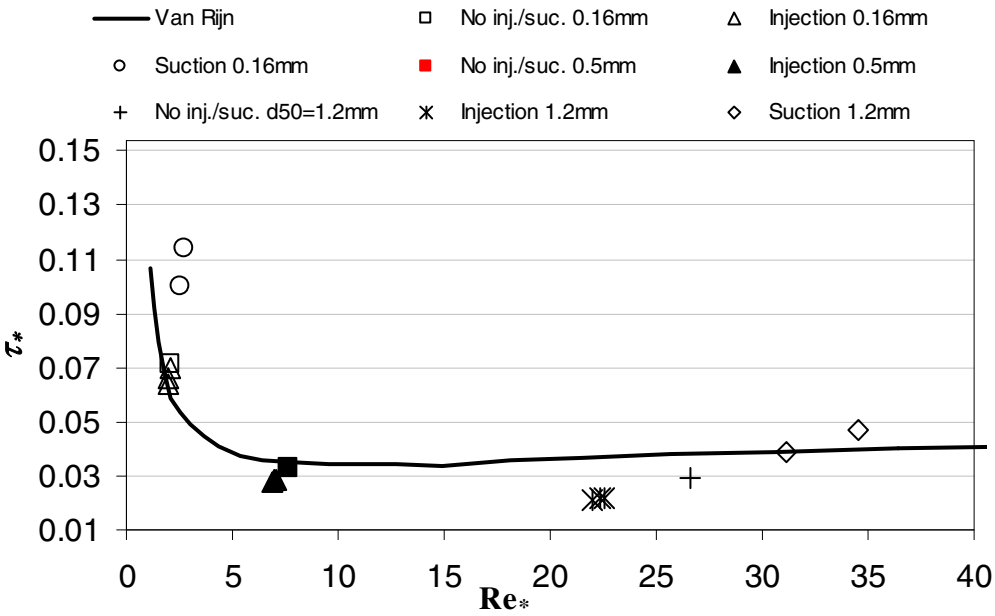

Figure 3. Experimental data on conventional Shields curve.

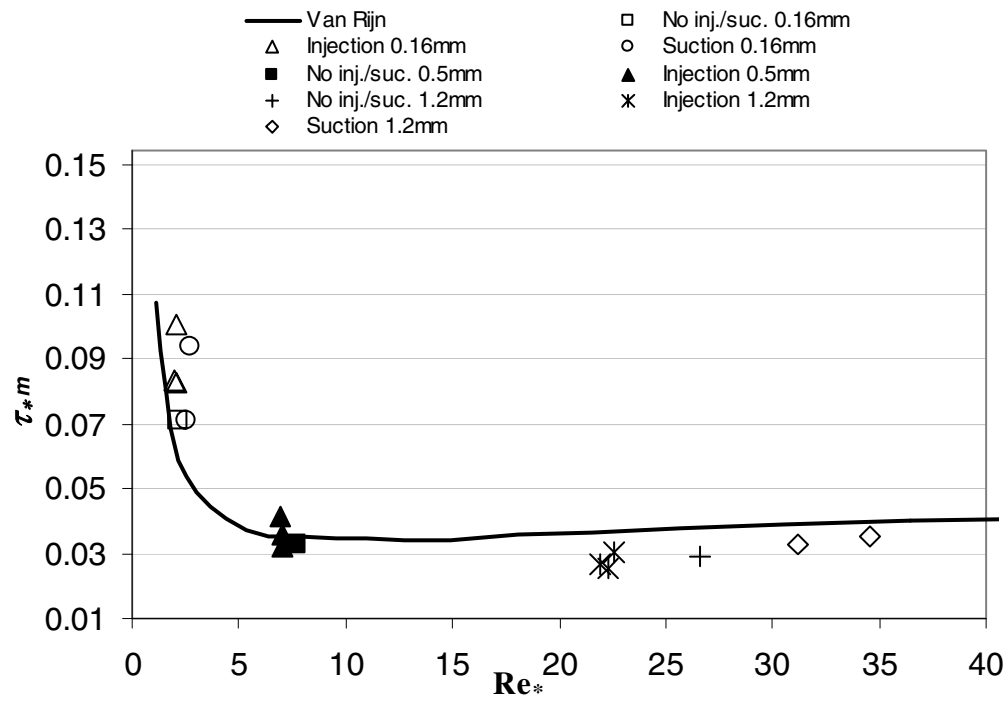

Figure 4. Experimental data on modified Shields curve.

SUMMARY AND CONCLUSIONS

This study was undertaken in part to resolve contradictory findings in the literature regarding the effect of bed seepage on the initiation of motion of non-cohesive sediments. Although several studies report that positive upwards bed flow (injection) reduces the stability of bed sediments and downwards seepage (suction) reduces it, other studies report the opposite conclusion. A review of previous studies suggests that one issue may simply be the inability to accurately estimate bed shear stress especially in the spatially non-uniform flow conditions presented by significant bed seepage. An alternative method for estimating bed shear stress was developed, relying on the measurement of turbulence close to the bed. When the methodology was applied for measurements without suction or injection, the results are consistent with the conventional Shields curve. The same methodology was applied to analyze measurements with relatively high suction and injection rates and the results compared to a modified Shields curve formulation that was developed to describe the influence of suction or injection. Different sand sizes were selected for testing to cover relevant ranges of the Shields curve to avoid the possibility of the results being only valid for certain ranges of noncohesive sediment. The following conclusions are generated from this study:

- Injection or positive upwards bed seepage tends to reduce the bed shear stress required for incipient motion of bed sediments while downwards seepage into the bed increases the required bed shear stress;
- The experimental results can be made consistent with the conventional Shields curve when the modified dimensionless shear stress is used in the Shields curve;
- Hydraulic gradient through the bed is the most relevant parameter related to bed seepage influencing non-cohesive sediment stability. Gradients greater than 0.1 are required to have a noticeable effect on bed stability

1 ABSTRACT

This paper presents a laboratory study which examines the relationship between suspended sediment concentration and the signal to noise ratio recorded by a Nortek Vectrino Doppler velocimeter for two velocimeter acoustic output power levels. Tests are conduced in a tank with tap water and Kaolin clay for the concentration range of $0.0008 - 2.8$ g/L. Results indicated that the velocimeter signal to noise ratio saturates at approximately 10 mg/L for a High power level setting and at 100 mg/L for a Low+ level power setting. For concentrations less than the saturation condition, the signal to noise ratio was found to be proportional to the logarithm of concentration, indicating that the velocimeter is a useful tool for measuring synchronized velocity and suspended sediment concentration time series.

2 INTRODUCTION

Acoustic Doppler velocimeters are designed to measure time varying turbulent velocity signatures of fluids flows, and are common tools for doing so in both field and laboratory settings (Voulgaris and Trowbridge, 1998; Nikora and Goring, 2000; Maddux et al., 2003; Strom and Papanicolaou, 2007). However, since the Doper system measure velocity using an acoustic reflection from small particulate matter in the water, they also are capable of recording information concerning the suspended particulate matter in the water column (Lohrmann et al., 1994; Lohrmann, 2001; Nikora and Goring, 2002; Hosseini et al., 2006). Studies have shown that data mining of the strength of the acoustic return signal recorded by Doppler velocimeters can yield very reliable suspended sediment concentration measurements of fine sediment (Fugate and Friedrichs, 2002; Voulgaris and Meyers, 2004; Hosseini et al., 2006). If the strength of the acoustic return recorded by the Vector signal is properly calibrated, it has been shown that in some cases, the Doppler systems can give estimates of suspended sediment concentration (SSC) that are as good as Optical Backscatter Sensors (OBSs) and Sequoia instrument's

LISST-100x, both of which are designed to measure suspended sediment concentration (Fugate and Friedrichs, 2002; Voulgaris and Meyers, 2004).

If the strength of the acoustic return signal can be adequately calibrated to the suspended sediment concentration, then Doppler systems provide a single platform for simultaneous velocity-SSC measurements at turbulent frequencies. A unique feature of this is that the turbulent sediment flux term in the advection-diffusion equation for suspended sediment can be evaluated directly. Term 3 in the following equation represents the spreading of sediment concentration due to random turbulent motion:

$$\frac{\partial C}{\partial t} + \frac{\partial}{\partial x_i}\left(U_i C\right) + \frac{\partial}{\partial x_i}\left(\overline{u_i' c'}\right) = S_e - S_D \tag{1}$$

where the molecular diffusion term has been dropped and $u_i(\mathbf{x},t) = U_i(\mathbf{x}) + u_i'(\mathbf{x},t)$ is the velocity vector (note: $u_3 = w = W - w_s + w'$, where w_s is the fall velocity), $c(\mathbf{x},t) = C(\mathbf{x}) + c'(\mathbf{x},t)$ is the suspended sediment concentration, and S_e and S_D represent sediment deposition and erosion rates. The turbulent spreading terms, $\partial_i(\overline{u_i' c'})$, is typically modeled as a diffusive process,

$$\overline{u_i' c'} = -D_{Ti}\frac{\partial C}{\partial x_i} \tag{2}$$

where D_{Ti} is the turbulent diffusion coefficient in the x, y, z directions and needs to be determined via other relations or calibrated experimentally. However, with the coupled velocity-SCC measurements, the turbulent flux can be directly measured with the Doppler system. Furthermore, if the assumptions of 2D, steady, uniform flow are made, Eq. 1 reduces to,

$$w_s\frac{\partial C}{\partial z} + \frac{\partial}{\partial z}\left(-\overline{w'c'}\right) = 0 \tag{3}$$

and a direct estimation of the fall velocity can be made from the measured vertical turbulent flux; since integration of Eq. 3 in the z and application of the boundary condition gives,

$$w_s = \frac{\overline{w'c'}}{C} \tag{4}$$

Therefore, the bulk fall velocity w_s can be estimated either through a single point measurement of the average concentration and turbulent flux, or through linear regression of measured profiles along z.

This paper examines the use of a Nortek Vectrino velocimeter for quantifying the suspended sediment concentration and turbulent sediment flux of muddy sediments in a laboratory setting. The impetus for this, in addition to measurement of turbulent flux, is the quantification of site-specific critical erosional and depositional conditions of estuarine muds.

3 BACKSCATTER AND SSC

The Acoustic Doppler velocimeter used in the study was a 10 MHz Nortek Vectrino with a side-looking 3D/2D probe. The system is a dual-pulse Doppler system

which calculates velocity using the phase shift between an emitted and reflected signal. The Vectrino has a single acoustic emitter ($f = 10$ MHz) and four receivers located a fixed distance from the emitter and angled to receive reflected sound from the sampling volume which is located 5 cm from the emitter. The sample volume is 6 mm diameter and has a variable length of $3 - 15$ mm. The Vectrino has an internal sampling frequency of $426 - 2564$ Hz, a data output range of $1 - 200$ Hz, and a dynamic echo intensity range of 25 dB. The Vectrino represents a second generation acoustic velocimeter and has shown excellent performance for turbulent measurements, especially in low SNR conditions (Rusello et al., 2006)

As mentioned, the strength of the return echo from sediment in the the sampling volume is a function of the SSC. Rayleigh scatter theory shows that the volume backscatter strength, S_v is,

$$S_v = 10 \log \left(\frac{3\phi k^4 r^3}{\rho_s} C \right) \tag{5}$$

where ϕ is a material property, k is the acoustic wave number ($k = 2\pi/\lambda$, where λ is the wavelength), ρ_s is the density of the sediment, r is the particle radius, and C is the concentration (mass/volume). For a given emitted frequency and sediment type/size, Eq. 5 shows that,

$$S_v \propto 10 \log(C), \quad \text{or} \quad C \propto 10^{S_v/10} \tag{6}$$

when $kr < 1$ (Urick, 1983). For the acoustic Doppler system, we can model the strength of the backscatter using the following version of the sonar equation in dB units (Lohrmann, 2001; Gartner, 2004; Hoitink and Hoekstra, 2005),

$$S_v = K_c(E - E_r) + 20 \log(R) + 2\alpha R \tag{7}$$

Here E is echo strength (counts), E_r is the reference receiver noise (counts), K_c is a conversion factor (counts/dB), α is a water and sediment adsorption factor, and the R is the range to the sampling volume. The last two terms in Eq. 7 are known as the major contributors to the two-way transmission loss, $2TL$, in acoustic energy as a wave travels from the emitter to the control volume and back,

$$2TL = 20 \log(R) + 2\alpha R \tag{8}$$

The first term in Eq. 8 accounts for loss due to spreading, and the second term accounts for adsorption. The adsorption coefficient, α, can be decomposed to reflect adsorption from the water and that due to sediment, $\alpha = \alpha_w + \alpha_s$. α_w is a function of pressure, salinity, and frequency; however, for $f = 10$ MHz, α_w can be taken as $\alpha_w = 26.9$ and does not vary with salinity (Lohrmann, 2001). Estimates for α_s can be made assuming uniform size particle (Urick, 1983) as,

$$\alpha_s = \left[\frac{k^4 r^3}{96\rho_s} + \frac{ks(SG-1)^2}{2\rho_s(s^2 + [SG + \delta]^2)} \right] \frac{20}{\ln(10)} C \tag{9}$$

where, k is the wave number (m^{-1}), r is particle radius (m), $s = [9/(2\beta r)]\,[1 + 2/(\beta r)]$, $\beta = \sqrt{\pi f/\nu}$, f is frequency, ν is the kinematic viscosity of water (m^2/s), SG is the specific gravity of the sediment, $\delta = [1 + 9/(\beta r)]\,/2$, and C is the concentration (kg/m^3).

For the Vectrino, R and α_w are constants ($R \approx 0.05$), and combining Eq. 6 and 7 gives,

$$\log(C) = K_c(E - E_r)/10 + c_1 + c_2\alpha_s \tag{10}$$

where $\alpha_s = \alpha_s(C)$. For reasonably low concentrations ($C \leq 1000$ mg/L), $\alpha_s 2R$ is relatively small compared to the other terms and can be neglected. Taking $K_c(E - E_r) \cong SNR$, results in linear relationship between the Signal to Noise Ratio, SNR (dB), and the logarithm of C,

$$\log(C) = c_1 SNR + c_2, \quad \text{or} \quad C = 10^{(c_1 SNR + c_2)} \tag{11}$$

The coefficients c_1 and c_2 are sediment and velocimeter dependent parameters that can be found through linear regression applied to experimental measurements of C and the corresponding average SNR value. It should be stressed that such calibrations are intrinsically dependent on the sediment properties of the suspension.

4 METHODS

This relation between S_v and C was examined for the Vectrino over the concentration ranges from $0.0008 - 2.8$ g/L using tap water and Kaolin clay. For the tests, the Vectrino "power" and "velocity range" parameter settings were varied at each concentration level to explore the effect of the user set parameters on the $C = C(SNR)$ relationship for a range of typical values, i.e. Power = (High, Low+) and Nominal Velocity Range = (± 0.3, ± 1.0 m/s). The test were conducted in a tank of known volume of water, and Kaolin clay ($d_{50} \approx 10$ μm) was systematically added to create the desired concentrations. All suspensions were continuously mixed at a constant rate during data acquisition. 3000 data points were collected at 25 Hz (2 minute samples) for each of the 148 different experimental combinations.

5 RESULTS

At each concentration level, the average SNR (dB) values for the time series were averaged per receiver and then averaged over the four receivers to give an overall average SNR for each experimental condition. The data was grouped first by transmitter power level and then by velocity range setting and plotted to examine the linearity expected by Eq. 11 (Fig. 1). Fig. 1a shows that the Vectrino quickly reached a saturation level around $SNR \approx 23$ (dB) where increases in concentration result in no further increase in SNR value. As expected, the concentration at which this happens, C_{sat}, is a function of the power setting since a reduction in the emitted intensity will result in a reduction in the echo. For Low+ power,

C_{sat} = 100 mg/L, whereas for the High power setting, C_{sat} = 10 mg/L (Fig. 1b,c). Overall, user set nominal velocity range had no significant effect on the measured *SNR* values.

Below the saturation condition, $C < C_{sat}$, both power levels yield the linear response of $C \propto 10^{(c_1 SNR + c_2)}$ anticipated by Eq. 11 (Fig. 1c). Increasing the power from Low+ to High results in a constant shift of the linear portion of the response towards higher *SNR* values for a given concentration (Table 1). Since the slope remains constant, the linear portion of the curve for which $C_i < (C_{sat})_i$ can be modeled with the coefficients obtained for the Low+ power settings and a modified signal to noise ratio, $SNR^* = SNR - \Delta$, where Δ is the difference in dB between the two power settings (Fig. 1d). For the Vectrino, $\Delta = 7.5$ dB between Low+ and High power settings.

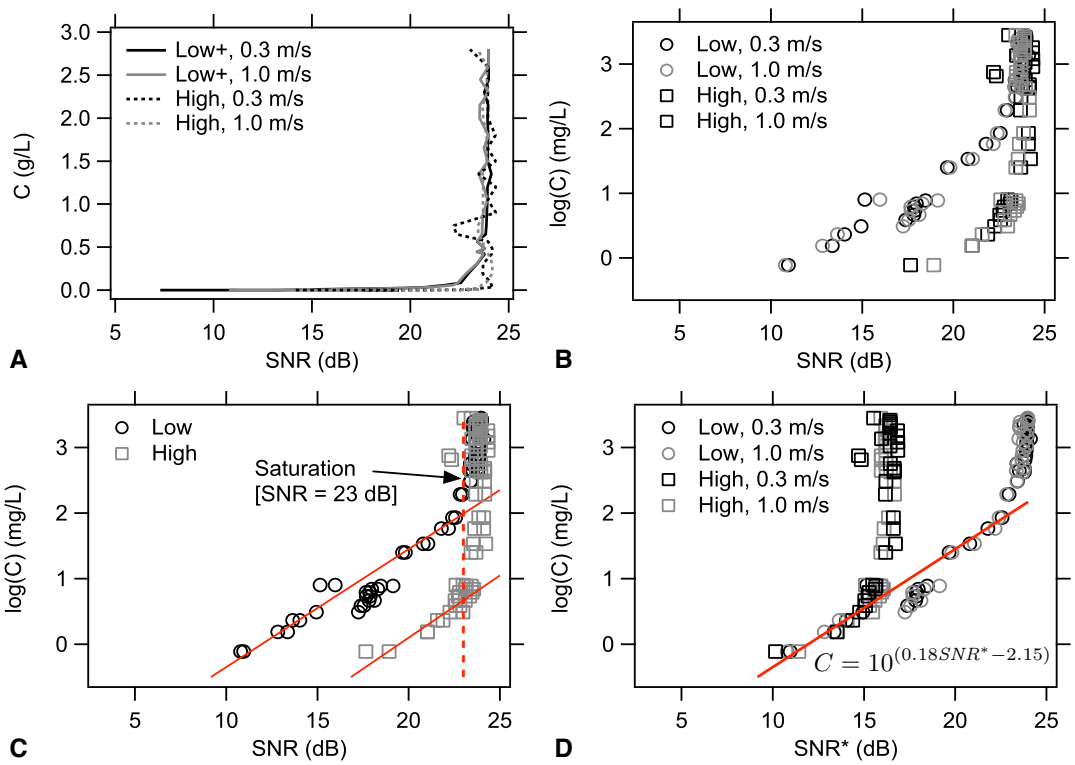

Figure. 1: Summary of results for the four conditions. (A) Suspended sediment concentration C in g/L as a function of *SNR*; (B-C) log(C) versus *SNR* (C in mg/L); and (D) C versus SNR^* along with the fit regression equation.

Table 1: Regression results for C in mg/L

Power	C_{sat} (mg/L)	c_1	c_2
Low+	100	0.18	-2.15
High	10	0.19	-3.7

6 CONCLUSIONS

This study has examined the relationship between the suspended sediment concentration of Kaolin clay and the Vectrino measured *SNR* value in a laboratory. Results show that the Vectrino reaches a saturation condition in *SNR* response at $C = 10$ mg/L for a power setting of High and $C = 100$ mg/L for a power setting of Low+. The user setting for the nominal velocity range had little effect on the relationship between concentration and *SNR* . For concentrations less than saturation, a proportionality between the logarithm of concentration and the *SNR* was found. This suggests that within this range, the Vectrino is a useful tool for recording simultaneous velocity and SSC time series data for sediment flux and fall velocity analysis.

A practical limitation in the methodology outlined in the study is the limit set on particle size by the acoustic frequency. The relationships discussed are based on the Rayleigh scattering model which is restricted to the particle size range $d < k^{-1}$, which translates to $d < 50$ μm for the 10 MHz system(Lohrmann, 2001; Hoitink and Hoekstra, 2005). The Kaolin primary particles do fit the criteria of $d < 50$ μm; however, it is unknown as to how flocculation might have affected the results.

ABSTRACT

The transport dynamic and fate of sediments in rivers is closely interrelated to upland activities within a watershed. Commonly, much of the degradation of surface waters in rivers is linked to excessive fine sediment and sediment-bound pollutants coming from the uplands. Phosphorus, some pesticides, most metals, and many organic compounds are transported to the stream primarily adsorbed to fine sediment. Different land use activities in a watershed contribute to the increased influx of fine sediments and pollutants into streams. This research seeks to provide a methodology to qualitatively describe the inputs from the uplands into a stream segment, i.e., to account for the connectivity of upland and instream processes.

In order to link fate of sediment within the river with upland activities, this research aims to integrate two models, namely, WEPP an upland non-point source pollution model with 3ST1D, an instream model that can handle inputs of silts and clays. The analysis is performed in the Clear Creek Watershed of Eastern Iowa using existing data for model calibration and verification.

INTRODUCTION

The components of a watershed may be simplified into three parts: hill-slopes, floodplains, and streams (Figure 1). Each element has its own complexities and interactions with the others. First, the hill-slopes shall be considered to be made up of two different mechanisms: rill and inter-rill areas. The rill areas are considered to be ditch-like in nature and carry concentrated flow directed towards the nearest link to lesser elevations. The inter-rill areas are sections of land that are in-between and above the rills carrying overland flow. These two components are considered the most temporally complex because of the intricacies of sediment movement. Second, the flood plains are directly adjacent to the streams and allow for inundation during large events. Though a large part of the floodplain's functionality is for inundation, it too has many different components that can affect the morphology of the system. The floodplain's mechanisms include wetlands, gullies, stream-bank (collapse and erosion), an assortment of head-cuts, and other nuances making up the various

sinks/sources involved with sediment entrainment and availability. Lastly, the streams, which are the connectors for the vast watershed systems and have been the heaviest studied, seem to maintain a certain level of ambiguity. Researchers have been able to model and predict some of the hydraulic and transport mechanisms of in-stream processes, but predictions are mostly reserved for some finite control volumes and specific characteristics. Even under these circumstances, the models must then be verified by some amount of ground truth. Therefore, whatever amount of knowledge we have concerning a watershed system's components, we know much less about the connectivity and interactions of each.

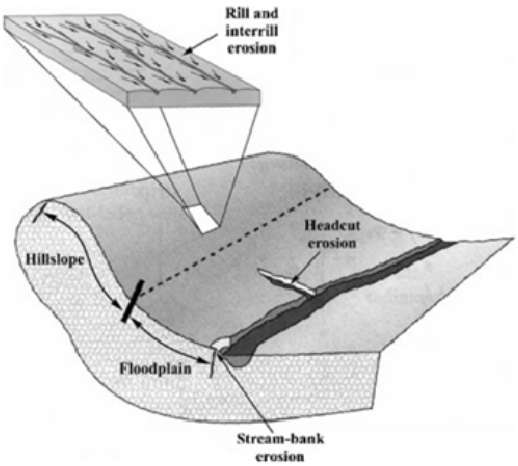

Figure 1. Sketch of the hillslope, floodplain and instream components

OBJECTIVE

The overarching objective of this research is to show the plausibility of numerical models simulating upland erosion and transport throughout a watershed. Specifically, this research will provide, for the first time, the interconnectivity between upland erosion and instream sediment transport processes using a didactic blend of field data and numerical models.

METHODOLOGY

Study Area

The study area is located within the Clear Creek Experimental Watershed (CCEW). The CCEW is a HUC-10 (Hydrological Unit Code) watershed located in east-central Iowa within Iowa and Johnson Counties (Figure 2). The CCEW drains approximately 270 km^2 into the Clear Creek River which discharges into the Iowa River slightly North of Iowa City, IA. This research is focused in the headwaters of the system, more specifically within the South Amana Catchment (SAC). The SAC is in the northwest corner of the CCEW and encompasses 26 km^2. Some of the highest erosion rates in the CCEW are in this catchment and result from a combination of swelling and highly erodible soils with steep gradients and intensive

agriculture. It is predominantly rural with only single farmsteads in the catchment borders. The SAC is mostly row-crop agriculture generally consisting of maize and soybean production. The dominant soil layer in the SAC is silty clay loam. As can be seen in Figure 4, the southern sub basin of the uplands is comprised mostly of Tama, and in the northern region Downs is the most prominent, while the floodplain soils are predominantly Colo (Papanicolaou and Abaci 2008). When simulating overland flow, topography of the watershed is vitally important, specifically for determining the shape of hillslopes (concave vs. convex). Through GIS analysis techniques it has been determined that the SAC consist mainly of concave hillslope structure. In addition, the elevation ranges from 235 to 274 m above mean sea level, and the average gradient is 4%, with a range of 1 to 10% (Papanicolaou and Abaci 2008). The outlet for the Clear Creek South Amana Catchment is a typical stream of the Midwest. Being a fairly small, 2nd order stream, it is un-gauged with no historical record concerning the flow regime.

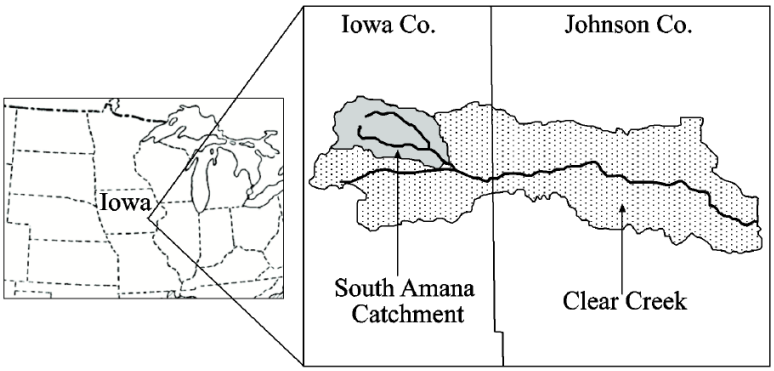

Figure 2. The South Amana Catchment in the Clear Creek Watershed, IA

Field data and instrumentation

Various instruments were deployed at the SAC outlet to record the topography of the region of interest, determine the bed composition, perform flow measurements, and gauge the suspended load. Surveying was carried out by using a Leica-TC 605 Total Station in order to determine the exact geometry of the SAC outlet. Extensive bed sampling was undergone to determine the grain size distribution of the bed. Flow measurements were conducted by using a 3-D Side Looking Flow Tracker ADV manufactured by SonTek. The Flow Tracker ADV had a velocity range of 0.001 – 4 m/s and an accuracy of ±1% of the measured velocity. Mean flow measurements of the velocity in a cross-section were used to determine the flow discharge.

Turbulent measurements were conducted by using a field ADV with a higher sampling frequency than the Flow Tracker ADV. Although turbulence strongly influences the velocity distribution, shear stress, energy transfer, sediment transport, and spread of pollutants in river channels (Sukhodolov, 1998), results from ADV measurements are outside the scope of this paper. It is important to note, though, that accurate measurements of depth-averaged velocity were derived from these measurements and are vital for validation purposes. Stage measurements were taken using Pressure Transducers manufactured by Global Water Instrumentation Inc. One pressure transducer was fixed at the exit of the reach at a known location, and another

was installed for redundancy at the entrance of the reach. In order to verify the pressure transducers, rulers were fixed at two locations along the stream and relative stages were recorded during site visits. The pressure transducers recorded the depth and time at an interval of 15 minutes, giving us data to create continuous stage hydrographs for any given precipitation event. From this stage information, once coupled with flow data, a stage discharge curve was created and is useful for any storm event. Suspended sediment loads were measured by way of a volumetric sediment sampler, namely Sigma 900 Max Portable Samplers. Volumetric samples were taken regularly on a 24hr schedule, and select precipitation events were captured at a 1 hour sampling rate.

Uplands Erosion Model

To numerically simulate upland erosion the Water Erosion Prediction Project (WEPP) model was utilized. WEPP is a process-based erosion simulation model developed by the United States Department of Agriculture (USDA). based on physical parameters. A physically based distributed watershed model (such as WEPP) ventures to account for an exhaustive amount of parameters while allowing the user to specify a forcing. A comprehensive review of the model formulation is available in Flanagan and Nearing (1995). Papanicolaou and Abaci (2008) have shown that WEPP, as a physical-based distributed model, can adequately simulate runoff and erosion processes for larger watersheds (e.g., 26 km^2) when the flow/sediment pathways are well understood. The key data needed for WEPP simulations are the following: rainfall patterns for specific events (depth, distribution, and intensity), topography, soil characteristics (hydraulic conductivity, erodibility criteria, etc.), and land management regimes.

One of WEPP's most defining and appealing assets is the model's ability to predict rill and interrill erosion. WEPP solves the sediment continuity equation for rill erosion and provides results of rill width and depth within a hillslope profile. The driving sediment transport equation for rill erosion in the model includes the steady-state sediment continuity equation for a hillslope given as

$$\frac{dG}{dx} = D_f + D_i$$

where G is sediment load (kg/s/m), D_i is the interrill erosion rate (kg/s/m^2) or interrill source term, and D_f can be rill detachment or deposition rate (kg/s/m^2). D_f is detachment in rills when the applied hydraulic shear stress exceeds the critical shear stress of the soil and when the sediment load is less than the sediment carrying capacity. Rill detachment is

$$D_f = K_r(\tau_f - \tau_c)\left(1 - \frac{G}{T_c}\right)$$

where K_r is a rill erodibility parameter (s/m), τ_f is bed shear stress exerted by the fluid (Pa), τ_c is the critical shear stress (Pa), and T_c is sediment transport capacity (Kg/s/m). Net deposition in the rill is computed when sediment lad, G, is greater than sediment transport capacity, T_c. The equation for deposition follows:

$$D_f = \frac{\beta V_f}{q}(T_c - G)$$

where V_f is the effective fall velocity for the sediment (m/s), q is unit discharge in the rills (m^2/s), and β is a raindrop induced turbulence coefficient.

Instream Model

To simulate flow and sediment transport within the SAC outlet the Steep Stream Sediment Transport 1-Dimensional (3ST1D) model was utilized (Papanicolaou et al. 2004). 3ST1D was chosen based on the following considerations: First, the section of interest (the SAC outlet) is comprised of a heterogeneous bed material (Figure 3), classified as silty-sand (ASTM D2488), and 3ST1D can handle bed mixtures consisting of cohesive and sand materials. Second, the stream reach being modeled, is predominantly unidirectional and free from any sinuosity. Therefore, secondary currents are minimal and computationally expensive programs, such as 2-Dimensional and 3-Dimensional models are unnecessary.

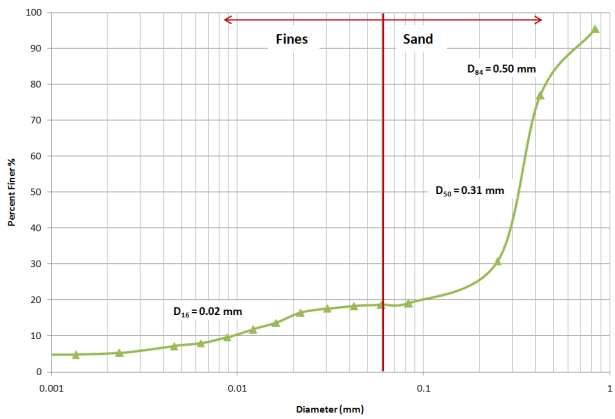

Figure 3. Grain size distribution for the outlet of the SAC. D_{16}, D_{50} and D_{84} represent the characteristic grain sizes for the 16th, 50th and 84th percentiles, respectively (i.e. 84% of the bed material is less than 0.50 mm in diameter)

Instream numerical modeling is explicitly intertwined with the uplands from which it is fed, but, from the modeling perspective, streams operate under an entirely different set of parameters. Descriptions of the stream reach such as geometry and bed composition are imperative parameters. Also, specific flow characteristics, such as depth, discharge, and velocity, are vital for attaining accurate simulations.

Flow is calculated by means of the 1-D Saint-Venant equations. The Saint-Venant equations are derived from the Navier-Stokes equations which express the law of conservation of mass and momentum along the flow direction (Papanicolaou et al. 2004). Sediment calculations require the user to apply sound engineering judgment. There are a plethora of empirical equations in the literature that may be utilized, but only for specific physical and climatic conditions. Understanding the sediment composition, flow regime, channel form and other such properties of the SAC outlet are vital when determining appropriate transport equations.

The sediment calculations follow a step by step process. First, the channel's resistance to flow is determined (Manning's n and friction factor). Next, incipient motion criterion for the commencement of sediment motion is determined based on the critical erosional strength. Critical erosional strength is defined as the strength

provided by interparticle forces that resist erosion and the value is set by the user during the calibration process. Next, the flow's transport capacity for a given section is calculated via an equation formulated by Yalin (1963). Next, an erosion and deposition algorithm is employed (Papanicolaou et al 2004), followed by a suspended concentration model, and finally the bed is updated for each successive time-step.

Calibration and Verification

The simulations for this study are meant to replicate the natural environment, but the user must exploit some ground truth measurements to anchor them in the real world. Therefore a calibration and verification process is used to improve the accuracy of our models.

For a watershed model a successful calibration will minimize the difference between observed and predicted values of sediment yield while maintaining validity over a range of events. Calibration starts with flow and then moves to sediment (Santhi et al., 2001), and this is the philosophy we will consider with our design. Since the input parameters in a watershed model are cumbersome in number, it is important to know the meaningful ranges for each of the parameters. The dominant factors governing the sediment yield from a watershed are precipitation, rill/interrill erodibility, rill and interrill residue cover, critical erosional strength, and hydraulic conductivity (Nearing 1990).

For the calibration of instream models, the process should prove accurate prediction of flow velocities and depths in the channel, while predicting closely the deposition and detachment rates within the reach. Similar to the watershed model, predictions should be based on input parameters and boundary conditions that are reasonable and reflect the natural processes that occur within the stream reach.

RESULTS

Below are some of the results that will aid describing the interactions between uplands erosion and instream processes via field data and numerical modeling. First we shall present some of the input data for the uplands erosion model WEPP; this will include historical rainfall data for the SAC, soil characteristics, land management practices, and topography. Second we shall present some of the input data for the instream numerical model 3ST1D; this will include bed composition, stage hydrograph, stage discharge relationship and velocity measurements. Also, to compliment both models, a sediment rating curve and ADV measurements are presented.

WEPP inputs include the following: Topography, which was previously discussed, soil characteristics (Figure 4), and land management regimes (Figure 4), and rainfall patterns for specific events (Figure 5). With these inputs WEPP will estimate the water discharge and sediment yield resulting from specific precipitation events. In order to validate the upland erosion model we shall utilize the following tools: continuous stage hydrograph (Figure 5) coupled with the stage discharge relationship (Figure 6), and the sediment rating curve (Figure 7) created from numerous suspended sediment samples.

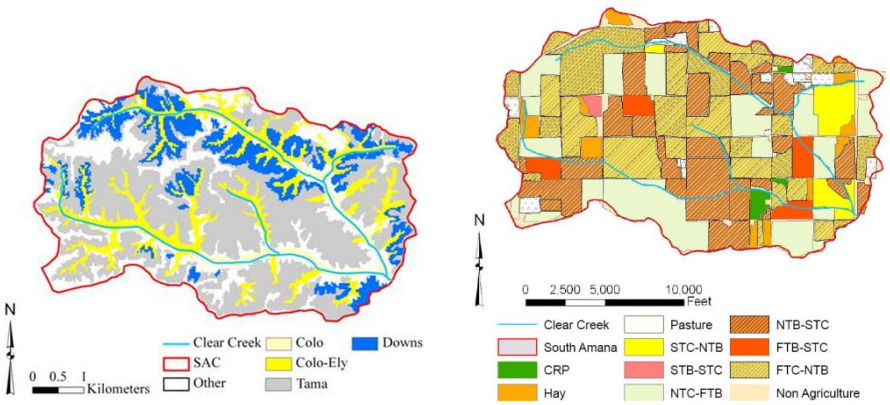

Figure 4. Soil characteristics and crop rotations for the SAC (Papanicolaou and Abaci 2008)

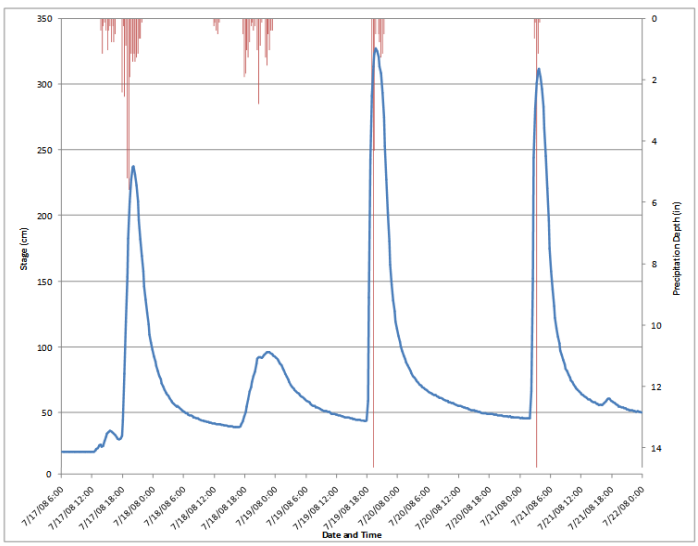

Figure 5. Time series showing rainfall in the SAC and stream hydrograph for the SAC outlet

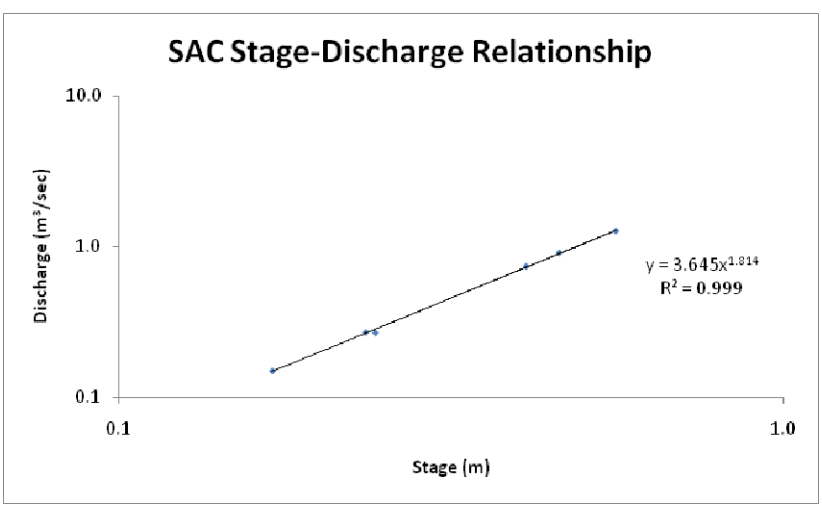

Figure 6. Stage discharge relationship for the SAC outlet

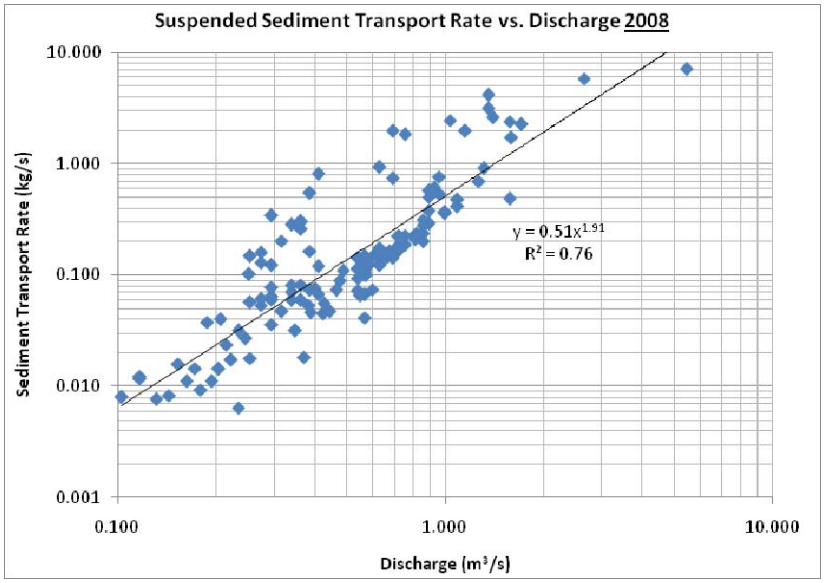

Figure 7. Sediment rating curve for the SAC

3ST1D model inputs are summarized in Table 1. With these inputs 3ST1D will estimate the flow velocity and depth, bed evolution, and sediment transport rate resulting from specific precipitation events (WEPP inputs). In order to validate the in-stream model we shall utilize the ADV velocity measurements (Figure 8) and the stream hydrograph (Figure 5) for the hydrodynamic component, whereas for the sediment transport component we shall use the sediment rating curve (Figure 7).

Table 1. Input variables for the 3ST1D model and their respective sources of origin

Input	Source
Geometry and bed elevation	Survey
Discharge	WEPP
Depth	Stage-discharge relationship
Sediment Inflow	WEPP
Bed Composition	Grain Size Distribution
Sediment Transport Equation	Yalin (1963)
Erosion deposition algorithm	Papanicolaou et al. (2004)
Incipient motion criterion	Set during calibration process
Manning's n	Set during calibration process
Active layer thickness	Papanicolaou et al. (2004)

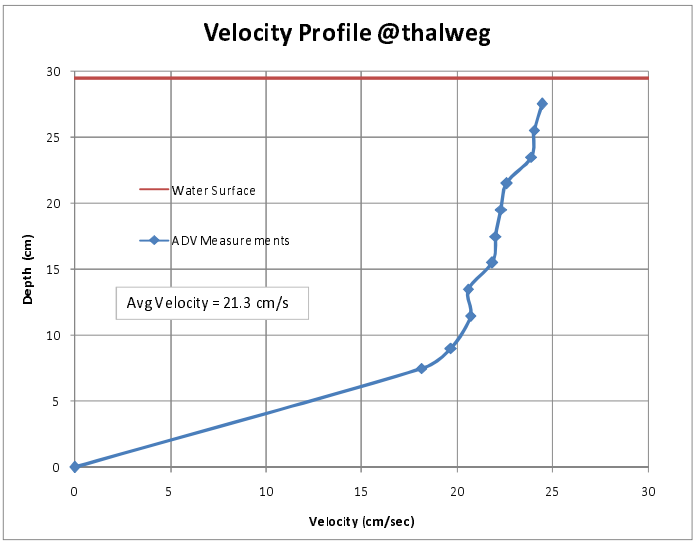

Figure 8. ADV velocity measurements at the SAC outlet

CONCLUSION

Through the various instrument measurements and constant observations, we hope to have developed a concise representation of the in-stream processes of the South Amana Catchment outlet, along with a quantitative assessment of erosion occurring in the uplands of the watershed. By coupling the already established models (WEPP and 3ST1D) a digital watershed may be developed for the South Amana Catchment. Though the technology is not fully developed this research will further the knowledge of interactions of the fluvial system at a catchment level, and can lay the framework for watershed management on larger scales.

ABSTRACT

Bubbly Creek is a tributary of the Chicago River, IL. It is used mainly as a Combined Sewer Overflow (CSO) route to the Chicago River. The CSO events from the Bubbly Creek carry sewers into the main channel and have a great impact on the overall water quality downstream. The sewer water mixed with particles usually has a higher density than the ambient water in the main channel. Upstream intrusion of sewer water is possible during the CSO event. In this paper, the three-dimensional environmental fluid dynamics code (EFDC) is used to simulate the CSO event in Bubbly Creek. The main purpose is to investigate the extent of the upstream intrusion and its implications for the water quality effects on the Chicago River. The results show that the front location is a function of the relative CSO flow and the CSO particle concentration.

INTRODUCTION

The Chicago River is a vital part of Chicago, Illinois, which is the third largest city in the United States with a population of more than 3 million. Bubbly Creek is a tributary, which is also known as South fork of the Chicago River's South branch. The location of the river system is shown in Figure 1. Bubbly Creek is notorious for its heavy pollution because the meatpacking industry used it as an open sewer and massive quantities of animal remains were dumped into it in the 1900s (Hill, 2000).

Under wet weather condition, the discharge of Combined Sewer Overflow (CSO) from Bubbly Creek into the Chicago River induces high flow velocities and high shear stresses on the stream bed which has poor sediment quality. Therefore, Bubbly Creek, which is a frequent source of contaminant into the Chicago River, plays an important role for the water quality of the whole river system.

To fully understand the transport and fate of the pollutants, it is important to know the flow structures associated to the CSO events. Because of its high content of particulate matters and the resuspension/deposition process, the sewer flow in the Bubbly Creek could be heavier than the ambient water in the Chicago River and density current could happen at the junction. Polluted heavy water might flow upstream in the Chicago River as an intruding underflow. In this research, the specific questions which need to be answered are how long the impaired water can travel upstream, what the control factors

are, and what are their environmental implications. Besides this density current study, water quality modeling has also been done using a two-dimensional BOD and DO model to study both short term and long term changes (Motta *et al*, 2009) .

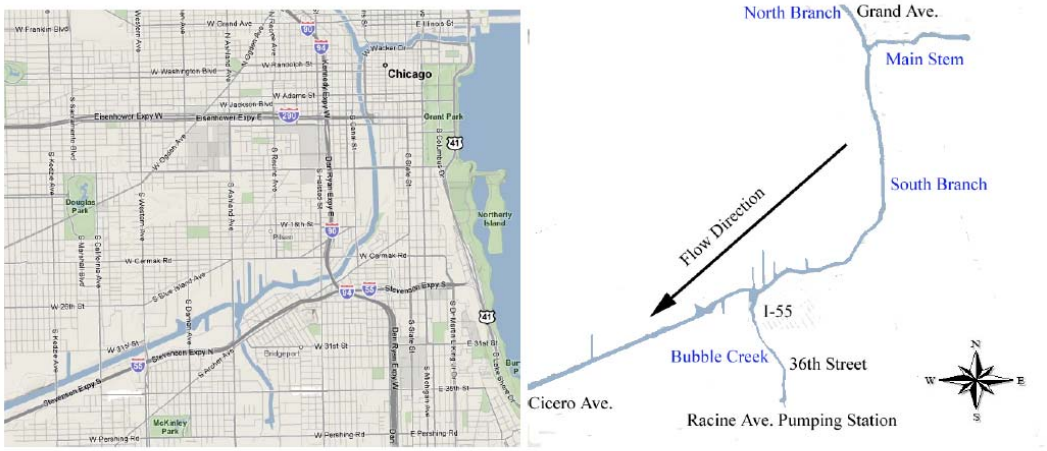

Figure 1. Aerial view of the Chicago River, Illinois: (a) Whole River Domain (b) River Segmentation and Boundaries.

The three-dimensional Environmental Fluid Dynamics Code, EFDC, is used to simulate the CSO dynamics (Hamrick 1992). EFDC is a public domain code which is supported by the US Environmental Protection Agency (EPA) and has been widely used for many rivers and estuaries. EFDC uses stretched or sigma vertical coordinate and Cartesian or curvilinear, orthogonal horizontal coordinate. It solves the three-dimensional vertically hydrostatic, free surface, turbulent-averaged equations of motions for fluid. Water quality models are also implemented. For this paper, only the hydrodynamics and the sediment transport part of the EFDC code are used. For calibration purpose, the domain includes the North branch up to Grand Avenue, the Chicago River main stem, the South branch down to Cicero Avenue, and the Bubbly Creek. The total length of the waterway in this domain is 20.3 kilometers (about 12.6 miles). For simulations of density currents due to CSO events, only the portion of the Bubbly Creek and its junction with the main channel is included (Figure 2(b)). The bathymetry data are provided by the United States Geological Survey (USGS) and are shown in Figure 2.

CALIBRATION

Before the model can be used for the density current study, the hydrodynamic part needs to be calibrated. The bottom resistance is one of the important factors which affect the behavior of the river system. In EFDC, the only parameter which needs to be specified for the resistance of river bottom is the roughness height. Equivalent to Manning's roughness coefficient n, it is used in the log law formula when computing the bottom shear stress. Even with the information on the sediment, vegetation, and river geometry, the determination of the roughness height is still a challenge. In this paper, the roughness height is selected as a calibration parameter.

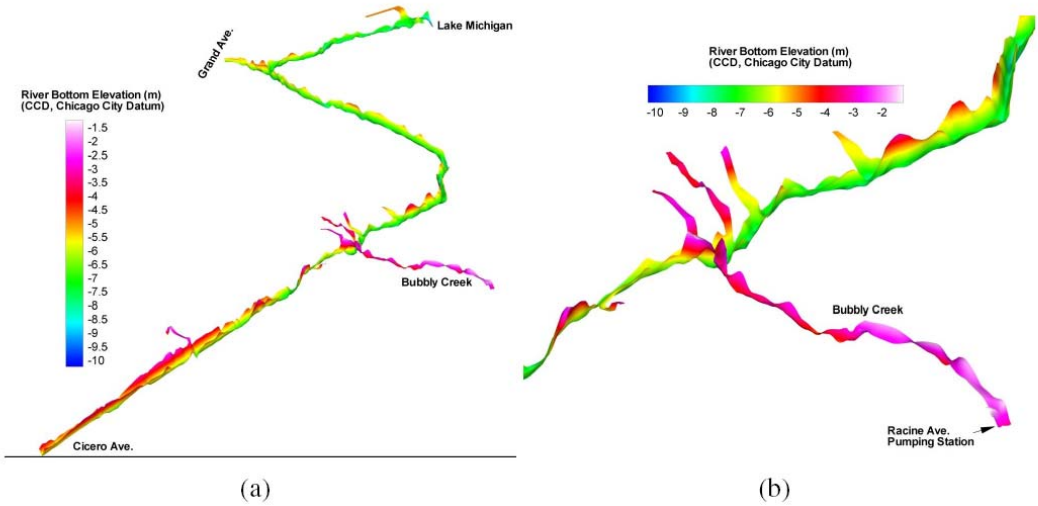

Figure 2. Bathymetry of the Chicago River, IL: (a) Bathymetry of the Whole River (b) Bathymetry near Bubbly Creek.

The boundary conditions and the calibration data are provided by the USGS gauge stations along the river. They include station 05536118 at Grand Avenue, station 05536123 at Columbus Drive, and a new gauge station which is installed at Cicero Avenue. At these gauge stations, water-stage recorders, acoustic velocity meters, and water-temperature sensors are installed. The discharge at the Grand Avenue gauge station and the stage at the Cicero Avenue gauge station form the boundary conditions for the calibration simulation. The measurement from the USGS gauge stations are plotted in Figure 3. The goal of the calibration is that the water surface elevations at the Grand Avenue and Columbus Drive gauge stations are matched. The calibration period is from 01/01/2008 to 03/01/2008. During this period, the Chicago Lock at Lake Michigan is closed and the leakage from the lock is neglected. So the boundary condition for main stem at the Chicago Lock is set as a rigid wall.

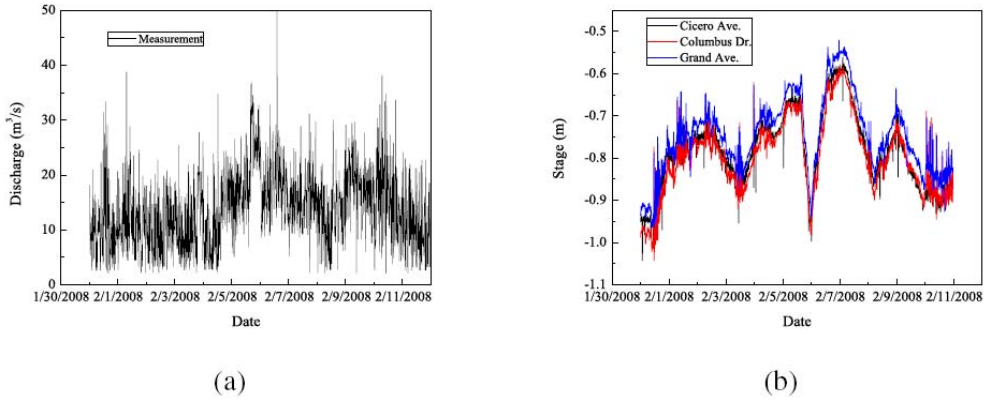

Figure 3. Measurement Data for the Calibration of the Hydrodynamic Model: (a) Flow Discharge at Grand Avenue Gauge Station (b) Stages at Grand Avenue, Columbus Drive, and Cicero Avenue Gauge Stations.

The river system is divided into four segments: North branch, South branch, main stem, and Bubbly Creek. This segmentation is similar to Barkau (1991) and Shrestha and Melching (2003). In each segment, the roughness height (i.e., Manning's *n* coefficient) is uniform. The calibration results for the roughness height are shown in Table 1. The Bubbly Creek has a roughness height of 0.2 m (Manning's *n* value of 0.026) which is higher than the rest of the river system. The calibrated stages at Grand Avenue, Columbus Drive, and Bubbly Creek Junction are plotted in Figure 4.

TABLE 1. Calibrated Values for Roughness Height and Equivalent

Name	Roughness Height	Manning's n from Strickler's formula $n = 0.034 k_s^{1/6}$
North Branch (NB)	0.1	0.023
South Branch (SB)	0.1	0.023
Main Stem (MS)	0.15	0.025
Bubbly Creek (BC)	0.2	0.026

APPLICATION

Since the model is calibrated, the next step is to investigate the transport of the particles and use the results to infer how the CSO event effects on the water quality in Chicago River. The parameters of the CSO particles and river bottom sediments are from measurement. The particle density in the bed cores and the bed surface grabs at the Bubbly Creek junction are 2392 kg/m^3 and 2423 kg/m^3, respectively (Yin *et al.*, 2007). According to USACE (2005), the particle density along the whole length of the Bubbly Creek ranges from 1370 kg/m^3 to 2570 kg/m^3. In this paper, an average value of 2000 kg/m^3 is selected for the particle density. The porosity for the Bubbly Creek is set to a

value of 0.7 from the analysis in Yin *et al.* (2007). For the main channel, a typical value of 0.4 is used. The sediments in Bubbly Creek (both the cores and the grab samples) are fine sand, which have an average diameter of 82 μm, with maximum and minimum diameters of 258 μm and 20 μm (USACE 2005). Particle size distribution measurements were also done for the main channel in 2004 at Archer Avenue, which locates upstream of the junction. The mean diameter in the main channel ranges from 57 μm to 191 μm. Since only one typical particle is used in current research, the mean diameter D_{50} is set to 100 μm.

Following, three major variables are studied, i.e., the main channel (the Chicago River) flow, the CSO flow, and the CSO particle concentration.

Effects of the main channel flow

In order to investigate the effects of the main channel flow, seven cases are simulated (see Table 2). The main channel flow ranges from 1 m^3/s to 30 m^3/s at the Grand Avenue gauge station, according to the USGS measurement. The CSO flow from Bubbly Creek is fixed at 35 m^3/s, which is a typical value when half of the CSO pumps at the Racine Avenue Pumping Station are turned on. The CSO particle concentration is fixed at a typical value which is 1000 mg/l.

TABLE 2. Test Cases for the Effects of the Main Channel Flow

Case #	Main Channel Flow (m^3/s)	CSO Flow (m^3/s)
1	1	35
2	5	35
3	10	35
4	15	35
5	20	35
6	25	35
7	30	35

The typical flow features can be observed in Figure 5. It shows the flow streamlines and particle concentration field around the Bubbly Creek junction at T = 4 hours. The CSO flow from Bubbly Creek is split into three parts due to the effect of density difference, i.e., flow upstream, flow downstream, and flow going up the step into the first slip. Due to the effect of high concentration of particles, the water from the CSO event is denser than the ambient water in the main channel and therefore the density current is formed. Instead of uniquely flowing downstream, part of the CSO flow from Bubbly Creek plunges under the water surface and flows upstream. The distance of this upstream-traveling current is one of the main features which will be investigated. This distance depends on the relative strength of the CSO flow and the particle concentration. Another apparent flow feature is the big recirculation at the junction when the CSO event happens. The big open water space is called the turning basin and is used for the commercial ship transportation. From the water quality perspective, the big recirculation

will stir the bottom of the turning basin and resuspend the polluted sediment and the upstream traveling underflow will bring the pollutant upstream.

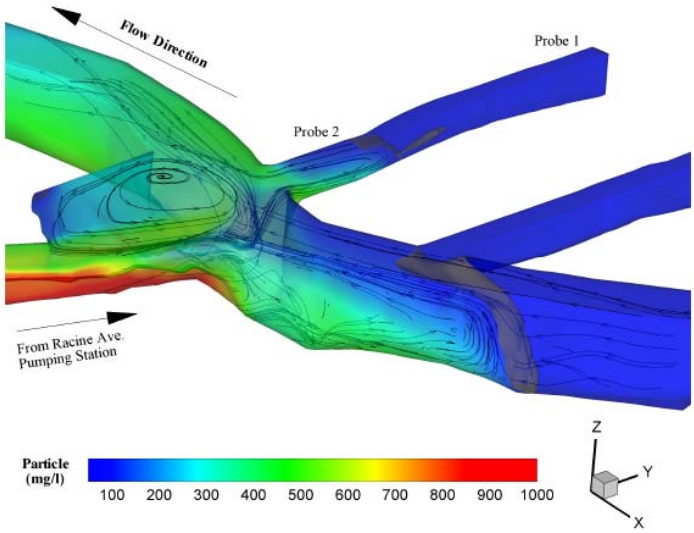

Figure 5. Flow Features at T = 4 Hours for Case 1 (Main Channel Flow = 1 m^3/s, CSO Flow = 35 m^3/s, CSO Particle Concentration = 1000 mg/l).

Figure 6 shows the flow streamlines in the turning basin at different stages of the CSO event. This figure allows for visualizing the flow field around the junction. From the beginning to the end, there is always a big vortex in the turning basin. This is due to the effect of the main channel or the CSO flow, or both. At the initial stage (T = 2 hours), there is another vortex around the first slip. This might be caused by the initial momentum of the CSO flow. With the flow developing, the second vortex around the first slip disappears (T = 4 hours). The flow structure around the turning basin does not significantly vary during the CSO event (compare time = 4 hours and 6 hours). Again, due to the effect of the density current, the CSO flow travels both upstream in the main channel and into slips, as it is evident from the streamlines. When the CSO event ends, the vortex in the turning basin becomes smaller.

In order to evaluate the effects of the main channel flow (when the CSO flow is fixed at 35 m^3/s), the front location and the plunging point are measured. The front point is measured at the point where the front meets the ambient sediment concentration (100 mg/l). The plunging point is defined as the location where the sediment concentration is 150mg/l at the water surface. The coordinate L along the river starts from the downstream origin (Cicero Avenue). The Bubbly Creek junction is located at about L = 700 m. Figure 7 shows the quantitative relation between the front location, plunging point, front slope, and the main channel flow. It is observed that with the increase of the main channel flow, the front location and the plunging point are pushed downstream. The front becomes sharper as the main channel flow increases.

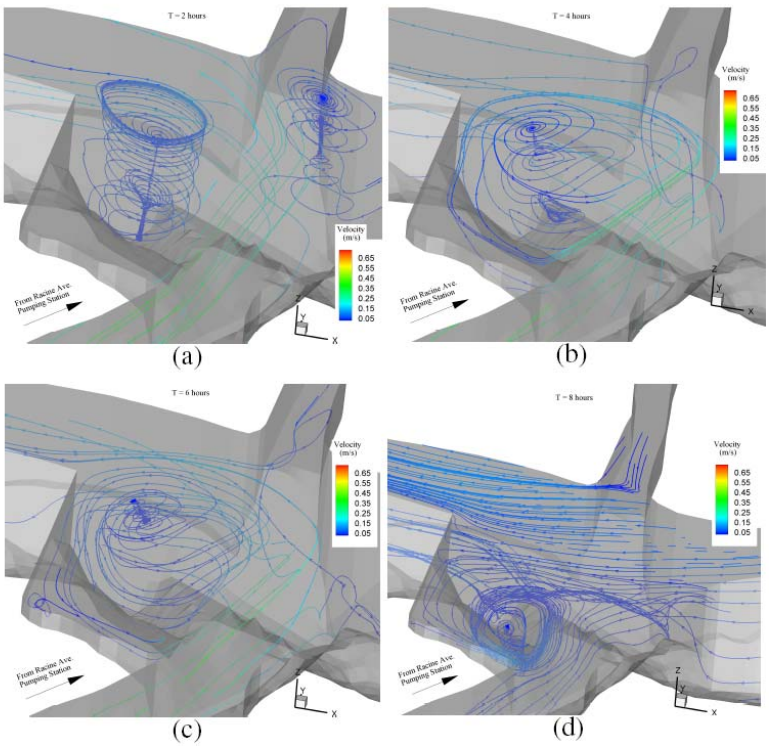

Figure 6. Details of the Flow Feature in the Turning Basin at Different Time: (a) T = 2 Hours (b) T = 4 Hours (c) T = 6 Hours (d) T = 8 Hours

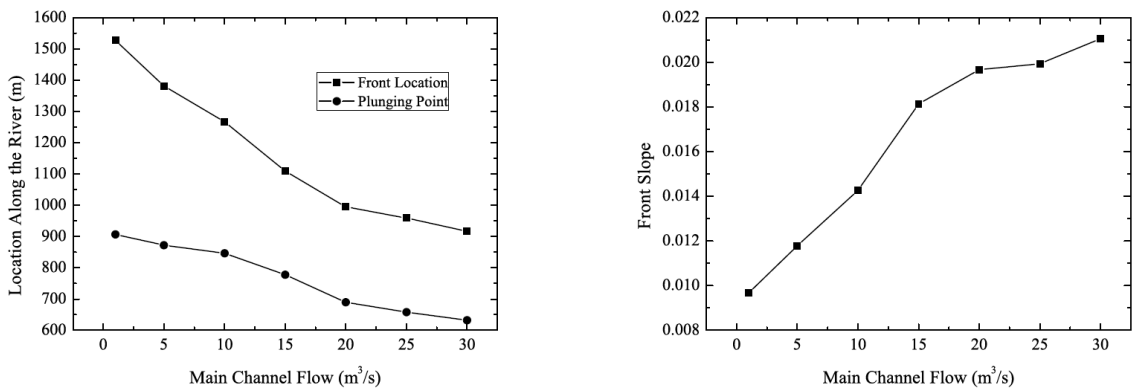

Figure 7. Effects of the Main Channel Flow on the Front Location, Plunging Point, and Front Slope: (a) Front Location and Plunging Point (b) Front Slope.

Effects of the CSO flow

For the effects of the CSO flow, seven cases are simulated (see Table 3). The main channel flow is fixed at 10 m^3/s, which is the average flow in the river according to the USGS measurements. The CSO flow ranges from 20 m^3/s to 120 m^3/s, which corresponds to the cases where only one pump to all six pumps are turned on at the Racine Avenue Pumping Station. The main channel ambient particle concentration is set

to 100 mg/l and the CSO flow particle concentration is set to 1000 mg/l. Case 9 in Table 3 is the same as Case 3 in Table 2.

TABLE 3. Test Cases for the Effects of the CSO Flow

Case #	Main Channel Flow (m^3/s)	CSO Flow (m^3/s)
8	10	20
9	10	35
10	10	50
11	10	75
12	10	90
13	10	105
14	10	120

Figure 8 shows the simulation results for front location, plunging point, and the front slope. The effects of the CSO flow are not as significant as the effects of the main channel flow. With the increase of the CSO flow, the front point and the plunging point quickly increase to their asymptotic values. For CSO flow greater than 50 m^3/s, the front location and the plunging point almost keep constant. This is because the momentum of the CSO flow is restricted in the area of the junction. The upstream intrusion of the pollution is dominated by the buoyancy effect. The slope of the front decreases slightly as the CSO flow increases. However, it reaches an asymptotic value very quickly. The small increase of the slope when the CSO flow is 90 m^3/s may be due to the uneven bottom of the river.

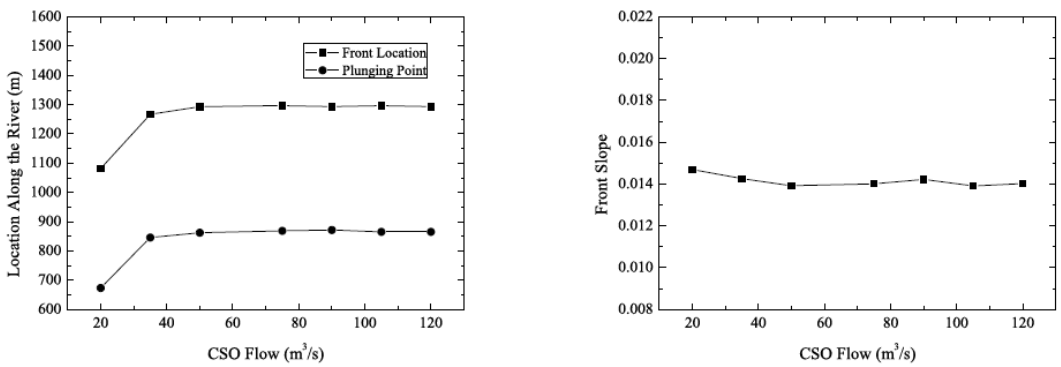

Figure 8. Effects of the CSO Flow on the Front Location, Plunging Point, and Front Slope: (a) Front Location and Plunging Point (b) Front Slope.

Effects of the CSO particle concentration

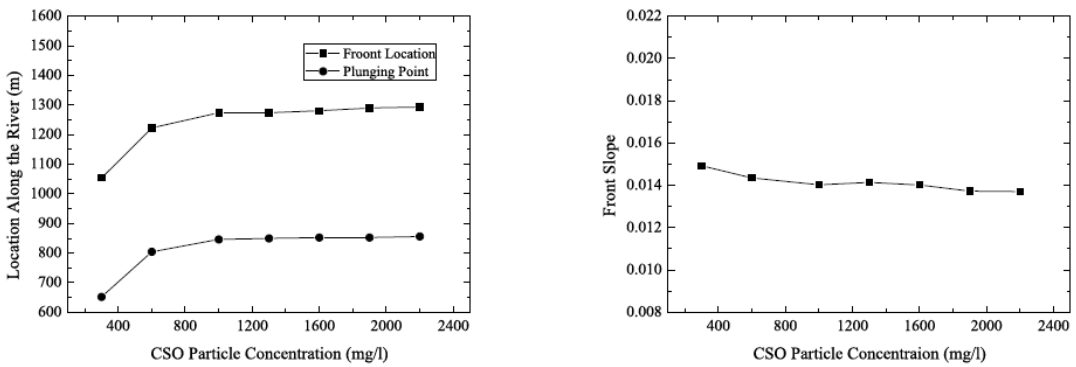
In this section, the effects of the CSO particle concentration are studied. The main channel flow is fixed at 10 m^3/s and the CSO flow is set at 35 m^3/s, which are both typical values for the river. The main channel ambient particle concentration is set as 100 mg/l. The CSO flow particle concentration ranges from 300 mg/l to 2200 mg/l. This

range was defined according to the CSO water sampling at the Bubbly Creek pumping station.

TABLE 4. Test Cases for the Effects of CSO Particle Concentration

Case #	Main Channel Particle Concentration (mg/l)	CSO Particle Concentration (mg/l)
15	100	300
16	100	600
17	100	1000
18	100	1300
19	100	1600
20	100	1900
21	100	2200

With the increase of the CSO particle concentration, the front travels further upstream. But the momentum of the front getting from the CSO event is not as significant as those cases by varying the CSO discharge. For cases from 17 to 21, since there is a small step just upstream the junction, the front is stopped there for all the cases simulated. That is the reason the front location did not change even the CSO particle concentration is increased to a very high value. The only difference between cases 17 to 21 is that the front concentration is higher when the CSO particle concentration is higher. The slope of the front is a function of the CSO particle concentration. With the increase of the CSO particle concentration, the front slope becomes smaller, i.e. the front becomes less steep. Figure 9 shows the quantitative relationship between the front location, plunging point, front slope and the CSO particle concentration.



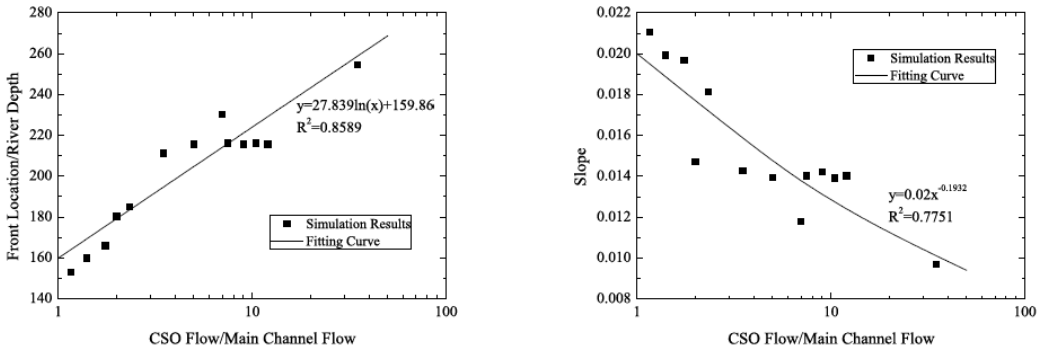


Figure 9. Effects of the CSO Particle Concentration on the Front Location, Plunging Point, and Front Slope: (a) Front Location and Plunging Point (b) Front Slope.

DISCUSSION

From the simulations, the CSO flow and the main channel flow are two competing factors which drive the current when the CSO particle concentration is fixed. Figure 10 shows the dimensionless front location as a function of the relative CSO flow. The dimensionless front location is defined as L_f/H_r, where L_f is the front location and H_r is

the river depth. The relative CSO flow is defined as Q_{cso}/Q_{main}, where Q_{cso} is the CSO flow and Q_{main} is the main channel flow. Regression relations are developed to quantify the dependence of the front location and shape on the relative CSO flow (Figure 10).

(a) (b)

Figure 10. Effects of the Dimensionless CSO Flow on the Front Location and Front Slope: (a) Dimensionless Front Location (b) Front Slope.

CONCLUSION

Using the CSO particles as an indicator for water quality, it was shown that the pollutant discharged into Bubbly Creek travels upstream in the main channel and also intrudes into the slips. Three most important variables, main channel flow, CSO flow, and CSO particle concentration, were investigated. With the increase of the main channel flow, the front location and the plunging point are shifted downstream. This is due to the flushing effect of the main channel flow. Increasing both the CSO flow and the CSO particle concentration moves the front location further upstream. However the effect of increasing the CSO particle concentration is not as significant as that of increasing the CSO flow.

ACKNOWLEDGEMENTS

This research is supported by the Metropolitan Water Reclamation District of Greater Chicago (MWRDGC). The authors gratefully thank Dr. John M. Hamrick for his helpful discussion and suggestions.

ABSTRACT

This paper presents an analytical design method for realignment of small alluvial channels with non-cohesive bed material. This method follows the general approach recommended by the U.S. Army Corps of Engineers and the Natural Resources Conservation Service. The realigned reach is designed to convey the same bankfull discharge and sediment load as a stable reach directly upstream. The length, slope, sinuosity and cross-sectional dimensions of the realigned reach are obtained from an analytical solution to Manning's equation for flow resistance and a simplified version of the Meyer-Peter and Muller equation for bed-load transport. The bankfull width and meander wavelength are obtained from geomorphic relationships for stable natural streams. Consequently, the realigned reach should have stable geomorphic characteristics that are typical of a natural stream in a similar setting.

INTRODUCTION

Highway departments occasionally find it necessary to realign short reaches of small streams in connection with highway improvements or to protect the highway embankment against stream encroachment. Several key goals guide the design of the realigned reach. First, the new reach should have geomorphic characteristics that are typical of a natural stream in a similar setting. These characteristics include the channel's bankfull capacity, cross-sectional dimensions, planform, bottom profile, and bed and bank materials. Second, the realigned reach should be stable, with little change in the bottom profile, planform or cross-sectional dimensions once the channel is established. Third, the realigned reach should eventually provide similar in-stream and riparian habitat as a natural stream in a similar setting. If the stream that must be realigned has been degraded by prior channelization, then a realignment project that meets these objectives will help to restore the natural stream functions.

Analytical methods for natural channel design use hydraulic equations for flow resistance and sediment transport, as well as geomorphic relationships, to determine the channel's cross-sectional dimensions, slope and sinuosity. The objective is a stable configuration with natural geomorphic characteristics that will convey the natural bankfull discharge and the associated sediment load. The Army Corps of Engineers' *Hydraulic Design of Meandering Channels* (Copeland, et al., 2001) and

the Natural Resources Conservation Service's *National Engineering Handbook, Part 654* (NRCS, 2007) present a general framework for the analytical approach to natural channel design.

This paper presents the main elements of a simple analytical design method, termed the Kansas Analytical Method, for small alluvial channels with non-cohesive bed materials. In the Kansas Analytical Method, the realigned channel is designed to convey the same bankfull discharge and sediment load as the nearest stable reach upstream of the design reach. A hydraulic geometry equation relates the bankfull width to the bankfull discharge.

PRELIMINARIES AND FIELDWORK

The design process necessarily starts with the establishment of some boundary conditions and the selection and characterization of the "upstream supply reach." The endpoints of the project reach should be located at riffles wherever possible. The thalweg elevations at the endpoints must be surveyed. The designer must lay out the general alignment of the new reach, exclusive of meanders. The length of this non-meandering alignment is termed the valley length.

A stable reach on the same stream, preferably directly upstream of the project reach, is selected as the upstream supply reach. The selected reach should start and end at riffles and should contain at least one intermediate riffle. The thalweg profile and the channel cross-section at the most representative intermediate riffle are surveyed. The bankfull stage at the representative riffle is identified from field indicators. A bed-material sample from the representative riffle is analyzed to determine the d_{50} particle size (the sieve-opening size through which 50% of the material, by weight, would pass). The Manning resistance coefficient for bankfull flow through the reach is estimated by the best available method, considering the bed and bank roughness and other relevant factors. The bankfull flow condition is approximated as uniform flow, and the bankfull discharge is calculated with the Manning equation using the average bottom slope for the reach and the bankfull cross-section at the representative riffle.

CHANNEL SLOPE AND CROSS-SECTIONAL DIMENSIONS

Three main considerations determine the slope and cross-sectional dimensions of the realigned reach. The new reach should convey the same bankfull discharge and sediment load as the upstream supply reach, and its bankfull width should be typical of natural streams with the same type of bed material and the same bankfull flow. Discharge continuity is achieved by setting the bankfull discharge for the design reach equal to the previously estimated bankfull discharge in the upstream supply reach.

Bankfull flow through the design reach is approximated as uniform flow governed by the Manning resistance equation, which can be stated in terms of the wetted perimeter and hydraulic radius as

$$Q_b = \frac{c}{n_d} P_d R_d^{5/3} \sqrt{S_d} \quad (1)$$

in which Q_b is the bankfull discharge, n_d is the Manning resistance coefficient, P_d is the wetted perimeter, R_d is the hydraulic radius, S_d is the channel slope (the "d" subscripts designate the design reach), and c is a units-related constant (1.49 for U.S. units; 1 for SI units) .

Bed-load transport is modeled with the following simplified form of the Meyer-Peter and Muller (MPM) equation:

$$Q_s = \frac{8P}{\sqrt{\rho}} \left[\gamma R S - 0.047 (\gamma_s - \gamma) d_{50} \right]^{3/2} \quad (2)$$

in which Q_s is the bed-load transport rate (submerged weight per unit time), ρ is the density of water, γ is the specific weight of water, γ_s is the specific weight of the sediment, and d_{50} is the median sediment size by weight. This form of the MPM equation, applicable to channels with plane beds and large width-to-depth ratios, is a satisfactory approximation for design applications. The first term inside the brackets is the average shear stress over the wetted perimeter, and the second term is the critical shear stress required to initiate motion of the d_{50}-size sediment. Therefore, the sediment transport rate varies with the 3/2 power of the excess shear stress (the amount by which the average shear stress exceeds the critical value).

Equating the sediment-transport rates in the upstream supply reach and the design reach yields the sediment-transport continuity equation:

$$P_u \left[R_u S_u - 0.047 (G_s - 1) d_{50} \right]^{3/2} = P_d \left[R_d S_d - 0.047 (G_s - 1) d_{50} \right]^{3/2} \quad (3)$$

in which the "u" subscripts designate the upstream supply reach and G_s is specific weight of the sediment.

A preliminary bankfull width, W_b, for the design reach is obtained from a hydraulic geometry equation. The recommended equation for sand-bed streams in the U.S. is

$$W_b = 2.34 \sqrt{Q_b} \quad (4)$$

and the recommended equation for gravel-bed streams in the U.S. is

$$W_b = 2.03 \sqrt{Q_b} \quad (5)$$

for W_b in feet and Q_b in cfs (NRCS, 2007).

The three unknowns in the discharge and sediment-transport continuity equations are the wetted perimeter, hydraulic radius and slope of the design reach. In the Kansas Analytical Method, the wetted perimeter is assigned a value equal to 110% of the bankfull width obtained from the hydraulic geometry equation:

$$P_d = 1.1\, W_b \tag{6}$$

Solving Eqs. 1 and 3 simultaneously for S_d by eliminating R_d yields the following equation for the slope of the design reach:

$$S_d = \left(\frac{c\, P_d}{Q_b\, n_d} \right)^{\frac{6}{7}} \left\{ \left(\frac{P_u}{P_d} \right)^{\frac{2}{3}} R_u\, S_u + \left[1 - \left(\frac{P_u}{P_d} \right)^{\frac{2}{3}} \right] \left[0.047 \left(G_s - 1 \right) d_{50} \right] \right\}^{\frac{10}{7}} \tag{7}$$

The corresponding length of the design reach, L_d, is computed from the slope and the thalweg elevations at the end-points. The hydraulic radius of the design reach is then obtained from the discharge equation, rearranged as follows:

$$R_d = \left(\frac{Q_b\, n_d}{c\, P_d} \right)^{\frac{3}{5}} S_d^{\,-\frac{3}{10}} \tag{8}$$

The cross-sectional area of the design reach is the product of the wetted perimeter and the hydraulic radius:

$$A_d = P_d\, R_d \tag{9}$$

The design reach would normally have a trapezoidal cross-section for constructability. The area and wetted perimeter of a trapezoidal channel can be expressed in terms of the bottom width, B_d, the depth, y_d, and the side slope, m, as follows:

$$A_d = B_d\, y_d + m\, y_d^{\,2} \tag{10}$$

$$P_d = B_d + 2\sqrt{1 + m^2}\, y_d \tag{11}$$

Solving Eqs. 10 and 11 simultaneously for y_d by eliminating B_d yields the following explicit equation for depth:

$$y_d = \frac{P_d - \sqrt{P_d^2 - 4A_d\left(2\sqrt{1+m^2} - m\right)}}{2\left(2\sqrt{1+m^2} - m\right)} \tag{12}$$

The bottom width is then obtained from either Eq. 10 or Eq. 11. The bottom width, depth, and side slope determine the actual top-width of the design reach, W_d:

$$W_d = B_d + m\,y_d \tag{13}$$

This top width might differ slightly from the preliminary bankfull width used to establish P_d.

The computed channel slope and cross-sectional dimensions must be checked for reasonableness and practicality. The realigned reach should be no steeper than the existing reach (i.e., no loss of stream length). The channel length is also checked by examining the associated sinuosity. Sinuosity is defined as the ratio of the channel length to the valley length (the length of the desired alignment exclusive of meanders). Most natural streams have sinuosities between 1.2 and 2.0. If the preliminary design calculations yield a reach length that is too short or a sinuosity that falls outside the normal range, then the design should be revised. A different bankfull width is selected, a new slope is computed, and the slope and sinuosity are re-checked.

The practicality of the computed channel depth should also be checked by comparing the bankfull level with the level of the natural floodplain at various points along the desired alignment. The bankfull level should not exceed the natural floodplain level, but also should not be far below the natural floodplain level, so that the desired connection between the channel and the natural floodplain is maintained. If the channel depth lies outside the desired range, then a different bankfull width is selected and the analytical design calculations and the design checks are repeated.

PLANFORM

The meanders of a natural stream, although irregular and varied, can be characterized by dimensions such as the average meander wavelength and the average radius of curvature of meander bends. In channel realignment design, the objective is a planform with the desired sinuosity and meander characteristics that are typical of a natural stream.

A stream's meander wavelength, λ, tends to be proportional to its bankfull width. Soar and Thorne (2001) examined the ratio of meander wavelength to bankfull width for 438 sites from nine independent datasets, and found that this ratio has a mean value of approximately 12. Therefore, in the Kansas Analytical Method, the meander wavelength is initially set to 12 times the bankfull width:

$$\lambda = 12\ W_d \tag{14}$$

Typical meander patterns of natural streams are often idealized by mathematical functions such as Leopold's "sine-generated curve" (NRCS, 2007). The sine-generated curve has some theoretical justification, but it is difficult to apply in practice. Numerical integration is required to calculate the coordinates of points along the curve. Sine-generated meander bends are complicated to describe on a plan sheet and difficult to lay out and construct in the field.

The form of the sine-generated curve can be approximated satisfactorily by a series of circular arcs and straight lines, which are easier to describe, lay out, and construct. Figure 1 shows the relevant variables for this meander geometry, in which

ω = angle at which stream intersects longitudinal axis of symmetry
L_s = length of each line segment
L_c = length of each circular arc
R_c = radius of curvature of each circular arc

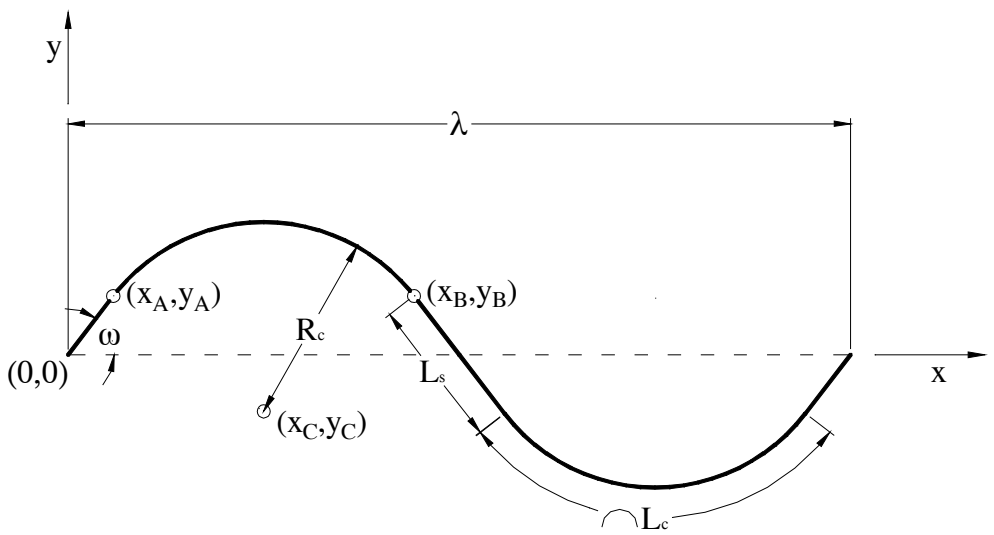

Figure 1. Representation of meander geometry by circular arcs and line segments

The sinuosity, p, is related to the characteristic angle, ω, and the ratio $L_s/(L_s+L_c)$, the fraction of the channel length composed of line segments. Setting the ratio $L_s/(L_s+L_c)$ equal to 0.3 yields meanders that closely resemble sine-generated meanders. With $L_s/(L_s+L_c)$ set to 0.3, the sinuosity and the characteristic angle in radians are related as follows:

$$p = \frac{1}{0.3\cos\omega + 0.7\frac{\sin\omega}{\omega}} \tag{15}$$

In the meander design problem, the desired sinuosity is known and the characteristic angle must be calculated. Eq. 4-26 cannot be solved closed-form for ω. However, over the range $1 \le p \le 3$, Eq. 4-26 is fitted very well by the following explicit equation for ω in radians:

$$\omega = -0.0032 + 1.9947\,z - 0.2438\,z^2 + 0.5457\,z^3 \tag{16}$$

in which

$$z = \sqrt{\frac{p-1}{p}} \tag{17}$$

The lengths L_s and L_c, the radius of curvature R_c, and the coordinates of points A, B and C are given by the formulas:

$$L_s = 0.15\,\lambda\,p \tag{18}$$

$$L_c = 0.35\,\lambda\,p \tag{19}$$

$$R_c = \frac{L_c}{2\omega} \tag{20}$$

$$x_A = \frac{L_s}{2}\cos\omega \tag{21}$$

$$x_B = \frac{\lambda}{2} - \frac{L_s}{2}\cos\omega \tag{22}$$

$$y_A = y_B = \frac{L_s}{2}\sin\omega \tag{23}$$

$$x_c = \frac{\lambda}{4} \tag{24}$$

$$y_c = \frac{L_s}{2}\sin\omega - R_c\cos\omega \tag{25}$$

These relationships provide a starting point for laying out a planform for the realigned reach. The meander characteristics can be varied and adjusted to fit the project constraints, provided that the realigned reach has the desired length and slope.

BOTTOM PROFILE

The bottom profiles of most alluvial streams exhibit a somewhat regular sequence of riffles and pools. The riffles tend to occur near the inflection points of meander bends, and the pools tend to be deepest about two-thirds of the way through the meander bends. The pools retain water and provide valuable aquatic habitat during periods of little or no flow.

If the design for the realigned reach incorporates riffles and pools, the cross-sectional dimensions computed with the analytical relationships should be applied at the riffles. The bankfull depth at the deepest point in the pools should be approximately 150% of the bankfull depth at the riffles. Riffles should be located at the inflection points, or at the midpoints of the line segments connecting the circular arcs. The deepest point in a pool should be located downstream of the bend apex approximately one-third of the distance from the bend apex to the downstream riffle. The bankfull depth can be varied linearly between the upstream riffle and the deepest point, and between the deepest point and the downstream riffle, which results in a saw-tooth bottom profile.

CONCLUSIONS

The analytical design method presented in this paper is appropriate for realignment of small alluvial channels with non-cohesive bed material. This method follows the general approach recommended by the USACE and the NRCS. The realigned reach is designed to convey the same bankfull discharge and sediment load as a stable reach directly upstream. The bankfull width and meander wavelength are obtained from geomorphic relationships for stable natural streams. Consequently, the realigned reach should have stable geomorphic characteristics that are typical of a natural stream in a similar setting.

Abstract

In this study we present an equation that predicts bankfull discharge for Kansas streams based on watershed characteristics. This equation can be used for natural channel design projects such as stream realignments and restorations. To develop this equation, we first determined that the recurrence intervals of bankfull flow on 46 natural streams in Kansas range between <1.0 and 1.7 years. The median and mean recurrence interval are both 1.2 years. We then derived a multivariate regression equation for the 1.2-year discharge from a database of 72 small rural streams in Kansas, using ten different watershed characteristics as possible predictors. The regression analysis led to an equation that predicts the 1.2-year discharge as a function of the drainage area, the mean annual precipitation, and the length of the longest flow path. This equation can be used for natural channel design in Kansas.

Introduction

Engineers design river modification projects for a number of reasons, including flood protection, highway safety and capacity improvements, drinking water supply, navigation, hydropower, and recreation. In the past, river designers sought to maximize these human benefits while minimizing costs. Today, engineers also see the importance of maximizing environmental benefits such as habitat enhancement, bed and bank stability, decreased sediment transport rates, and water quality. Often, the best way to maximize these environmental benefits is for the designed channel to simulate the form and function of a self-formed channel. A stream design that simulates important features of self-formed streams is termed a natural channel design.

One of the most important aspects of a natural channel design is the design discharge. This discharge should be similar to the capacity that a stable, self-formed stream in the same location would have. The capacity of a self-formed channel that is well connected to its floodplain is termed the bankfull flow (FISRWG, 2001). Equations that predict the bankfull flow in self-formed streams can be used to determine the design discharge for a natural channel design. Equations for bankfull flow must be based on region-specific data because of the high variability in the driving hydrologic and geomorphic factors.

In this paper we present a multivariate regression analysis for bankfull flow in Kansas streams, based on local hydrologic records and geomorphic surveys. We derived this equation during the development of the Kansas Analytical Method, a natural channel design method for small rural streams in Kansas. In the sections that follow, we first describe the datasets used in the analysis. Then, we present the results of a recurrence interval analysis of bankfull flow in Kansas streams. Next, we discuss the development of the regression equation. Finally, we discuss the uses and limitations of the equation.

Datasets

The equation developed for this study is based on two datasets. Both datasets consist of stream and watershed data for rural basins in Kansas. The first dataset contains bankfull stage, bankfull discharge, and other geomorphic data for 46 stable, gaged streams. We selected these 46 streams from a larger geomorphic dataset that was developed with funding from the Kansas Water Office and US Environmental Protection Agency (Emmert and Hase, 2001). We selected the 46 streams by removing streams for which: (1) The surveyors could not identify the bankfull stage with certainty, (2) The stream was degraded, (3) The survey was incomplete or of poor quality, (4) The stream bottom was predominantly bedrock, or (5) The streamflow record was too short to determine a return period.

The majority of the streams in this dataset are far larger than streams that are typically candidates for realignment or restoration. Only four of the streams in this first dataset have drainage areas less than 30 square miles, whereas 34 of the 46 streams have drainage areas of over 500 square miles. We used this dataset to determine the average recurrence interval (annual maximum series) of bankfull flow in Kansas rivers and streams, but we needed additional stream data to produce a design equation.

The second dataset used in this study contains extensive hydrologic and watershed data for 72 gaged Kansas streams with drainage areas under 30 square miles. This dataset has been used in previous research to derive flood frequency estimates for Kansas rural, ungaged streams (McEnroe, et al., 2007). These streams are similar in size to streams that might be considered for realignment and restoration. However, geomorphic surveys were not available for these locations. We used this dataset in the regression analysis to create a design equation for discharge capacity.

Recurrence Interval of Bankfull Flow

Figure 1 displays the distribution of the recurrence intervals (annual maximum series) for bankfull flow for streams in the first dataset. These recurrence intervals ranged from < 1.01 years to 1.7 years, with both a median and a mean recurrence interval of 1.2 years. This range of recurrence intervals is consistent with numerous studies in other regions, including the pioneering work of Wolman and Leopold (1957). The recurrence interval of bankfull flow appears to be independent of geographic location and of channel material, as shown in Figure 2. In addition, the recurrence interval of bankfull flow is independent of drainage area (see Figure 3). We conclude that the

1.2-year discharge is an appropriate approximation for bankfull flow for design purposes in Kansas.

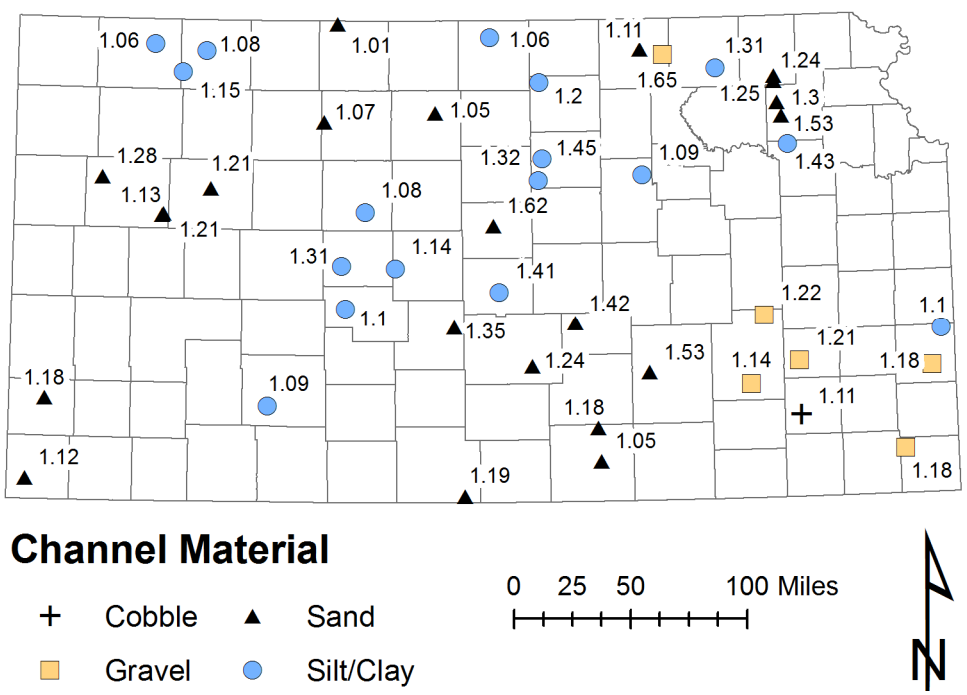

Figure 2. Recurrence Intervals for Bankfull Flow in Kansas Streams, Sorted by Channel-Bed Material

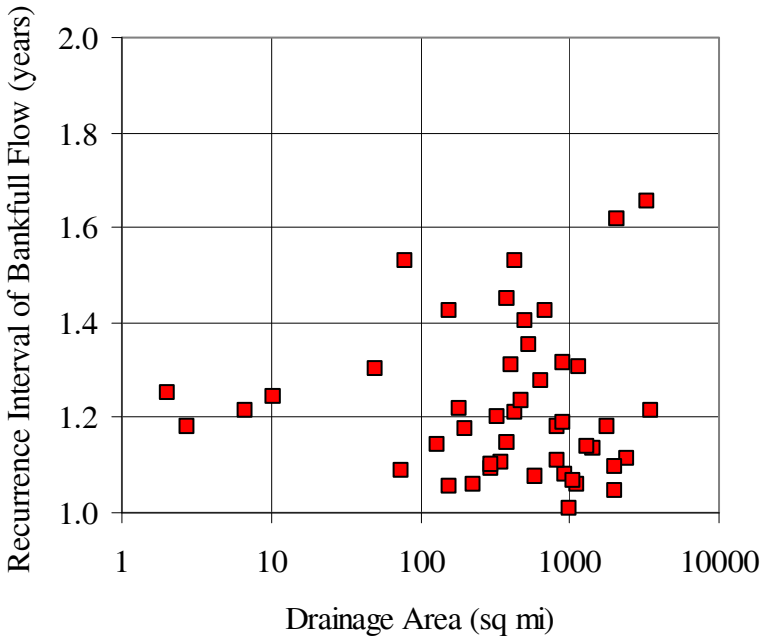

Figure 3. Independence of Recurrence Interval from Drainage Area

Regression Analysis

We used forward stepwise linear regression to develop a predictive equation for the 1.2-year discharge for small Kansas streams, following the methodology used by McEnroe, et al. (2007). We removed five stations from the dataset because they had $Q_{1.2}$ values equal to zero. Table 1 lists the five stations excluded from the regression analysis. Four of these stations are located in western Kansas, where zero-flow years are not uncommon. The fifth station excluded from the analysis is a small watershed (1.62 mi^2) located in Washington County, Kansas.

Table 1. Stations with $Q_{1.2}$ Equal to Zero

Site #	Station name	County	CDA (mi^2)	MAP (in)
6884100	Mulberry Creek tributary near Haddam	Washington	1.62	30.1
6846200	Beaver Creek tributary near Ludell	Rawlins	10.55	20.5
6873300	Ash Creek tributary near Stockton	Rooks	0.88	23.0
7141600	Long Branch Creek near Ness City	Ness	29.58	21.4
7141800	Otter Creek near Rush Center	Rush	17.20	22.9

Table 2 lists the predictors that were considered in the regression analysis. The 2-year rainfall intensity (for duration equal to the watershed time of concentration) was used in lieu of the 1.2-year rainfall, as tables of 1.2-year rainfall intensities are not available in Kansas. Details on the determination of these watershed characteristics can be found in McEnroe et al. (2007).

Table 2. Watershed Characteristics used in the Regression for $Q_{1.2}$

Symbol	Watershed Characteristic	Units
CDA	Contributing Drainage Area	mi^2
Sh	Basin Shape Factor	--
Sl	Average Slope of Main Channel	ft/mi
SP	Generalized Soil Permeability	in/hr
CN	NRCS Runoff Curve Number	--
i_2	2-year Rainfall Intensity for Duration t_c	in/hr
MAP	Mean Annual Precipitation	in
MAE	Mean Annual Lake Evaporation	in
MAD	Mean Annual Precipitation Deficit	in
L	Length of the Longest Flow Path	mi

The regression analysis led to the following equation for $Q_{1.2}$:

$$Q_{1.2} = 0.00258\,CDA^{1.26}\,MAP^{3.17}\,L^{-1.10} \qquad (1)$$

where $Q_{1.2}$ is in cfs. The mean annual precipitation, MAP, is determined from Figure 3. The longest flow path, L, is measured along the channel from the watershed outlet to the drainage divide. Eq. 1 has a standard error of estimate of 0.217 log units (-39%, + 65%) and a coefficient of determination, R^2, of 0.827. This standard error and coefficient of determination are similar to previously published equations for 2, 5, 10, 20, 50, and 100-year discharges (McEnroe et al., 2007).

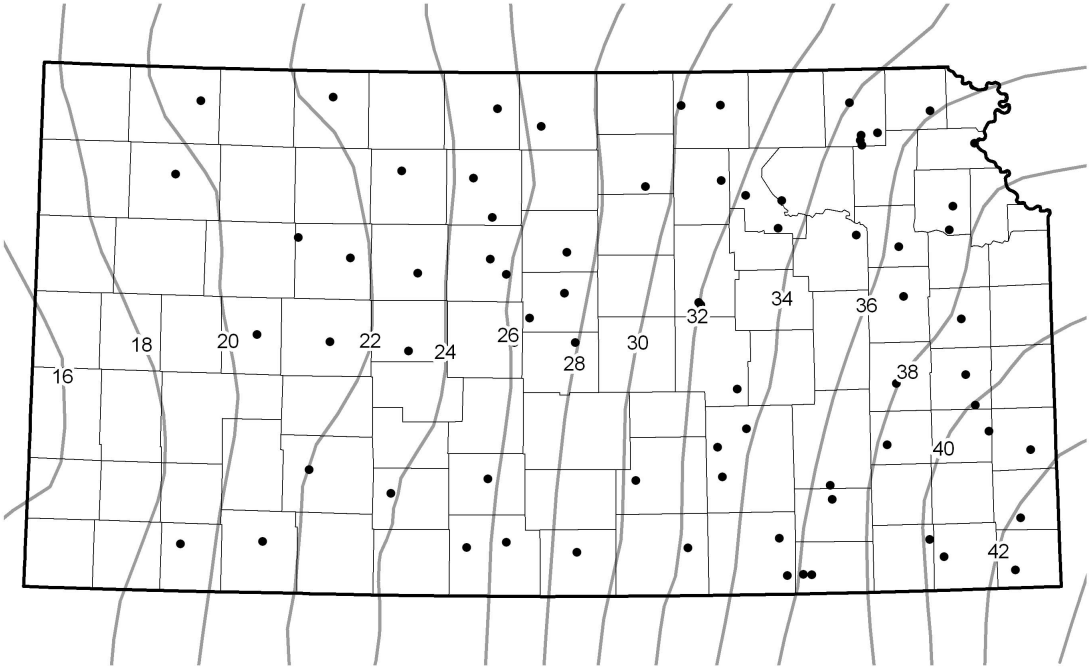

Figure 3. Mean Annual Precipitation (inches) in Kansas along with Gages used in Regression Analysis

Equation Uses and Limitations

The bankfull discharge for small rural streams in Kansas can be approximated by the 1.2-year discharge, estimated from Eq. 1. This equation can be used to determine the discharge capacity in a natural channel design, such as a stream realignment or restoration. However, the following limitations should be kept in mind: First, the use of local data to derive Eq. 1 makes it applicable to Kansas streams only. Second, Eq. 1 only applies to non-degraded channels with a mobile bed. Third, this equation may not be applicable in stream systems that regularly experience zero-flow years, as is the case for many streams in western Kansas. Finally, Eq. 1 should not be applied to urban stream design, because urban streams were not included in the recurrence interval analysis or the regression analysis. Future research that derives a bankfull flow equation using urban watershed parameters, such as percent impervious, is warranted.

ABSTRACT

Past studies have demonstrated the relation between channel-perimeter sediment type (i.e., the weighted mean percent silt-clay in the channel and banks, M) and channel shape (i.e., the width-depth ratio). Moreover, M was found to be an indicator of the predominant sediment transport mode. Motivated by the reasoning and results of this earlier work we propose a classification scheme for single thread rivers that relies on the median bed material grain size (D_{50}) to classify streams as predominantly transporting either a fine suspended load (D_{50} <= 0.062 mm), coarse suspended load (0.062 mm < D_{50} <= 0.50 mm), mixed load (0.50 mm < D_{50} <= 25.0 mm), or bedload (D_{50} > 25.0 mm). For classifying channels, we use Shields curve to define conditions of incipient sediment motion and the criterion $u_* = w_s$ (u_* = shear velocity and w_s = sediment fall velocity) to define the onset of significant suspended load transport. This work is warranted because in most studies of rivers and canals the D_{50}, rather than M, is the only measure recorded for describing channel-perimeter sediment type. Distinctive relationships between B_{bf} and Q_{bf}, and H_{bf} and Q_{bf} are noted for each of the stream classes we propose, that is, trendlines for these variable differ systematically between stream classes. In contrast, width-to-depth ratios for the stream classes are not distinctive; the width-to-depth ratios range from 3 to 100 across all stream types and values as large as 1,000 are common for coarse suspended-load streams.

INTRODUCTION

Classification schemes are generally proposed with the intention of imposing some sort of rational order on the wide variety of channels formed by fluids flowing in erodible channels (Knighton, 1998) and a variety of criteria have been proposed for classifying channels (e.g., Davis 1899; Harvey 1969; Rosgen 1996, Schumm 1960, 1963; and others). Herein we present a basis for classifying stable, single-thread alluvial rivers with a median bed-material size, D_{50}, between 0.062 mm and 25 mm. Rivers meeting this criteria are both common in the natural environment and studied extensively.

The analyses which are presented herein are in part motivated by earlier work reported by Schumm (1960, 1963). That work, therefore, is briefly reviewed. Schumm (1960) showed that the weighted mean percent silt-clay in the channel and banks (M) could be used as a sediment parameter for predicting channel shape expressed as a width-to-depth ratio (F or B/H). Specifically, stream shape was shown to vary according to:

$$F = \frac{B}{H} = 255M^{-1.08} \tag{1}$$

Figure 1 shows a plot of this relationship and the data used to derive it. Neither the percentage of silt and clay in the banks nor in the channel alone showed a correlation with the width-to-depth ratio. Also, neither mean annual discharge nor the mean annual flow significantly affects this relationship in spite of the importance of discharge to the absolute width and depth of a channel. Equation (1) indicates the importance of channel-perimeter sediment type to channel shape.

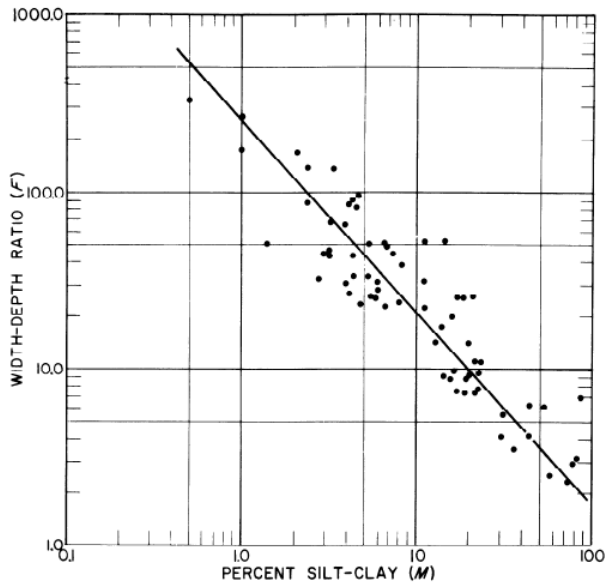

Figure 1 – Relation between width-to-depth ratio and weighted mean percent silt-clay at different cross sections. The regression line was determined graphically. Standard error is 0.202 log units and correlation coefficient is 0.81. (Source: Schumm 1960).

Schumm (1963) proposed tentative classification criteria for alluvial channels that are similar to the criteria described herein. The criteria are similar because in both cases the delineative criteria are based on channel perimeter sediment and the proposed channel classes are differentiated by their predominant sediment transport mode. In his analyses Schumm used M as a sediment parameter. Also, three channel types were identified: bed-load ($M < 8$), mixed-load ($8 \leq M \leq 30$), and suspended-load ($M > 30$). As used by Schumm, the term suspended load is synonymous with wash-load and is

generally comprised of sand and clay particles. The term bed-load is synonymous with bed-sediment load and is generally comprised of sand and coarser sediment. Schumm also provided a range of width-to-depth ratio's for stable channels of each type. For bedload, mixed load, and suspended load channels, the respective ranges were >25, between 7 and 25, and less than 7.

Schumm (1968) provides additional data that supports the tentative alluvial river classification proposed by Schumm (1963). As a result of the additional data, the limits for the three classes of channels were revised as follows: bed-load ($M < 5$; $F > 40$), mixed-load ($5 \leq M \leq 20$; $10 \leq F \leq 40$), and suspended-load ($M > 20$; $F < 10$). Also noted by Schumm (1968) were the following limitations to the proposed classification:

(1) application must be restricted to alluvial rivers which contain less than about 20 percent gravel in their channel and which are not influenced by bedrock outcrops in their channels, and

(2) compared to river channels in sub-humid, semiarid, and arid regions, major perennial streams of humid regions seem to show much less variability and may be more difficult to relate to the proposed classification.

The results presented by Schumm (1960, 1963, 1968) indicate that channel-perimeter sediment composition significantly influences channel shape and the mode by which sediment load is transported in a channel. Schumm (2003) further outlines the basis for the classification system outlined above by noting that discharge is an independent variable that largely determines the size of stream channels and the amplitude of wavelength of meanders but is not a valid basis for stream channel classification. The other independent variable noted by Schumm (2003) is sediment load. Schumm proposes that either the type of material transported or the predominant mode of sediment transport should be used as the basis for classification rather than the median grain size of the bed material. The given reason being that great changes in the morphology of a stream can occur when the median grain size of bed material is essentially constant. Ultimately, Schumm's tentative classification scheme is founded on data from a restricted range of sand-bed streams, which may limit its overall applicability, and rests on the assumption the M adequately reflects transport mode (Knighton, 1998; Schumm 2003).

Schumm (1960, 1963, 1968, 2003) uses M to characterize channel-perimeter sediment type, the predominant mode of sediment transport, and ultimately to classify channels. In contrast, Rosgen (1996) uses D_{50} to represent channel material in his stream classification scheme (where bimodal particle distributions are observed the particle size observed most frequently is take as the dominant particle size). In addition to D_{50}, Rosgen's classification scheme uses an entrenchment ratio (width of flood prone area at an elevation twice the maximum bankfull depth/bankfull width), and the width-to-depth (ratio of bankfull width/mean bankfull depth), water surface slope, and sinuosity as principle measures for "Level II" classification of channels. Rosgen recommends Level II classification as for addressing questions pertaining to

sediment supply, stream sensitivity to disturbance, potential for natural recovery, channel response to changes in flow regime, and fish habitat potential.

Herein we discern classes of single thread alluvial channels using the particle size Reynold's number, the Shields number at bankfull discharge, and criteria for specifying the onset of (1) bed sediment motion and (2) significant bed sediment suspension. We compare the findings of this study with those reported by Schumm (1960, 1963, 1968, 2003) and attempt to identify similarities and reconcile differences in the findings.

METHODS/DATA

An extensive review of published literature in which bankfull discharge and bankfull channel morphology data were reported was conducted by the writers. It is concluded from that effort that in the overwhelming majority of cases where bankfull data are reported, the D_{50} is the only reported information regarding channel perimeter sediment. The only notable exception to this observation pertains to stream reaches identified as having riffle-pool geometry. Reaches of channel with riffle-pool geometry characteristically have heterogeneous bed material; for such reaches separate D_{50} values for pools and riffles were commonly reported. None of the stream reaches represented in this study is known to contain pool-rifle sequences. Given that D_{50} is the only generally available information about channel sediment, we are motivated to identify a means for using D_{50} to characterize channels. Given the results reported by Schumm (1960, 1963, 1968), we have reason to expect that a channel's dominant sediment transport mode can be predicted from a characteristic channel perimeter particle size such as the D_{50}.

We obtained stream reach data (data points) for this study from numerous published sources and then assigned each data point to one of four stream classes: fine suspended load ($D_{50} \leq 0.062$ mm), coarse suspended load ($0.062 \text{ mm} < D_{50} \leq 0.50$ mm), mixed load ($0.50 \text{ mm} < D_{50} \leq 25.0$ mm), bedload ($D_{50} > 25.0$ mm). The number of points obtained for each stream class is summarized in Table 1. As will be discussed later, the stream classes indicate the predominant sediment transport mode during bankfull discharge. Parameters for the coarse suspended-load stream data span the following ranges: $12.0 \text{ cfs} \leq Q_{bf} \leq 21{,}600$ cfs, $9.75 \text{ m} \leq B_{bf} \leq 9{,}450$ m, $0.57 \text{ m} \leq H_{bf} \leq 48.0$ m, $8.75E\text{-}6 \leq S \leq 6.40E\text{-}3$, $0.094 \text{ mm} \leq D_{50} \leq 0.50$ mm.

Table 1. Number of streams sites in each stream class.

Stream Class	No of Points
Fine suspended-load ($D_{50} \leq 0.062$ mm)	7
Coarse suspended-load ($0.062 \text{ mm} < D_{50} \leq 0.50$ mm)	60
Mixed-load ($0.50 \text{ mm} < D_{50} \leq 25.0$ mm)	86
Bedload ($D_{50} > 25.0$ mm)	72

In selecting streams for this study, we have attempted to choose only stable single-thread alluvial streams that could be considered stable. In addition, streams were included only if the reported value of Q_{bf} was measured. Excluded were streams for which Q_{bf} was presumed equal to $Q_{1.5}$, Q_2, or $Q_{2.33}$ (i.e., discharges having return periods of 1.5, 2, and 2.33 years, respectively); assumed equal to the mean annual flood; or derived from the Manning-Strickler equation or some other flow resistance equation.

Basis for Stream Channel Classification

Presented in the following paragraphs is the basis for the stream classification we propose. We note that the approach was originally developed and presented by Parker (2004).

Bed sediment motion occurs when flow conditions are such that the bankfull Shield's parameter (τ^*_{bf}) exceeds the critical value of the Shield's parameter (τ^*_c). Shields parameter is given by:

$$\tau^*_{bf} = \frac{\tau_{bf}}{\rho R g D_{50}} = \frac{H_{bf} S}{R D_{50}} \tag{2}$$

where

$$\tau_{bf} = \rho g H_{bf} S \tag{3}$$

is the bed shear stress corresponding to bankfull discharge, ρ = fluid density, g = gravitational constant, H_{bf} = bankfull depth, S = bed slope, and R = submerged specific gravity for sediment. The submerged specific gravity is given by:

$$R = \frac{\rho_s}{\rho} - 1 \tag{4}$$

where ρ_s = sediment density. For natural quartz sediments, R is usually close to 1.65 and therefore we assume this value, with one exception, for the streams represented herein. The exception is for the 23 bedload streams reported in Parker et al. (2007) and originally described by Charlton et al. (1978). Charlton et al. reported measured values of R ranging from 1.49 to 1.76.

For estimating values of τ^*_c we use Parker (2003):

$$\tau^*_c = \frac{1}{2}\left[0.22\ Re_p^{-0.6} + 0.06 \cdot 10^{\left(-7.7\, Re_p^{-0.6}\right)}\right] \tag{5}$$

where Re_p is the Reynold's particle number and is given by:

$$Re_p = \sqrt{R g D_{50}}\, D_{50} / \nu \tag{6}$$

and ν = kinematic viscosity of water.

Significant suspended sediment motion occurs when the bed shear velocity at bankfull discharge ($u_{*,bf}$) exceeds the bed sediment fall velocity (w_s), that is, when $u_{*,bf} / w_s > 1.0$, where:

$$u_{*,bf} = \sqrt{\frac{\tau_{bf}}{\rho}} = \sqrt{\rho g H_{bf} S} \tag{7}$$

For discussing w_s, we use the dimensionless parameter W_*, given by:

$$W_* = \frac{w_s^3}{Rg\nu} \tag{8}$$

Dietrich (1982) developed the following relation for estimating values for W_*:

$$\begin{aligned} \log W_* = &-3.76715 + 1.92944(\log D_*) - 0.09815(\log D_*)^{2.0} \\ &- 0.00575(\log D_*)^{3.0} + 0.00056(\log D_*)^{4.0} \end{aligned} \tag{9}$$

in which D_* is a dimensionless particle size defined by:

$$D_* = \frac{RgD_n^3}{\nu^2} = Re_p^2 \tag{10}$$

In applying (10) we replace D_n with D_{50}. Equation (9) is valid for $0.05 \le D_* \le 5E9$ which corresponds to $0.20 \le Re_p \le 7.0E4$. Given (7) to (10), the ratio $u_{*,bf} / w_s$ can be expressed as follows:

$$\frac{u_{*,bf}}{w_s} = \frac{\sqrt{\tau_{bf} / \rho} \Big/ \sqrt{RgD_{50}}}{w_s \Big/ \sqrt{RgD_{50}}} = \frac{\sqrt{\tau_{bf}^*}}{\left(W_* / Re_p\right)^{1/3}} \tag{11}$$

When $u_{*,bf} / w_s$ = 1.0, the corresponding value of Shield's parameter is the critical shear stress for the onset of significant suspended sediment transport, $\tau_{c,sus}^*$, that is:

$$\tau_{c,sus}^* = \frac{W_*^{2/3}}{D_*^{1/3}} \tag{12}$$

Equations (5) and (12) can be used, respectfully, to plot curves representing the onset of significant bed and suspended sediment motion as a function of D_* or D_{50} as shown in Figure 2. Also plotted in Figure 2 are data for the streams represented in Table 1.

Figure 2 illustrates is that streams having $D_{50} \leq 0.50$ mm tend to plot above Dietrich's curve and therefore significant suspended sediment motion is expected in such streams. Streams for which 0.50 mm $\leq D_{50} \leq$ 25.0 mm plot in the region between Dietrich's and Shield's curve, and therefore sediment transport in suspension and as bedload is expected in these streams. Streams where $D_{50} >$ 25.0 mm plot in a narrow region near Shield's curve and therefore sediment transport as bedload sediment is expected. Respectfully, we designate these streams as being suspended-load, mixed-load, and bedload streams to reflect their prevailing sediment transport mode. Further, we sub-classify suspended-load streams as being fine ($D_{50} \leq 0.062$ mm) or coarse (0.062 mm $< D_{50} \leq$ 0.50 mm) since cohesive forces are generally significant for particles smaller than about 0.062 mm.

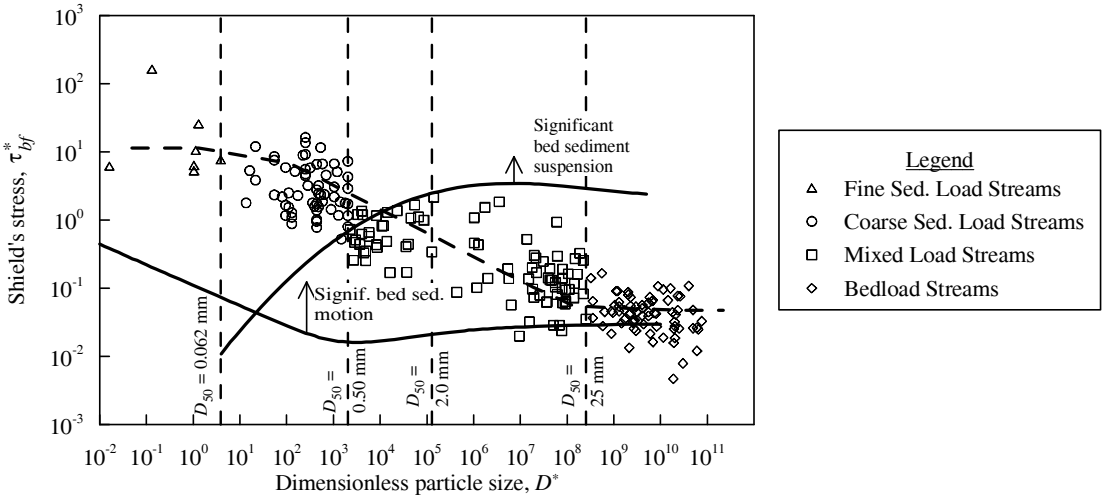

Figure 2. Shields regime diagram with (1) Shields curve (as modified by Parker et al. 2003) indicating the onset of bed sediment motion, (2) Dietrich's (1982) relation for particle settling velocities to indicate the onset of significant suspension of bed sediment.

RESULTS AND CONCLUSIONS

A physical basis for stream classification is developed using Shields curve to define conditions of incipient sediment motion and the criterion $u_* = w_s$ (u_* = shear velocity and w_s = sediment fall velocity) to define the onset of significant bed sediment suspension. Considering bankfull discharge, Figure 2 indicates that the predominant sediment transport mode in a channel can be predicted from D_{50}. We propose the use of D_{50} for classifying channels rather than M (the weighted mean percent silt-clay in the channel and banks), as proposed by Schumm (1960, 1963, 1968) because for most studies of rivers and canals the D_{50}, is the only channel-perimeter sediment parameter recorded.

Also, based on Figure 2, we classify streams as predominately transporting sediment as either fine suspended-load ($D_{50} \leq 0.062$ mm), coarse suspended-load (0.062 mm < $D_{50} \leq 0.50$ mm), mixed load (0.50 mm < $D_{50} \leq 25.0$ mm), or bedload ($D_{50} > 25.0$ mm). It is commonplace for channels with 0.062 mm $\leq D_{50} \leq 2.0$ mm to be classified as sand bed-rivers. Noting that the particle size that separates coarse suspended-load and mixed-load streams is 0.50 mm, we recommend reconsidering the practice of using 2.0 mm as the particle size separating sand and gravel.

Based on the reasoning and results presented by Schumm (1960, 1963, 1968) we expect the shape of single thread alluvial channels is significantly influenced by the predominant sediment transport mode in a stream channel. To demonstrate, width-to-depth ratios (F) are plotted against D_{50} values in Figure 3 but there are no noticeable trends. As noted earlier, Schumm (1960, 1963) made the same observation so this result is not a completely surprising.

What is noteworthy in Figure 3 is the wide range of F values. Earlier we mentioned that Schumm (1968) identified three stream classes and provided corresponding M and F value ranges. Since M is not known for the channels in this study they cannot be grouped into the stream classes identified by Schumm to directly compare F value ranges. However, the F values in Figure 3 range from 3 to 100 across all stream types and F values as large as 1,000 are common for coarse suspended-load streams. We believe, therefore that the narrow range of F values observed by Schumm (i.e., from 0.5 to about 100; Figure 1) is not truly representative of sand bed alluvial channels in the natural environment.

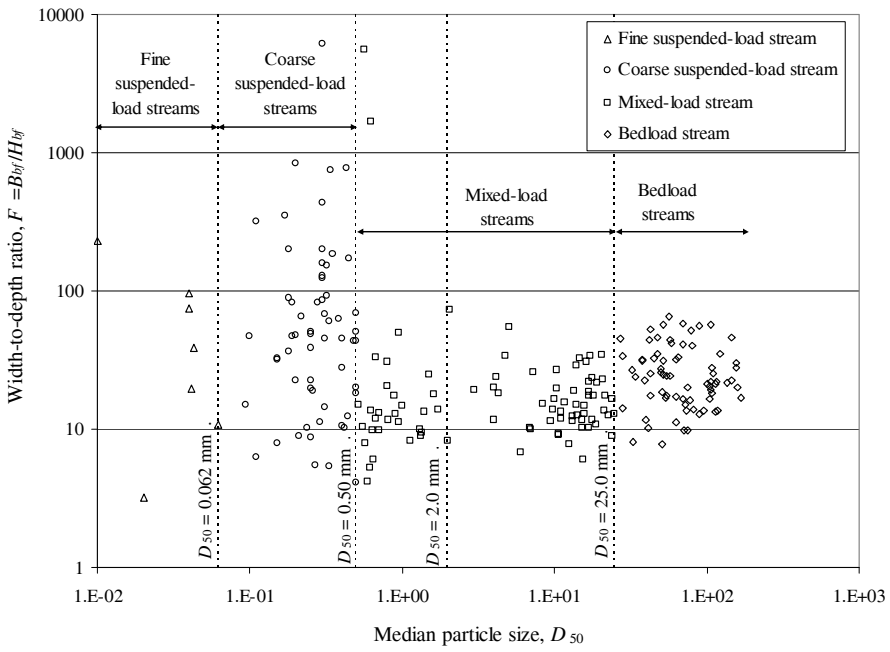

Figure 3. Width-to-depth ratio's for streams included in study.

Evidence that the proposed stream classes have distinct shapes is still needed and thus we plotted B_{bf} and H_{bf} against Q_{bf} in Figure 4. In Figures 4a and 4b different symbols are shown and separate trend lines are plotted for each stream class. To facilitate discussing the trend lines they are plotted alone in Figures 4c and 4d. Figure 4c shows trendlines for the relationship between B_{bf} and Q_{bf}. Ordering the stream classes by the D_{50} sizes represented, that is, from fine suspended-load to the bedload rivers, we find that as the stream class (or D_{50}) increases, the trendline slopes decrease. Trendlines for the relationship between H_{bf} and Q_{bf} are shown in Figure 4d. Again ordering the stream types by D_{50}, what Figure 4d shows is that as D_{50} increases, the trendline slopes increase.

In spite of not finding distinctive width-to-depth ratios for the proposed stream classes, Figure 4 indicates that for each stream class there are distinctive relationships between B_{bf} and Q_{bf}, and H_{bf} and Q_{bf} for the four stream classes we propose. Ultimately this result supports the notion that the shape of single thread alluvial channels is significantly influenced by the predominant mode by which sediment is transport in the channel. Nonetheless, additional work is needed to improve understanding of the interrelationship between sediment transport, channel perimeter sediment, and channel shape.

USING WATERSHED SCALE GEOMORPHIC ASSESSMENT TO IMPROVE URBAN STREAM RESTORATION DESIGN

Sue L. Niezgoda, Ph.D., P.E., Affiliate Member, ASCE[1]

[1]Assistant Professor, Department of Civil Engineering, Rose-Hulman Institute of Technology, 5500 Wabash Avenue, Terre Haute, IN 47803, PH (812)877-8814; FAX (812)877-8440; email: niezgoda@rose-hulman.edu

Abstract

The initial phases of a stream restoration project typically include a watershed geomorphic assessment to classify, identify, and assess a variety of environmental problems that can occur over a fairly large geographic area. There are three phases of geomorphic assessment at the watershed-scale, including the desktop phase, the qualitative field study phase, and the quantitative field study phase. Each phase successively offers more detailed information on system-wide instability; however, each phase also successively requires more resources to implement. An evaluation of the methods involved with each phase of assessment is needed to offer the restoration community guidance on selecting a method or combination of methods that can be used to assess system-wide stability based on time and funding constraints. This paper examines existing quantitative and qualitative assessment techniques, the strengths and weaknesses of those techniques, and their applicability to urban stream restoration design. In particular, those methods that are most beneficial to urban stream restoration are examined and how they can potentially be used to improve the stream restoration design effort by focusing on the watershed scale. An example of the selection and application of qualitative and quantitative assessment techniques to an urban stream restoration design in Bloomington, Indiana is also presented.

Introduction

The initial phases of a stream restoration project typically include a watershed assessment to identify and assess a variety of environmental problems that can occur over a fairly large geographic area. A watershed scale assessment of channel stability in the urban setting requires four main tasks: 1) delineate the watershed, 2) divide the stream network into reaches with similar characteristics, 3) categorize those reaches, and 4) characterize each reach according to level of stability and the protection of critical infrastructure (Chin and Gregory 2005). Watershed delineation is typically completed with topographic maps or GIS data. However, in the urban setting, delineation becomes more complicated due to the existence of ephemeral stormwater drainage channels and roadways that can act as stormwater drainage channels.

Topographic maps, field surveys, remote sensing data, planning documents, and aerial surveys should all be used in conjunction with stormwater drainage plans to identify the total channel network.

Once the watershed has been delineated, it is necessary to subdivide the urban stream network into segments of similar characteristics for geomorphic analysis. In an urban setting, it is difficult to segment a stream based on a standard length or homogeneous geomorphic characteristics due to the fact that infrastructure and other urban constraints act to fragment the drainage network. Therefore, it is suggested that streams be segmented based on hydraulic controls, including road crossings, bridge or utility crossings, or stormwater outfall locations (Chin and Gregory 2005). By segmenting the channel in this manner, management units are delineated because crossings and outfalls are often points at which channel runoff is augmented by stormwater flow and hazard potential is high (Chin and Gregory 2004).

Following network segmentation, each reach can be characterized through geomorphic assessment. Jokay and Watson (2005) suggest that there are three phases of geomorphic assessment, including the desktop phase, qualitative field study phase, and quantitative field study phase. The desktop phase typically includes gathering data and information on land use, soils, and geology from maps and aerial photographs. During this phase, conclusions with respect to channel planform, gradient, valley width, riparian zone width, watershed development, and soil erodibility are inferred from map and soils data (Jokay and Watson 2005). The qualitative field study phase includes conducting a Rapid Geomorphic Assessment (RGA) that field truths data collected during the desktop phase. Qualitative site specific data are gathered on indicators of stream instability (e.g., bank cutting, mass wasting). The quantitative phase involves characterizing reach-level, site specific measurements on geometry and bed material to quantify stream form and processes.

Evaluation of Available Assessment Methods

Chin and Gregory (2005) and Johnson (2005) provide excellent summaries of many existing qualitative and quantitative channel assessment methods. In addition, a collaborative work effort between George Mason University and the National Park Service has resulted in the development of an Ecological Assessment Methods Database (http://assessmentmethods.nbii.gov/). This searchable database focuses on methods and includes selected guidance documents. Based on a review of this material, existing assessment methods can be grouped into four general categorizations (Chin and Gregory 2005): (1) quantitative methods that involve a comprehensive inventory describing characteristics; (2) quantitative methods that emphasizes channel change using thresholds, degree of disturbance, and stability analyses; (3) qualitative methods that focus on management and include the rapid assessment of channel stability using rating systems; and (4) qualitative methods that focus on management of critical infrastructure and include the rapid assessment of channel stability using rating systems. The selection of an appropriate category and method for the characterization of urban stream condition requires consideration of the following specific qualities (Parsons et al. 2002):

- Level of resources required to implement;

- Incorporation of parameters that are relevant to determining channel stability based on biotic, chemical, energy, habitat, and flow regime factors;
- Conformity with a rapid philosophy of data collection and analysis;
- Scientific outputs presented in a form that is easily interpreted by managers;
- Adaptability and applicability to a wide range of river types;
- Ability to predict physical stream characteristics;
- Ability to account for high-hazard urban constraints (e.g., bridges) and;
- Ability to identify environmental problems within an urban drainage network (e.g., exposed utility pipes, fish migration blockages, etc.).

The representation of each of these qualities within the four categories of assessment methods is summarized in Table 1.

Application of Assessment Methods to an Urban Stream Restoration Project

The City of Bloomington, Indiana plans to renovate Cascades Park which is located within the city limits. In order for the city to continue with their renovation plans, Cascades Creek, which runs through the park, needed to be stabilized. A thorough environmental engineering investigation was completed as part of a senior design project conducted by students at Rose-Hulman Institute of Technology. In order to meet project requirements, the student team needed to apply methods that examine stability parameters (chemical and biotic factors, energy source, habitat structure, and flow regime), that were rapid in data collection and analysis, that could potentially predict physical stream characteristics, that account for high-hazard urban constraints (retaining walls, concrete ford, bridges, etc.), and that identify environmental problems within an urban setting. According to Table 1, to meet all these needs, the students needed to apply a combination of quantitative and qualitative approaches presented in Categories 1 and 3.

Prioritization of Reaches

The student team used the Natural Resource Conservation Service's (NRCS) Stream Visual Assessment Protocol (SVAP) to evaluate various reaches of Cascades Creek and prioritize which have the greatest need for restoration. First, the team divided the section of Cascades Creek under investigation into separate smaller reaches (12 total). In this case, the student team found the presence of bank retaining walls to be the major factor in reach delineation. Next, the student team scored each reach in ten different SVAP categories on a scale of one to ten (ten being the best). The categories presented in the SVAP that were rated included 1) channel condition, 2) hydrologic alteration, 3) riparian zone, 4) bank stability, 5) water appearance, 6) nutrient enrichment, 7) barriers to fish movement, 8) in-stream fish cover, 9) pools, and 10) insect/invertebrate habitat. Rankings for each category within each reach were based on the NRCS criteria (NRCS 1998). An example of an individual reach result from the application of the SVAP is displayed in Figure 1. Figure 2 provides photographs of the example reach to provide an illustration of reach conditions at the time the SVAP was applied. The SVAP results for the entire 12 reaches of Cascades Creek are summarized in Table 2. The reach ratings given in Table 2 provide a general indication of the relative health of the reach, especially when compared to the ratings of surrounding reaches.

Table 1 - Evaluation of four categories of assessment against desired qualities of an assessment protocol for urban streams. Representation of qualities is designated as yes (Y), no (N) or potentially (P). (Adapted from Parsons et al. 2002)

Qualities of an Urban Stream Assessment Protocol	Category 1 Methods that Provide a Comprehensive Inventory of Stream Characteristics	Category 2 Methods that Emphasize Channel Change using Thresholds, Degree of Disturbance, and Stability Analysis	Category 3 Methods that Focus on Management and Include Rapid Stability Assessment using Rating Systems	Category 4 Methods that Focus on the Management of Infrastructure and Include Rapid Stability Assessment using Rating Systems

12	5.4	Poor

As part of the environmental engineering study, the student team also collected stream survey data for use in stream classification and hydraulic model studies. The survey results were applied to the Rosgen (1994) classification system to classify each reach and provide insight into stream type (Category 1). The determination of bankfull stage in urban streams for use in the Rosgen (1994) classification was difficult as there was typically no clear indicator of bankfull elevation (breaks in slope, tops of point bars, vegetation lines, changes in sediment size, etc.). To better represent the main channel in Cascades Creek the team looked beyond the use of bankfull indicators and examined other key stream features that were determined to be more appropriate in the urban setting: 1) changes in channel roughness (Manning's n) – point where channel boundary characteristics change such that it indicates a change in roughness characteristics; 2) channel top of banks – where there is a clear break in slope from the channel banks to the floodplain (i.e., top of retaining walls); 3) elevation of flooding impact - elevation at which flooding would significantly impact adjacent infrastructure or property. For most reaches in Cascades Creek the main channel top of bank indicator ("bankfull indicator") was identified as a break in slope or top of a retaining wall. The results of the Rosgen (1994) classification are summarized in Table 3.

Stream bank erodibility was characterized through the application of Rosgen's (1996) Bank Erodibility Hazard Index (BEHI). At each reach cross section location, stream bank erosion potential variables were determined including (1) bank height, (2) bankfull height (if possible to determine in the urban stream) (3) riparian root depth (4) riparian root density (5) bank angle (6) surface protection (7) bank materials, and (8) bank stratification. Rosgen (1996) organized these streambank erosion variables into a hazard rating procedure that includes indices that are used to estimate streambank erodibility. The BEHI results for Cascades Creek are summarized in Table 4. Based on these results, the team determined that the natural banks range from very low to extreme erodibility and used this information to prioritize the banks for erosion protection.

Table 3 – Rosgen (1994) Classification Results for Cascades Creek

Reach	Stream Type	Sensitivity to Disturbance	Recovery Potential	Sediment Supply	Stream Bank Erosion Potential	Vegetation Controlling Influence
1	C5	very high	fair	very high	very high	very high
2	B1c	very low	excellent	very low	very low	negligible

13	n/a	High
14	High	Very High

Reach 1 Summary and Preliminary Recommendation Based on Assessment Results

Reach 1 is located at the southernmost, upstream end of the project area (Figure 1). The reach is approximately 79 meters long and is characterized by a gently sloping bank to the right side of the stream. The bank extends at a gentle slope until it reaches the road. Most of the right bank does not appear to be eroding and is almost entirely covered by grass with one large tree and a patch of shrubbery at its northern edge (Figure 2). However, severe erosion was observed at the most downstream portion of the reach along the right bank. The eroded area is about 3.7 meters wide and extends the entire height of the bank. The erosion is coming dangerously close to an adjacent road. The left bank is steeply sloped and extends upward in elevation for more than 15 meters, forming the left edge of the valley. The slope of the left bank is covered in moderate to dense vegetation consisting of trees, brush, and some grasses. The left bank is also eroding, characterized by exposed roots (Figure 2) The stream bed is made up of a range of sediment from bedrock in places, to small pebbles, and small boulders.

Based on the results of the Category 1 and 3 assessments, the student team recommended that a rehabilitation structure be placed along the right bank at the downstream end of the reach to stop the erosion that is threatening the road. They further suggested the placement of boulder revetments or rock vanes to correct the deficiency. Also, with a moderate to high bank erosion potential, the team recommends planting more vegetation on the right and left banks to better hold the soil in place during large storm events. Although grass provides good soil cover, vegetation with larger root structures can provide more stability and protection.

Summary

There are a number of advantages and disadvantages of assessment techniques that need to be considered. The desktop assessment requires the least amount of resources but also provides the least amount of information regarding reach level stability. Conversely, the quantitative field study offers the most site-specific data for analyzing fluvial forms and processes, but it also requires the most resources to implement. Most restoration resources are devoted to the actual restoration design, leaving little available for initial watershed-scale assessments or post-construction monitoring (Bernhardt et al 2005). As a consequence, most projects begin with only a desktop assessment which produces a report that contains little information based on recent observations and may not be very useful for decision making (Jokay and Watson 2005). Qualitative assessment using RGA techniques (Categories 3 and 4) can provide a better understanding of the natural processes and stream reach condition throughout the watershed while only requiring a moderate amount of resources (Chin and Gregory 2005, Jokay and Watson 2005, Johnson 2005). Quantitative field studies (Categories 1 or 2) may only be necessary when focusing on a given high priority reach, in which specific information on fluvial forms and processes are necessary for design (Chin and Gregory 2005). In general, qualitative assessments (or RGA's) appear to be the most suitable to the urban environment, because they validate desktop assessments by assessing various parameters

qualitatively in a short amount of time (Chin and Gregory 2005). Ultimately, conducting a qualitative assessment using methods presented in Categories 3 and 4 in Table 1 can help prioritize impacted stream reaches and better direct future stream restoration and stabilization efforts within an urban watershed. This prioritization can ensure long-term effectiveness of future restoration projects and serve as a foundation for a coordinated and effective watershed management plan.

ABSTRACT

Multi-disciplinary stream assessments are currently being conducted on tributaries to the Columbia River, including the Methow, Wenatchee, Entiat, and John Day River Basins. The primary objective of these studies is to develop an improved understanding of the physical processes acting on the watershed to identify river restoration opportunities that address limiting factors of ESA-listed species. This objective is met through interpretation of the biological conditions, including the fisheries and vegetation ecosystems, the geologic setting, anthropogenic constraints, geomorphic processes, basin hydrology, and hydraulic and sediment transport processes. Local knowledge, compiled data and modeling results are synthesized to evaluate potential physical and biological response to restoration actions. In particular, hydraulic modeling, sediment transport analyses, and geomorphic studies help define the spatial and temporal scale of river processes and offer a predictive tool to assess proposed actions. This paper presents an example of how this objective is being accomplished along a 23-mile reach of the Middle Fork John Day River located in northeastern Oregon.

Results of these investigations assist other technical staff, resource managers, planners, and stakeholders in determining how and where to focus resources for implementation of identified restoration projects. In this paper, we also illustrate a scientific methodology for evaluating the linkages between fluvial processes and biological response to proposed habitat improvements and present results from a two-dimensional hydraulic model to quantify potential increases in floodplain connectivity and channel complexity.

INTRODUCTION

In compliance with the Federal Columbia River Power System Biological Opinion (NOAA, 2008), the Bureau of Reclamation (Reclamation), U.S. Army Corps of Engineers, and Bonneville Power Administration are working to implement habitat restoration projects in the Upper and Lower Columbia River basin. Recovery efforts are focused on limiting factors for the survival of Endangered Species Act (ESA)-listed and other culturally important species within the four general sectors of harvest, hatcheries, hydropower, and habitat. Implementation of a combination of actions in all four sectors is expected to be necessary for recovery of ESA-listed species. Within the habitat sector, Reclamation provides technical assistance for project identification, design, and construction in partnership with States, Tribes, Federal agencies, and other local workgroups. Initially, technical assistance was provided to address critical path projects such as stream flow improvement, removal of in-stream barriers, and fish screen enhancement projects. More recently, Reclamation has been incorporating

habitat complexity projects, which have been a challenging endeavor for both scientists and resource managers.

Reclamation initiated assessments in multiple tributaries to the Columbia River, including the Methow, Wenatchee, Entiat, and John Day Rivers, to develop planning tools that can be used collectively by partners within a subbasin to focus resources to identify and prioritize floodplain connectivity and channel complexity restoration/ protection projects. Within this paper, we present how scientific assessments are being developed and applied in the Middle Fork John Day River (MFJDR).

The John Day River is a tributary to the Columbia River and drains nearly 8,000 square miles. The Middle Fork subbasin originates in the Blue Mountains of the Malheur National Forest and flows 75 miles to its confluence with the North Fork John Day River north of Monument, Oregon. The assessment area of the MFJDR is a 23-mile stretch of river located in Grant County, Oregon, from the confluence of Camp Creek to just downstream of the confluence of Crawford Creek. This area has a range of private and federal ownership, including some national forest lands. Multiple properties are owned by the Confederated Tribes of the Warm Springs Reservation of Oregon (CTWSRO) and by The Nature Conservancy.

Within the MFJDR, substantial changes to channel processes and resulting habitat have occurred over the last century. Populations of several important fish species, including spring Chinook (*Oncorhynchus tshawytscha*), summer steelhead (*Oncorhynchus mykiss*), and bull trout (*Salvelinus confluentus*), have markedly decreased. Spring Chinook and summer steelhead are of particular importance to the region because the John Day River is managed exclusively for wild fish production (NPCC, 2005).

METHODS

To develop habitat restoration strategies, a multi-disciplinary team worked to provide a cross-discipline understanding of important river processes that help create and sustain habitat conditions important to ESA-listed and other culturally important species. Habitat restoration projects implemented with a clear understanding of the existing physical processes are more likely to provide both short- and long-term benefits to important fish species. A sound understanding also helps reduce the likelihood for unanticipated, potentially adverse impacts to landowners and even the species itself.

Stream evaluation efforts aim for a high degree of certainty by using state of the art tools and more quantitative than qualitative data. While quantitative methods provide more certainty to results than qualitative methods, they are not always necessary and are more costly and time consuming to employ, particularly for large study areas. Therefore, a multi-tiered spatial approach was used in the MFJDR that began with a coarse-scale analysis of physical processes, and then focused in more detail in areas identified to have more complex river processes. The initial coarse-scale analysis, referred to as a stream assessment, provided the technical basis for proposed restoration concepts. Upon completion of the stream assessment, resource managers worked with the technical team to determine where impacts are localized and design work can begin, or alternatively, where a refined analysis within a specific reach of

river was needed. The reach-scale evaluation addresses questions specifically tailored to processes operating within that reach that are important to further understand prior to implementing a restoration action. Reach assessments typically occur in areas with a high degree of impacts and a high potential for improving habitat complexity.

Stream Assessment. To determine the degree of impact to altered habitat availability and quality, a conceptual model was developed for the MFJDR to outline typical channel processes and expected river functions that may have existed prior to widespread anthropogenic impacts. Not all river reaches can support the same level of floodplain complexity due to variations in geologic control, floodplain width, sediment size, channel slope, and local hydrology. Comparison of the present river setting to a conceptual model of the MFJDR prior to anthropogenic impacts helps determine which processes may have been altered and to what degree. It is recognized that processes cannot be fully returned to pre-development conditions due to changes in vegetation, the physical setting, or current land use. Documented historical changes in morphological river features (e.g., channel form, floodplain character, presence and type of riparian vegetation) can help define the rate of change from pre-development conditions, how the changes relate to historical floods and anthropogenic activities, and whether the changes are continuing or have stabilized. Following the compilation of previously existing data, components of the ecosystem were further explored to improve understanding of system processes influencing the generation and maintenance of salmonid habitat, including:

Fisheries- An investigation of historical trends of ESA-listed and other culturally important species was conducted based on past work to understand changes in abundance, spatial distributions, and potential habitat factors limiting their populations. An understanding of current species presence and habitat use relative to historical presence and habitat use laid the framework for how anthropogenic impacts or processes that influence the availability and quality of habitat important to their continued survival may have been altered over time.

Geomorphic/Geologic setting- Existing geologic information was collected at a regional level to understand the geologic history of the basin and identify the presence of major geologic structures (i.e., faults, folds, rock types, and their spatial relationships) that may be important to the present-day morphology of the MFJDR. Within the stream assessment area, aerial photography, Light Detection and Ranging (LiDAR) data, regional geology maps, and field reconnaissance were used to define surficial geologic units (floodplain, stream terraces, landslides, and alluvial fans) and identify specific geologic controls that may restrict the lateral and vertical position of the river (e.g., resistant bedrock, large boulders, talus). Historical trends of channel position, slope, and width were evaluated to document rates of change and relate changes to anthropogenic impacts or natural river processes.

Reaches within the stream assessment area were defined on the basis of their physical characteristics and dominant processes affecting channel form and function needed to maintain habitat features. Initially, geologic controls such as alluvial fans and bedrock outcrops were identified through field evaluation of the assessment area. Other physical characteristics used in identifying the reaches included valley width, tributary inputs of flow and sediment, and present riparian vegetation. Other more

subtle geomorphic processes that influence the physical characteristics of the river, such as changes in channel form and position, channel slope, sediment transport capacity, and notable areas of erosion or deposition, were also evaluated to further define reach characteristics

Hydrology- A hydrologic analysis was conducted to identify historical flood events that may have impacted channel morphology, to characterize significant impacts to the flow regime within the basin, and to provide an estimate of the recurrence interval of specific peak discharges for input to hydraulic and sediment transport models. The analysis relied primarily on literature documenting diversion magnitude and timing, long-term stream gage data, and documented accounts of historical floods. A geographical information system (GIS) layer was then created to provide easy access to flood frequency estimates anywhere in the basin based on regional regression equations for northeastern Oregon.

Hydraulics and sediment transport- Hydraulic and sediment transport analyses were performed to evaluate floodplain connectivity, identify potential areas of bed degradation, and examine the influence of anthropogenic activities on hydraulics and sediment transport. The hydraulic analysis consisted of the development of a one-dimensional, steady flow hydraulic model using Hydrologic Engineering Center-River Analysis System (HEC-RAS). For evaluation of channel processes in the stream assessment, cross-sectional averaged hydraulic parameters were sufficient to approximate water surface elevations, extent of inundation, and in-channel velocities for selected peak discharges. Various surrogates, which included incipient motion, unit stream power, total stream power, and sediment transport capacity, were used to evaluate how sediment moves through the MFJDR under various peak discharges. These surrogates provide an improved understanding of the relative degree to which channel forming processes vary throughout the system and of the relative capacity of reaches to transport sediment.

Riparian Vegetation- Large areas of riparian vegetation clearing have occurred along the MFJDR over the last century. To locate and quantify the impacts, aerial photography from 1939, 1956, 1976, and 2006 were used in combination with LiDAR data to visually interpret canopy vegetation community classes such as conifer, hardwoods, shrub, or meadows. Vegetation communities in the floodplain were mapped in GIS, and changes in vegetation over time were quantified. Based on the mapping of present day conditions, the potential for recruitment of large woody debris (LWD) and shading by trees along the river channel was characterized. These data could be further refined and validated using a field assessment of species present.

Anthropogenic constraints and impacts- Anthropogenic activities including logging, grazing, and mining of placer deposits immediately adjacent to or in the river have occurred for over a century in the Middle John Day basin. A literature review was conducted to capture major changes in land use since the late 1800s. Mapping of constructed features on and adjacent to the floodplain, including levees, roads, bridges, and water diversions, was conducted using aerial photography and LiDAR data and verified with field observations (Reclamation, 2008). Impacts of the constructed features on floodplain connection and channel position were also quantified and mapped.

Findings from each of the components described above were integrated to identify reaches that displayed the greatest impacts to the physical river setting relative to the conceptual model of typical channel processes. Inferred changes to river processes were then interpreted to determine how the impacts may have potentially influenced habitat conditions. From this information, a technical ranking of reaches was developed to provide other technical staff, resource managers, planners, and stakeholders with a way to identify, sequence, and prioritize opportunities for protecting or restoring channel and floodplain connectivity and channel complexity at the reach-scale. Proposed rankings consider potential for protection of existing habitat, restoration opportunities, degree of departure from fully-functioning conditions, and present fish use.

Reach-scale Evaluation. Results from the stream assessment of physical processes on the MFJDR combined with landowner willingness led to a refined investigation of restoration opportunities within one segment of the stream assessment area. The reach selected lies within the Oxbow Conservation Area (OCA), an area that was drastically altered by dredge mining operations in the 1940s. The key objective of the reach assessment was to further investigate hypotheses on river process identified in the stream assessment and by a working group of stakeholders that would lead to implementation of restoration projects with the greatest opportunity for success. These hypotheses included (1) mining activities have severely impacted floodplain connection and lateral channel migration, (2) returning all flow to the historical South Channel would benefit habitat without adversely impacting channel morphology, and (3) geomorphic conditions within the reach influence potential restoration options. To accomplish the objective, these steps were followed:

Data gap analysis- An interdisciplinary team comprised of geomorphologists, biologists, ecologists, hydraulic engineers, design engineers, and stakeholders was convened to help identify missing information needed to better understand reach processes relative to implementation of restoration actions. Specific items identified were longitudinal and seasonal variations in stream temperature, composition of native vegetation within the riparian corridor, and a refined interpretation of the channel morphology including the hydraulic properties of the river associated with multiple channels, substantial flow splits, a meandering channel, and a channel with extensive point bar and pool-riffle formation.

Geomorphic investigations- Coarse-scale geologic mapping completed for the stream assessment was refined to gain a better understanding of geomorphic processes controlling the channel morphology, the history of development, and evolution of the channel over the last several thousand years. In addition, specific information regarding the character of the floodplain, terraces, and deposits from the tributaries was needed. A single mapped unit of surficial deposits associated with the river was subdivided into four alluvial units based primarily on surface morphology, relative age, and elevation above the active channel. Shallow pits were excavated on each of the alluvial units to describe the character of the sediment comprising the deposits, document the extent of soil formation (an indicator of relative age and landscape stability) and collect detrital charcoal and sediment samples in an attempt to evaluate the type of vegetation growing adjacent to the river pre-historically.

2D hydraulic model- The OCA is comprised of a complex network of multiple channels and tributaries. Therefore, a 2D hydraulic model was developed using Reclamation's Sedimentation and River Hydraulics 2D hydraulic model (SRH-2D; Lai, 2006) to gain insight and predictions of floodplain processes, side channel connectivity, and split flow dynamics through the selected reach. Simulations were conducted for the 2- through 100-year peak discharges with inlet flows ranging from 881 cubic feet per second (cfs) to nearly 2700 cfs. In addition, the model was applied to evaluate a "proposed conditions" scenario to examine how hydraulic parameters and habitat features may change following a specified restoration action. Proposed conditions included blocking off the North Channel, an artifact of dredge mining, downstream from the bifurcation of the historical South Channel, and just upstream of the confluence with a major tributary, Granite Boulder Creek (Figure 1).

Following completion of these individual tasks, results from the geomorphic investigations were linked with results from the hydraulic modeling to better understand pre-disturbance physical processes in the reach, identify potential restoration opportunities, and identify limitations to habitat restoration.

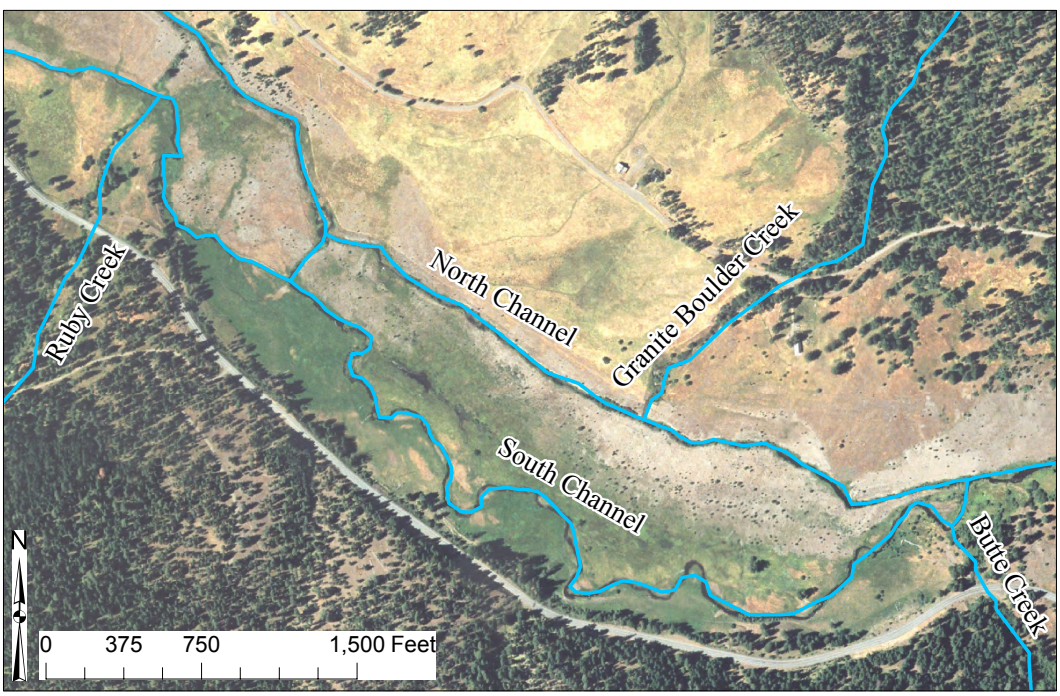

Figure 1. Aerial image of key features examined in the Reach Evaluation.

RESULTS AND DISCUSSION

Summary of stream assessment findings. The form of the river and channel processes can be affected by changes in flow regime, sediment regime, and topographic elements, such as constructed features and vegetation. The flow regime in the MFJDR is relatively unaffected by historical development with the exception of minor flow diversions. The sediment regime is mainly affected by short-term increases in fine sediments from anthropogenic activities, localized changes in channel slopes resulting from channelization, and possibly localized degradation or bed coarsening. The greatest apparent impacts to river form and habitat result from

historical changes to the topography and riparian vegetation due to anthropogenic activities. Notable changes to topography, vegetation, and the river form that impact the availability and quality of habitat for spring Chinook and steelhead include: (1) reduced side channel access and floodplain connectivity due to bridges, roads, levees, and bank protection measures that disconnect the channel from the historical channel migration zone and floodplain area; (2) reduced access to the historical channel migration zone through increased channel slope and decreased sinuosity due to confinement of high flows, manual channel straightening, and bank protection measures; (3) reduced quantity of large trees available for recruitment to the river and altered rates of regeneration of riparian vegetation due to timber harvest, conversion of riparian forests to agricultural fields, and minimal lateral reworking of the channel and floodplain; (4) reduced habitat complexity within the channel, along channel margins, and within the floodplain due to alterations in cover, LWD inputs, and hydraulic and sediment diversity (e.g. wet meadows, beaver ponds) and due to the conversion of banks to rock protection; (5) reduced competency of the channel to rework floodplain materials due to dredge mining activities; and (6) increased water temperatures resulting from alterations in channel complexity, increased width-to-depth ratios, disconnected floodplains, and reduced shade.

Development of restoration concepts. Results of the stream assessment were used to evaluate the potential for restoring channel processes that create and maintain desired habitat. It was determined that actions with the greatest potential to create habitat are those that restore natural river processes and generate habitat complexity, particularly in reaches that experience frequent channel migration and floodplain inundation. Short-term actions, such as the placement of LWD, may be needed to supplement long-term riparian vegetation recovery. Protection and monitoring opportunities were also identified as part of a restoration strategy to maximize beneficial effects of restoration projects in adjacent areas.

Several restoration concepts were recommended for long-term recovery of habitat complexity. First, a major revegetation effort is needed to restore healthy riparian processes, provide shade and cover to the channel, provide a source for the future recruitment of LWD, and moderate lateral channel migration and bank erosion. A second important restoration concept in areas with a wide floodplain is the setback or removal of topographic (anthropogenic) features that negatively impact river processes, including floodplain connectivity, lateral channel migration, and the availability and formation of off-channel and main channel complexity features. In areas with narrow floodplains, the largest impacts to habitat function result from the loss of riparian vegetation and the presence of bank armoring (rock spurs, riprap). Modification or removal of these features in conjunction with riparian planting offers the best opportunity for improving habitat.

Technical ranking of reaches. Within the MFJDR, three of the twenty defined reaches were ranked considerably higher than all other reaches based on their potential for restoration of floodplain connectivity and channel complexity. These three reaches included properties at the Dunstan Ranch managed by The Nature Conservancy and the Oxbow and Forrest Conservation Area managed by the CTWSRO. All of the high-ranking reaches are characterized by wide floodplains with

high potential for frequent floodplain inundation, lateral migration and formation of side channels, which encourages continual regeneration of a healthy riparian corridor that would add shade, organic material, and additional complexity to the channel. The final prioritization for further analyses on the OCA was made on the basis of stakeholder preference, availability of funding opportunities and prior dedication of resources to site-specific restoration efforts

Substantial findings of the reach-level evaluation of the OCA. The 3.5 mile stretch of the OCA selected for reach-level evaluation has been substantially modified, primarily due to ranching, grazing, timber harvest, road and levee construction, channel stabilization, and dredge mining. The first three activities mentioned led to the removal of vegetation from the floodplain and adjacent valley floor. Road and levee construction resulted in disconnection of floodplain, while bank stabilization structures, consisting principally of rock spurs and riprap, have constrained lateral channel migration. The most substantial impact, however, was the dredge mining activities that occurred on the property in the early 1940s. This activity altered the channel and floodplain characteristics dramatically by changing the location, geometry, and planform of the channel, as well as the number of channels. Dredging operations turned over floodplain deposits, winnowed out available fines, and altered the size of the channel bed and floodplain sediment. After mining ceased, stream flow was split between two channels, the North and South Channels (Figure 1). The South Channel is the remnant of the natural channel to the south of the dredge tailings; the North Channel was constructed through the dredge tailings and across the toe of the Granite Boulder Creek alluvial fan. During high flows, most of the stream flow is routed through the South Channel, but during low flows, the hydraulic conditions are reversed due to the conveyance conditions at the bifurcation of the North Channel.

Two significant contributors of stream flow and sediment to this reach are Granite Boulder Creek, located downstream from the bifurcation of the North and South Channels, and Ruby Creek, just downstream from the confluence of the North and South Channels (Figure 1). Both tributaries would have provided substantial physical constraints on the river geomorphology, particularly on lateral channel migration. However, parts of each fan were dredged, and the creeks have been at least partially diverted into artificial channels. Channelization resulting from the dredge activities now severely impacts channel position and river function.

Geomorphology. Several important aspects of the geology, how it influences the river geomorphology, and the processes controlling it were observed in the OCA. In general the three larger tributaries, Ruby, Butte, and Granite Boulder Creeks, shed alluvial fans into or across the valley. The formation of these alluvial fans directly influences the channel gradient and channel form immediately upstream of each tributary. Material shed onto the valley floor by Ruby Creek is in general very coarse grained, and primarily of volcanic composition. As a consequence, the Ruby Creek alluvial fan has a strong influence on the position of the MFJDR in the valley pushing it northeast (Figure 1). In combination with a landslide at this location, the Ruby Creek alluvial fan provides a constraint on the valley width, and as a result, controls the channel gradient locally and channel form immediately upstream.

The valley is significantly wider downstream of Ruby Creek, and as a consequence, the areal extent of the floodplain historically was much greater as the MFJDR migrated laterally across this area. Despite impacts of the mining locally, evidence for this is provided by channel scars on the valley floor visible in the 1939 aerial photographs. Older stream terraces preserved along the margins of the valley are indicative of an overall trend of incision by the MFJDR into older alluvial valley fill during the last 7600 years. However, the wide floodplain and numerous abandoned channels on the valley floor visible in the 1939 photographs suggest that the recent history of the river (for at least the last 1200 years) has been predominately of lateral migration (Bandow, 2003).

The Granite Boulder Creek alluvial fan also has a strong influence on the position and character of the MFJDR in the valley pushing it south (Figure 1). Unlike the Ruby Creek fan, its areal extent is significantly larger. Historically, the distal portion of the alluvial fan (toe) was modified by the MFJDR. Evidence for this is provided by abandoned channel scars and other lineations that are subparallel to the course of the MFJDR and by patterns in the vegetation visible on the 1939 aerial photography. As implied by its name, material shed onto the valley floor from Granite Boulder Creek is very coarse and primarily of granitic composition. Based on the areal extent of its alluvial fan, it is apparent that the Granite Boulder Creek drainage is the major contributor of coarse-grained gravelly sediment to the MFJDR. The Granite Boulder Creek alluvial fan constrains the channel position of the MFJDR where it pushes the river against the Butte Creek alluvial fan (at the present day split between the North and South Channels). The result once again is that the alluvial fan is a control on the channel gradient locally and channel form immediately upstream.

The Butte Creek alluvial fan is small in terms of its areal extent relative to Granite Boulder Creek. However, its steep gradient, which is similar to that of the Ruby Creek alluvial fan, allows very coarse-grained material to be delivered from its basin directly to the margin of the MFJDR valley. And as with Ruby Creek, the sediment comprising the fan is primarily of volcanic composition. The coarse-grained nature and steep form allows the Butte Creek alluvial fan to exert some influence on the position of the MFJDR pushing it north against the upstream margin of the Granite Boulder Creek alluvial fan (Figure 1).

Because vegetation on the valley floor was removed as a result of logging and agricultural activities and later by mining, little is known about the type and extent of historical riparian vegetation on the OCA. Thirty-four charcoal samples were collected from each of the stream terraces and alluvial fan deposits, either in soil pits or natural exposures. Each sample was identified to genus level in an attempt to document the type of large woody vegetation present prehistorically. Several trends were recognized in the type and distribution of paleobotanical material recovered. First, samples recovered from terrace deposits along the MFJDR are dominated by conifer charcoal. A single fragment of Alder (*Alnus*) charcoal was recovered from the youngest stream terrace deposit. Typically, samples recovered from the floodplain and youngest terrace deposits include material representing riparian species, for example willow (*Salicaceae*) and cottonwood (*Populus*). Also, the youngest deposits (in this case the youngest terrace and floodplain deposits) generally contained

charcoal indicative of the diverse riparian ecosystem. While there was diversity in the type of charcoal recovered along the MFJDR, more commonly represented riparian species were missing. An interesting finding was the presence of Hemlock (*Tsuga*) charcoal in the older terrace deposits (>1200 years). Apparently hemlock is not found in the area today. Sediment samples were also collected to examine pollen content; results of these analyses are pending.

2D hydraulics. Using the results of the 2D model, split flow dynamics were evaluated and several habitat indicators, including side channel access, floodplain connectivity, and high quality high flow habitat, were investigated. Comparisons were made between existing and proposed conditions (blocking off the North Channel) based on predicted changes to water surface elevation, depth-averaged velocity, and bed shear stress. These hydraulic parameters were compared along the channel thalweg and across the floodplain.

Flow split patterns were evaluated to better understand complicated hydraulics between the North and South Channels and through several smaller alternative channels (e.g. abandoned ditches). Model results indicate that the North Channel has a reduced influence on flood conveyance as the peak discharge increases in magnitude. The capacity of the North Channel is estimated to be approximately 450 cfs (17 percent of the total) at a 100-year peak discharge, with the remaining flow being conveyed through the South Channel and across the adjacent floodplain. The model also improved the ability to predict the influence of other constructed flow paths and abandoned side channels on floodplain inundation.

Present floodplain connectivity was determined by quantifying the area of the floodplain outside of the low flow channel that experienced depths exceeding 0.5 feet. Model results predicted substantial floodplain connectivity at the 2-year peak discharge throughout a substantial portion of the study area. Locations not experiencing floodplain connectivity under the peak flows evaluated were channelized portions of the river, which were artifacts of mining activities. The model also predicted that almost all of the side channels present were connected at flows equivalent to the 2-year peak discharge and greater. Side channels that may have been present historically through the dredged areas were drastically altered during the dredging operations of the 1940s. One channel that appears to have been the main low flow channel in the 1939 aerial photographs begins to convey flow at the 10-year peak discharge and is well connected at the 100-year peak discharge. High-quality high-flow habitat, which was defined as areas experiencing greater than 0.5 feet of flow depth with velocities less than 2 feet per second, accounted for 10% to 17% of the floodplain, depending on peak discharge.

Comparisons of the channel hydraulics under existing and proposed conditions suggest slight improvements to the habitat indicators. Notable changes only occurred in a 1.5 mile section downstream of the North and South Channel bifurcation. Models of the proposed conditions predicted increased floodplain connectivity along the South Channel, which decreased in magnitude as the peak discharge increased. At discharges exceeding a 10-year annual exceedance probability, areas of floodplain connectivity lost along the channel margins of the North Channel were greater than those gained along the floodplain of the South Channel. Although most of the flow

across the South Channel floodplain was not conveyed through well-defined side channels, the proposed conditions did result in increased overbank flow. The proposed condition resulted in more high flow habitat at 2-year peak discharges, but was slightly less for all other peak discharges evaluated. This change was primarily due to a loss of habitat along the margin of the North Channel. Comparisons of hydraulic parameters between the two conditions indicated minimal changes in channel depths, velocities, and bed shear stresses along the South Channel. However, the model predicted increased inundation and flow velocities along the South Channel floodplain.

Linking results of the assessments to restoration options. Currently, several restoration options are being considered on the OCA. The first, discussed above, is focused on blocking the North Channel and returning all of the stream flow into the South Channel. Due to conditions resulting from dredge mining in the area of the bifurcation, concerns have been raised as to potential impacts of increased depths, velocities, and shear stresses in the South Channel and along the channel bed, banks, and floodplain. Hydraulic modeling results suggest that these parameters will not substantially change from current conditions. Based on geomorphic characteristics of the river that are visible in the 1939 aerial photography, it is evident that the proposal to block the North Channel would essentially return the river to a position in the valley that it occupied historically. While the current channel form appears to be quite similar to that of the river in 1939, data does not exist to allow comparison of the current channel geometry relative to the geometry of the river in 1939. However, a dramatic change in the channel morphology of the South Channel is not expected as a result of blocking the North Channel given the character of the Granite Boulder Creek alluvium and current processes, which further alleviates recognized concerns.

An additional option under consideration is the reconnection of Granite Boulder Creek to the South Channel as a result of a channel reconfiguration. If reconnected, Granite Boulder Creek would serve as an important source of colder water inflow to the MFJDR, which could help mitigate high water temperatures not conducive to salmonids. As a result of dredging operations, much of the fine-grained sediment may have been winnowed out of the alluvium in the area between the confluence of Granite Boulder Creek with the North Channel and the South Channel floodplain. Concerns with this reconnection are the potential loss of a surface flow connection due to the disruptions by mining activity in the grain size of the Granite Boulder Creek alluvium. However, geomorphic evidence suggests that loss of this surface connection would not be expected given three factors: (1) evidence of such a connection in 1939, (2) similarities in the character of the sediment between the confluence of Granite Boulder Creek and the South Channel and the character of the sediment across which the North Channel currently flows downstream to Ruby Creek confluence, and (3) the general nature of alluvial fan deposition.

In additional to restoration alternatives discussed previously, several more restoration actions have been proposed for consideration based on the results of the hydraulic modeling and geomorphic conditions. Results from the geomorphic analysis will continue to be evaluated in conjunction with the 2D model and used as tools to investigate additional restoration actions and subsequent results on habitat.

CONCLUSIONS

This report presents the results of an assessment approach designed to address restoration of floodplain connectivity and habitat complexity based on integration of information from multiple disciplines including biology, geomorphology, hydraulic engineering, and other natural sciences. A coarse-scale analysis of the river system processes (a stream assessment) provides essential technical information to help guide resource managers and decision makers with potential restoration actions and the locations where such actions may have the most benefit to habitat. The multi-tiered approach allows for the addition of information as needed to address reach-specific restoration questions and concerns in a reach-level evaluation. Specific questions regarding the effects of restoration actions or additional information needs can be further investigated and developed through refined analyses of a given reach.

Findings from the stream assessment for the MFJDR resulted in a focused reach-level evaluation on the OCA, a property managed by CTWSRO. Due to mining activity, installation of bank protection, water diversions, and vegetation changes related to agriculture and logging, the majority of the study area on the OCA has experienced dramatic changes in river processes resulting in disconnection of floodplain, constrained lateral channel migration, and a lack of floodplain and channel complexity. A refined understanding of the geomorphic and hydraulic conditions was applied to investigate existing habitat and how blocking the artificial North Channel may influence processes and resultant habitat. Comparisons of the channel hydraulics suggest slight improvements to habitat indicators when the North Channel is blocked. Results of the effort also indicate minimal changes in channel depths, velocities, and bed shear stresses along the South Channel and alleviate concerns regarding potential changes to the morphology of the South Channel and the potential loss of a surface flow connection between Granite Boulder Creek and the South Channel. The 2D model and refined understanding of geomorphic processes will be applied in the future to understand the viability of additional proposed restoration actions within the reach and determine the most suitable actions for habitat improvement.

Hungry Canyons Alliance: Streambed Stabilization in Western Iowa

J. T. Thomas[1]

[1]Hungry Canyons Alliance, Golden Hills RC&D Office, P.O. Box 189, Oakland, IA 51560-0189; PH (712) 482-3029; email: john.thomas@rcdnet.net

ABSTRACT

The Hungry Canyons Alliance (HCA) was formed locally to provide financial and technical assistance for streambed stabilization projects in the 19 counties of the deep loess region in western Iowa. Stream straightening and land-use changes, coupled with the erosive nature of loess, caused streams to downcut and widen, undermining bridges, farmland, and utility lines. The most efficient and affordable way to stop channel degradation has proven to be the construction of grade control structures (GCS). GCS allow a drop in stream elevation in a controlled setting, prevent further degradation, decrease sediment loads and turbidity, and increase water quality. With over 750 GCS of all types in western Iowa, western Iowa has been referred to as a "laboratory" for GCS design. The HCA has conducted research on GCS design and fish passage, the use of directional drilling to control gully erosion, the use of scrap tires in GCS, knickpoint migration, and aerial stream classification.

THE PROBLEM

In western Iowa, 19 counties contain deposits of loess ranging from 4 m to over 61 m deep. Loess is highly erodible and very susceptible to stream channel erosion and degradation. Beginning with settlement of the area around the late 1840's and early 1850's, land use changed dramatically from prairie to farmland, likely causing rapid erosion in upland areas and deposition in stream networks. Stream channel dredging and straightening from the early 1900's to the 1950's was done to reduce flooding, increase the amount of farmland in production, and to clean out the sediment clogged channels.

After straightening, streambed bed slopes were steeper because streams still had the same fall per mile, yet there was a shorter distance over which that fall occurred. The steeper bed slopes increased water velocities, increasing stream erosion. Streams could either re-meander or downcut. Due to the high erodibility of loess soils, streams downcut, causing accelerated soil erosion in western Iowa (Fig. 1). Knickpoints, which are naturally occurring overfalls (Fig. 2), would form and rapidly advance upstream, eventually affecting the entire watershed. Unstable, vertical stream banks would slump to a more stable slope; if high flow events flushed the slumped bank debris, vertical banks would again be unstable and slump, widening the channel. Tributaries of degraded streams would also erode and adjust to the lowered base level, often initiating gully formation where no channel had previously existed.

These erosional processes recurred until the streambed stabilized. As streams downcut bridge pilings were destabilized, and as streams widened bridges would collapse. Many bridges were forced to be closed (Fig. 3), or replaced with taller, longer, more expensive bridges.

What might have been a 1.5 m high stream bank 50 years ago may now be a 9.1 m deep canyon with bare vertical banks. Erosion of streams into "hungry canyons" has undermined bridges, farmland, and utility lines, and already caused an estimated $1.1 billion in damage to public and private infrastructure in western Iowa in the 19 county area of the deep loess soils region of western Iowa (Baumel, 1994). Stream degradation has also eroded away thousands of acres of valuable farmland, increased stream sediment loads, and decreased water quality. A survey of western Iowa bridges in 2000 revealed that 404 were endangered due to stream channel degradation.

THE SOLUTION – GCS AND HCA

A proven, affordable solution to this problem is to build grade control structures in streams. Grade control structures (GCS) at regular intervals help streams stabilize by changing their longitudinal profile from an erosive steep incline to a stable stair-step pattern. Streambed stabilization is the key to preventing further erosion and protecting infrastructure (Fig. 4).

GCS design is largely dependent on drainage area. Small drainage areas < 7.8 km^2 can often be controlled with reinforced concrete box (RCB) or corrugated metal pipe (CMP) culverts with drop inlets and/or flume outlets (Fig. 5). Large drainage areas > 7.8 km^2 are often controlled with weirs constructed with steel sheet pile, driven into the streambed 6.1 m, with a riprap and concrete grout slope immediately downstream, a riprap stilling basin downstream of the weir slope, and riprap covered banks (Fig. 6). Only limestone bedrock is available in western Iowa, and it is found in relatively thin ledges (< 2.4-3.1 m), but due to bedding planes and stratification boulders greater than a 0.77 m^3 are very rare. Riprap also tends to fracture due to freeze/thaw processes and then move under higher flow conditions, so concrete grout is used to lock the riprap in place. Both RCB/CMP and weir designs allow the stream elevation to drop in a controlled setting, restore lost stream grade, prevent further degradation, and reduce streambed slope upstream creating a calm backwater condition where silt can settle out, decreasing sediment loads and turbidity and increasing water quality. Sediment re-deposited upstream also helps support exposed bridge pilings.

The Hungry Canyons Alliance (HCA) provides financial and technical assistance to the 19 counties affected by streambed degradation in western Iowa with deep loess soils. State and federal money appropriated to the HCA is made available to the counties through a GCS cost share program; county governments provide a minimum of 20% match for each GCS. Approximately 20 GCS are constructed every year. From 1992-2008, the HCA provided $16 million in state and federal cost share, enough to complete 297, and approve another 22, GCS in 17 counties in western Iowa. These structures will protect an estimated $77.75 million in property value. It is estimated that 231 hectares of land, equivalent to 18.1 million metric tons of

sediment, will be protected from erosion by construction of the 319 GCS. HCA GCS, with an average cost of $64,737, protect approximately $243,742 in property per structure. For every $1 invested in HCA GCS, more than $4.24 of property value and an average of 889 kg of sediment are protected from streambed degradation. A second HCA program, funded with the interest earned from state appropriations, provides funding to landowners where grade control is necessary to stabilize active gully erosion. With the help of the NRCS, this program has built 84, and approved another 9, structures for a total cost share of $619,406. The HCA has quarterly meetings at which issues concerning stream erosion and streambed stabilization are discussed. Regular attendees include county engineers, county supervisors, NRCS employees, Soil and Water Conservation District commissioners, Iowa Department of Natural Resources fisheries biologists, engineer consultants, contractors, and landowners.

Severe rains in May 2007 and June 2008 caused widespread flooding and stream channel damage; this was the worst flooding to hit western Iowa since 1993. However, Federal Emergency Management Agency (FEMA), Natural Resources Conservation Service (NRCS), the Hungry Canyons Alliance (HCA), and counties have all seen evidence that GCS have directly reduced flood damage costs and FEMA/NRCS Emergency Watershed Protection (EWP) Program claims in numerous instances. The vast majority of GCS were undamaged, and infrastructure protected by GCS had no damage. A small proportion of these GCS also suffered damages during the flooding; however, the damages to these structures are minimal compared to the total loss of our bridges that may have resulted without these GCS. The HCA is providing technical assistance to the counties by documenting which erosion control measures have worked, which have not, and what new techniques can be used to enhance performance of the original erosion control design if it has not adequately solved the erosion problem.

Over 750 GCS of all types have been constructed in western Iowa by county governments, HCA, NRCS, NRCS-EWP, Iowa Department of Transportation, cities, utility (water, gas, telephone, electric, etc.) companies, railroad companies, Army Corps of Engineers, Iowa Department of Natural Resources, landowners, and Soil and Water Conservation Districts. With so many GCS located in one area, western Iowa has been referred to as a "laboratory" for GCS design. Because western Iowa has, and still is experiencing such dramatic streambed degradation, the Hungry Canyons Alliance is one of the unheralded leaders in innovative GCS research, design, and construction (Thomas, 2007).

A CASE STUDY

A 1.5 m concrete grade control structure (Fig. 7A), built and maintained by Northern Natural Gas (NNG) since the early 1970's, had been destabilized and nearly destroyed by advancing, in-stream, knickpoint migration (Fig. 7B). Streambed downcutting had caused the structure to vertically control approximately 4.9 m (Fig. 7C), when it was only designed to vertically control 1.5 m. The spillpad itself was starting to crumble (Fig. 7D), was almost completely undermined, and was separating from the sheet pile, causing the sheet pile to begin to bow. The structure had a

projected life of 0.5 to 1 year. NNG had spent millions of dollars since building the original structure, trying to protect the structure from knickpoint migration. NNG had given up on the structure and was planning on re-drilling their pipelines under the stream to a greater depth, at a cost of $2.4 million, and allowing their structure to fail.

In 2002, the HCA became aware of the problem and knew that allowing the structure to fail would destabilize Walnut Creek upstream from the structure, endangering 23 bridges and hundreds of hectares of farmland. The HCA and NNG began discussing how the site could be stabilized. An agreement was reached in which the HCA provided technical assistance and coordinated repair of the existing NNG grade control structure and construction of three new GCS downstream. Repair work was completed in spring of 2004 (Fig. 7E), at a total cost of about $68,000, and construction of the three new GCS (Fig. 7F-H) were completed in spring of 2005 at a total cost of about $372,000. NNG and HCA paid for $358,000 and $82,000, respectively. The project saved NNG and its customers over $2 million. NNG has repeatedly expressed their appreciation for the HCA's assistance and has begun modifying more of their GCS throughout the Midwest in accordance with what they learned in western Iowa.

HCA RESEARCH PROJECTS

Controlling Erosion While Allowing Fish Migration

The HCA has been working with the Iowa Department of Natural Resources (DNR) to design and construct weirs that will allow fish to migrate upstream yet be cost effective to construct. Streams were prioritized for importance of fish, such as catfish, to be able to migrate up and down. A proposed GCS design for fish passage, consisting of a 1:20 or 1:15 (rise/run), grouted rock slope downstream from a V-notch sheet pile weir was agreed upon and several existing weir structures were modified to this design. Before and after the modifications, the DNR and the Natural Resource Ecology and Management Department at Iowa State University caught, tagged, and released fish from above and below the weirs (Larson et al., 2004; Litvan, 2006; Litvan, et al., 2008a-c). The major results of these studies were: 1) catfish were documented moving over the 1:15 weirs, 2) fish communities were slightly better (5%) near the weirs compared with reaches without weirs, and 3) macroinvertebrate abundance and diversity was 60% greater near the weirs compared to reaches without weirs. A second study, performed by the University of Iowa's IIHR–Hydroscience and Engineering Department, measured velocities on different weir backslopes and performed modeling of different weir slopes to optimize for channel catfish migration while reducing flow velocities, slope lengths, and costs (Papanicolaou and Dermisis, 2006; Papanicolaou and Dermisis, in press). The variable controlling fish passage was either the flow depth or maximum velocity, dependent on the drainage area. Both 1:20 and 1:15 weirs allowed fish passage, however, 1:15 was recommended because it was less expensive. This subject is discussed in much greater detail in an accompanying paper in these proceedings entitled "Fish Passage and Abundance around Grade Control Structures on Incised Streams" by Thomas, et al.

Top: Figure 8. Scrap tire project designed like a weir.
Bottom: Figure 9. Scrap tire project designed like a toewall.

Using Scrap Tires in GCS

The HCA has built two experimental GCS with scrap tires (Fig. 8-9). Scrap tires are difficult to recycle and often reduce landfill capacity. Theoretical and experimental research was done by Iowa State University followed by construction of the prototype weirs with the help of the NRCS and landowners. Scrap tires were arranged in layers, bolted together with lag screws, and filled with flowable concrete grout. A design manual which described construction technique and evaluated its cost, effectiveness, and structural stability compared to traditional grade control structure designs and materials was disseminated to county engineers and NRCS offices in western Iowa so similar structures may be built.

Aerial Stream Classification

The HCA has conducted an aerial assessment and classification of streams in the deep loess region of western Iowa (Fig. 10) to determine areas of active stream erosion and the impact GCS have on controlling stream degradation (Thomas and Cutler, 2003). Upon encountering locations of extremely erosive streams and threatened bridges, responsible county/agencies were notified. The stream assessment consisted of flying along streams in a small helicopter while videotaping the stream channel and recording positions with a global positioning system receiver. Streams were classified based on a six-stage channel evolution model to describe the dominant channel processes occurring along stream reaches. Streams across the region in 1993 and 1994, and in a smaller area in 2000, were similarly classified. Comparison of the recent classification to those of the past allows us to describe how GCS have impacted the streams and make predictions as to

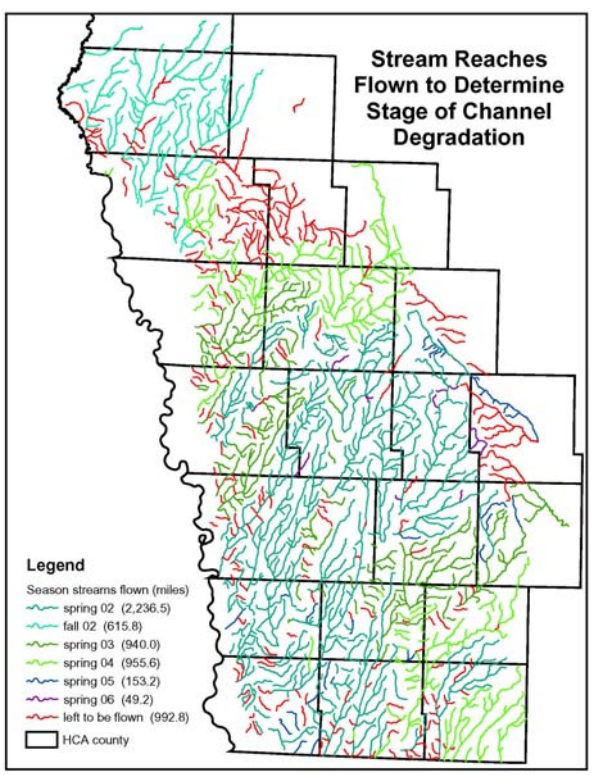

Figure 10. Stream reaches flown to determine the stage of channel evolution.

where future stream erosion will occur. Approximately 9,560 km of stream in 22 western Iowa counties will be classified during the 2002-2010 project. Videos and maps are made available to county engineers and NRCS offices for stream stabilization project planning.

Experimental Bored Headcut Basin Projects

Some gullies in the deep loess soils of western Iowa, especially in the loess hills region, can be very deep, reaching depths of approximately 21.3 m, with near-vertical headcuts and side walls (Fig. 11). Primary deposits of loess soil are highly erodible and unstable when wet, but unlike other types of sediment deposits, they are very stable when vertical and dry. Gullies expand and erode upstream during rain events due to surface runoff, entering the gully via the headcut, and due to groundwater flow, entering the gully at the base of near-vertical walls, both of which de-stabilize the gully walls causing bank collapse. Runoff then carries away the collapsed bank debris, preparing the walls again for collapse.

Stabilization or control techniques are limited to pipe-drop structures, but associated fill of the gully and excavation of a core trench in an area of such high relief makes these types of structures often cost-prohibitive, and definitely not cost-effective. The HCA is experimenting with the use of directional drilling techniques to bore at an angle through the primary loess soil from upstream of the headcut to the base of the gully wall. A plastic PVC pipe is inserted into the borehole and the bentonite slurry, used to drill the hole, acts as the sealant that makes the borehole watertight as it dries. A vertical PVC riser is added to the angled pipe to serve as an inlet. A water-retention basin is excavated upstream of the inlet, and a terrace is built downstream of the inlet, between the inlet and the headcut (Fig. 12). The basin allows a larger storm event to be controlled by a smaller pipe. No work is done in the gully and there is no filling of the gully, dramatically reducing earthwork costs. The near-vertical gully headcut will gradually slump to a stable slope over time because collapsed debris will not be carried away by runoff.

Top: Figure 11. The headcut was located at the second fence (behind one in foreground) only five years ago. Bottom: Figure 12. Basin (in which the directional drilling machine sits) built upstream of the terrace (at right) which is built upstream of the gully headcut (out of picture to the right).

The HCA has built three of these experimental Bored Headcut Basin (BHB) structures to control three 9.1-12.2 m deep gully headcuts with small drainage areas (< 6.9 hectares) in the deeply incised small watersheds of the Loess Hills. Non-

terraced sites were chosen to limit the amount of infiltration occurring upstream of the BHB's. Survey and design assistance was provided by the USDA-NRCS. The three BHB's have averaged only $10,560 and have weathered > 76.2 mm rain events without problem. Considering a typical pipe drop structure may have cost as much as $60,000, the BHBT has proven to be very cost-effective. We are continuing to monitor their progress, while planning for future more BHB projects.

Knickpoint Migration Study

An actively eroding stream knickpoint is being monitored closely to: (1) measure knickpoint propagation rates in the field, (2) examine the morphodynamics of actively migrating knickpoints for different flow conditions, and (3) to develop a knickpoint erosion model that is applicable to the deep loess area of western Iowa. An accurate knickpoint erosion model for loess will aid in the placement of future GCS. The study is being conducted by the University of Iowa's IIHR–Hydroscience and Engineering Department and the HCA.

Stage-Discharge Project

There are no gaged (measures water discharge) medium to small sized (≤ 259 km^2 drainage area) streams in western Iowa, which limits our ability to predict erosion. To remedy this, a semi-automatic, permanent, sensor network is being installed on 11 representative, ungaged streams in the deep loess area of Western Iowa. Stage-discharge relationships for these streams will be developed. The project is being implemented by the University of Iowa's IIHR–Hydroscience and Engineering Department, the HCA, and possibly the U.S. Geological Survey.

ABSTRACT

The stream rehabilitation design for Tributary Creek in the Coeur d'Alene National Forest, Shoshone County, Idaho, was performed using the following general design concepts: reference reach selection, stream geometry and slope modifications, evaluation of stream habitat features, and channel stability. The stream rehabilitation used undisturbed reference reaches and the Rosgen method to aid in stream rehabilitation design. An overview of the hydraulic modeling and U.S. Fish and Wildlife Service Habitat Suitability Index (HSI) models for the target species will be presented in addition to design plans.

INTRODUCTION

Tributary Creek is a highly degraded stream located within the Jack Waite Mine and Mill site in the Coeur d'Alene National Forest, Shoshone County, Idaho (see Figure 1). Historic mining activities have disturbed the entire Tributary Creek drainage impacting water quality, geomorphology, and aquatic habitat. The mine operated from 1909 until the early-1960s primarily mining silver, lead, and zinc ore. Four tailings piles (TP-1, TP-2, TP-3, and TP-4) were constructed along Tributary Creek by placing tailings along and over the stream channel (see Figure 2).

The U.S. Environmental Protection Agency (EPA) and the U.S. Forest Service (USFS) are currently implementing mine reclamation activities at the Jack Waite Mine and Mill site under an Action Memorandum. One of the goals of the reclamation activity is long-term aquatic restoration of Tributary Creek. As part of these activities,

the USFS would like to rehabilitate the impaired channel to a "natural" stream channel because the stream is an important Westslope Cutthroat Trout habitat and potential Bull Trout recovery habitat area.

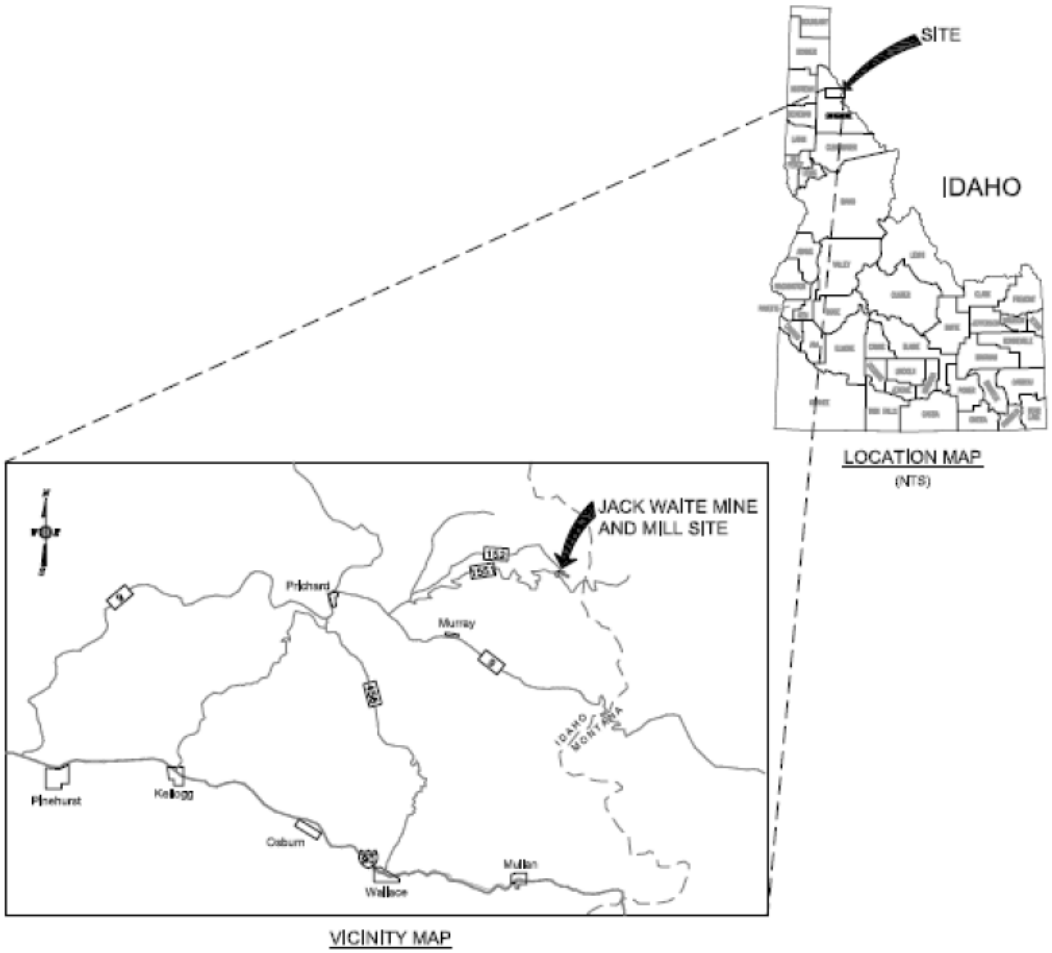

Figure 1. Site Location Map of Jack Waite Mine and Mill Site

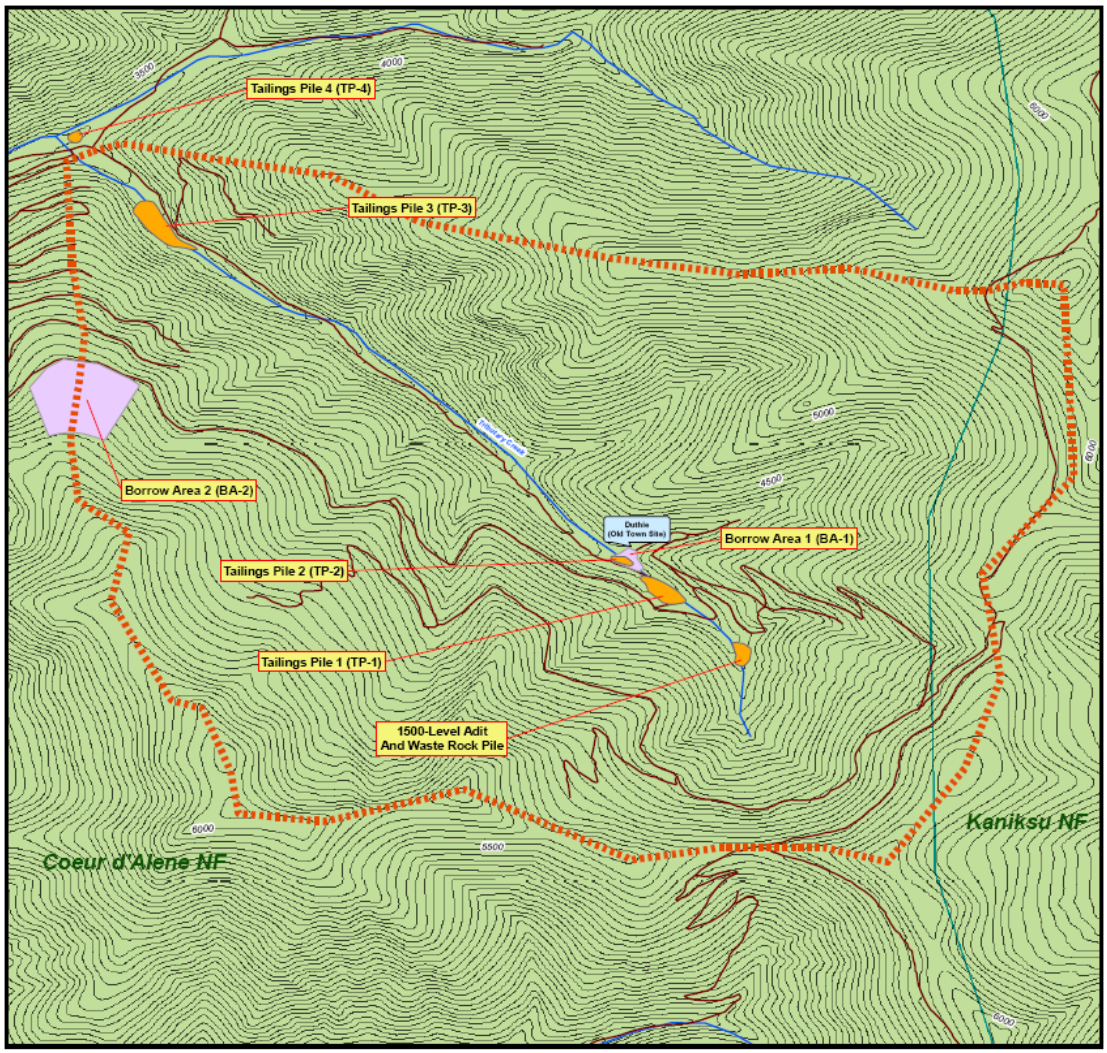

Figure 2. Site Feature Map of Jack Waite Mine and Mill Site

DESIGN APPROACH

The new stream alignment, slope, channel geometry, and in-stream structures of the design reach were determined based on a reference reach downstream of TP-2 (see Figure 2), the Rosgen stream classification method, 1937 aerial photographs, 2007 field photographs and the 2007 aerial photogrammetric and light detection and ranging (LIDAR) survey data.

The major elements of the design approach used for the rehabilitation design included:

1. Reference channel morphological analysis
2. Stream rehabilitation structures
3. Fish habitat design
4. Hydraulic analysis
5. Rock sizing

REFERENCE CHANNEL MORPHOLOGICAL ANALYSIS

The limited spatial extent of the aerial and LIDAR survey data required the selection of a reference reach within the Upper Tributary Creek basin. Therefore, a 1,000-foot reach located downstream of TP-2 was selected as the reference reach. This reference reach was classified according to the Rosgen classification scheme (Rosgen, 1996).

The reference reach was classified as Rosgen A3-type due to the steep slope (~8%), channel geometry (deeply entrenched and confined channel) and channel material (coarse depositional soil). A3-type channel slopes range from 4 to 10 percent and streamflows at bankfull state are typically described as a step-pool, cascading channel, which often stores large amounts of sediment in the pools. The width to depth ratios and entrenchment ratios are low (< 12 and < 1.4, respectively), with low sinuosity (< 1.2). These A3-type channel features were used as stream rehabilitation design criteria (Rosgen 1996).

A new alignment was developed for Upper Tributary Creek because historical information indicated the stream channel was initially located to the east of its current alignment (beneath the current TP-1 location) and curved up at tributary junctions prior to mining activities (see Figure 3). The proposed alignment was determined by inspection of the aerial photos and LIDAR data. Also, the existing stream channel alignment did not follow the natural channel meandering pattern shown in the reference reach and typical of Rosgen A3-type channels.

Following selection of a stream alignment, geometric properties were determined. The proposed stream channel has a width to depth ratio and entrenchment ratio of approximately 9 and 1.2, respectively. The sinuosity for the proposed stream channel is approximately 1.1, which are consistent with Rosgen A3-Type channels.

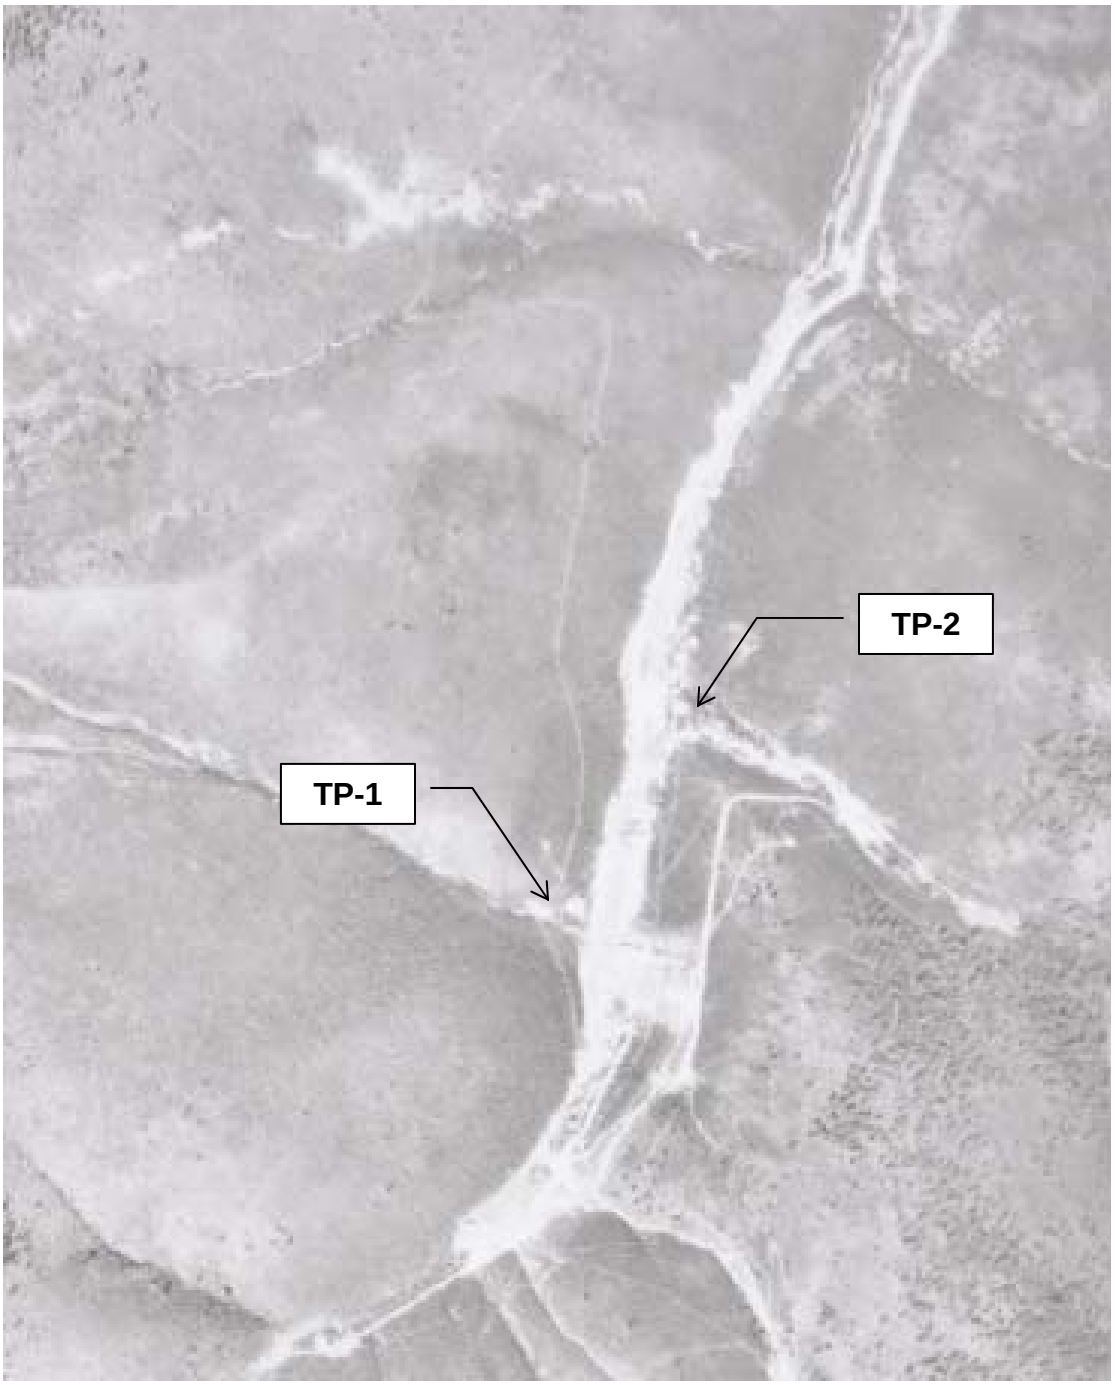

Figure 3. Historical Aerial Photograph – Upper Tributary Creek

STREAM REHABILITATION STRUCTURES

River restoration design guidelines, including Rosgen, recommend the following in-stream structures to create step-pool/riffle-pool sequences. The bed profile of the existing stream channel does not show step-pool sequences; however, the step-pool sequences are shown in the reference reach and are typical of Rosgen A3-type channels. These in-stream structures will recreate critical habitat for native fish species and maintain a desired stream bed elevation. The structures will also stabilize the channel banks.

Rock Vortex Weirs with Downstream Pools

Rock vortex weirs will be installed to create aquatic habitat in the form of scour pools and for grade control, while still maintaining the bed load sediment transport regime of the stream. In addition, the downstream side of the vortex weirs will be excavated by 2- to 3-feet to increase the depth of scour pools required for fish habitat. By shifting the apex of the structure toward one bank or the other, vortex weirs will be used to control the thalweg location through meander bends and prevent bank erosion.

Weirs should point upstream with the arms angling downstream. The angle the arms make with the upstream banks should be approximately 20 to 50 degrees so that flows are directed away from the banks and deeper pool areas are created directly downstream of weirs. The arms are carried up the streambank to just above the bankfull elevation. Rock vortex weirs are constructed first by placing a foundation of boulders (footer rocks) two to three feet in size in a trench excavated along the stream bottom. Large rocks (vortex rocks) are then placed in the trench behind and against the footer rocks so that they extend up to the desired elevation. The key component of rock vortex weirs is that the vortex rocks do not touch each other with the exception of the end rocks. Most design details call for spacing the vortex rocks 1/3 and 1/2 a rock diameter apart. The overall drop controlled by the weir should be less than 2 feet for stability reason (Maryland 2000).

Root Wad Revetments

Root wad revetments will be installed at outer bends of the stream to prevent stream bank erosion by directing the flow away from the outer bank. The root wads will also trap sediment between revetments and create in-stream habitat structure for fish spawning and rearing.

Footer logs should be positioned in the trench below the stream invert such that each upstream log is shingled over its downstream neighbor. The root mass should be oriented perpendicularly to the direction of flow. An angle of 30 to 60 degrees to the channel center line is usually adequate. The root wad revetment should be backfilled, and fill material should be tightly packed in the joints, connections, and gaps to firmly secure all components. Stone may be necessary on flashy stream (Maryland 2000).

Toe Protection

Two tributaries join Upper Tributary Creek within the rehabilitation reach. At junctions with the tributaries, flexible and/or rigid protection will be installed to reinforce bank

toes and protect against bank erosion. Types of protection include vegetation, bioengineered materials, and riprap.

Step-Pool Sequences

Step-pool sequences will be constructed in steep reaches for grade control and the creation of aquatic habitat through flow diversification. Step-pool sequences are characterized by a succession of channel-spanning steps formed by large grouped boulders that separate pools containing finer bed sediments. As higher velocity flow tumbles over the step, energy is dissipated in roller eddies causing lower velocity flow within the downstream plunge pool. Typical spacing for pools is 1 to 4 times of channel width.

Step rocks shall be placed on footer rocks so that they rest on two halves of each footer rock below, and so that the step rock is offset in the upstream direction. Footer rocks should extend below the scour hole elevation (Maryland 2000).

Stream Crossings (Modified Newbury Riffles)

USFS Road #152 crosses the existing alignment of Upper Tributary Creek at six culvert locations. The rehabilitation design removes all six culverts. Under the rehabilitation design, USFS Road #152 crosses the proposed stream alignment at only two locations. In place of culverts, modified Newbury Riffles will be constructed to provide stream crossings for vehicles while facilitating the natural passage of fish. According to the typical Newbury Riffle design (see Figure 4: Newbury and Gaboury 1993), the downstream slope is very gradual at 20H:1V while the upstream slope is steeper at 4H:1V. However, due to the steep slopes of the design reach, the downstream slope of 10H:1V was used. Also, the typical Newbury Riffle does not include a top crest width; however in this channel design, a top crest width of 20 feet was used to provide stream crossings for vehicles.

Newbury Riffle substrate is composed of gravels, cobbles and boulders. Riffle height generally runs 1 to 3 feet. On the crest and downstream face of the riffle, large boulders are placed to create a range of chutes between them, which are observed in the natural riffles. These boulders create locally-varied flow conditions. Hydraulic jumps and aeration zones occur in different areas on the riffle surface as the water stage rises and falls. At the lowest stages, the flow dwindles into two or three smaller channels crossing the riffle surface between the large boulders. Therefore, to create this kind of natural varied flow conditions, large boulders should be placed randomly or close to natural riffle conditions.

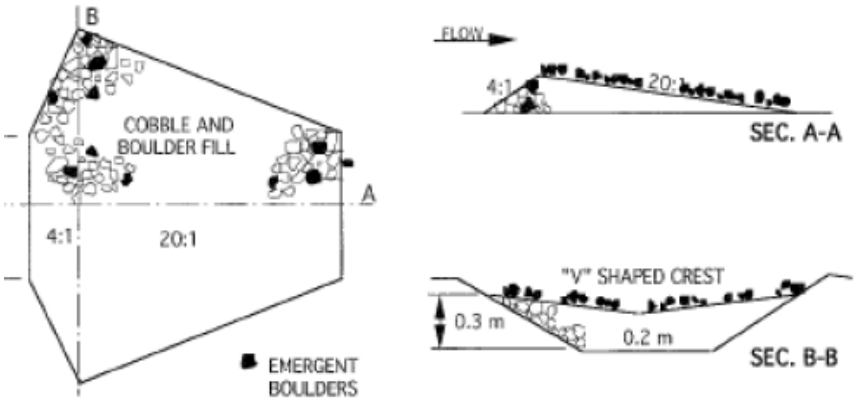

Figure 4. Newbury Riffle typical plan view (Newbury and Gaboury, 1993)

FISH HABITAT DESIGN

The rehabilitation design includes design of fish habitat to improve available fish habitat for target fish species in Tributary Creek. The USFS Idaho Panhandle National Forests identified the West Slope Cutthroat Trout as the target species with long term restorative goals of targeting Bull Trout.

To find the relationship between in-stream habitat area and channel hydraulic parameters, U.S. Fish and Wildlife Service (USFWS) Habitat Suitability Index (HSI) models were reviewed. HSI models were available for three trout species; Cutthroat, Brook and Rainbow Trout (USFWS 1982a;1982b;1984). A Bull Trout HSI was not available. Suitability index graphs of these three species were compared to determine the most appropriate habitat conditions. The comparison found that these three species have the same optimum suitability conditions for the following variables:

1. Average thalweg depth during the late growing season low water period > 30 cm (1.0 ft) for stream width ≤ 5 m (16.4 ft)
2. Average thalweg depth during the late growing season low water period > 45 cm (1.5 ft) for stream width > 5 m (16.4 ft)
3. 30 cm/sec (1 ft/sec) < Average velocity over spawning areas during embryo development < 60 cm/sec (2 ft/sec)
4. Pool class rating during the late growing season low flow period (Aug-Oct): ≥ 30% of the area is comprised of first-class pools (First-class pool: the greatest pool depth ≥ 1.5 m (4.9 ft) in streams ≤ 5 m (16.4 ft) wide or ≥ 2 m (6.6 ft) in streams > 5 m (16.4 ft) wide)

The rehabilitation design incorporates these variables through the in-stream structures mentioned above.

HYDRAULIC ANALYSIS

To evaluate the designed fish habitat, a HEC-RAS model (USACE 2005) was constructed for the existing and proposed stream. The model was run for 2-, 5-, 10-, 25-, 50-, and 100-year peak discharges. Due to the absence of measured flow data, these peak discharges were estimated using U.S. Geologic Survey (USGS) regionalized flood-frequency equations for Idaho (USGS 2002). The standard errors of these USGS equations range from 60 percent to 69 percent. Therefore, to consider these errors associated with these equations, the calculated discharges were increased by the standard errors. Table 1 presents estimated peak discharges.

Table 1. Estimated Peak Discharges

	For Tributary Creek above TP1		For Tributary to Tributary Creek above Duthie	
Frequency	Calculated (cfs)	Increased by SE (cfs)	Calculated (cfs)	Increased by SE (cfs)
2-year	27.5	44.0	17.5	28.1
5-year	40.7	65.2	26.1	41.8
10-year	50.8	81.9	32.6	52.6
25-year	63.9	104.8	41.2	67.5
50-year	73.5	122.1	47.4	78.7
100-year	83.7	141.0	54.0	91.0

The maximum flow depths and velocities were calculated by the HEC-RAS model for each of peak discharges. Figures 5 and 6 present 100-year discharge water surface profiles of the existing and proposed conditions, respectively. The output from the HEC-RAS model is summarized in Attachment B. The calculated values were used to evaluate the change in HSI habitat variables between the existing and proposed stream. The discharge of the late growing season low flow period was estimated as the 2-year discharge (44 cfs) since flow data was not available.

A comparison of the existing and proposed stream flow depths illustrates the reach length where the maximum flow depth is greater than 2 feet increases from 50 feet to 265 feet (see Table 2). The increase shows the creation of more pool habitat area. Also, the reach length having maximum flow depth greater than 2.5 feet and 3 feet increases from 0 feet to 85 feet and from 0 feet to 30 feet, respectively. The reach length having flow velocity between 1 and 1.5 ft/sec, which is the optimum velocity range for the trout spawning area during embryo development, increases from 0 feet to 90 feet.

Table 2. Comparison of Predicted Habitat Parameters

	Reach length that the maximum flow depth is greater than			Reach length that the flow velocity is between 1 and 1.5 ft/sec
	3 ft	2.5 ft	2 ft	
Existing	0 ft	0 ft	50 ft	0 ft
Proposed	30 ft	85 ft	265 ft	90 ft

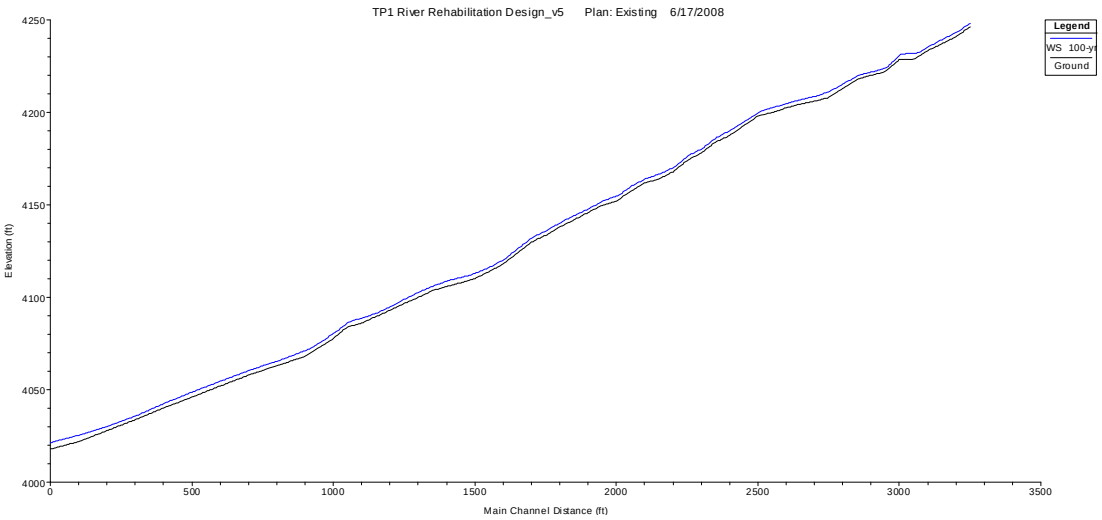

Figure 5. Water surface profile of existing conditions model (100-year discharge)

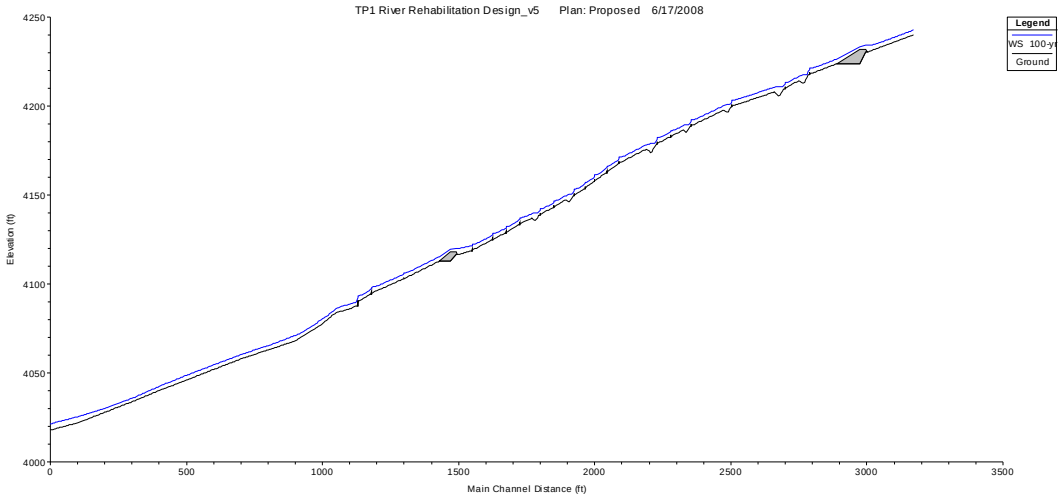

Figure 6. Water surface profile of proposed conditions model (100-year discharge)

ROCK SIZING

Rock for vortex weirs and stream crossings was sized to be stable at the 100-year peak discharge, which was estimated at 141 cfs. The USFS recommends 24 inch diameter boulders for construction of the vortex weirs. The stream crossings generally requires cobble-sized rock. The USACE riprap design program, CHANLPRO was used to determined the rock size required for the vortex weirs and stream crossings (USACE 1999).

The maximum flow velocity and depth overtopping the weirs and stream crossings were calculated from the HEC-RAS model, and CHANLPRO was run for these values. As shown in Attachment C, D_{100}(max) = 9 inches was suggested for both the vortex weirs and stream crossings. However, USACE riprap gradation D_{100}(max) = 18 inches (D_{50}(max) = 12 inches), which is specified in Specification 02380 RIPRAP (Table 3), was selected for the stream crossings. 24-inch boulders was selected as the appropriate size for the vortex weirs based on the USFS designs.

Table 3. Gradation for Riprap Placement (USACE 1994)

Limits of Stone Weight in Pounds for Percent Lighter by Weight								
D_{max} in inches	D_{100}		D_{50}		D_{15}		$D_{30(min)}$ in inches	$D_{90(min)}$ in inches
	Max	Min	Max	Min	Max	Min		
9	36	15	11	7	5	2	5	7
18	292	117	86	58	43	18	9	13
24	691	276	205	138	102	43	12	17

Specific weight of stone = 165 lbs/cu ft

ABSTRACT

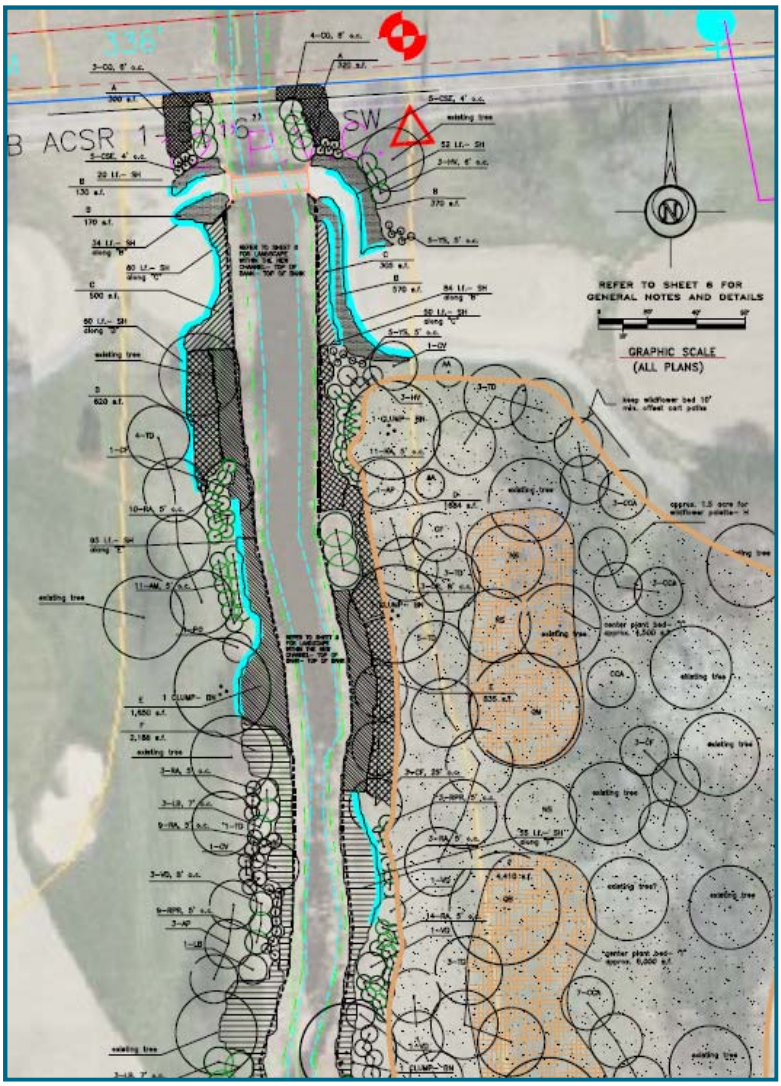
Keywords: stream restoration, phosphorus, removal cost, TMDL

One of the many appealing features of the Ozarks is the quality and beauty of our lakes and streams. Frequent algae blooms in the James River arm of Table Rock Lake however threatened not only valuable tourism dollars but also the quality of Ozark life. A nutrient based TMDL focusing on phosphorus and nitrogen was adopted for the James River in 2002. As we move into implementation, the question of the most cost effective method to reduce phosphorus loads is paramount. This paper compares the local cost of phosphorus removal from point sources as well as non-point sources. Specific Ozarks examples investigated included phosphorus reduction from a waste water treatment plant, stormwater BMP's, stream buffers and stream stabilization. The paper findings indicate Stream restoration is an excellent solution to preventing this phosphorus from being transferred to Ozark lakes and is cost efficient when compared to other non-point source reduction strategies. This paper briefly introduces the audience to many other economic benefits to stream restoration such as flood attenuation, greenways trails, and home price increase.

1.0 Introduction

As the Ozark's see increased development, area streams are beginning to show the telltale signs of urbanization. One common impact from urbanization is accelerated stream bank erosion.

Picture 1. Bank erosion threatening an Ozark condominium building (2008 photograph by Olsson)



Stream and bank erosion liberates a tremendous amount of sediment and causes the loss of property. The City of Springfield and Greene County are making progress toward restoring degraded streams. As part of Springfield's stormwater management plan, the city began daylighting Jordan Creek. This project removes drainage tunnels and reconstructs the stream corridor. The daylighted area also features a greenway trail connecting two parks.

Picture 2. Jordan Creek Daylighting Project (Springfield MS4 Report, 2007). This entire portion was previously in an undersized box culvert. Small fish are now prevalent in the base flow stream, and the trail system is heavily used.

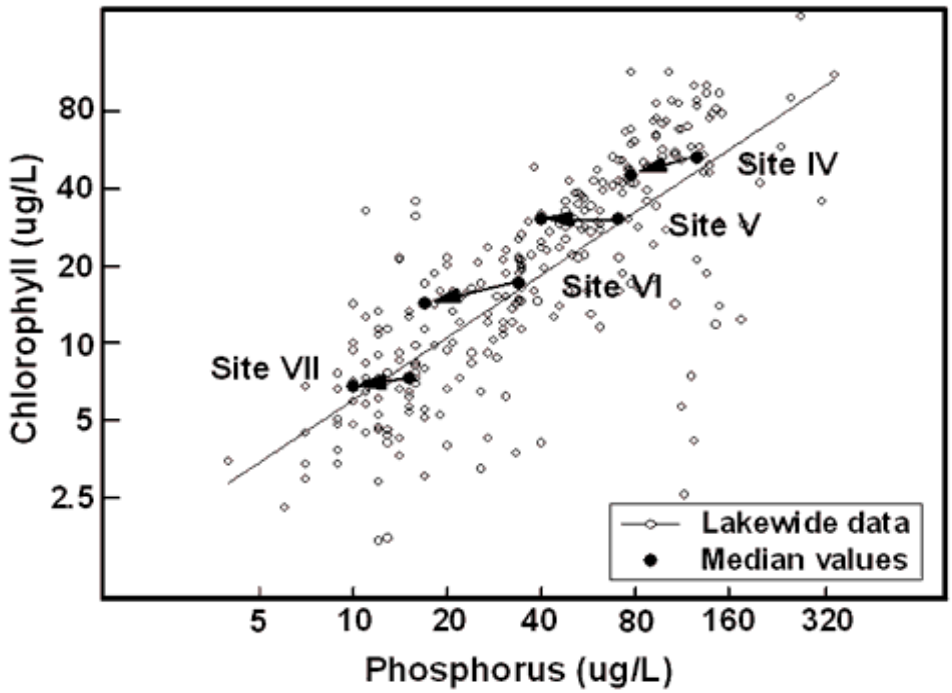
Greene County completed a stream restoration project in 2007, stabilizing Ward Branch using geomorphic and bioengineering approaches instead of concrete. This project was 1,289 feet long, made extensive use of native plantings, and, in the future,

will incorporate a greenway trail. The cost for restoring Ward Branch was $347,000 or $269 per linear foot.

Picture 3. Map of Ward Branch restoration project. Located adjacent to Twin Oaks Country Club Golf Course in southern Springfield, the stream bank was heavily eroded and contributed to phosphorus pollution in James River.

Using Ward Branch as an example, at a cost of $269 per linear foot, is it worth stabilizing the Ozark streams? This paper presents some of the economic impacts from not stabilizing the Ozark streams. The discussion focuses mainly on phosphorus (P) impacts and costs, but some of the benefits associated with a stable greenway are also considered. Local studies and local examples are used when possible and are compared to national data.

2.0 Background



2.1 Impact of Phosphorus (P) on Water Quality

P is a particular concern because many of the Ozark's waterways and lakes are P limited (DNR 2001 TMDL). Nutrient loading analysis typically focuses on either P or nitrogen, depending on which is the limiting factor in a water body. A nitrogen to P ratio of greater than 10:1 indicates that the water body is P limited and vice versa. Stating that the nutrient is "limited" does not mean that there isn't much of it; it means that it will limit the total productivity of the water body. The following table shows published Nitrogen Limiting Thresholds taken from the DNR Total Maximum Daily Load (TMDL) for James River:

Table 1. Nitrogen:Phosphorus limiting thresholds

Information Source	N Limiting Threshold	Transition	P Limiting Threshold
Schanz and Juon (1983)	<10:1	10:1-20:1	>20:1
Petersen et al. (1993)			>20:1
Stockner and Shortreed (1978)			>20;1
Pringle (1987)	<10:1		
Grimm and Fisher (1986)	<10:1		
Dodds et al. (1998)	<12.6:1		
Borchardt (1996)			>17:1
Lohman (1988)	<12:1		

The high sediment trap efficiencies of lakes cause them to become sinks for pollutants. In addition, through sedimentation and anaerobic digestion, P can be recycled through the water column. Dissolved P is quickly utilized by algae, macrophyte, and epyphite communities for increased cellular growth. The resulting biomass shades out larger plants and benthic micro-algae or macrophytes. Picture 4 shows the relation between P and algal chlorophyll a. The implication of this relationship is that every pound of P can sustain approximately 200 lbs of biomass when all other nutrients are abundant. In comparison, one pound of nitrogen can only support 12.5 lbs of biomass (CE-QUAL, 1995).

Picture 4. Graph showing relation between chlorophyll and total phosphorus concentrations in Table Rock Lake.

2.2 Table Rock Lake Eutrophication

In the 1990s, the James River Arm of Table Rock Lake, located near Branson, Missouri, started experiencing frequent algae blooms. This high dollar tourism location was well known for its crystal clear water, and the algae blooms became a stark reminder that a lake's water quality is a reflection of its watershed and streams. In the James River Basin, tourism brings over $900 million per year to the local economies (DNR TMDL 2001). Local officials and businesses understood the potential impact of poor water quality on the local economy. This led the Table Rock Lake/Kimberling City Area Chamber of Commerce to form the corporation Table Rock Lake Water Quality, Inc. in 1998. The Chamber's board of directors recognized that improving and preserving Table Rock Lake's water quality was vitally important. They concluded that the corporation would be an action group dedicated to projects that would stop pollution resulting from non-point sources such as nutrient enrichment, bacterial contamination, and contamination from point sources. This group was instrumental in formalizing and implementing the James River TMDL.

Picture 5. Table Rock Lake (algae bloom of 1999 in the James River Arm of Table Rock Lake – Missouri DNR photo).

Water quality studies performed as far back as 1969 have indicated that high nutrient loads existed in the James River. In May of 2001, the James River TMDL of 0.075 mg/L of P and 1.5 mg/L of in-stream total nitrogen was approved. The first phase of the TMDL implementation plan focuses on point sources. A P limit of 0.5 mg/L was imposed on all point sources discharging greater than or equal to 22,500 gallons per day. A major result of this first phase was the 2001 improvement to the City of Springfield Southwest Treatment Plant to reduce average P discharge to 0.5 mg/L.

The second phase of the TMDL (Total Maximum Daily Load) focuses on non-point sources and relies on riparian corridor restoration, Best Management Practices (BMPs), septic tank cleanouts, and soil testing. The City of Springfield's Stormwater Management Plan has been put into place and has helped by upgrading/creating stormwater treatment in addition to performing full spectrum detention, acquiring floodplain areas, cleaning streets, and improving the de-icing procedures. The James River Basin Partnership and the Watershed Committee of the Ozarks have also helped by contributing volunteer time, organizing cleanups, educating the public, and managing grant funds. The following chart from the DNR's TMDL Data Sheet shows the difference in P loads before the TMDL and after the combined point and non-point source controls have been partially implemented:

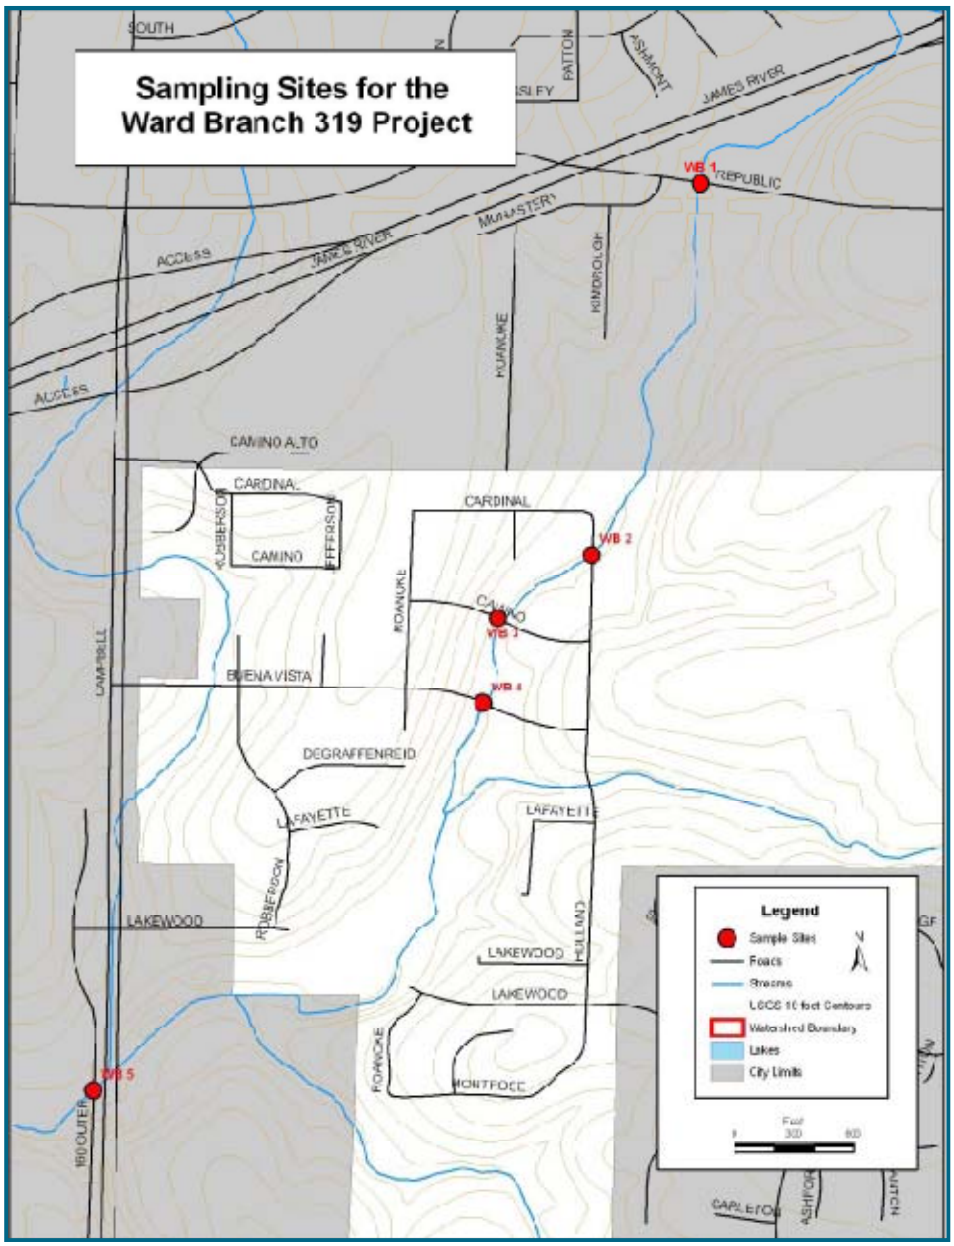


Table 2. James River TMDL

Mean Nutrient Levels for Two Locations on James River Comparing Data from 1999 to 2003 (in mg/L)				
Nutrient	**James R. near Boaz**		**James R. at Galena**	
	1999	**2003**	**1999**	**2003**
Total P	0.62	0.15	0.51	0.21

The dramatic reduction in P is notable but is largely a result of improvements at the wastewater treatment plant. Non-point sources of P, however, are much more elusive to treat. According to the TMDL for the James River Basin, 0.033 to 0.06 tons/acre/year of sediment is released from stream bank erosion. The amounts of sediment that can be liberated from modest reaches of streams are extensive. The rate of erosion found at Ward Branch produced 77 tons of soil liberated in eight months from only a 1,000-foot long stretch (OEWRI, 2007).

2.3 Phosphorus (P) Loaded Stream Banks

Fine-grain sediment in alluvial deposited stream banks is laden with nutrients such as P. This is not a surprise; the agricultural community has long valued the highly productive floodplain bottoms. Research performed by Iowa State University (Moeller, Kovar, Russell, and Haan, 2006) has found that total P concentrations of 200-to-500 mg/kg were common in grazing land in Colorado. Soil testing performed by Missouri State University on Ward Branch Stream in Green County, Missouri, has found a similar range of total P. The average P found in the stream banks was 400 mg/kg (0.035 lbs of P per cubic foot of bank material). This implies that even minor amounts of stream bank erosion have a large potential to release P into the stream and ultimately into sensitive water bodies such as Table Rock Lake.

Picture 6. Sampling sites for Ward Branch (OEWRI, 2007)

Using the averages mentioned above for the Ward Branch Study, it was estimated that erosion would liberate 93 lbs of P per 1,000 feet of channel per year. Testing found that the total P load in the stream was 175 lbs/year, so this bank alone contributed 53 percent of the P load in the stream.

The Ward Branch findings on the volume of sediment generated from stream banks are not the only such findings. Based on reservoir water quality studies performed by Olsson Associates in Nebraska, 20-to30 percent of sediment and nutrients are from stream bank erosion (Cunningham, 2003). Studies on San Diego Creek in suburban Los Angeles found that over 60 percent of the

sediment resulted from channel erosion (Trimble, 1997). Likewise, a study on Goodwin Creek in northern Mississippi found that better than 80 percent of the total sediment yield originated as channel and gully erosion (Grissinger, 1990). A study of a channelized stream in Illinois found that one storm eroded as much as 1,150 tons of soil from a single bank in 1982 (Roseboom and Russell, 1985). The amounts of sediment liberated from stream banks can be greatly increased as a result of channelization, urbanization, and widespread stream instabilities such as incision (head cuts).

A link exists between the riparian buffers and stream bank stabilization. A study of 748 stream bends found that 67 percent of bends without vegetation suffered erosion during a storm, while only 14 percent of bends with vegetation were eroded (Beeson and Doyle 1995). Keep in mind, the bank erosion potentially could have removed the vegetation rather than the de-nuded banks causing the erosion. Nevertheless, this 1995 study makes it clear that bends void of vegetation are 30 times more likely to erode.

Studies have shown that P removal has been measured along a healthy stream segment (Watson, 2001). Unhealthy or deforested riparian areas cause channel narrowing, which reduces the total amount of stream habitat and ecosystem per-unit channel length and compromises in-stream processing of pollutants (Sweeny, et al., 2004). Sweeny has suggested, "Forested stream channels have a wider and more natural configuration, which significantly affects the total in-stream amount and activity of the ecosystem, including the processing of pollutants. Riparian corridors and grass filter strips work together to cause sedimentation of clay particles containing phosphorus and to slow the water as it enters the stream. The woody vegetation further assists in stream bank stabilization. These results reinforce current policies used in the U.S. to incentivize riparian buffers as BMPs resulting in re-forestation for stream restoration and water-quality." A forest and grass buffer combination not only reduces non-point source pollutants from entering streams; they also enhance the in-stream processing of both non-point and point source pollutants, thereby reducing their impact on downstream rivers and impoundments (Welsch, 1991, Lowrance, 1997). This in-stream P processing further improves the cost efficiency for stream restoration.

2.4 Other Non-Point Sources of Phosphorus (P)

The point source wastewater treatment plants are only one of the many sources of P to our streams. Urban runoff contains a considerable amount of non-point P. Table 3 breaks down sources of P pollution from an area in Marquette, Michigan (Steuer, Selbig, Hornewer, and Prey, 1997). The table also summarizes event mean concentrations in runoff from residential and commercial areas completed by the Watershed Committee of the Ozarks on Pierson Creek. Pierson Creek is located along the eastern edge of Springfield, Missouri. The 1994 Pierson Creek study sampled runoff downstream from a

general residential or commercial area, so the land use was not itemized as discreetly as the Michigan study.

Table 3. Sources of phosphorus in urban areas from various data sources.

Source Area Sampled	Michigan Study Total P (mg/l)	Pierson Creek Study Total P (mg/l)	NURP Data (mg/l)
Commercial Parking Lot	0.2	0.281	0.201
High Traffic Street	0.31	-	
Medium Traffic Street	0.23	-	
Low Traffic Street	0.14	-	
Commercial Rooftop	0.09	-	
Residential Rooftop	0.06	0.40	0.383
Residential Driveway	0.35		
Residential Lawns	2.33		
Basin Outfall	0.29		

Based on the MS4 monitoring being performed by the City of Springfield in areas of the community that do not have water quality stormwater treatment, total P concentrations range from 0.05 mg/L to 0.8 mg/L, with an average of 0.26 mg/L, which compares favorably to the Michigan study. The Michigan study and the Nationwide Urban Runoff Program (NURP) data have focused on these urban sources, but many of these studies neglect stream bank erosion sources of P.

The City of Springfield has begun a notable stormwater treatment program for all new developments over one acre in size. The water quality storm of one inch must be treated using systems such as rain gardens, bioswales, extended detention, filter strips, porous concrete, and several other mechanisms to decrease the water quality impairments to our streams. Watershed groups in the area are working hard to reduce the amount of P and other stormwater pollutants from entering streams. The James River Basin Partnership sponsored the 2006 James River Watershed 319 Project. This $3.1 million project created a variety of BMPs, including riparian corridor restoration, septic tank cleanout, urban and agricultural soil testing, and educational/outreach programs. The Watershed Committee of the Ozarks is currently working with the City of Springfield to install storm water education signage at key locations around the city. In addition, the Watershed Center at Valley Water Mill is being developed as an educational showpiece for a variety of water quality BMPs.

3.0 Phosphorus (P) Removal Costs

The impacts of hyper utrophic conditions caused by excess P are well documented, but what about the costs to remove P from Ozark waterways? P enters our water from both point and non-point sources. This section will discuss an Ozark's example on the costs of P removal from a point source and will also discuss the costs of non-point source P removal using stormwater BMPs.

3.1 Point Source Phosphorus (P) Removal Costs

Point source pollution can contribute a high percentage of P to our water, but our research indicates it is much cheaper to reduce the amount of P being discharged from point sources than non-point sources. In response to the imposed TMDL on James River and the algae blooms on Table Rock Lake, the Springfield Southwest Treatment Plant performed treatment upgrades to decrease P discharges into the James River. The upgrade began in 1997 and was completed March of 2001. The project cost was $2.2 million and involved installing an alum treatment system. The most recent project followed a 1993 project, which also reduced the discharge concentrations of P.

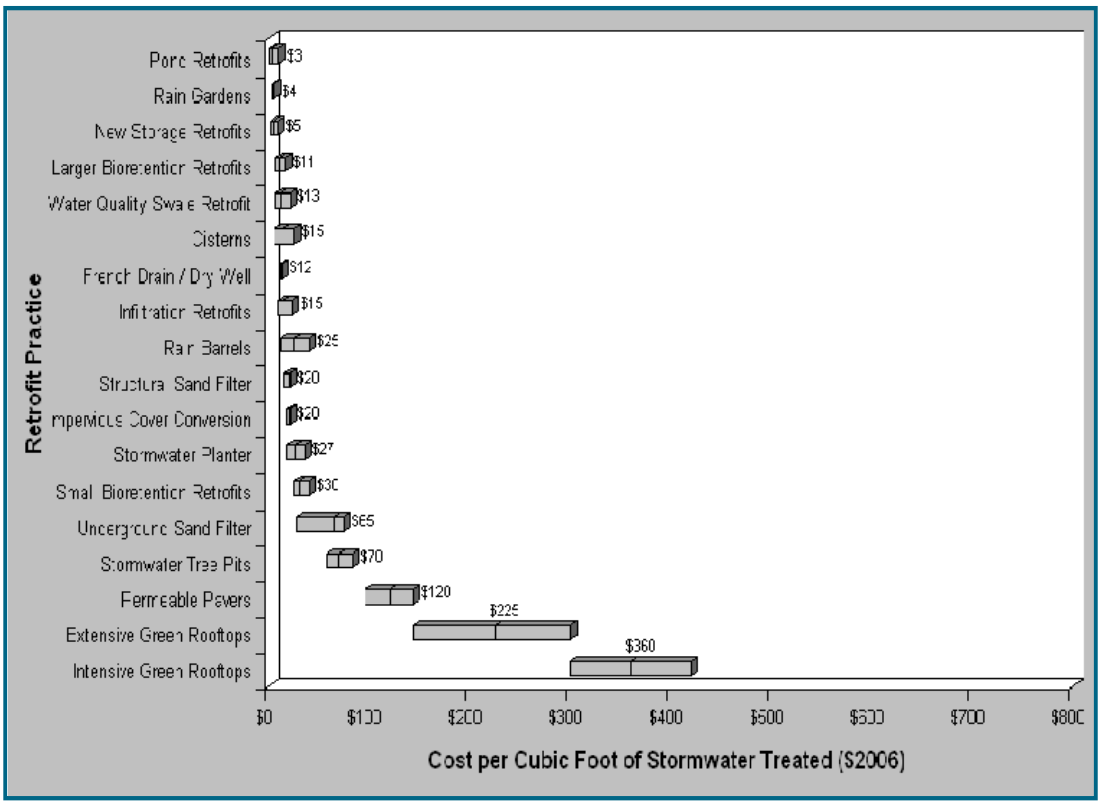

Table 4. Wastewater treatment plant upgrades and the associated pre and post total phosphorus discharges to Wilson Creek.

Southwest Treatment Plant Upgrade	Completion Date	Cost	Post-Upgrade Avg. Lbs of P to Creek	Prior Avg. Lbs of P to Creek
Plant Expansion	1993	$30 million	850 lbs/day	1,650 lbs/day
Alum Treatment	2001	$2.2 million	110 lbs/day	850 lbs/day

Including the operation and maintenance cost of the alum system, the cost for P removal at the treatment plant, due to the 2001 upgrade, resulted in approximately $4.60 per pound of P removed per year, assuming a 50-year life cycle and including an estimated O&M cost of 54 percent of construction.

3.2 Non-Point Source Stormwater BMP Phosphorus (P) Removal Costs

Olsson Associates and Wright Water Engineers recently completed a stormwater BMP retrofit cost analysis study for Overland Park, Kansas. We specifically evaluated the costs associated with constructing and maintaining various non-point source pollution treatment methods. The cost for these systems varied but is generally summarized in Picture 7.

Picture 7. Graph of BMP Cost (Olsson, 2007)

Based on the monitoring being performed by the City of Springfield in areas of the community that do not have water quality stormwater treatment, total P concentrations range from 0.05 mg/L to 0.8 mg/L, with an average of 0.26 mg/L (City of Springfield, 2007). Mean average cost was used from the graph above for a BMP of $10 per cubic foot for a 50-acre development site, which gives a total BMP cost of $1.12 million (including 4.5 percent operation and maintenance costs). BMPs all have varying percent removal rates for P, which range from zero percent for green roofs, 15 percent for grass channels, and up to 75 percent removal for wetlands (EPA, 1999). We should note that an increasing amount of data has been suggesting the removal efficiency of BMPs that may not be the most appropriate measure used in designing these systems due to the variability of inflow concentrations and a practical lower limit of removal. For simplicity, we are using a 40 percent removal rate for an average inflow concentration of 0.26 mg/L P. Using these inflow and removal rates, the BMPs would cost $466 per pound of P removed per year (EPA, 1999). Some agricultural BMPs are cheaper, such as terracing. These BMPs result in average costs of $185 per pound of P removed per year (Tippett, 1995).

3.3 Cost of Stream Stabilization Using Geomorphic and Bioengineering Approaches

National data indicates a wide range in costs for stream stabilization, from $42 per linear foot to as much as $1,000 per linear foot (especially for daylighting culverts). Projects performed by Olsson Associates in Nebraska, Kansas, and Missouri have found a range of costs from $260 per linear foot to $350 per linear foot. The Ward Branch stabilization in Greene County resulted in a cost of $269 per linear foot. Assuming a 4.5 percent operation and maintenance cost, the total cost for 1,000 feet of stream would be $874,250. In 1,000 feet of stream channel on Ward Branch, MSU measured 93 lbs of total P being exported per year from bank erosion. For Ward Branch, the cost in terms of the amount of total P prevented was $188 per pound annually for a 50-year life cycle.

It should be pointed out that these approaches do not completely eliminate stream bank erosion. Natural systems in dynamic equilibrium will migrate over time, and sediment will be liberated and subsequently deposited so that the net transport out of the system balances with the net sediment inflow rate.

Picture 8. Before and after stream restoration done by Newbury Hydraulics – Waukegan Brook – Washington Park, Michigan: 1991 before restoration (left), and three years post-construction in 1995 (right).

One approach historically taken to reduce stream bank erosion is to concrete line or enclose the stream. This approach is quite expensive and also reduces environmental benefits. Using lower Ward Branch as an example, the upstream culvert is a 10-by-12-foot concrete box culvert. Assuming this culvert was extended with the same size structure, it would result in a construction cost of nearly $1.6 million ($1,580 per linear foot) for the culvert and fill necessary to the cover 1,000 feet of conduit. This cost does not include permitting costs and downstream erosion protection. This cost is over five times more costly than the natural stream design.

3.4 Stream Buffers

To arrive at a unit cost basis, several design parameters were applied. Using a 100-foot wide buffer with woody vegetation for the first 50 feet next to the

stream and a 50 grass filter outside the woody area yielded a 50 percent removal efficiency using a relatively flat slope of 1-to-5 percent (Wenger 1999). A flow through velocity of 0.5 fps with a design depth of 1-inch deep during the two year storm was used to establish the number of acres a unit width of buffer could treat (Harner et al 2000). Combined with an assumed predominantly residential land use, the buffer could treat 0.0148 drainage area acres per foot of width. Installation bid tabulations from the Jordan Creek daylighting project in Springfield and projects in Christian County, Missouri, were reviewed, and, based on these local Ozark projects, an average installation cost of $15,000 was estimated. The installation cost includes three-to-five gallon trees, shrubs, native grass seeding, erosion control, and grading to ensure sheet flow through the buffer. Maintenance costs are estimated to be similar to stormwater BMPs at 4.5 percent of construction. The sediment accumulated in buffers must be removed to maintain the buffer treatment efficiency (Daniel and Moore, 1997). An assumed 10 year cleanout of the accumulated sediment in the grass area, followed by reseeding, was assumed at a 10 year interval over the 50 year design life. These calculations indicate that a 100-foot wide grass and tree buffer would cost approximately $20 per linear foot to install and an additional $140 per linear foot to maintain for a 50 year period. The amount of phosphorus removed during the 50 year design life was estimated at 0.58 lbs per foot of buffer. The cost efficiency is calculated at $278 per pound of phosphorous removed.

4.0 Cost Efficiency Comparison

We have presented some of the costs associated with removing P from the water column once it has been liberated and also the costs associated with stabilization measures taken to prevent the P from being eroded from the stream banks. Is an ounce of prevention worth a pound of cure? The following table summarizes the results:

Table 5. Phosphorus removal cost comparisons

P Removal Method	Data Source	Cost per Pound Removed Annually
Wastewater Treatment Plant	Springfield WWTP Upgrades, EPA Guidance Documents	$4.60
Stormwater BMPs	EPA 1999 Study	$698 to $1,535
	Olsson 2006 Study	$466
Stream Restoration	Ward Branch and Other Restoration Plans in Nebraska, Kansas, and Missouri	$188
Stream Buffers	Jordan Creek, Springfield Christian County, Missouri	$278

Point source reductions stood out as the most effective method to reduce P entering the James River. Of the three non-point source methods reviewed, the data indicates that performing stream stabilization projects is a cost-efficient method to reduce the amount of P in our streams and lakes. Stream bank stabilization projects should be an integral portion of a watershed plan and a TMDL implementation strategy. However, if full-spectrum detention and adequate stream buffers are in place, the stabilization projects may not be needed, and the phosphorus processing of the healthy corridor is, in essence, "free" treatment. The associated prevention of stream instabilities offers an even more attractive economic proposal, as do the added benefits of healthy streams and the ensuing recreational opportunities.

5.0 Other Economic Benefits of Stream Restoration and Greenways Trails

The prior discussion was limited to quantifiable dollars spent to prevent P from reaching critical areas. As the Ozarks continue to see urban development, increasing pressures will encourage us to encroach on our streams. Riparian areas are dynamic and provide many functional benefits to the stream ecosystem. Effective riparian management could ameliorate many ecological issues related to land use and environmental quality. Riparian corridors should play an essential role in conducting water and landscape planning, in the restoration of aquatic systems, and in catalyzing institutional and societal cooperation for these efforts (Nainmen et al 1993). Riparian zones need to be viewed as an active river area framework, which includes a spatially explicit, holistic view of rivers that comprises both the channels and the riparian lands necessary to accommodate the physical and ecological processes associated with the river system. The framework informs river conservation by providing an approach to account for the areas and processes that form, change, and maintain a wide array of habitat types and conditions in and along rivers and streams.

By leaving a buffer around streams during construction, developers realize not only immediate cost savings, but also the possibility of gaining long-term value to the property. The developer realizes an economic advantage for keeping the stream open and employing an adequate stream buffer, full-spectrum detention, and erosion control during construction and stormwater quality treatment.

The National Park Service has well-documented studies on the economic value of greenways (NPS, 1995). Greenways that border streams offer many benefits, one of which is a marked increase in home values. In a subdivision in Springfield, the assessed valuations of the homes that back to the South Creek greenway is 15 percent higher than comparable homes in the remainder of the subdivision. In Boulder, Colorado, a study of property values found that homes next to a greenway had 32 percent higher property values than homes 3,200 feet away. In Apex, North Carolina, developers of the Shepherd's Vineyard subdivision found that they could charge $5,000 more for a home adjacent to a greenway. In Brown County, Wisconsin, homes along the Mountain Bay Trail sold for nine percent more than similar property not adjacent to a trail. Assuming an average lot width of 120 feet, an average lot value of $35,000, and residential houses backing to both sides of the stream, the benefit is

approximately $87 per linear foot of stream. In a 2002 survey of recent homebuyers sponsored by the National Association of Realtors, trails ranked as the second most important community amenity out of a list of 18 choices. The increase in home values also leads to increased property tax revenue. In Boulder, Colorado, a study of one subdivision revealed that the greenway increased the aggregate property value by $5.4 million. This resulted in $500,000 more in potential property tax revenue, which could pay for the $1.5 million greenway in three years.

Greenway trails also decrease the amount of pollution reaching our streams by serving as alternative modes of transportation. Studies have shown that two-thirds of the trips that people living in urban areas make are less than five miles in distance. Using the trails for walking and biking has also been shown to decrease public health costs $3 for every $1 spent on trail development (Wang, Macera, Scudder-Soucie, Schmid, Pratt, and Buchner, 2005).

Greenway trails can be incorporated as floodplain acquisitions. FEMA estimates that flooding causes over $1 billion in damages every year, and approximately 10 million homes are currently located in floodplains. After flooding in Tulsa, Oklahoma, the city designed a greenway along Mingo Creek that included woods, wetlands, and parks to enhance the floodplain. As a result, flood insurance rates in Tulsa dropped 25 percent. The Minnesota DNR found that the average value of one acre-foot of flood storage is $300. Therefore, if one acre-foot of floodplain or wetland is developed, it would cost the public $300 to replace the water storage. Preserving and maintaining an "active river area" provides for future economic return while at the same time preventing future costly restoration or remediation projects.

Streams, trails, and lakes also bring tourism dollars to communities. In the James River Basin, tourism brings over $900 million per year to the local economies (DNR TMDL 2001). The recreational benefits of trails, healthy streams, and lakes can be quantified using the "willingness-to-pay" system (National Parks Service, 1995). These values (converted to 2008 dollars) show what the average person would be willing to pay to have certain activities available to them per person, per day.

Table 6. Willingness to Pay

Average Willingness to Pay by Activity	
Activity	**Average Value per Activity Day**
Picnicking	$25
Hiking	$40
Non-motorized Boating	$68
Warm Water Fishing	$41
Non-consumptive Wildlife	$28

6.0 Conclusion

This study has shown that stream restoration can be one of the most cost-effective methods of preventing phosphorus from entering lakes. BMPs are more expensive,

though necessary, because not only do they treat a myriad of pollutants, including phosphorus, they also decrease the rate of runoff, thereby preventing some erosion. The calculations in this study show that phosphorus emissions from point sources such as treatment plants are the least-costly to reduce. However, as the James River TMDL states, non-point source pollution needs to be addressed in conjunction with point source pollution to decrease the amount of nutrient loading in our lakes.

Our streams and lakes are very valuable resources. What would happen today if the entire Table Rock Lake was affected the way the James River arm was affected by the algae blooms of 1998? As recent as the spring and summer seasons of 2008, visitation to Table Rock Lake decreased dramatically due to two factors: 1) lake levels remaining at or near record flood stages for several weeks due to large amounts of rainfall, and 2) public perception and fear that the lake was contaminated and unsafe to swim or boat in (Table Rock Lake Water Quality). As a result, local business owners realized decreased revenues. This recent event emphasizes the impacts impaired water quality has to local economies. Considering alone the amount of P that is released by eroding stream banks, compared to the cost of removing P by other non-point source removal methods, it is obvious that our streams need to be protected. The economic benefits of having healthy streams and lakes equate to millions of dollars per year in tourism, health care benefits, and home values. Protecting streams in urban settings generates approximately $250 worth of increased land value per linear foot and results in one of the least costly methods of reducing non-point source P. Protecting Ozark Streams is a necessary investment into the sustainability of the environment and the future economic viability of the region.

Abstract:
Stream restoration projects are proliferating in all regions of the country to provide improvements to streams disturbed by highway construction, urbanization, and channel modifications. The morphologically-based natural channel design method is commonly used to design stream restoration projects; however, the design approach is often vague, qualitative, and lacking in guidance. This can lead to an increase in project uncertainty and costs. A two-step method of incorporating uncertainty and risk in stream restoration design has been developed as a combination of Design Failure Modes and Effects Analysis (DFMEA) and risk quantification. The purpose of DFMEA is to prioritize failures in accordance with their risk. The definition of risk contains two components: (1) probability of failure and (2) consequence of failure. Probability of failure of stream restoration design components is often difficult to determine due to lack of published failure data. In the existing risk assessment method, the likelihood of occurrence ratings from the DFMEA are used to estimate the probability of failure. A set of tasks were carried out to improve the application of the two-step risk assessment method by developing better estimates of probability of failure for stream restoration design components. A literature review was performed to compile potential failure modes, causes of failure, associated predictor variables, and uncertainty in the predictor variables for stream restoration design components. Following this, advanced probabilistic techniques, namely Logistic Regression Analysis (LRA) and Monte Carlo

Simulation (MCS), were applied to develop improved failure probabilities for stream restoration design. MCS was used to incorporate the results of the literature review and to select values for the predictor variables for use in the LRA. The LRA provided a model that was used for prediction of the probability of occurrence of an event. The results were incorporated into the existing risk assessment method to create a better decision making tool for stream restoration design. The incorporation of the resulting risk assessment method in the design phase of stream restoration projects can be important to decision making and will improve the likelihood of success.

Introduction:

Stream restoration projects are proliferating in all regions of the country to provide improvements to streams disturbed by highway construction, urbanization, and channel modifications. The morphologically-based natural channel design method (Rosgen 1996) is commonly used to design stream restoration projects; however, the design approach is often vague, qualitative, and lacking in guidance. This can lead to an increase in project uncertainty and costs (Kondolf 1998, Johnson and Brown 2001). A two-step method of incorporating uncertainty and risk in stream restoration design has been developed as a combination of Design Failure Modes and Effects Analysis (DFMEA) and risk quantification (Niezgoda and Johnson 2007).

Design Failure Modes and Effects Analysis:

DFMEA is a qualitative procedure for systematically identifying potential component failure modes and the effects associated with those failures on the operation status of the system (Dushnisky and Vick 1996). Previously, the DFMEA method has been used to evaluate and rank potential problems in the manufacturing processes. It has also been applied to advance the understanding of complex electrical and mechanical systems including numerous applications in nuclear safety (McCormick 1981, American Nuclear Society 1983, Fullwood and Hall 1988, Henley and Kumamoto 1992, Shimizu et al. 1993).

In the case of stream restoration design, the components consist of elements such as cross sectional geometry, cross rock vanes, rootwads, and meander pattern that are utilized by practitioners to design a stable, functional stream. The failure modes for each component typically consist of dislocation, unintended scour or unintended deposition. The consequence of a specific failure mode for a specific component is an estimate of the cost of restoration or damage to the stream as a whole, induced by said component failure. Additionally, there are a set of detection methods used by the designer to determine if a given failure will occur prior to implementation. These detection methods can be indirect, such as an incipient motion analysis, or direct, such as checking state mandated installation guidelines to ensure that each component is designed according to existing standards.

The DFMEA method is performed in the design stages prior to implementation allowing time to assess the risk/cost of component or system failure and so that changes to the implemented design can be made early and at low cost. The purpose

of DFMEA is to prioritize failures in accordance with their risk (Kmenta and Ishii 2000). The definition of risk contains two components: (1) probability of failure and (2) consequence of failure. Based on this definition, the following mathematical expression is used to calculate risk:

$$Risk = C_o + \sum_{i=1}^{n} (p_i C_i) \quad (1)$$

where, C_o = initial cost of the project, including assessment, design, and construction costs; p_i = probability of failure of component *i;* C_i = consequence of failure of component *i* in terms of costs of repair, replacement, and damage; and n = the total number of components in the system. Probability of failure of stream restoration design components is often difficult to determine due to lack of published failure data. In the existing risk assessment method, the likelihood of occurrence ratings from the DFMEA are used to estimate the probability of failure (Niezgoda and Johnson 2007).

The results of this project will improve upon this risk assessment method by creating a method of empirically calculating the probability of failure. Failure, for this project, is determined by the following definitions:

- *Overall Design Failure:* When a stream no longer operates as intended due to instability. This can happen if the incoming sediment is greater than the outgoing or vice versa.
- *Component Failure:* When an element no longer operates as intended and either induces stream instability or causes any unintended change downstream. A design component can fail both structurally and/or functionally.
- *Structural Failure:* This refers to a collapse of the physical system or components of the system sufficient to prevent fulfillment of the design objectives (Brown and Johnson, 2001).
- *Functional Failure:* This implies that the project objectives cannot be realized due to the ineffectiveness of the design, although the structure or form may be intact and in place (Brown and Johnson, 2001).

The requirements to execute the DFMEA method include the following (McCollin 1999):

- A hierarchical structure for the system illustrating all system components
- Failure modes of all components of the system
- An objective criterion for implementing corrective action (typically a risk priority number)

The goal of this project is to develop a more accurate way of determining stream failure and component failure when performing the DFMEA. This is accomplished by

performing advanced probabilistic techniques on data that is collected for real streams.

Current Study:

The following set of tasks were carried out to improve the application of the two-step risk assessment method by developing better estimates of probability of failure for stream restoration design components:

- A literature review was performed to compile potential failure modes, causes of failure, associated predictor variables, and uncertainty in the predictor variables for stream restoration design components.
- A survey was developed and sent out to various agencies to collect failure information for actual stream restoration projects.
- This data was used to run advanced probabilistic techniques, namely Logistic Regression Analysis (LRA) and Monte Carlo Simulation (MCS). These techniques were applied to develop improved failure probabilities for stream restoration design.
- Results were incorporated into the existing risk assessment method to create a better decision making tool for stream restoration design.

The incorporation of these results into the risk assessment method in the design phase of stream restoration projects can be important to decision making and will improve the likelihood of success with a stream restoration project.

Literature Review:

In the risk assessment method presented above, failure probabilities of design components are highly uncertain. To improve the risk assessment method for wide-spread use, it is proposed here that LRA and MCS techniques be used to develop improved estimates of failure probability and risk. Currently, the probability of failure for design components and the expected failure costs are estimated based on engineering judgment, experience with similar projects, and the review of literature (Brown 2000).

To supplement this data, a literature search of more current material was completed to compile component information used to develop a data survey. The component information gathered includes commonly used components within stream restoration (e.g., cross sectional geometry), typical failure modes of these components (e.g., excessive degradation) as well as all traditional design methods (i.e., detection methods) for each component (e.g., incipient motion analysis). The survey results were used to run the LRA and MCS techniques to better understand failure probabilities.

Stream Failure Data Survey:

The survey created was in an excel spreadsheet that was sent out to numerous agencies to obtain stream failure data, as seen in Figure 1.

	#	Component	Component Failure	Failure Mode	Design Method (Direct/Indirect)	Design Detection Method
9						
10	1	Boulder Placement	Yes	Unintended movement/dislocation	Direct	Boulder diameter 2'-5' (no more than 1/8 of stream width)
		Boulder Placement Brush Layering Brush Mattresses Cross Sectional Geometry Construction Cross Vanes Culvert Baffles Gabions Imbricated Riprap			Indirect	Shear Stress
12	1				Direct	Boulder volume 35-70 cubic feet
13	2	Brush Mattresses	Yes	Other	Direct	Live branches are cut from fresh, green, healthy, dormant parent plants that are adapted to site conditions
14	2				Direct	Wood branches 5'-10' length
15	3	OTHER	Yes	Describe in Other Values	Indirect	Judgement/Experience

Design Detection Method	Predictor Variables List	Known Predictor Variables Values	Other Values
Boulder diameter 2'-5' (no more than 1/8 of stream width)	*Boulder diameter*	Diameter = 6'	
Shear Stress	*Shear Stress, Critical Shear Stress, Hydraulic Radius, Channel Slope, Particle Size, Reynolds Number, Dimensionless Stress, Shields Parameter*	Shear Stress = …, Critical Shear Stress = …, etc.	Particle Size is unknown, etc.
Boulder volume 35-70 cubic feet	*Boulder volume*	Boulder Volume = …	
Live branches are cut from fresh, green, healthy, dormant parent plants that are adapted to site conditions	*Live branch material*	Branch Material = …	Failure Mode = …
Wood branches 5'-10' length	*Branch length*	Branch Length = …	
Judgement/Experience	*Please describe methodology and known data*		Component = …, Failure Mode = …, Methodology = …, etc

Figure 1. Example Survey Results

First, the user would fill out general stream information, such as if the stream failed to meet its design objectives and if so then how. This general stream information is above the cells depicted in Figure 1. Then the user would select the stream component from a list of common components utilized within stream restoration projects, such as "Boulder Placement" as seen in the first component row of Figure 1. Next, the user would select "Yes" if the component failed and "No" if it did not. This forces the user to decide upon component failure and prevents the grey area associated with varying engineers' opinions. The user would then select the failure mode associated with the selected component, such as "Unintended movement/dislocation." Following this it would be necessary to select the first design method, either "Direct" or "Indirect." Here "Direct" refers to design of a stream component by state guidelines for materials and installation and "Indirect" refers to design of a stream component by calculating its affect on the stream as a whole. The final selection by the user is the first design detection method from a list associated with the component and design method already chosen. From this selected information the spreadsheet fills the following cell with a list of predictor variables associated with the chosen design detection method. If the user selected the same information as that in the first component row in Figure 1, the predictor variable list would output "Boulder Diameter." The user would then fill in the following cell with the known predictor variable values, in this case the actual boulder's diameter. There is also an Other Values column for any additional data the user may have.

The survey was a simple to use tool that allowed the user to select component information from a series of drop boxes and fill out unique information in allocated cells. This survey provided the component and predictor variable information necessary to run the numerical methods.

Logistic Regression Analysis (LRA):

LRA is a model used to predict the probability of occurrence of an event by fitting data to a logistic curve. In this model the input data is a set of independent variables, often called covariates, that are continuous, discrete, and/or dichotomous (1 or 0) and the result is categorical and dichotomous (Hosmer and Lemeshow 2004).

LRA is used extensively in the medical sciences, social sciences and in marketing applications. For example, LRA could be used to predict a customer's inclination to purchase a product or if an adult will have a heart attack within a specified time period. To develop the predicting function a set of covariates are required. In the examples given the covariates could consist of the customer's purchase habits or the adult's body mass index. In the case of stream restoration the covariates would consist of the predictor variables associated with each component.

Monte Carlo Simulation (MCS):

MCS is a method for iteratively evaluating a deterministic model using sets of random numbers as inputs. This method is often used when the model is complex, nonlinear, or involves uncertain parameters (Ayyub and McCuen 2003).

MCS has been useful for modeling phenomena having significant uncertainty associated with their inputs and for studying systems with a large number of coupled degrees of freedom. Specifically, MCS has been used in the physical sciences, visual design, finance, mathematics, and for solving "What If" scenarios.

Results:

The results of the literature review and survey will consist of a list of stream failure data. Most importantly stream restoration component details, whether or not the component failed, and if the stream as whole did not meet the design objectives. This data is necessary to perform the LRA and MCS.

One additional goal of the survey is to collect data for later use. Such data includes the failure mode of each component. This can be used to judge whether or not a component's failure caused the stream as whole to not meet its design objectives. Similarly the detection method (Direct or Indirect) can be later used to judge if a component's failure could have been prevented. This is valuable information that can lead to a better understanding of stream restoration design.

Future Work:

For this project, LRA will incorporate the results of the literature review and survey to develop a function that models the probability of failure of each component. The covariates for each component's function are a set of predictor variables. The result will be a binary definition of component success or failure.

From the component function generated by the LRA we can develop distributions for each predictor variable. The distributions will give insight into how sensitive component success is to each predictor variable. Furthermore, once the functions are generated for all common components the functions can be combined into a tool that calculates risk in Equation (1), where p_i is determined by the function for component i and the predictor variable values are input by the user.

For this project, MCS will incorporate the results of the literature review and survey to perform uncertainty propagation for each component's predictor variables. The final MCS results will be evaluated using a histogram to visualize the uncertainty in the calculated risk. The mean, median, and standard deviation will also be evaluated to best describe the distribution and results. This provides improved quantitative estimates of risk for a given design configuration.

Previously MCS has been incorporated within stream restoration as a method to perform sensitivity analyses for the Goulburn River in Australia (Grayson et al. 2005). The sensitivity analyses were conducted to identify key variables for predicting bank

erosion rates using a particular bank erosion model. Similarly, MCS can be conducted to determine the predictor variables for stream restoration.

Summary:

The ultimate goal of this project is to develop a tool that incorporates the results of the LRA and MCS analysis in the determination of the risk using Equation (1). This tool will improve upon the current DFMEA method which utilizes engineering experience to determine the probability of component failure. Here the probability of component failure will be determined through the function developed in the LRA and inputs given by the user. The desired inputs will be chosen based on the results of the LRA and MCS.

This tool will reduce the uncertainty that is inherent to the stream restoration design process. It will provide practitioners with a straight forward way to predict the failure of stream restoration design components and through this whether or not the stream itself will meet the design objectives. Furthermore, the data collected in this project will advance the stream restoration community's understanding of stream failure. Additionally, this data can prove useful beyond the scope of this project. The data can later be used to better understand the consequence of failure associated with each component failure.

Abstract:

A central problem in the field of stream restoration is that of designing a stable channel that supports a healthy benthic population. Many stream restoration projects take place in urban or urbanizing watersheds. The relationship between changing watershed characteristics and local channel conditions within that watershed is poorly understood. This study is made up of two major components that address aspects of this problem: first, a physical study of bedload flux in watersheds representing rural, urban, and developing conditions and second, verification of results from the Computational Hydraulic Engineering Two-Dimensional Sediment Model (CCHE2D) on the reach scale and correlation of CCHE2D results with Rapid Bioassessment Protocol III (RBP III) scores. Study sites were selected in Knox County, Tennessee including twelve sites for the bedload study and a single site for the CCHE2D model verification. The bedload flux portion of the study combines field collection of bedload via portable bedload traps and an estimate of energy slope from peak stage recorders. Information derived from the field collection will be combined with watershed data via geographic information system (GIS) analysis. Watershed metrics including percent impervious area, roadways adjacent to streams, and average watershed slope determined via GIS will be correlated with the measured bedload composition for each research site. The CCHE2D model verification will combine the study of bedload flux with a previous study correlating the surficial bed material composition with macroinvertebrate biotic integrity scores (RPB III) for 76 reaches in East Tennessee. The combination of this information will provide a valuable tool in stream restoration design in allowing practitioners to have an empirical metric with which to design/predict channel substrate composition as an indicator of physical habitat quality.

Introduction:

Urbanization and Hydrology:
Urbanization in a watershed begins a chain reaction of effects in the water resources of that watershed (Bledsoe and Watson, 2001; Booth and Jackson, 1997; Walsh et al., 2005). Hydrologic changes lead to changes in sediment flux which lead to changes in form and function of the streams from both a biological and structural perspective. As infiltration and storage capacities are altered due to construction activities including clearing and grubbing, paving, and building construction; hydrograph values and shapes change, with peaks and durations increasing. Delivery paths to the streams are concurrently altered by use of stormwater collection and distribution infrastructure which delivers high volumes to the stream with a low time of concentration. USGS Flood Regression Equations suggest that the Q2 of Tennessee watersheds increase by a factor of

1.9 at 10% impervious surface in the watershed and by a factor of 2.5 at 20% impervious over values from watersheds with no impervious surface. Percentage of impervious surface is commonly used to quantify urbanization due to the availability of USGS raster files produced by spectral analysis techniques (Arnold and Gibbons, 1993).

Stream Restoration in Urban Environments:
Goals of stream restoration in urban areas include geomorphic stabilization and reestablishment of biotic integrity while leaving established infrastructure intact. Input from stakeholders in the community along with engineering and scientific perspectives must be balanced in a way that is acceptable to all parties in order to be fully and successfully implemented (Rhoads et al., 1999). As new information on the effects of urbanization is compiled, a more complete understanding of natural versus anthropogenic influence is developed. A better understanding of the interaction between these two classes of influence on streams allows for incorporation of natural processes in stream restoration practice.

Urbanization's Effects on Channel Stability:
Hydrologic and sediment changes both in turn affect channel stability. Higher flow rates with lower upstream sediment loads tend to lead to channel widening, incision, or a combination of the two. Incision can increase transport of fine sediment downstream through both erosion and by isolating the channel from its floodplain. Separate from hydrologic changes, other effects on the channel are felt. Riparian areas are often removed during urbanization activities, removing a valuable habitat resource as well as a sediment filtering feature (Hook, 2003). Bank armoring due to close proximity construction or stormwater collection features can cause down-cutting or widening of the channel as new hydraulic forces are developed in a reach. Simon (1995) identified six stages of channel evolution in a disturbed watershed; the primary features of the post-disturbance channel being downcutting and widening. As channel area has been sufficiently increased, aggradation takes place, leading to restabilization.

Urbanization's Effects on Sediment Supply:
Three significant stages of sediment availability are noted in the typical shift from non-urban to an urbanized watershed: the undisturbed condition, for which the stream is assumed to be in regime; the construction phase, which can lead to sediment loads up to 100,000 tons/sq.mi/year; and finally the urbanized phase, where many previous sediment sources have been altered or removed completely (Wolman, 1967). Efforts to mitigate the effects of the construction phase have improved over the years with the development of Best Management Practices (BMPs) for construction work. New sources of sediment are also introduced including slope instability and roadway erosion. Coarse substrate can be stripped due to higher flows but may not be replenished due to sealing of upland sediment sources (Nelson and Booth, 2004). Fining of bed sediment toward sand due to changes in sediment sources has been noted in urbanized portions of watersheds (Simon et al., 2004). Sampling of bedload in non-urban, urbanizing, and urban watersheds to determine effects on bedload composition is not extensive at this point.

Project Objectives:
This study intends to address a central problem in the discipline of stream restoration: that of designing a stable channel that adequately supports biological activity. Bedload composition of various watersheds will be analyzed to determine the effects of urbanization on bedload supply, combining this information with previous regional research linking fine sediment substrate with Rapid Bioassessment Protocol III (RBP III) scores. This will provide a powerful design tool that relates the primary concern of regulators (improving biological conditions in the stream) with a critical design component that is currently addressed only by semi-quantitative or qualitative methods.

Study Design:
This study is made up of two major components: First, an analysis of bedload composition in rural, urbanizing, and urban watersheds in the Knox County, TN area to determine if significant bedload is present in these systems and if so to determine if impervious surfaces have an effect on the composition. Geographic Information System (GIS) analysis of the watersheds is used to quantify these characteristics of the research watersheds. Watersheds were chosen to represent various percentages of impervious area, which is a surrogate for urbanization in this study. Figure 1 is an overview map of the research watersheds.

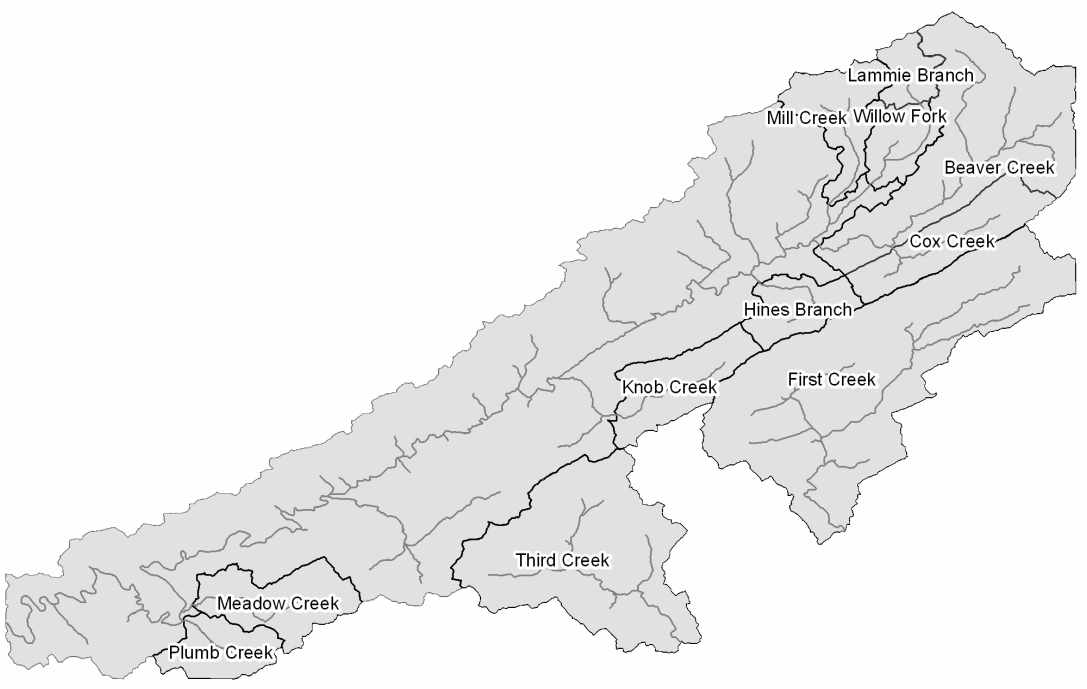

Figure 1. Map of Research Sites

Secondly, verification of results of the CCHE2D sediment model on a short, hydraulically simple reach that is typical of potential stream restoration sites in the area. The model output will be combined with previous research in the area by Williams (2005) which analyzed the relationship between channel stability/bed material and Rapid Bioassessment Protocol III (RBPIII) scores. Boundary conditions developed from one storm event will be used to generate the simulation. Previous attempts to use this model

to predict bed composition (Johnson, 2008) were hampered by insufficiently dense sediment rating curve information, so monitoring will continue throughout the runoff event.

Methods:

Selection of Research Sites:
Bedload sampling sites were selected in a limited geographic/geologic area in an effort to limit extensive differences in sediment yield due to variation in geologic processes. Nine of the research watersheds are subwatersheds of Beaver Creek in Knox County, Tennessee. The other two watersheds are adjacent to the Beaver Creek watershed. Beaver Creek is a high priority watershed in the area and is the focus of hydrologic remediation activities by the Knox County government and has an active watershed association. Watershed size was not a consideration due to the prevalence of moderate urbanization at any appreciable downstream distance in any area with basin sizes ranging from just over 1 mi^2 to almost 12 mi^2. GIS analysis of watersheds above sampling sites provided the primary variable of percent impervious surface, along with two additional secondary variables: average watershed slope and length of roadways within 50 ft of the stream. Table 1 shows the watersheds chosen, total area, and percent impervious surface.

Table 1. Percent Impervious in Research Watersheds

	Total Area (ac)	Percent Impervious
Third Creek	7541.2	27.3
Hines Branch	1408.9	20.9
Plumb Creek	1481.8	18.4
First Creek	11950.8	17.7
Knob Fork	2163.5	14.9
Meadow Branch	2278.4	12.1
Cox Creek	2363.8	5.5
Beaver Creek	9597.0	5.4
Mill Branch	1985.3	3.0
Willow Fork	2098.1	1.3
Lammie Branch	842.0	1.2

Bedload Sampling Method:
Temporary bedload sampling devices with capacity to sample during the duration of the flow event were modeled after a combination of Bunte's (2004) bedload traps and the Helley-Smith (1971) bedload sampler. The final design consisted of 5/16" x 3 ½" aluminum bar stock frame with an opening measuring 3" x 12"; an interior sampling net with openings sized .05"; and an exterior reinforcing net. Figure 3 shows the assembled sampling device. Before a predicted storm event, the samplers were secured to the bed in a riffle area of each sampled research reach using #8 rebar driven into the bed. After the peak stage has decreased by at least half, the samplers are removed and returned to the laboratory. Organic material is removed from the collected sample and the remaining soil particles are initially dried. Smaller organic debris is then burned in an ignition oven and

a dry sieve is performed, providing the information to develop a particle size distribution (p.s.d.).

Figure 2. Assembled Bedload Sampler

Data Processing:
In order to determine possible correlations with indicator variables, a matrix of watershed properties will be produced. GIS produced watershed metrics, stream order values, d_{85}, d_{50}, and d_{35} particle size values will be included. Multiple linear regression techniques will be applied to this data in order to assess any trends present. Peak stage recorders were placed upstream and downstream at each site. These will be used to generate an approximate energy slope at peak flow for the reaches. As a sanity check, bed shear will be checked against pebble count sizes to determine the presence of any non-mobile bed material. Peak stage will also be used to classify flow events as a percent of bankfull stage.

Modeling:
The Willow Fork site was chosen as the one to be modeled in CCHE2D. A topographic survey of the channel and immediate flood plain was performed using a total station and prism. Mesh generation, hydraulic simulation, and sediment simulation will be performed in the National Center for Computational Hydroscience and Engineering's CCHE2D two dimensional sediment model. Sediment rating curve and current bed composition information will be gathered in the field. Hydrograph information will be recorded at the upstream and downstream boundaries with Global Water stage recorders. If sufficient data is not recorded for a successful modeling run, a sensitivity analysis will be performed on the reach to determine threshold conditions for degradation and aggradation, particularly of fine sediment. These threshold values of bed composition will be determined through the work of Williams (2005), in which channel stability and bed composition were correlated with EPA RBPIII scores. In this way, the biological connection will be made.

Preliminary Results:

Eleven bedload samples have been collected from six sites as of January 2009. A map of the research watersheds is included as Figure 1. The particle size distribution summary and percent impervious in the watershed are included in Table 2. Figure 3 shows a flooded research site with the peak stage recorder near the lower left corner. Consistent values have been obtained in the 3rd Creek and Beaver Creek watersheds only. Figure 3 shows this research site at flood stage with the peak stage recorder near the lower left corner. Other sites have either had p.s.d. values that are not stable over the first two measurements or have only one or no samples. It is expected that d_{85} values will drop with an increase in impervious area, with d_{50} and d_{35} values remaining consistent or decreasing. Large amounts of organic debris and small samples of present biota have been noted in the samples that have been processed. Insufficient data has been collected for statistical analysis at this time.

Table 2. Particle Size Summary

Site Location	Storm Date	d_{85} (mm)	d_{50} (mm)	d_{35} (mm)
3rd Creek	11/14/2008	2.32	0.81	0.66
3rd Creek	12/10/2008	2.24	0.59	0.40
3rd Creek	1/7/2009	2.60	0.53	0.41
Beaver Creek	12/10/2008	1.14	0.58	0.38
Beaver Creek	1/7/2009	1.10	0.70	0.51
Willow Fork	12/10/2008	1.70	0.42	0.30
Willow Fork	1/7/2009	0.91	0.43	0.35
Lammie Branch	1/7/2009	>9.75	0.65	0.29
Cox Creek	12/10/2008		9.36	3.55
Cox Creek	1/7/2009	1.52	0.51	0.28
Hines Branch	1/7/2009	1.55	0.31	0.18

Figure 3. Third Creek Research Site at Flood Stage

Sediment sampling is ongoing and with sufficient storm events will reach 2-3 values for each site. Any anomalies noted in nested watersheds will be followed up by field investigation with a goal of identifying impoundments, active construction, and other disturbances such as cattle crossings. As the research draws to a close, a relationship between impervious area and bedload composition will be developed as well as a valuable modeling tool for stream restoration practitioners. Developments such as this are hoped to develop stream restoration as an activity integrating both geomorphological and biological perspectives.

Acknowledgements:

I would like to thank both the University of Tennessee, Knoxville and S&ME, Inc. for their continued financial support for this research. Dr. John Schwartz and Ken Barry have been instrumental in defining the research priorities and providing insight into the problems at hand. Construction of the bedload traps would not have been possible without the help of Larry Roberts and Ken Thomas in the Civil and Environmental Engineering Department Shop. Laura DeVilbiss, Andy Dodson, Michael Hamrick, and Daniel Johnson have provided indispensable help with field work, technical advice, or both.

ABSTRACT

Bubbly Creek was historically used as a drainage channel for the waste resulting from Chicago's stockyards. Nowadays there is flow in the creek only during rainfall events resulting in Combined Sewer Overflows (CSO) and water quality is a very important issue, particularly during the summer months, when the dissolved oxygen levels are extremely low and sediment oxygen demand is expected to be large.

Due to the particular flow regimes of the creek and the conditions of the benthic sediments in the bed, a special BOD-DO (Biochemical Oxygen Demand - Dissolved Oxygen) water quality module was developed and implemented into the two-dimensional depth-averaged numerical model STREMR-HySedWq. The approach illustrated represents a substantial improvement to the state-of-the-art of water quality modeling methodologies.

The model was able to capture the key processes and provide useful preliminary results for the two following scenarios: [1] CSO events, for which the model was coupled to a one-dimensional cross-section-averaged BOD-DO water quality model, and [2] potential "purification" solutions, such as flow augmentation and supplemental aeration, with the goal of increasing the DO levels in the creek during dry weather periods.

DESCRIPTION OF BUBBLY CREEK

Bubbly Creek, located South-West of Chicago (Figure 1), is the South Fork of the South Branch of the Chicago River and has a length of approximately 2000 meters, a mean width of about 44 meters (varying between 23 and 61 m) and a mean water depth of 2.2 m (ranging from 1.2 to 3.6 m). The mean channel bottom slope is about 0.0013. From 1865 to 1939, Bubbly Creek was used as a drainage channel for the waste resulting from Chicago's stockyards (Hill, 2000). Today, this historically industrial area is being transformed into a residential development, with strip malls and residences, and therefore there is a revived interest in Bubbly Creek.

Four different regimes characterize Bubbly Creek: [1] during dry periods, the water in the creek is essentially stagnant; [2] with light rainfall events, there are no noticeable changes, since the combined sewage conveyed from the 36 square miles service area to the Racine Avenue Pumping Station (RAPS, Figure 1) is pumped to the Stickney Water Reclamation Plant of the Metropolitan Water Reclamation District of Greater Chicago (MWRDGC) and not discharged into the creek; [3] during heavy storms, the RAPS discharges Combined Sewer Overflow (CSO) into the creek, so that there is a northward flow in Bubbly Creek which finally discharges into the South Branch of the Chicago River; [4] for excessively heavy storms, several CSO outfalls located along the channel (Figure 1) may discharge into the creek depending on the intensity of the rainfall event.

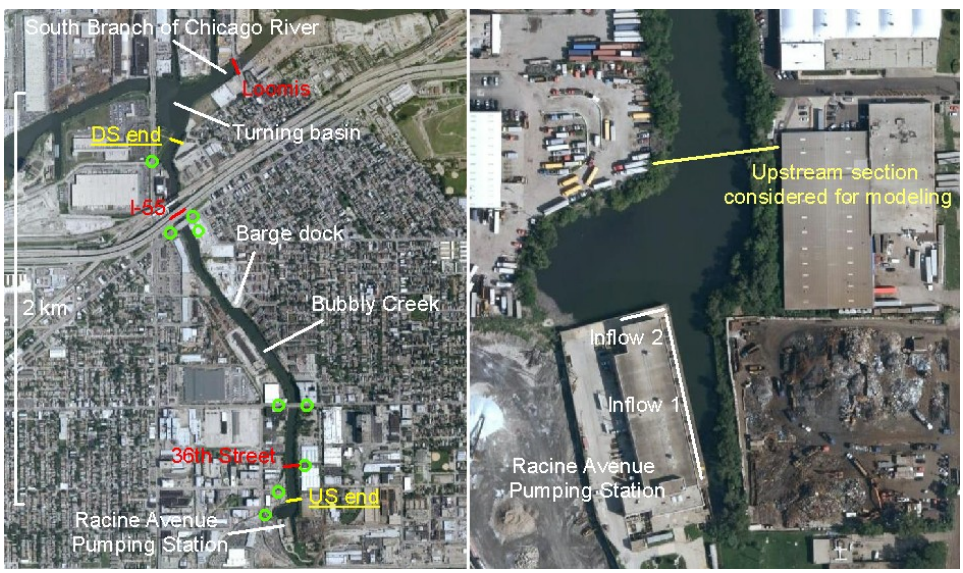

Figure 1. Aerial view of Bubbly Creek (left) and detail of the Racine Avenue Pumping Station (right). Circles denote outfalls along the banks.

MODELING SCENARIOS

As part of a larger study of Chicago's waterways, the water quality dynamics in Bubbly Creek was modeled for two scenarios: CSO events (indicated above as regime [3]) and potential "purification" solutions, such as flow augmentation and supplemental aeration, to increase the Dissolved Oxygen (DO) levels in the creek during dry weather periods, which are particularly low during the summer months due to the presence of oxygen demanding sediments along the bottom of the creek.

Density currents in Bubbly Creek caused by CSO events and the upstream intrusion of denser flow both upstream and downstream of the South Branch of the Chicago River have been observed and modeled by Liu *et al.* (2009).

CSO SCENARIO

Characteristics. During a CSO event, resuspension of the organic sediments can occur, with a consequent additional oxygen demand in the water column, which

cannot be modeled as benthic oxygen demand from the bed (Briskin *et al.*, 2002). A theoretical and quantitative approach for the evaluation of the transport of organic matter across the bed/water interface was therefore derived and implemented numerically, by coupling hydrodynamics, sediment transport and water quality.

Notice that a CSO event is an intermittent discharge scenario. As mentioned, when water is flowing in the creek ("Phase 1"), sediment resuspension can occur. For the following phase, characterized by quiescent flow ("Phase 2"), the situation reduces to a dispersion-reaction problem. This is evident from the observation of the biggest CSO event in the period 2005-2007, which occurred on September 13, 2006, and was characterized by a measured CSO volume of 505.84 MG, overflow lasting 7.66 hours and producing a mean flow rate of 69.4 m^3/s (Figure 2).

From Figure 2 it can be observed that: [1] once the CSO event starts the DO concentration increases at both monitoring stations at 36th Street and Interstate Highway I-55 (whose location is indicated in Figure 1). As shown by the numerical modeling presented below, this increase is mainly due to high DO content of the CSO input, while reaeration of the flow plays a minor role; [2] once the CSO discharge ends, an increased oxygen demand, due to the Biochemical Oxygen Demand (BOD) input and/or BOD resuspension from the bed associated to the CSO flow, causes DO depletion; [3] this depletion is recovered relatively quickly at the I-55 Station, which is closer to the South Branch of the Chicago River, whereas it is observed to persist for days in the case of the 36th Street Station, far from the South Branch.

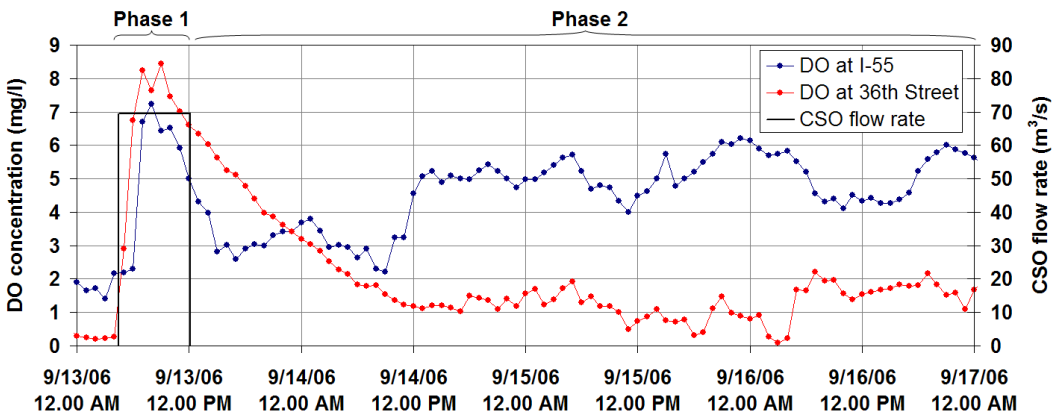

Figure 2. Dissolved Oxygen (DO) concentration measured at the 36th Street and I-55 monitoring stations and input hydrograph at the Racine Avenue Pumping Station (RAPS) for the CSO event on September 13, 2006.

Modeling. "Phase 1", with the RAPS discharge flowing into the creek was modeled with the code STREMR-HySedWq, which is able to handle the bed/water exchange of organic matter and whose two-dimensional nature allows for accounting of the cross-sectional variation of the shear stress and BOD resuspension and settling. "Phase 2", when water in Bubbly Creek is quiescent again, was modeled with a one-dimensional, area-averaged, dispersion-reaction model.

Two-dimensional depth-averaged STREMR-HySedWq model for "Phase 1". Bernard (1993) developed a two-dimensional depth-averaged hydrodynamic model called

STREMR. It includes a k-ε turbulence model and a correction due to secondary flow, and it imposes a rigid lid approximation for the free surface which requires the specification of the water surface elevation. For the case of flows in Bubbly Creek, the rigid-lid assumption was verified to be adequate (Motta *et al.*, 2007). Abad *et al.* (2008) incorporated a sediment transport module (bedload and suspended sediment for multiple size classes) and the model was renamed STREMR-HySed. The original assumption of fixed bottom elevation was relaxed according to the Exner formulation, while maintaining the water surface elevation constant.

The water quality module implemented in the new version STREMR-HySedWq considers the oxygen balance. It solves the depth-averaged mass balance equations for the concentration of Biochemical Oxygen Demand (C_{BOD} in mg/l) and Dissolved Oxygen (C_{DO} in mg/l), which consider the net rate of production S, in terms of concentration/time, properly defined for BOD and DO. The kinetic processes involving the BOD are oxidation and bed/water exchange

$$S_{BOD} = -K_D \Theta_D^{(T-20)} \left(\frac{C_{DO}}{K_{BOD} + C_{DO}} \right) C_{BOD} + Bed\ /\ water\ exchange \qquad (1)$$

where K_D is the oxidation coefficient at 20 °C, Θ_D is the temperature coefficient for oxidation, T is the water temperature in °C and K_{BOD} is the half saturation constant for the BOD oxidation.

The source/sink terms involving the DO are reaeration, oxidation, bed sediment oxygen demand and any localized DO input (e.g. supplemental aeration)

$$S_{DO} = K_a \Theta_a^{(T-20)} \left(C_s - C_{DO} \right) - K_D \Theta_D^{(T-20)} \left(\frac{C_{DO}}{K_{BOD} + C_{DO}} \right) C_{BOD} - \frac{SOD}{H} \Theta_s^{(T-20)} + W_{DO} \qquad (2)$$

where K_a is the reaeration coefficient, Θ_a is the temperature coefficient for reaeration, C_s is the dissolved oxygen concentration at saturation, SOD is the bed sediment oxygen demand per unit area and time, H is the water depth and Θ_s is the temperature coefficient for the bed sediment oxygen demand.

As regards the bed/water exchange in equation (1), extensively illustrated by Motta (2008), the bed is divided into top and lower layers (Figure 3). The thickness of the top layer is considered to be constant in time at each location. BOD can be present, both in the water column and in the bed top layer, as dissolved constituent or attached to sediments (Figure 3). The dissolved (subscript "d") BOD concentrations in the water column $C_{BOD,w,d}$ (subscript "w") and in the top layer pore water $C_{BOD,b,d}$ (subscript "b") are expressed as

$$C_{BOD,w,d} = f_{w,d} C_{BOD,w} \quad , \quad C_{BOD,b,d} = f_{b,d} \frac{C_{BOD,b}}{n} \qquad (3a,b)$$

where $C_{BOD,w}$ is the BOD total concentration in the water column (indicated so far as C_{BOD}), $C_{BOD,b}$ is the BOD total concentration in the sediment top layer, $f_{w,d}$ and $f_{b,d}$ are the dissolved fractions (between 0 and 1) in the water column and sediment

bed top layer respectively (assumed as constant) and n is the bed porosity. The BOD concentrations attached to the particles (subscript "p") in the water column, $C_{BOD,w,p}$, and in the bed top layer, $C_{BOD,b,p}$, are expressed as

$$C_{BOD,w,p} = (1 - f_{w,d}) C_{BOD,w} \quad , \quad C_{BOD,b,p} = (1 - f_{b,d}) C_{BOD,b} \tag{4a,b}$$

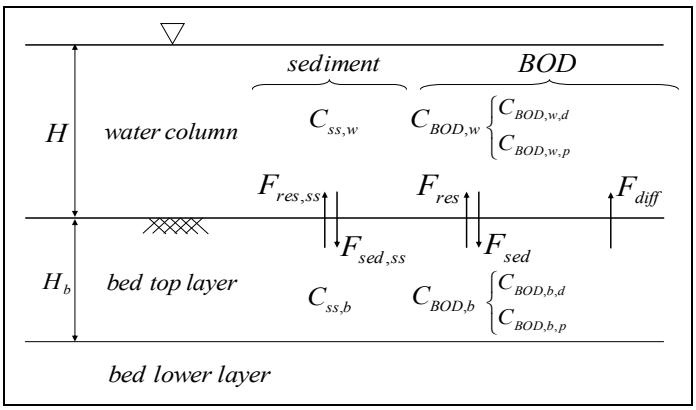

Figure 3. Sediment (SS) and Biochemical Oxygen Demand (BOD) concentrations in the water column and in the bed top layer with fluxes across them.

The total exchange of BOD between the bed and the water column in the equation (1) is given by the algebraic sum of three fluxes in the vertical direction (Figure 3): sedimentation flux F_{sed}, resuspension flux F_{res} and diffusive exchange flux F_{diff}. The sedimentation flux F_{sed} is given by the sum of the settling of BOD attached to the sediments and the inclusion of pore water due to the bed aggradation caused by sedimentation of suspended sediments:

$$F_{sed} = v_s (1 - n) \frac{C_{BOD,w,p}}{C_{ss,w}} + v_s n C_{BOD,w,d} \tag{5}$$

$C_{ss,w}$ is the suspended sediment concentration in the water column (Figure 3) and v_s is the sedimentation rate. The resuspension flux F_{res} is given by the sum of the resuspension of BOD attached to the sediments in the bed and the release of pore water due to the bed erosion caused by sediment resuspension:

$$F_{res} = v_r (1 - n) \frac{C_{BOD,b,p}}{C_{ss,b}} + v_r n C_{BOD,b,d} \tag{6}$$

v_r is the erosion rate. The diffusive exchange flux F_{diff} is proportional to the difference between the concentration in the bed interstitial water, $C_{BOD,b,d}$, and in the water column, $C_{BOD,w,d}$, with E_{diff} indicating the BOD diffusion coefficient and H_b the thickness of the bed top layer:

$$F_{diff} = \frac{E_{diff}}{H_b}\left(C_{BOD,b,d} - C_{BOD,w,d}\right) \tag{7}$$

The sedimentation and erosion rates v_s and v_r refer respectively to the sedimentation (deposition) of sediments $F_{sed,ss}$, which depends on the sediment concentration in the water column, and the resuspension (entrainment) of sediments $F_{res,ss}$, which is related to the bottom shear stress exerted by the flow (Figure 3):

$$v_s = \frac{F_{sed,ss}}{(1-n)} = \frac{F_{sed,ss}}{C_{ss,b}} \quad , \quad v_r = \frac{F_{res,ss}}{(1-n)} = \frac{F_{res,ss}}{C_{ss,b}} \tag{8a,b}$$

$C_{ss,b}$ is the sediment volume concentration in the bed (m_{ss}^3/m^3). The deposition rate v_s is proportional to the sediment settling velocity and the sediment volume concentration at the bed/water interface (Abad *et al.*, 2008). The erosion rate v_r can be calculated, in absence of an *in situ* relation, with one of the formulations presented in literature for non cohesive sediments, once sediment size and density are known. For this study, the formula by Smith and McLean (1977) was used, the details of which are reported by Motta (2008).

From equations (1) for BOD and (2) for DO it can be seen how the BOD bed/water exchange affects the DO levels in the water column: the bed/water interaction terms in (1) have an impact on the BOD concentration in the water column C_{BOD}, and, as a consequence, on the DO concentration C_{DO}, since the BOD-DO system is coupled through the oxidation term.

One-dimensional area-averaged model for "Phase 2". The one-dimensional area-averaged conservation equation is written, for both the concentrations of BOD and DO, as

$$\frac{\partial C}{\partial t} + u\frac{\partial C}{\partial x} = \frac{1}{A}\left(\frac{\partial}{\partial x}EA\frac{\partial C}{\partial x}\right) + S \tag{9}$$

where C is the concentration of BOD or DO, t is time, u is the flow velocity in the x direction, x is the longitudinal distance, A is the flow area, E is the dispersion coefficient and S is the source/sink term. In this case, after the CSO discharge, there is no advection (i.e., $u = 0$). The sink term S_{BOD} is similar to (1) and considers only oxidation and settling (obviously no resuspension occurs), while the source/sink term S_{DO} is similar to (2) and considers oxidation and bed sediment oxygen demand. Equation (9) is solved numerically for a reach by setting appropriate initial and boundary conditions.

Results. For most of the data needed for modeling purposes, measurements are available for Bubbly Creek. However, some information was taken from literature and some other parameters were calibrated.

The bathymetry of Bubbly Creek was provided by the Illinois Water Science Center of the U.S Geological Service (USGS) and it is displayed in Figure 4a, in terms of water depths for a constant horizontal typical water stage of 175.9 m a.s.l.

For the CSO event of September 13, 2006, a suspended sediment and BOD input concentration of $C_{ss,w,input}$ = 604.8 mg/l and $C_{BOD,w,input}$ = 68.1 mg/l, respectively, were calculated with the regression formulations proposed by Alp and Melching (2006) for a CSO volume of 505.84 MG. It was assumed that all BOD in the water column, as well as in the bed, is attached to the particles. The input of DO was calibrated to match the DO concentration measurements in the creek (Figure 2) and was set equal to 9 mg/l, which is slightly less than the value at saturation (9.4 mg/l for a measured temperature of 18.9 °C) given that the combined sewage comes from a system of shafts and pipes which promotes the aeration of the turbulent flow.

A spatially constant bed sediment oxygen demand of 2.32 g/m^2/day (MWRDGC, 2007) was used. The porosity of the bed is on average 0.82 (Yin *et al.*, 2007). The density of the sediment at the upstream boundary as well as at the bottom was set to 2100 kg/m^3 (USACE, 2005). The particle size, expressed as median size D_{50}, is on average 82 μm, corresponding to fine sand - coarse silt (USACE, 2005).

As regards the BOD concentration in the bed sediments, relevant discrepancies were found in the literature in terms of its quantification; therefore, it was calibrated, resulting in a value of 5000 mg/l, assumed spatially and temporally constant and corresponding to a concentration over the mass of sediments of 13.2 mg/g. Currently, there are plans to measure SDO in-situ along Bubbly Creek.

The settling velocity of the CSO suspended sediments is also a parameter very difficult to estimate, because it is characterized by a strong *in situ* variability. In absence of measured data, its value was calibrated and set equal to 4.5 m/day.

Figure 4b shows the flow velocity field in the creek for the September 13, 2006 event. Observe that the upstream portion of Bubbly Creek is characterized by water depths of around 1.5-2.5 m, while the downstream portion, because of navigation, is characterized by higher depth values of about 2.5-3.5 m (Figure 4a). This difference has a direct impact on the erosion pattern during a CSO event, since lower depths are associated with higher velocity and friction coefficient values and therefore higher bed shear stresses, erosion rates and sediment resuspension. From Figure 4b, velocities are higher in the upstream portion (around 0.8-1.0 m/s), while downstream the values are lower (around 0.5-0.7 m/s).

The CSO event dynamics is dominated by advection, bed/water interaction and kinetics, while diffusion plays a minor role. The flow regime is net erosional. Erosion is especially high in the upstream portion of the creek, varying from 80-90 cm at the upstream end of the creek to about 20-30 cm at the downstream end.

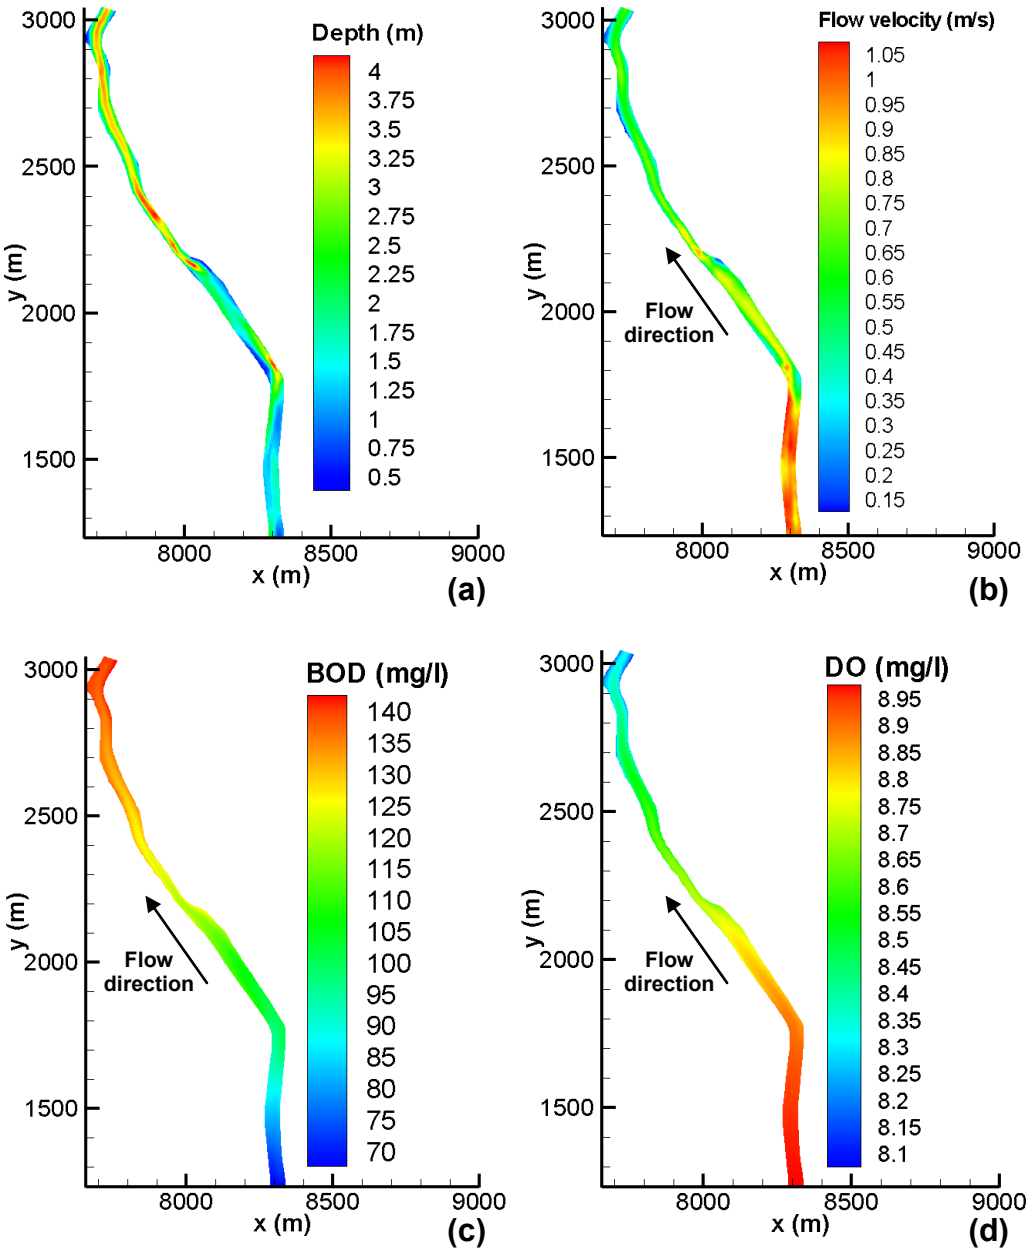

Figure 4. (a) Bathymetry of Bubbly Creek for a constant horizontal water stage of 175.9 m a.s.l. (b) Flow velocity field for a discharge of 69.4 m^3/s; (c) BOD and (d) DO concentration in the water column after 7.66 hours.

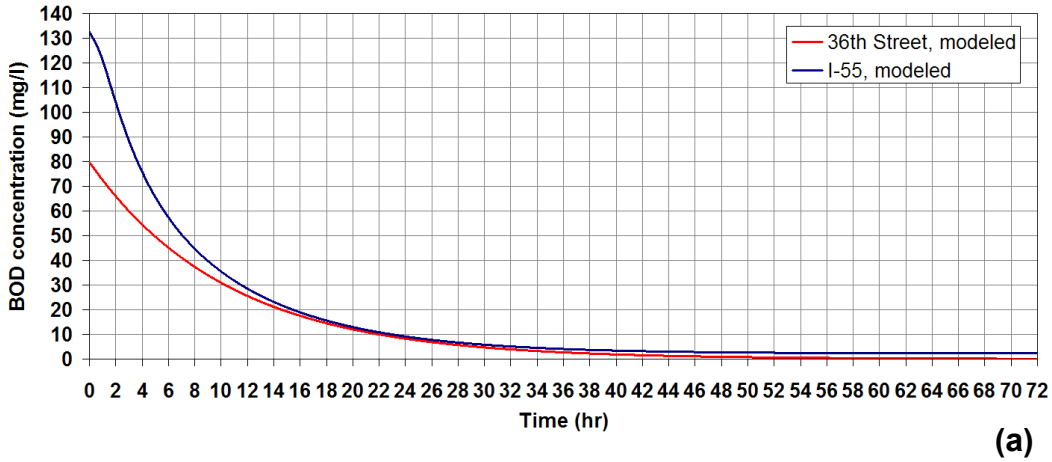

Since the regime is net erosional, both the suspended sediments and BOD concentrations in the water column increase in the downstream direction. In particular, the BOD concentration, from the input value of 68.1 mg/l at the Racine Avenue Pumping Station, reaches a value of about 140 mg/l at the downstream end (Figure 4c). Its concentration after 7.66 hours is essentially determined by the input concentration in the upstream portion of the creek and mainly by the resuspension of BOD from the bed in the rest of the channel. The DO field (Figure 4d) is dominated by the upstream input, while the oxidation and bed sediment oxygen demand

processes cannot cause a significant depletion in the downstream direction during the relatively limited discharge period. Therefore, the effect of a CSO event, as observed in Figure 2 for "Phase 1", is to temporarily increase the DO levels in the creek.

The post CSO discharge stage ("Phase 2") was modeled using the averaged measured DO level at the Loomis Street station in the South Branch (Figure 1), equal to 6.86 mg/l, as downstream boundary condition for DO, while a BOD concentration of 5 mg/l (Alp and Melching, 2006) was used. The dispersion coefficient for BOD and DO, which "lumps" the effect of the continuous water stage variation in the South Branch on the scalars transport in Bubbly Creek (estuarine effect), was calibrated and set equal to 4 m^2/s in the downstream portion of the creek (last 1000 m of the creek) while upstream the BOD and DO concentrations are exclusively governed by kinetics, since the constriction of the creek and the abrupt decrease in water depth at mid-channel (Figure 4a) damp down the estuarine effect.

Three days after the end of the CSO discharge, conditions in Bubbly Creek were simulated, assuming, from measurements, a constant water temperature of 21.9 °C, and starting from the modeled conditions in the creek at the end of "Phase 1". Figures 5a and 5b show the temporal evolution of the concentration of BOD (modeled) and DO (modeled vs. measured) at the monitoring stations at 36th Street and I-55 (Figure 1) after the end of the CSO discharge.

Several observations can be made: [1] the model predicts a monotonic temporal decrease of the BOD concentration in the water column for both stations, because of BOD settling and oxidation. The decrease rate is higher at the I-55 Station, characterized by a higher BOD content in the water right after the CSO discharge (effect of the BOD resuspension from the bed); [2] the model is also able to capture, qualitatively and quantitatively, the evolution of the DO level at both the stations: at I-55, that is close to Bubbly Creek's mouth, the DO decreases very rapidly for the first hours, due to the oxygen demand exerted by the BOD in the water column, entering from the pumping station but especially resuspended from the bed. At the 36th Street Station, which is about 1800 m far from the South Branch of the Chicago River, the DO concentration decreases without recovering in the days following the CSO discharge, because the effect of higher DO concentration in the South Branch is not felt; [3] the predicted DO levels at the 36th Street Station after about 30 hours are lower than the measured ones: this was expected, since the model presented does not adjust the bed sediment oxygen demand, which is important for the DO depletion once most of the BOD in the water column has been oxidized or has settled down on the bottom, for anaerobic conditions, which do occur in the upstream portion of the river after about 30 hours. In anaerobic conditions the bed sediment oxygen demand decreases, explaining why the DO concentration in reality does not go to zero.

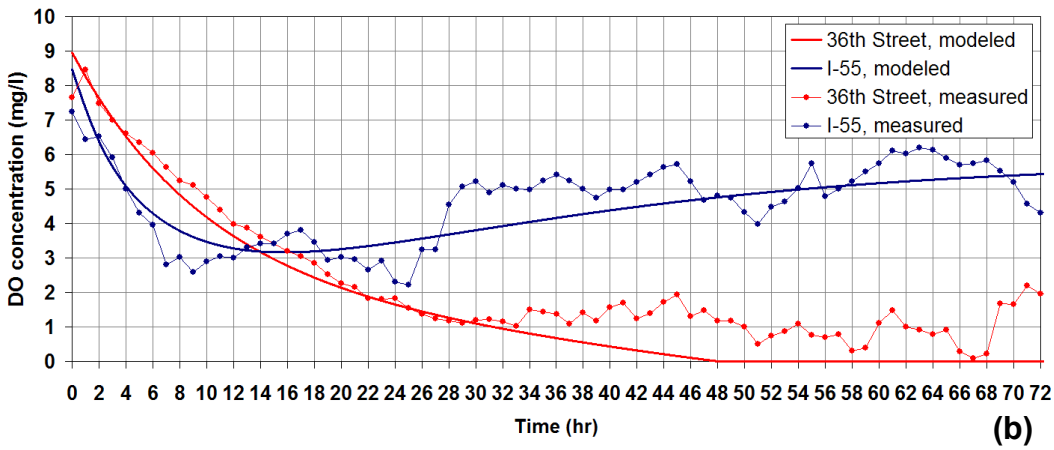

Figure 5. Temporal evolution of the concentration of (a) BOD (modeled) and (b) DO (modeled vs. measured) at the monitoring stations in Bubbly Creek at 36th Street and I-55, after the CSO discharge of September 13, 2006.

"PURIFICATION" SCENARIOS

Characteristics. Recently, two possible flow augmentation scenarios, with or without coupling with supplemental aeration, were proposed with the goal of improving the dissolved oxygen levels in Bubbly Creek, which are very low especially after CSO discharge events and in general during the summer months. The two main solutions proposed were opening a gate at the Racine Avenue Pumping Station and drawing flow backward from the South Branch of the Chicago River, inducing reaeration (MWRDGC, 2003; 2004), or drawing flow with a pipe from the South Branch towards Bubbly Creek headwaters, inducing flow in the creek and discharging back into the South Branch (Alp and Melching, 2006). Both scenarios plan to take water from the South Branch: this means that the water quality in Bubbly Creek would essentially depend on the water quality of the South Branch. To avoid this situation and, in general, any interaction with the South Branch, three alternative solutions were preliminarily analyzed using STREMR-HySedWq: [1] flow recirculation (northward flow in the creek). Flow is withdrawn by a pipe at the

downstream (North) end of the creek, and it is discharged back into the creek at its upstream (South) end; [2] flow recirculation plus supplemental aeration at one location in the creek; [3] flow recirculation plus supplemental aeration in the recirculation pipe.

Modeling. The analyses were performed for a "worst case" scenario: the initial conditions for BOD and DO, as well as the water temperature, were selected with reference to a typical summer period after CSO is discharged from RAPS. BOD in the water column was assumed to be oxidized and to settle down; DO is used for oxidation of the BOD in the water column and by the sediment oxygen demand from the bed, while reaeration from the atmosphere, once flow is forced in the creek, is a positive contribution to the DO levels.

The scenario modeled is indeed idealized; on the other hand, its analysis allowed for a first evaluation of the potential effectiveness of some "purification" technologies. The "purification" goal was set, in terms of DO concentration, to 4 mg/l suggested by the Illinois Pollution Control Board (IPCB).

Results. The results obtained for the three "purification" solutions listed above are herein briefly illustrated, considering a recirculation discharge of 50 MGD (2.19 m^3/s), for which sediment resuspension from the bed is avoided. Figure 6a shows the corresponding flow velocity field, which is on average 0.02 m/s, with a maximum value of 0.04 m/s.

The O'Connor and Dobbins formula (1958) was used to compute the reaeration coefficient K_a ($K_a[day^{-1}] = 3.93(U[m/s])^{1/2}/(H[m])^{3/2}$, where H is the water depth and U is the flow velocity) and Mortimer formula (1956) for the DO concentration at saturation C_s ($C_s[mg/l] = \exp[7.71 - 1.31\ln(T[°C] + 45.93)]$,where T is the water temperature). The BOD settling velocity was conservatively assumed equal to 1 m/day (Alp and Melching, 2006).

Scenario 1: flow recirculation. Figures 6c and 6d show respectively the spatial field of the reaeration coefficient K_a in day^{-1} and the difference between the reaeration (DO source term) and bed sediment oxygen demand (DO sink term) in mg/l/day for a flow rate of 50 MGD and a typical summer temperature of 25 °C (the diurnal variation of temperature, which is in general in the order of 1-2 °C, was neglected). Rearation is relevant especially in the upstream portion of the creek, where the flow is faster and shallower. The overall effect of flow recirculation is to increase the DO levels. Figure 6b shows the DO field at equilibrium starting from an initial concentration of 1 mg/l, typical value after a CSO event. The equilibrium condition for DO, ultimately determined by the balance between reaeration and bed sediment oxygen demand, is reached after about three weeks, when considering an initial post-CSO BOD concentration of 60 mg/l in the water column, which gradually goes to zero because of settling and oxidation.

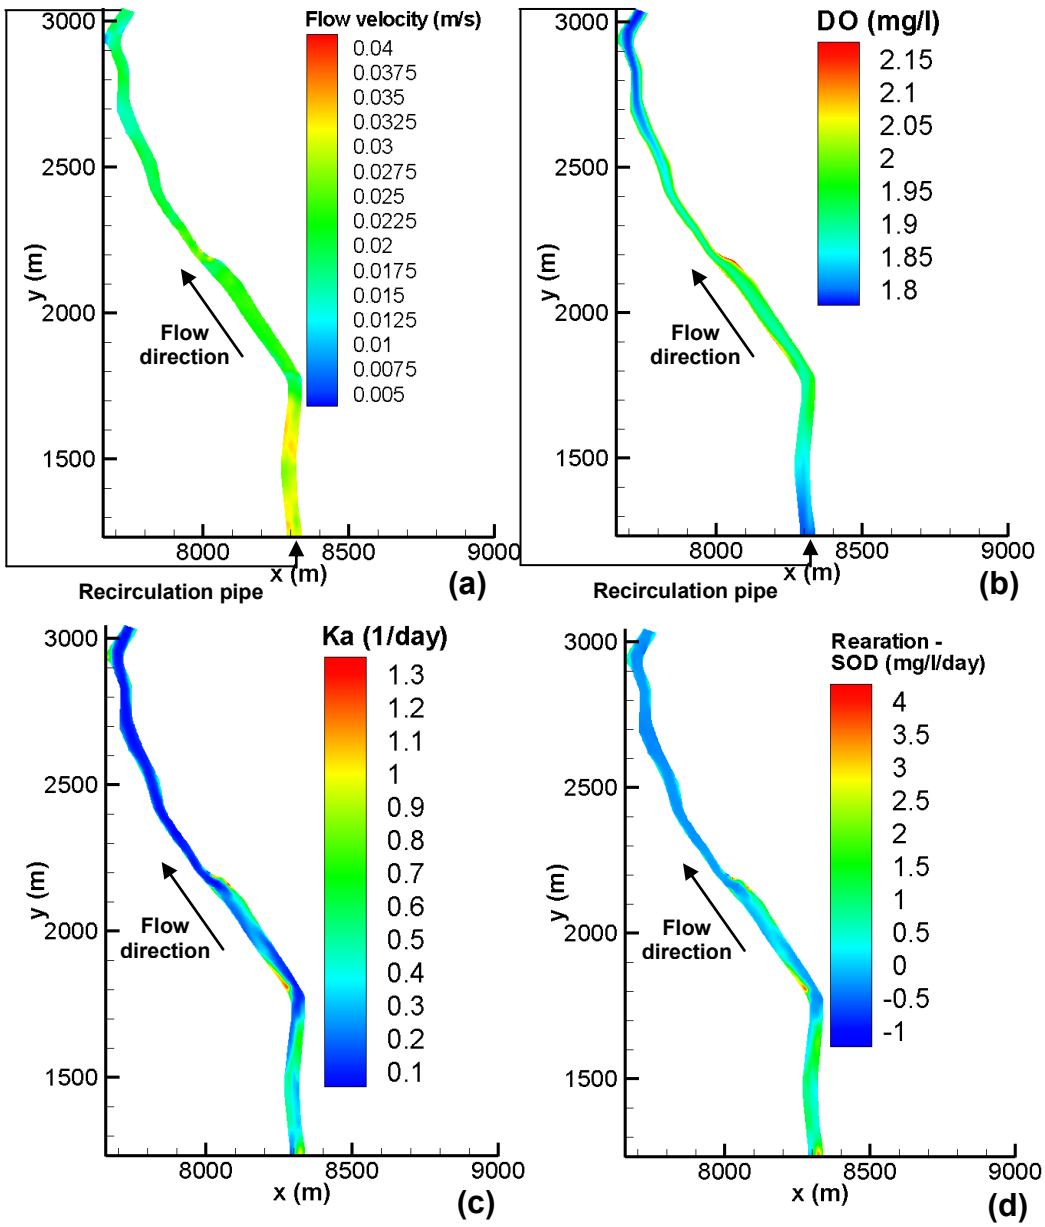

Figure 6. (a) Flow velocity field for a flow rate of 50 MGD. (b) DO concentration field at equilibrium. (c) Reaeration coefficient. (d) Difference between the reaeration (source) and bed sediment oxygen demand (sink) terms.

Scenario 2: flow recirculation plus supplemental aeration in the creek. From Scenario 1 it appears that a flow recirculation of 50 MDG is not enough to meet the IPCB standard of 4 mg/l for DO (Figure 6b). Supplemental aeration can therefore be coupled with flow recirculation. Figure 7a shows the DO field at equilibrium, when a continuous DO supplemental input of 1.31 g/s, minimum required to meet the IPCB standard of 4 mg/l everywhere in the creek, is introduced at about mid-channel.

Scenario 3: flow recirculation plus supplemental aeration in the recirculation pipe. The location of the DO supplemental aeration input can be alternatively set in the

recirculation pipe, rather than in the creek. This solution allows for complete mixing of the oxygen in the water before it flows into the upstream (South) end of the creek. Obviously, the minimum DO input rate that is necessary for meeting the IPCB standard everywhere in the creek is the same as calculated for Scenario 2. However, if the additional oxygen is introduced in the pipe, the time to reach equilibrium of the DO field in the creek is noticeably reduced, since mixing occurs in the pipe and not in the creek itself: only a bit more than one day is enough to reach, in the summer, the equilibrium field in Figure 7b.

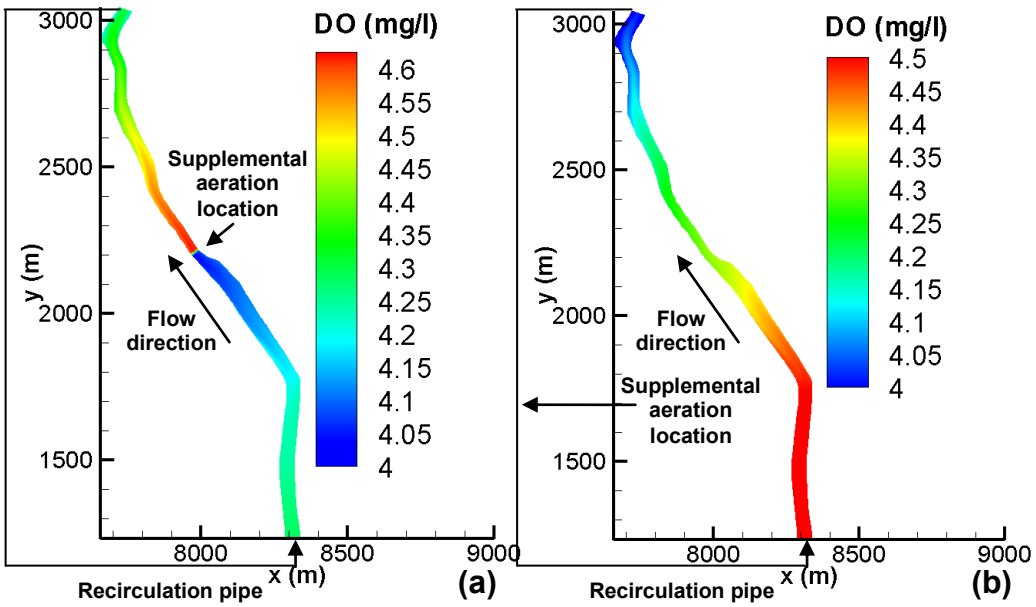

Figure 7. (a) DO concentration field at equilibrium for Scenario 2. (b) DO concentration field at equilibrium for Scenario 3.

The analysis presented shows that flow recirculation, when coupled with supplemental aeration, represents a potential solution for the creek restoration in terms of DO levels. The disconnection from the South Branch appears to be convenient, since the water quality in Bubbly Creek would not depend on the water quality of the Chicago River. Moreover, recirculation allows for significantly reducing the supplemental aeration rates.

CONCLUSION

A new two-dimensional depth-averaged water quality BOD-DO model was implemented in the numerical code STREMR-HySedWq. The model allowed for evaluating two different scenarios for Bubbly Creek in Chicago, i.e. Combined Sewer Overflow events and potential "purification" technologies such as flow augmentation, flow recirculation and supplemental aeration.

In particular, a quantitative framework for the evaluation of the BOD transport across the bed/water interface in rivers was derived, in order to capture the additional oxygen demand in the water associated with the resuspension of organic sediments

from the bottom. The process was described in terms of its dependency on the properties of the flow, the sediments and the bed.

The application of the model to Bubbly Creek showed its potential use in the evaluation of the DO depletion associated to high BOD content in the water column, both in the short and long term period after a CSO event. The results showed that the described conceptual framework is able to capture, both qualitatively and quantitatively, the DO dynamics during and after a CSO discharge, through calibration against measurements of DO levels. It also provides physical insight into the processes which govern the water quality in the creek and guidance for implementing water quality remediation and sediment management solutions in the future.

Abstract

The Copeland method for designing geomorphologically stable channels has been included in the Army Corps of Engineers' Hydraulic Engineering Circular River Analysis System (HEC-RAS). This method requires the bottom width, depth, and side slopes of a representative cross-section from a stable, upstream reach as input. This assumes the upstream cross-section can be approximated by a trapezoidal channel, but no instruction on how to derive this trapezoidal approximation is given in available literature. Additionally, the method requires a side-slope Manning 'n' value, for which the available documentation provides only qualitative guidance. This paper presents a step-by-step design example for using the Copeland method, including approximating the upstream channel as a trapezoid and calculating the sidewall Manning 'n'.

Introduction

The Army Corps of Engineers' Hydraulic Engineering Circular River Analysis System (HEC-RAS) includes capabilities for calculating bankfull discharge and for designing geomorphologically stable channels. One of these tools is the Copeland method for stable channel design.

The Copeland method is an analytical stable channel design method. The goal of this method is to design the bottom width, depth, and slope (side slopes are a required input) of a trapezoidal channel so that the sediment transport capacity in the designed channel equals the sediment transport capacity of a stable, upstream supply reach. The method uses Brownlie's resistance and sediment transport functions, which apply only to sand bed channels (Brownlie, 1981). Additional limitations on the method's applicability are presented in the HEC-RAS Hydraulic Reference Manual (USACE, 2008) and should be consulted prior to using the method. The basic steps for performing a Copeland stable channel design are provided in the HEC-RAS Users Manual (USACE, 2006). Unfortunately, currently available scientific literature, users manuals, and case studies do not provide sufficient guidance in selecting several crucial input parameters. The bottom width, depth, and side slopes of a representative

cross-section from a stable, upstream reach are required as input. These inputs assume the upstream channel is a trapezoid. Since the upstream channel will typically be a natural cross-section, question arises as to how the trapezoidal measurements are to be supplied. Also, the Copeland method requires a Manning 'n' value for the sidewalls of the main channel. While engineers are familiar with choosing Manning 'n' values for the entire main channel, they seldom need to choose sidewall 'n' values. Only qualitative guidance exists in the literature.

This paper provides a complete step-by-step example of how to use the Copeland method for stable channel design in HEC-RAS. It demonstrates how to calculate an equivalent trapezoid for the upstream cross-section and how to calculate the side-wall Manning 'n' values. Required inputs include a surveyed cross-section and slope for an upstream supply reach, and channel average Manning 'n' values for the upstream cross-section and the project reach.

Stable Channel Design (Copeland Method)

Given:

$n_{upstream}$ = .0388
n_{des} = .0345

I. Field Reconnaissance

A. Perform a cross sectional survey at a stable upstream riffle or inflection point. Record the station/elevation of the left and right edges of the moveable bed and the elevation of the bankfull stage. This is shown in Table 1 below.

Table 1. Cross-sectional Survey

Sta	Elev	Notes	Sta	Elev	Notes	Sta	Elev	Notes	Sta	Elev	Notes
0	1298.54		30	1293.55		50	1292.37		66	1293.6	
2	1298.41		32	1293.05		51	1292.5		68	1293.87	
4	1298.03		34	1293.24		52	1292.74		70	1294.44	
6	1297.81		36	1293.22		53	1292.76		72	1294.81	RB
8	1297.12		38	1293.32	LEOMB	54	1292.78		74	1294.93	
10	1296.5		40	1293.27		55	1292.87		76	1295	
12	1295.84		41	1292.95		56	1292.77		78	1294.86	
14	1295.22		42	1292.82		57	1292.74		80	1294.96	
16	1294.81		43	1292.73		58	1292.81		82	1294.99	
18	1294.72		44	1292.56		59	1293.11		84	1295	
20	1294.58		45	1292.58		60	1292.89		86	1295.1	
22	1294.36		46	1292.44		61	1292.87		88	1296.16	
24	1294.35	LB	47	1292.53		62	1292.84		90	1296.98	
26	1293.66		48	1292.45		63	1293.09				
28	1293.74		49	1292.41		64	1293.14	REOMB			

LB = Left bank
LEOMB = Left edge of moveable bed
RB = Right bank
REOMB = Right edge of moveable bed

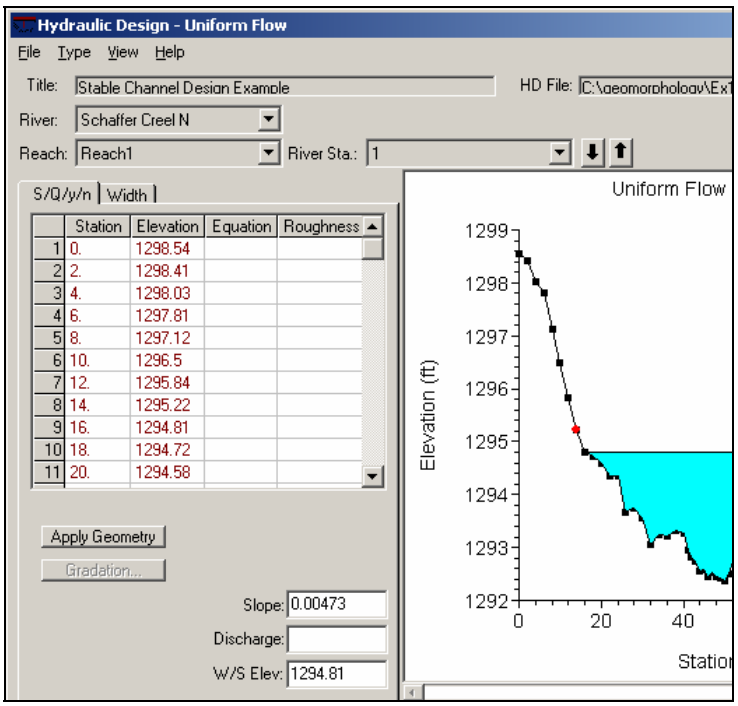
B. Determine the slope of the upstream section from riffle to riffle or inflection point to inflection point.

Slp = 0.00473

C. Estimate the bankfull stage by geomorphologically observation or some other method.

Bankfull stage (h_{bnk})= 1294.81 ft

D. Take a bed-sediment sample to determine the sediment gradation of the upstream cross section, consisting of the d_{16}, d_{50}, and d_{84} (sieve size for which, 16%, 50%, and 84% of the material is finer by weight.) Note that a by-weight sediment characterization is not the same as a "pebble count," (a by-number characterization).



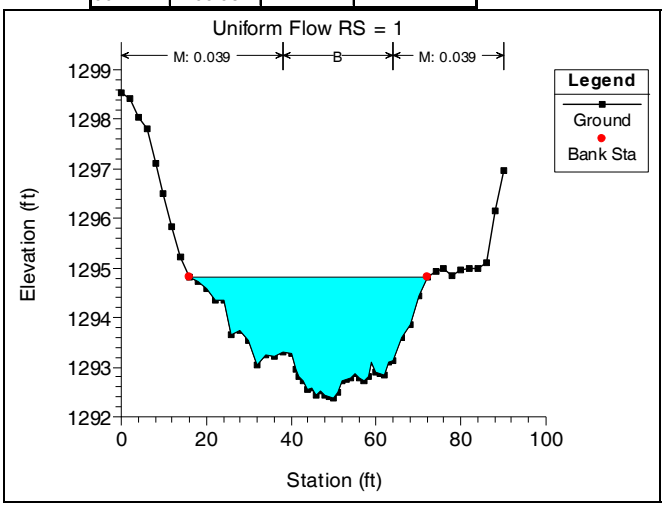
d_{16} = 0.8 mm
d_{50} = 1 mm
d_{84} = 1.5 mm

II. HEC-RAS

A. Calculate the design bankfull flow

1. Create a new HEC-RAS project.
2. Create a new river and reach in the geometry editor window.
   River name: Schaffer Creel North
   Reach name: Reach1
3. Create a new cross section. *[Cross Section, Options, Add a new Cross Section]*
4. Paste the surveyed station/elevation points into the new Cross section then add the location of the left and right bank stations (14 and 72 feet, respectively). *[Using Ctrl C and Ctrl V for the copy and paste commands, respectively, is often need in building HEC-RAS models.]*

5. Choose the *Run/Hydraulic Design Functions…* menu item from the main menu.
6. Choose the *Type/ Uniform Flow* menu item.
7. If it is not already selected, choose the correct river and reach from the drop down combo boxes.
8. Enter the elevation of the field-selected bankfull stage and the channel slope into the appropriate fields. (1294.81 ft and 0.00473, respectively.)



9. Click on the field next to the elevation on left most station/elevation point, under the heading "Equation" and choose Manning as the resistance equation.
10. Enter the Manning 'n' value for the upstream reach of 0.0388.
11. Click inside of the "Discharge" field then click the "Compute" button to calculate the discharge.

$Q_{bnkfull}$ = 266 cfs

B. Choose a Manning's n-value for the channel side walls and bed

1. Click on the field next to the elevation on the station/elevation point for the start of the movable bed under the heading "Equation" and choose the Brownlie resistance equation. The station/elevation values for this point are (38, 1293.32).
2. Choose the Manning's resistance equation for the left-most station/elevation point in the cross section and for the point at the end of the moveable bed. Enter the same Manning's n-value at these points. Here those station/elevation points are (0, 1298.54) and (64, 1293.14). Note that a resistance equation will apply from the station/elevation point where it is entered across the channel from left to right (down the table) until a different equation is specified. The table below shows the location of the Manning and Brownlie resistance equations and the n-values for this example. The initial n-value used was 0.039.

Station	Elevation	Equation	Roughness
0	1298.54	Manning	0.039
2	1298.41		
4	1298.03		
Hidden Cells			
36	1293.22		
38	1293.32	Brownlie	
40	1293.27		
41	1292.95		
Hidden Cells			
62	1292.84		
63	1293.09		
64	1293.14	Manning	0.039
66	1293.6		
68	1293.87		
Hidden Cells			
88	1296.16		
90	1296.98		

3. Click the compute button to calculate the discharge. Compare the discharge to the calculated bankfull discharge, $Q_{bnkfull}$. Adjust the two Manning's n-values and click Compute again. Readjust the Manning's n-values until the discharge equals the expected discharge. The Brownlie resistance equation applied for the movable bed portion of the channel throughout the calculations.

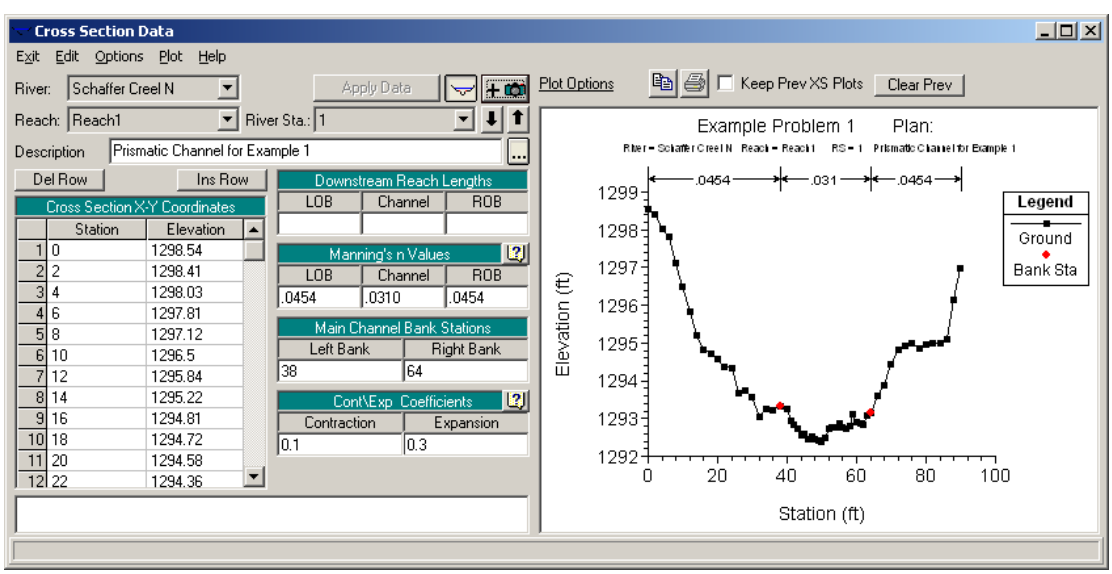
Sta	Equation	n	Q	$Q_{bnkfull}$
0 and 64	Manning	0.039	292	266
0 and 64	Manning	0.04	288	266
0 and 64	Manning	0.043	275	266
0 and 64	Manning	0.045	268	266
0 and 64	Manning	0.0454	264	266

$n_{sides} = 0.0454$

This Manning's n-value is the sidewall Manning's n-value for use in the Copeland method stable channel design.

4. Change the resistance formula for the moveable bed region from "Brownlie" to "Manning." Enter an intial n-value for the movable bed region (station 38) and click compute. Readjust this Manning's n-value until the discharge equals the expected discharge without altering the two sidewall Manning's n-values. Here the sidewall n-value is 0.0454.

Station	Equation	n	Q	$Q_{bnkfull}$	
38	Manning	0.03	271	266	
38	Manning	0.032	263	266	
38	Manning	0.0310	266	266	OK



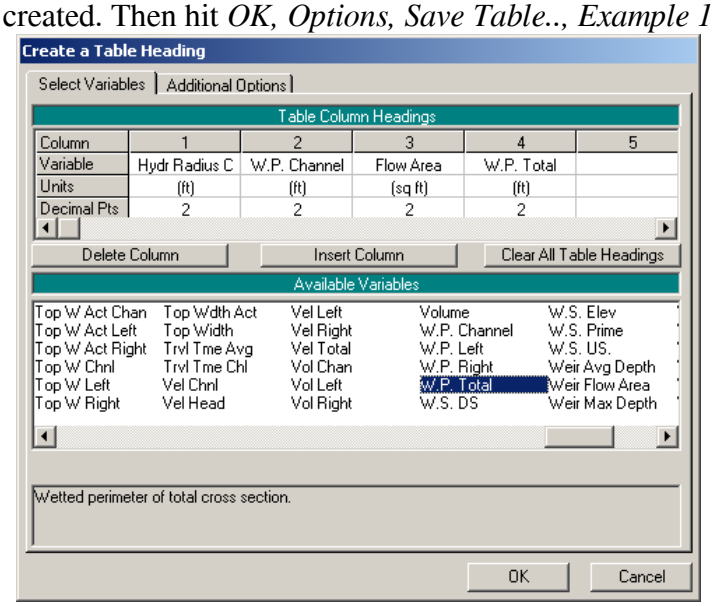
$n_{bed} = 0.0310$

The Manning's n-value found is the Manning's n for the movable bed at bankfull flow. In summary the Manning's n-values are 0.0454 for the overbanks and 0.0310 for the main channel.

C. Create a Prismatic Hydraulic Model for the Upstream Reference Cross Section.

Use the river, reach and cross section created earlier.

1. Set the bank stations to the edges of the moveable bed (not the bankfull level) and set the overbank and main channel n-values to 0.0454 and 0.0310, respectively.



2. Copy Cross Section 1 to Cross Section 100. [*Options, Copy Current Cross Section*]
3. Adjust the elevations of Cross Section 100 by 100*slope. [*Options, Adjust Elevations*]
    1. +100 * Slp = +100 * 0.00473 = +0.473

4. Set the downstream reach lengths for Cross Section 100 to 100.
5. Copy the Cross Section 100 to Cross Section 200. [*Options, Copy Current Cross Section*]
6. Adjust up the elevations of Cross Section 200 upward by 0.473 ft. [*Options, Adjust Elevations*]
7. Exit the cross section editor then in the Geometric Data editor, save the geometric data as Prismatic. *[File, Save Geometry Data As….., Prismatic]*
8. From the main menu open the Steady Flow Editor and input the design bankfull discharge of 266 cfs determined above. [*Edit, Steady Flow Data*]
9. In the Steady Flow Editor, input the "normal depth" downstream boundary condition. Enter the slope. [*Reach Boundary Conditions, Downstream, Normal Depth, 0.00473*].
10. From the main menu, run the steady flow analysis of the prismatic upstream reach. [*Run, Steady Flow Analysis, Subcritical, Compute*]
11. Use the HEC-RAS Profile Summary Tables to determine the following parameters from the upstream prismatic reach:

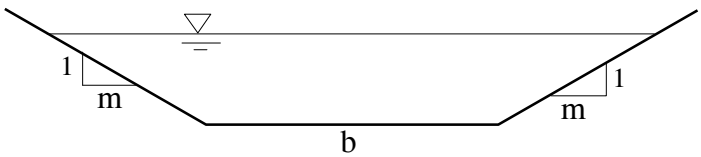
Table 2. Parameters

Parameter	Symbol	HEC-RAS Designation
Hydraulic radius of the channel above the moveable bed	R_{mov}	Hydr Radius C
Wetted perimeter of the moveable bed	P_{mov}	W.P. Channel
Cross sectional flow area of the entire bankfull channel	A_{bank}	Flow Area
Wetted perimeter of the entire bankfull channel	P_{bank}	W.P. Total

12. To find these values, perform the following steps from the main menu *View/Profile Summary Table, Options, Define Table, Clear All Table Headings.* You can then double click on the variables until the following table is created. Then hit *OK, Options, Save Table.., Example 1 Prismatic*.

Profile Output Table - Example 1 Prismatic

File Options Std. Tables User Tables Locations Help



HEC-RAS Plan: Plan 01 River: Schaffer Creel N Reach: Rea

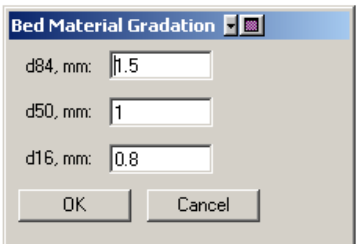
Reach	River Sta	Profile	Hydr Radius C	W.P. Channel	Flow Area	W.P. Total
			(ft)	(ft)	(sq ft)	(ft)
Reach1	200	Bankfull Flow	1.77	26.25	67.55	51.28
Reach1	100	Bankfull Flow	1.77	26.25	67.54	51.28
Reach1	1	Bankfull Flow	1.77	26.25	67.38	51.23

13. Determine the bottom width and height of the equivalent upstream trapezoid. Use the values from Cross Section 200.

$b = P_{mov} = 26.25$ ft
$y = R_{mov} = 1.77$

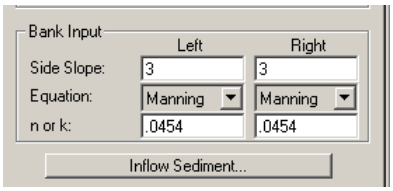
14. Calculate the side slopes of the equivalent trapezoidal channel for the upstream cross section, using the following equation, where m is defined in the drawing below.

$$\frac{(A_{bank})^5}{(P_{bank})^2} = \frac{(by + my^2)^5}{\left(b + 2y\sqrt{m^2+1}\right)^2} \rightarrow \frac{(67.55)^5}{(51.28)^2} = \frac{(26.25(1.77) + my^2)^5}{\left(26.25 + 2(1.77)\sqrt{m^2+1}\right)^2}$$



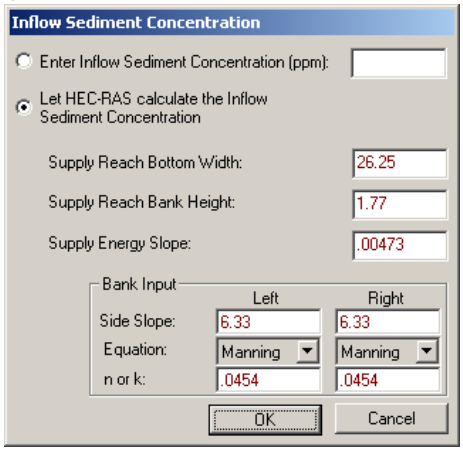
By trial and error or by using the Solver in EXCEL one can solve for m = 6.33.

A_{bnk} =	67.55 ft^2
P_{bnk} =	51.28 ft
b =	26.25 ft
y =	1.77 ft
m =	**6.33**



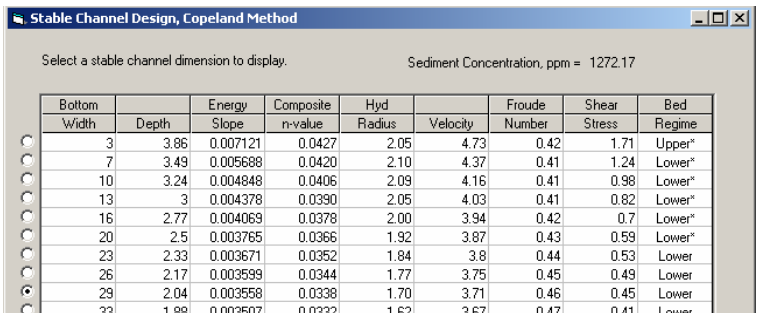
-8E-07 ← $\frac{(A_{bank})^5}{(P_{bank})^2} - \frac{(by+my^2)^5}{\left(b+2y\sqrt{m^2+1}\right)^2}$

C. Calculate a Copeland Stable Channel Design



1. Choose the *Run/Hydraulic Design Functions…* menu item from the main menu.
2. Choose the *Type/Stable Channel Design…* menu item and the *Copeland* tab.
3. Enter the design discharge. Keep the defaults for the specific gravity and temperature. The Optional Input boxes can be left blank.
4. Click the *Gradation* button and enter the values of d_{16}, d_{50}, and d_{84}.

5. Enter the side slopes and the side slope Manning's n-values for the design channel. The side slopes should be chosen for stability and constructability. 2 to 3H:1V (m=2 to 3) may be appropriate. Here we will use a side slope n-value of 0.0454 for the design channel. Probably an n-value with two significant digits would be preferable. For instance, 0.045 rather than 0.0454. Here we have kept the extra significant digit to maintain the equivalent conveyances using different methods.



6. Click the *Inflow Sediment…* button and a window will appear. Choose the option to let HEC-RAS calculate the inflow sediment concentration. Enter the bottom width (b), bank height (y), Energy Slope (channel slope) and side slopes (m), calculated earlier for the upstream representative channel. If the upstream section is a meandering channel and the channel design will be a meandering channel, the same n-value for the side slopes should be used in both the upstream and the design section. When the upstream section is stable, but non-meandering, and a meandering channel will be designed downstream, or when a straight channel will be designed downstream from a meandering channel, then the n-values should be different.

7. Click the *Compute* button. The values that go into this table are for the upstream reference cross section. The program computes the sediment inflow

from the upstream reference reach and provides many design options for the design channel.

8. Choose the desired design from the table of solutions. HEC-RAS plots the chosen solution. The channel has been designed to carry incoming bankfull flow at the bankfull stage and to have the same sediment transport capacity at bankfull flow as the upstream cross section.

Bottom Width	Depth	Energy Slope	Composite n-value	Hyd Radius	Velocity	Froude Number	Shear Stress	Bed Regime

Conclusion

A procedure was developed for designing a geomorphologically stable channel using the Copeland method of stable channel design within HEC-RAS. An example was presented that applied the procedure to a natural channel reach.

Acknowledgments

This project was sponsored by the Kansas Department of Transportation through KTRAN project KU-08-5. Special thanks are due to Mr. Jim Richardson, the project administrator, and to Mr. Brad Rognlie for their support in this endeavor.

Abstract:

Urbanization has a significant impact on rivers and streams, modifying flows, sediment loads, channel morphology, water quality and nutrient processing, and aquatic biota. Because of these impacts, a majority of the streams in urban and urbanizing watersheds are reported on §303(d) state lists as impaired from siltation, habitat alteration, nutrients, bacteria, and other stressors. States are required to develop total maximum daily loads (TMDLs) under 40 CFR 130, and watershed-scale implementation plans are produced to rehabilitate impaired streams by achieving target TMDL allocations. Stream restoration practices are commonly used as corrective measures to meet TMDLs, particularly for siltation and habitat alteration. However, urban stream restoration typically consists of reach-scale projects that may not be well integrated into a watershed corrective plan. Rather, project scope and location are commonly determined by local perceptions of need and accessibility. Watershed planning is needed in urbanizing watersheds for various reasons. Most importantly, planning is needed because hydrology and sediment loads change as developments occur over time until ultimate build-out, and future infrastructure constraints affect channel planform stability. These reasons underscore the critical need for restoration projects to be implemented based on a watershed plan, and a plan that integrates implementation of stormwater management best management practices (BMPs). The objective of this paper is to present a framework for monitoring and assessment protocols for urban and urbanizing watersheds, with the aim to better support planning of stream restoration projects and improve restoration outcomes. This is the

product of a joint task committee by the Urban Stream Committee of the Urban Water Resources Research Council and the River Restoration Committee of the Hydraulics and Waterways Council.

Introduction:

Watersheds impacted by urbanization have altered chemical, physical and biological processes, impacting how water, sediment, organic matter, nutrients, and pollutants are transported from a more impervious land cover to the stream (Paul and Meyer 2001; Chin and Gregory 2005; Palmer et al. 2005; Bernhardt and Palmer 2007). Meyer et al. (2005) terms this degradation of watershed processes as the "urban stream syndrome". Impacted streams range in size from 1st to approximately 5th order, which is of a scale where land cover in entire watersheds can be converted to urban. Impacts to urban streams include degradation of water quality by increased nutrients, suspended sediments, toxins and water temperatures (Carle et al. 2005; Walsh et al. 2005). Altered hydrological patterns can include increased stormflow peaks, decreased lag time to peaks, greater frequencies and duration of erosive flows, and altered summer baseflow (Booth and Jackson 1997; Walsh et al. 2005). Channel morphologies in early stages of watershed urbanization adjust by deepening and widening, typically referred to as channel incision (Hammer 1972, Booth 1990; Bledsoe and Watson 2001). Less systematic responses occur in channel adjustments such as excessive local scour, altered pool-riffle spacing, and reach-scale bed aggradation or degradation (MacRae 1996; Chin and Gregory 2005; Kang and Marston 2006). Ecologically, organic matter retention is lowered and algae biomass frequently increases, simplifying benthic macroinvertebrate communities (Moerke et al. 2004; Meyer et al. 2005). Fish assemblages are less diverse in urban streams, typically consisting of tolerant, pool-dominant species (Moerke and Lamberti 2003; Schwartz and Herricks 2007). Based on clear needs, the numbers of restoration projects in these impacted watersheds have greatly increased to contend with the urban stream syndrome (Bernhardt et al. 2005).

In the United States, increased use of stream restoration practices in urban watersheds has been driven, in part, by Clean Water Act (CWA) regulations. Many urban streams are identified as impaired on CWA §303(d) state lists because they do not meet state water quality and/or biocriteria standards due to siltation, habitat alteration, nutrients, bacteria, and various toxic pollutants. Once listed as impaired, states are required to develop total maximum daily loads (TMDLs) under 40 CFR 130 for these reaches (EPA 1997, 1999). TMDLs are issued at the hydrologic unit code (HUC) 8 scale, in which annual load reductions are prescribed along with suggested corrective action plans. Because impairment in urban watersheds is a function of multiple stressors on aquatic biota, corrective action plans require an array of best management practices (BMPs) that are integrated spatially at the watershed or subwatershed scales (Schueler 2005). Also, it must be recognized that different regulatory rules guide BMP implementation. For example under CWA §402 National Pollutant Discharge Elimination System (NPDES), stormwater permits require municipalities and urban counties to complete stormwater management plans. Plans include watershed maps of stormwater outfalls and predict future hydrology through models that account for runoff changes from proposed urban land developments (Schueler and Kitchell 2005). BMPs commonly used include

detention ponds, grass swales, solids removal devices, and community retrofits using low impact development (LID) and integrated management practices (IMP). Stream mitigation banks and BMPs are promoted by federal and state regulators when urban developments require CWA §404 permitting.

In fact, the stream restoration practice has grown into a major business with over one billon dollars spent on projects annually (Bernhardt et al. 2005). Support for restoration projects by state and local governments are endorsed, in part or combined, by CWA regulations §130, §303(d), §402, §404, and others (Deason et al. 2009). However, recent concerns as to what constitutes project success have arisen within the restoration practice community, largely due to vague project objectives and a lack of post-construction monitoring (Brown 2000; Bernhardt et al. 2007). Slate et al. (2007) also noted engineering liability issues have arisen due to conflicts between design methodologies, regulatory guidelines, and project failures related to instream structures and channel stability. The concern over project success is driven by the legal requirement to return streams to a "fully supporting" status with respect to designated uses such as aquatic life, and community-level accountability for project expenditures. It is difficult to predict or assess success for watershed-scale objectives when stream restoration projects are implemented at the local reach scale, and impairment occurs from modified land uses and multiple stressors throughout a watershed.

It is imperative that stream restoration projects in urban watersheds be implemented within a broader watershed-scale context, in which project objectives are clearly linked to stressors. In addition, project designs must take into account constraints imposed by urban infrastructure, and the changing hydrology, sediment yield, and channel morphology over time from urbanization. Project objectives and designs differ in urban and urbanizing watersheds than those in rural watersheds; therefore, urban-specific monitoring and assessment information must guide the pre-design decisions to optimally target projects. In general, urban stream restoration objectives include: flood mitigation; channel stability; mitigation credit to offset CWA §404 permitted impacts; infrastructure protection; stream channel relocation; aesthetics, water quality improvement; and, stream riparian habitat enhancement. Because of the difficulty in setting specific objectives linked to measurable stressors, it has been noted that objectives for restoration projects are often vague (Johnson and Brown 2001; Bernhardt et al. 2007). This is particularly true when restoration projects are implemented without adequate watershed monitoring and assessment.

Because most stream reaches in urbanizing watersheds are not in a geomorphic equilibrium state, this precludes monitoring and assessment guided by an analog, or reference reach approach (Fischenich 2001). It is commonly recognized that urbanization permanently alters watershed processes, and that restoring a stream back to a preexisting morphology is highly unlikely. Monitoring and assessment in urban and urbanizing watersheds needs to comprehensively identify stressors on aquatic biota and describe current environmental conditions. Future conditions must be predicted by use of watershed modeling guided by municipal land use planning documents (Schueler 2005). Many monitoring and assessment tools are freely available that can be used in urban streams and support restoration practices. For example, HEC-HMS and HEC-RAS can be used predict future stream flows based on the composition of land use types at

ultimate build-out (USACE 2002, 2008). Engineering regime equations can then be applied to assess channel stability once channel morphology and future flows have been established (Copeland et al. 2001; Shields et al. 2003). Indirectly, placement of stormwater detention affects predicted flows and sediment yield; thus, it must be part of the watershed restoration planning so that hydrological modeling can more accurately estimate future flows. Within the current restoration practice, a greater recognization and integration of available monitoring and assessment tools is needed to address the "urban stream syndrome" and to better aid in the recovery of degraded urban streams.

The objective of this paper is to propose a framework for monitoring and assessment protocols that integrates currently available, public domain tools specific to urban and urbanizing watersheds. The framework recognizes the need to assess present and future urban conditions, and to integrate stormwater management into watershed-scale stream restoration plans. It is suggested that this integration can be cost effective because many municipalities already fund watershed hydrological studies, and for larger cities studies are funded through stormwater utility fees. In this proposed framework, monitoring tools are those that quantify baseline conditions and support modeling efforts to predict future channel morphology and water quality. Assessment outcomes from the framework prioritize restoration project needs within watersheds, and support restoration planning and design. Project implementation will always be one reach at a time as currently practiced, however a scheduled program of projects through a watershed planning process would better guarantee watershed recovery.

Framework for Monitoring and Assessment Protocols

The framework for monitoring and assessment protocols has four main components and many supporting protocols within each main component (Figure 1). The four main components are: 1) delineate watershed boundaries to define hydrological management units; 2) conduct watershed-scale analysis using various monitoring and assessment tools; 3) delineate reach boundaries based location of instream hydraulic controls to define reach-scale management units; and, 4) develop a watershed plan for restoration projects. Monitoring and assessment protocols are described below.

The framework is based on an engineering modeling perspective that is essential to predict future streams flows and sediment loads over time accounting for urbanization of the watershed. Coordinated with municipal land use plans, hydrological models (e.g., HEC-HMS, SWMM, WinHSPF) and sediment yield models (e.g., AnnAGNPS, SWAT) can be used to predict future watershed conditions. Watershed-scale assessments rely on many different monitoring tools that are multidisciplinary in origin. These tools quantify necessary data for hydrological/sediment yield model development, and identify spatial problems including channel stability, pollutant sources for poor water quality, and degraded physical habitat. The framework, hierarchical in structure, allows watershed assessments to guide selection of reaches for more detailed modeling and assessment at the reach scale. Reach boundaries are defined at hydraulic controls in the channel, tributary confluences, and major stormwater outfalls to run hydraulic models for channel stability and ecohydraulic habitat investigations (e.g., HEC-RAS, ConCEPTS, PHABSIM, River2D). This hierarchical approach links observed impairments between

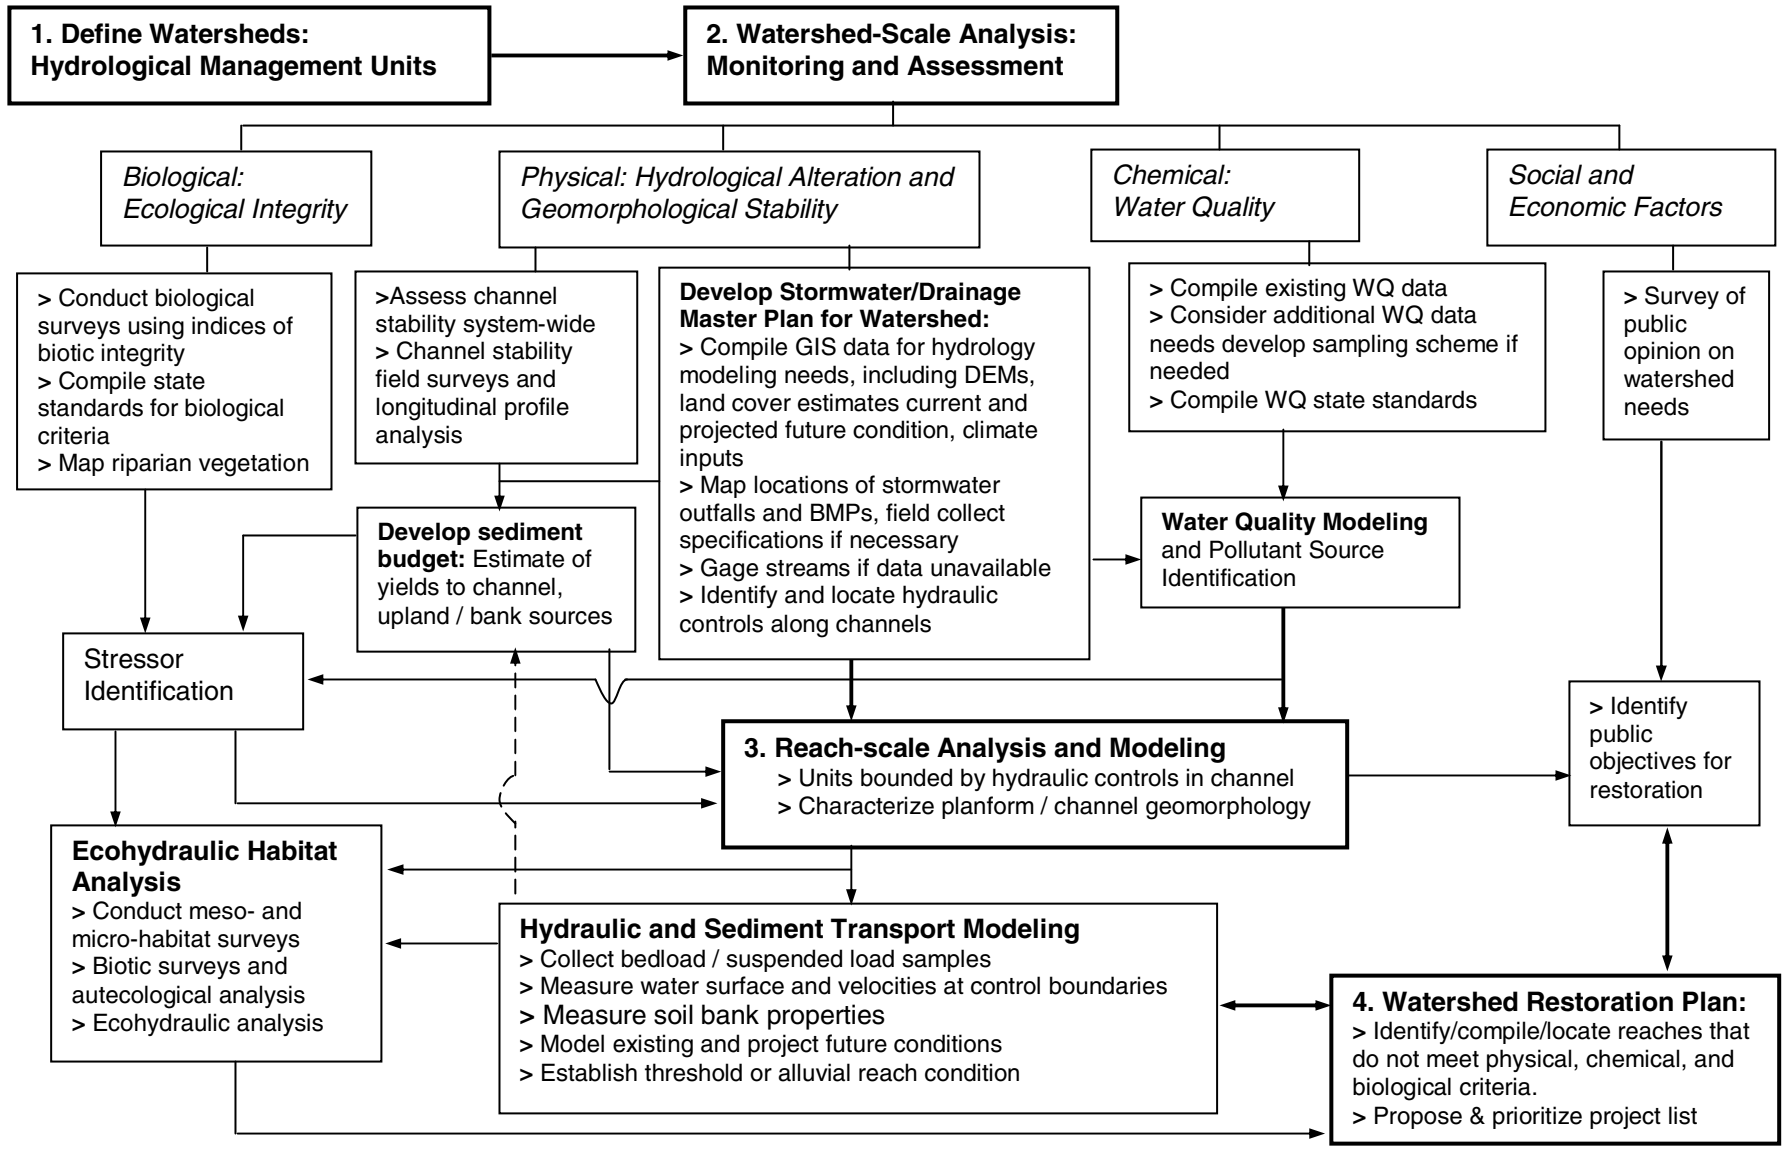

Figure 1. A monitoring and assessment framework for watershed planning to support urban stream restoration practices.

watershed and reach scales, and provides the critical information for appropriate use of stream restoration practices.

Descriptions of the monitoring and assessment protocols within the framework are illustrated below:

1. Define Watersheds: Hydrological Management Units

The first step in any watershed assessment is to define boundaries of the hydrological management unit. Watershed size can vary depending on state, but management units will likely be either HUC-12 or -14 designations. GIS tools are available to delineate watershed boundaries from DEMs, such as ArcHydro and BASINS (EPA 2001). USGS seamless spatial databases can provide the DEMs. The Center for Watershed Protection also provides a general procedural description for delineating watershed boundaries (Schueler 2005).

2. Watershed-scale Analysis: Monitoring and Assessment Protocols

In this framework the focus of the watershed-scale analysis is two-fold: one is to quantify existing conditions of water quality, hydrology, channel morphology and stability, habitat quality, biotic integrity, and mapping urban infrastructure and land uses; and two, is to develop a stormwater/drainage master plan to predict future hydrology and sediment yields. Thorne (1998) and FISRWG (1998) are good resources for basic watershed reconnaissance protocols. Developing a stormwater/drainage master plan requires use of municipal land use plans to model runoff changes from urbanization. In addition, social and economic factors need to be identified, and public opinion must be considered as part of the decision-making process for watershed corrective action plans (Wade et al. 2002). Many urban centers have watershed associations that provide a means of communication between citizens and technical professionals.

Accomplishment of the watershed-scale analysis includes seven tasks, which will be described in detail in a future joint task committee product. The tasks are:

a. Develop stormwater/drainage master plan;
b. Assess channel stability system-wide;
c. Develop watershed sediment budget;
d. Conduct biotic integrity and physical habitat surveys;
e. Conduct riparian vegetation surveys;
f. Conduct water quality analysis and modeling; and
g. Conduct a stressor identification (CADDIS) analysis.

Outcomes from the watershed-scale analysis provide a fundamental understanding of the causes of the impaired condition, identifying reaches that fail to meet water quality standards, levels of biotic integrity, and/or channel stability. At the watershed scale, qualitative field studies are beneficial to field truth the data collected during desktop analysis efforts (Schueler and Kitchell 2005). Qualitative site-specific data are gathered on geomorphic indicators of stream instability, such as bank cutting and mass wasting, local bed erosion, and debris jams that are contributing to local erosion. Rosgen (2006) has developed protocols for watershed-scale reconnaissance and assessment to identify geomorphically unstable reaches that may attribute excessive sediment to channels; the protocols are known as WARSSS (Watershed Assessment of

River Stability and Sediment Supply). The CADDIS analysis can be used to systematically link multiple stressors to sources of biological impairment (USEPA 2000). To accomplish the hydrological and water quality modeling, an essential task requires the drainage network to be delineated into nodes and links, a standard practice for hydraulic modeling in watersheds (Morris 1996).

Key to the effort is to delineate nodes at existing hydraulic controls, i.e., road crossings, bridge or utility crossings, stormwater outfall locations, major channel slope changes, lateral constrictions, or bedrock outcrops. Although seemingly simplistic, identifying hydraulic controls is critical because geomorphic characteristics and reach stability are typically bounded by these controls. From a holistic view of the watershed, an integrated strategy of using both stream restoration practices and stormwater BMPs can be planned. Locations of problem reaches are mapped for interpretation and prioritization of potential project needs. Identified problem reaches may need further monitoring and assessment utilizing tools appropriate at the reach, or local scale.

3. Reach-scale Analysis and Modeling

Once a watershed has been analyzed and reaches identified with potential restoration needs, monitoring and assessment specific to the reach-scale can be implemented at these locations only. Potential restoration needs are based on identified locations of stressors, including geomorphic, water quality, and biological conditions. Geomorphic data collected at this reach scale can be used to quantify stream channel form and processes, and supplement sediment transport modeling activities (Niezgoda and Johnson 2005; Smith and Prestegaard 2005). Reach-scale geomorphic analyses can be accomplished with spreadsheet-type aids, e.g., STREAMS (Ward and Mecklenburg 2005), and GeoTools (Bledsoe et al 2007). Important elements of this analysis include the determination of threshold or alluvial reach conditions. Bank stability models based on fluvial and geotechnical processes include the USDA Bank Stability and Toe Erosion Model (Simon et al. 2008). Sediment transport models to estimate whether aggradation/degradation processes dominate include: SAM, ConCEPTS, CCHE2D, and other models. In addition, stream habitat and biological data can be collected (Barbour et al. 1999; Kaufmann et al. 1999), and ecohydraulic models applied for detailed ecological assessments (Schwartz 2003; Bockelmann et al. 2004; Pasternack et al. 2004).

Accomplishment of the reach-scale analysis includes three tasks, which will be described in detail in a future joint task committee product. The tasks are:

a. Geomorphic and bed sediment characterization;
b. Hydraulic and sediment transport modeling;.and,
c. Ecohydraulic habitat analysis.

Outcomes from the reach-scale analyses include a prioritization of restoration needs, and compilation of monitoring data that can support the design process. Geomorphic, hydraulic, and ecological data are integrated in this analysis to recommend ecohydaulic habitat-based restoration projects (Rabeni and Jacobson 1993; Schwartz et al. 2001; Jannsson et al. 2005). If additional monitoring data are needed for project design, a monitoring plan can be developed.

4. Watershed Restoration Plans

Watershed restoration plans are developed based on urban-specific monitoring and assessment efforts at both the watershed- and reach-scales. A system-wide interpretation of the data is completed and reaches with restoration needs are prioritized. Stormwater BMPs must also be identified and prioritized because future stream flows are dependent on implementation of these practices. The final watershed restoration plan must be achieved through community acceptance, where technical professionals and community leaders discuss the technical outcomes from the monitoring and assessment findings.

Summary Conclusions

Because urbanizing streams are impaired by multiple stressors, and these stream systems are continually evolving to a new geomorphic state while infrastructure development persists, approaches to stream restoration will differ from those applied to rural watersheds. Specific monitoring and assessment protocols are needed for urban watersheds, relying on engineering-based hydrological models to predict future stream flows as impervious surfaces increase. This does not preclude the use of other geomorphological- and ecological-based tools; they are needed as well. Watershed restoration plans must incorporate thorough hydrological modeling of existing and future conditions, including the use of stormwater management BMPs. Restoration objectives need to be clearly linked with quantified stressors, to systematically rehabilitate impaired watersheds. Because municipalities with stormwater management programs typically have completed hydrological-based modeling for existing and future conditions, it would be cost effective to develop watershed restoration plans that integrate stormwater management BMPs and instream restoration practices.

ABSTRACT

Best Slough flows through Beale Air Force Base and used to come into contact with groundwater contaminated by trichloroethene (TCE) at Site 17 during low flow periods when it was a gaining stream. An interim remedial action was developed for Site 17 to halt further migration of the contaminated groundwater plume by surrounding it with a slurry wall and establishing a phytoremediation system on top of the site within the slurry wall. The portion of Best Slough in contact with the contaminated groundwater plume was realigned upgradient of the plume with more natural channel morphology and riparian vegetation as well as sufficient hydraulic capacity and channel stability to protect the remedial features on the site. Channel banks were designed with terraced slopes to provide additional acreage for riparian vegetation habitat. Side-channel islands were included in the channel design to provide isolated riparian habitat for waterfowl as well as for aquatic reptiles and amphibians. A complex of deep-water channels was incorporated into the design to provide rearing habitat and thermal refuge for warmwater fish. And all channel features were incorporated, where possible, into the overall erosion control and bank stability design for the channel. Project construction was completed in 2000, and periodic site visits have documented development of aquatic and riparian habitat features and performance of the channel realignment and restoration elements of the project with respect to their design objectives. We summarize observations of channel, riparian, and vegetation performance over the past eight years and present lessons learned from this complex, multi-objective river restoration project.

INTRODUCTION

Past land-use practices on Air Force Bases throughout the United States altered channel form in many Base streams. In addition, past waste disposal practices contaminated soil adjacent to Base streams and degraded water quality in Base streams connected to groundwater (Mengel et al 2000). In the mid 1900's, a 500 meter reach of Best Slough on Beale Air Force Base in an area known as Site 17 (Figure 1) was channelized. Riparian vegetation was also removed in the reach flowing through Site 17. The intent of both of these modifications was to enhance agricultural use of the area (Bruce Reinhardt, Beale Air Force Base, personal communication). Also in the mid 1900's, several years after the channel modifications occurred, several thousand liters of trichloroethylene (TCE), a known carcinogen, were disposed of by draining large drums of the material into shallow pits adjacent to Best Slough (Bruce Reinhardt, Beale Air Force Base,

personal communication). The TCE infiltrated the soil surface and collected on the underlying bedrock about 12 meters deep. TCE also entered the groundwater and flowed into Best Slough during the summer months. Though the TCE in Best Slough volatilized quickly, potentially harmful concentrations were regularly detected. The uniform geometry and degraded water quality (from TCE and increased temperatures) in this 500 meter reach of Best Slough impaired local habitat conditions and created a discontinuity in the aquatic and riparian habitat present upstream and downstream of Site 17.

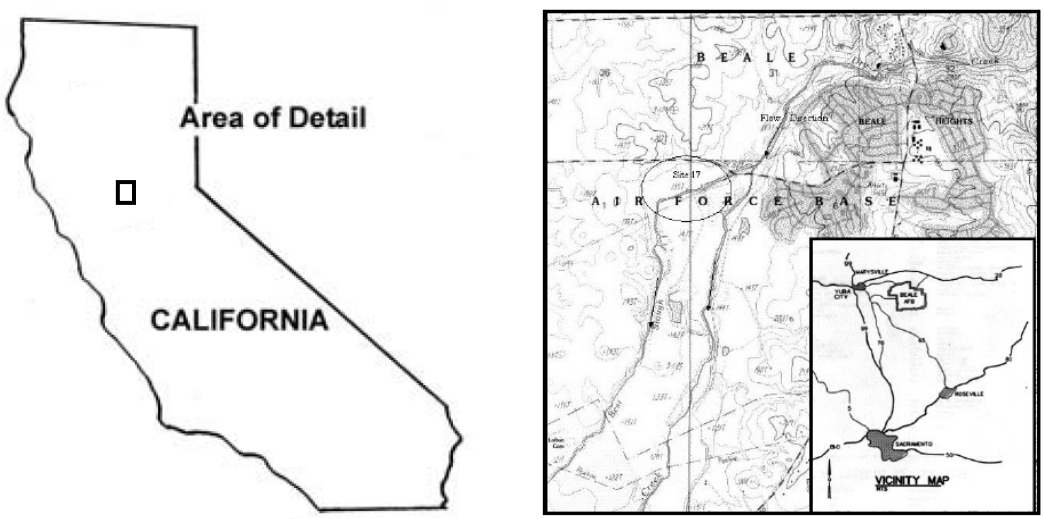

Figure 1: Location maps for Beale Air Force Base and Best Slough

In the 1990's, the Air Force Center for Environmental Excellence (AFCEE) initiated a process to remediate the contaminated soil and groundwater on Air Force bases throughout the country and, when possible, restore or enhance stream corridors adjacent to the contamination sites. As part of this process, Beale Air Force Base designed a solution to the groundwater contamination and stream corridor habitat degradation problems at Site 17. The design (Figure 2) consisted of the following components:

- Impervious slurry wall enclosing the TCE-contaminated area
- Native tree phytoremediation system within the area enclosed by the slurry wall
- Realignment of the reach of Best Slough flowing through the contaminated area
- Temporary and permanent erosion control on the banks of the realigned reach
- Aquatic and riparian habitat creation in and along the realigned reach

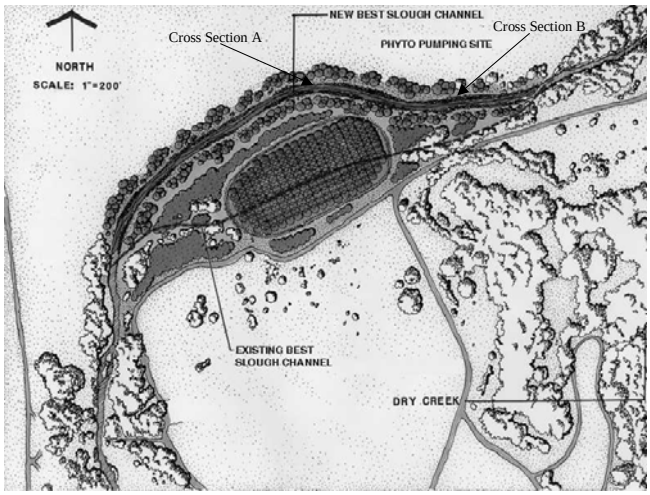

Figure 2: Conceptual design drawing of the Best Slough realignment and restoration project. The locations of the cross sections surveyed for this study are also shown.

The project design team selected a realignment route that removed Best Slough from contact with the contaminated area and designed channel planform and geometry that resembled the planform and geometry of the system upstream and downstream of the project site. The design team selected a variety of erosion control and habitat creation techniques for this project. Erosion control techniques included bioengineering (willow pole plantings, brush bundles, and root-wad boulder clusters), biodegradable fabrics, riprap, and various combinations of each of these treatments. Habitat creation techniques included protection of a backwater wetland area, varied channel geometry, revegetation with native plants, and placement of woody debris. When possible, the design team selected techniques that provided both erosion control and habitat creation benefits.

The design was completed in 1999 and construction was completed in August of 2000. The design team developed a plan and budget for post-project monitoring of chemical, physical, and biological conditions, however funds were only available for chemical monitoring. Therefore, no formal monitoring of channel form, vegetation success, or habitat colonization was performed in the first year after construction was completed. Because of the complexity of fluvial systems and the length of time required to observe change in restored streams, the true success of stream restoration projects can be difficult to adequately assess (Kondolf and Micheli 1995) without such monitoring. We conducted a quantitative post project appraisal approximately one year after construction and a qualitative post project appraisal approximately nine years after construction to assess how the realigned and restored stream corridor performed with respect to the objectives of the project. This simple study highlighted the importance of post-project monitoring to the evaluation of the project and to the planning and design of future stream restoration projects.

STUDY APPROACH

We reviewed the design documents for the geomorphic channel realignment, riparian revegetation, and aquatic habitat enhancement elements of this project (CH2M HILL 1999). We also reviewed the “as-built” drawings (Versar 2000) produced by the contractor at the

completion of the project. The design documents and as-built drawings provided information about the objectives and design criteria of the project, and the physical conditions at the project site immediately after construction was completed. Our post-project appraisal protocol was designed to provide useful information about the performance of the realignment and restoration project on Best Slough and was divided into two general categories:

- Geomorphology
- Biology

Geomorphology

In 2001 (approximately one year after construction) we collected information on the topography of the realigned channel and banks by surveying longitudinal profiles and channel cross sections. We measured longitudinal profiles along the channel thalweg and along the tops of both banks of the realigned reach and compared them to the "as-built" profiles surveyed immediately after the project was completed. We also surveyed two channel cross sections in locations that we suspected would be most prone to change given their location and configuration in the realigned reach, and compared them with the "as-built" geometry generated at the completion of the project. We also identified the location of the base-flow water surface elevation relative to the elevation of specific channel design features described in the design documents. In 2009 (approximately eight years after construction), we observed and documented reach-scale geomorphic conditions and compared them with conditions observed in 2001 and in 2003.

Biology

In 2001, we estimated percent cover in each of the five revegetation zones (tule and emergent wetland, scrub riparian, mixed riparian, valley oak, and valley oak and cottonwood) identified in the riparian revegetation document by randomly sampling three different square meter plots in each zone. We visually estimated percent cover in each sample plot and then averaged the three values for each zone. We also collected kicknet samples in each of the aquatic habitat enhancement treatments to assess aquatic insect colonization. We performed three kicknet samples at each site and recorded the families present at each site. In 2009, we observed and documented reach-scale biological conditions (primarily riparian vegetation condition) and compared them with conditions observed in 2001 and in 2003.

RESULTS AND DISCUSSION

Geomorphology

The slope of the thalweg through the project reach immediately after construction ("as-built") and in 2001 ("post-project") was essentially flat. However, the project team designed a long, relatively deep run-pool (Figure 3) in the middle third of the realigned reach to provide cool water habitat and refugia for resident fish. As described in the aquatic habitat enhancement design document, the run-pool design depth was based on the depths of naturally formed pools upstream and downstream of the project area. However, the length of the run-pool was not based on natural channel forms observed elsewhere in Best Slough. The 2001 post-project profile shows that sediment had accumulated at the upstream end of the run-pool. We also surveyed longitudinal profiles along the top-of-bank on both sides of Best Slough in 2001. Because the

winter of 2000 was relatively dry, and no overbank flows occurred in the realigned reach, only insignificant changes (due to vegetation) were apparent in the top-of-bank longitudinal profiles. The extensive development of microtopography on the channel banks and on the floodplain adjacent to the top of bank observed in 2009 suggests that overbank flow events have occurred between 2001 and 2009.

We surveyed two cross sections in the realigned reach of Best Slough (A and B in Figure 2) in 2001. Cross section A (Figure 4), located in the deep run-pool, shows the cross-sectional component of the sediment accumulation observed in the longitudinal profile of the thalweg in 2001. It appeared that additional sedimentation had occurred between 2001 and 2009, however some deeper areas were still present in 2009. These smaller deep pools may have persisted in this portion of the realigned reach due to complex local hydraulics. Therefore, it appears that the extensive excavation required to create the large run-pool was probably not necessary or sustainable with respect to habitat creation goals. The resources used to excavate this large area could have been used to determine the geomorphic processes responsible for creating the deep pools upstream and downstream of the project reach and to restore those processes to create sustainable pool habitat under the existing hydrologic conditions. Cross section B (Figure 5) was located near the upstream end of the realigned reach of Best Slough. In this section of the realigned and restored reach, the design team created a terraced cross section (Figure 5) to support emergent wetland species. This cross section also shows sediment accumulation in 2001. This accumulation could be attributed to the absence of flows large enough to scour sediment from the pool in the winter of 2001. In 2009, this cross section had developed extensive aquatic and riparian vegetation that has likely accelerated deposition. In general, this reach appears have become more geomorphically stable over the past eight years.

We also surveyed the water surface elevation in 2001 as an assessment of the geomorphic design, the revegetation effort, and the aquatic habitat enhancements in the context of the base flow water surface elevation. The design documents supporting each of these project elements stressed the importance of the base flow water surface elevation to the performance of each element of the realigned stream reach. The measured water surface elevation is shown on the thalweg longitudinal profile plot and the cross section plots (Figures 3, 4, and 5, respectively). No significant rainfall had occurred in the Best Slough watershed immediately prior to the 2001 survey, so the measured water surface elevation was a good approximation of the base flow water surface elevation at the project site. The revegetation design document and the geomorphic design document indicated that the terrace on this cross section should have been approximately 0.15 to 0.30 meters below the base flow water surface elevation. At the time of the 2001 survey, the base flow water surface elevation was approximately 0.63 meters above the terrace elevation (Figure 5). Several beaver dams downstream of the project reach appeared to be controlling water surface elevations. It appears that ongoing beaver activity between 2001 and 2009 has controlled base flow water surface elevations and therefore the establishment and succession of aquatic and riparian vegetation.

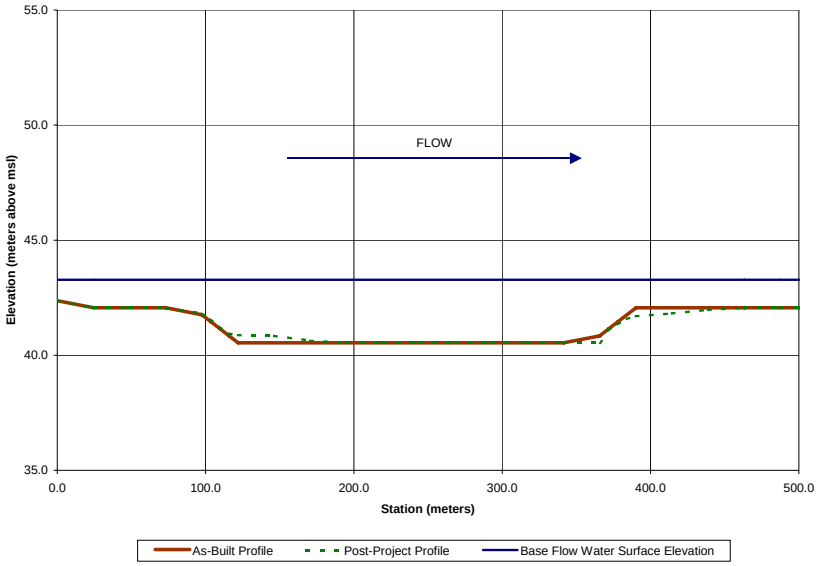

Figure 3: Thalweg longitudinal profile showing as-built elevations and elevations one year after construction. The location of the large run-pool is indicated in the middle third of the profile.

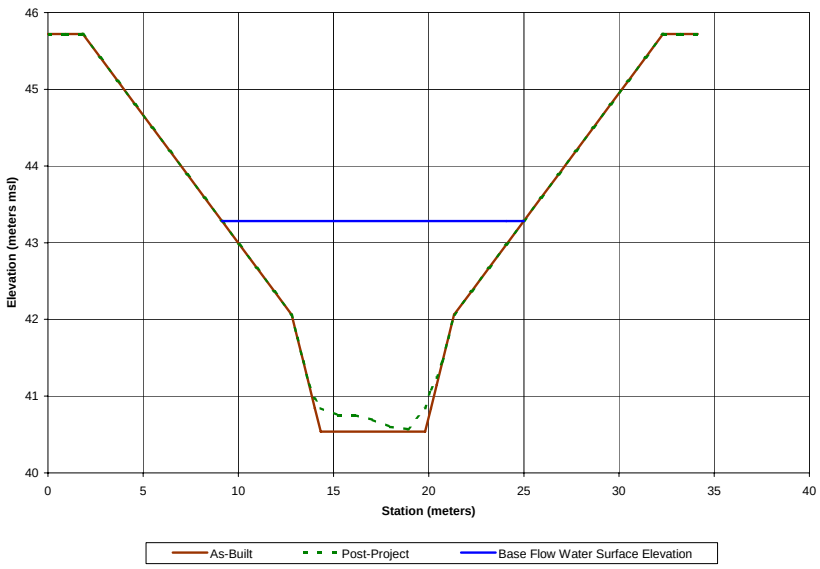

Figure 4: Channel cross section showing as-built elevations and elevations one year after construction. The location of this cross section is shown in Figure 2. Note the sediment accumulation at the head of the run-pool.

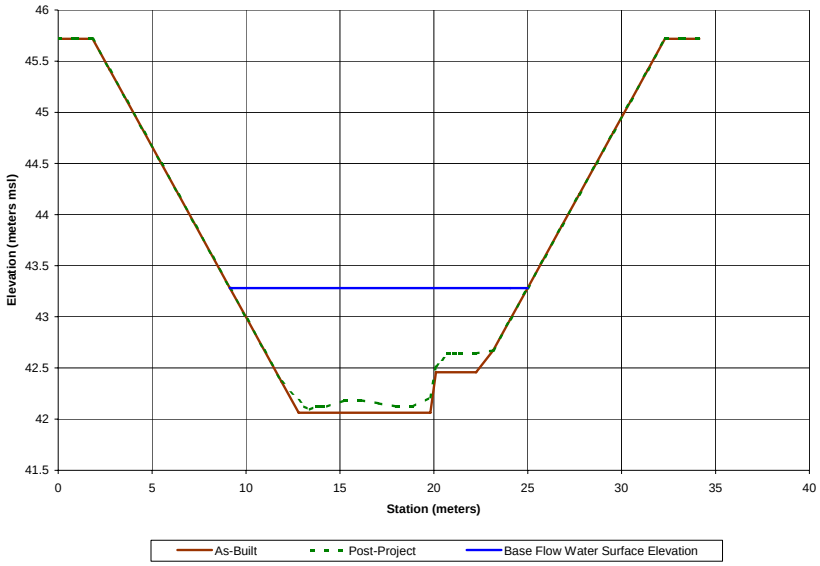

Figure 5: Channel cross section showing as-built elevations and elevations one year after construction. The location of this cross section is shown in Figure 2. Note the sediment accumulation on the terraced portion of the cross section.

Biology

Figures 6 and 7 show the same location just after construction of the realigned and restored reach was completed and in 2001. To the casual observer, the rapid and lush establishment of riparian vegetation could be seen as an indication of project success. However, a structured examination of the vegetation indicated potential performance issues in 2001. Table 1 shows the estimated percent cover of each of the five planting zones specified in the revegetation design document. The percent cover of the scrub riparian, mixed riparian, valley oak, and valley oak and cottonwood plant assemblages were all at or above the desired levels listed in the revegetation design document. However, the tule and emergent wetland plantings covered only 24% of the area in the zones where they were planted. This is approximately 50% less than the desired area listed in the revegetation design document. The high base-flow water surface elevation described in the section above is the most likely reason that the tule and emergent wetland species planted on the channel terraces had not become successfully established by 2001. However, by 2009 coverage of emergent and wetland vegetation appeared to meet and in many locations exceed design objectives.

Table 1: Percent cover in the design revegetation zones

Revegetation Zone	*Percent Cover*
Tule and Emergent Wetland	24%
Scrub Riparian	81%
Mixed Riparian	90%
Valley Oak	75%
Valley Oak and Cottonwood	73%

Revegetation zones were shown on the design drawings and the native species to be planted in each zone were listed in the revegetation design document.

Figure 6: Realigned channel before revegetation. The new channel banks were completely bare before vegetation and erosion control fabrics were installed.

Figure 7: Realigned channel 1 year after construction. The flowering plants are native lupines and the grasses include a range of native riparian species.

We also sampled for the presence and absence of aquatic insect families in the three primary aquatic habitat restoration types included in this project to assess the early colonization in each area in 2001. Table 2 lists the aquatic insect families collected from the aquatic habitat restoration areas. The backwater wetland was a portion of the old Best Slough channel that the design team connected to the new channel alignment as an off-channel slackwater area. The insect families collected in this area were indicative of lentic habitats (Thorp and Covitch 1991), and were dominated by predatory damselfly nymphs (Coenagrionidae). This could indicate the local presence of high concentrations of prey species, as damselflies are commonly voracious feeders. We collected very few aquatic insects (4 individuals) from the rootwad / boulder clusters in 2001. We also collected crayfish and small fish fry from these structures. This could indicate that the root-wad / boulder clusters were an inappropriate choice for aquatic habitat in Best Slough. However, we also observed several bass and sunfish in and around the root-wad / boulder clusters in 2001, so the lack of aquatic insects could also have been due to fish predation. We collected high numbers (113 individuals) of mayfly larvae (baetidae) from the shallow water habitat areas in 2001. The shallow water habitat areas of the realigned reach generally included banks with willow pole plantings interspersed with native riparian vegetation, a toe-of-slope constructed with 0.15 – 0.30 meter diameter riprap, and invert elevations similar to the invert elevations upstream and downstream of the realigned reach. Mayflies are commonly sensitive to poor water quality conditions (Thorp and Covitch 1991) and their presence indicates that water quality in this section of the realigned reach of Best Slough is at least good enough for organisms with pollution tolerance levels similar to Baetid mayflies. We also collected high numbers (54 individuals) of caddis fly larvae (hydropsychidae) in 2001. These organisms feed on fine particulate organic matter (Merritt and Cummins 1996) and their abundance indicates an adequate nutrient supply in this section of the realigned reach. The aquatic insect colonization in the shallow water habitat areas and the backwater wetland area in 2001 indicates that these areas were appropriately designed and created habitat for aquatic species. The appropriateness of the root-wad / boulder cluster design was uncertain in terms of aquatic insects, however it appears to have been beneficial to fish. No sampling was conducted in 2009, however aquatic insect observations indicated that aquatic insect abundance and diversity has likely increased over the past eight years.

Table 2: Aquatic insect families collected in aquatic habitat restoration areas

Habitat Type	*Aquatic Insect Families Present*
Backwater Wetland	Coenagrionidae, Libellulidae, Carabidae, Caenidae, Ameletidae
Root-wad / Boulder Clusters	Corixidae, Chironomidae, Caenidae
Shallow Water Habitat	Hydropsychidae, Baetidae, Simuliidae, Corduliidae, Coenagrionidae, Haliplidae, Philopotamidae, Chironomidae

CONCLUSION

We observed specific successes and failures of the Best Slough realignment and restoration project through a simple post-project appraisal one year and eight years after construction. Elements of the geomorphic design, the revegetation design, and the aquatic habitat design have been successful to date. However, the resources expended to design and build this project could probably have been used more efficiently. Additional pre-design surveys could have provided more appropriate pool lengths and aquatic habitat types, and indicated the importance of beaver activity on water surface elevations. The observations from this simple post-project appraisal highlight the importance of post-project monitoring programs and showed that even a relatively unsophisticated monitoring program can detect problems that could easily be remedied by adaptive management actions.

Abstract. Streambank failures result in loss of land and increased stream sediment loads. Variably saturated flow models integrated with bank stability models are being used to predict bank failure; however, understanding of the level of soil characterization necessary to predict when seepage contributes to bank failure is needed. ROSETTA, a pedotransfer function, was used to estimate hydraulic parameters for various levels of soil data (from texture class to saturated hydraulic conductivity, K_s). A two-dimensional groundwater flow code, SEEP/W, was used to model a hypothetical streambank and estimate seepage velocity. Results suggested that K_s and/or percent clay measurements are necessary to adequately predict seepage. A layered bank was also simulated with several combinations of soil types. Results indicated that only one order of magnitude difference in K_s (equivalent to a resistance ratio of 10) may be necessary to induce perching and seepage from the top layer. This research suggested that, if a field reconnaissance is performed to locate streambanks susceptible to perching, K_s and/or bulk density measurements are necessary to indicate the presence of a restrictive layer.

Introduction

Streambank failures result in loss of land, increased stream sediment loads, and increased nutrient loads if soil nutrient levels are high. At least three groundwater mechanisms of streambank failure have been observed. An increase in soil moisture can reduce cohesion and soil frictional strength. The importance of this instability mechanism has led to work by Darby et al. (2007) and Rinaldi et al. (2008) in linking groundwater flow, fluvial hydraulics, and streambank stability models. Second, seepage gradient forces exert body forces on streambank sediment proportional to the hydraulic gradient (Lobkovsky et al. 2004), which has been incorporated into slope stability analyses for noncohesive banks. Finally, undercutting due to fluvial or seepage erosion can contribute significantly to bank collapse (Fox et al. 2006; Wilson et al. 2007).

Hagerty (1991) discussed the difficulty of identifying sites with seepage in the field, especially since seepage is often intermittent. Could sites with the potential for seepage erosion be predicted during a field reconnaissance based on easily defined soil properties (e.g. textural class)? Seepage often results from a perched water table above a restrictive layer. It is uncertain what difference in saturated hydraulic conductivity (K_s) is required to induce seepage. Field observations of seepage include 1.0-2.5 order of magnitude difference in K_s (Fox et al. 2007; Wilson et al. 2007).

Variably saturated flow models integrated with bank stability models are used to predict bank failure (Chu-Agor et al. 2008a,b); however, an improved understanding of the soil conditions under which seepage mechanisms become prevalent is needed. Groundwater seepage is driven by several soil hydraulic properties. However, data on water retention and hydraulic conductivity functions often are not available and are uneconomical and/or laborious to acquire. Pedotransfer functions (PTFs) are a convenient option for estimating missing parameters based on readily available soil data. ROSETTA is a neural network model that predicts hydraulic parameters (residual water content (θ_r), saturated water content (θ_s), van Genuchten parameters (α and n), and K_s) for various levels of soil data (Schaap et al. 2001).

It is unknown what degree of site characterization is necessary, and what soil properties should be targeted in the characterization, in order to predict bank failure from seepage erosion. The objective of this study was to determine the necessary level of soil data needed to adequately model streambank seepage velocity and to predict the occurrence of perched seepage.

Materials and Methods

Flow Modeling: SEEP/W & ROSETTA

Following Chu-Agor et al. (2008a), a hypothetical streambank was modeled with SEEP/W (Geo-Slope International Ltd.) to simulate the variations in the soil-water pressure and cumulative discharge. SEEP/W is a finite element model of Richards' equation for two-dimensional variably saturated flow (Krahn 2004). Specifying and assigning material properties in SEEP/W involves defining the water retention function, $\theta(h)$, and the hydraulic conductivity function, $K(h)$, where h is the soil-water pressure (Krahn 2004). The van Genuchten (1980) model, which requires hydraulic parameters (θ_r, θ_s, α, n, and K_s), was used to represent $\theta(h)$and $K(h)$.

Hydraulic parameters were estimated with the ROSETTA program (Schaap et al. 2001), which is composed of five hierarchical PTFs for five levels of input data: soil textural class only, textural distribution (percent sand, %S; silt, %Si; and clay, %C), textural distribution and bulk density (BD), the previous parameters and water pressure at field capacity, or the previous parameters and water pressure at wilting point. This research utilized the second and third PTFs.

Soil Properties

First, SEEP/W was used to estimate the average seepage velocity (v_s) for a homogenous, single-layer bank. Soil types (sand, S; loamy sand, LS; sandy loam, SL; sandy clay loam, SCL; and loam, L) were selected that could serve as conductive layers within a more complex bank profile. Boundary conditions included a zero flux boundary for the top and bottom boundaries and a fixed water table (WT) on the side opposite the bank face. The bank height (BH) was 1 m and the width was 1 m. The WT ranged from 0.25 to 1.00 m, resulting in WT/BH ratios of 25, 50, 75, and 100%. SEEP/W continued until dynamic equilibrium was reached.

Eight levels of soil data were simulated, resulting from combinations of the following: known or unknown %S (representing a sieve analysis), K_s, and BD. Researchers have used the centroid of a polygon on the soil texture triangle to estimate %S, %Si, and %C when only the textural class was known (Shirazi et al. 2001a,b). These values (Shirazi et al. 2001a) were used as the baseline %S, %Si, and %C for each soil type (Table 1). Similarly, the K_s that ROSETTA estimated for the centroid %S, %Si, and %C was used as the baseline K_s. These values were used to find the baseline v_s. Finally, the BD for which ROSETTA estimated the baseline K_s (an iterative process) was considered to be the baseline BD.

When only the textural class was known, each of the points on the exterior of its polygon on the soil texture triangle (gray circles in Figure 1) was simulated. For each point, a SEEP/W simulation was performed, using the ROSETTA estimated hydraulic parameters for that point. In this way, v_s was estimated for the potential worst case scenarios (i.e. largest deviations in v_s from the baseline v_s).

When a hypothetical sieve analysis was performed, the %S was assumed equal to the %S at the centroid, making a line of possible clay and silt contents through the centroid. For this situation, the two endpoints on this line of constant %S (white circles in Figure 1) were simulated. If BD was known, the third PTF in ROSETTA was used to estimate hydraulic parameters. For simulations where K_s was known, the baseline K_s was used instead of the K_s estimated by ROSETTA.

Table 1: Baseline soil parameters used for calculating baseline seepage velocity. The %S, %Si, and %C are the centroid of the polygon for the soil textural class. The K_s and BD were determined with ROSETTA.

Soil Texture	Sand (%)	Silt (%)	Clay (%)	K_s (cm d^{-1})	BD (g cm^{-3})
S	92	5	3	469	1.54
LS	82	13	5	117	1.57
SL	65	26	9	43	1.50
L	41	41	18	11	1.48
SCL	60	14	26	13	1.59

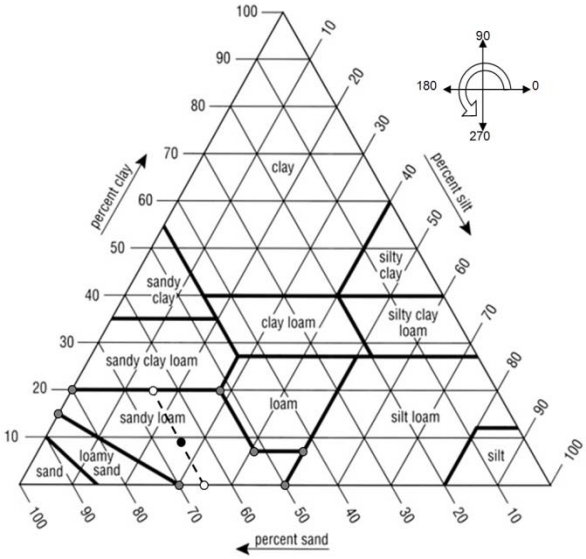

Figure 1: USDA Soil texture triangle. Data points selected for sandy loam are illustrated. The black dot is the centroid (65% S, 26% Si, and 9% C). Gray dots represent the worst case scenarios if only textural class is known. White dots represent the worst case scenarios if a sieve analysis was performed.

Output v_s was compared with the baseline v_s for each run, and the percent difference was calculated. Within each level of soil data, the maximum and minimum (e.g. most negative) errors were used to illustrate the range of possible error. The data analysis also utilized a relative sensitivity coefficient:

$$S_r(y/x) = \frac{\frac{y - y_b}{y_b} \times 100}{\frac{x - x_b}{x_b} \times 100} \quad (1)$$

where $S_r(y/x)$ = relative sensitivity coefficient for output y relative to input parameter x, y = output under consideration, y_b = baseline value for output y, x = parameter under consideration, x_b = baseline value for parameter x. $S_r(y/x)$ is essentially the percent change in output divided by the percent change in input.

Bank Layering

In order to determine the conditions necessary to induce a perched water table, a hypothetical streambank with two layers of equal thickness was modeled with SEEP/W. The finite element grid for the numerical simulation and a flow example is shown in Figure 2. The simulated BH was 1 m and the width was 5 m. Boundary conditions included a zero flux boundary for the bottom and the side opposite the bank face, and a constant infiltration rate for the top surface. The infiltration rate was set to either 10 or 15% of K_s in the top layer (in order to ensure no ponding and therefore an equivalent infiltration volume in each case), and continued until a 5.1 cm rainfall had been applied. All possible combinations of soil types in the soil texture triangle (using the centroid %S, %Si, and %C for each) were considered. Subsoils with higher K_s values were also included in order to simulate dense restrictive layers.

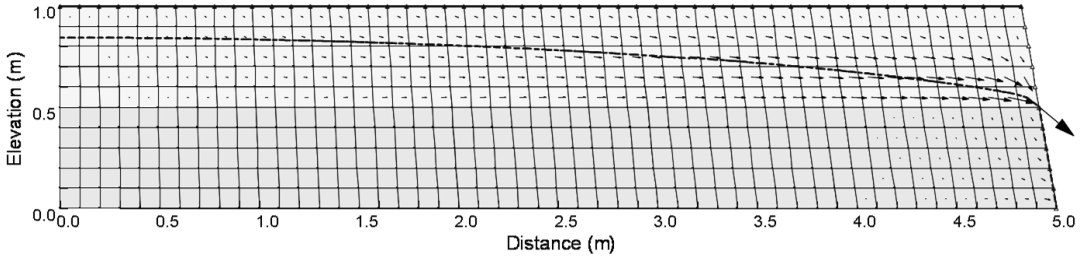

Figure 2: SEEP/W flow data at the end of the simulation for an S layer (light gray) over an L layer (dark gray) resulting in perched seepage. The bank face is on the right. The dotted line is the water table. Arrows are flow vectors. In this case, 74% of the total discharge emerged from the top layer.

For each combination of soil layers, perched seepage was determined as the ratio of seepage in the top layer to the seepage from both layers (based on cumulative discharge). Perched seepage was compared to the bank layer resistance ratio:

$$R_r = \frac{\frac{L_b}{K_{s,b}}}{\frac{L_t}{K_{s,t}}} \qquad (2)$$

where R_r = resistance ratio, L_b = thickness of the bottom soil layer, $K_{s,b}$ = saturated hydraulic conductivity of the bottom soil layer, L_t = thickness of the top soil layer, and $K_{s,t}$ = saturated hydraulic conductivity of the top soil layer. Soil layer resistance accounts for the impact of the thickness of a restrictive layer on its ability to induce lateral flow. It is noted that R_r (bottom/top) is equal to the K_s ratio (top/bottom) for these simulations since the bank layers have the same thickness.

Results and Discussion

Soil Properties

The range of seepage velocity errors across the five different textures indicated the range of possible error for a given level of soil data (Figure 3). Results were the average of the results for the four water table heights (different WT/BH ratios had little impact on the results). Knowing textural class only resulted in considerable errors in predicted v_s across all simulated soil textures. Potential errors ranged from -65% to 272%.

Sieve analysis beyond knowledge of the texture (using the baseline %S) reduced the potential error in estimating v_s for sand-dominated textures (i.e., S and LS), but only minimally reduced the potential error for SL and L textures. Sieve analysis was beneficial for the coarse grained materials, where seepage process often occur; however, as the percent fines increased, the determination of %S by sieving became of little value.

Knowledge of the K_s consistently reduced potential errors in predicted v_s across all simulated soil textures. Percent error in predicted v_s when measuring K_s only (-7% to 16%) were comparable to the errors when having a detailed knowledge of the %S (sieve analysis) and K_s (-4% to 13%).

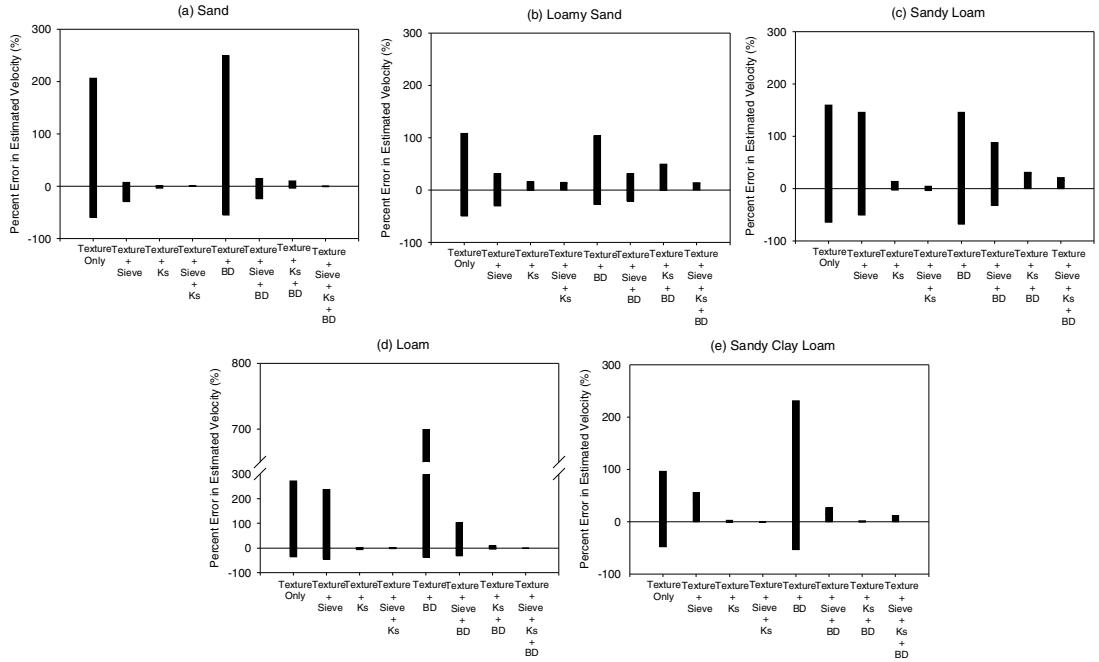

Figure 3: Range of seepage velocity error for varying levels of soil data. Data reported are for average of all WT/BH ratios.

Distance and Direction of Divergence across the Soil Texture Triangle

The $S_r(y/x)$ was calculated for the seepage velocities relative to change in soil texture input, based on results from runs when neither K_s nor BD was known. Due to the difficulty of measuring change in texture (e.g. %S can not be changed while holding %Si and %C constant), an innovative approach was needed. The $S_r(v_s/d)$ was calculated as the percent change in v_s divided by the distance (d) moved across the soil texture triangle, a surrogate for change in texture from the centroid.

The $S_r(v_s/d)$ did not correlate well to location on the soil texture triangle, when represented by %S, %Si, or %C. The $S_r(v_s/d)$ did, however, correlate well with the direction of divergence on the soil texture triangle (Figure 4a). The angle from the centroid to each point was measured counter-clockwise from the horizontal, as indicated in Figure 1.

Also, the correlation was more apparent when the logarithmic nature of the seepage velocity was accounted for by using $\log(v_s)$ instead of v_s (Figure 4b). The $S_r(\log(v_s)/d)$ relationship resembles a negative sine wave. The peak occurred near 270° (straight down on Figure 1), which was when %C decreased and %Si and %S increased. In other words, this was the direction of divergence that resulted in the greatest increase in v_s for a given distance. Likewise, 90° was the direction that resulted in the greatest decrease in v_s.

When a sieve test was performed, error was reduced partly because the direction of divergence was limited to 120° or 300° (as well as the limit on the possible distance of divergence when %S was known). If %C would have been known, the direction of divergence would have been limited to 0° and 180°, where $S_r(\log(v_s)/d)$ was near zero. Data points with angles near 0° and 180° have $S_r(\log(v_s)/d)$ values between -0.25 and 0.25. The implication is that testing for %C (which is easier than measuring

K_s) and using a PTF for other soil parameters may reduce error in v_s sufficiently. While the relationship in Figure 4 did not hold for the entire soil texture triangle (the data set included S, LS, SL, SCL, and L), it was applicable to soils where seepage problems are most likely.

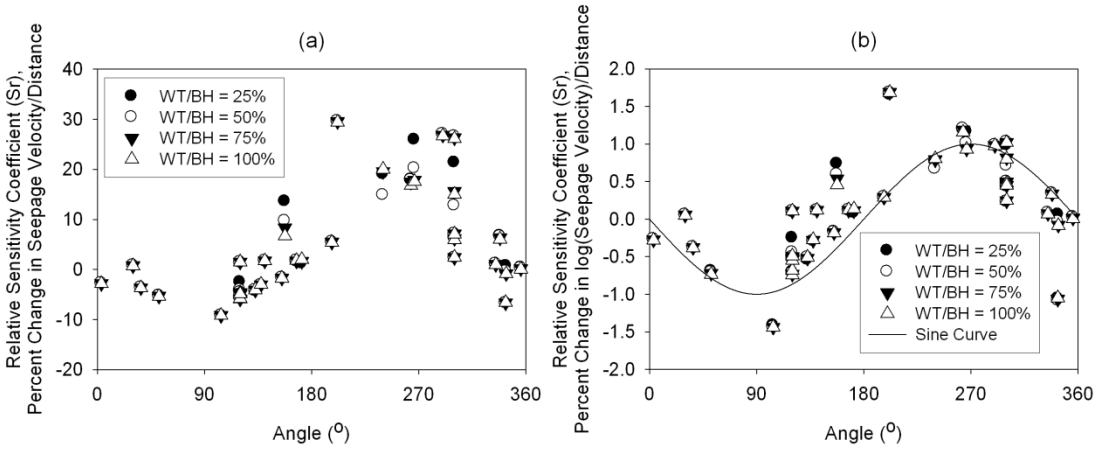

Figure 4: Correlation of the sensitivity coefficient, based on v_s (a) or log(v_s) (b), with the angle of divergence. Moving 0° or 180° (horizontally) across the soil texture triangle results in minimal change in seepage velocity.

Impact of BD on K_s and Seepage Velocity

Although a higher level of soil data would be expected to improve seepage estimates, knowledge of BD provided little if any reduction in error (Figure 3). Since K_s is the primary driving parameter (compared to other hydraulic parameters) for impacting v_s in the SEEP/W model, the relationship between K_s and BD was analyzed. Laboratory data from Chu-Agor et al. (2008b) were compared to ROSETTA estimated K_s values for two soil samples and three BDs (Table 2). The $S_r(K_s/BD)$ indicated the high sensitivity of K_s to changes in BD. Also, SEEP/W was used to estimate v_s for both laboratory and ROSETTA K_s values. BD had a disproportionate impact on v_s, with $S_r(v_s/BD)$ based on lab data ranging from -29.5 to -5.4; however, $S_r(v_s/BD)$ based on ROSETTA estimates ranged from -5.6 to 0.4.

Table 2: Comparison of saturated hydraulic conductivity (K_s) and seepage velocity (v_s) sensitivity to bulk density (BD) for both laboratory and ROSETTA (PTF) K_s.

Soil	S	Si	C	BD	K_s (cm d^{-1})		$S_r(K_s/BD)$		v_s (μm s^{-1})		$S_r(v_s/BD)$	
Text	(%)	(%)	(%)	(g/cm^{-3})	Lab	PTF	Lab	PTF	Lab	PTF	Lab	PTF
S	99	1	0	1.6	665	1248	-5.4	-1.7	104	194	-5.4	-1.7
				1.45	1521	1512	n/a	n/a	237	235	n/a	n/a
				1.3	2454	1467	-5.9	0.3	377	226	-5.8	0.4
LS	85	13	2	1.7	52	113	-8.0	-4.7	8	17	-8.1	-4.8
				1.6	104	160	n/a	n/a	15	24	n/a	n/a
				1.5	294	215	-29.3	-5.5	43	32	-29.5	-5.6

It is uncertain why an increased level of input data resulted in an increase in error. Based on Table 2, it appeared that ROSETTA may not be sensitive enough to BD. It should also be noted that ROSETTA is a neural network model. That is, it does not use physically based equations to account for the impact of parameters, including BD. Rather, it is highly dependent on the amount, extent, and quality of data used in developing the model. For example, the unexpected positive $S_r(v_s/BD)$ and $S_r(K_s/BD)$ in Table 2 may indicate that ROSETTA has little available data on both K_s and BD for sand samples. Also, the use of two separate PTFs within Rosetta (one for known BD and one for unknown BD) may be a confounding factor for the results in Figure 3. Another observation is that some PTFs which account for BD include both texture and organic matter content (Kaur et al. 2002; Nemes et al. 2005).

Bank Layering

A perched water table was predicted based on soil textural class only. All possible combinations of soil textures were considered, using baseline data (hydraulic parameters) for each textural class. The presence of a perched water table was indicated by seepage from the top layer (Table 3). According to these data, either an S or LS top layer was necessary for perching to be possible, but this was not consistent with field observations (Fox et al. 2007; Wilson et al. 2007). A primary limitation of this approach was neglecting variation in BD. It is quite possible that subsoils may have a higher BD than topsoils. Due to the large impact of BD on v_s (Table 2), soil texture alone was not sufficient to predict perching during a field reconnaissance. Data such as BD or K_s was necessary to indicate the presence of a restrictive layer.

Dense subsoils with a lower K_s than ROSETTA predicted (without inputting BD) were simulated in SEEP/W, together with the four topsoils that had the highest K_s values (S; LS; silt, Si; and silt loam, SiL). The correlation between perched seepage and R_r is shown in Figure 5. According to these SEEP/W simulations, an R_r of approximately 10, equivalent to only a one order of magnitude difference in K_s, was required to induce a perched water table. This was consistent with field observations of Fox et al. (2007) who also noted small differences in K_s resulting in perched seepage, not the two or three order of magnitude contrast in K_s as was previously expected.

Table 3: Percent of the total seepage that emerged from the top layer due to a perched water table, without accounting for variation in BD.

		Bottom Layer											
Soil Texture		S	LS	Si	SL	SiL	C	SC	SiC	SCL	SiCL	L	CL
K_s (cm d^{-1})		469	117	44	43	29	17	16	15	13	12	11	7
Top Layer	S	0	0	18	20	41	63	65	67	71	73	74	84
	LS		0	0	0	0	0	0	0	0	0	0	40
	Si			0	0	0	0	0	0	0	0	0	0
	SL				0	0	0	0	0	0	0	0	0

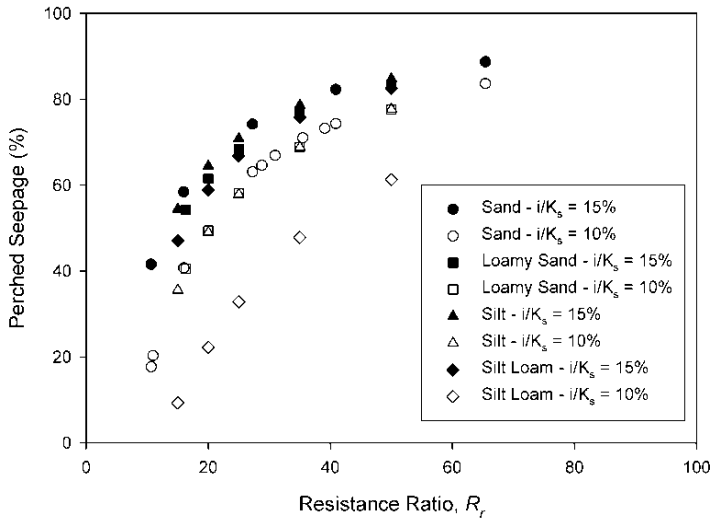

Figure 5: Perched seepage for S, LS, Si, and SiL soils (top layer) and infiltration (*i*) rates at 10 or 15% of K_s.

Conclusions

A two-dimensional groundwater flow code, SEEP/W, was used to model a hypothetical streambank. The sensitivity of groundwater seepage relative to various levels of soil data was determined. Sole use of the soil texture's centroid %S, %Si, and %C as a surrogate for soil texture (i.e., only textural class was known) resulted in considerable errors in predicted v_s across all simulated soil textures. Sieve analysis in addition to knowledge of the texture reduced the potential error for sand-dominated textures (i.e., S and LS), but only minimally reduced the potential error for SL and L textures. Knowledge of K_s consistently reduced potential errors in predicted v_s across all simulated soil textures to levels comparable to the error when knowing both K_s and %S. Measuring %C may be an economical alternative to K_s for minimizing error for conductive layers.

A dense, restrictive layer (high BD) was the necessary condition for perching, not the more commonly assumed difference in soil types. Subsoils may have a lower K_s than ROSETTA predicted for a particular soil textural class due to a high BD. For a field reconissaince, either BD or K_s may be needed to identify sites with potential for perched seepage. Only one order of magnitude difference in K_s may be necessary to induce perching.

Abstract

Seepage erosion is an important factor in hillslope instability and failure. However, predicting erosion by subsurface flow or seepage and incorporating its effects into stability models remain a challenge. Limitations exist with all existing seepage erosion sediment transport functions, including neglecting the three-dimensional geometry of the seepage undercut. The objective was to develop a sediment transport model that can predict sediment mobilization (i.e., seepage erosion and undercutting) with time based on previously reported three-dimensional soil block experiments covering a wide range of hydraulic, soil type, and packing (i.e., slope and bulk density) combinations. The transport function was represented by an excess velocity equation wherein the rate of erosion was related to the difference between the steady state velocity and the critical velocity (R^2 = 0.62). The critical velocity was derived from a critical head measured in the laboratory using the three-dimensional soil block. The relationship between the eroded volume per bank face area and the amplitude of the headcut was also derived. Using a three-dimensional Gaussian function, the geometric relationships between the lateral and vertical dimensions of the headcut were then estimated. Linear regression analysis between the predicted and observed time at which a given amount of headcut developed resulted in an R^2 of 0.86. The ground water velocity exfiltrating a hillslope can be used with the derived sediment transport function to predict the dimensions of the headcut and the geometry of the undercut which enables the prediction of the impact of seepage erosion undercutting on hillslope stability.

Introduction

Seepage erosion is an important factor in hillslope instability and failure. However, predicting erosion by subsurface flow or seepage and incorporating its

effects into stability models remain a challenge. The complexity results from the difficulty in quantifying the soil, hydrologic, and geotechnical mechanisms affecting this phenomenon as well as understanding the interaction between them. To start with, measuring subsurface flow and seepage erosion in the field is difficult (Hagerty, 1991; Fox et al., 2007; Wilson et al., 2007). Furthermore, the variability and heterogeneity of the porous media add another level of uncertainty to seepage flow and erosion estimation (Hagerty, 1991). According to Sidorchuk (2005), the nature of soil erosion is determined by the interaction between water flow and structured soil. This interaction is stochastic in nature due to the complexity and microscopic scale of the geo-mechanical and electro-chemical forces between particles in the soil and of the velocity oscillations in water flow.

Another aspect adding to the complexity of seepage erosion analysis is its three-dimensional nature (Crosta and di Prisco, 1999; Chu-Agor et al., 2008a). Since seepage erosion is not uniformly distributed throughout the bank, but is isolated to the preferential flow path of the seep, the dimensions of the seepage undercut is important in quantifying the amount of sediment eroded. According to Crosta and di Prisco (1999), bank failure due to seepage erosion is the final result of a complex chain of events taking place during a certain time period. Because of these factors, seepage erosion is not extensively studied compared to fluvial erosion other than the seepage influence on the soil pore-water pressure (Darby and Thorne, 1996; Crosta and di Prisco, 1999; Rinaldi and Casagli, 1999; Simon et al., 1999), although it has been demonstrated to be an important instability mechanism (Cancienne et al., 2008; Chu-Agor et al., 2008b).

Several studies to date have developed relationships that predict sediment transport due to seepage. Seepage erosion has been analyzed by different researchers as either due to: (1) individual particle mobilization (Howard and McLane, 1988; Dunne, 1990; Lobskovsky et al., 2004), or (2) small mass failure employing Coulomb's failure mechanism (Dunne, 1990; Chu-Agor et al., 2008a,b). Sediment transport models (i.e., Howard and McLane, 1988; Fox et al., 2006) have also been developed based on laboratory experiments on specific, usually noncohesive, soils. Equations for initiation of particle motion attempt to predict the limiting conditions when the seepage force across the grain exceeds the shear strength of the particle resulting in that particle detaching out of its intergranular "pocket" (Dunne, 1990). Mass failure analysis evaluates the balance of forces acting on a soil element of an infinite slope. It attempts to predict the conditions when the resultant of the driving forces exceeds the resultant of the stabilizing forces causing small or large masses of soil to fall.

Most studies on seepage erosion have focused their analysis on one failure mechanism, specific soil types, and/or specifically for noncohesive soils, limiting their application to the conditions under which they were derived. Furthermore, seepage undercutting in the field has a three-dimensional geometry not addressed in previous studies. In this study, a sediment transport model which can predict sediment mobilization (i.e., seepage erosion and undercutting) over time will be derived and evaluated based on previously reported three-dimensional soil block experiments (Chu-Agor et al., 2008a) covering a wide range of hydraulic, soil type, and packing (i.e., slope and bulk density) combinations.

Materials and Methods

Three-dimensional Soil Block Experiments

Data gathered from the three-dimensional block experiments of Chu-Agor et al. (2008a) were used in this research. The three-dimensional soil block was constructed of Plexiglas with dimensions 50 cm by 50 cm by 50 cm. It had two compartments: a water reservoir at one end where a constant water head was maintained and a soil compartment that simulated a single-layered streambank (Figure 1). Water flowed from the water reservoir to the soil compartment through a 10 cm by 10 cm inlet centered at the bottom of the wall dividing the two compartments. Two soil textures were used in the experiments: sand and loamy sand. Each soil type was packed in the box at various bulk densities (ρ_b): 1.30, 1.45, and 1.60 Mg m^{-3} for the sand and 1.30, 1.45, 1.50, 1.60, and 1.70 Mg m^{-3} for the loamy sand. All experiments consisted of soil blocks with heights of 25 cm, widths of 50 cm, and lengths of 25 cm. The bottom of the soil block was lined with a 2.5 cm densely packed clay layer to serve as a restrictive layer. The rest of the block was packed with soil to the desired ρ_b in 2.5 cm lifts. The soil was then cut to simulate various bank angles, α' (90, 75, and 60 degrees), such that the horizontal centerline for each bank remained 20 cm away from the water inlet. For the experiments, heads (H) of 15, 25, or 35 cm were maintained in the inflow reservoir.

During the experiment, a three-dimensional, medium-range laser scanner (3D Digital Corporation, Sandy Hook, CT) was used to monitor seepage erosion at the bankface of the soil block. Scanned images were taken at regular intervals to capture the change in the bank due to seepage erosion (Figure 2). The scanned images were then exported to ASCII files in terms of the xyz coordinates and used to create 2.0 mm square grids. A program was developed to compute the eroded volume by subtracting the scanned surface at a given time from the scanned surface of the initial bank. A five-parameter Gaussian function (Weisstein, 1999) was fit to the volume of the eroded surface in order to determine the typical undercut shape and dimensions (Chu-Agor et al., 2008a), where the function is given as the following:

$$z(x,y) = A\exp\left[-\left\{\left(\frac{x-x_o}{\sigma_x}\right)^2 + \left(\frac{y-y_o}{\sigma_y}\right)^2\right\}\right] \quad (1)$$

where $z(x,y)$ is the measured seepage headcut from the original bank face, A is the amplitude or maximum distance of seepage erosion, x_o and y_o is the center of the amplitude, and σ_x and σ_y are spreads of the seepage headcut (Figure 2). The variables σ_x and σ_y are related to the full width at half-maximum ($FWHM_j$) of the Gaussian function:

$$FWHM_j = 2\sqrt{2\ln(2)}\sigma_j \quad (2)$$

where j is either x or y (Weisstein, 1999).

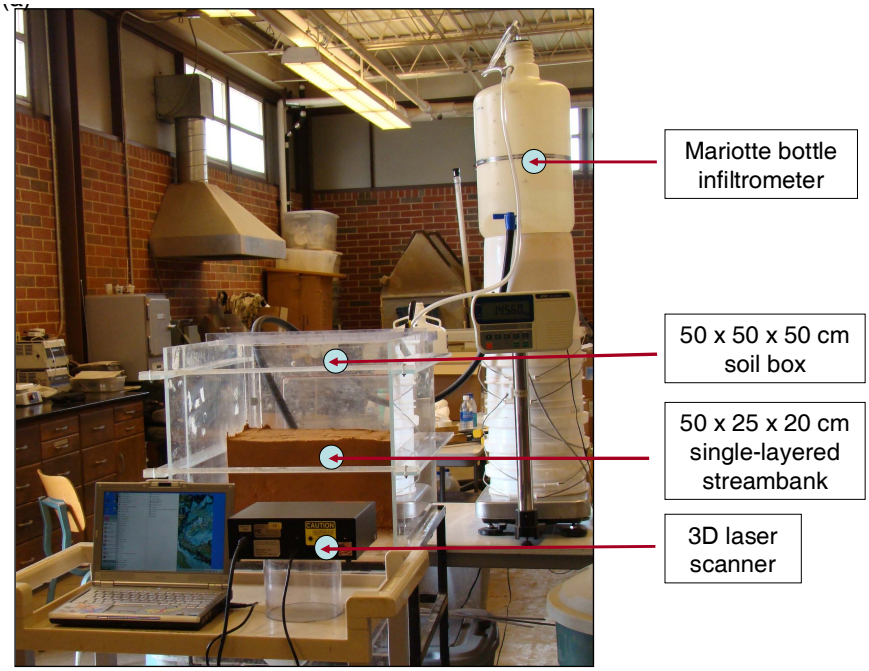

Figure 1. Three-dimensional soil block set-up used to simulate seepage erosion of single-layer, repacked soil banks.

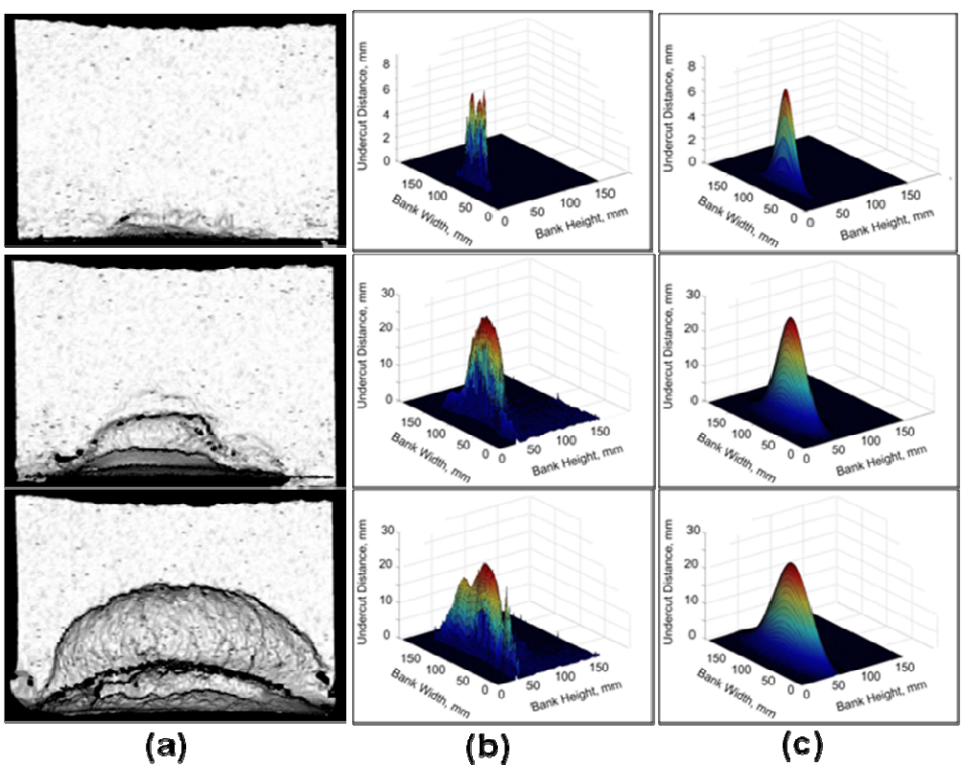

Figure 2. (a) Time sequence of seepage particle mobilization and undercutting. (b) Distance of seepage undercutting (vertical axis). The bank face is the x-y plane. (c) A Gaussian function fit to the seepage particle mobilization data.

Derivation of a Sediment Transport Model

The sediment transport function was represented by an excess velocity equation, where velocity, v, was the steady-state ground water velocity:

$$E_{rs} = K_{ds}\left(v - v_c\right)^a \tag{3}$$

where E_{rs} is the seepage erosion rate (i.e., volume of sediment per bank face area per time, m^3 of sediment per m^2 of bank face per s), K_{ds} is the seepage erodibility coefficient, v_c is the critical velocity, and a is an exponent. The steady-state ground water velocity was estimated from Darcy's Law with Dupuit-Forcheimmer assumptions:

$$v = \frac{q}{n} = \frac{KH\sin(\alpha')}{nL_{sc}} \tag{4}$$

where q is the flow per area of the seepage undercut per time, L_{sc} is the length of the soil block, K is the saturated hydraulic conductivity, and H is the hydraulic head. Thus, v is equivalent to the pore water velocity.

For cases with undercutting by seepage erosion, the imposed ground water velocity, v, was estimated from the steady-state flow based on the imposed hydraulic gradient (i.e., a function of the head, H) and corrected for the measured depth of undercutting (A) from the laser scanner during each experiment, such that the path length is $(L_{sc}\text{-}A)$ (i.e., increases in A increases v by reducing the flow path length):

$$v = \frac{q}{n} = \frac{KH\sin(\alpha')}{n(L_{sc} - A)} \tag{5}$$

Critical Velocity

The critical groundwater velocity necessary for seepage erosion initiation, v_c, was a function of the critical gradient, i_{cr} (i.e., the gradient that must be imposed on the sediment before seepage erosion initiates). The critical gradient was determined by dividing the critical head, H_{cr}, which was measured using the three-dimensional soil block set-up of Chu-Agor et al. (2008a), by the length of the soil block. The soil block was packed with sand and loamy sand at various ρ_b. The bank face was maintained at a 90-degree angle. At the start of the experiment, the head in the water reservoir was set at 4 cm (i.e., 1.5 cm above the clay layer). Once steady state flow was reached, the head was increased by 1 cm and the system was allowed to reach equilibrium. If no undercutting was observed, this process was repeated until a sufficient head was reached that was capable of propagating an undercut. Each experiment with a given set of soil and hydraulic controls was carried out in duplicate. Since the head was increased in 1 cm increments, a minimum and a maximum were used to define the critical head. The minimum value being the head before undercutting occurred and the maximum value when undercutting propagated.

Model Development

Experiments conducted by Chu-Agor et al. (2008a) that experienced seepage undercutting were divided into two groups. Two-thirds of the experiments (34

experiments) were used for model development and the remaining one-third (18 experiments) for model evaluation. The groups were chosen randomly based on a random number generator. Each experiment consisted of one or more scanned images representing the evolution of the undercut before mass wasting occurred. Thus, each experiment contained measurements of A at different times during the experiment (i.e., 93 observations for model development and 40 observations for model evaluation).

From the laboratory experiments, the observed erosion rate, E_{rs}, was computed by dividing the ratio of the eroded volume to the bank face area of the undercut, V/A, by the observed time. The average value of i_{cr} was used with the soil properties for the specific type and packing to calculate the critical velocity, v_c (equation 4). A nonlinear regression of E_{rs} versus v-v_c was fit to all 34 experiments with varying soil type, bulk density, H, and bank angles. A limitation of the proposed sediment transport function is that it assumes laminar flow conditions. Therefore, the equation is only valid for i_{cr} less than a maximum gradient at which turbulent flow occurs. Laminar flow conditions should be prevalent in the field except under cases of macropore or pipe flow (Wilson, 2007). Also, for model development, relationships were derived between V/A and A. Geometric relationships between A and σ_x and σ_y for the experiments in the model development data set were also defined.

Model Evaluation

The model was evaluated by comparing the predicted time using the relationships discussed previously to the observed time for a given A. First, a value of A as measured during the model evaluation experiment was selected. The ratio V/A was then computed using the relationship between V/A and A obtained during model development. The steady-state velocity, v, was computed as a function of the selected A using equation (5). The critical velocity, v_c was determined based on the measured critical head, H_{cr}, using equation (4). Next, the erosion rate, E_{rs}, was calculated using the empirical equation derived from the model development dataset; i.e., equation (3). The time required for a given amount of A to develop was then calculated as:

$$t_{pred} = \frac{V / A}{E_{rs}} \tag{6}$$

Finally, a linear regression analysis was performed between the observed time to reach the specific, A, to the predicted time, t_{pred}, calculated using the seepage erosion sediment transport function and the geometrical headcut relationships.

Estimating the Headcut Dimensions

From knowledge of A, σ_x and σ_y, the five-parameter Gaussian function can be simplified to approximate the height (h) or width (w) of the undercut at different distances along A. For example, at the bank face, one can solve for h_{bf} and w_{bf} (i.e., height and width of the undercut at the bank face, respectively) when z is reasonably close to zero (i.e., $z = \varepsilon$). To solve for the h_{bf}, simply substitute $x = 0$ with $x_o = 0$ and $y_o = 0$ into equation (1) and solve for $y = h_{bf}/2$; to solve for w_{bf}, substitute $y = 0$ with

$x_o = 0$ and $y_o = 0$ into equation (1) and solve for $x = w_{bf}/2$. The following equations are derived:

$$h_{bf} = 2\sigma_y \sqrt{-\ln\left(\frac{\varepsilon}{A}\right)} \quad , \; w_{bf} = 2\sigma_x \sqrt{-\ln\left(\frac{\varepsilon}{A}\right)} \tag{7}$$

Similarly, solving for the h and w at any z, where $z < A$, results in the following equations that allow prediction of the entire undercut shape:

$$h(z) = 2\sigma_y \sqrt{-\ln\left(\frac{z}{A}\right)}, \; w(z) = 2\sigma_x \sqrt{-\ln\left(\frac{z}{A}\right)} \tag{8}$$

In order to compute h_{bf} and w_{bf} using equation (7), it was assumed that ε was equal to the average particle diameter or the median particle size, d_{50}, of the particle size distribution since an undercut cannot be formed until at least one particle is dislodged from the bank. The values of σ_y and σ_x were computed using the Gaussian function for a given A. The scanned images of experiments with 60-degree banks did not show the full extent of the width of the undercut and were excluded from the analysis.

Results and Discussion

Model Development and Evaluation

Results of the non-linear regression between experimental data on E_{rs} versus v-v_c for all the 34 experiments with varying soil type, bulk density, H, and bank angles resulted in regression constants of a and b equal to 0.001 and 0.5, respectively, with a coefficient of regression, R^2, of 0.62 (Figure 3). This function covered a wide range of variability (i.e., different hydraulic controls, different packing conditions, and two soil types) as well as the three-dimensional nature of the seepage erosion. The function also related the erosion rate to the seepage velocity. Unlike that of Howard and McLane (1988), the derived sediment transport model does not use empirical coefficients which are difficult, if not impossible, to estimate. The function however, requires an estimate of i_{cr}.

Prior to deriving the sediment transport model, the critical gradient, i_{cr}, was determined. Using H_{cr}, the relationship between i_{cr} and effective cohesion, c', was established. Cohesion in soil added an extra force that has to be exceeded in addition to gravity and water forces before mobilization could occur. According to Dunne (1990), for soil with some amount of cohesion, an extra force is acting on the soil mass resisting the separation of the mass. He added that i_{cr} depended on the thickness of the volume that eventually separated. Cohesion therefore is a parameter which can also be used to estimate i_{cr}. Regardless of soil type and packing condition, i_{cr} and c' followed a logarithmic relationship ($R^2 = 0.99$) as follows:

$$i_{cr} = 0.19\ln(c') + 0.09 \tag{9}$$

Since the model considers the three-dimensional nature of seepage erosion, the geometry of the headcut has to be defined. For the model development data sets consisting of data from both soil types (coarse sand and loamy sand) and across a range of several different bulk densities (1.3 to 1.7 Mg m^{-3}), heads (15 to 35 cm), and bank angles (60 to 90 degrees), a linear relationship was observed between V/A and A,

with $A = 2.8\ V/A$. The ratio V/A represents the average depth of the undercut. Using this relationship, the average depth of undercut, V/A, was related to the maximum depth, A, which can be predicted from E_{rs} at a given time.

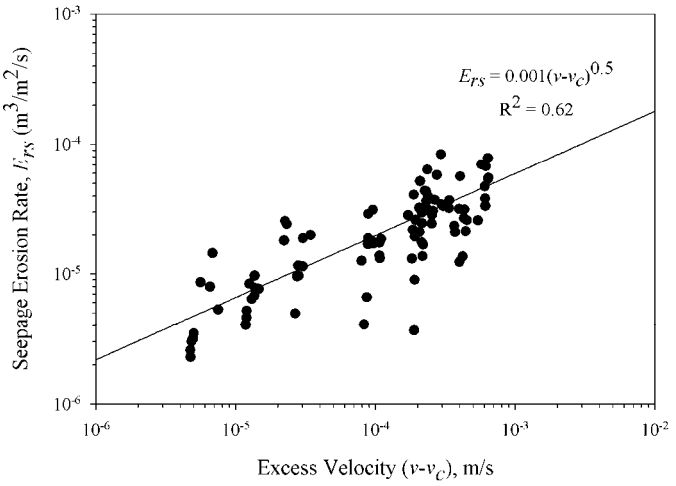

Figure 3. Relationship between seepage erosion rate (E_{rs}) and excess velocity (v) above the critical velocity (v_c) from model development studies.

The model was evaluated using the remaining 18 experiments by comparing the observed time with the predicted time for which a chosen headcut amplitude, A, developed. The linear regression analysis between the predicted time and the observed time resulted in an R^2 of 0.86 (Figure 4). The model was found to slightly over predict the time to develop a given A at large time. Larger observed times corresponded to experiments performed on stable banks (i.e., lower α' and H, and higher ρ_b). This means that for more stable banks, the model under estimated E_{rs}.

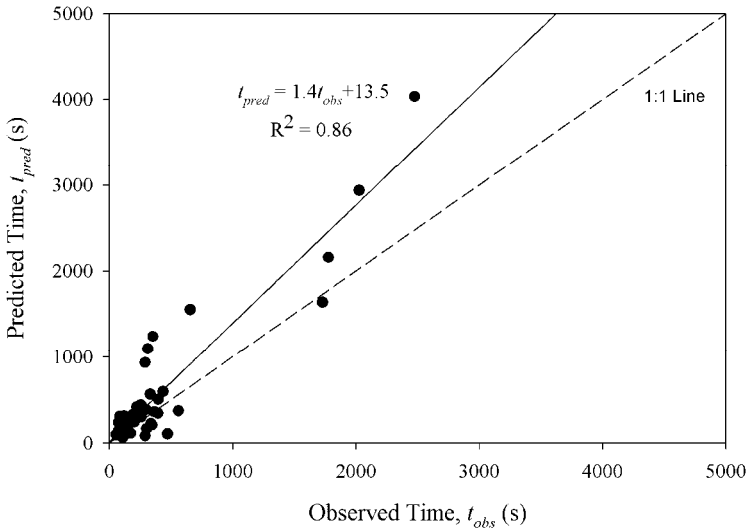

Figure 4. Linear regression between predicted time (t_{pred}) and observed time (t_{obs}) calculated using the seepage erosion sediment transport function and geometrical headcut relationships to obtain the observed headcut amplitude (A) for the model evaluation studies.

From a prediction of A, Chu-Agor et al. (2008a) and this research documented the appropriateness of a Gaussian distribution, from which predictions of σ_x and σ_y of the undercut could be made. Relationships between A and σ_x and σ_y included:

$$\sigma_x = 2.4A \qquad \sigma_y = 0.2A^{0.7} \tag{10}$$

Once σ_x and σ_y are known, w_{bf} and h_{bf} were computed using equation (7). When assuming ε equal to d_{50}, linear regression analysis between the measured and computed w_{bf} and h_{bf} for the model evaluation data set yielded slopes of 1.4 and 1.6, intercepts of -0.1 and 0.0, and R^2 of 0.85 and 0.84 for w_{bf} and h_{bf}, respectively.

Summary and Conclusions

A sediment transport function was developed and evaluated based on the three-dimensional soil block experiments conducted by Chu-Agor et al. (2008a). Two-thirds of the 54 experiments were used for model development and the remaining for model evaluation. The transport function was represented by an excess velocity function wherein the rate of erosion was related to the difference between the steady-state velocity and the critical velocity. The former was estimated from Darcy's Law with an adjusted hydraulic gradient to take into account the depth of seepage undercut measured by the laser scanner. The latter was determined as a function of the critical gradient which was measured in the laboratory using a three-dimensional soil block. The critical gradient was related to the effective cohesion through a logarithmic relationship. A power relationship (R^2 = 0.62) was established between erosion rate and excess velocity. The relationship between the eroded volume per bank face area and the amplitude of the headcut was also derived. Using a three-dimensional Gaussian function, the geometric relationships between the dimensions of the headcut were established. The model was evaluated by comparing the predicted time to the observed time at which a given amount of headcut developed. The linear analysis between the predicted time and measured time resulted in an R^2 of 0.86. The sediment transport model together with the derived relationships between the dimensions of the headcut and its geometry can be used to incorporate the effects of seepage erosion undercutting into bank stability analysis with integrated groundwater flow and stability models.

A Blueprint for Advancing Hydrologic Predictability in Developing Countries: A Case Study for the Nile River Basin

M. Gebremichael

Civil & Environmental Engineering, University of Connecticut, Storrs, CT 06269; PH (860) 486-2771; FAX (860) 486-2298; email: mekonnen@engr.uconn.edu

ABSTRACT

Lack of reliable hydrologic monitoring and prediction tool in the Nile River basin is hindering the planning and management of water resources in the region. This paper presents the broad outlines of an emerging approach for improving hydrologic monitoring and predictability in the Nile basin. The new approach embraces the space-time heterogeneities of hydrologic processes, and the integrative observations-modeling uncertainty in characterizing those processes. Instead of relying solely on sparse ground-based measurements, it will take advantage of recent developments in satellite remote sensing technology to observe space-time patterns of hydrologic variables. It will acknowledge the various observational and modeling error sources, and quantify the residual errors. Instead of using hydrologic models that have not been proven to work in the Nile basin, it will seek to identify the level of complexity needed maximize the performance of models driven by satellite datasets for the Nile basin. The defining feature of the new approach will be a sharp focus on the use of satellite data, hydro-meteorological models of appropriate complexity, establishment of a ground validation site and implementation of field campaigns for error characterization. This new focus will advance hydrologic monitoring and predictability in the Nile basin, and improve the accuracy of water balance components that would feed directly into the making of more-efficient, more-equitable and better-informed water management and planning decisions.

1. Introduction

The Nile River Basin (NRB) covers an area of over 3 million km^2, and a length of about 6700 km, the longest in the world. Water is a scarce resource in the NRB countries, and 'water resource management' is often a top priority in these countries. Proper utilization of the Nile water requires a good scientific understanding of (1) the space-time variability of Nile hydrology, and (2) assessment of the impacts of land use and climate changes on Nile hydrology. However, due to the sparse network of ground-based observation systems in the NRB, the space-time variability of Nile hydrology remains largely unknown. This problem could potentially be addressed by the use of satellite remote sensing (SRS) systems. SRS systems involve the detection and recording of electromagnetic radiation reflected/emitted by the Earth's surface/atmosphere, and the use of inverse techniques to convert those energy measurements to magnitudes of hydro-meteorological variables (e.g., precipitation, soil moisture, clouds, etc.). Retrieval equations are typically empirical algorithms, and this situation has led to the development of a plethora of such retrieval techniques. For example, one can apply different retrieval equations to a remotely sensed measurement to obtain quite different estimates of the same physical variable. For this reason, existing SRS products exhibit significant variations that limit our ability to improve the scientific understanding of the space-time variability of hydrological variables in the NRB.

Although satellites can observe key hydrological variables (mainly rainfall and evapotranspiration), there are still other important hydrological variables, particularly basin responses to rainfall forcing, such as, streamflow and groundwater flow, which cannot be observed by current SRS technology. To estimate the latter at ungauged locations, hydrologic models are typically used. Hydrologic models also play a crucial role in decision making for water management by simulating the basin responses under possible future scenarios (e.g., land use change, climate change, drought and flood forecasts, etc.). There are a number of hydrologic models developed in different regions of the world with different levels of complexity. Similar as with the SRS retrieval techniques, different models could give different simulation results, and there is no consensus on the hydrologic model most appropriate for the NRB as such consensus would need to be supported by exhaustive ground validation.

As a summary, we note that addressing the following two questions is the key to improve hydrologic monitoring and predictability in the NRB:

1. How can existing SRS systems lead to enhanced understanding of the space-time variability of rainfall and evapotranspiration at the NRB basin scale?

2. How can hydrologic models lead to enhanced understanding of the space-time variability of hydrological responses, particularly streamflow and groundwater flow?

In this paper, we present an approach that can be used to address these questions. Although we use the NRB to demonstrate our point, our approach can be applied to any major transnational river basin particularly in developing countries with inadequate ground-based observation systems.

2. How can existing SRS systems lead to enhanced understanding of the space-time variability of rainfall and evapotranspiration?

Rainfall

Background

Rainfall is the major driving force of the hydrologic cycle, and its estimation accuracy affects significantly the prediction accuracy of basin responses. Furthermore, rainfall is the most significant source of uncertainty in river basin hydrology. Data from rain gauges are commonly used in hydrological applications; however, the existing network of rain gauges in the NRB is by far inadequate for any hydrological application. Maintaining an adequate rain gauge network is difficult in this region, due to the vastness of the basin as well as the insurmountable operational issues to run such a large network in developing countries that do not have the resources to do so. As an alternative, spatial rainfall information over large basins could also be obtained from weather radar or SRS. Although weather radars are commonly used in most developed countries, there is no radar coverage in the NRB due the expensive capital and operational cost to run a radar network. This leaves us with SRS as the only currently viable means of obtaining spatially distributed rainfall data over the NRB.

Uncertainty in SR products

SR products are contaminated by several sources of error, which can be broadly grouped into temporal (sampling) and retrieval (algorithm) error. Temporal sampling errors arise from infrequent satellite visits and the variability of rainfall fields in space and time (e.g., Bell and Kundu 2000; Gebremichael and Krajewski 2004). Algorithm errors are associated with the algorithm approximation to the physical process (e.g., Wilheit et al. 1991). Information on rainfall estimation error is as critical as the rainfall estimate itself. In addition to providing objective measures to ensure progress in the satellite rainfall algorithm, estimation errors also help the user by providing information necessary for making rational decisions, enabling the user to take risk explicitly into account. To quantify the errors in the SR estimates, comparison of the SR estimates with independent, high-quality, ground-based rainfall observations are needed at selected locations. Sites that provide such high-quality ground-based rainfall observations are typically referred to as validation sites. Validation sites have been established or are underway in several developed countries. Such sites are now available in the US, UK, Spain, Italy, Japan, Kwajalein, and Australia, among others (Smith et al. 2007).

To assess the errors in the SRS estimates in the NRB region, recently we carried out the first validation field campaign in the Beressa watershed (BW) of the NRB in the summer of 2008. The BW is a mountainous, 220 km^2 watershed, located in the headwater of the NRB in Ethiopia (Figure 1). The watershed fairly represents most of the highlands of the NRB. During this field campaign, we installed 22 non-recording rain gauges within an area of 5 km × 5 km inside the BW, and collected daily measurements of rainfall at each of these locations for 40 days, from July 1 to August 9, 2008. Superimposed in Fig. 1 is the location of the rain gauges. We used these data to evaluate the accuracy of CMORPH (NOAA's Climate Prediction Center MORPHing technique; Joyce et al. 2004) rainfall product. CMORPH is the global rainfall product with the finest resolution (30 min, and ~ 8km × ~8km). CMORPH products rely exclusively on passive microwave and geostationary infrared measurements, with no ground-based measurement information.

Figure 1 shows that one of the CMORPH pixels contains about 19 rain gauges. This dense rain gauge network provides a very good reference dataset to evaluate the accuracy of CMORPH. We obtained area-averaged daily rainfall values from the rain gauge network by averaging the daily rainfall data from all 19 rain gauges. We aggregated the half-hourly CMORPH products to daily time scales, and compared them to the area-average values derived from the rain gauge network. As can be seen from Fig. 2, CMORPH performance varied by day. Overall, CMORPH tends to underestimate daily rainfall by 27%.

In a separate study, we had evaluated the accuracy of CMORPH in the central United States (see Zeweldi and Gebremichael 2008), and found that CMORPH overestimates rainfall in this region by a factor of 2 in July. The differences in the CMORPH accuracy over Little Washita and BW could be explained by the regional differences in climate and topography. Compared to BW, Little Washita is hotter in July and therefore has more evaporation below the cloud base that typically leads to overestimation by the SR product. Compared to Little Washita, BW is also characterized by more complex terrain rainfall.

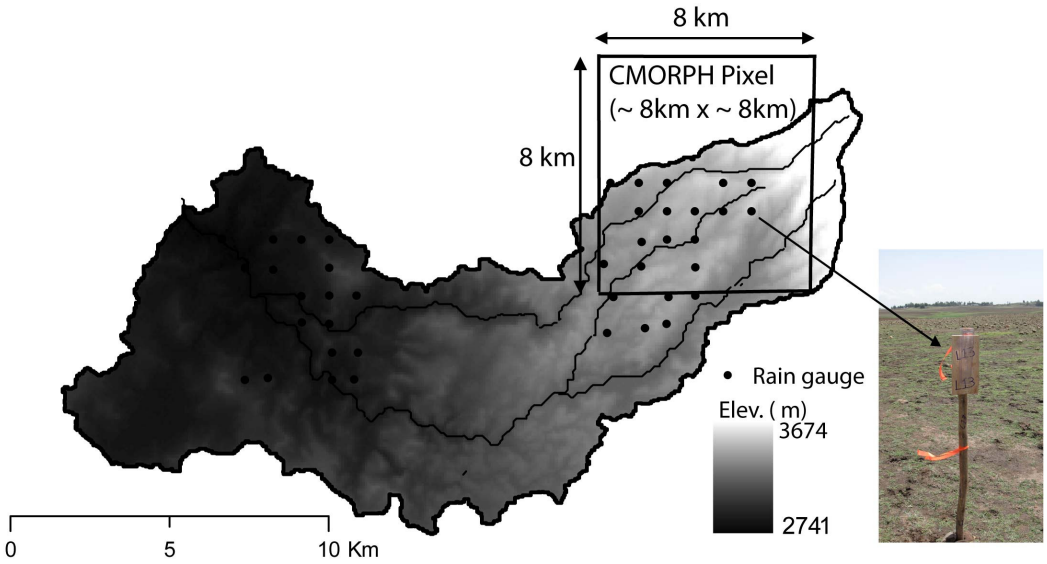

Figure 1. The 220-km^2 Beressa Watershed within the Nile River Basin, and its topographic characteristics derived from a 90-m digital elevation model. The inset shows the CMORPH rainfall product pixel (~8 km by ~ 8km), and a network of 19 rain gauges within this pixel. The rain gauges are graduated cylinders as shown in the picture, and manual readings were taken every morning.

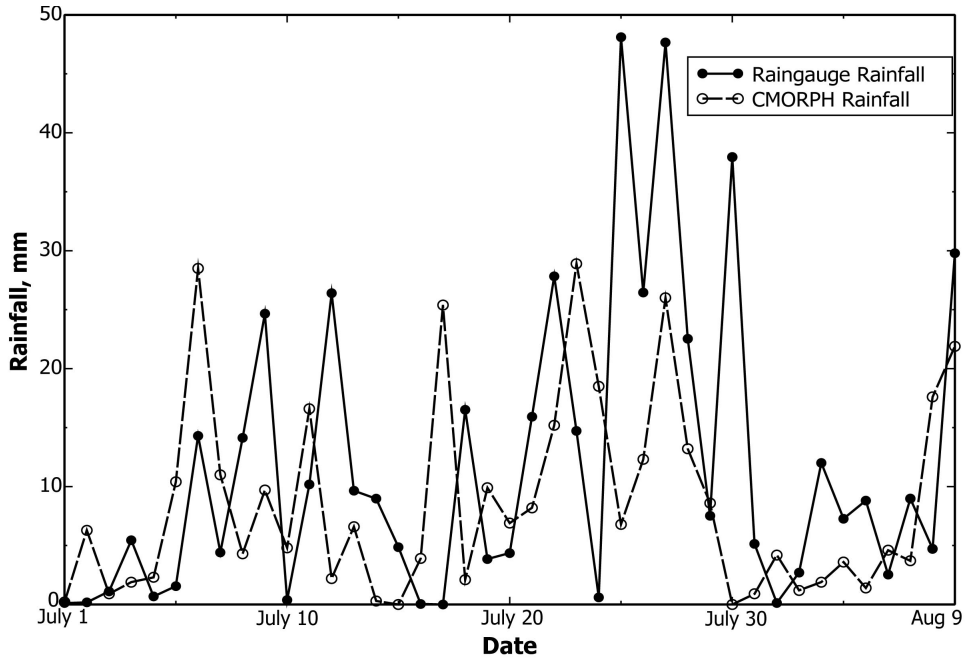

Figure 2. Comparison of time series of daily CMORPH and gauge-averaged rainfall values over one CMORPH pixel (see Fig. 1) within BW. The gauge-averaged rainfall is obtained by averaging daily rainfall data from 19 rain gauges within the CMORPH pixel.

Proposed Solution

It follows from the above discussion that information on the SR error is critically important to use the SR products as well as to improve the accuracy of the SR products. The NRB does not yet have a permanent validation site that can be used to quantify the errors in the SR estimates. We propose the establishment of a validation site in the NRB. The validation site should be equipped with a dense, permanently deployed, tipping bucket rain gauge network. SRS systems coupled with a validation site could make a breakthrough in characterizing the space-time variability of rainfall in the NRB.

Evapotranspiration

Background

Actual Evapotranspiration (ET) in the NRB is a major component of the hydrologic cycle, and so there is a strong interest in its accurate estimation. The traditional techniques for determining ET are either direct measurements in lysimeters (point scale) or from dedicated installations measuring gradients of temperature and water vapor (plot scale), or indirect estimation approaches based on the partitioning of the energy balance at the land surface (plot scale) (Brutsaert 1982; Monteith and Unsworth 1990). ET rates vary with soil moisture content, surface roughness and vegetation type, and so, it is often difficult to estimate ET using only ground-based measurements. For example, in the heterogeneous landscape in the central plateau of Spain, as many as 13 ground ET measurements in a relatively small area of 5000 km^2 were not sufficient to predict the area-averaged ET rate (Pelgrum and Bastiaanssen 1990). Thus, SRS remain the only viable alternative.

Uncertainty in SET products

Errors in Satellite ET (SET) estimates mainly result from uncertainties in the retrieval algorithms. SET retrieval algorithms contain a series of empirical equations, and so these equations might need some adjustments when they are applied to different regions. Most of the SET algorithms solve for ET as a residue of the energy balance equation. In these schemes, estimation of the sensible heat flux is the most significant source of error in SET estimates. Quantifying the uncertainty in the SET or sensible heat flux estimates over the NRB will help to (1) select the best SET algorithm, (2) modify the empirical equations involved in the SET algorithm, and (3) quantify the uncertainty of the resulting ET estimates. Information on the SET uncertainty is currently missing for the NRB.

Proposed Solution

We propose that well-organized field experiments designed to assess, improve, or develop new, SET algorithms be carried out in the NRB. This requires deploying ground-based sensors that provide accurate ET estimates at scales that are comparable to satellite pixels. This could be done by combining scintillometers and weather stations. Scintillometer can provide reliable measurement of sensible heat flux from the propagation statistics of an electromagnetic wave emitted over a certain distance along the surface (DeBruin 2002). The scintillometer has a

unique advantage over other ground-based sensors (e.g., eddy covariance sensors) in that it provides (1) measurements at scales comparable to remote sensing methods, (2) high temporal resolution, (3) access to remote areas, and (4) high accuracy.

3. How can hydrologic models lead to enhanced understanding of the space-time variability of hydrological responses, particularly streamflow and groundwater flow?

Reliable quantification of the temporal and spatial variability of basin responses (e.g., streamflow, groundwater flow) in a basin requires the use of a hydrologic model. A very important step in applying hydrologic models is selecting the optimal model complexity level. The model complexity level refers to the numerical method used for representing a basin: lumped, semi-distributed or fully-distributed. The premise that the explicit representation of spatially varying fields should lead to significant advances in the skill to simulate and forecast hydrologic response is the central hypothesis in the development of distributed hydrologic models (e.g., Beven 1989; Goodrich et al. 1995). The ability for detailed representation of spatial information (e.g., topography, soils, vegetation, and meteorological forcing) and hydrological dynamics comes at the expense of computational burden. Many studies also point out the possible overparameterization of the process description (e.g., Refsgaard 1994, 1997) and the general inability to validate the distributed dynamics with currently available spatial data (Grayson et al. 2002). Jakeman and Hornberger (1993) and Woolhiser (1996) have questioned the need for complex, physically-based models. This leads to the question: how much complexity is optimally needed in a hydrologic model for the NRB? Grayson and Bloschl (2001) argue that the performance of hydrologic models depends on the relationship between data availability/uncertainty and model complexity (Fig. 3). The level of model complexity required, and the relationship between this complexity level and sub-basin area and data uncertainty is yet to be assessed for the NRB.

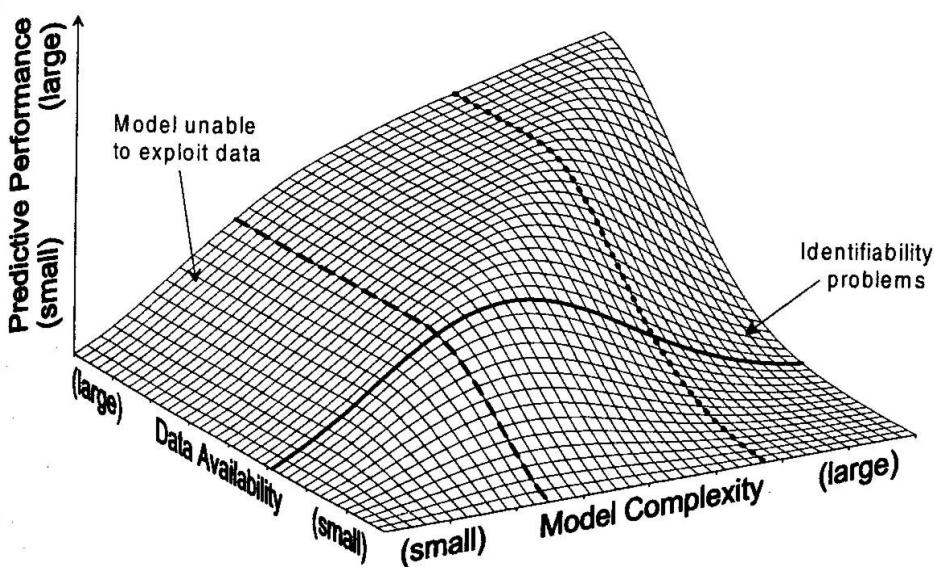

Figure 3 – Predictive performance of hydrologic models as a function of model complexity and data availability (Grayson and Bloschl 2001).

Proposed Solution

Research is needed to quantify the appropriate model complexity level for the NRB, given the availability of spatially distributed inputs from satellites and their uncertainty. This may depend on the space-time scale of interest, and season. To perform this research, it is important to maintain high-quality streamflow gauges at different spatial scales. The existing streamflow gauges network within the NRB can provide a good starting point for this research.

4. A blueprint for Advancing Hydrologic Monitoring and Predictability in the Nile River Basin

The NRB does not yet have a reliable hydrologic monitoring and assessment/prediction tool. This places serious limitations for the planning and management of the water resources in the Nile basin. Based on the discussion in the foregoing sections, we propose a new approach for advancing hydrologic monitoring and predictability in the NRB. As depicted in Figure 4, the approach stands on four pillars: establishement of a validation site, deployment of field campaigns, and integration of satellite data with hydrologic models. The validation site is important to provide ground reference for satellite rainfall estimates and hydrologic model streamflow simulations. The field campaign will provide ground reference data for satellite ET estimates. Major progress on the subject of Nile water management can be achieved by integrating the above research aspects to improve our understanding of Nile hydrology and lead to advanced data-modeling tools. To realize the transition to the new approach, we provide a brief assessment of the current strengths and existing barriers.

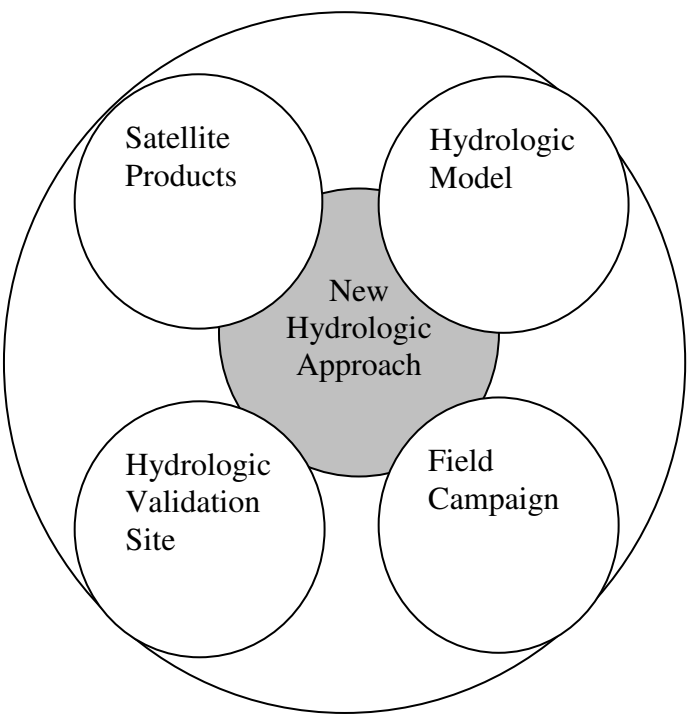

Figure 4 – The key components of the proposed hydrologic approach to advance hydrologic monitoring and predictability in the Nile River Basin.

ABSTRACT

The Yuna River basin, a watershed of about 5500 km^2 in the Dominican Republic (DR), is affected by both broad floods in the valley and flash flooding in the upper mountainous reaches. A better understanding of flood behavior and an assessment of flood control options is necessary in this watershed to protect human life and property, as highlighted by the particularly active 2008 hurricane season. Distributed hydrologic models using *Vflo*™ of both 250m and 500m cell resolution have been developed to provide flood prediction and flood control assessment in the basin. The Upper Yuna subwatershed is topographically diverse, with steep tributaries falling from 3,000m mountains into a main channel through a relatively flat valley. The *Vflo* software has great applicability for this watershed compared with more standard hydrologic models because it can model the challenging topography, provide flow outputs for any portion of the watershed, and handle variable-detail GIS inputs of elevation data, soil, and land-use maps. An analysis has been performed that compares influence of cell size and hydrologic detail on tributaries of varying steepness and flow output, which proves important for location selection of flood control options. A main goal of this work is to aid this flood-prone community by getting a first model running that can provide inputs to flood timing prediction, basic floodplain mapping, and flood control assessment, but that can be quickly refined as more data of greater detail becomes available.

INTRODUCTION

Flooding along the Yuna River, which is the second largest river in the Dominican Republic, is deadly and frequently damaging to the economy and agriculture of the region. Between 2000 and 2008, approximately 8 tropical storms and hurricanes hit or affected the Dominican Republic, and multiple storms took the

lives of citizens. The basin of the Yuna River covers approximately 5500 km^2 of land, and drains along two major tributaries into the larger Lower Yuna River and eventually into the Caribbean Sea (see Figure 1 below).

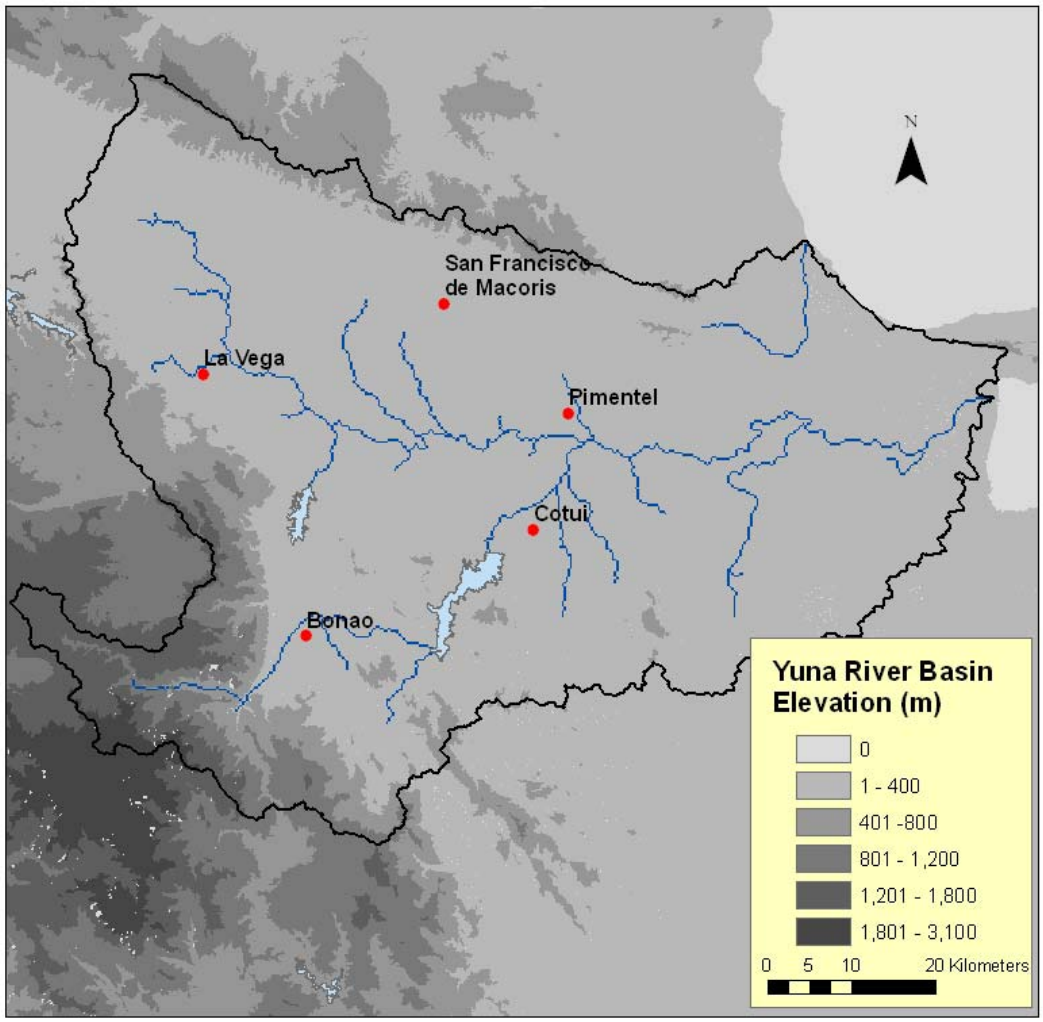

Figure 1: Yuna River Basin and Elevation Map

The Yuna River basin is characterized by steep tributaries that flow into the Lower Yuna River through a relatively flat valley. The runoff through the steep regions creates dangerous flash-flooding behavior in the Upper Yuna River through the city of Bonao. In the valley, wide floods occur that maintain high water for multiple days. The floodplain is estimated to be nearly 15 km wide in some places. There are fewer people living in the valley but many homes are clustered next to rivers for resources and access.

Agriculture is a vital component of the Yuna River Basin economy. The lower valley is very productive in rice, and the upper valley is used for mixed crops. A better understanding of flood behavior is necessary in this watershed to protect agricultural property. Currently, no comprehensive study of flood risk or flood control potential exists for the Yuna River basin. The model created in this study

provides a foundation for understanding flood risk in the basin and for making plans to mitigate it.

BACKGROUND

Hydrologic models can run calculations in a lumped, distributed, or semi-distributed format, which is a hybrid version between the former two. Each has more appropriate applications, as established in Das et al (2008). In this study, semi-distributed models outperformed, though comparison was based on only discharge at the outlet, for which the semi-distributed and lumped models were created (Das et al 2008). Distributed models, specifically, are designed to simulate flows along an entire channel. Zimmerman et al (2007) confirmed that a distributed model can successfully predict peak flows when results are needed at all points along a channel. They showed that the cumulative effects of detention ponds can be determined using a distributed model for which hydrographs can be extracted at every point along a tributary.

Various distributed hydrologic models are available, requiring different sets of parameter inputs. These models also address topography in different ways, which is an important focus in variable watersheds. Yang et al (2000) compared topography simulations within three distributed models: MIKESHE, TOPMODEL, and GB (geomorphology-based). MIKE SHE is thorough but slow in computation time; TOPMODEL requires greater calibration yet utilizes variable data better; GB is flexible and was determined by Yang et al (2000) to be the best for hydrologic modeling of large watersheds. The methodology in MIKE SHE parallels the gridded system that is run by the distributed model, *Vflo*™, which is provided by Vieux and Associates out of the University of Oklahoma (Vieux 2004). *Vflo*™ is a fully distributed model that provides outputs at both the local- and broad-scale without modification of the model setup. The platform of its flow computations is physically-based and requires the finite element method, which is used to solve the following kinematic equations:

Overland flow $$\frac{\partial h}{\partial t} + \frac{S^{1/2}}{n}\frac{\partial h^{5/3}}{\partial x} = R - I$$

Channel flow $$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} = q$$

where h = flow depth, S = slope, R = rainfall rate, I = infiltration rate, n = hydraulic roughness, Q = discharge or flow rate, q = rate of lateral inflow per unit length, and A = cross-sectional area (Vieux 2004). *Vflo*™ is an established model that can hot-start to minimize computation time and can handle very large basins (Vieux 2004). *Vflo*™ has been able to successfully replicate historical flood events, as seen in Vieux (2004) and Tachikawa et al (2003) and has been used in large, tropical watersheds, such as in Puerto Rico in Rojas and Harmsen (2007).

MODEL SETUP

The development of the Yuna River basin model involved a compilation of remotely sensed data into a detailed *Vflo*™ model of interconnected cells. One model was created with cells of 250m on a side, the other with cells of 500m. The flow direction grid that establishes the basis of the model was derived from NASA SRTM 90x90m data, which is comparable with SRTM 30mx30m data provided for the mainland United States. LiDAR data is expected to become available in Summer 2009 from the University of Texas Center for Space Research, which will provide important detail to the hydraulic model. However, the hydrologic model, running with 250m cells, should be adequately formed by the SRTM data.

Parameterization

Major inputs to a *Vflo*™ model are imperviousness, Green and Ampt infiltration parameters, overland and channel roughness, slope, and channel width. For the Yuna River basin, slopes were derived from the same elevation data that was used for determining flow direction. Channel width and roughness were estimated from the satellite imagery of GoogleEarth, in the absence of higher-detail images. Supplementary photos were taken during a helicopter flight over the watershed to obtain detail of bank erosion and stream vegetation.

Overland roughness Manning's coefficients are derived from a land use map created by the National Institute for Hydraulic Resources (INDRHI) of the Dominican Republic. The map's texture indicates the land use parcels were pulled from satellite images in an automated process. Manning's coefficients have been defined for each of the land use categories, ranging from 0.015 to 0.4. Over 30 categories are displayed, specifying a number of crops that are grown in the region.

Infiltration parameters for the local soil types were created using average values of the Soil Conservation Service's (SCS) four main soil groups. Descriptions of local soils obtained from INDRHI aided in determining which soil group was most appropriate, and Green-Ampt parameters were assigned based on these groups.

Precipitation

Full parameterization of the watershed allows for simulation of rainfall frequency storms. A Log-Pearson III frequency analysis was performed for three gages. The area represented by each gage slightly surpasses common limits seen with areal reduction coefficients, but no other gage operated for long enough to perform a statistically significant analysis. Annual 24-hr 100-yr storm maximums ranged from 160 to 320 mm for these gages, which is a high level of variation and is probably accounted for by coastal and topographical effects.

Typical rainfall distribution must be estimated to input a frequency storm at a given gage. Telemetered rainfall gage data is available on an hourly basis in certain Yuna locations starting in 2006. Cumulative plots of significant Yuna River basin storms have been compared to the four common distributions that have been developed by the Soil Conservation Service to approximate storms seen in the United States: Types I, II, III, and IV. This method provides dimensionless coefficients that can be multiplied by storm depth to depict hyetograph shape and placement of peak

intensity (McCuen 2005). The Yuna River basin is best approximated by the Type III curve.

RESULTS

The goal of these hydrologic simulations is to better our understanding of flood behavior along the Yuna River. The influence of a tributary is a telling indicator of its flood control potential. A comparison has been performed to assess this potential for the main tributaries of the Yuna River, even without sufficient data to represent historical storms. Figure 2 shows the tributary assignment in the watershed, with channel cells created for any cell draining more than 400 other cells for the 500m model.

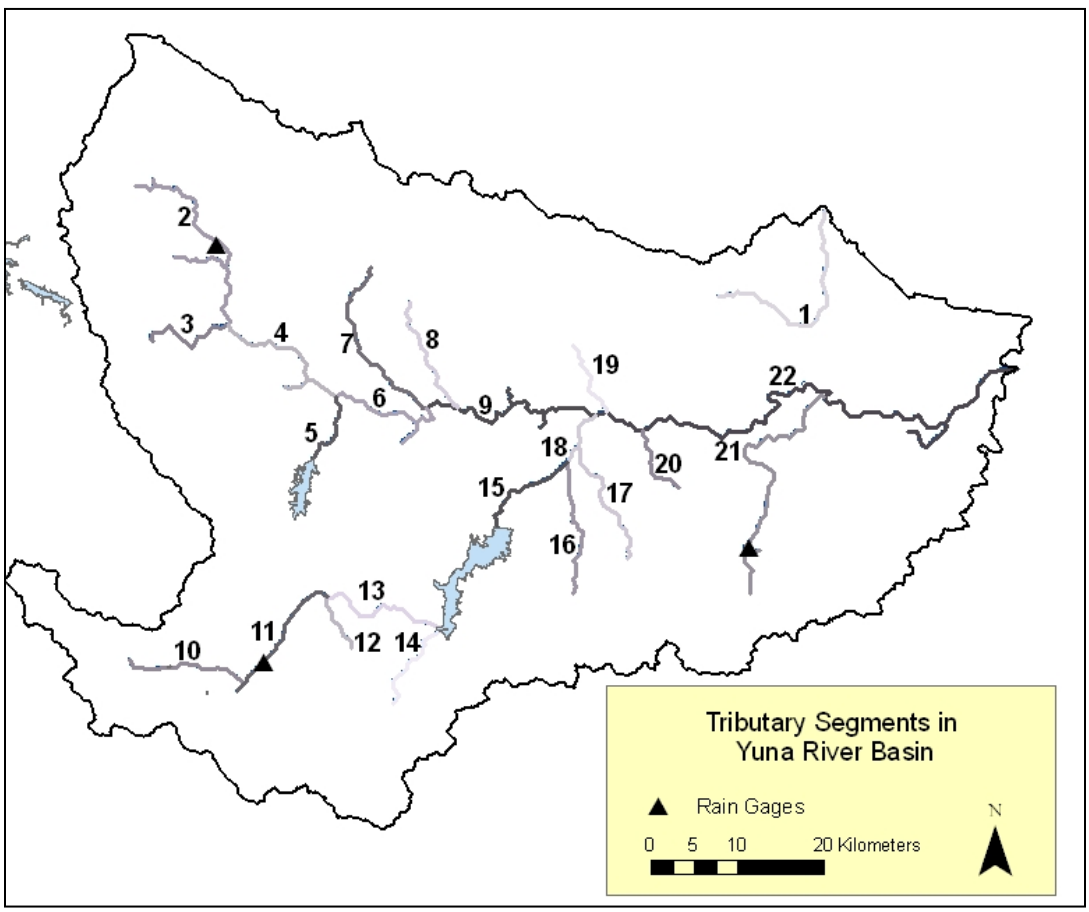

Figure 2: Labeled tributaries and segments of river for Tributary Comparison Analysis in Table 1

A 24-hr synthetic uniform storm of 200 mm was used for this analysis. Tributary influence is shown as a relative percentage of volume and peak flow, as compared with the river outlet. Where volume can be controlled, the potential to mitigate wide downstream floods may be present; where peak flow can be controlled, there may be the potential to mitigate flash flooding. The full tributary comparison is

shown in Table 1. While a local flood assessment or calibration might be best performed with the 250m cell model, the 500m cell model was used for this broad analysis, limiting computation time significantly.

Table 1: Comparison of tributary contributions using 500m preliminary model

Tributary Segment	% Volume of Outlet	% Peak Flow of Outlet		Tributary Segment	% Volume of Outlet	% Peak Flow of Outlet
1	5	5		12	5	5
2	14	19		13	21	33
3	6	10		14	5	8
4	27	31		15	29	36
5	5	6		16	6	8
6	36	40		17	5	6
7	5	4		18	39	44
8	5	4		19	5	4
9	50	50		20	1	3
10	5	14		21	10	11
11	13	26		22	100	100

DISCUSSION

A tributary analysis has been performed that denotes each tributary's contribution (at its outlet) as a proportion of the total flow. This process normalizes the results to eliminate calibration issues and still provides valuable information for selecting flood control locations. Because of the steep slopes and varied infiltration in the watershed, comparisons are possible that would otherwise not be obvious.

Table 1 highlights differences in tributary influence, such as the relative importance of tributaries 2, 3, 10 and 21 over tributaries 7, 8, 17, and 19. These tributaries have larger runoff volume or peak flow than would be expected from their relative length and size. Tributary 21 may be particularly influential, or for some storms, insignificant, because its timing is far off from other tributaries of similar size. Further investigation of historic storm movement is needed to determine timing specifics, but this analysis quickly narrows the list of potential flood control locations.

An interesting optimization of flood control location can be made for tributaries 10, 11, and 13, which drain into each other successively toward Bonao. The change in peak flow from tributary 10 to 11 is from 14% to 26%, or almost double. The change in peak flow from tributary 11 to 13, as more area is drained and slopes flatten, is from 26% to 33%, or just over a quarter larger. The volume comparison shows similar results, with volume increasing 160% between tributaries 10 and 11, yet increasing less then two thirds between tributaries 11 and 13. The relative increases do not match up linearly between peak flow and volume, showing the importance of the model in understanding behavior. Perhaps a flood control would be better located in tributary 11 than in tributary 13 if geography or expense made it more difficult to construct downstream. There would still be sufficient influence to affect the local runoff.

Tributary 15 results are particularly significant, as they indicate flood control effectiveness in the Hatillo Reservoir. About a quarter of the watershed's full volume enters the reservoir, while the peak flow through the reservoir is about a third of the greatest expected flow. These comparisons show useful conclusions can be reached using the tributary analysis, even without full calibration to historical events.

CONCLUSION

The preliminary hydrologic model has great potential for use in hydraulic modeling and floodplain delineation. As greater elevation and hydraulic detail becomes available, HEC-RAS modeling will be able to produce floodplains using the results of the Yuna River model. As it is, the tributary comparison is particularly useful for selecting flood control locations. Certain tributaries have been shown to have greater influence than is first discernible, especially when drainage area does not linearly match peak flow rates. A preliminary list of significant tributaries can be easily compiled. For future work, one of the benefits of using the distributed model, *Vflo*™, is that hydrographs can be pulled from the existing basin model at any location desired. An engineer selecting specific sites for flood controls can focus in on a cell within one of the more influential tributaries. Storage can be added at that specific site to determine extent of possible volume and peak flow mitigation. The distributed model is an ideal template for this work, as it remains calibrated at the scale of the watershed, and yet permits comparison of flood controls for very small shifts in location down to 250m .

Abstract

In the present study, Palleru sub basin (K-11) has been considered for the evaluation of land use land cover changes. Ten rain gauge stations were identified in and around the study area and accordingly the sub basin was divided into ten sub areas namely Palakurthy, Kodagandla, Torrur, Tungaturthy, Aravapally, Maripeda, Noothankal, Atmakur, Kushmanchi and Mothey based on Thiessen polygon network. The land use/land cover classification was made based on Normalized Difference Vegetation Index (NDVI) with two scenes in a year. The areal extent of bare soil was computed as 26.16 sq km and 372.03 sq km for the years 2000 and 2002 respectively in the Rabi season and 87.73 and 182.82 sq km for the years 2000 and 2002 respectively in the summer season. Bare soil increased by 345.87 sq km and 95.09 sq km in Rabi and summer seasons respectively. The areal extent of fallow lands with bushes decreased from the year 2000 to 2002 with respect to Rabi and summer seasons due to limited rainfall in the year 2002. However, the cropped area did not register much difference. The areal extent of water bodies in Rabi season was estimated as 198.83 sq km and 92.57 sq km for the years 2000 and 2002 respectively. The decrease in water spread area from the year 2000 to 2002 was due to corresponding decrease in rainfall in the study area from 920mm to 556 mm. Similarly, the areal extent of water bodies in summer season was estimated as 22.74 sq km and 18.27 sq km for the years 2000 and 2002 respectively.

Introduction

Land use/land cover inventories are essential for the optimal utilization and management of resources in a given sub basin. Land cover refers to different features covering the earth's surface including vegetation cover, water bodies, open scrub etc. It integrates the sum of human activities having an influence on the environment. The USGS has devised a land use/land cover classification system for use with remote sensor data (Anderson et al., 1976). Land use and land cover information should be presented on separate maps and should not be

intermixed (Lillesand et al., 1979). With the latest advancements and the wide range of applications in the field of remote sensing, Geographic Information System (GIS) facilitates the adoption of new methodologies which prove to be highly efficient. (Sahai et al., 1985) used multidate, multispectral Landsat imagery of pre and post monsoon studies. The overlay of the toposheet on the satellite image with appropriate ground truth provides the features of the land use/land cover of the selected area. The same study if implemented periodically enables to understand the variations in resources. ERDAS 8.7 has been used to study land use/ land cover features of the sub basin. The objective of the present study is to study and evaluate the land use and land cover changes in the sub basin of River Krishna, Andhra Pradesh, India. Nayak and Jaiswal (2003) observed that the conventional hydrologic data are inadequate for the purpose of design and operation of water resources systems. In such cases, remote sensing data are of great use for the estimation of relevant hydrological data. RS data can serve as a model input for the determination of river catchment characteristics such as land use /land cover, geomorphology, slope, drainage etc. GIS offers the potential to increase the degree of definition of spatial sub units, both in number and descriptive detail.

Holben (1986) studied that Normalized Difference Vegetation Indices (NDVI) increased as one proceeds from water through ice, snow, opaque clouds, bare soil, to green vegetation. (Wiegand et al., 1991) have argued that, at a specific site, the cumulative evapotranspiration and cumulative vegetation index should be highly correlated because the same green plant tissue measured by NDVI is due to absorbed active photo synthetic radiation. Reddy (1997) described that satellite data provides integrated information on rock types, land forms, geological structures, weathering, soil types, erosion, land use/land cover, surface water bodies, distribution of ground water, slope details, soil type, rainfall, irrigated areas and their acreage etc., All these data, incorporated into the GIS package, it will form an excellent data base and becomes useful for judicious planning, proper development and effective management of water resources.

Study area

The Krishna basin is situated between longitudes $73^0$21' to $81^0$09'E and $13^0$07' to $19^0$25' N in the Deccan plateau covering large areas in the States of Maharashtra, Karnataka and Andhra Pradesh. The Krishna basin extends over an area of 2,58,948 km^2, which is nearly 8% of the total geographical area of the country. Krishna catchment was divided in to 12 sub basins. In the present study, K-11 sub basin i.e Palleru basin of River Krishna has been considered to analyze land use/land cover at each rain gauge sub area. The Palleru sub basin lies between

latitudes 16^0 $39^{'}$ and 17^0 $50^{'}$ North and longitudes 79^0 $17^{'}$ and 80^0 $09^{'}$ East. The Palleru sub basin has a catchment area of 3,263km^2, which constitutes 1.3% of the total basin area. The catchment area of the Palleru sub basin entirely lies in the State of Andhra Pradesh. In the present study, sub basin has been considered up to Palleru reservoir only (2068km^2) as shown in Fig.1.

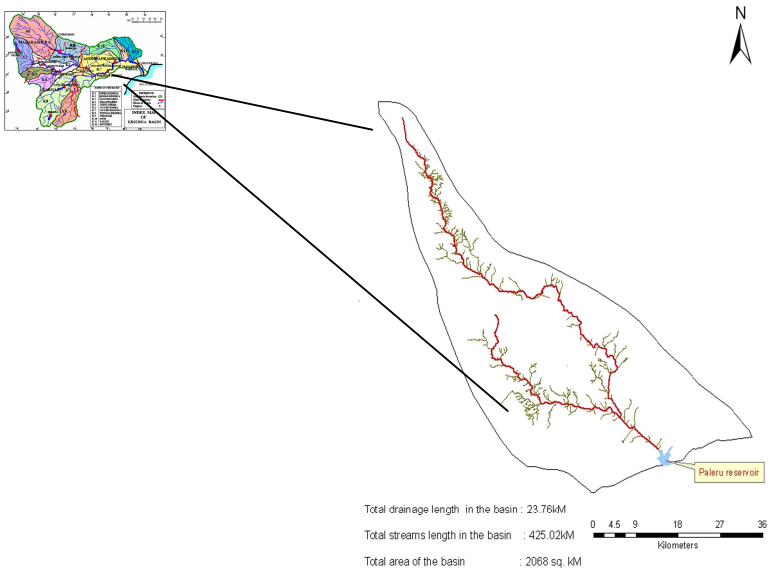

Fig 1 : Location plan of Palleru sub basin (K-11).

Data Used

Spatial data in the form of satellite imageries for the preparation of Land use/Land cover details at sub basin level were procured from National Remote Sensing Agency (NRSA), the details being listed in Table 1. These satellite imageries for both Kharif and Rabi seasons for two years pertain to Indian Remote Sensing Satellite (IRS) 1C & 1D, Linear Imaging and Self Scanning Sensor (LISS –III) with a resolution of 23.5m. The topographic maps used namely 56 O7, O10, O11, O12, O15, O16, 56P13, 65C4 and 65D1 on a scale of 1:50,000 were collected from Survey of India (SOI), Uppal, Hyderabad on 1:50,000 scale for the delineation of watershed boundary.

Table 1 Details of Satellite Imageries

Sl. No	Date of pass	Path, Row, Shift and Scanner	IRS	Season
1	09-04-2000	101, 60, 50% SHIFT, LISS-III	IC	Rabi
2	29-12-2000	101, 60, 50% SHIFT, LISS-III	IC	Kharif
3	11-05-2002	101, 60, 50% SHIFT, LISS-III	ID	Rabi
4	22-12-2002	101, 60, 50% SHIFT, LISS-III	ID	Kharif

Methodology

Identification and delineation of Land use/Land cover, location, extent and their spatial distribution patterns are possible because of the synoptic view provided by the Satellites and their ability to resolve both macro and micro details on a single imagery. It provides periodic coverage of the same area thus enabling to obtain Multi-temporal data useful for monitoring the dynamic aspects of Land use/Land cover. It provides data both in analog and digital form. Such data is amenable for both visual interpretation and digital analysis for extracting thematic information. It is relatively fast, cost effective and economical for inventorying several details of LU/LC than the most of the other methods of surveying. The different Multi-spectral and Spatial data can be merged with other satellite data for optimizing the LU/LC identification and discrimination.

Image classification: The overall objective of image classification procedures is to automatically categorize all pixels in an image into land cover classes or themes. Different feature types manifest different combinations of Digital Numbers (DN) based on their inherent spectral reflectance and emittance properties. The elements of image interpretation are shape, size, pattern, tone (or hue), texture, shadow, site, association and resolution.

Spectral Response of Vegetation: The visible and near infrared bands on the satellite multi spectral sensors allow monitoring of the greenness or vigor of vegetation. Green vegetation is highly absorptive in the visible part of the spectrum, mostly owing to the presence of chlorophyll. Beyond a wavelength of about 700nanometers, the absence of absorbing pigments and leaf structure results in high reflectivity for green vegetation. In contrast, other features such as bare ground, water, snow and clouds have similar reflectance in visible channel compared to near infrared channel. Stressed vegetation is less reflective in the near infrared channel than non-stressed vegetation and also absorbs less energy in the

visible band. Stratification of the Normalized Difference Vegetation Index (NDVI) response to broad scene components was shown in Table 2. Vegetation indices were found to increase as one proceeds from water through ice, snow, opaque clouds, bare soil, to green vegetation Holben (1986). Out of the various vegetation indices available, NDVI is very widely used as it minimizes the effect of change in illumination condition and surface topography (Holben, 1986). The NDVI is defined as the ratio of difference between the near infrared and red reflectance to their sum.

$$NDVI = \frac{CH2 - CH1}{CH2 + CH1} \quad (1)$$

where,

CH1 = Spectral reflectance from red band / channel

CH2 = Spectral reflectance from near infrared band / channel

Table 2 Albedo Values for Different Cover Types.

Sl. No	Cover Type	Planetary Albedo		
		CH1	CH2	NDVI
1	Dense green leaf vegetation	0.050	0.150	0.500
2	Medium green leaf vegetation	0.080	0.110	0.140
3	Light green leaf vegetation	0.100	0.120	0.090
4	Bare soil	0.269	0.283	0.025
5	Clouds	0.227	0.228	0.002
6	Snow and Ice	0.375	0.342	-0.046
7	Water	0.022	0.013	-0.257

The thematic map of Land Use / Land Cover has been prepared using ERDAS 8.7. The classification of land Use / Land Cover classes were evaluated using NDVI. Of all the available methods of image classification with regard to vegetation and its sub classification, NDVI forms the basis for a better classification and hence

adopted for the present study. And also, as the study area is considerably large comprising predominantly of vegetation, NDVI classification is better suited and hence employed for the classification of Land Use / Land Cover. This data is used as an input for direct runoff estimation.

Preparation of Land Use / Land Cover Thematic Map

Spatial data in the form of satellite imageries for the preparation of Land Use/Land Cover details at sub basin level were procured from National Remote Sensing Agency (NRSA) the details are listed in Table 1. These satellite imageries for both Kharif and Rabi seasons for two years pertain to Indian Remote Sensing Satellite (IRS) -1C & 1D, Linear Imaging and Self Scanning Sensor (LISS –III) with a resolution of 23.5m. The collected satellite images were georeferenced in ERDAS 8.7 then rectified and finally projected. The delineated watershed in vector form was overlaid on projected satellite imagery to get sub set of the study area. Thiessen polygon coverage which was prepared in GIS in vector form was overlaid on sub set image of the study area in ERDAS 8.7 to get delineation for all ten sub areas namely Palakurthy, Kodagandla, Torrur, Maripeda, Tungaturthy, Noothankal, Aravapally, Atmakur, Mothey and Kushmanchi. Normalized Difference Vegetation Index (NDVI) was employed as the basis for Land Use / Land Cover classification. This method of classification has been found to be suitable for the study area i.e., Palleru sub basin as the data used was pertaining to the past period i.e., years 2000 and 2002 and also the study area is considerably large comprising predominantly of vegetation. Study area has been classified for Land Use / Land Cover into four classes viz., Water bodies, Crop land, Bare soil and Fallow land with bushes in each sub area based on NDVI values generated in ERDAS 8.7. Area under each class has been calculated from the attribute table in Arc.GIS9.1. The flow chart used in this analysis has shown in Fig. 2. The classified thematic map was converted from raster to vector format for further analysis. The Land Use / Land Cover thematic map and soil map were intersected in command tools of ARC/INFO.

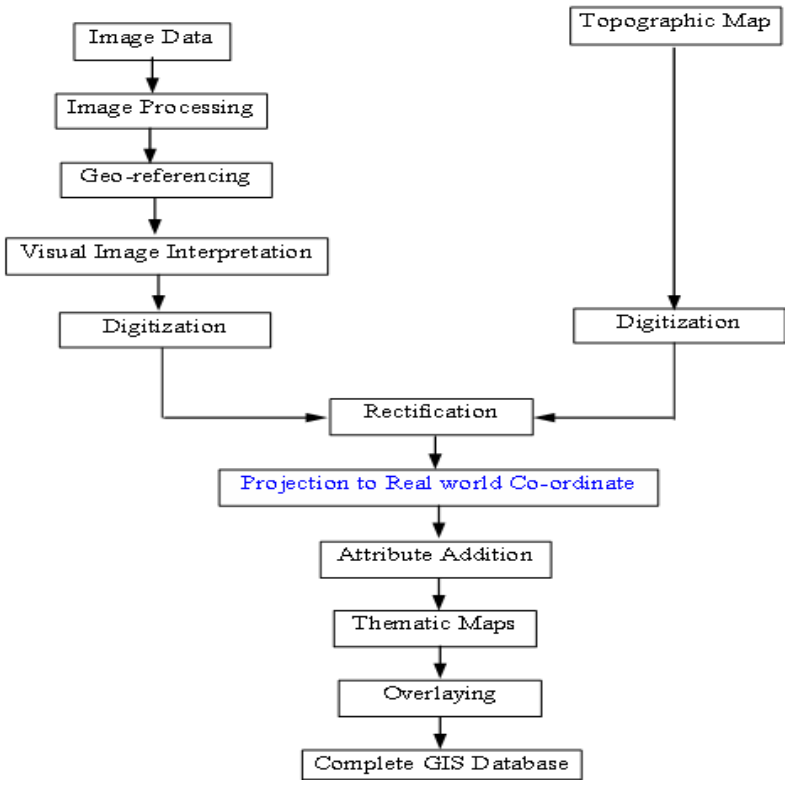

Fig 2. Flow chart for the preparation of land use and land cover thematic map.

Results and discussion

Four satellite imageries were analyzed using ERDAS 8.7, two of them pertaining to Rabi season and another two related to summer season in the years 2000 and 2002 respectively. The thematic map of Land Use / Land Cover has been prepared using ERDAS 8.7 for all imageries. The land Use / Land Cover classes were evaluated using Normalized Difference Vegetation Index (NDVI). Study area has been classified into four classes viz., Water bodies, Crop land, Bare soil and Fallow land with bushes in each sub area based on NDVI values for Land Use / Land Cover classification. Areal extent under each class has been calculated from the attribute table of ERDAS 8.7. The areal extent of Water bodies, Crop land, Bare soil and Fallow land classes has been listed in Table 3 for each sub area.

The areal extent of water bodies in Rabi season was estimated as 198.83 sq km and 92.57 sq km for the years 2000 and 2002 respectively. The decrease in water spread area from the year 2000 to 2002 was due to corresponding decrease in rainfall in the study area from 920mm to 556 mm. Similarly, the areal extent of water bodies in summer season was estimated as 22.74 sq km and 18.27 sq km for the years 2000 and 2002 respectively.

The areal extent of bare soil was computed as 26.16 sq km and 372.03 sq km for the years 2000 and 2002 respectively in the Rabi season and 87.73 and 182.82 sq km for the years 2000 and 2002 respectively in the summer season. Bare soil increased by 345.87 sq km and 95.09 sq km in Rabi and summer seasons respectively. The areal extent of fallow lands with bushes decreased from the year 2000 to 2002 with respect to Rabi and summer seasons due to limited rainfall in the year 2002. However, the cropped area did not register much difference. The variation of areal extent of water bodies, Crop land, Bare soil and Fallow land classes of land use and land cover in each sub area has shown in Figs. 3 to 5.

Conclusions

The classification of land Use / Land Cover classes were evaluated using NDVI. Of all the available methods of image classification with regard to vegetation and its sub classification, NDVI formed the basis for a better classification. It can also be safely concluded that for the considerably large areas comprising predominantly of vegetation, NDVI classification is better suited. NDVI classification is found to be especially suitable in such cases where the analysis was carried out using either past imageries or present imageries with no ground truth data.

Abstract

The HEXB (Hydrological EXperiment in Blue nile) experiment provided an opportunity, via dense network of rain gauges, to study the spatial variability of daily rainfall at a 5 km × 5 km scale in a tropical and mountainous part of the Blue Nile river basin, for the period of July 1 – August 9, 2008. The results of daily rainfall spatial analyses are shown in this paper. High intensity rainfall events have more absolute spatial variability (e.g., standard deviation) and less relative spatial variability (as measured by coefficient of variation), compared to lower intensity events. The coefficient of variation varies from 12% to 320%, with a median of 50%, indicating that there is a significantly large variability from one gauge observation to the other, and one gauge does not represent 5 km × 5 km grid-average daily values. A careful rain gauge layout design is critical to get accurate estimates at smaller number of rain gauges.

1. Introduction

It is known that rainfall events in the tropics can have large spatial variability over short distances. This variability has implications in the establishment of rain gauge networks and assessment of spatial sampling uncertainty. However, quantitative information on this variability is missing in tropical mountainous regions due to the lack of adequate ground observations.

The HEXB (Hydrological EXperiment in Blue nile) experiment has provided the opportunity, via a dense network of rain gauges, to explore a range of issues related to spatial rainfall characteristics. In this study, we consider the variability within a 5 km × 5 km area, here called "local" scale, which is commensurate with the resolution of high-resolution satellite rainfall products, such as PERSIANN-CCS (Precipitation Estimation from Remotely Sensed Information using Artifical Neural Networks – Cloud Classification System; Hong et al. 2004) and CMORPH (NOAA's Climate Prediction Center MORPHing technique; Joyce et al. 2004), and therefore, is important to validate these satellite products.

Firstly, we characterize the spatial statistics of daily rainfall using marginal statistics (probability distribution, standard deviation, and coefficient of variation) as

well as bivariate statistics (correlation coefficient as a function of separation distance). The effect of temporal aggregation on the spatial statistics is also considered. Secondly, we assess the sampling uncertainty introduced by the use of smaller number of rain gauges to estimate local-scale-averaged rainfall estimates.

2. The Watershed

The Beressa Watershed is located in the central highlands of Ethiopia, within 9°33′43″N to 9°42′27″N and 39°28′34″E to 39°44′23″E (Fig. 1). It covers an area of 283 km^2. Geologically, it is part of the highlands that largely owe their altitude to the uplift during the rifting process. The Beressa watershed is on the western plateau edge of the rift system. It is characterized by diverse topographic conditions; elevation ranges from 1850 m to 3700 m. Climate is considered humid, with 1100 mm of annual precipitation. Most of the annual rainfall comes from summer monsoon.

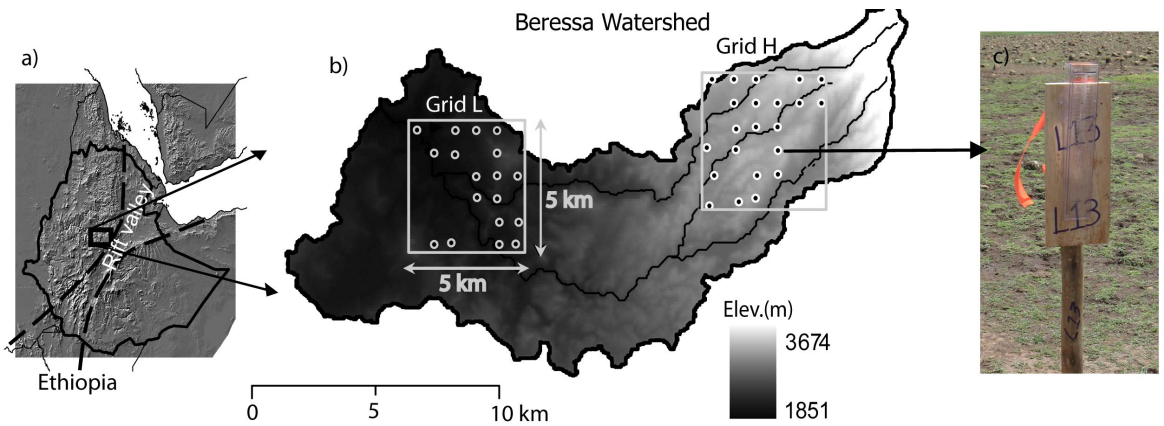

FIG. 1. (a) Map of Ethiopia showing the location of the Beressa watershed with respect to the rift valley. (b) The Beressa Watershed (283 km^2) delineated using a 90-m DEM. The inset contains two grids (5 km × 5km) located in the high-elevation and low-elevations areas of the watershed; and the rain gauges within them. (c) A picture showing an example of one of the installed non-recording rain gauges.

3. The Experiment

The HEXB project started in June 2008, with the aim of advancing hydrological science in a tropical and mountainous region through gaining a better understanding of the space-time variability of rainfall, as sensed by rain gauges network and remote sensors, and how this variability influences hydrologic simulation at the catchment scale. The project has been administered by the University of Connecticut, in collaboration with Addis Ababa University and the Amhara Regional Agricultural Research Institute-Debreberhan Research Center. It has been funded by the National Science Foundation.

An important focus of the project was a set of experimental facilities within the Beressa Watershed. This comprised two new networks of non-recording rain gauges (Fig. 1). The first network consisted of 21 non-recording rain gauges over a 5 km × 5

km area, in the upstream mountainous region of the watershed, we call "Grid H". The second network consisted of 18 non-recording rain gauges over a 5 km × 5 km area, in the downstream hilly region of the watershed, we call "Grid L". The separation distance between two neighboring rain gauges was about 1 km, within each grid. Initially, we put rain gauges every kilometer within each grid, but we lost some of them during the experimental period. We believe that the remaining density of 18 or 21 rain gauges is adequate to capture the spatial pattern of rainfall, and to estimate accurately the mean rainfall over each grid.

We selected the two grids to look at the effect of elevation on rainfall's spatial variability. Figure 2 presents the elevation of each rain gauge. Grid H's rain gauges have elevations ranging from 3100 to 3270 m, while Grid L's have elevations ranging from 2730 m to 2900 m. Grid H has higher elevation than Grid L. However, both grids have similar sub-grid variability in elevation; for example, the range of elevations within each grid is about 170 m.

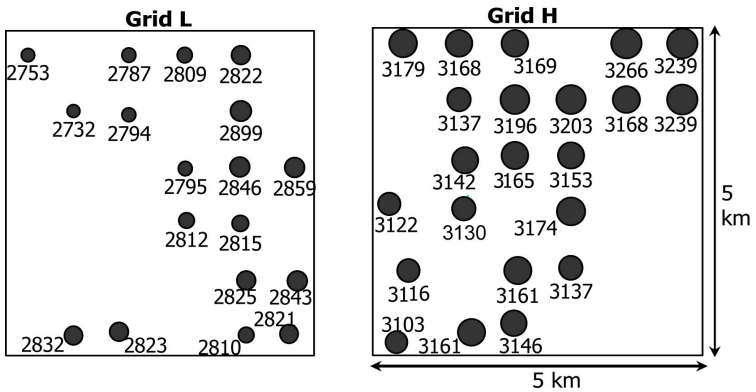

FIG. 2. Elevation (m) of each rain gauge location over (left panel) Grid L, and (right panel) Grid H.

The non-recording rain gauges used were the "Tru-Chek®" plastic rain gauges manufactured by the Forestry Suppliers. The gauges have scales permanently marked on the front side. We mounted each gauge vertically on a wooden pole at a height of 2 m above the ground. A typical rain gauge installation is shown in Fig. 1c. Our research group and trained local research assistants took readings off each rain gauge, every morning from 7 to 8 am, for the period of July 1 to August 9, 2008. This is the major rainy period in the region; there were 38 rainy days during the 40-day experimental period.

4. Results and Discussions

a. Spatial Variability of Rainfall: Marginal Statistics

In Figs. 3a and 3b, we show the distributions of spatial variability of daily rainfall within an area of 5 km × 5 km, for Grids L and H. The spatial variability of rainfall varies from day to day. Higher spatial means tend to have more sub-grid variability than lower ones. We found a sample correlation coefficient of 0.74 for Grid L (and 0.84 for Grid H) between the interquantile range (i.e. the difference between the 75% and 25% quantiles of spatial rainfall) and spatial mean, indicating that the spatial mean explains about 55% for Grid L (and 71% for Grid H) of the day-to-day

variation in the spatial variability of daily rainfall, for 50% of the cases. For 80% of the cases, the spatial mean explains about 65% for Grid L (and 74% for Grid H) of the day-to-day variation in the spatial variability of daily rainfall.

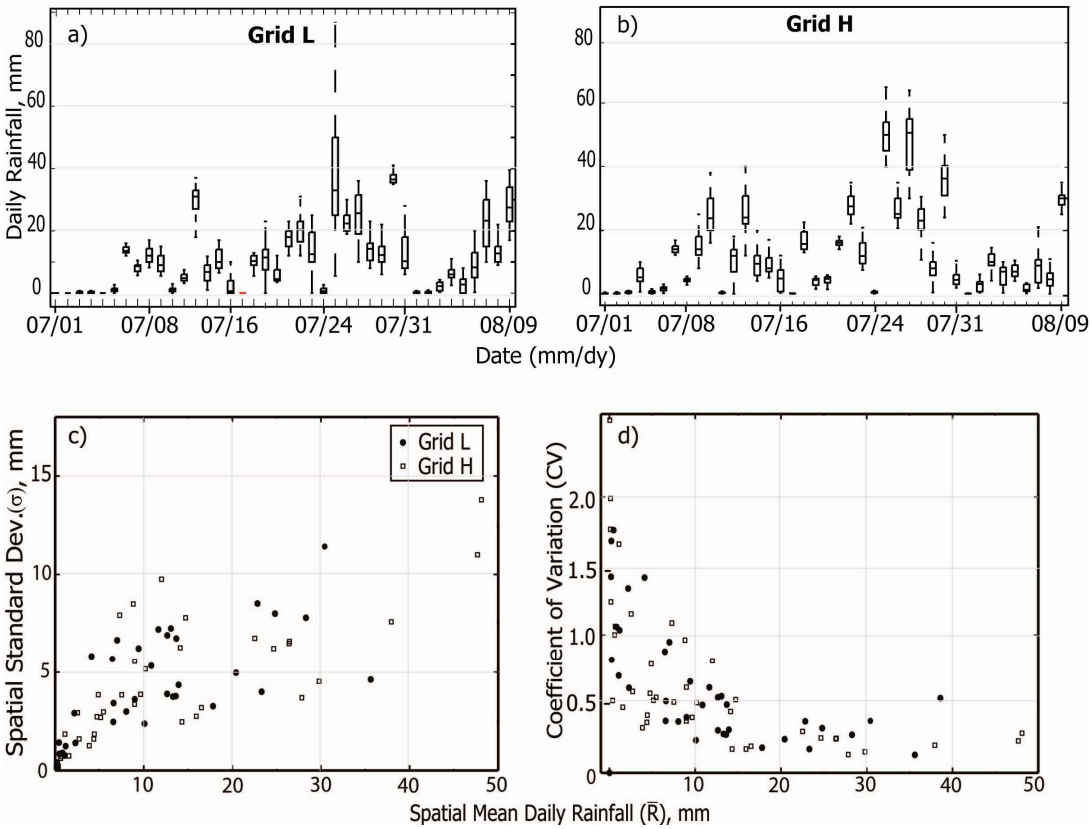

FIG. 3. Spatial variability of daily rainfall over each grid. (a) Box plots for the distribution of spatial rainfall on each day over Grid L. (b) Same as in Fig. (a), but for Grid H. (c) Spatial standard deviation versus the spatial mean rainfall. (d) Spatial coefficient of variation versus spatial mean rainfall. The statistics are obtained using all 18 gauges within Grid L and 21 gauges within Grid L, for each day within the observation period. The box plots represent 10%, 25%, 50%, 75%, and 90% quantiles, from the bottom up.

In Fig. 3c, we present the spatial standard deviation (σ) as a function of the spatial mean daily rainfall ($\overline{R}$). Overall, σ increases with increasing $\overline{R}$, indicating that higher spatial means tend to have more absolute sub-grid spatial variability. However, the relationship between σ and $\overline{R}$ is non-linear: the slope is steeper and the scatter is narrower for low $\overline{R}$ values, than for high values.

The increase in σ with increasing $\overline{R}$ is consistent with the fact that absolute variability tends to be greater for higher values of measured positively defined random variables than for small values. To filter out the effect of this fact, we normalized σ against $\overline{R}$, and looked at how this relative variability (expressed as coefficient of variation, CV=$\sigma / \overline{R}$) behaves with respect to the spatial mean. Figure 3d shows that, overall, high spatial means have less sub-grid relative variability than

lower spatial means. The relative variability decreases exponentially with increasing $\overline{R}$, for $\overline{R}$ smaller than 15 mm/day, and then remains fairly constant for $\overline{R}$ exceeding 15 mm/day. The CV varies from 12% to 320%, with a median of 50%, indicating that there is a significantly large variability from one gauge observation to the other. For the days with CV above 100%, the rainfall intensities were of low to medium intensity.

Let us look at the effect of temporal aggregation on spatial variability. We calculated σ, CV, and $\overline{R}$ for 5-day accumulations, and show the results in Fig. 4. The absolute variability (σ) exhibits a strong linear dependence on $\overline{R}$: it increases linearly with increasing $\overline{R}$. However, the relative variability does not show a clear dependence on $\overline{R}$. This indicates that aggregating the data to longer time scales filters out the effects of other factors (e.g., rain type, storm direction, etc.) that could cause spatial variability. From the comparisons of 1-day and 5-day accumulations, it becomes clear that (1) at the daily time scale, the absolute spatial variability depends on $\overline{R}$ in a non-linear way; and the relative variability shows a strong dependence (exponential decay) on $\overline{R}$, particularly for small to medium events; (2) aggregating the daily data to longer time scales (for example, 5-day) will lead to spatial variability, where the absolute spatial variability depends on $\overline{R}$ strongly in a linear way, and the relative variability does not depend on $\overline{R}$.

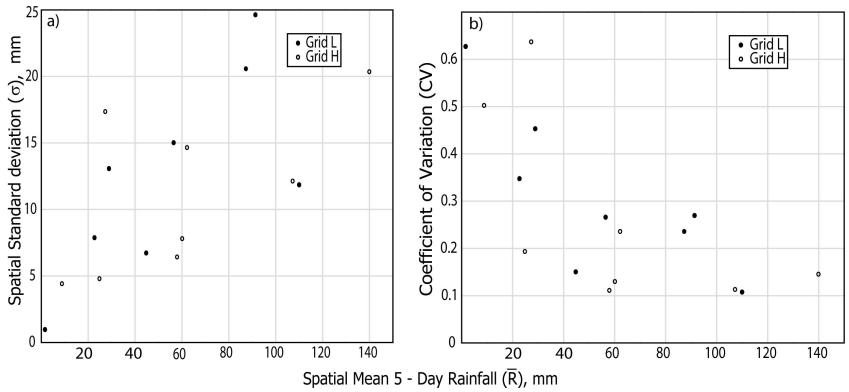

FIG. 4. Spatial variability of 5-day rainfall accumulation over each grid. (a) Spatial standard deviation and (b) coefficient of variation versus the spatial mean rainfall.

b. Spatial Variability of Rainfall: Joint Statistics

To quantify the spatial correlation structure, a plot of correlation coefficients between time series data of pairs of rain gauge observations, with respective separation distances, is often examined (e.g., Morrissey et al. 1995; Ciach and Krajewski 1999; Gebremichael et al. 2003). Using a similar approach, the results are shown in Fig. 5 for each grid. The results show that correlation does not depend on distance, suggesting that the large variability (CV) observed from one rain gauge to the other has a random characteristic.

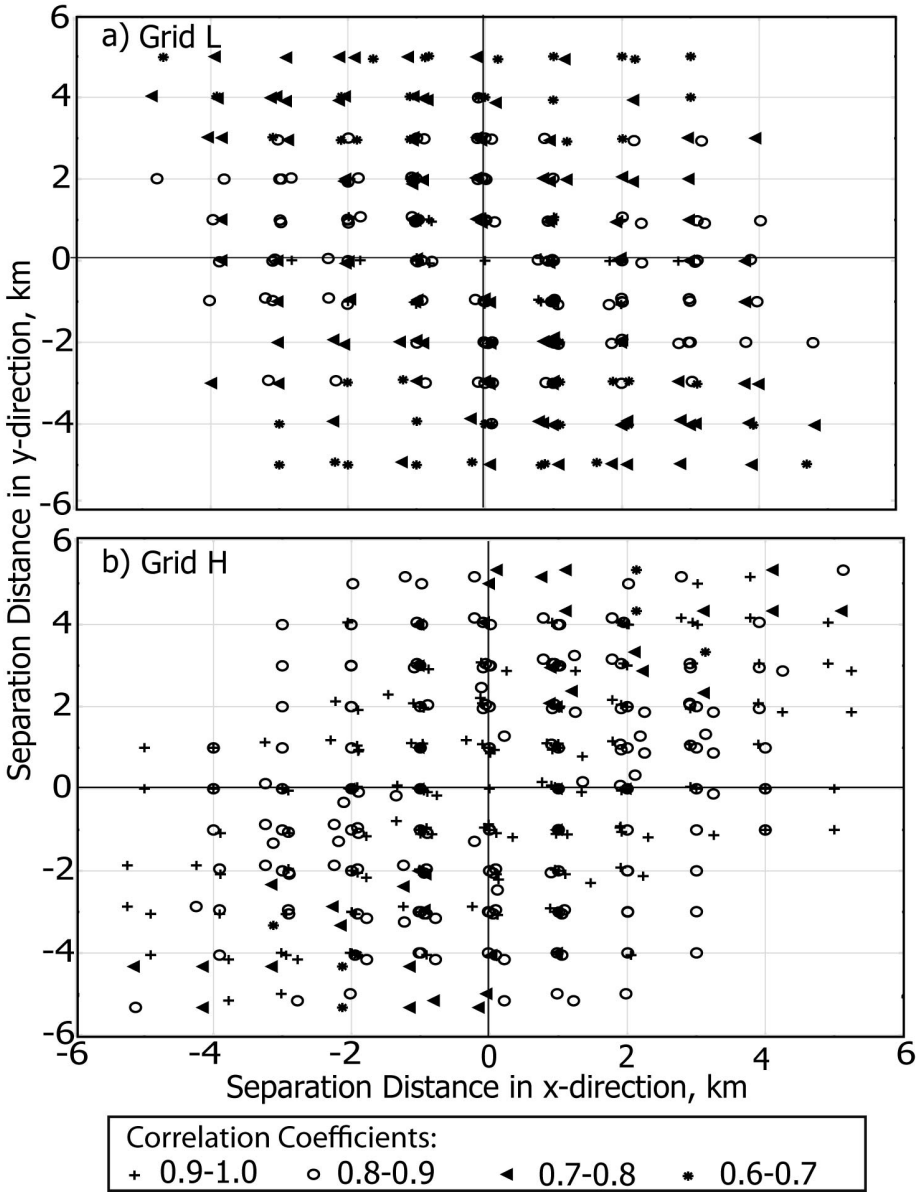

FIG. 5. Correlation coefficient between daily time series data of pairs of rain gauges with separation distances in both directions, for (a) Grid L, and (b) Grid H.

c. Rain Gauge Spatial Sampling Uncertainty

One of the impacts of the spatial variability of rainfall is the number of rain gauges required to accurately estimate grid-averages, and the uncertainty level resulting from the use of smaller number of rain gauges. Let us assume that the spatial mean of rainfall from all rain gauges within each grid, hereafter referred to as "Reference rainfall $\overline{R}$) represents the "true" rainfall. The expression for $\overline{R}$ is:

$$\overline{R} = \frac{1}{n}\sum_{i=1}^{n} R_i,$$

where, $i = 1, 2, \ldots, n$ (number of all rain gauges within Grid L or H).

By sampling smaller number of rain gauges, we can simulate the "Estimated rainfall $\overline{R}_e$" resulting from these gauges::

$$\overline{R}_e = \frac{1}{n}\sum_{i=1}^{n} R_i \delta_i,$$

where, the Kronecker delta function, δ_i, is one if the rain gauge is selected and zero otherwise. The estimation error is, therefore, the difference between $\overline{R}$ and $\overline{R}_e$, and it obviously depends on the number of rain gauges as well as the network configuration.

Consider two daily events over Grid H: the July 15 and July 30 events. The July 15 event had a spatial mean of 9 mm/day, which is equivalent to the 50% quantile of the spatial mean time series data. The July 30 event had a spatial mean of 38 mm/day, equivalent to the 90% quantile of the spatial mean time series data. So the July 15 event represents typical event, while the July 30 event represents an extreme event. Our interest is to quantify $\overline{R}_e$ and estimation error resulting from the use of smaller number of rain gauges (1, 2, 4, 8, 16) in estimating area-averaged values for these typical and extreme events. For each gauge density, we simulated 16 realizations of rain gauge networks by randomly generating each network from a uniform distribution, and show the results in Figs. 6a and 6b.

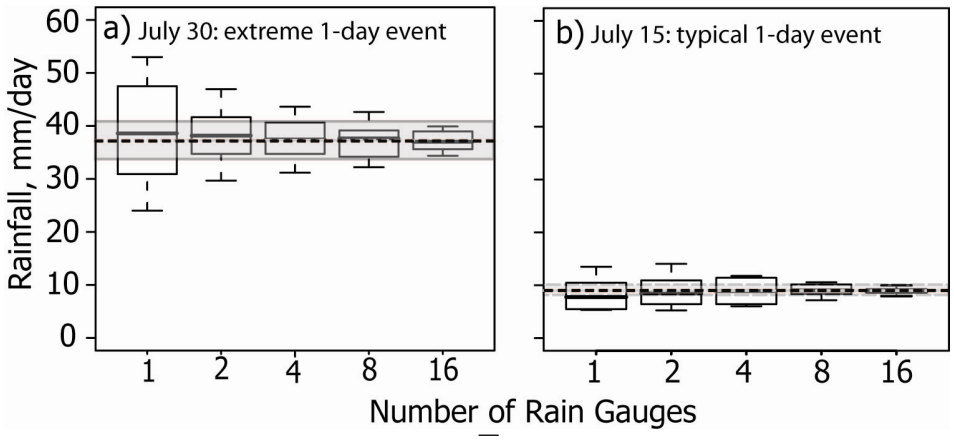

FIG. 6. Distribution of rainfall estimates ($\overline{R}_e$) as a function of rain gauge network density, for (a) the July 30 extreme event, and (b) the July 15 typical event. The bold dashed line shows the reference $\overline{R}$. The shaded region indicates the ±10% deviation from $\overline{R}$.

Consider the event of July 30 ($\overline{R} = 30$ mm/day), which is the 90% quantile extreme value. When only one rain gauge is used to estimate this grid-average rainfall, the estimate could be anywhere from 24 to 53 mm/day (equivalent to estimation error of -14 to 15 mm/day, or –37% to 39% of $\overline{R}$) for 80% of the configurations, and from 31 to 48 mm/day (estimation error of -7 to 10 mm/day, or –18% to 26% of $\overline{R}$) for 50% of the configurations. When four rain gauges are used, the rainfall estimate ranges from 31 to 44 mm/day (estimation error of -7 to 6

mm/day, or –18% to 16% of $\overline{R}$) for 80% of the configurations, and from 35 to 41 mm/day (estimation error within ± 3 mm/day, or ± 8% of $\overline{R}$) for 50% of the configurations.

Let us look at the corresponding values for the typical event of July 15 ($\overline{R} = 30$ mm/day). When one rain gauge is used, the rainfall estimate ranges from 5.3 to 13.5 mm/day (estimation error of -3.7 to 4.5 mm/day, or –40% to 50% of $\overline{R}$) for 80% of the configurations, and from 5.5 to 10.5 mm/day (estimation error of -3.7 to 4.5 mm/day, or –39% to 16% of $\overline{R}$) for 50% of the configurations. With four rain gauges, the rainfall estimate ranges from 6.4 to 11.8 mm/day (estimation error within ± 2.8 mm/day, or ± 30% of $\overline{R}$) for 80% of the configurations, and from 6.4 to 11.4 (estimation error within ± 2.6 mm/day, or ± 30% of $\overline{R}$) for 50% of the configurations.

Let us compare and contrast the estimation errors for the two rainy events. The first feature is that the magnitude of the estimation error is larger for the extreme event than for the typical event. This can be explained by the fact that strong events have more absolute spatial variability than those of weaker events (see Fig. 3c). The second feature is that the proportion of the estimation error to $\overline{R}$ is smaller for the extreme event than for the typical event. This can be explained by the fact that strong events have less relative variability than those of weaker events (see Fig. 3d).

How many rain gauges do we need to obtain a reliable estimate of the grid-average daily rainfall estimate? It depends on the level of uncertainty we accept. Let us say, we accept 10% level of uncertainty. For the extreme event, this can be achieved by having (i) 16 rain gauges of pretty much any configuration used in this study, or (ii) 2, 4, or 8 rain gauges with any of the 50% of the configurations used in this study. This indicates that a careful rain gauge layout design is critical to get accurate estimates at smaller number of rain gauges. There are studies that looked at optimal network configuration (e.g., Moore et al. 2000). For the typical event, the 10% uncertainty level can be achieved by having (i) 16 rain gauges of pretty much any configuration used in this study, or (ii) 8 rain gauges having any of the 50% of the configurations used in this study. Apparently smaller numbers of rain gauges, that were deemed adequate for the extreme event, were found inadequate for the typical event. This is due to the fact that our objective measure (i.e. 10% level of uncertainty) is relative to the actual rainfall value, and strong events have lower percentage of estimation errors with respect to their rainfall value.

5. Conclusions and Recommendations

HEXB provided an opportunity, via dense network of rain gauges, to study the spatial variability of daily rainfall at a 5 km × 5 km scale in a tropical and mountainous part of the Blue Nile river basin. High intensity rainfall events have more absolute spatial variability (e.g., standard deviation) and less relative spatial variability (as measured by coefficient of variation), compared to lower intensity events. The coefficient of variation varies from 12% to 320%, with a median of 50%, indicating that there is a significantly large variability from one gauge observation to

the other, and one gauge does not represent 5 km × 5 km grid-average daily values. The correlation does not depend on distance, suggesting that the large variability observed from one gauge to the other has a random characteristic. The smallest number of rain gauges required to estimate grid-average rainfall depends on the rainfall magnitude. It is generally smaller for high intensity events than for low intensity events. A careful rain gauge layout design is critical to get accurate estimates at smaller number of rain gauges. Four rain gauges with the right configurations can have better performance than ill-placed 16 gauges.

ABSTRACT

"The Provision of adequate fresh-water resources for people and ecosystems will be one of *the most critical and potentially contentious issues facing society and governments at all levels during the 21st century*" (American Meteorological Society, 2008).

Integrated Water Resources Management (IWRM) is evolving as a contemporary means to address complex and critical issues associated with making the most effective and efficient use of water resources. Water resource challenges in the Zambezi River Basin include both quality and quantity issues including potential diversions from the basin to localities outside the basin and lack of an agreed upon institutional framework for the management of the Zambezi River system. In 1972, the United States and Canada signed the first Great Lakes Water Quality Agreement. This agreement committed the two countries who share the trans-boundary waters of the Great Lakes to restore and enhance water quality in the Great Lakes System. Amendments in 1987 resulted in establishing the goal to virtually eliminate persistent toxic substances into the Great Lakes resulting from human activities. In 2008, the Great Lakes Compact was approved by all of the eight Great Lakes States plus the Provinces of Ontario and Quebec. This compact was subsequently approved by the Congress of the United States and signed by President Bush on October 3, 2008. Both the Zambezi River Basin and the Great Lakes Basin offer valuable insights into the application of IWRM to critical water resource planning and management challenges in their respective geographical locations.

INTRODUCTION

Integrated Water Resource Management (IWRM) has evolved during the last two decades of the 20th Century. IWRM has developed in response to population growth placing greater demands upon water resources that are showing reduced quality and

increasing shortages in certain geographic regions. The IWRM approach is one that is evolving from a supply-oriented, engineering-based approach towards a demand-oriented, multi-sector approach (Loucks and van Beek, 2005). Loucks and van Beek (2005) develop the relationship between the importance of providing sustainable water resource systems and IWRM by citing the importance of the Dublin Principles developed in early1992 prior to the Rio Sustainability Conference. The Dublin Principles are as follows:

1. Water is a finite, vulnerable and essential resource, essential to sustain life, development and the environment.
2. Water resources development and management should be based on a participatory approach, involving users, planners and policy makers at all levels.
3. Women play a central role in the provision, management and safeguarding of water.
4. Water has an economic value in all its competing uses and should be recognized as an economic good.

In 2000, the Global Water Partnership made a clear connection between Integrated Water Resource Management (IWRM) and sustainability as follows: "IWRM is a process which promotes the coordinated development and management of water, land and related resources, in order to maximize the resultant economic and social welfare in an equitable manner without compromising the sustainability of vital ecosystems" (Global Water Partnership, 2000). IWRM clearly moves away from "top down" master water planning towards a more comprehensive approach that includes the inter-relationships between different water sectors as well as the institutional requirements and capacity building needed to implement the priority water programs (Loucks and van Beek, 2005).

ZAMBEZI RIVER BASIN: CHARACTERISTICS AND CHALLENGES

The Zambezi River Basin (ZRB) is located between 9-20° South and 18-36° East in Southern Africa (Figure 1). The basin, with total area of 137 million hectares (1.37 million km^2) is the fourth largest in Africa after the Congo, Nile, and Niger River basins. It extends through Angola (18.2%), Botswana (2.8%), Malawi (7.7%), Mozambique (11.4%), Namibia (1.2%), Tanzania (2.0%), Zambia (40.7%) and Zimbabwe (16.0%)

The basin receives a mean annual rainfall of about 950 mm, with a rainfall pattern characterized by a distinct wet and hot summer and a dry period in the remainder of the year. The north and east of the basin receive significantly more precipitation than the south and west. Climate change may have an effect on evaporation from reservoirs, on crop production and fish stocks. Less than 10% of the mean annual rainfall in the basin contributes to the flow of the Zambezi River into the Indian Ocean whereas more than 90% evaporates and returns to the earth's atmosphere. Given the relatively high rainfall in summer, it is a safe assumption that a significant part of the resulting water resource is temporarily stored in sub-soil aquifers. However, detailed information about the availability and use of these

groundwater resources is, as yet, not available. Even so, groundwater may become a more prominent source of water over time.

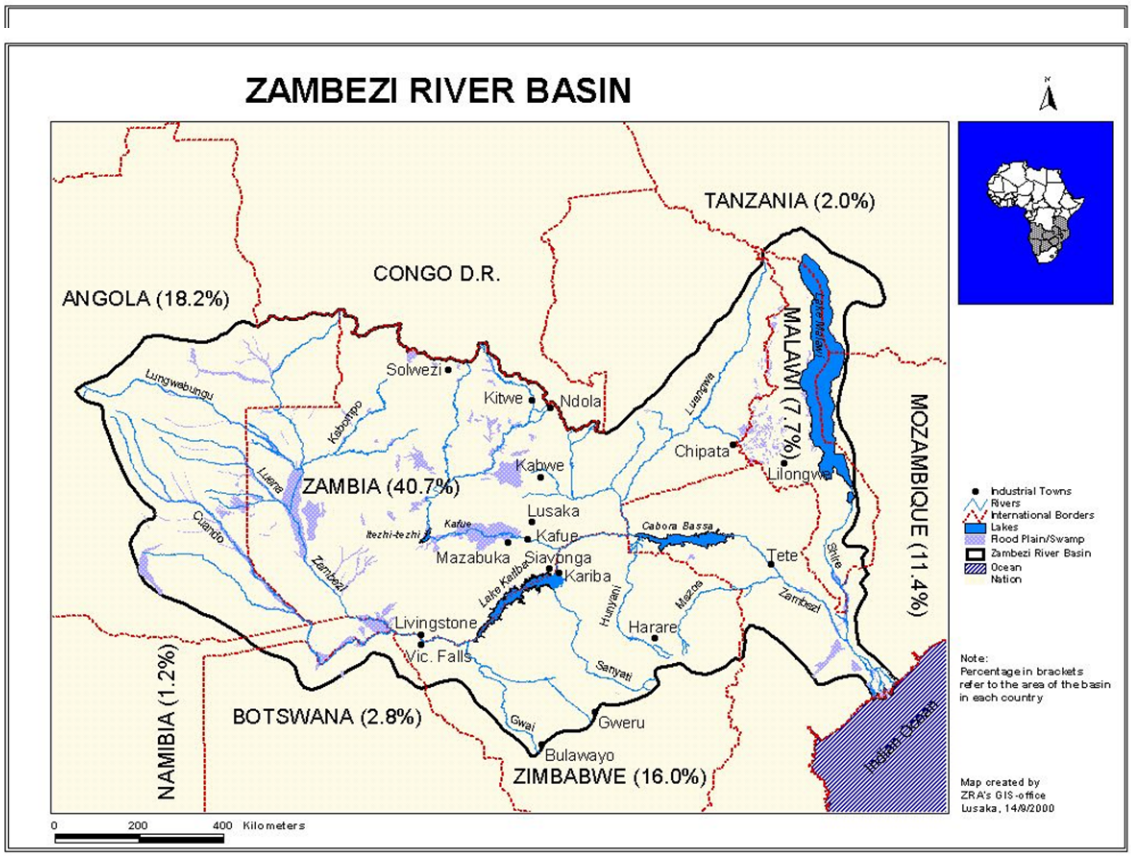

Figure 1: The Zambezi River Basin [adapted from Zambezi River Authority (ZRA), 2000]. Note the area occupied by the Basin in each riparian state).

Most of the Zambezi River Basin is high plateau land varying between 800 and 1,450m above mean sea level with most of the basin above 1,000m. This high elevation contributes to the significant hydropower potential of the Basin.

The population in the Zambezi River Basin (ZRB) is estimated to be 40 million people, of which about 7.5 million live in the urban centers. This is expected to increase to 47 million by 2025 with urbanization steadily increasing. Two economies exist in the basin: a fast high income generating and growing economy centered on exploitation of mineral resources, and a rural economy with high levels of poverty and low coverage of basic services. In recent years, most riparian countries have witnessed encouraging economic growth and therefore a need to consolidate and sustain this through the sustainable development of the water resources of the Zambezi Basin. However, there are a number of major water resources challenges that must be overcome to satisfy the fast growing population and economic development. These challenges are summarized in Table 1.

Table 1: Challenges of water resources in the Zambezi River Basin

Physiography	Climate Change & Variability	• Increased frequency of droughts and floods • Small change in rainfall ► Large change in river flow
	Ecosystems	• Biodiversity e.g. effects of deforestation for agriculture & woodfuel • Desertification • Wetland degradation e.g. the Kafue flats in Zambia
	Surface Water	• Limited resources, unevenly distributed and over-exploited and poorly known in terms of quantity and quality • Assessment and monitoring of the resource are lacking • Industrial and municipal effluent loading in Kafue River Basin – Copperbelt Zambia (pollution) • Pollution from industrial and urban centre activities e.g. Lusaka, Harare
	Groundwater	
Socio-Economy	Demography	• High population growth rate in urban areas • Poor water and sanitation coverage and service delivery e.g. the karstic aquifer in Lusaka is a non-renewable water resource that is highly affected by poor sanitation coverage. • Water-related diseases (Cholera) & HIV/AIDS. Region has a higher incidence of HIV/AIDS and Cholera outbreaks due to inadequate access to clean water and sanitation in peri-urban and rural areas • Agriculture is the most important economic activity and the biggest water consumer (~80%) resulting in competition for water e.g. there is high competition between irrigation and hydropower in the Kafue River Basin…
	Economy	
Management	Legislation	• Water legislation is varied across the riparian countries • Inadequate institutional strength and capacity • Establishment of cooperative frameworks for managing shared waters in the context of IWRM is still in its infancy. • ZAMCOM not yet operational
	Institutional	
	Knowledge	• Data access, sharing, reliability and standardization is not available • Monitoring is scattered, except for example the reservoirs such as Lake Kariba by Zambezi River Authority. • Gaps o Insufficient insight into climate change and variability o Water pollution inadequately addressed o Groundwater recharge largely unknown o Environmental flow requirements largely unknown

A principle challenge for the Basin concerns water quantity. The Zambezi River has an average run-off of 103,224 Mm^3. Approximately 20% of this stream flow is used currently. However, use is expected to increase to 41% if the various ambitious plans by riparian states for irrigation and hydropower development are implemented by 2025. Given the high degree of seasonal and spatial variability in available water resources, and the possible effects of climate change, increasing demands on the Zambezi River are likely to push the river to its limits. In addition to issues of water quantity, there are a number of water quality issues that demand attention. These challenges include: point pollution around manufacturing and mining centers, municipal effluents, and the spread of aquatic weeds, wetland degradation among others. These challenges are highlighted in Table 1.

Two examples of challenges are given here to illustrate some of the issues in ZRB:

(a) Hydropower: This sector is by far the largest water user because of the evaporation from hydropower reservoirs estimated at approximately 17 km^3 (17 billion m^3). Only three existing reservoirs in the ZRB have a regulating

capacity of significance: Kariba, Cahora Bassa and Itezhi-Tezhi. A total capacity of 4,684 MW has been developed in the Zambezi River basin, of which 75% is on the Zambezi River itself, producing an average of almost 33,000 GWh per year. Of the total developed capacity 5% is in Malawi, 45% in Mozambique, 36% in Zambia and 14% in Zimbabwe. Zambia, for example is planning to further develop another 2,870 MW through expansion and new ones.

(b) Water and Sanitation Coverage: In Zambezi River Basin, water and sanitation coverage of the member states is at its lowest level (Table 2) such that even the better economy of Botswana is below 50% for rural.

Table 2. Water (W) and Sanitation (S) Coverage for selected 4 riparian states of ZRB

	Angola		Malawi		Mozambique		Zambia	
	W(%)	S(%)	W(%)	S(%)	W(%)	S(%)	W(%)	S(%)

Rural	40	16	62	42	24	14	37	13
Total	50	30	67	46	42	27	53	23

ZAMBEZI RIVER BASIN: OVERCOMING CHALLENGES

In trying to overcome some of these challenges, the Southern Africa Development Community (SADC) Water Division adopted IWRM as an intervention strategy to manage transboundary water resources within the SADC region. The Zambezi River Basin sits within the SADC region wherein which IWRM is being applied.

SADC Water Division established an enabling environment for IWRM through the ratification of the SADC Protocol for Shared Water Courses (Protocol) in 1997. The Protocol was revised in 2000 by SADC member states. This is the main instrument for guiding reform processes at transboundary basin levels. However, additional instruments are now in place that compliments the Protocol:

- Regional Strategic Action Program (RSAP I) for IWRM and development, 1999 to 2004, with 7 priority areas and more than 33 IWRM projects at Regional and National Level
- In 2000, SADC vision on Water, Life and Environment was developed and sets out the overall SADC Water vision
- RSAP II was developed in 2005 and is being implemented & provides a regional IWRM implementation framework
- 2005 Regional Water Policy Developed
- 2005 Regional Water Strategy Developed

In addition to these instruments and the Protocol, several commissions have been established. One such commission is the Zambezi Watercourse Commission (ZAMCOM). ZAMCOM will provide a governance structure for the ZRB once ratified by all the riparian countries. Until then, the only joint management of the ZRB is through the Zambezi River Authority (ZRA) (1980), a bilateral institution

between Zambia and Zimbabwe. The ZRA provides a success case story of basin level cooperation and management for Lake Kariba on the Zambezi River and perhaps hints at the cooperation possible in the ZRB.

At present Zambia is the only country that has not signed the ZAMCOM Agreement entitled: "Agreement on the Establishment of the Zambezi Watercourse Commission" despite being a signatory to SADC Protocol on Shared Water Courses. The ZAMCOM Agreement has a broad and challenging agenda for regional cooperation including: synchronizing water resources development plans; revising reservoir operation so as to serve a wide variety of functions (e.g., such as flood control, support to flood plain agriculture, river and estuarine fishery and navigation); cooperation in the control of aquatic weeds; and the development of climate change adaptation strategies appropriate to the Basin (e.g., the use and recharge of groundwater). To further enable the sharing of the benefits of cooperation the ZAMCOM Agreement also focuses on joint planning of electricity grids, road networks and navigation opportunities.

Implementation of the ZAMCOM Agreement at the national level will be equally challenging particularly because except for Zimbabwe and Namibia, who have incorporated the main elements of an IWRM approach in their institutional frameworks, the others are still in progress. Malawi and Zambia have their IWRM plans completed but the institutional and legal frameworks are yet to be adopted or enacted into law.

GREAT LAKES BASIN: CHARACTERISTICS AND CHALLENGES

The combined U.S. and Canadian population within the Great Lakes Basin is about 40 million people. The political jurisdictions include the two countries, eight states (U.S.), two provinces (Canada) plus a very large number of sub-state and sub-province units of government. Four of the Great Lakes plus a portion of the St. Lawrence River comprise the boundary waters between the United States and Canada in the Great Lakes Region of North America. The most direct route from the western shore of Lake Superior to the exit from Lake Ontario into the St. Lawrence River is 1,249 miles (2,011 kilometers).

.

GREAT LAKES BASIN: OVERCOMING CHALLENGES THROUGH IMPLEMENTATION OF "IWRM LIKE" APPROACHES

Three examples of actions with the Great Lakes Basin are presented that illustrate aspects of IWRM in the context of the Great Lakes Water System. The first example is the 1909 Boundary Waters Treaty between the U.S. and Canada which includes the waters of the Great Lakes. As the population grew and industrial development took place in these boundary water regions of the U.S. and Canada including the Great Lakes, the two countries recognized that means needed to be provided to ensure the long-term productive use of the shared waters. The Treaty established processes to enable disputes regarding the use of the boundary waters

between the two countries to be settled. The Treaty established the International Joint Commission (IJC) to address issues identified by the governments of Canada and the United States impacting the Boundary waters and to make recommendations for issue resolution. The IJC's Mission Statement is as follows:

> "The International Joint Commission prevents and resolves disputes between the United States of America and Canada under the Boundary Waters Treaty and pursues the common good of both countries as an independent and objective advisor to the two governments. In particular the Commission rules upon applications for approval of projects affecting boundary or transboundary waters and may regulate the operation of these projects; it assists the two countries in the protection of the transboundary environment, including the implementation of the Great Lakes Water Quality Agreement and the improvement of transboundary air quality; and it alerts the governments to emerging issues along the boundary that may give rise to bilateral disputes" (IJC, 1998).

On April 15, 1972, Prime Minister Pierre Trudeau and President Richard Nixon met to sign the Great Lakes Water Quality Agreement. This milestone event committed Canada and the United States to control pollution in the Great Lakes and to clean up waste waters from industries and communities. The major issue at that time was phosphorus over-enrichment (Environment Canada: Great Lakes Water Quality Agreement, 2009). This agreement committed the two countries who share the trans-boundary waters of the Great Lakes to restore and enhance water quality in the Great Lakes System. This first Great Lakes Water Quality Agreement was replaced in 1978. Subsequent amendments in 1987 resulted in establishing the goal to virtually eliminate persistent toxic substances into the Great Lakes resulting from human activities. The IJC monitors and assesses progress towards achieving the eventual goal of eliminating persistent toxic pollutants from the Great Lakes (IJC, 1998). This action requires addressing the atmospheric deposition of toxic pollutants as well as contaminated sediments, ground water sources, and non-point source pollution into the Great Lakes. The long-term goal is one example of the value and importance of IWRM and its necessity in viable planning and management of trans-boundary water resources. The eventual achievement of this long-term goal requires not only the coordination of leadership and activities of government at international, national and sub-national levels but also the additional critical participation of civil, public and private sector interests.

A second example is the control of untreated discharge of ballast water into the waters of the Great Lakes. Ocean vessels navigate into and out of the Great Lakes through the St. Lawrence Seaway and the Welland Ship Canal. The discharge of ballast water from these ships into Great Lakes waters has enabled the introduction of aquatic invasive species into the Great Lakes. Previous introductions of invasive species, such as the zebra mussels via vessels' untreated ballast have cost states and provinces millions of dollars in damage to municipal, industrial, and recreational infrastructure, loss of fisheries, and loss of recreational water uses (Ballast Water Final Determination, 2005). On April 13, 2005, the Michigan

Department of Environmental Quality (MDEQ) issued a rule that effective January 1, 2007, all ocean going vessels shall obtain a permit from the MDEQ to operate in state waters. This permit will only be issued if the applicant can demonstrate that the ocean going vessel will not discharge aquatic nuisance species or if the ocean going vessel discharges ballast water, it will use one of the several technologies approved for use by the MDEQ.

It should be noted that the U.S. EPA had exempted ballast water discharges from the provisions of the Clean Water Act in 1973. The failure of the Federal government to effectively regulate ballast water discharges has shifted the responsibility to individual states. The Rule issued by the MDEQ was challenged by a consortium of shipping interests in March 2007 in federal court in the Eastern District of Michigan. The Federal court upheld the state's new law requiring shipping vessels to obtain a ballast water discharge permit to operate in state waters. The shipping consortium appealed this decision to the U. S. Court of Appeals for the Sixth Circuit. In November 2008, the Federal appeals court issued a decision upholding Michigan's ballast water statue. In this specific situation, a legal remedy developed by the MDEQ to address issues not effectively regulated by the federal government is being implemented to protect the Michigan waters of the Great Lakes. Other states within the Great Lakes are actively considering similar legislation since they too have a legal obligation to protect their waters from invasive species (Hall, 2008). This example demonstrates that IWRM must include the broad legal and policy framework necessary to protect critical water resources.

A third example illustrating the importance of IWRM in the Great Lakes Basin is the Great Lakes Compact. This Compact agreement was signed by President Bush on October 3, 2008. It is a working example of trans-boundary IWRM activities. The driving force that motivated the creation of the Great Lakes Compact dates from 1997 when a Canadian entrepreneur developed the concept of sending Lake Superior water to the Far East via tanker ships. Basically, the idea was to bring an empty tanker ship with a liner in its cargo hold that would fill its cargo space with Lake Superior water and then transport this liquid cargo (158 million gallons per year by tankers) to the Far East to be sold (Annin2006). In March 1998, a permit to export the Lake Superior water was issued to this entrepreneur by the Ontario government. The news of this potential diversion spurred action in both the United States and Canada. The individual who was issued the permit was convinced by Canadian officials to withdraw the permit with the assurance that if diversions from Lake Superior were permitted in the future, he would be the first inline to receive such permission (Annin, 2006). These events began a nearly decade long period of intense discussion and negotiation between the eight Great Lake states and the provinces of Ontario and Quebec to craft a legally binding agreement between all of the parties that would provide a reasoned approach to evaluate any and all applications for diversion of waters from the Great Lakes. It was paramount that all applicants be treated fairly. The resulting legally binding approach was to craft a Great Lakes Compact that would be approved by all of the Great Lakes states plus the two Canadian provinces. All have to pass equivalent binding legislation for their jurisdictions. In addition, the U.S. Congress would approve the Compact and the Compact would then be signed by the President of the United States.

The key provisions of the legally binding Great Lakes Compact include the following:

1. Economic development will be fostered through sustainable use and responsible management of Basin waters.
2. A ban on new diversions of water from the Basin but limited exceptions could be allowed for communities near the basin when rigorous standards are met.
3. Communities that apply for an exception will have a clear and predictable decision making process: standards to be met and opportunities to appeal decisions. These processes do not exist under current law.
4. The States and Provinces will use a consistent standard to review proposed uses of Basin waters. The States and Provinces will have flexibility regarding their water management programs and how to apply this standard.
5. Regional goals and objectives for water conservation and efficiency will be developed, and they will be reviewed every five years. Each State and Province will develop and implement a water conservation and efficiency program that may be voluntary or mandatory.
6. There is a strong commitment to continued public involvement in the implementation of the Compact.

These key elements of the Great Lakes Charter incorporate the IWRM process as articulated by the Global Water Partnership in 2000.

OBSERVATIONS

IWRM interventions are new concepts to the riparian states of ZRB. The adoption of IWRM and the creation of relevant enabling environments (policies), institutional, legal and management instruments are indeed at their infancy. Except for Zimbabwe (fully adopted with IWRM focused policies, law and institutions), Namibia (partially), Zambia (policy and implementation plan), Malawi (plan), the remaining four basin states are still in the very early stages. Interestingly, IWRM has been adopted as a way through which water should be managed in the broader SADC region of which the ZRB is a part. This high level of embracing IWRM in the region coupled with the many challenges in ZRB (Table 1) requires first, a human resource capacity development of individuals that have an understanding of IWRM and second, data and information for decision making.

The lack of data, information, and human capacity for decision making has important implications. For example, Zambia has not signed the ZAMCOM Agreement. There may be many answers to the question "Why has Zambia not yet signed the Agreement?" One clear constraint is lack of data or information for decision making. Another example is that most economies in ZRB would like to diversify and improve the productivity and value-added of the sectors that provide the bulk of the employment, services and agriculture, and hence achieve sustainable development. To achieve this goal of sustainable development ZRB countries must also achieve sustainable use of ZRB water resources. Data, information and data exchange, expanding on the Zambezi Water Information System (ZAMWIS) that set

up ZACPRO II will ultimately provide for an effective Zambezi Watercourse Commission and contribute to effective governance of the ZRB.

UNZA IWRM Centre in collaboration with U.S. universities such as the University of Michigan therefore finds itself at an opportune moment to contribute in education & training, research and consultancy in ZRB providing the much needed manpower first to implement IWRM interventions in ZRB and second, to assist in the development of data, information and data exchange for the well-being of ZRB citizens.

ABSTRACT

The purpose of the International Upper Great Lakes Study (IUGLS) is to investigate improvements to the regulation of the outflow of Lake Superior given the impacts regulation may have on water levels, flows, and consequently affected resources throughout the upper Great Lakes system. It also is closely examining the physical processes driving current Great Lakes water level conditions, and possible ongoing changes in the St. Clair River and their impacts on river flow and Lakes Michigan and Huron levels (Phase I). The issues are being investigated by two Task Teams (TTs): the Lake Huron Outflow/ St. Clair River Task Team (SCR TT) and the Lake Superior Regulation Task Team (LSR TT). This paper describes the investigations being conducted by the SCR TT for Phase I of the Study which is scheduled for completion in October 2009. The entire Study will be completed in April 2012.

INTERNATIONAL UPPER GREAT LAKES STUDY

The International Upper Great Lakes Study was initiated in March 2006 by the International Joint Commission (IJC), a U.S.-Canadian Commission formed by the International Boundary Waters Treaty of 1909, to oversee issues and settle disputes related to boundary waters between the two countries. The purpose of the Study was to develop alternative outflow management plans to Plan 1977-A, the plan which has been used to specify outflows from Lake Superior since June 1990, that better serve the interests upon which that plan was developed (hydropower, commercial navigation and water uses) and emerging interests (recreational boating, riparian issues and the ecosystem) under various hydrologic conditions including climate change. However, due to recently declining levels on the upper lakes, the scope of the work was modified to examine the St. Clair River and its possible conveyance changes that may be responsible for the decline.

The geographic scope of the Study is shown in Figure 1 and a detail of the St. Clair River investigative area is shown in Figure 2.

Figure 1. Upper Great Lakes

The Lake Huron Outflow/ St. Clair River Task Team

The Lake Huron Outflow/ St. Clair River Task Team has focused on that part of the Study which addresses the issues related to historic changes in the hydraulic conveyance capacity of the St. Clair River due to man-made changes (dredging, gravel mining, ship wrecks, hardening of the shoreline, conveyance constrictions due to bridges and other infrastructure, etc), natural conveyance changes, physical changes associated with glacial isostatic rebound, overall reduction in net basin supplies due to climate change and variability effecting the Lake Huron outflow, or a combination of all of the aforementioned causes. There is a concern that physical changes in the St. Clair River, which is part of the connecting channel between Lake Huron and Lake Erie, may have increased the flow conveyance, thereby significantly contributing to the lowering of the levels of the Upper Lakes.

The SCR TT is organized into three Technical Work Groups (TWG): Data Verification and Reconciliation/ Surveys and Monitoring, Hydraulic Modelling, and Sediment Studies. The TT has also worked closely with the Study's Hydroclimatic Group which is investigating hydrologic factors which may be responsible for the decline.

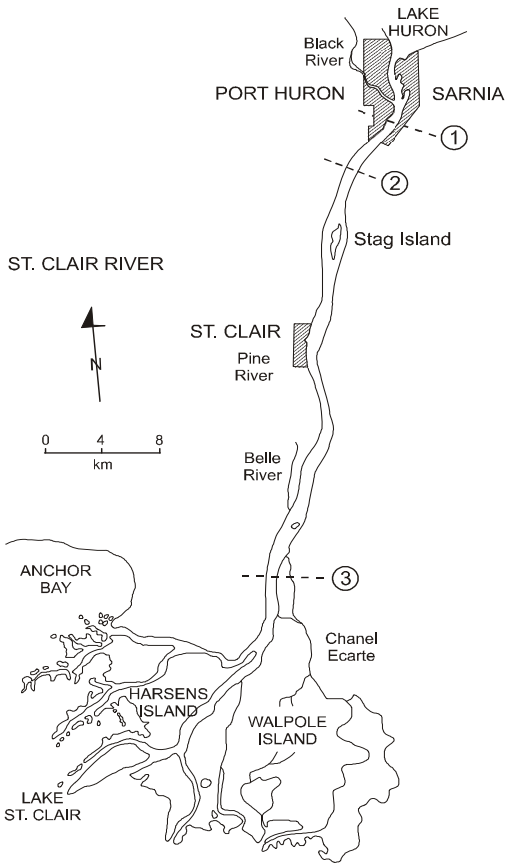

Figure 2. The St. Clair River

Data Verification and Reconciliation/ Surveys and Monitoring TWG

The Data Verification and Reconciliation/ Surveys and Monitoring TWG is responsible for investigations related to defining the bathymetry of the river, how it may have changed due to natural and man-made factors, level and flow verification and issues related to glacial isostatic adjustments. The following activities were initiated for the group by various agencies and universities:

- U.S. Army Corps of Engineers, Detroit District gathered archived data on cross-sections and dredging from 1954, 1962, 1971 and also collected new bathymetric data in 2007;
- U.S. Geological Survey, Woods Hole Science Center conducted side-scan sonar mapping of the upper reach (Fort Gratiot to mouth of the Black River) of the river;
- U.S. Geological Survey, Great Lakes Science Center performed GIS analysis of fluvial mapping;
- U.S. Geological Survey, Woods Hole Science Center in conjunction with the University of Illinois-Urbana-Champaign conducted multi-beam echo sounding and acoustic Doppler profiler mapping.

At issue through all these investigations has been the extent of coverage throughout the period of investigation. Single beam bathymetric data are available for 1971 and 2000, but not in years between these dates. The latest survey was taken in 2007 using multi-beam technology. Coverage has varied from 11,000 points in 1971 to 13 million points in 2007. The differences in coverage at transects has created a level of uncertainty regarding how river cross-sections may have changed. Figure 3 demonstrates this issue showing a possible ("actual") bed surface and what a survey may show.

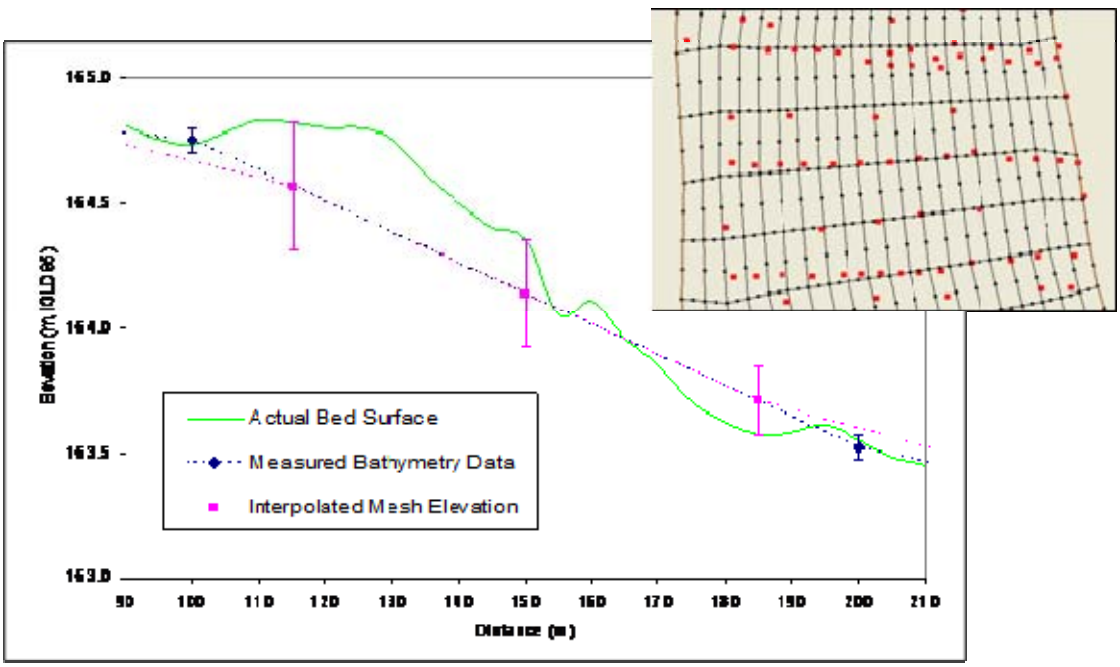

Figure 3. Cross-sectional Uncertainty

Studies are underway to verify river rating curves, by the University of Illinois- Urbana-Champaign, since precise calibration of lake levels and river flows is critical for both phases of the Study. Determination of flows is also being substantiated by new international side-looking acoustic Doppler current profilers, installed by the USGS in four locations on the St. Marys, St. Clair and Detroit Rivers.

Hydraulic Modelling TWG

The Hydraulic Modelling TWG is conducting various studies, some of which are complementary, while others provide a level of redundancy, through various techniques. The following agencies and universities are performing studies to determine how conveyance may have changed:

- U.S. Army Corps of Engineers, Detroit District developing 1-D models;
- U.S. Geological Survey, Michigan Water Science Center developing 1 -D models;

- U.S. Army Corps of Engineers, Hydrologic Engineering Center developing 1 - D modelling and performing sensitivity analyses;
- U.S. Army Corps of Engineers, Cold Regions Research and Engineering Lab modelling of ice-restricted flow events;
- Environment Canada developing 1 and 2-D models;
- In collaboration with the Sediment Studies TWG University of Illinois-Urbana-Champaign developing limited reach 3-D sediment and full reach 1.5 and 2-D mobile bed models.

Sensitivity has been examined through the modelling with various cross-sectional and Manning's "n" assumptions. These models have resulted in various results and are being refined in an attempt to reduce uncertainty.

Sediment Studies TWG

The Sediment Studies TWG has investigated the nature of the river bed to determine the sediment transport capabilities. Environment Canada performed video-mapping of bed features to determine the nature and estimation of sediment transport. These investigations are continuing. The work of the USGS, Woods Hole Science Center and the University of Illinois-Urbana-Champaign are also evaluating the fluvial nature of the river in critical reaches.

Hydroclimatic Group

To determine the hydrology impacting changing water levels and flows, the Hydroclimatic Group is performing the following investigations:

- NOAA- Great Lakes Environmental Research Lab (GLERL)/ Case Western University are determining which net basin supply and climate change and variability scenarios to consider;
- Environment Canada is developing atmospheric and land coupled numeric models to generate regional climate and hydrology;
- The net basin supply sensitivity for both component and residual techniques is being evaluated.

The University of Colorado and Environment Canada have installed an eddy co-variance evaporation measurement device at Stannard Rock in Lake Superior. A second device will be installed at a location on Lake Michigan.

Table 1 shows the studies and investigations that are underway or completed. The investigations are grouped under two headings intended to answer questions relative to 1962 dredging which was the last significant man-made activity that may have altered the river's conveyance.

Result Integration - St. Clair River Tasks

Table 1. Investigations linked to Science Questions Framework

The strategies being proposed for the various investigations are being reviewed by an independent peer group (IPG) composed of experts in respective fields of study. The IPG review, managed by and reporting to the International Joint Commission, is being conducted through ASCE-EWRI and the Canadian Water Resources Association.

PRELIMINARY FINDINGS

Studies of conveyance appear to indicate that there may have been a decrease in the modeled level of Lake Huron of about 0.12 m (+/- 0.03 m) between 1971 and 2007. Since 2000, the modeled level of Lake Huron may have increased by 0.03 m (+/- 0.02 m) between 2000 and 2007.

Contributing factors are:

- Conveyance changes due to natural and man-made impacts;
- Net basin supply changes and spatial changes over the upper and lower lakes; and
- Glacial isostatic rebound.

The exact contribution of each factor is uncertain, which complicates the justification for remedial actions.

FURTHER INFORMATION

Further information about the investigations of the IUGLS, its findings under Phase I and the continuing study work under Phase II, studies to develop alternates for Lake Superior outflow management plans, can be found at the Study web site: www.iugls.org. The International Joint Commission web site, www.ijc.org, also provides information about the Study and its other Study and Control Boards.

Abstract

One of the strategic components of progress in societies is Water Resources Development Projects that have a key role for expanding regional infrastructures in safe and affordable water. These plans have direct and indirect economic impacts. In order to measure them, one needs to consider different parameters affected by regional conditions and project characteristics.

Among the newest approaches to utilize water is to evaluate it as a "socio-economic good". Global Water Partnership (GWP) guideline has been developed using this point of view. It follows economic sustainability evaluation in water projects and considers two main terms of full cost and full value. The former consists of: Full Supply Cost, Opportunity Cost, Economic and Environmental Externalities, and the later includes: Economic Value and Intrinsic Value. This statement explains that economic sustainability will be attained when the full value is equal or greater than the full cost of the project.

In this paper, evaluation of economic sustainability based on GWP guidelines has been applied for an Inter-basin Water Transfer Project (IWTP) in Iran. The goal of this project is to supply water from the Karoon River in the South-Western part to the central region in Iran for agricultural activities.

For this purpose, different components of the project are identified, and then its full cost (such as capital investment, loss of revenue from hydropower generation and crop production and the cost of improving water quality in the basin of origin) and full value (such as benefit from agricultural production, aquifer restoration) are calculated by using a simulation model and an accounting method. The results show the value and cost of each component of the project as a basis for identifying the stable economic elements of the project. Finally, certain recommendations for improving the sustainability of the system are presented.

Keywords: Full Value, Full Cost, GWP, Inter-basin Water Transfer

* Global Water Partnership

1. Introduction

Water Resources Development Projects play a key role in society's progress. In regions with non-uniform temporal and spatial distribution of water resources an alternative to balance the water resources and demands is the Inter-basin water transfer project. Diversions of water from one river basin to another are multi-disciplinary problems (yevjevich, 2001), which involve complex issues and may cause a variety of negative social and environmental impacts. They require careful consideration of the costs and benefits, environmental issues, along planning period, and painstaking negotiations between numerous stakeholders before decisions can be made (Ghassemi and White, 2007).

These are geomorphologic, hydrological, water quality, water resources planning, and hydraulic engineering components, which are intimately connected with political, administrative, economic, environmental, cultural and legal components. Controversies that have surrounded water diversion scheme in the past have many issues in common. However, each case also has its own specific problems (Committee on Western Water Management, 1992).

Economic appraisal assists the decision-making process among projects competing for limited government funds. Since the beginning of rapid urbanization and industrialization that have caused water quantity and quality impacts, some other economic aspects of the projects are considered in addition with the capital and operational costs (Ghassemi and White, 2007).

In 1992, the statement at Rio de Janeiro during the WCED claimed that water should be regarded as an integral part of the ecosystem, as a natural resource and as a social and economic good. The charging mechanisms should reflect as far as possible both the true cost of water when used as an economic good and the ability of consumers to pay (Agenda 21, 1992). The 1992 Dublin Statement on Water and Sustainable Development further affirmed that water has an economic value in all its competing uses and that it should be recognized as an economic good (Zhong and Mol, 2007). In 2003, the Asian Development Bank [ADB] said that: it will support the evolution of water allocation through markets of transferable water rights once the necessary policy, legal, and institutional frameworks for Integrated Water Resources Management in a river basin context have been put in place (ADB, 2003,pp.18–19). After that a lot of effort has been put into introducing water as a valuable good and developing effective water pricing policies for the main water consumers e.g. urban, agriculture and industry (Schuck and Green,2001; Gomez and Riesgo, 2004; Arpke and Strong, 2005; Shiferaw *et al.*, 2008; Webber *et al.*, 2008). Global Water Partnership (GWP), formally established in 1996, formulated the concept of water as an economic good and explained, in practical terms, the economic tools that can be used to effect the environmentally, socially, and economically efficient use of water (GWP, 1998). In this paper, an Inter-basin Water Transfer Project (IWTP) in Iran is evaluated based on GWP guideline. For this purpose different components of the project are identified and evaluated. Then to evaluate the amount of these components, some indicators and a simulation model (WEAP) have been used. After calculation of full cost and full value, the degree of sustainability of the project is assessed. Finally some recommendations are given followed by a summary and conclusion.

2. Methodology

After AGENDA 21 and THE DUBLIN PRINCIPLES put the concept of water as an economic good, Global Water Partnership (GWP) in 1998 developed a guideline for evaluation of the sustainability of vital environmental systems. This guideline can be used to consider the environmental, social, and economical aspects of water usage, by formulating the concept and explaining in practical terms. It follows economic sustainability evaluation in water projects and considers two main terms of Full Cost and Full Value. The former consists of: Full Supply Cost, Opportunity Cost, Economic and Environmental Externalities Cost, and the later includes: Economic Value and Intrinsic Value. This statement explains that economic sustainability will be attained when the Full Value is equal or greater than the Full Cost of the project.

The full cost was calculated for the IWTP project includes capital investment, Operation and Maintenance (O&M) costs, loss of revenue from hydropower generation and crop production (as the opportunity cost), the cost of river dredging and improving water quality in the river (as the economic externalities). Moreover Full value involved benefit from agricultural production (as the Value of the users of water) and aquifer restoration (as net benefit from return flows) was calculated for estimating the degree of suitability of the project.

3. Case Study

Rafsanjan plain is located in the central part of Iran between 55^{o} and 57^{o} longitude and 29^{o}, 53' and 31^{o}, 15' latitude with a 16096 km^2 area. In this plain, 97 percent of 73607 ha cultivated area is pistachio arbor. Groundwater is a common property resource in Daranjir watershed and the approximate total demand (agricultural, industrial and domestic demands) in the case study is supplied by groundwater resources (See Table 1). Frequent droughts and groundwater depletion are critical constraints to improving agricultural productivity in this plain.

Table1. Rafsanjan water resources, consumption and irrigation efficiency

Plain	Surface Resources		Underground Resources		Total Consumption	Average Consumption	Irrigation Efficiency
	MCM	%	MCM	%	MCM	m^3/ha	%
Rafsanjan	8.00	1.14	695.00	98.86	703.00	10848	36.5

In the Rafsanjan plain each year, 212 MCM in excess of the aquifer safe yield is discharged. Furthermore; the water salinity has been increased to three times the standard upper limit EC for pistachio production in recent years. The average of annual water drawdown has been 0.75 m in the last 10 years. For improvement of this problem the inter-basin water transfer has been suggested.

Transferring 250 MCM water from Solegan (origin of water transfer in the headwaters of the Karoon River) which is located 450 Km away from the Rafsanjan plain (as destination), is an alternative for supplying water demand in this plain (see Figure 1). The goal of this project is supplying water demands for 110000 ha agricultural area and accordingly economic improvement, social satisfaction and aquifer restoration will be achieved.

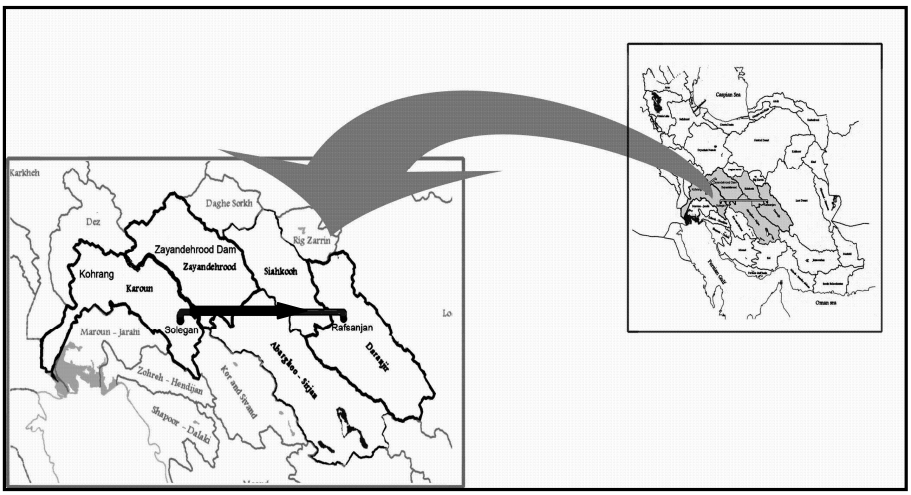

Figure1. Divided main watersheds in Iran and the transfer project

In the origin basin, Karoon River flows from Zagros range into the Persian Gulf. A part of the river that is located downstream of the Gotvand Dam, plus the Dez River as a middle section of river, supply the water demands for more than 660,000 hectares of agricultural networks, eight cities and several industries.
On this river there are 5 reservoirs out of which three reservoirs are operational with the objective of supplying water, hydropower generation and flood control and the rest are under construction (For more details see Table 2). Increasing water demands and waste-loads of domestic and agricultural sectors have severely decreased the water quality of the Karoon River. Due to these circumstances, local resistances against inter basin water transfer projects from this basin (including the project mentioned above) are increased.

Table2. Specifications of dams on Karoon System

Dam	Operation status	Capacity (MCM)	Height (m)	Lake Expansion (ha)	Target of Operation
Karoon 1	operational	3139	177	5500	Water supply & Hydropower generation
Karoon 3	operational	2970	205	4600	Water supply Hydropower generation Flood control
Gotvand	under construction	4500	178	7500	
Godarlandar	operational	230	177	600	
Karoon 4	under construction	2192	230	2700	Water supply & Hydropower generation

4. Results & Discussion

In this section all of the elements of full cost and full value are evaluated based on GWP Guideline, 1998. The terms are set at a 30-year horizon begins by 2008, with an

interest rate of 10% (i=0.1).

4.1. Full cost

a. *Capital Charge:* this term includes the cost of setting up a diversion dam, excavating a transferring tunnel and establishing a pipeline set. (951 million dollars)

b. *O&M cost:* this term is calculated for operating and maintaining the infrastructures mentioned above. (95 million dollars)

c. *Opportunity cost:* In this project, the losses of agricultural development (calculated by Eq.1) and revenue from hydropower generation (used WEAP model) caused of water transfer have been evaluated as the opportunity cost in origin basin.

$$\mathrm{Cost_C} = V \times \overline{\mathrm{CPD}}_{\mathrm{origin}} \times \alpha \times \overline{\mathrm{P}}_{origin} \qquad (1)$$

$\overline{P}_{origin}$ = Price of crop in origin basin

V = Volume of water transfer

$\overline{\mathrm{CPD}}_{\mathrm{origin}}$ = Crop per Drop coefficient in origin basin

α = Net benefit coefficient

$\mathrm{Cost_C}$ = Annual cost of agriculture's losses (37.54 million dollars)

Assessing the impact of the IWTP on the hydropower generation of Karoon Reservoirs, WEAP model (a water Evaluation and planning software) is developed (Figure 2). The model consists of all urban, agricultural and industrial users, Reservoirs and the IWTP. The results show that the average difference in cost between scenarios with and without performing the project is 562.1 GWh/yr. (10.2 million dollars)

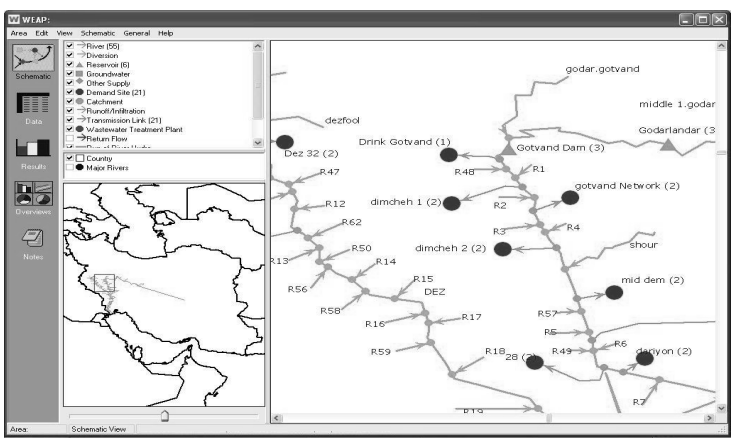

Figure2.Karoon-Daranjir WEAP model interface

d. Economic Externalities

As the lower discharge of the river causes more sedimentation, therefore diversion of water from upstream of Karoon River increases the dredging costs (8 million dollars/year). For calculating this term a diagram was developed by Zahiri and Kordestani (2004) was used to estimate the dredging cost with and without the water transfer plan.
The cost of improving water quality up to its threshold has been defined as another element of Economic Externalities. Agricultural wastewater inflow to the Karoon River is about 1.6 BCM with an average concentration of EC equal to 2600 µmhos/cm. The power of declining the salinity depends on the volume of freshwater in the river and the volume of the wastewater drainages into the river. By diminishing the volume of the freshwater in the river because of the IWTP implementation, the volume of the wastewater needs to be decreased. For achieving this, a ratio of the wastewater could be diverted to large wastelands. The cost of buying these lands for maintaining the water quality is considered as economic externalities (224 million dollars).

e. Environmental Externalities
Although an important factor, it is not yet explored in this study.

4.2. Full Value

f. Value To Users of Water
The marginal value of products in the Rafsanjan plain is calculated as follows:

$$VWA = \frac{NVOI - NVOWI}{VWDI} \tag{2}$$

Where *VWA* is the value of water in agriculture, *NVOI* is the net value of output with irrigation, *NVOWI* is the net value of output without irrigation and *VWDI* is the volume of water of diverted for irrigation.
Because of the complete dependence of agricultural products on irrigation in the destination basin, the *NVOWI* is equal to zero. Therefore *VWA* is the ratio of *NVOI* to *VWDI* (107.25 million dollars).

g. Net Benefits From Return Flows
Although the return flows from agriculture activities could not met the aquifer because of its significant depth (more than 150m), the IWTP allows aquifer to restore itself by reducing the groundwater pumping (0.53 million dollars /year).

h. Net Benefits From Indirect Use
There are no Indirect Users in this project and so the "Net Benefit from Indirect Users" estimated to be zero.

i. Adjustment For Societal Objectives & Intrinsic Value (not considered in this paper)

In order to analyze economic sustainability of this project, all of the estimated values are changed to Cent (1 Cent = 0.01 dollar) per cubic meter per year (Figure 3). Results show in the full value term, the "value to users of water" has the major character (42.9 Cents/m^3) and almost the "net benefit from return flows" is negligible (0.2 Cents/m^3). In the full cost term, the "full supply cost" (14 Cents/m^3) and the "opportunity cost" (19.1 Cents/m^3) have the main role, also the amount of "economic externality" (6.2 Cents/m^3) is considerable.

4.3. Analysis of Economic Stability of Water Use

Economic stability is achieved by differing full value and full cost. Therefore, in this project it is equal to 3.8 Cents/m^3 (=43.1(full value) – 39.3 (full cost)). It shows a stability situation, because of the enormous difference between the price of pistachio in Rafsanjan (destination region) and wheat in the origin basin.

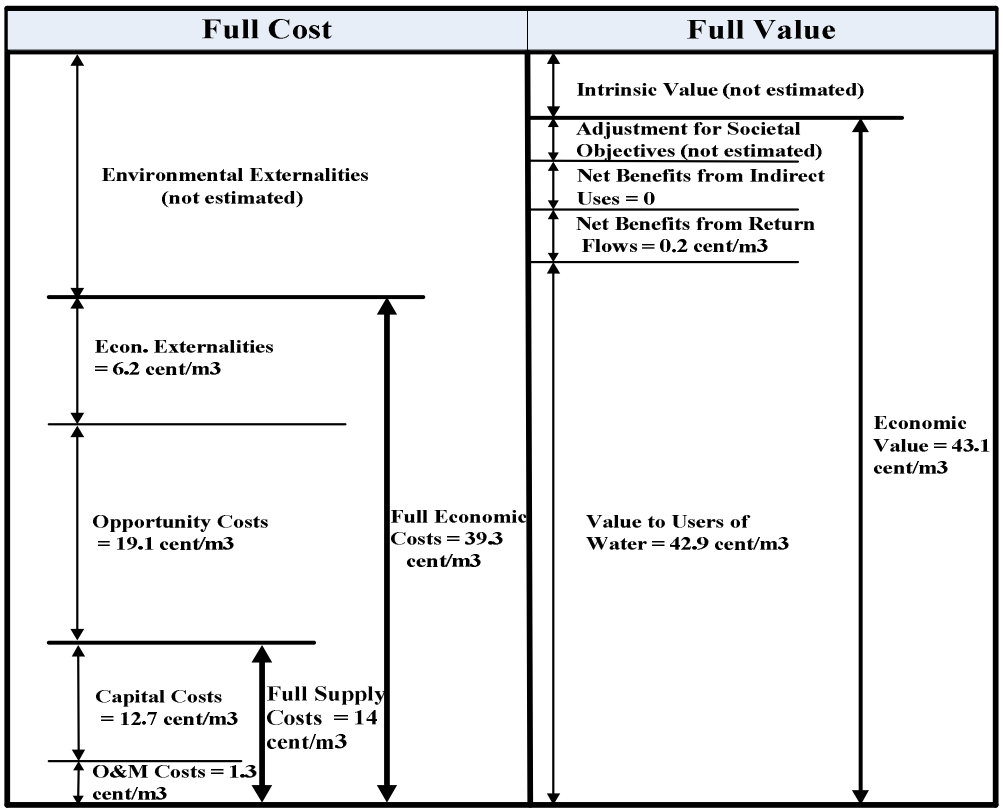

Figure3. Comparison of Estimation of costs and values for the IWTP (Not to scale)

5. Summary & Conclusion

GWP has formulated the concept of water as a socio-economic good to be applied in practice. In this paper, an IWTP in the central part of Iran is evaluated based on GWP guidelines. For this purpose the components of full cost and full value which could be estimated using the available data, are employed. The analysis of the full cost and the

full value of the project show the economic stability of the project. However the difference of these values is too low. This might be because of neglecting some effective terms such as intrinsic value and environmental externalities. Therefore, in order to increase the suitability of the region, some considerations should be involved in the project assessment process. The main recommended issues could be summarized as follows:

- Considering indirect users such as hydropower generators to make a more accurate estimation of "Net Benefit from Indirect Users" (which has been considered equal to zero in this study).
- Developing a method for computing the "Intrinsic Value" for aquifer restoration.
- Utilizing the methods of the efficient water use to decrease the aquifer depletion.

Abstract

This paper reviews recent work by EWRI, AWRA, ANEAS, FECIC and other entities actively developing water policy statements in preparation for the Fifth World Water Forum, scheduled for Istanbul, Turkey, March 16 through 22, 2009. EWRI participated in many of the preparatory events including:

- International Symposium on the 5th World Water Forum held in conjunction with the EWRI World Environmental & Water Resources Congress 2008 in Honolulu Hawaii in May 2008.
- Fourth National Water Resources Policy Dialogue, September, 2008, Washington, DC (sponsors included AWRA, EWRI and NWF).
- 22nd Annual Convention of ANEAS and the North American Regional Water Forum, Guadalajara, Mexico, November, 2008.
- Mexican Federation of Colegios (Sections) of Civil Engineers' (FECIC) 2nd World Congress on Water and Climate Change, Merida, Yucatán, Mexico, November 2008.
- Water Forum of the Americas, Iguazu Falls, Paraná, Brazil, November 2008.

Introduction

As of January 2009, preparations are well underway for the Fifth World Water Forum scheduled for March 16 through 22, 2009 in Istanbul, Turkey. Since the America's Regional Process plays a prominent role in identifying current water policy issues in the Western Hemisphere, and EWRI is participating in this process, this paper attempts to summarize many of the key concerns in this arena and policy related initiatives such as the recent FECIC Congress in Mexico.

For the Fifth World Water Forum, six principal themes have been identified including:

1. Global Change & Risk Management
2. Advancing the Human Development and the Millennial Development Goals

3. Managing and Protecting Water Resources and their Supply Systems to Meet Human and Environmental Needs
4. Governance and Management
5. Finance
6. Education, Knowledge and Capacity Building

Efforts for the Americas Region are sub-divided into 4 different sub-regions: Central America, Caribbean, North America and South America. Each sub-region is working in order to identify its main subjects of interest and to give answers to the different usual problems inside their own region. Each subregion developed its own Subregional document. In preparing for the Regional Process, for the Fourth World Water Forum, the Committee for the Americas identified the following challenges in water management in the Americas region:

1. Coastal zone management
2. Dam safety
3. Decentralization, Municipal role and local community
4. Energy options: hydropower
5. Financing water infrastructure
6. Flood, droughts, and risk management
7. Governance, institutional quality, and public participation
8. Groundwater management
9. Health implications of sanitation
10. Legal and regulatory framework for IWRM: advances and reforms
11. New frontiers in irrigation approaches
12. Payment for environmental services
13. Privatization: options for financing
14. Public versus private irrigation
15. Reaching the Millennial Development Goals
16. River basin organizations and institutions-appropriate level
17. Rural sanitation
18. Transboundary river basins
19. Urban water management
20. Water and Trade
21. Water as a human right
22. Water as an end versus water as a means
23. Water management of indigenous population
24. Water quality management-adequate water quality standards.

A key issue identified in the new North American Subregional Document (Herrera, 2008) is the need for mitigating flood risks in vulnerable areas and improved forecasting systems. Clarifying hydrometeorological risk and better forecasting systems combined with disaster prevention will improve the status

quo. An area of special relevance is transboundary watersheds, particularly the U.S. Mexico border in the case of drought and flood risk along the US Canada border. Herrera also characterizes the hydrology of the North American subregion and identifies key stakeholders in the region.

Climate change is another factor adding stress to water scarce regions. Developing Methods to address water scarcity under increasing populations in an ecologically sustainable way is identified as key.

The document identified the US and Canada as using an ecosystem approach to solve water problems. This approach includes land, air and water media. Considerable focus deals with water quality impacts from atmospheric contaminants along with land use.

The case of Mexico illustrates the need to provide clean drinking water and sewerage services, particularly in the southeast and in rural communities, where the problems is more serious. The document also states that "in the case of the United States and Canada, it is necessary to address new demands of quality standards for drinking water and the eradication of some contaminants, like the presence of lead in some places. In these countries, it is also necessary to make investments to renew the drinking water supply and sewerage infrastructure, which is reaching the end of its useful life." The latter item has been a key focus of ASCE's Infrastructure Report Card Program.

The Message of Iguazu Falls

The participants in the Water Forum of the Americas in Iguazu Falls, Brazil developed a message for the Fifth World Water Forum. The Water Forum of the Americas served as the conclusion of the Americas Regional Process in preparation for the 5th Forum. More than 250 people from different sectors of water management throughout the Americas participated. Participants included Ministers of State, Governors, Mayors, Parliamentarians, international organizations, academics, the private and public sectors, non-governmental organizations and river basin committees. Key participants in Brazil were the Ministers of Environment from Brazil and Turkey.

Over the course of several interactive sessions, the following recommendations were made by the participants:

- Promote social inclusion and the eradication of poverty through universal access to water supply and sanitation as well as through the productive use of water, by means of the usage of hydroelectric power, irrigation for food production, transportation, tourism and recreation, within a sustainable development context.

- Institutional strengthening of management bodies and promotion of internal and external integration of water resources policies with other sect oral policies.
- Incorporate the principle of common but differentiated responsibilities in water resources management, and the need for technology transfer and additional financial resources, in particular in strategies to face climate change.
- Because of the transversality principle, water management must be at the core of public policy in all three phases; planning, implementation, and control.
- Within specificities of each region, one should consider the multiple use of water on an efficient and rational basis, incorporating environmental conservation, protection and reclamation as necessary actions toward the improvement of water availability.
- Water sustainability requires good regulation and economic incentives.
- Promote agreements on the management of transboundary aquifers and basins.
- Decentralized, participative and integrated management of water resources with local stakeholders and indigenous and traditional communities, taking into account a gender perspective.
- We need to promote cleaner production by making investments in applied research, technological development and capacity development.
- The challenge of water management in small islands (SIDS) and the wider Caribbean region must be recognized and receive special attention due to their vulnerability to global climate changes.
- Support capacity development to help cope with the impacts of climate change.
- Need to raise awareness about water with training and education for everybody at different socio-economic levels connecting people with the basins where they interact.

Fourth Water Policy Dialogue

On September 22, 2008 EWRI (Kyle Schilling, Mark Killgore and Daene McKinney) along with EWRI Director, Brian Parsons and ASCE's Senior Manager, Government Relations, Michael Charles participated in the American Water Resources Association's (AWRA) Fourth National Water Resources Policy Dialogue. The Dialogue was cosponsored by EWRI and the National Wildlife Federation and included over 70 water leaders and others from around the nation including several congressional staff members with active interests in water resources' policies. This event built on the International Symposium on the 5th World Water Forum held in conjunction with the EWRI Congress in Honolulu in May, 2008.

The theme of the Fourth Dialogue was "Moving from Concepts to Action." The purpose of the Dialogue was to discuss how the outcomes of the first three Dialogues might best be moved from concepts to legislative and executive action. The outcomes of the Fourth Dialogue may provide input to the presidential

campaigns. Richard Engberg, AWRA's Technical Director and Jerry Della Priscolli from the Corps facilitated the discussions.

Three major issues were discussed including "Reconciling Contradictory Water Policies"; "Improving Collaboration"; and "Broadening the Role of Science"; as they relate to the overarching concerns of drought, flooding, infrastructure, population demographics, and climate change among many others. At the conclusion of the Dialogue, AWRA Past President (and active EWRI member) Gerald Galloway, EWRI President Kyle Schilling and David Conrad, Senior Water Resources Specialist for the National Wildlife Federation provided their insights gained from the dialogue. Conclusions from the Policy Dialogue were presented at the Water Forum of the Americas at Iguazu Falls in Brazil in November. Schilling stressed the importance of lessons learned from a historical perspective about implementing integrated water resources planning in North America, particularly the importance of both water quality and quantity. Other major conclusions included needs for a fresh assessment of the nation's water resources, better coordination, updated principles on water and development and planning for water resources in both a political and watershed context.

The offices of the co-chairs of the Congressional Water Caucus (Rep. John Linder, R-Ga.; Rep. Jim Costa, D-Calif.; Rep. Bart Stupak, D-Mich.; Rep. Grace Napolitano, D-Calif., and Rep. George Radanovich, R-Calif) welcomed the participants. The Caucus was formed to promote a dialogue about water issues and provide timely, scientific information about water resources and water use. The box below lists the Twelve Principles of Water Policy developed by the Caucus.

Twelve Principles of Water Policy
Congressional Water Caucus

1. Ensure an adequate supply of fresh water for U.S. citizens, securing a sufficient water supply for both urban and rural areas;
2. Consider all available technologies for increasing water supply efficiently, while safeguarding the environment, including the use of best management practices;
3. Recommend a means of capturing and storing excess water for future droughts;
4. Implement strategies to improve water use efficiencies and reduce water waste;
5. Support adequate funding to implement water re-use strategies wherever appropriate;
6. Advocate the coordination of efforts by Congress, the President, and state and local government to solve water issues;
7. Consolidate and streamline efforts between local, state, and Federal government agencies to reduce the bureaucratic red tape many local communities face when trying to build water reservoirs and other infrastructure needs;
8. Protect the rights of state and local governments;
9. Suggest financing options for new public works water projects;

10. Encourage Federal assistance to state and local governments to identify potential groundwater banking as part of sustainable water supplies;
11. Recognize international implications for water resources shared with other nations; and;
12. Collect and share data related to water use and water quality to determine effectiveness of policy.

Kyle Schilling, Mark Killgore and Brian Parsons along with others participate in breakout session at the Fourth National Water Resources Policy Dialogue at the Nation's Capitol.

Following the Dialogue, the sponsors consolidated many of the remarks and published a four page summary entitled "National Water Policy Dialogue". The summary was submitted to the President Obama Transition Team and ultimately published on the Obama Transition Website (AWRA, 2008).

The primary conclusions of the Dialogue included:

- There is an immediate need for an assessment of the Nation's water resources to include the current status of the resource, the future needs for water and identification of gaps that exist in fulfilling these needs.

- The federal government, in cooperation with state and local agencies, needs to develop a national vision and overarching principles to guide water resources development activities supported by the federal government.

- There is increasing need for mechanisms that will better coordinate the water related activities of federal agencies and among congressional committees. The absence of effective coordination is apparent in the conflicts and overlaps that exist in legislation, programs, and agency activities.
- The relationship among the federal government, states and local communities is changing and must be addressed. The federal government's role in water resources, long seen to be a driving force, must be reevaluated in light of growing state attention and direction of water resource activities.

- Federal actions with regard to water resources must be taken in a watershed context where the underlying planning is conducted in partnership with the states and local entities.

The conclusions of the policy dialogue echo many of the twelve principles above.

Conclusions

Many challenges face water planners and government officials as we gather in Istanbul to share experiences and ideas. EWRI will be participating in a session on Hydrosolidarity (Falkenmark, 2005). Hydrosolidarity is described as an increasingly integrated approach to managing water resources that relies heavily on participation and coordination among community stakeholders, water-related management agencies, and local, state, and national governments. A fundamental goal of hydrosolidarity is the cooperative, unified management of transboundary water resources, whether at the national or the international level.

Another session to be possibly included in the sessions is "Utility of IWRM Lessons Learned by Developed Countries for Developing Countries". Additionally EWRI has proposed a short course "How to Develop a Tool Box to Facilitate Transboundary Water Resources with an Emphasis on Water Quality".

Under Theme 6 "Education, Knowledge and Capacity Building", EWRI will share lessons learned in effective outreach via institute international programs and

participation. Specifically EWRI is participating in Topic: 6.1 Education and Capacity Development Strategies."

The Water Forum promises to be a stimulating discussion on where our field is headed and may directly contribute to EWRI's strategic planning initiatives.

ABSTRACT

In April 2008 the University of Michigan and the University of Zambia signed a Memorandum of Understanding (MOU) that approved a cooperative agreement to foster the development of a collaborative research and exchange program focused on concepts of integrated water resources management (IWRM) to be applied in the Zambezi River Basin in Southern Africa and the Great Lakes Basin in the U.S. The Zambezi River Basin, home to nearly 40 million people, is the largest river basin in Southern Africa covering 1.37 million square kilometers in eight countries. The Great Lakes Basin watershed is home to about 40 million people living in eight U.S. States and two Canadian Provinces and covers over 1/2 million square kilometers.

The MOU marks the culmination of a sixteen month effort which began in January 2007 and included two trips to Southern Africa, one in August 2007 and a second in November 2007. Individuals from The Nature Conservancy's Great Rivers Program, which includes the Zambezi River, facilitated the first trip to the basin through their contacts at the African Wildlife Foundation Zambezi Heartland team based in Kariba, Zimbabwe. The first trip provided an introduction to the range of problems and issues confronting application of IWRM in the Zambezi River and served to establish contact with a number of key organizations and people working to enhance and improve the management of the Zambezi's water resources. Following the first visit, we were invited to participate in the "Championing Effective IWRM in the Zambezi Basin" Conference held in Victoria Falls, Zimbabwe in November of 2007. The second trip and Conference provided an opportunity to reconnect with colleagues met during the first visit to the basin and, in addition, to meet new colleagues including Professor Imasiku Nyambe.

INTRODUCTION

In the summer of 1960, one of the authors of this paper, Jonathan Bulkley (age 22), traveled to Ghana as a member of an Operations Crossroads Africa two-month work camp project. One purpose of this work camp experience was for a racially mixed group of young Americans and Canadians to join with a counterpart group of young Ghanaian students in order to build a water supply system for a rural training camp located in the rainforest of the Ashanti Region. An equally important objective of the experience was to expose the Crossroads team to the 1960 realities of living and working in a tropical rainforest region in West Africa. For me, this overall experience had a profound impact on my life. First, as a consequence of the direct observation of the critical need for a safe and secure water supply system, I changed my civil engineering major from transportation engineering to water resources. Second, I became highly motivated to seek graduate education since I believed the most effective way I could assist these types of situations was to acquire as much education as possible. Finally, I had never before lived as a minority in a society where I was different from the population as a whole. All of these factors combined and guided me to graduate school in the field of water resources and to seek an academic position for my professional career.

As my forty year career in teaching and research at the University of Michigan is coming to a close, I want to explore the possibility of providing a similar 21st Century experience for Michigan. These students working to resolve water related problems here in the U.S. would meet and interact with a counterpart group of students from an African University working to resolve water related problems and issues in their country and region.

In January, 2007, we became aware of the recently established Great Rivers Program of The Nature Conservancy (TNC). One of the Great Rivers identified by TNC is the Zambezi River in Southern Africa. Contacts were made with TNC and they subsequently provided an important introduction to the African Wildlife Foundation. These two organizations (TNC and the African Wildlife Foundation) provided outstanding assistance that greatly facilitated our first trip to Southern Africa.

INITIAL TRIP

The initial trip to Southern Africa by Jonathan Bulkley and Christine Kirchhoff occurred in late August and early September, 2007. As noted earlier, both the itinerary and logistics of the visit were greatly facilitated by the staff of the African Wildlife Foundation based in Kariba, Zimbabwe. This working visit to Zambia, Zimbabwe and Botswana resulted in a series of nineteen meetings in fourteen days in the three countries with key water related agencies, non-governmental organizations and members of the faculty at the University of Zambia

and the University of Zimbabwe. All of these meetings were greatly aided through the good offices of the Great Rivers Program of The Nature Conservancy (TNC).

TNC provided us with an introduction and subsequent close association with Mr. Jimmiel Mandima, Director of the Zambezi Heartland, an African Wildlife Foundation (AWF) designated protected area. The Zambezi Heartland encompasses 18,000 square miles including a significant length of the Zambezi River from Lake Kariba in Zimbabwe to Lake Cahora Basso in Mozambique. Jimmiel and his staff are based in Kariba, Zimbabwe, not far from the Zambia border. This close association with AWF enabled us to have a very productive and valuable visit to the Zambezi River Basin by facilitating numerous meetings and contacts and by providing extensive logistical support. The latter included arranging for all of our transportation needs, facilitating border crossings and making reservations for all of our overnight accommodations in Kariba and Harare, Zimbabwe as well as in Kasane, Botswana and Lusaka, Zambia.

SECOND TRIP

As a consequence of the meetings held during the initial visit, we were invited to attend the annual Zambezi River Basin Stakeholders Forum (Forum) in Victoria Falls, Zimbabwe on November 25-27, 2007. The Victoria Falls meeting marked the third Stakeholder Forum. As a consequence of teaching responsibilities at Michigan, Jonathan Bulkley was not able to accept this invitation. However, Christine Kirchhoff and a second Ph.D student from the University of Michigan whose African research focuses upon fisheries, Mr. Ted Lawrence, did attend and both made presentations at the Forum. The overall Forum objective was to develop a shared vision for the Zambezi Basin including the following specific objectives: (1) Share knowledge and experiences regarding sustainable management of the Zambezi River Basin; (2) Identify key issues and challenges that need to be addressed to guarantee sustainability; (3) Collect ideas for an Integrated Water Resource Management (IWRM) strategy for the Zambezi River; and (4) Network with Zambezi River Basin Stakeholders.

Integrated Water Resource Management (IWRM) is an ongoing process in the Zambezi River Basin with the objective of creating and subsequently implementing the Zambezi Action Plan. The Southern Africa Development Community (SADC) is the custodian of the Zambezi Action Plan. SADC encompasses 15 different countries and brings more than 200 million people together in Southern Africa. Furthermore, the SADC region is notable because 70% of the water resources and 15 major river basins in the region are shared by two or more countries. Progress has been made in developing the IWRM strategy. Effective participation and stakeholder involvement has advanced through efforts such as the annual Forums. In addition, a platform has been established for each basin country to address local and national concerns. However, a number of challenges must be overcome in order to fully realize IWRM in the Zambezi River Basin. In his

Keynote Address at the Stakeholder Forum, Mr. Khupe, a retired government hydrologist, identified the following challenges in the Zambezi River Basin:

(a) Ecosystems transcend national boundaries and as such need to be jointly managed;

(b) Water management doesn't abide by boundaries;

(c) Upstream activities affect downstream;

(d) Decisions (mostly made by politicians) impact everyone but not everyone is included in the deliberation (e.g., Communities are not adequately represented at the Stakeholder Forum); and,

(e) Multiple stakeholders.

Mr. Khupe offered the following observations to overcome the above challenges:

(a) Information sharing builds trust. Need to exchange information and be open.

(b) Stakeholders need to be included. Communities, civil society – haven't been involved.

(c) Approach the media**.**

One of the challenges to implement the IWRM is the full realization of the Zambezi Action Plan which includes the establishment of a joint governance and implementation mechanism through the creation of the Zambezi Watercourse Commission (ZAMCOM). Further insights regarding progress of establishment of this joint governance/implementation structure was presented by Dr. Z. Phiri during the first day of the Stakeholder Forum. Dr. Z. Phiri, Professor at the University of Zambia School of Engineering, noted that ZAMCOM was signed in 2004 and is now undergoing ratification by the eight riparian countries. The objectives of the agreement are to efficiently develop and utilize the water resources of the Zambezi River. Dr. Phiri noted a number of challenges that had emerged during the ratification process including:

(a) Water governance constraints;

(b) Weak stakeholder participation; and,

(c) Inadequate infrastructure.

Dr. Phiri suggested two responses to facilitate the ratification process:

(a) National agendas must move to cooperative agendas; and,

(b) Perception of benefits for ratification is of key importance.

A number of other speakers at the Forum weighed in on the IWRM strategy itself. One speaker, Ms. Tabeth Chiuta, an International Union for the Conservation of Nature (IUCN) wetlands policy expert, provided a number of key recommendations IUCN hoped to see in the final IWRM strategy. These recommendations included:

(a) Mainstream wetlands functions into IWRM;

(b) Improve understanding and appreciation of wetlands functions;

(c) Invest in wetlands ecosystem functions;

(d) Manage water infrastructure and development to maintain environmental Functions; and,

(e) Facilitate partnerships to facilitate mainstreaming wetland functions.

Other speakers discussed the need to include environmental flows in the IWRM strategy, to provide incentives to local people who would implement the strategy, the promotion of co-management strategies, and the importance of funding.

This second trip focused upon the Zambezi River Basin Stakeholders Forum (Forum) plus subsequent follow-up visits at the University of Zambia in Lusaka, Zambia. It should be noted that Ms. Kirchhoff and Professor Nyambe from the University of Zambia made presentations at the same Water Quality session at the Forum. Their meeting at Victoria Falls together with the subsequent discussions at the University in Lusaka laid the foundation for the drafting and approval of the Memorandum of Understanding between the University of Michigan and the University of Zambia.

THE MEMORANDUM OF UNDERSTANDING (MOU)

The overall objective of the Memorandum of Understanding signed on April 17, 2008 is to provide an opportunity for students and faculty members from the two universities to meet and learn from one another in the context of undertaking important and relevant water resources research. This joint experience will strengthen the overall capacity for these young men and women to be come leaders in their professions and to function more effectively in the global world of the 21st Century.

Four major activities will be undertaken to further the achievement of this overall objective. These four major activities are as follows:

(a) Joint Research: Undertake joint research of mutual benefit and interest focused upon identifying effective water policies and practices, and related

institutions and institutional frameworks to provide more efficient and sustainable management of trans-boundary water resources.

(b) Workshops: Conduct at least two workshops each year one in Southern Africa and one in the United States where the research teams would meet together at the host institutions to share results and identify further research initiatives.

(c) Report Research Results: Seek opportunities to report research results at annual water meetings held in the United States and in Southern Africa.

(d) Capacity Building: Participate in scholarly exchange and learning through the joint research efforts, workshops and research presentations. Also, jointly explore and identify appropriate short courses designed to assist in capacity building among students, staff and the wider community.

Activities to be carried out during the implementation of the MOU include the following:

(a) External Funding: Each of the parties shall seek external funding to support the implementation of this MOU. The parties may, through joint proposals, also jointly seek funding.

(b) Time Period: The MOU should be for an initial time period from the date it is approved by the parties through September 2011.

(c) Annual Review: There will be an annual review conducted to evaluate the yearly accomplishments and identify any changes needed to further the future effective implementation of this MOU.

(d) Comprehensive Review: During the last six months of this MOU, a comprehensive assessment of the accomplishments achieved will be undertaken and any modifications required for the continuance of the MOU will be identified.

UNIVERSITY OF ZAMBIA: REASONS TO UNDERTAKE THE MEMORANDUM OF UNDERSTANDING (MOU)

In 2006, the University of Zambia (UNZA) established the UNZA IWRM Centre (IWRMC) a centre of "excellence" in line with the UNZA's motto of "service and excellence" guided by University's development **Mission** of "meeting the needs of individuals and society through excellence in teaching and learning, research and service in order to foster sustainable human development and a culture of peace, human rights and justice".

The Centre was established as a response to the Water Sector Support program through the Ministry of Energy and Water Development (MEWD) in collaboration with Royal Danish Embassy (RDE) (MEWD-Danida, 2005). It is based on the concepts and policies that are underlying the draft Water Resources Management Bill and the Human Resources Capacity study in the Water Sector in Zambia, which pointed out critical shortages of human resources to champion IWRM interventions in Zambia (Nyambe, 2005). In addition, the Government of Zambia also realized the pivotal role water plays in the socio-economic development of Zambia through the Fifth National Development Plan (2006-2010) and Vision 2030 (Ministry of Finance and Planning, 2006), where agriculture and tourism are priority areas aimed at creating wealth and reduction in poverty and community levels.

The Center's **Vision** is therefore that of "advancing and implementation of IWRM interventions in Zambia and the region through education and training, advanced research and consulting services for a sustainable water sector performance" with the main objective of "to build capacity in IWRM in Zambia focusing on water resources covering surface and groundwater employing techniques for assessments, quantifications, quality analysis and modeling (e.g. use of remote sensing and GIS). Also to improve water sector performance and ensure that there is sustainable management of the water resources through human resource development and capacity building" with the following specific objectives:

- To contribute to capacity building (human resource development, institutional strengthening and policy reform) in the water sector.
- To promote and undertake the training of water sector personnel and trainers in technical, managerial, economic and social issues to increase performance and productivity.
- To develop an independent advisory service to government, local authorities, private sector and international organizations in management of water and environment.
- To develop an information support service for information pertaining to Integrated Water Resource Management.
- To promote and undertake applied research in the work place and at graduate and postgraduate levels in the area of Integrated Water Resource Management and Environment.

The IWRMC is a hub currently with seven schools represented on its technical committee (Agricultural Sciences, Engineering, Education, Humanities and Social Sciences, Law, Mines and Natural Sciences). These seven schools bring together geology (hydrogeology), civil and environmental engineering – hydrology

of surface water focused), agriculture, mining, physical sciences (biology, chemistry, physics), life sciences (human and veterinary medicine), socio-economic, law and education. The IWRMC is also a hub for collaboration with stakeholders in Zambia and universities and NGOs outside of Zambia. The Zambia Water Partnership sits within the premises of the centre.

To advance its objectives, with support from Danida, IWRMC put in place a twinning arrangement with Danish universities in which Zambians are trained, followed by a Swiss program. However, despite the two arrangements, the academic quality and breadth, and teaching and research enhancement at the departments contributing to the center is at its lowest infancy. Accordingly, exchanges and collaboration with other universities is still a must. As a result a Memorandum of Understanding (MOU) was signed with the University of Michigan in order to pursue the Center's objectives.

THE UNIVERSITY OF MICHIGAN AND THE SCHOOL OF NATURAL RESOURCES AND ENVIRONMENT: REASONS TO UNDERTAKE THE MEMORANDUM OF UNDERSTANDING (MOU)

In late February and early March 2008, University of Michigan President Mary Sue Coleman led a delegation to South Africa and Ghana to extend existing collaborations with several African universities, forge new relationships between the University of Michigan and African counterparts, and develop new initiatives. President Coleman's trip occurred during the very time that the drafting of the MOU between the University of Zambia and the University of Michigan took place. This joint effort between our universities reflects the ongoing activities of both universities to join in partnerships across the globe to bring together faculty and students to engage and learn from and with each other in order to address the problems facing our societies individually and globally.

The School of Natural Resources and Environment (SNRE) at the University of Michigan is the active party to our MOU. A prime reason for SNRE to become a partner with the University of Zambia through this MOU is articulated in the MOU provision that addresses joint research. Through the MOU, the SNRE and the University of Zambia will undertake joint research of mutual benefit and interest focused upon identifying effective water policies and practices, and related institutions and institutional frameworks to provide more efficient and sustainable management of trans-boundary water resources. It is the achievement of "more efficient and sustainable management of trans-boundary water resources" that ties the MOU directly to the roles and mission of the SNRE at the University of Michigan.

"Achieving a sustainable society is the core focus of the University of Michigan's SNRE. Its overarching objective is the protection of the earth's resources for the benefit of present and future humanity as well as that of all other life on the globe. The only way that protection can be achieved is through creation

of knowledge and strategies that result in current needs being met in a way that creates a foundation for future generations to thrive. Hence SNRE's mission is to foster wise stewardship of environmental resources through effective and just strategies for achieving sustainable societies over the long term. This need for SNRE's work is seen in rising U.S. and worldwide demands on water, land, food and energy resources along with unsustainable land use and consumption patterns and ineffective decision making processes. Climate change, globalization, demographic change and economic insecurity all exacerbate these fundamental problems, and result in the loss of biodiversity in terrestrial and aquatic systems and diminished health and quality of human life" (SNRE Executive Committee, January 10, 2009). We enter into this MOU with hope and optimism that this small, joint undertaking will inform and ultimately lead to more sustainable management of water resources in the U.S. and Southern African and beyond.

OBSERVATIONS

The signing of the MOU between the two universities indicates commitments by the university administrators for this collaboration. Continuous exchange of ideas between the Principle Investigator of the Joint UM/UNZA Collaboration (Professor Jonathan W. Bulkley and the Coordinator, The University of Zambia IWRM Center (Professor Imasiku A. Nyambe) has resulted in two papers to be presented at EWRI/ASCE conference in Kansas City, Missouri in May 2009. These papers ultimately demonstrate the resolve of the two universities to collaborate in one area of River Basin management where UNZA is lacking experience. Current programs at IWRMC are designed for national water resources covered by Zambezi River Basin, and yet the Zambezi River itself is shared by eight countries in Southern Africa.

The coming in of the University of Michigan, to foster a partnership on the study of the Zambezi River Basin with a comparative approach to the Great Lakes Region of the U.S., which has been studied and researched for many years will provide a rich experience to the basin management of the Zambezi that is still at its infancy. The emphasis in the MOU by the two universities on staff and student exchange is to ensure the transfer of knowledge and skills that will enhance capacities for programs at UNZA's IWRMC and associated Department levels to deliver high-quality science, social science, and engineering programs (education and research related to resource assessment, modeling, monitoring and its application to developmental sectors of Zambia particularly natural resource management with a focus on stakeholder participation). Above all, our understanding of basin level management focusing
on the intersection of natural resources, socio-economic development, and environmental sustainability will be enhanced.

It is IWRMC's hope that relationships with stakeholders (e.g., "consumers" of students and research products such as agriculture, industry, government agencies, and public interest entities) and partners in the region and abroad will be

strengthened through provision of relevant accessible information for decision making. This in turn may open the doors for IWRMC to access relevant and appropriate development assistance, student and program support, collaboration and resource sharing, and endowment and foundation gifts.

These collaborative relationships will build and strengthen the UNZA IWRMC's capacity to assist the Zambian Government in attainment of the water resources goals articulated in Zambia's Vision 2030. The opportunity for students and faculty from the University of Zambia and the University of Michigan to work together on key water resources research is of critical importance. These students, young men and women, will represent a new level of achievement in global water resource collaboration. These students in both countries are among the water resource professionals who will provide the leadership in the integrated planning, implementation and management of water resources for the 21st Century.

Abstract

India is developing country among the world. Most of the people in India depend on agricultural industry. Near about 70% population depends on agriculture. Hence, India's development mostly depends on development of agricultural sector. But it is very difficult to construct big dams across the rivers due to environmental damage and protest of farmers against acquisition of land. Also major or medium irrigation project cannot provide the irrigation benefit to every farmer. Due to scarcity of water for irrigation, one lac farmers did suicide in last ten years in India. If the micro irrigation facilities are provided then there will be considerable recharge of ground water aquifer take place. It will create agricultural reform without causing natural hazard.

The present paper deals with development of micro irrigation facility at Parsoda village, district Aurangabad, Maharashtra State in India. In this project micro irrigation techniques like farm pond, earthen bunds are used for development of irrigation facility, near about 3500 acres of agricultural land is benefited due to micro irrigation technique with minimum expenditure.

INTRODUCTION

India is one of the developing countries in the world. Near about 75 percentages Indian population is dependent on the agricultural sector and they are living in rural areas, so it is very clear that development of the country like India is totally dependent on development of its agricultural sector. Indian Agriculture accounts for almost 25 percentage of the total GDP.

Agricultural sector is interlinked with natural resources such as land, water, vegetation and humans. Moreover Agricultural sector does not have any negative effects on the environment. If agricultural industry is developed by considering the environmental factors then we come to know that it is the only industry which becomes a part of environmental and water conservation. All the crop plants form the engines of the Oxygen regeneration cycle of the earth. Crop vegetation also acts as an infiltrator of rain water into ground by leading the stagnated rain water into the soil up to the full depth of the roots thereby recharging the water table. This increased water table is very helpful for the irrigation purpose. Hence the economy of the nation depends on the natural resources and its management.

In recent past suicide of farmers is a big issue in India. The rate of farmer suicides in India is increased and it will affect the economy of country nearly 150000 farmers committed suicide in nine years from 1997 to 2005,while farmer suicides have occurred in many states, nearly two third of these deaths are concentrated in five states. The five worst-hit states are Maharashtra, Andhra Pradesh, Karnataka, Madhya Pradesh, and Kerala. Maharashtra is the worst affected state in the country. Farmer suicide rate is from 1083 in 1995 to 3925 in 2005 (TISS, 2005).

There are many causes for this tragic situation one of the major causes being lack of irrigation facilities. Day by day the ground water table is getting depleted, hence the farmer are not getting water for irrigation. Construction of large reservoir creates many socio –environmental problems also it cannot provide benefit to each and every farmer. Hence development of country and agricultural sector is dependent on Micro watershed development. This is the only solution to overcome the above problems.

LAND AND WATER MANAGEMENT

Land and water resources are limited and their wide utilization is imperative especially for countries like India where the population increase day by day and it creates the pressure on land and water resources. Thus proper planning and management of natural resources is essential for the development of country. The economical development of an India depends to a significant extent on the natural Resources and its management. The average annual rainfall in India is around 114 cm and in terms of volume, it is in the order of 370 million mm (M) ha-m of Which 123 M ha-m is lost in evaporation, 167 M ha-m are runoff and the rest of The 80 M ha-m goes into the subsoil annually. While about 43 M ha-m gets absorbed in the top layer of the soil, thereby contributing to soil moisture, the remaining 37 M ha-m accounts for the ground water from rainfall. According to Raghunath (1987), the average annual ground water recharge from rainfall and seepage from canals and irrigation systems is in the order of 67 M ha-m of which 40% is extractable economically. The present utilization of ground water is approximately 13 M ha-m and about 14 M ha-m is available for further exploitation and utilization. Agriculture in India is heavily

dependent on Rainfed Farming Systems. Out of about 328 M ha of geographical area in the country, the net cultivated area is around 142.2 m ha of which about around 33.3% (47.4 M ha) is under irrigation. About 56% of the total food grain is produced from the irrigated area while the remaining 44% is contributed by 95.8 M ha. rainfed areas (Sarkar, 1997). This data reveals that the rain water inflow is good but its utilization is poor. On the other hand, the dependency on rainfed agriculture is very high. Hence the strategy to meet the increasing demand of agricultural produce is to initiate micro level watershed planning. Watershed development provides an Opportunity for optimum utilization of land and water resources and increasing the crop yield by over two folds. Apart from the area under agricultural lands, there are vast stretches of denuded forests, overgrazed pastures and barren lands. It is estimated that about 100 M. ha wastelands are presently lying underutilized or idle, and posing a threat to agriculture and environment.

Watershed development program creates employment through development of wasteland and for countries like India where population growth rate is high it is very essential to create the employment. It will more helpful for increasing economy of country.

MICRO-WATERSHED DEVELOPMENT

The watershed management concept recognizes the inter-relationships among the linkage between uplands and low lands, land use, geomorphology, slope and soil (Tideman, 1996).Considering watershed conservation work it is not feasible to take the whole are at once. Thus the whole basin is divided into several smaller units, each unit is called micro –watershed.

Micro- Watershed is more beneficial rather than construction of big reservoir from socio - environmental point of view. For the construction of big reservoir land acquisition and rehabilitation of people is the major problem in highly populated country like India, also large reservoir creates environmental problems. So that micro watershed development is the only way for the developing country like India.

Micro-watershed development consisting of following methods

A) Structural methods
B) Vegetative measures

A) Vegetative Measures: It consist of watershed measures in the following forms so that soil erosion in the watershed is controlled,

- Cover crops
- Horticulture
- Afforestation along bunds
- Block plantations

B) Structural Methods: It consisting of following engineering structures for the rain water harvesting, these structures are economical also required less maintains cost. Such type of structures does not cause any harm to socio - environmental. Table no. 1 shows salient features of watershed structures

- Gully checks
- Staggered trenches
- Continuous contour trenches
- Mini percolation tanks
- Sunken gully pits
- Rock fill dams
- Bunding
  Contour Bunding
  Boundary Bunding
- Farm ponds
- Percolation tanks
- Check dams

ECONOMIC ANALYSIS

Economic Analysis can be done for the following Structures taken up under water - shed Development.

- Bunding
- Percolation tanks
- Check dams
- Farm ponds

Benefits of Micro Watershed Structures

- Soil erosion due to runoff can be controlled
- Crop damage due to runoff can be controlled
- It provides facility for easy ground water recharge
- Less land required for its construction. Hence there is no possibility of land acquisition
- Irrigated areas stabilized and yields increased in the crops raised in these stabilized areas
- The additional areas come under irrigation from fallow (before) to single crop (after) and their yields
- The additional areas come under irrigation during second crop and their yields
- The additional areas brought under irrigation from fallow (before) to double crop and their yields

Case Study of Parsoda Village:

The Parsoda village is the one village of Maharashtra State situated at Aurangabad district having population 6000 and nearly 3500 acres of land is used for agriculture. The permeable soil is available .It is one of the drought prone village of Aurangabad. It is on going project in Parsoda village we are awareing the people about development and construction of Micro watershed through ECO NEEDS FOUNDATION (NGO)

In this village micro watershed development carried out through Farm ponds, Percolation tanks, and bunding .These structures are very economical as it required only soil and stones and it is locally available.

Farm pond Details

Farm pond is the excavated trench into ground for harvesting the rain water .It controls the soil or agricultural loss due to runoff. It also very help full for ground water recharge. Hence at Parsoda village close network of form pond is proposed, for avoiding silt deposition in farm pond depth of farm pond is divided in to different part so that it provides the soil stability to farm pond and facility for cleaning. One of the advantages of such pond after rainy season is over it can be used for manufacturing of compost fertilizer Following are the some details of farm pond considering ground water recharge.

Size:-
For top part = 9m x 9 m x 2.5 m
For bottom part = 6m x 6m x 2.5 m
Total storage available for water or volume of pond =292.5 cubic meters
As per local survey it is found that there are five maximum rainfalls during which maximum runoff taken place. It means that farm pond store the water and recharge the ground water in five times during rainy season.

Total ground water storage due to each farm pond = 5x 292.5
= 1462.5 cubic meters
= 1462000 liters

Proposed 25 Number of farm pond at Parsoda village

Total ground water storage possible due to farm pond = 25 x 1462000
= 36550000 liters
= 36.55 M liters

Conclusion

Micro watershed promotes socio cultural, socio economical and socio ecological development .the present paper deals with different micro watershed structures and its utilization according to the topographical situation. These structures are economical and are very help full for raising the farm income, enhancing agricultural productivity, soil and water conservation and also for, generating rural employment.

Table 1: Salient features of watershed structures

Name of the structures	Objectives	Visualization
Gully Checks	Arresting of soil –erosion promoting infiltration of rain-water Improving the soil-moisture.	Over a period of time Gully checks heal up the small gullies, prevention of further deepening and widening of gullies. Help in increasing vegetation leading to stabilization of gullies.
Rock fill dams	Increasing soil moisture Recharges of ground-water arresting of soil erosion	Improved vegetation in the vicinity of structures
Staggered Trenches	Increasing soil moisture Reducing soil erosion	Improved vegetation
Continuous contour Trenches	Increasing soil moisture Reducing soil erosion Recharge of Ground-Water	Improved vegetative growth, increase in the well population, and increased crop yields in the influence area.
Percolation Tanks	Recharge of ground-water through percolation by impounding water.	Increased crop yields, Increase in the cropped area, Increase in the well population
Sunken gully pits	Controlling the erosion Recharging of ground-water	Improved vegetative growth on the banks of stream.
Bunding	Soil-moisture conservation	Increase in crop yields. Increase in the cropped area.
Farm ponds	Storage of surface water	Utilization of stored water for pesticide spraying, drinking water for cattle and life saving irrigation to the crops.
Check dams	Basically Recharge of ground-water through percolation by impounding water.	Increased crop yields-Increase in the cropped area. Increase in the well population

Feasibility Study for Implementing Renewable Energy to Power a Groundwater Pump in Rural Guatemala

Will Granich[1] and Andrew Curtis Elmore[2]

[1]Department of Geological Engineering, Missouri S&T, 125 McNutt Hall, Rolla, MO 65409;
PH (573) 690-0276; e-mail: wagr38@mst.edu

PH (573) 341-6784; e-mail: elmoreac@mst.edu

Abstract:

Communities in rural Guatemala often struggle with obtaining adequate, clean drinking water. A deep groundwater well can provide a clean and sustainable water source for near-by communities. To obtain the groundwater, an electric submersible pump must be installed in the well. Utility power in rural Guatemala can be unreliable and expensive, thus a study has been conducted to establish if using alternative energy is sustainable and economically viable for a groundwater pump for a rural Guatemalan community. The study focused on effectiveness, reliability and cost. A weather station was erected in Sacala las Lomas to collect baseline data for the feasibility study. Wind velocity, wind direction, solar radiation, temperature, precipitation and barometric pressure data were collected. The data were analyzed to determine the potential power generated with solar and wind power. Although the location was in a particularly superior location for sun and wind exposure, installing solar panels and/or a wind turbine would not be feasible for supplying the amount of energy required for a submersible groundwater pump that would meet the needs of the community.

Introduction:

Throughout Guatemala a lack of sanitation infrastructure and poor solid waste management has left most of the country with drinking water infected with pathogens. Coliform bacteria are often used as indicator organisms of pathogens. This is because coliforms consist mainly of the species Escherichia coli (E. coli) which thrive in the intestines of warm-blooded animals (Reynolds and Richards 1996). Since E. coli bacteria occur in the intestines, the presence of E. coli suggests that the water is being contaminated from fecal matter. Some strains of E. coli bacteria can lead to sickness and possibly death. This problem has led to Guatemala producing one of the highest infant mortality rates in Central America (WHO 2000).

Guatemala is topographically separated into the lowlands and highlands. The lowlands, located in northern Guatemala and along the coastlines, consist of a flat terrain with a tropical climate. The highlands of Guatemala are mountainous with a

very rugged terrain. The highlands have a temperate climate with a wet season (May-October) and a dry season. Water sources for most villages in the highlands usually are spring water systems distributed by gravity for several kilometers. The spring water is often contaminated with E. coli at the source, and often becomes more contaminated from bacterial growth in the pipeline (Elmore et al. 2005).

A proven, safe and sufficient water source in Guatemala is deep aquifers (Elmore et al. 2005). A submersible pump is used to bring the groundwater to the surface where it can be distributed. In many rural villages in the highlands of Guatemala, electricity is costly and there can be long power outages (EIA 1997). Therefore, if a groundwater pump is being used and there is a power outage, the community only has the volume of water in a storage tank until the electricity is restored. Typically a storage tank contains three days volume of water. Possible resolutions to avoid this problem are the implementation of alternative energy sources, such as solar and wind power, to run the pump without relying on grid-power.

Project Background:

Sacala las Lomas (Sacala) is a rural village in the highlands of Guatemala. Sacala is located approximately 1,910 meters (m) above mean sea level (amsl) in the Sierra Madre mountain range, in the Department of Chimaltenango. Sacala is approximately 4 kilometers southwest of the city of San Martin Jilotepeque as shown on Figure 1.

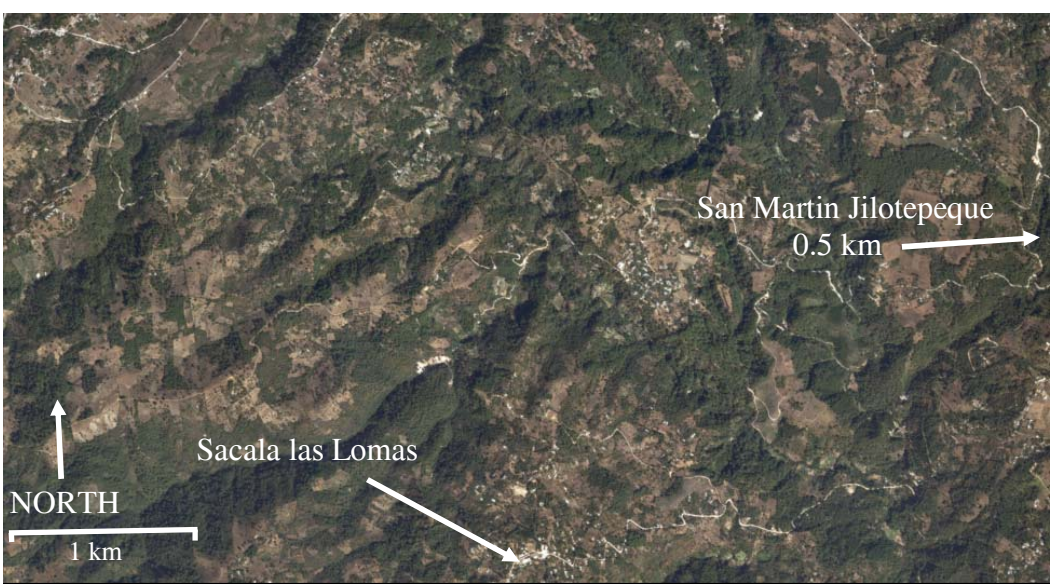

Figure 1. Location Map of Sacala

As of 2001, Sacala's population is 662, and there are 223 homes dispersed throughout the mountain side (Martin 2001). Sacala has been trying to attain funding, with assistance from a non-profit group from Canada, to drill and develop a deep groundwater well. The community is asking for a groundwater well because the current drinking water supply, a spring-based system, runs dry during the dry season. Lepper and Elmore (2005) found that a groundwater well in rural Guatemala is beneficial to both water quantity and quality if installed properly.

Although deep groundwater wells are costly and rare in rural Guatemala, a few deep groundwater wells have been installed in the highlands of Guatemala. According to a Guatemalan drilling company, Daho Pozos, a typical groundwater well in the area has a dynamic water level around 150 meters below ground surface and will cost around US $60,000. Although the solution is very costly, it may be the most effective solution to the water problems in Guatemala.

A feasibility study has been conducted to determine if an alternative source of energy can replace the utility power grid. The study compared solar power, wind power, and utility power to determine the best method to providing reliable energy to the submersible pump. Weather data was collected using a weather station set up in Sacala. Upon concluding the study, a recommendation was given to the community of Sacala and the non-profit group searching for finances for the groundwater well.

Weather Station:

There are a limited number of weather stations collecting solar and/or wind data in Guatemala. The closest known functioning weather station to Sacala is located 35 kilometers away near Guatemala City, at an elevation of 1,490 m amsl. Due to the horizontal distance, elevation change and topographical features (mountains and valleys) between Guatemala City and Sacala, it was decided that on-site data would be required to determine the feasibility of using solar and/or wind power to run a groundwater pump. In March of 2008, a three-meter weather station with a Campbell Scientific Datalogger was installed on a piece of property in Sacala. The Datalogger was powered by a 12V battery which was charged using a 10W solar panel. The Datalogger was programmed to collect data averages every minute from a pyranometer and anemometer located three meters above ground surface, and 30 minute averages from a temperature probe, barometric pressure meter and precipitation tipping bucket. Table 1 shows the manufacturer and model numbers of each piece of equipment of the weather station.

Table 1. Equipment List

Item:	Manufacturer:	Model Number:
Datalogger	Campbell Scientific, Inc.	CR800-ST-SW-NC
Tipping Bucket	Texas Electronics	TE525
Barometric Pressure	Setra	CS100
Temperature Probe	Campbell Scientific, Inc.	107
Anemometer	R.M. Young	05103-L15
Pyranometer	Apogee Instruments	CS300-L15
Tripod Stand (10ft)	Campbell Scientific, Inc.	CM110
Tripod Crossarm(4ft)	Campbell Scientific, Inc.	CM204
10W Solar Panel	Campbell Scientific, Inc.	SP10
12V Power Supply	Campbell Scientific, Inc.	PS100-SW
Datalogger Enclosure	Campbell Scientific, Inc.	ENC10/12-ES-MM

The location for the weather station was selected based on: land ownership, land elevation, adjacent suitable sites for a groundwater well, wind potential, solar radiation potential, and security. The selected site was near a suitable site for a

groundwater well, on a steep saddle with good wind potential (few trees and buildings), on land with little shade and not easily seen by passer-bys.

For a renewable energy feasibility study, the longer the data is collected, the more reliable the values (Derrick 1992). However, since Sacala wants a groundwater well as soon as possible, a long-term collection of data is not possible. Derrick (1992) states that study periods can be reduced to 12 months or less if there are sufficient long-term data elsewhere in the vicinity. Therefore, a short-term collection plan was implemented, and, if needed, more data could be attained from other Guatemalan weather stations to correlate the sites

Photovoltaic Performance Prediction Methodology:

The performance of a photovoltaic (PV) array was predicted using the pyranometer data from the datalogger. The sunlight potential is called the solar radiation and is measured in kilowatts per meter squared (kW/m^2). The pyranometer is located in a horizontal position, thus the horizontal radiation is measured. To maximize the amount of power generated from a fixed solar array, the solar panels are tilted to match the latitude of the site (Ewing 2007). Since the solar radiation is measured from a horizontal position while solar panels are installed at a tilted position, the tilted solar radiation is calculated. Also, since the energy used by pumps is generally measured in kilowatt-hours (kW-hrs), the average daily horizontal radiation measured at the site is converted to $kW\text{-}hrs/m^2/day$ by multiplying the horizontal radiation by 24. The tilted radiation is calculated using Equation 1 (Honsberg and Bowden 2002):

$$S_{module} \approx \frac{S_{horizontal} * \sin(\alpha + \beta)}{\sin(\alpha)} \qquad (1)$$

Where: S_{module} is the tilted radiation ($kW\text{-}hrs/m^2/day$),
$S_{horizontal}$ is the horizontal radiation ($kW\text{-}hrs/m^2/day$),
α is the elevation angle of the sun (degrees), and
β is the tilt angle of the solar panel measured from horizontal (degrees)

The elevation angle of the sun (α) differs with each day, and can be calculated using Equations 2 and 3 from Honsberg and Bowden (2002):

$$\alpha \approx 90 - \phi + \delta \qquad (2)$$

Where: ϕ is the latitude (degrees) and
δ is the declination angle:

$$\delta \approx 23.45 * \left(\sin\left(\frac{360}{365}\right) * (284 + d) \right) \qquad (3)$$

Where: d is the day number of the year (i.e. January 1st is 1, January 2nd is 2, etc.)

The daily kilowatt-hours required for the groundwater pump was calculated by multiplying the pump power, in kilowatts, by the efficiency of the pump and the daily pumping time in hours. To size the pump, the water demand was calculated. The system was designed for a life of ten years. The design population was used assuming the current population growth of 3% for the next ten years with a safety

factor of 10% (Martin 2001). A typical rural Guatemalan community uses about 84 liter/day/capita of water (Trigg 2000). That means, for the design population of 920 people, the pump is required to pump 77,280 liters per day. A storage tank, installed on the ground surface, was assumed to hold three days worth of water which will act as a buffer if there is an increase in water demand or lack of power. Using a total dynamic head of 188 m (150 m to the dynamic groundwater level and a 25% safety factor) and a flowrate of 235 liters per minute (lpm), an 11.19 kW pump, similar to the Grundfos Model 85S150-13, was selected for the design. At the flowrate of 235 lpm the pump operates at an efficiency of about 70%, and would require 7.84 hours per day to pump the average daily demand. Using these numbers, the daily power draw from the pump is 87.7 kW-hrs.

From the power required and the tilted solar radiation values, the number of solar panels required can be calculated using Equation 4 from Ewing (2007):

$$S \approx \frac{P_{req}}{(P_{\max} * \eta * S_{\mathrm{mod}})} \qquad (4)$$

Where: S is the solar panels required,

P_{req} is the power draw from the equipment used (kW-hrs/day)

P_{max} is the maximum power generated from the solar panel (kW/panel)

η is the system efficiency

S_{mod} is the calculated tilted solar radiation (kW-hrs/m^2*day)

The study assumed the parameters of Sharp ND-216U2 solar panels. The maximum power generated from one solar panel is 216 W and the system efficiency, assuming a Fronius IG 2000 inverter, is about 90%. Using the maximum number of solar panels over any three day span and the average cost for solar panels, the cost of solar power for a submersible pump was calculated. A three day span was used because this is the size of the proposed storage tank.

Wind Power Methodology:

Wind velocity is measured using an anemometer. Placement of the anemometer is crucial in wind energy studies. As height from the ground surface is increased, wind velocity also increases and can be approximated using a power law equation, typically the one-seventh power-law (Johnson 2001). The increase in velocity is due to the reduced friction from the ground, vegetation and buildings. Wind velocities are generally higher on ridges with steep slopes on either side of the ridge. This phenomenon occurs when the wind is compressed on the prevailing wind side of the hill. The wind blows up the side of the hill and upon reaching the ridge the air expands and quickens its velocity to the low pressure zone on the other side of the hill (Johnson 2001). So by placing the wind turbine in a well chosen location, the output can be increased significantly.

Wind velocities were collected on one minute averages for the study period. The anemometer was placed three meters above ground surface. For a high wind resource area, a typical wind turbine for the power that is required for the Sacala project (87.7 kW-hrs/day) is similar to the Bergey Excel S 10 kW wind turbine. Bergey Windpower has developed a spreadsheet using a Weibull distribution to predict the wind energy generated at different heights. The spreadsheet takes into

consideration the elevation, predicted Weibull K value, the estimated wind shear exponent, the anemometer height, the hub height of the wind turbine, and the turbulence factor. The elevation is known as 1,910 m amsl, the Weibull K is estimated as 2, the wind shear exponent is assumed 0.22 for rough terrain, the anemometer height is 3 m, the wind turbine height is assumed to be 36.5 meters and the turbulence factor is assumed to be 0%. Upon plotting the equation's results, the wind turbine power produced each day was calculated for the study period.

Solar Power Results:

Upon collecting eight months of data (April through November of 2008), the solar power for Sacala was analyzed. The Datalogger was non-functional from July 1-July 4 for unknown reasons; however, all other days in the study produced consistent data. The average tilted radiation value for the eight month period was 4.41 kW-hrs/m^2/day. The month with the highest solar radiation value was April with a value of 5.96 kW-hrs/m^2/day.

For each day during the study period, the number of sunlight hours each day was more than the hours of pumping time required. Knowing that there was sufficient day light to power the pump, the number of solar panels required was calculated. Figure 1 shows the number of solar panels required for each day of the study period.

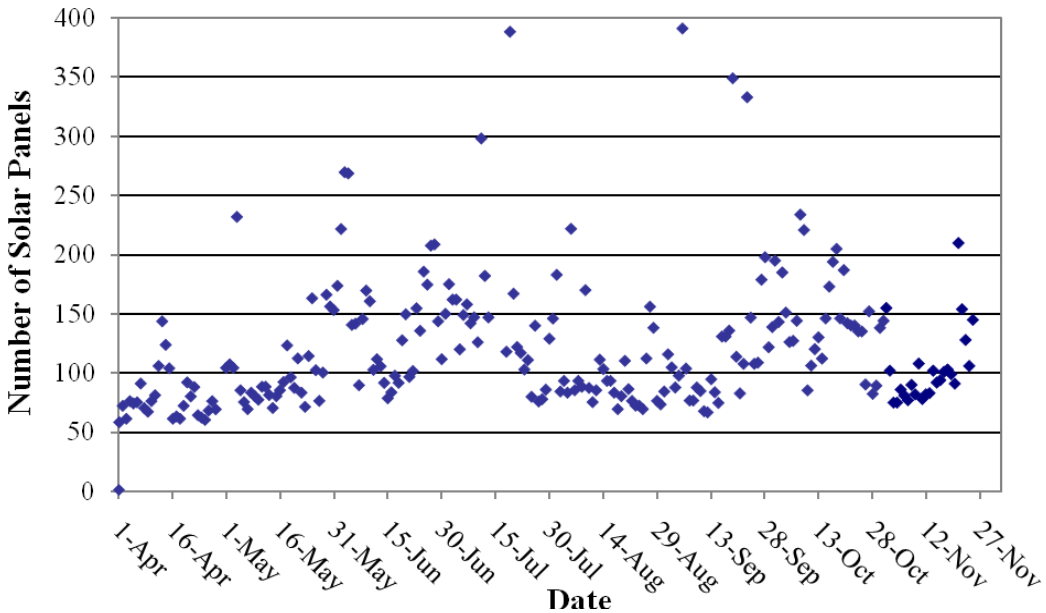

Figure 1. Solar Panels Required to Produce 87.7 kW-hrs/day

Wind Power Results:

The Bergey Windpower worksheet was used to determine how much potential power was produced from April through November using a 36.5 m tower. The Datalogger was non-functional from July 1-July 4 for unknown reasons; however, all other days in the study produced consistent data. The average wind velocity for the study period was 1.15 m/s at 3 m, which corresponds to about 1.99 m/s at 36.5 meters. The month with the highest average wind velocity was April with an average

velocity of 1.5 m/s at 3 m, or 2.60 m/s at 36.5 meters. Using the Bergey Windpower worksheet, the daily average power produced with one wind turbine was 1.94 kW-hrs. The month with the highest daily average was April with an average of 2.49 kW-hrs per day.

Figure 2 shows the estimated number of wind turbines required to produce the 87.7 kW-hrs needed per day.

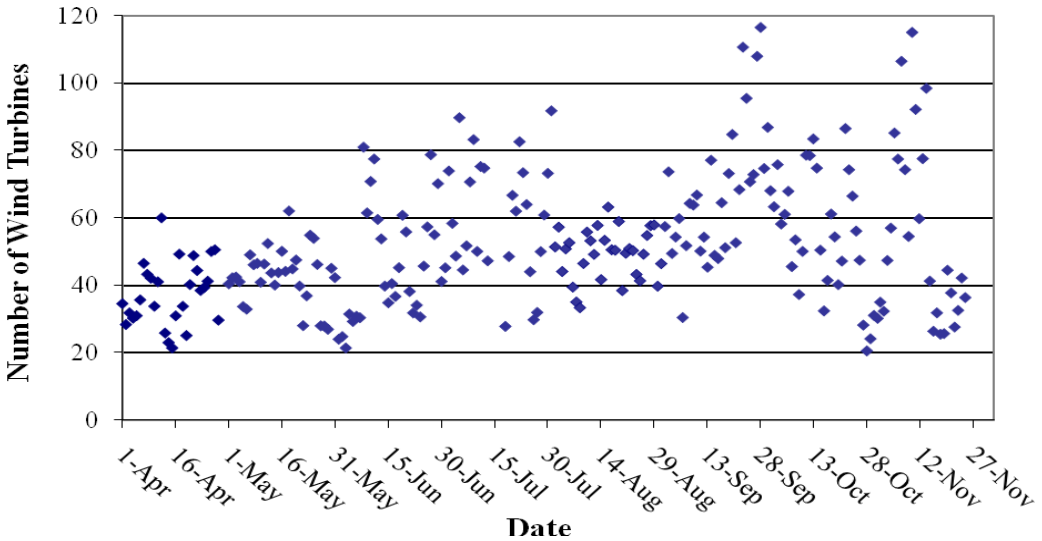

Figure 2. Wind Turbines Required to Produce 87.7 kW-hrs/day

Hybrid Results:

Since a large number of both solar panels and wind turbines would be required to power the pump, a hybrid analysis was considered. Using the average daily power generated by one wind turbine over the study period, the difference in energy produced and energy required was recovered by solar panels. Figure 3 shows the total number of solar panels needed to produce sufficient energy with the assistance of a 36.5 meter tall wind turbine.

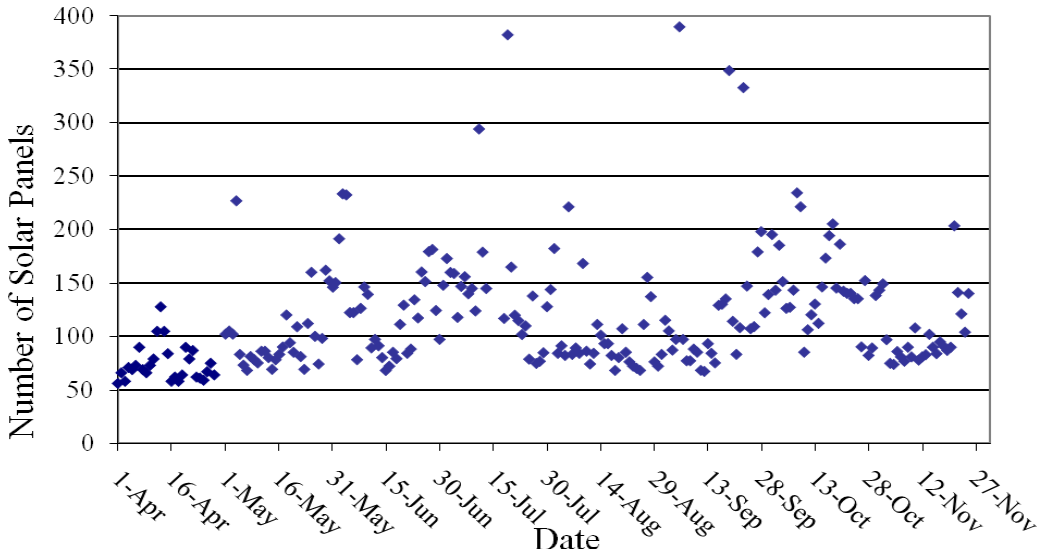

Figure 3. Solar Panels Required for 87.7 kW-hrs/day Using One Wind Turbine

Table 2 shows the cost estimates of the PV array, grid power, wind turbine, and hybrid system. Equipment and installation costs for the solar array and wind turbine were based on costs from the manufacturer in 2008.

Table 2. Cost Estimation of the Alternative Energy Generation Methods

PV Array Cost

Item:	Unit Price:	Quantity:	Est. Cost After 10 Years
Sharp ND-216 U2	$1,100	222	$244,200
Fronius IG 2000 Inverter	$1,800	4	$7,200
Ground Mount Racks	$800	23	$18,400
		Total:	**$269,800**

Grid-Power Cost

Item:	Unit Price:	Quantity:	Est. Cost After 10 Years
Electricity	$0.20/kW-hr	87.7/day	$64,021
		Total:	**$64,021**

Wind Turbine Cost

Item:	Unit Price:	Quantity:	Est. Cost After 10 Years
Bergey Excel S Turbine	$27,900	78	$2,176,200
Guyed Lattice Tower	$11,920	78	$929,760
Installation	$14,000	78	$1,092,000
		Total:	**$3,105,960**

Hybrid Cost

Item:	Unit Price:	Quantity:	Est. Cost After 10 Years
Sharp ND-216 U2	$1,100	191	$210,100
Fronius IG 2000 Inverter	$1,800	4	$7,200
Ground Mount Racks	$800	20	$16,000
Bergey Excel S Turbine	$27,900	1	$27,900
Guyed Lattice Tower	$11,920	1	$11,920
Installation	$14,000	1	$14,000
		Total:	**$287,120**

Discussion:

The solar and wind power potential for Sacala was calculated using measurements collected for eight consecutive months. Although Sacala has a relatively high solar power potential, the power required from a 11.19 kW submersible groundwater pump is significant and would require approximately 222 216W solar panels, which would require 23 ground mounts and 4 inverters (maximum of 60 panels per inverter).

The current price for electricity is $0.20 per kW-hr for Sacala. Although this is relatively expensive, there are no maintenance costs incurred over the design life of the pump. There are also no installation costs since the well can be situated near power lines.

The wind resource of Sacala is considerably lower than needed for the groundwater pump. To power the pump, 78 10 kW wind turbines, 36.5 m tall would have to be installed. Clearly, this would require a lot of space and a huge installation cost for one groundwater pump.

If a hybrid system would be installed, using one wind turbine would be most economically feasible. However, 191 solar panels would still have to be used to power the pump. This would require 20 ground mounts and 4 inverters.

Conclusions and Recommendations:

Even though grid-power in rural Guatemala is often unreliable, the community of Sacala has expressed that they have experienced no significant loss of electricity, and they feel grid-power is reliable in Sacala. With the current electricity cost for Sacala at $0.20 per kW-hr, and the community of Sacala having high faith and little complaints about the utility company's reliability, there is no reason to abandon grid-power.

When financing is possible, alternative energy has become a popular alternative to traditional power plants. The highlands of Guatemala offer good solar power potential; however, to power energy demanding products, such as a deep groundwater pump, solar power is not feasible. Also, Sacala has a low wind potential, and the installation of a wind turbine would not be economically favorable. Even when environmental interests are a higher priority than economic interests, the area of land needed to install the required solar panels or wind turbines for this project is more than what is feasible.

Acknowledgments

The feasibility study was funded by a grant from the National Science Foundation award number 0623091. Additional support was provided by the Sisters of Saint Joseph, the community of Sacala las Lomas and Missouri University of Science and Technology.

ABSTRACT

An analysis of drinking water contaminant concentrations in the highlands of rural Guatemala evaluated the Coliscan EasyGel as a field method for the detection and enumeration of coliform bacteria in drinking water and found it adequate. In developing countries like Guatemala, many deaths among infants and young children may be due to dehydration, malnutrition, or other complications of waterborne bacterial infections. Students and engineers are challenged to find sustainable means to provide safe drinking water. A field applicable method of quantifying microbiological contamination is needed to improve the evaluation of engineering solutions. A pour plate method using the patented Coliscan EasyGel medium is commercially available and marketed for field use by Micrology Labs Incorporated. However, the validity of the field data is called into question when the results are compared qualitatively and quantitatively to duplicate Membrane Filtration (MF) analysis using M-Endo medium, an ASTM accredited method. To evaluate comparability, this work splits subsets of the samples for duplicate MF analysis and non-parametric statistical evaluation due to the non-normal nature of data distribution.

INTRODUCTION

In developing countries like Guatemala, the costs of disease and productivity losses linked to inadequate clean water and sanitation are equivalent to 2% of gross domestic product (Swedish Water House 2007). Many deaths among infants and young children are due to dehydration, malnutrition, and other complications of waterborne bacterial infections. More than 2 billion people living in poverty in the developing world are considered at high risk. Students and engineers are challenged to find sustainable means to provide safe drinking water supplies in the rural highlands of Guatemala and other locations in similar stages of development. In an effort to improve evaluation of engineering solutions, this work measured the density of coliform bacteria, an indicator organism, to determine the presence and/or degree of fecal pollution rather than presence of pathogens.

Few naturally occurring bodies of water are free of indicator organisms; however, the presence of coliform bacteria in treated water is cause for concern because standard treatment processes are expected to remove naturally occurring nonfecal coliform bacteria. It is customary, therefore, to test for the total coliform group rather than for fecal coliforms, specifically *Escherichia coli* (*E. coli*). This distinction is useful when characterizing a pollution source

because nonfecal members of the coliform group are known to survive longer in a stressed environment. Both the Membrane Filtration (MF) procedure and the Coliscan EasyGel method have been modified to determine *E. coli* density.

As a result of the U.S. EPA Total Coliform Rule (TCR), the presence or absence of microbiological contaminants in drinking water is typically analyzed using a qualitative binary method. Yet such methods do not quantify or provide data on the magnitude of contamination needed to evaluate the effectiveness of an engineering solution. Prior to adoption of the TCR, an MF procedure was used to analyze samples transported to certified laboratories. Because this method was developed for a laboratory setting, it is impractical and costly when applied to field work in remote locations. A simplified method designed for field interpretation and requiring little equipment and training, therefore, would be valuable.

MATERIALS AND METHODS

In 2003, Micrology Labs Inc. developed Coliscan Easygel, a medium targeted specifically for field use with the pour plate method. This method appears designed for typical field conditions; however, the validity of field data is questionable when compared qualitatively to a well documented technique such as MF. The MF technique uses a typical vacuum filtration apparatus to target bacterial cells on a cellulose membrane. After the water is filtered, the membrane filter is incubated on a 5 mL plate of appropriate medium at a set temperature for a specific period of time. Several types of medium are marketed for detection of total coliforms using the MF technique. The United States Environmental Protection Agency (USEPA) approves the use of MF with M-endo LES medium, and this has become the method of choice for routine analysis of drinking water (Grabow 1979). The MF technique is considered useful for analysis of a wide range of sample volumes or dilutions because it detects a wide range of contamination levels. Whether using m-Endo agar on pre-poured plates or m-Endo liquid broth and nutrient pads, total coliform forming units appear as colonies with a metallic green sheen. The MF technique should be avoided when sampling highly turbid water or water expected to have large amounts of non-target organisms that could clog the filter and generate data. Rarely, non-coliform organisms may produce the characteristic total coliform sheen, creating a potential source of errors, such as false positives. Because MF uses the same non-disposable equipment (vacuum filtration setup) for each sample, data is reliable when samples are analyzed in a sterile laboratory setting and isolated to control cross contamination. With the use of disposable equipment MF may be easily adapted to field testing. Considering the cost of the incubator and glassware, however, this technique may not be feasible for students or professionals interested in analyzing water samples in remote field locations. Despite these limitations, however, the effectiveness of MF using m-Endo is well documented; and the method requires less space and time than other equally established methods.

The pour plate technique using Coliscan EasyGel is sold in a kit of 10 for $20.00. Each kit includes all required equipment. A user friendly method promising reliable results with little equipment and low cost, Coliscan Easygel lends itself to field work. The medium is formulated to distinguish between total coliforms (represented by pink/magenta colonies) and *E. coli* (represented by blue/purple colonies). A sample of 1-5 mL, depending on sample source and expected contamination level, is mixed with Coliscan EasyGel broth and poured onto a

pretreated Petri dish. The Coliscan EasyGel medium contains pectin-gel that solidifies approximately 40 minutes after pouring. At the discretion of the technician, the sample is then incubated either at 35^{o}C for 24 hours or at room temperature for 48 hours. Occasionally, colonies display a range of color, thus complicating identification of colony types. Despite these limitations and the novelty of the technology, the Coliscan EasyGel is an innovative method assumed to be superior in terms of cost feasibility and amount of equipment required.

A public health study in Guatemala analyzed water samples using the Coliscan EasyGel technique to measure the concentration of total coliforms and *E. coli* in drinking water. To evaluate the validity of the data, a subset of the samples was split for testing with MF using m-Endo. Because data involving micro-organisms is likely to assume a non-normal distribution, the Mann-Whitney hypothesis test was used to perform a non-parametric analysis of results and thus to compare the data generated by the Coliscan EasyGel with that from MF with m-Endo. The results of this initial comparison were evaluated against those of a parallel analysis using the same procedure performed in the laboratory with water samples of known concentration. During both laboratory and field analyses, samples were read after varying periods of incubation. To evaluate the effect of unforeseen field conditions, duplicate samples were incubated at temperatures outside those recommended for each method.

RESULTS

Table 1 is the result of a trial and error analysis evaluating the feasibility for field application of several MF medium options approved by the USEPA and available commercially in various forms. Because the field site was extremely remote, the samples analyzed there could not be transported for duplicate laboratory analysis. Therefore, comparison of the field results generated by the Coliscan Easygel method with those produced by MF may not permit conclusive evaluation of the accuracy of the Coliscan Easygel method. Each water sample collected was assumed to have a uniform contaminate distribution; however, all samples (including dilutions) were analyzed in triplicate to accommodate the possibility of significant variance.

The comparative analysis was performed in both the laboratory and the field to ensure appropriate characterization of discrepancies independent of field conditions. The results are shown in Fig. 1. Using standard methods, a batch of E. coli was cultured to provide a sample of contaminated drinking water for laboratory analysis by both Coliscan Easygel and MF techniques. To quantify the contamination in the sample, a duplicate serial dilution was analyzed by turbidimetry and plated on nutrient broth.

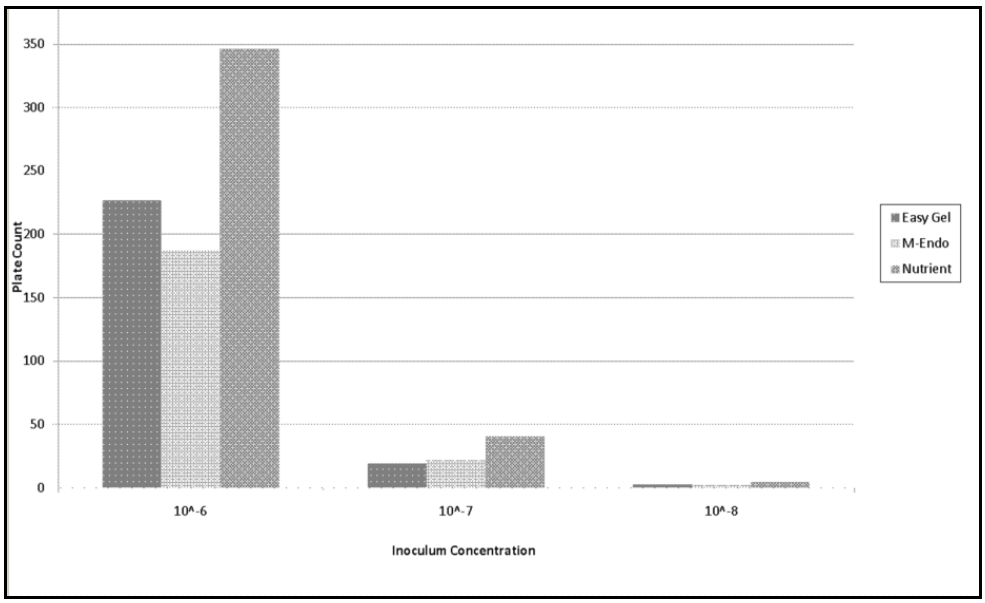

Fig. 1: Laboratory Comparative Analysis

Medium	Positive Reaction	Preparation		Transportation		Cost (per 50ml)
		Advantages	Disadvantages	Advantages	Disadvantages	
m-endo LES (2 mL ampules)	TC metallic green sheen	Pre-measured, pre-mixed, & pre-sterilized	none	Small, easy to pack	Must be kept cold	$10*
MI agar (50 mL glass bottle)	TC blue	Pre-mixed	Must be measured & sterilized between testing	none	Breakable & must be kept cold	$21.75
MI broth (50 mL bottle)	TC blue	none	Must be measured, mixed, & sterilized between testing	none	Breakable & must be kept cold	$22.35

All medium must be incubated at 35°C +/- 0.5°C. Table does not include shipping costs.
*Sold only in sets of 50.
TC = Total coliforms

Table 1: MF medium selection analysis

The Coliscan Easygel method is capable of detecting a contamination level as low as 1 coliform forming unit (CFU) per 100 mL; however this level is too dense to generate linearity among absorbency data. Therefore, samples were diluted to absorbency in the linear range and multiplied by the dilution factor to obtain a more representative value. During incubation, the Coliscan Easygel plates were counted every hour from hour 18 through hour 22, as illustrated in Figure 2. To evaluate further the usefulness of incubation temperature flexibility offered by in the Coliscan Easygel method, samples were analyzed in duplicate using incubation temperatures of approximately 37°C, 30°C, and 25°C for 24 hours (see Table 2). Plated samples were counted every hour from hour 18 through hour 22, as shown in Figures 2 and 3.

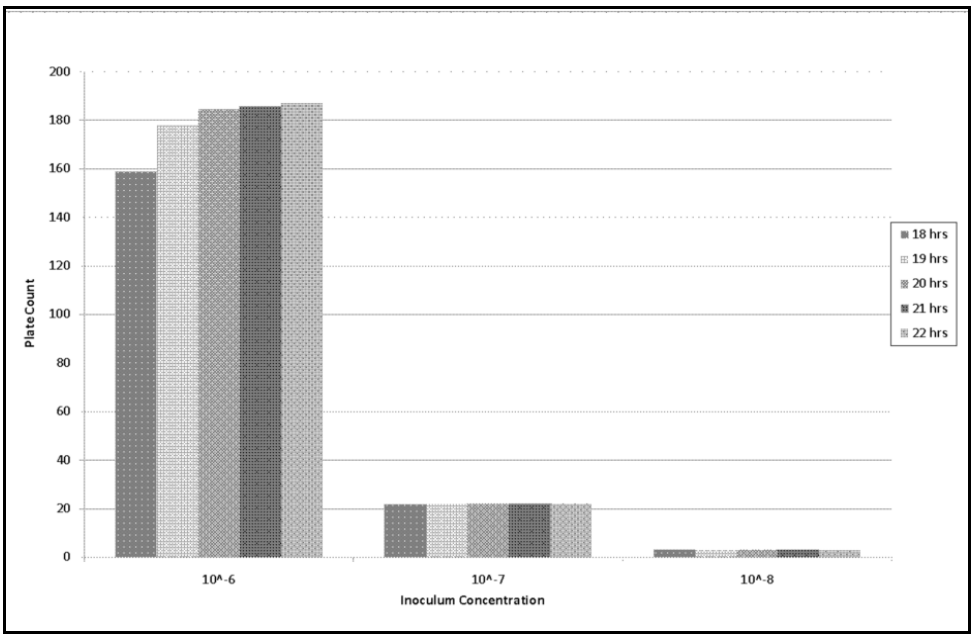

Fig. 2: Coliscan Easygel Laboratory Analysis

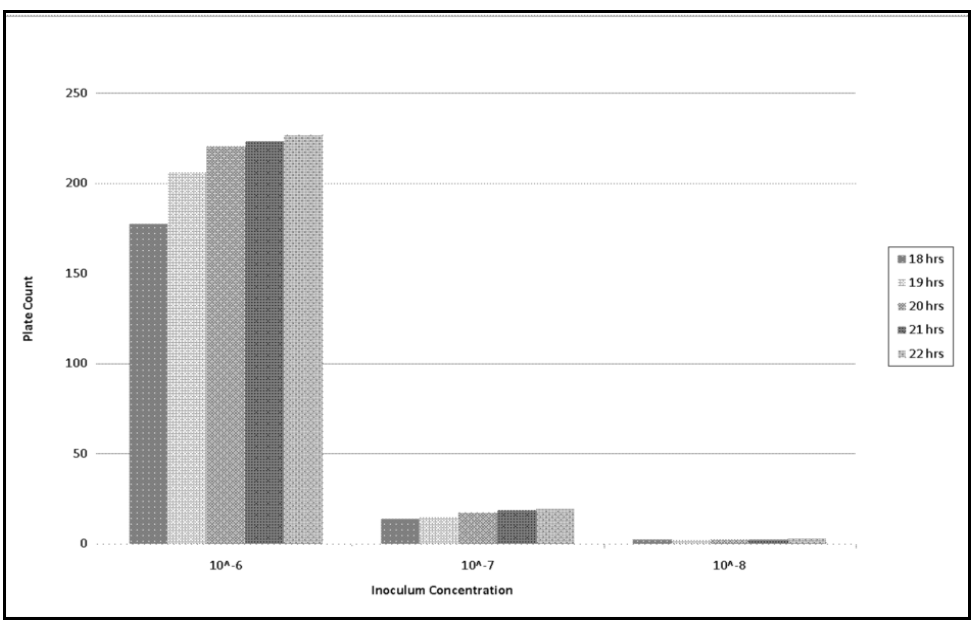

Fig. 3: Membrane Filtration Laboratory Analysis

Table 3 summarizes the costs associated with field analysis of 10 samples using Coliscan Easygel and MF with m-endo. Comparing advantages and disadvantages of Coliscan Easygel, Table 4 more clearly evaluates the comprehensive cost of this method. The Mann-Whitney hypothesis test was used as a nonparametric analog of the two-sample hypothesis tests, comparing the medians of the Easygel and MF data sets rather than the means, thus adjusting for the non-normal distribution. Table 5 presents the results of the statistical evaluation for the comparative analyses performed both in the field and in the laboratory.

Table 3: Coliscan EasyGel versus MF using m-endo cost comparison

Table 3 summarizes the costs associated with field analysis of 10 samples using Coliscan Easygel and MF with m-endo. Comparing advantages and disadvantages of Coliscan Easygel, Table 4 more clearly evaluates the comprehensive cost of this method. The Mann-Whitney hypothesis test was used as a nonparametric analog of the two-sample hypothesis tests, comparing the medians of the Easygel and MF data sets rather than the means, thus adjusting for the non-normal distribution. Table 5 presents the results of the statistical evaluation for the comparative analyses performed both in the field and in the laboratory.

LAB RESULTS				
Dilution Series		**10^{-6}**	**10^{-7}**	**10^{-8}**
1	**P**	0.0122	0.6015	-
	H_o	Reject	Fail to reject	Fail to reject
FIELD RESULTS				
Dilution Series		**3ml**	**4ml**	**5ml**
1	**P**	-	0.0809	0.0809
	H_o	-	Fail to reject	Fail to reject
2	**P**	-	0.1904	0.1489
	H_o	-	Fail to reject	Fail to reject
3	**P**	0.0809	0.1489	0.1489
	H_o	Fail to reject	Fail to reject	Fail to reject
H_o (null hypothesis) – The two population medians are equal. H_a (alternative hypothesis) – The two population medians are not equal. Alpha – 0.05				

Table 4: Mann-Whitney hypothesis test results

Advantages	Disadvantages
Easier to differentiate colonies with larger plates	Plate lids fit loosely – plates must be stationary 40 minutes prior to traveling to ensure no spilling
Incubation temperature is flexible	Unable to detect less than 1 CFU/100mL
Decreased cost in terms of time spent testing and training	Larger plates require more space in incubator, limiting number of tests that can be performed simultaneously
Decreased monetary cost (less equipment required)	Positive reaction capable of producing various shades of color causing uncertainty in results

Table 5: Qualitative Coliscan EasyGel

DISCUSSION

Although its use of minimal equipment makes Easygel relatively inexpensive in monetary terms, time spent training and testing depends largely on the medium. Not only must the composition of the medium be considered, but the physical state in which the medium is available also affects the ease with which this method can be used in the field and the validity of its results. This work found that medium sold in pre-measured, pre-sterilized ampoules decreased the number of sample results discarded due to spills, fractures, and possible contamination. The MI medium results showed a better recovery rate for EasyGel than for m-endo medium (USEPA 1992); however, the MI medium is commercially available as both powered broth and bottled agar. Further, additional equipment and care are required to prepare and protect pre-pour plates prior to and during travel.

Small discrepancies found between duplicate samples analyzed using both techniques appear to reflect the nature of the medium used or the technician's ability to distinguish colonies representing a positive reaction. This ability may be affected by incubation temperature, size of Petri dish relative to magnitude of contamination, or amount of training and experience in identifying and counting colonies.

Table 2 indicates that although dependant on contamination level and dilution, both techniques offer valid results an incubation time of less than 24 hours. Reliance this conclusion is ill-advised when conducting field work due to uncertain levels of contamination in field samples. As expected, samples analyzed using the Coliscan Easygel technique showed similar results at varying temperatures. In some cases, the number of colonies representing a positive reaction decreased over time, perhaps because colonies grew together or because the technician was unable to quantify colonies representing a positive reaction. For example, non-coliform colonies may have been identified as a positive reaction before color uptake was absolute. A similar analysis was performed in the field using duplicate Coliscan Easygel results after incubation at 95^{o}F (32^{o}C) for 24 hours, then at room temperature for 48 hours; as suggested by Micrology Labs Inc. These results are unavailable for quantitative analysis, however, because due contamination levels were misjudged resulting in an unproductive dilution series. Nonetheless, the colonies identified as total coliforms were better differentiated after incubation at a higher temperature for a short period of time.

In general, the MF technique using m-Endo LES broth ampoules produced a slightly better recovery of total coliforms in both laboratory and field settings. This method, however, was significantly more expensive and required more time for both training and testing. In both field and laboratory comparative analyses using the Mann-Whitney hypothesis test, the duplicate samples analyzed using Coliscan Easygel and MF techniques were shown to come from the same population within a 95% confidence level. The Coliscan Easygel data meet the data quality objectives for characterizing the magnitude of contamination found in natural field samples, permitting more accurate calculation of the effectiveness of engineering solutions. Samples, however, should be analyzed in duplicate or triplicate to account for inherent variance. Further, due to limitations specified by the manufacturer on sample volume, the Coliscan Easygel technique is practicle only for a specific range of expected contamination.

Sustainability of Rural Water Supply Projects in Nicaragua

Jairo Hernandez Alvarado

Fondo de Inversion Social de Emergencia (FISE), Direccion de Operaciones y Desarrollo Local (DODL), Managua, Nicaragua. FAX (505) 278-1673; PH (505) 412-9135; email: jairoihernandez@hotmail.com

Abstract

Access to safe and freshwater service without sustainability is a critical issue for many developing countries. From the past decade, Nicaragua has been working on increasing access to water and sanitation services with sustainability in rural areas through the Emergency Social Investment Fund (Fondo de Inversion Social de Emergencia, FISE) which is the governmental agency in charge of investments in rural water and sanitation solutions. The experience with rural water and sanitation rural systems began in 1977 with the Rural Basic Sanitation National Plan (PLANSAR). PLANSAR was designed to increase coverage of water and sanitation services, using technical solutions of the urban sector. During the period 1977 through 2000 there was no community participation at all. In 2000, The World Bank conducted an evaluation of the social fund and found that half of the sampled systems supplied water on a regular basis, and half supplied water on average only three days per week. The low supply systems experienced operations and maintenance difficulties. In these sampled systems, the operations and maintenance was under the responsibility of the central and municipal agencies and community participation and training was virtually non-existent.

Currently, FISE efforts are focused on providing adequate access to safe water for human consumption and on improving sustainability of water supply and sanitation projects. The enhancement of sustainability is based on the application of a current rural model that has incorporated lessons learned from previous experiences. The key to this improvement is the community participation in the entire project cycle. In addition to technical aspects, the rural model strengthens the local community's capacity to manage services by supporting an effective community participation process during the project cycle, by introducing sound financial and economic principles to value water and sanitation services, by training community-based water committees and by clarifying the roles and responsibilities of the various stakeholders including the municipalities. Since 2004, FISE has been applying the rural model and has funded 117 water supply and sanitation projects and trained the same number of Water and Sanitation Committees with the main task of operating and managing their water supply and sanitation systems in coordination with their municipalities.

Introduction

The purpose of this paper is to present the experience of the Emergency Social Investment Fund (FISE) at the rural water sector in Nicaragua. In this paper are summarized the processes implemented by FISE and the lessons learned in the field under the perspective of a participatory approach at local level as a central element in the sustainability of rural water supply projects in Nicaragua.
The paper starts by describing the background and the evaluation process practiced for the 2002-2004 period. Afterwards, it explains the rural model, the decentralization process and the institutional mechanisms currently implemented by FISE. Further it outlines the project cycle highlighting the community participation in every stage. Finally, the paper concludes by stating the community participation as a decisive component in the project cycle with emphases in the reinforcement of other components from the last stage of such cycle.

Background

FISE is a governmental agency created in 1990 as a decentralized institution and a temporary body to alleviate the poverty caused by the lack of investment in basic social infrastructure in the countryside of Nicaragua. Some years later, FISE became a permanent entity and innovative institution concerned about the impact and sustainability of its investments in sensitive issues such as education, health, road infrastructure and potable rural water and basic sanitation.
Nicaragua's rural water and sanitation sector is characterized by a low coverage level. In this context, FISE has increased the allocation of national and international funding for projects on the rural water sector as part of the National Development Program (NDP) to provide adequate access to safe water for human consumption. Currently, FISE is committed not only to increase coverage of water and sanitation services but also to improve sustainability of projects developed under the rural water sector program. From lessons learned in the field, sustainability has become a major concern of water supply projects once the infrastructure has been completed. The problem is mainly characterized by a short-term disuse or premature deterioration of part or sometimes the entire water systems.
As part of a an institutional initiative of summarizing the experiences and impacts in the rural water sector, FISE conducted a survey for the 2002 – 2004 term in which collected water supply project information was connected with construction, management, operation, maintenance, community participation and environmental protection. That survey showed serious problems threatening the long-term sustainability for water supply projects (Martinez, A., 2005). More than one third (36%) of the sampled systems were not working properly since they were supplying water only three or four days per week. Some of the main weaknesses identified in this evaluation can be summarized as follows:

Low Cost Recovery. In small piped systems using electric pumps often the tariffs are modified by reducing them to rates generally lower than the pre-established tariff

rates established in the formulation stage of the project. Many times, this situation pushes municipalities towards subsiding operation and maintenance costs in order to keep the systems working properly to supply water on a regular basis. Eventually, these subsidies are withdrawn leading to a total collapse of the system.

Poor Communication. Lack of communication at the local level weakens project the sustainability. In the evaluation, community members mentioned that they do not understand how the tariffs were calculated or even worse how much money was needed for the system operations and maintenance in any given month. Such lack of communication creates problems of distrust among the project beneficiaries.

Poor Planning Work at Local Level. At the feasibility stage, technical consultants in charge of the planning were not interested in getting feedback from community members and then integrating the public comments into the final plan. Typically the consultants developed their studies by focusing only on technical aspects without including interaction at local level.

Community Participation

Typically, in Nicaragua the rural water supply systems can be gathered into five groups: (1) small piped systems using electric pumps (Miniacueducto por Bombeo Eléctrico, MABE), (2) small gravity-fed piped systems (Miniacueducto por Gravedad, MAG), (3) boreholes with hand pumps (Pozos Perforados Equipados con Bombas de Mano, PPBM), (4) hand-dug wells with hand pumps (Pozos Excavados Manualmente Equipados con Bomba de Mano, PEBM) and (5) Rehabilitation and Extension of Existing Systems (Mejoramiento y Ampliación de Sistemas Existentes, MASE). While these types of water systems do not represent complex technologies, when governmental agencies or international donor organizations practice their periodical evaluations, a high number of those systems are non-functional or poorly maintained, being consequently classified as non-sustainable in the long-term.

A lesson learned over the past few years is that community participation in rural water supply and sanitation projects is vital. The higher the level of community participation in establishing a service, in implementing it and in operating it and maintaining it, the better sustained the service (Olatunji, 2003). Therefore, communities should be properly involved throughout the entire project cycle process, from identification, investment, selection of technologies, financial contribution, construction and the operation and maintenance stage.

There is no a precise definition for community participation, but it can be understood in terms of activities performed by the communities in development projects including elements such as assessment of the local situation, definition of the problems, setting of priorities, making decisions, planning of action programs to solve the problems, sharing responsibilities in project implementation and evaluating and modifying the project (Whyte, 1986). This kind of definition involves all the role players regardless of age, gender, educational level or socio-economic standing. Historically in Nicaragua, the ‘idea’ of community participation was limited to the

concept that plans and decisions were made by major leaders and consultants and then communities were informed of the decisions taken on their behalf.

Although community participation is nowadays an essential foundation-stone of water and sanitation projects in developing countries, this alone is no automatic guarantee of success. The only way of approaching such a guarantee is to build in all stages, in as many aspects as possible, and for all stakeholders, a clear understanding that participation is more worthwhile than non-participation (Carter, Tyrrel and Howsam, 1999). In order to encourage greater participation from community, municipalities, civic groups and all stakeholders, FISE implemented a project development model in which municipalities and communities play a paramount role in all stages of the project cycle. This model is implemented under the decentralization process where all the responsibilities in the project cycle including long-term support to the community organizations are transferred to municipalities.

From evidence in the field, it is known that both municipalities and communities are not capable of developing, at least in the short-term, all stages of a water supply or sanitation project without institutional support. The need of institutional support at local levels is a concern addressed by National Decentralization Policy "defining" FISE as the institution in charge of implementing actions or mechanisms aimed at developing local capacities focused on improving the investment management and strengthening organizations at the local tier (Reglamento Operativo, 2006). The implemented mechanisms are accompanied by integral approaches such as gender, environmental management and social inclusion. The application of these approaches takes into consideration the fact that Nicaragua presents a diversity of cultural, ethnical and lingual aspects and considers poor's needs for the selection of technical service options and training needs.

Institutional Support

The institutional support to strengthen municipality and community capacities is provided through three modalities: (1) Direct Technical Assistance (from FISE), (2) From External Technical Assistance (Service Providers) and (3) Training.

Direct Technical Assistance. It is provided by Municipal Advisors directly from FISE and is aimed at Municipal Technical Unit (Unidad Técnica Municpal, UTM) personnel to be supported in the process of formulation, assessment, tender procedures, hiring, supervision, training and community organization. Direct Technical Assistance is also in charge of verifying the accomplishment of the all procedures established for the water supply project cycle.

External Technical Assistance. Outside consultants are hired by municipalities in order to deal with a specific stage in the project cycle. Usually, this kind of assistance is hired for cases in which municipalities need to carry out a task that requires a multidisciplinary staff. Municipalities have to guarantee that the assistance developed by the contractor (service provider) takes into account the application of the integral

approaches (genre, environmental management and social inclusion) and the training for community members on the aforementioned topics.

Training. Training has as its main objective the improvement of capacity building for local government, local stakeholders and community organizations. In this context, training has been conceived to update and extend the knowledge of investment management in a decentralized environment, cycle project administration, supervision, operation and maintenance of water systems and their legal aspects.

Integral Approaches

Gender. The gender policy implemented by FISE has the purpose of contributing to the equality of rights and opportunities among men and women to take part in the decision making process of a water supply project, assuming responsibilities and benefits from the human, social and economic development as an instrument to struggle against poverty (Reglamento Operativo, 2006). In rural regions of Nicaragua historically women and children spend a good part of the day fetching water from rivers or wells (World Bank, 2008). As part of the decentralization process undertaken by FISE, gender policy highlights the principles of equality of opportunities to have access to services through the empowerment of men and women in all stages of the project implementation.
The application of gender approach in water supply projects not only requires a positive attitude towards gender issues, but also the acquisition of relevant skills. Thus training modules for all categories of staff should have a gender component tailored towards their specific job performance with the aim of sensitizing all on the need to ensure women's participation in projects (Yankson, Dotse and Laryea, 1997). To ensure the application of gender approach, the following actions have been implemented as part of the decentralization process undertaken by FISE:

- Incorporation of gender approach into regulatory documents, operating manuals, educational materials, institutional programs, terms of references and contracts to be applied at any stage of the project.
- Incorporation of gender workshops into the institutional budget.
- Involvement of municipalities in the creation and implementation of their own gender policy promoting a wider women's participation as members of UTM staff. In the case of communities, women's participation in local committees should be encouraged to at least a level of 30% to include senior positions such as president or treasurer.
- Support the materialization of socio-economic infrastructure projects aimed to raise women's incomes and strengthen their self-esteem and leadership skills.
- Monitoring of the gender approach indicators for evaluating impacts of gender policy on projects (Reglamento Operativo, 2006).

Environmental Management. In Nicaragua, the regulatory framework that organizes the environmental evaluation system is contained in Decree No. 76-2006.

This framework is part of the strategy that Ministry of Environment and Natural Resources (Ministerio del Ambiente y Recursos Naturales, MARENA) is implementing to decentralize the national environmental administration. The purpose of this initiative is to see that the environmental assessment and permits requested by the General Law of the Environment (Law 217) can be obtained in more efficient and effective way.

According to Decree No. 76-2006, projects not included in its classification are those that can cause low potential environmental impacts and therefore, are not subject to an Environmental Impact Assessment (EIA) for a further environmental permission. In this Decree, rural water supply systems (MABE, MAG, PPBM, PEBM and MASE) are classified as projects that cause low environmental impacts and therefore are excluded from the Decree Classification. For this type of projects, municipal authorities can establish their own environmental procedures in the conferral of environmental permission. To support the municipalities and as part of the decentralization process, FISE developed the Environmental Management System (Sistema de Gestión Ambiental, SISGA) to incorporate all the environmental aspects and risk management in the respective stages of project cycle. SISGA allows municipalities apply preventive actions to mitigate possible adverse effects caused to the environment by the construction of water supply infrastructures.

Basically, SISGA is constituted by a set of instruments that establishes the procedures to be incorporated in the different project cycle stages in order to prevent or mitigate possible negative effects caused by the construction of water supply infrastructure. The major instruments used in the SISGA are the following: (1) Environmental Community Diagnosis, (2) Environmental Classification According to Decree No.76-2006, (3) Emplacement Evaluation, (4) Environmental Basic Requirements, (5) Environmental Analysis and (6) Environmental Assessment Report.

Social Inclusion. Social inclusion means state of being included in a community and society as a whole; a condition in which individuals and groups can access the range of available opportunities, services and resources and contribute to their planning and decision making. It also refers to the actions and processes needed to transform situation of those who are socially excluded, by influencing institutions and changing the perceptions that create and sustain exclusion (Beall, 2002).

The main objectives of the FISE social inclusion policy are: (1) promote social, economic and cultural development of vulnerable groups living in severe poverty, (2) guarantee facilities aimed at easing access to handicapped people and (3) sensitize local governments for inclusion of indigenous people in municipal programs (Reglamento Operativo, 2006).

Community Organization: Drinking Water and Sanitation Committee

Drinking Water and Sanitation Committee (Comité de Agua Potable y Saneamiento, CAPS) is the local organization in charge of leading community participation in all project cycle stages. CAPS is constituted by six members regardless of the type of water system (MABE, MAG, PPBM, PEBM and MASE). The positions in

hierarchical order are: President, Vice-President, Treasurer, Secretary, Hygiene and Environment Officer and Propaganda Officer. It is expected that women take at least 30% of the leading positions such as President, Vice-President and/or Treasurer (Manual de Administración del Ciclo de Proyectos Municipal, MACPM, 2007).
The CAPS constitution is carried out in a general assembly which is conducted by a municipal representative. The election process is valid with the attendance of at least 80% of head of the household. In the case of attendance less than 80%, another assembly should be carried out; if the next assembly attendance is still below 80% of head of the households, permanent project suspension from Multiyear Municipal Investment Plan (Plan de Inversión Municipal Multianual, PIMM) should be considered.

Project Cycle and Community Participation

The activities established for the rural water project cycle developed by FISE, emphasizes on the application of gender approach, environmental protection, community participation and community strengthening in management, operation and maintenance of water systems. The rural water and sanitation project cycle comprises the following stages (see Figure1): (1) Identification, (2) Pre-investment, (3) Construction and (4) Monitoring.

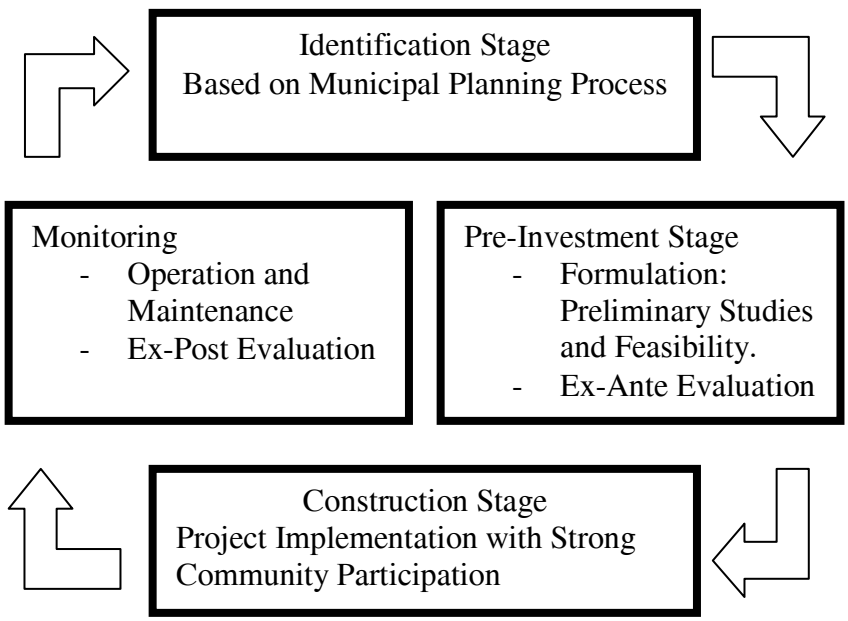

Figure 1. Project Cycle

Identification. This stage is based on a Municipal Planning Process (MPP) managed by the governmental agency Nicaraguan Institute of Municipal Development (Instituto Nicaragüense de Fomento Municipal, INIFOM). MPP is a participative

process at municipal level with the main purpose of establishing priorities in municipal investments (World Bank, 2008). This process involves consultations with all communities through participatory micro-planning workshops to review local problems, identify projects and analyze how the community, through its participation, can implement those projects. MPP leads to a Multi-year Municipal Investment Plan (PIMM) which is a tool for programming the use of municipal resources for every four- year period. Currently, FISE allocates funds only for projects included in the PIMM.

Pre-investment. In this stage all the activities related to formulation and project evaluation are developed. Formulation is divided in two phases: (i) Preliminary studies and (ii) Feasibility. Preliminary studies are conducted by municipal staff or a project formulator and comprise all the actions aimed at guiding community participation and establishing technical proposals. Preliminary studies are initiated when municipal representative or formulator meets local leaders and confirms the project request. Hence, it is set the date for the community assembly. In this case, local leaders assume the responsibility of guaranteeing the minimum attendance of household representatives.

Community assembly is the mechanism to confirm project demand and the occasion to organize local residents in the form of CAPS taking into consideration women's participation in leading positions. After the community has been organized, project formulator with CAPS support collects socio-economic and technical information, prepares and presents a preliminary report in a general assembly. The preliminary report should present the different alternatives proposed by formulator with pros and cons in each, so that local residents have the opportunity to select the most convenient and affordable alternative to fulfill their needs.

Once a community has selected what it considers its best alternative the formulator initiates the feasibility studies. In these studies the consultants are required to clearly demonstrate to the community and the municipality that the proposed project is technically, socially, legally, environmentally and economically viable through analyses, designs and all subsequent activities necessary for project completion. In addition to technical aspects, the formulator must include the two following community oriented training components: (1) Community Organization, Health, Environment and Gender (OSAG) and (2) Management, Operation and Maintenance in Water and Sanitation Projects (AOM). The OSAG training is aimed at water supply and sanitation project beneficiaries while AOM training is aimed at CAPS members.

As part of pre-investment stage, the Ex-ante Evaluation process basically will act as a quality control mechanism to ensure municipalities meet the necessary requirements to undertake a water and sanitation project. Currently, this process is still under FISE responsibility and is a mandatory step to obtain the project approval by donors or funding agencies. The Ex-ante Evaluation Stage implies verification of the appropriate technical regulations, community participation in the formulation process as stated in the MACPM and accomplishment of sustainability criteria.

Construction. At the beginning of this stage, the contractor along with the municipal representative present to local residents in a general assembly a detailed schedule of the different activities to be performed in the construction process, including the necessary community and CAPS training workshops. If the community undertakes to provide labor the community should be organized in task groups updating schedules monthly. Special attention should be paid to training workshops to guarantee full beneficiary participation. CAPS will be in charge of coordinating all the actions involving community participation and reporting to community about the project development.

Monitoring. Upon project completion, municipalities are in charge of monitoring the operation and maintenance of the project over a six-month period. During this time, municipal technicians are in charge of verifying the project sustainability through the effectiveness of operation and maintenance stage of the water system. In addition, the municipal technicians are responsible for assessing the CAPS performance and corroborating the implementation of the preventive maintenance annual plan designed in the pre-investment stage (project formulation).

Ex-Post Evaluation. Part of the author's duties as FISE Municipal Advisor is to monitor and evaluate the project sustainability once construction has been completed. In 2008 the author conducted an evaluation on small scale water supply projects finished in 2007 in the northern region of Nicaragua. The monitored projects had at least one year operating after their completion. In the inspection process, the author sampled 18 projects from which 4 were MABE, 1 MAG and 13 PPBM. From the sampled projects 6 (33%) were not supplying water to community mainly due to the following problems: (1) mishandling of electrical equipment, (2) vandalism (electrical equipment was destroyed), (3) reluctance to pay the pre-establish tariff, usually beneficiaries pay a lower tariff than that defined in the formulation stage to cover operation and maintenance costs and (4) lack of implementation of the preventive maintenance annual plan by CAPS. This was mainly observed in the PPBM equipped with hand pump whose major component is a rope that has to be replaced when wasted. The replacement of rope is not a complex activity since it does not represent a high cost for the maintenance stage and it does not require an expert labor for its installation. These systems were not operational due to the lack of rope which was not considered in the preventive maintenance annual plan.

Conclusion

The success about sustainability is determined by the understanding of this is a long-term process that requires full community participation in every stage of the project cycle. Comparing the lessons learned from the communities visited in 2007 to those learned from the 2002-2004 survey, there is a slight improvement in the proportion of operational projects after their completion. This small improvement is due to the remarkable local involvement in the entire project cycle in which community developed the sense of ownership and user's responsibilities. On the other hand, the

projects that did not produce the expected results after their completion, presented problems associated to the lack of community participation in the operation and maintenance stage. Hence, the encouragement of local participation in this stage is also crucial to avoid the waning of both the community enthusiasm and the CAPS motivation for keeping functioning.

Framework for Improving Water Security in the Middle East

John A. Kliem, PE

Commander, Civil Engineer Corps, U.S. Navy, Graduate, Industrial College of the Armed Forces, National Defense University, Fort McNair, Washington D.C. 20340. PH (703) 571-9780; email john.kliem@js.pentagon.mil. The information contained in this paper is solely the opinion of the author and in no way reflect the policy of the United States Department of Defense or any other agency of the U.S. Government.

Abstract

Middle Eastern water demands are going to exceed the supply by 2040 potentially exacerbating an already tense situation. Any lasting peace plan needs to address scarce water resource commodities. All stake holders need to play a role in determining the allocation of water to ensure water security needed for further economic development. The United States as part of an international coalition needs to guide the Jordan River riparian states in the development of a regional water governance body to provide the required transparency to fairly allocate water resources and to ensure that water does not become the flash point for future Middle Eastern conflicts.

Statement of the Problem

The water demands of the Israelis, Palestinians, and Jordanians by the year 2040 will exceed supply by 3,500 million cubic meters per year (mcm)(Shlomo, 2007). Any peace plan for this region will have to address many elements to include security for Israel, return of the Golan Heights for Syria, and an Independent Palestine. However, under this scenario each country would be free to manage the natural resources in the best interest of their country. The Palestinians and Jordanians have made valid claims that Israel is using more than their fair share of water from Lake Tiberias and the Mountain Aquifer that is partially located under the occupied portion of the West Bank. Additionally, Syria is demanding access to Lake Tiberias and the water that runs off the Golan Heights to support their settlements and recreation. These forces are aligned to reduce Israel's water supply. Consequently, it is difficult to imagine a stable peace in the Middle East without addressing the region's scarcest resource – water.

Background of the Issue Including U.S. Objectives

Water is an essential element of any civilization. Countries cannot thrive or begin to develop without water since it is required to support agricultural and industrial growth not to mention sustain and grow populations. The Syrians, Lebanese, Jordanians, Israelis and Palestinians all require water in order to develop their societies. All of these groups share principally the same water sources, the Jordan River watershed with associated springs and the Mountain Aquifer located beneath the West Bank and Israel, *figure 1*. Syria and Lebanon have several other better options for water than the Jordan River Watershed. Increases in population and agriculture are driving higher demand for this limited resource (Dillman, 1989).

Pollution from industry, sewage, and mineral deposits also threatens to diminish portions of the water supply in the region (Starr, 1989).

The water flows into the Jordan River in three ways surface water, ground water, and rainfall runoff. Four main tributaries the Hasbani, Dan, Banias and the Yarmuk Rivers feed the Jordan River (El Nasar, 2008). Prior to 1964 the flow of the Jordan River was 1,300-1,500 mcm (Amery and Wolf, 2000) today the flow is about 125 mcm (El Nasar, 2008). This reduction is due to the Israeli National Water Carrier and other water diversion projects by Syria and Jordan (El Nasar, 2008). The remaining 125 mcm has a high salinity and mineral content (El Nasar, 2008). Also during low flow periods a greater proportion of the flow consists of agricultural and sanitary sewer discharges. These discharges are most likely high in nitrates and biochemical oxygen demand making the water of little value and a potential pollutant to the Dead Sea that receives the flow from the Jordan River ("Jordan Water Resources", 2008).

During the 1967 War Israel took the Golan Heights from Syria and the West Bank from Jordan. The outcome of the conflict improved the hydro strategic situation for Israel. As a result of the 1967 War, Syria lost access to Lake Tiberias and its watershed including the Golan Heights but also lost access to the Banias Springs and River (Amory and Wolf, 2000). Not only did Israel gain access to more of the Jordan River Watershed but also exercised control over the aquifers in the occupied portions of the West Bank. Jordan and the Palestinians lost the most from this war from a hydro strategic stand point.

Israel's water requirements have grown to meet increased supplies as a result of the 1967 War. The country is known for its aggressive water development strategies that have made the "desert bloom" (Kay, 2003). However, with a finite supply of water and with many regional demands for this single resource some accommodations must be arrived at. Israel gets one third of its water from Lake Tiberias with the rest coming from the West and North Eastern Mountain Aquifer (Dillman, 1989). A large portion of the Mountain Aquifer is under the occupied portion of the West Bank, *figure 2*. Israel uses about 60 percent of its water for agricultural and only about a third of that water is made up of reclaimed wastewater (Amory and Wolf, 2000).

Jordan is truly a water limited country that shares most of its rivers with other countries ("Jordan Water Resources", 2008). The Yarmuk River, supplies Jordan with about 40 percent of its water distributed via the King Abdullah Canal with the rest of the required water comes from ground water supplies exceeding the safe yield for the aquifer by 120 mcm per year (Amory and Wolf, 2000). About 75 percent of Jordan's water goes to support agriculture of which only seven percent is from reclaimed wastewater ("Jordan Water Resources", 2008).

Palestinians living on the West Bank have very limited options for water supply (Amory and Wolf, 2000). As stated earlier, removing water from the Jordan River is not a good option due to upstream diversion projects and the remaining water being of very poor quality. The Israeli Government limits the number of wells and how much water the Palestinians can withdraw from the Mountain Aquifer (Dillman, 1989). Due to this practice Palestinians have access to about 18 percent of the ground water that is available in their territory (Amory and Wolf, 2000).

Syria wants access to Lake Tiberias as a source of national pride. It is doubtful that Syria would pump water out of Lake Tiberias simply due to the expense of pumping the water up and over the Golan Heights *(All Things Considered,* 2000 and Omestad; et al, 2000). Syria's primary water sources are from the Euphartes and other sources to the north which could be more economically developed. Once Syria gained access to the Golan Heights and Lake Tiberias they could begin to collect water run-off from the Golan for their settlements. One legitimate concern that Israel may have is that Syria since it is un-interested in water from Lake Tiberias may not be as rigorous in controlling the quality of water run-off from the Golan Heights. Settlements could substantially degrade the quality of water from point source and non-point source pollution (Omestad; et al, 2000).

It will be difficult for Israel's economy to relinquish control over the water resources of the Golan Heights and the Mountain Aquifer. However, this appears to be the course required for peace and peace is more important to Israel that any water source (Author Interview, 2008). The Palestinians and Jordanians are anxious to have more water resources and claim that Israel is taking more than their fair share of water. In addition to Israel's water quantity requirements equally important is Israel determination to maintain the quality of its water sources.

The 2006 National Strategic Strategy, Section IV states that the United States will "work with others to defuse regional conflicts" (Bush, 2006). This is not a new objective similar wording was used in the 2002 National Security Strategy. In 2002 we were concerned that even if the U.S. does not have a stake in the conflict we should work to defuse the conflict because our enemies may capitalize on the situation to achieve their own objectives (Bush, 2006). There is the potential of withdrawal of Israeli forces from portions of the Northern West Bank and the establishment of a Palestinian government. One possible next step could be the establishment of an independent Palestine and the return of the Golan Heights to Syria. Simultaneously we must create an environment to ensure security for Israel in order to realize lasting peace in the region.

It is in our country's interest to establish conditions that will lead to prolonged stability and economic growth for the Jordan River States Region. The issue of water supply for Jordan, Palestine and Israel is essential to lasting peace in the region and must be approached in a regional systemic manner as described in the 2006 National Strategic Strategy which has proved successful in dealing with past Israeli-Palestinian Issues (Bush, 2006).

Economic growth is certainly a requirement for stability in the Jordan River watershed area. Clean water is essential to economic growth and would be an essential ingredient in the creation of the Middle East Free Trade Area by 2013 as described in the 2006 National Security Strategy (Bush, 2006).

The creation of a stable Middle East is in the best interest of the United States. In order for our country to continue to serve as a viable World Leader we have an obligation to work for a fair and equitable solution to this issue. However, we have a credibility issue in the eyes of the Middle East. We have been seen as willing to go it alone and attack an Arab country as in the case of Iraq. Our country has been a very close ally of Israel since its inception. We have branded Syria as a state supporting terrorism and have recalled our ambassador. The Palestinian leadership is being run

by a state that we consider to be terrorists supported by Syria. In light of our credibility issue we must play a role of encouraging a resolution to this problem through a neutral party that has credibility in this region.

The water right issues that exist in the Jordan River watershed are very controversial and are closely linked to future economic if not survival of the countries involved. The solution must be brokered and monitored by a neutral party. It will take the United States to bring the interested parties to the table and establish the frame work that will lead to resolution of this issue. Fair water allocation is critical to regional stabilization and economic growth.

Analysis of Policy Options

As part of any peace agreement between Israel, Jordan, and the Palestinian Authority water rights need to be addressed for the Jordan River Watershed and the Mountain Aquifer. This paper presents several policy options to resolve the Jordan River and Mountain Aquifer rights. One possible option is the United States could adopt a policy that the water that is contained within a country's borders or on the boundary at the time of the Peace agreement would be retained by that country. The U.S. could promulgate a policy to transport water from "water rich" countries like Turkey and Egypt to meet the growing demands of the region. An alternative policy would involve the water resources of the riparian states and the Mountain Aquifer to be leased to a multinational water management company by the stakeholder countries. Finally, the Jordan River and the Mountain Aquifer could be declared a part of an International Water Management District led by a coalition of stakeholder countries and members of a United Nations Water management group.

One option would be for each stakeholder to control the water that is within its borders. Consequently, Israel, Jordan, Lebanon, Palestine, and Syria would have some claim to the Jordan River watershed and Israel and Palestine would have rights to the water in the Mountain Aquifer. The chief benefit to this option would be the U.S. could take a "hands-off" approach and not get bogged down in resolving regional water issues. Each country would be free to develop their water resources as they see fit. Most likely all countries to some extent would be in a race to exploit the existing water resources for their own benefit. We would see the existing supplies begin to become depleted or polluted through irresponsible drilling and uncontrolled agricultural and sanitary sewer run-offs (Dillman, 1989). Wealthier nations in the region would then invest in desalinization plants to sustain their countries leaving the poorer nations to fend for themselves. As the water becomes increasingly scarce tensions in the region would rise with a potential for environmental terrorism or attacks on other country's water resources out of frustration at the inequality of the water supplies. There would be a possibility that the region would continue to be unstable.

Another possibility is to transport water from water rich countries such as Turkey and Egypt or construct a large desalinization plant financed by the European Union or the US (Shuval, 1991). One author suggested that the price for a desalinization plant option is 3-5 Billion dollars (Shuval, 1991). This price tag appears low and most likely does not include the cost of distributing the water from the plant to the region. The price for desalinated water has decreased recently due to technological advances from two dollars a cubic meter to fifty cents a cubic meter

(Fry, 2006). However, the cost of moving water from a desalinization plant to the region's inland inhabitants would drive this cost much higher. The construction of a large desalinization plant is certainly possible with outside financing for the construction of the plant and possibly the distribution system. The simple construction of a plant and infrastructure is possible but this option lacks the overarching structure that would ensure continuity of service. Care would have to be taken to assure the region that the shipment of water from the desalinization plant would be stopped during times of political crisis as was recently done to the inhabitants of the Gaza Strip.

The idea of transporting water from Egypt or Turkey to the region is amazingly short-sighted and does not address the issues at hand leading to the water scarcity such as population control, predominance on an economy driven by a water intensive industry of agriculture. If water is piped into the region in the so called "Peace Pipeline" from Turkey, it would cost about 20 billion dollars to bring water from the Seyhan and Ceyhan Rivers to Israel, Jordan and Palestine (Cowell, 1991). Not to mention once these countries became dependent on Turkish or Egyptian water what would happen when a drought hit those countries. It is very doubtful that Turkey would support such an initiative as they are looking to ensure their own water supplies for the future (Author Interview, 2008).

The once international boundaries are agreed upon for the countries of Israel, Palestine, Syria, and Jordan. The countries of Jordan, Palestine, Israel, and Syria could jointly award a lease to an international water resource management firm consisting of principles from each stakeholder country. This water management firm would allocate the regions water supplies and develop water management projects that would enhance the economic development of the region. Each country would be charged for the water that they used. The poorer countries of the region would benefit from the capital of the multinational firm to use as leverage for water development packages that the might not have been able to afford normally. The Water Management firm would be responsible for getting water to all of the stakeholders' citizens in the region. They would have to work with each stakeholder country to ensure pollution control and that no one drills illegal wells into the aquifer.

This option has its benefits in that the entire region's water would be controlled by a single entity ensuring responsible management of the region's resources. If the company failed to manage the water resources appropriately, then the company would face economic penalties and possible the revocations of the lease. Poorer countries would have access to water development projects that may not have otherwise occurred. Each country would pay the same price for the water that is used. No longer would the strongest country get all the water.

There are some significant drawbacks for privatizing the region's water supply. It would be difficult to find an interested international company that would have the capital and other resources to take on this responsibility. An undertaking of this size in a region with such a troubled past possibly would pose too significant of a risk to be practical. A cost analysis is required determine the operational and maintenance costs of the existing distribution system with the capital expenditures required to bring the plants up to standards as well as future projects. These costs would have to be allocated across the regional water users to determine if such a

venture would be profitable. The economics and risk involved with this solution make this option unattractive.

The UN would declare the Jordan River Watershed and the Mountain Aquifer to be an International Water Management District. Declare the regional water sources to be an international resource to be managed by all stakeholders jointly under the leadership of a United Nations appointed Water Management Director. Each of the region's countries would appoint officials to be apart of the Water Management District. The district would set water rates for public and private consumption and establish water management policies concerning run-off and usage allocation. Rates would be developed to ensure operation and Maintenance of Plants, distribution systems and to ensure future capital development projects.

One attribute for this option is that the region's water resources are managed by a consistent entity in an attempt to fairly distribute the water resources. However, once again a major issue with this policy would involve if the stakeholders could trust the UN to manage their water resources. This is why it is important to ensure that each stakeholder appoints representatives to be involved in leadership of the Water Management District. In this way water management issues could become a source of cooperation vice conflict (Interview with Author, 2008). This Watershed Management entity would have to work closely with the stakeholder countries to oversee water quality to ensure that urbanization and pollution does not affect water quality. Each country would be required to enforce jointly agreed surface run-off water quality.

Another draw back for this option is the significant international financing required to get the water management district has established with the required infrastructure and initial water development projects. Eventually the International Water Management District could become self sustaining through water usage rates but this will take a substantial amount of time. The international community must decide if this region worth investing in to ensure peace and prosperity in the Middle East.

Policy Recommendation

The United States needs to work with the international community and the UN to establish an International Water Management District for the Jordan River Countries and the Mountain Aquifer. The U.S. should play a role in developing an international coalition to support this initiative to convince Jordan, Israel, Syria, Lebanon and Palestine to support the existence of an International Water Management District. It is critical that all stake holders fill leadership roles in the Water Management District under the leadership of a UN appointed director. This body has the greatest possibility of success since the stakeholders will be directly and jointly involved in solutions to their problems. This solution also removes the United States from the role of mediator or peace broker as previous administrations have done. The Arab world cannot view the United States has playing too heavy a role in the development of this solution as we are seen as an ally of Israel and not an honest broker.

ABSTRACT

It is the most precious commodity on earth, and billions of people do not have adequate means of obtaining it. Water both for drinking and sanitation use is essential to human life. Yet in a world where we have come so far in technological advancement, we still live amongst 2 billion people who do not have access to modern sanitation facilities and 1 billion people without safe and drinkable supplies of water. We have failed to address a problem that should have spurred world interest long ago. There are countries with millions of people, including children, dying each year due to a lack of clean drinking water and poor sanitation services. With a continuous rise in population throughout the world and an ineffective distribution of water resources, there can be as many as 140 million water-related deaths by 2025.

INTRODUCTION

"When the well is dry, we learn the worth of water." –Benjamin Franklin

For those of us who live in parts of this world where we are fortunate enough to have the luxury of clean sources of water, we may never fully comprehend the meaning of this phrase. Unfortunately, those living in underdeveloped countries may not understand it either. How can they appreciate the value of something as precious as water if the well was dry long before they even tried to pump? Sufficient and clean water is essential for the wellbeing of all living creatures. In an era where we have advanced in civilization, it is an unfortunate state of affairs that we are amongst a population where one in every six people lives without an adequate source of water.

Around the world today, poor developing countries are struggling with the lack sufficient and clean sources of water. A single person needs 4-5 gallons of water per day in order to survive. On average, a family in Africa uses about five gallons of water each day compared to that of the average American who uses 140 gallons of water at home each day. Water-related deaths are in the millions each year, and roughly 840,000 of these deaths are children under the age of 14. These deaths are not due to the lack of drinking water alone; the lack of proper sanitation systems brings a large risk of infection. There are more deaths caused by poor water sanitation and a lack of safe drinking water than by war, terrorism, and weapons of mass destruction combined.

WATER SOURCES

Water resources are classified in the form of surface water, sub-surface water, or frozen water. Surface water comes in the form of rivers, lakes, or fresh water wetlands. As they are constantly pumped out for human consumption, they are naturally replenished by precipitation. The volume of water also depends upon the rate it is lost through discharge into the oceans, evaporation rate, artificial reservoirs, permeability of the soil, and runoff characteristics of the land in the watershed. The sub-surface water known as groundwater is the fresh water located in the pore space of soil and rock or the water flowing within aquifers below the water table (Figure 1). The natural input to sub-surface water is seepage from surface water. The natural outputs from sub-surface water are springs, which are where the groundwater flows out of the ground and the aquifer surface meets the ground surface. The other form of output for sub-surface water is through seepage that leads into the ocean. Of all the Earth's water only 2.5 percent is found to be fresh water, with two thirds of that frozen in glaciers and polar ice caps. Several schemes have been proposed to make use of these glaciers but nothing has been done to date.

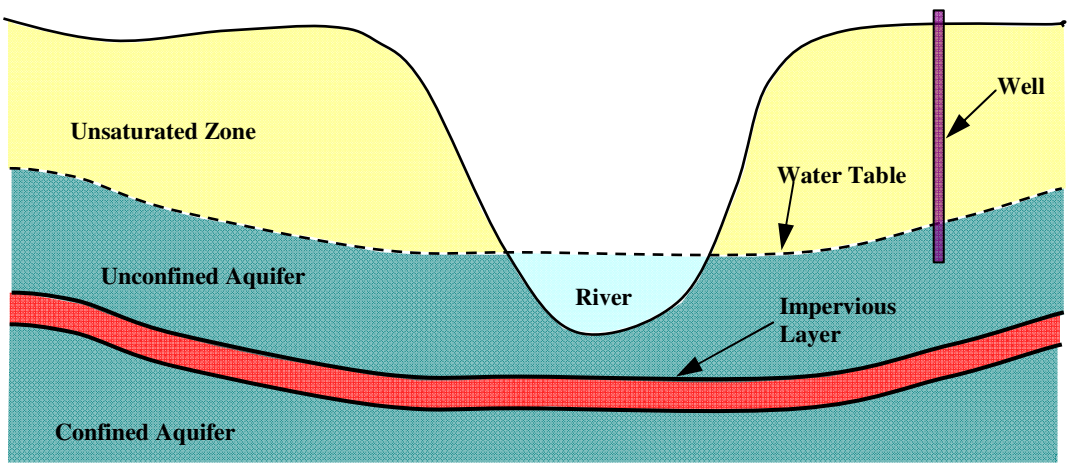

Figure 1. Water Table Varying With the Surface Topography

A new technology that has been widely used in arid areas such as the Persian Gulf is desalination. Currently there are over 7,500 desalination plants in operation worldwide with three out of five plants located in the Middle East. Desalination is an artificial process that takes sea water and converts it into fresh water. The more common practices of desalination are distillation and reverse osmosis. This technology has yet to make a major impact due to its high costs of operation. Most believe that as technology continues to advance, the costs will be significantly less. The cost to produce water from a desalination plant can range anywhere from $1,000 to $4,000 per acre-foot, compared to a cost of $20 to $150 per acre-foot for water pumped from rivers and lakes and $50 to $300 per acre-foot for reclaimed/recycled water depending on location. Groundwater pumping costs range typically from $600 to $700 per acre-foot. Small desalinations are slowly becoming more prominent but

until the cost is reduced to what communities can reasonably afford, this may not be an option.

With ongoing trends, many nations have fallen into a state of water stress or even worse, from water scarcity. Water stress is defined as occurring in an area where there is not enough water for all uses whether agricultural, industrial, or domestic. Water stress occurs when less than 1,500 cubic meters (or 52,972 cubic feet) of water is available per person within a year, while water scarcity occurs when less than 1,000 cubic meters (or 35,315 cubic feet) of water is available per person within a year. It is estimated that by 2025, more than 2.8 million people living in 48 countries may face either water stress or water scarcity.

POPULATION & GROWTH

The world's population has been growing steadily especially in the last century. Compared to the 1.6 billion inhabitants in the early 1900s, the population has grown exponentially to more than four times that over the past hundred years, now exceeding 6.7 billion people. The population is expected to grow to 7.8 billion by 2025 and 9 billion by 2050. Ninety percent of that growth is expected to take place in less developed nations. It has already been noted that over a billion people do not have safe and adequate sources of drinking water and that two and a half billion people are without adequate sanitation systems. What is even worse is that in 2025, it is expected that two out of every three people could possibly be without safe drinking water and basic sanitation services.

In 2000, the per capita average water usage in the United States was 1,430 gallons per day, which was down from 1,620 gallons per day in the previous decade. The U.S. is also the third largest population with very little or no threat of water scarcity. With a population of 305 million, Americans use up to 408 billion gallons per day. This includes water for drinking, bathing, cooking, washing, and maintaining lawns and gardens. In addition, water is in constant demand for the industrial and manufacturing sector to create products; the agriculture industry to provide food; and the energy industry to provide illumination, heat, and air conditioning. These are all critical needs to the consumer, who has long depended on such luxuries.

WATER-SCARCE NATIONS

The two largest countries, China and India, contain respectively 20 percent and 17 percent of the world's total population. That is a combined 37 percent of the world's population, and these two nations are also headed towards a scarcity of water, which should peak in the not too-distant future. Countries such as China and India may face severe water crises unless changes are made in their water management practices. China has already been regarded by the United Nations as one of the 13 water-deficient countries in the world. Though China has been diligently implementing seawater desalination plants along the coast of the southeast and near northern parts of China, there is still a shortage throughout the country. Currently there are an

estimated 400 cities throughout the country that are running short. With an expected 1.6 billion population by 2030, the water resources will likely plunge by more than 25 percent. In the past, India had greatly benefited from investing in the development of large water infrastructures, which resulted in enormous gains in food security and in the reduction of poverty. Unfortunately, India does not have the funds to develop new or upgrade existing facilities. In addition to that, India does not have the sources of water to provide for its growing economy and rising population. Due to its poor water supply services, farmers and urban dwellers have resorted to pumping out groundwater, which in turn has rapidly reduced water tables and depleted aquifers. In addition, 90 percent of India's territory is drained by inter-state rivers, and it is estimated that within the next decade, India's demand for water will exceed all sources of supply.

To some it may sound like a joke when one hears that the leaders in innovation of water technologies may be going through a water shortage crisis. Israel, the captain of the water industry who developed the technology of desalination and drip irrigation, has been fast approaching a water crisis. They currently have only three desalination plants with a fourth being built, which may not be completed until 2013. One of the factors that Israel is facing is poor management. Israel is in great need of a highly informed government that will address the problems that need the most focus and attention. After years of drought that have been plaguing their nation, and with increasing demand caused by a growth in population and the need to supply water pursuant to international undertakings, their resources have dwindled to a great extent.

In a country that's also a continent on its own, Australia anticipated that within the next decade, nearly every city will have to find and develop a new water supply. Next to Antarctica, Australia is the driest continent in the world. Due to a combination of a growth in population and recent prevailing climate changes, the already at-risk water resources have slipped into further jeopardy. Many of Australia's citizens have already experienced several water restrictions such as bans on washing cars, using sprinklers, and watering gardens. Australia will have to find new ways to provide water within the next 5 to 10 years. Building new infrastructure could very well cost up to $25 billion and would need to be paid for by higher charges to the consumers.

The hardest reality to accept is that there are potential water wars between countries that share rivers and lakes. Nearly 80 of Africa's river and lake basins are shared between two or more countries. Many countries also depend upon the inflow of water from outside their nation's boundaries. War and disputes over water may very well be the case within the next 25 years throughout Africa. Currently about half the population suffers from one of the major water-related diseases. More alarmingly, experts have estimated that one in every two people will face water scarcity. By 2025 it is predicted that 12 more African countries will join the 14 that are already suffering from water stress or water scarcity (Figure 2). Africa's water shortage woes result primarily from uneven distribution. One such example lies in the Congo basin,

an area where 30 percent of the continent's water drains but only 10 percent of the continent's population lives.

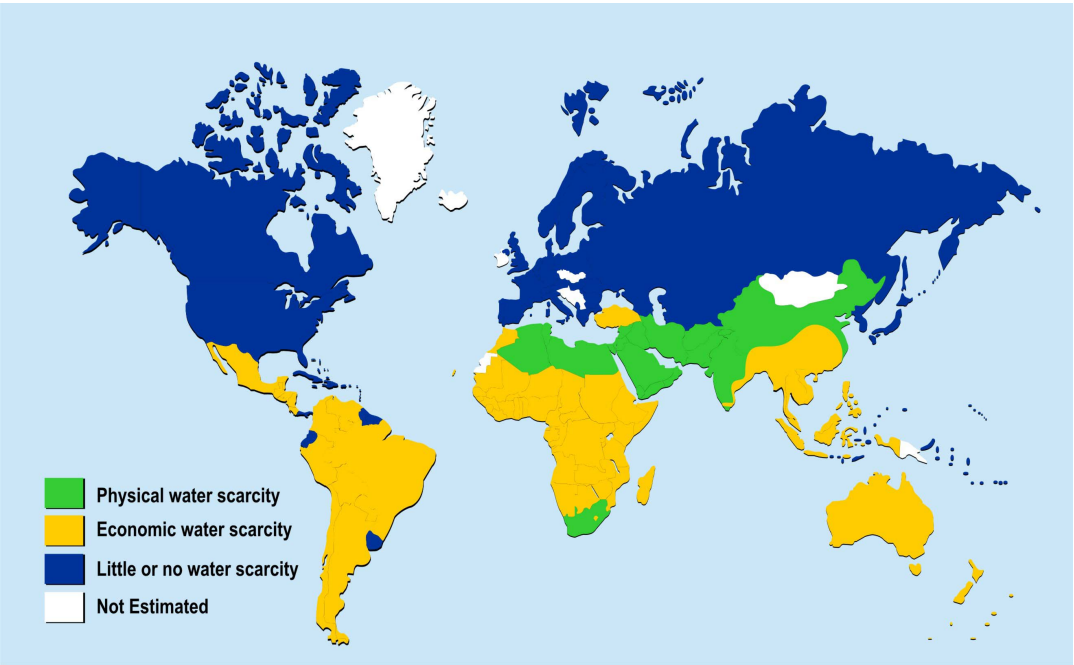

Figure 2. 2002 Trend of Worldwide Water Scarcity

WATER-BORNE DISEASES

It is a frightening thought that at any given moment, half the population of the developing world is suffering from a water-borne disease. A water-borne disease is any disease that is transmitted or spread through contaminated water. A disease can be spread by microorganisms such as protozoa, viruses, bacteria, and intestinal parasites. Contracting a disease can be easier than possibly imagined. It is as simple as eating food that was prepared by an individual who has already contracted a disease and did not wash their hands. It can also be contracted by touching something that was handled by an infected person and then transferring microorganisms to the mouth. The diseases just to list a few include:

- Diarrhea – Has been the leading cause of childhood death. Due to infection, may last from a few days to several weeks. Constant diarrhea may result in severe dehydration and shock. It can become life threatening due to fluid loss in water diarrhea especially in small infants or malnourished individuals.
- Cholera – Is one of the most rapidly fatal illnesses and a perfectly healthy person can become hypertensive with in an hour of the onset of symptoms. If proper medical treatment is not given immediately, an infected patient may die within three hours.
- Amoebiasis – Can be transmitted through the fecal-oral route in which water had come into contact with feces, poor sewage treatment, or

from the absence of cleaning after handling feces. It is estimated to have caused 70,000 deaths on an annual basis.

- Crytosporidiosis – A parasitic disease, whose symptoms include stomach pains, cramps, and a low fever. This disease is transferred by material such as earth water or uncooked or cross contaminated food that has come into contact with feces of an infected individual.
- Giardiasis – Caused by eating food contaminated by the unwashed hands of an infected person or drinking groundwater polluted by an infected animal. Symptoms include loss of appetite, fever, blood in urine, watery stools, upset stomach, and projectile vomiting. When present, symptoms may last one to three days.
- Schistosomiasis – Is transmitted when the larvae of the parasite are sheltered by snails and infect humans who come into contact with the infected water. The larva enters through the skin and travels through the bloods vessels and nests in the lungs. It is second following malaria as the most socioeconomically distressing disease. Schistosomiasis can damage internal organs and impair growth and cognitive development in children if it becomes chronic.
- Typhoid – Has been a continuous problem in less-industrialized countries mainly due to problems of unsafe drinking water, poor sewage disposal, and problem flooding. Transmission can be from contaminated water or milk. Symptoms include high fever, rose colored spots on the chest, and/or enlargement of the spleen and liver.

This is just a small list of over dozens of water-related diseases that have been a constant threat to the well-being of millions of people worldwide. An alarming 80 percent of illnesses in developing countries are water-related. The spread of these diseases is caused primarily by drinking water tainted with urine or feces of infected human beings or animals.

RECOMMENDATIONS

The first step to reducing this problem is to keep clean water clean and to dispose and treat sanitary waste in a safe manner. A common misconception is that the cost to repair the infrastructure of multiple countries would be too much for wealthier donor nations. Opportunities to help less developed countries do not lie in high-cost centralized water treatment and distribution systems alone. Practical innovative solutions such as point-of-use disinfection and safe water storage vessels can relieve short-term problems of water storage. The water supply, both clean and sanitary, is disinfected to kill any pathogens and to further prevent them from prevailing again in the distribution system. Without the disinfection process, the risk of water-borne disease is increased, and the problems will persist.

A fundamental answer to managing a water crisis begins with negotiating a standard of which nations are entitled to their share of water in a river or lake. Water crises are closely related to regional tensions, but history has shown that there has been far less

conflict over water than there has been conflict over cooperation. Formation of strong international institutions has been characterized as the way forward; they prevent costly disputes over a resolution and result in early intervention and management. Organization and collaboration are the keys to developing treaty agreements that promotes co-operative opportunities.

Another affordable method would be using electrolytic generators that produce sodium hypochlorite from salt water, then appropriately storing the treated water to prevent recontamination. This method has been proven to be effective in numerous households in Central America, Africa, and the Middle East. Much speculation has been developed that there is a short-term and a long-term measure to solving this large array of water-related issues. The short-term assessment should be for people to wash their hands as much as possible, boil water, and store it. Fifty percent of the places with unsafe water once had a system that functioned, but fell apart due to a lack of maintenance.

One of the major benefits that most are not seeing is that there can be a major return; for every dollar spent, there can be an economic return of $3 to $34 depending on the country. However, what can be far more precious is eliminating disease and death due to unclean water and poor sanitation, while supporting health and productivity gains. The United Nations has been diligently working to diminish by half the number of people without access to safe drinking water and basic sanitation by the year 2015. The United Nations created the Millennium Development Goals which is to reduce the number of people without access to safe drinking water by half and to stop unsustainable utilization of water resources. In 2002, two other goals were adopted which are to aim to develop integrated water resource management and water efficiency plans. By 2015 the goal is to halve the total number of people who do not have access to basic sanitation.

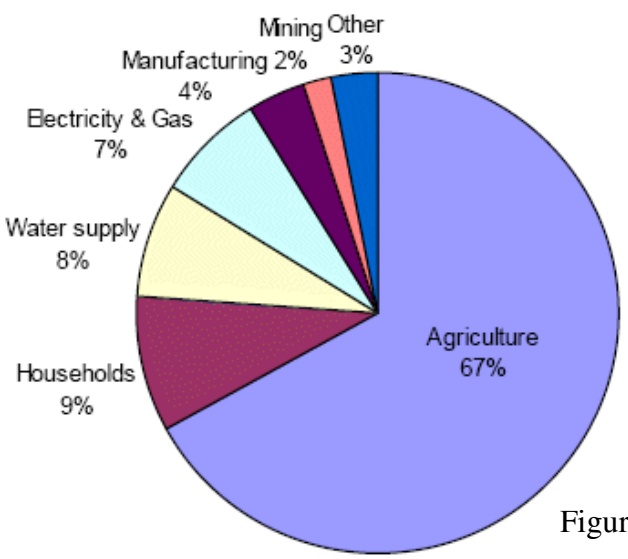

Figure 3. Breakdown of Water Usage

A long-term measure that can further impact the conservation of water would be the agricultural business. Worldwide agriculture plays a vital role in every economy and

therefore should be attended to. Most of our world's water supply is heavily focused on the agricultural business (Figure 3). But much of that water is being wasted from over-watering of crops. Developing countries especially would have to begin to produce more crop per liter of water, promote equitable access to water, and conserve their water resources. In order to avoid a future food shortage, there must be more investment to achieve productivity gains using existing and new technologies. For instance, if one farmer were to reduce water usage by a mere 1 percent, that would save over 7,000 cubic feet of water per year, which is enough to provide drinking water for 150 people. Irrigation technologies need to be upgraded, such as drip irrigation, which puts water where it is needed and is far more efficient than the use of sprinklers and flooding fields. Inexpensive technologies such as treadle (pump designed to lift water) or mechanical pump irrigation equipment on a smaller scale have also proven to be successful in increasing crop production and income. Further investment is not only cheap, but will ultimately save money on a much broader scope.

CONCLUSION

Water is the essence of life. Without water there is no life on earth and there is no more existence. We must treat water not as a commodity to be sold to the highest bidder or treat it as a right to only the privileged and wealthy, but as an indispensable component of human life. We, the nations of all mankind, must learn not only the system and practice of sharing equitably, but we must also embrace the furthering technologies and principles of protecting the environment and the sources of fresh water that belongs to us all.

It is not the obligation of the wealthy to establish an infrastructure of water conservation and sanitation facilities. However, for the sake of humanity and moral fiber, it would be a wise investment to help those less fortunate in the global mainstream. Repairing the damage that has already been done must take place immediately, eliminating water-borne diseases before they spread to the larger population. The more fortunate nations have an opportunity to do what is ethical and can reorganize the approach to providing water and sanitation services while at the same time protecting their existing establishments and preventing a similar fate. Unless these degrading conditions in poor, developing nations can be managed properly, even wealthier prominent countries will ultimately feel the impact of diminishing supplies of drinkable, useable clean water. Perhaps nations will one day be going to war not for oil, land, or other treasures, but the most important resource, water!

Abstract

The Hashemite Kingdom of Jordan, or simply Jordan, is a small county located in the Middle East. Jordan has borders with Saudi Arabia, Syria, Iraq, and Israel (see Figure 1). Jordan was established in 1921 and has very limited natural resources. Jordan's current (2008) population is estimated to be 6.5 million. The country has a total area of 750,000 km2, about one third (92,300 km2) of which is dry land while the other two thirds (329,000 km2) is irrigated land.

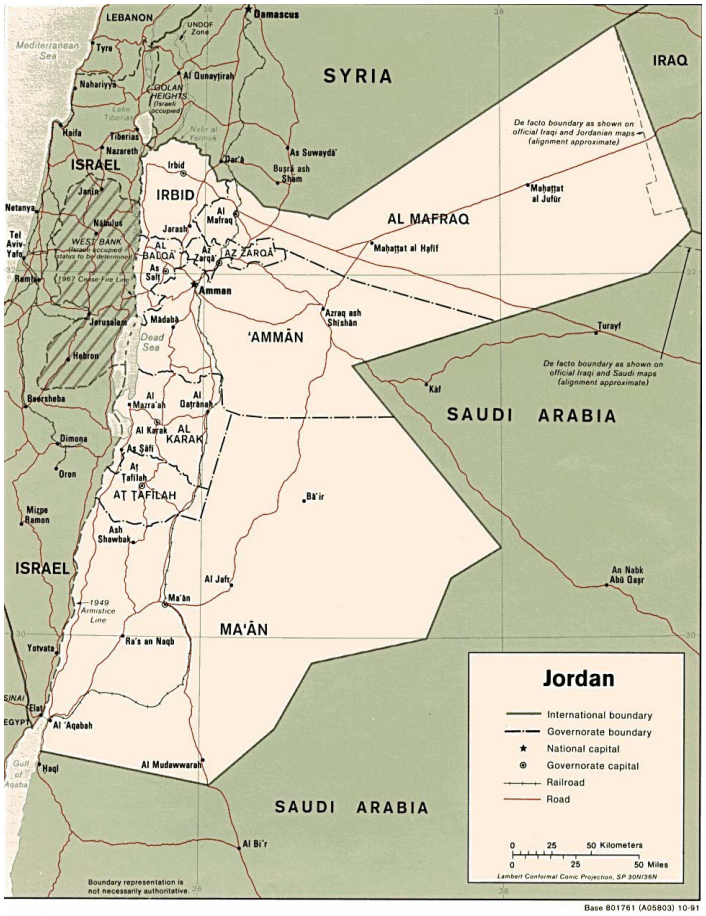

Figure 1. Map of Jordan (M. Mohsen, 2007)

Jordan's limited water resources fluctuated around a stationary. The normal population growth, in addition to the massive influx of refugees from neighboring countries, made the limited water resources in the country even worse. The majority of water resources experts classify countries with less than 1000 m^3 per (year-capita) as water poor countries. In 1997, Jordanians consumed only 883 million cubic meters (MCM), which translates to about 200 m^3 per (year-capita). The 1997 water consumption rate - when compared to the rates of neighboring countries - was 65% less than that consumed in Syria and Israel, and 85% less than that of Egypt.

The gap between water supply and demand is expected to increase due to the steady increase in population. If the current population growth trends follow what is projected, in 2025 the annual water consumption per capita will decrease from its 1997 level of 200 m^3 per (year-capita) to 91 m^3 per (year-capita).

In 2000, Jordan needed 1258 MCM to meet its domestic, industrial and agriculture demands. Faced with these challenges, the Jordanian government devised a plan aimed at reducing the demand and increases the supply of water. The increase of the water supply was partly achieved as an outcome of the peace treaty that was signed between Jordan and Israel in 1994, which ensures an additional estimated 215 MCM of water via the building of additional dams, as well as pipelines on the Yarmouk and Jordan rivers. Other projects that the Jordanian government proposed to improve water supply are purchasing water from other countries (i.e. Turkey) and/or constructing a canal "The Two Seas Canal or the Peace Conduit" to bring water form the Red Sea to the Dead Sea. The proposed Two Seas Canal will be constructed with the participation of Israel and the financial support of the United States and the European Union. The Canal will bring 1.8 billion m^3/yea of sea water which will then be treated using desalination to provide about 850 MCM of portable water to Jordan, Israel and Palestine.

The water issue in the Middle East is not only a limited resource, it's also a source of conflict that might require world intervention. Participation in and funding of such projects will, on the long run, provide the people of Jordan with the necessary supply of water , hence improving the overall status of the population as well as reducing any potential for conflict.

Climate

Jordan's weather is classified as semi-arid to arid with hot and dry summers, and cold and wet winters. Jordan's precipitation (see Figure 2) varies in magnitude, intensity, and distribution. Most of the precipitation in Jordan occurs between the months of October and May of each year. The average annual precipitation in Jordan is 50-200 mm, 100-300 mm, and 200-600 mm in Jordan's Desert, Jordan's Valley, and Highlands, respectively. In a typical wet year, the total precipitation is about 1200 MCM and is half of that in a typical dry year. The evaporation rates in Jordan vary form 63% from the highlands to 99% from the desert. The typical long-term evaporation average is 93%.

Surface Water Resources

The majority water re-charge comes from precipitation, which dramatically varies from year to year. The surface water, base flow, and runoff long-term averages are 713 MCM, 451 MCM, and 256 MCM, respectively. There are three major surfaces water systems in Jordan; theses systems are: Jordan River that has a catchment area of 18,194

km^2. The Yarmouk River which has a catchment area of 6,7890 km^2. About 1,160 km^2 of the Yarmouk River catchment area is located in Syria. The third major river in Jordan is the Zarqa River. The Zarqa River has a catchment area of 4025 km^2 and its water is not shared with any of Jordan's neighboring countries. The Zarqa River catchment area is densely populated; where about 65% of Jordan's population resides and about 80% of Jordan's industry located. The effluent form several wastewater treatment facilities (e.g. As-Samra, Jeresh, and Ba'qa WWTP) discharge to the Zarqa River. The Zarqa River is controlled by the King Talal Reservoir and its water is mainly used for agriculture and live stock demands. The percentage of treated sewerage that is discharged into the Zarqa River is 50% in the winter months and about 60% in the summer months. There are two surface water bodies in Jordan: The Dead Sea and the Gulf of Aqaba. Figure 3 shows the fifteen surface water basins while Table 1 provides a summary of the annual flow from each basin.

Groundwater Resources

Groundwater is considered to be the main source of water supply in many regions of Jordan and is the only water supply in other regions. More than half of the water supply in Jordan comes from groundwater basins. There are twelve groundwater basins in Jordan (see Figure 4). The Disi and Jafer basins are considered to be "fossil" aquifers. The annual safe yield from these two aquifers is 12 MCM. Recent studies showed that the Disi aquifer can support annual abstraction of 125 MCM for about 50 years. The two largest aquifers that are rechargeable aquifers are the Amman-Zarqa basin and the Dead Sea basin. The maximum annual safe yield from these two basins is 144 MCM. Table 2 provides a summary of the annual safe yield supply from various aquifers in Jordan.

Wastewater Resources

Twenty-six of Jordan's cities are served by nineteen wastewater treatment plants (WWTP). The Majority of these treatment plants are stressed. The treated wastewater is considered an integral part of Jordan's sustainable water resources system. About 70% of the population living in urban areas is serviced with sewer collection system. The annual treated wastewater effluent form theses serviced areas is about 80 MCM. The treated effluent is typically used to meet agriculture and live stock demands and as a groundwater recharge source. The agriculture demands are mainly directed towards the Jordan Valley, where the majorly of Jordan's agricultural is located.

The two largest wastewater treatment plants in Jordan are the As-samra and Irbid (Wadi AL-Arab) WWTP. The design capacity of the As-samra WWTP is 68,000 m^3/day and Irbid (Wadi Al-Arab) WWTP design capacity is 21,000 m^3/day.

Additional sustainable source of water in Jordan is obtained from desalination plants. There are two operating desalination plants in Jordan. They are the Abu Zeghan and Zara plants with a total combined treatment capacity of About 31 MCM (10 MCM from Abu Zeghan and 21 MCM form Zara). The desalinated water from these two plants is added to the overall water supply in Jordan. Desalination treatment plants are typically expensive to build and operate in a country with limited resources like Jordan.

Challenges

There are several challenges facing the water sector in Jordan. These challenges include elevated levels of normal population growth rates (including population migrations due to regional conflict), degrading surface and groundwater qualities, and changes in precipitation patterns due to climate change.

The annual average population growth rate is about 2.5%, which is relatively high when compared to other countries of Jordan's size and resources. The massive fluxes of

thousands of refugees (in the span of few months at a time) from neighboring countries as a result of several regional conflicts (e.g. the first Gulf War, the continuous Arab-Israeli conflict, and the second Gulf War) caused an alarming and sudden increase on the water demands in Jordan. In addition to the population increase, the living standards in Jordan are steadily improving and as a result the industrial and agricultural demands are increasing.

To make things worse, Jordan's population projections for the year 2020 is about 9.9 millions with 65% of the populations will be served with sewer service. The projected sewerage generation is about 237 MCM, which is a bout three times the sewerage generation form the current population estimates.

In 1999, the domestic water consumption was 231.5 MCM (29% of the total consumed water in the country). About 79% of the water supply for domestic uses comes from groundwater sources with the exception of the water that is pumped form the Yarmouk River to meet Amman's water demand. The portable water infrastructure in Jordan is not very efficient. Only 45% of the daily domestic consumption accounted for and about 55% of the daily domestic consumption is lost. Table 3 provides a summary of Jordan's water demands and their sources.

Table 3. Water Demand in MCM by Sector in 1999 (S. Tutundjian)

Use	Groundwater Sources (GWS)	% of Total GWS	Surface Water Sources (SWS)	% of Total SWS	Total Supply Sources TSS	% of Total TSS
Domestic	183	79	49	21	231	29
Industrial	35.5	94.4	2.1	5.6	37.6	5
Agriculture	256	49.1	265	50.9	521	65
other	7.3	64.6	4	35.4	11.3	1
Total	481		320		801	

The effluent's salinity from WWTP in Jordan is typically higher than normal due to low domestic use levels (due water conservation efforts, and intermittent service) and the use of standard treatment technologies like stabilization ponds in the current WWTP. In addition, to the reasons mentioned above, the high evaporation rate in Jordan results in loss of liquid sewerage water from the stabilization ponds to the atmosphere, which in turn increases the sewerage water salinity. The use of the brackish water to recharge groundwater sources result in additional degradation of the groundwater supply

The regulation on industrial discharge to the public sewer collection lines is loosely enforced in Jordan. Therefore, industrial effluent from various types of industries with varying industrial wastewater strengths are currently being discharged into public sewers collection lines and eventually treated by municipal WWTP using standard technologies that is used to treat domestic sewerage. As result, when released, the treated effluent from the municipal WWTP is less desirable for agricultural purposes.

Industrial demands accounts for about 5% (see Table 3) of Jordan's total water supply. About 94% of the industrial demand comes from groundwater resources. This is projected to increase due to improvements in the industrial sector in the country, Jordan's

inclusion in the World Trade Organization (WTO) and the signed free trade agreements between Jordan and the United States and the establishments of the free zones in different regions of Jordan. These agreements make Jordan a desirable destination for regional investors and manufacturers.

The agriculture sector in Jordan is the largest water consumer. This sector uses about 65% (see Table 3) of the total water demand in Jordan. About 49% of the agricultural demand comes from groundwater resources. The majority of the irrigated land in Jordan is located in the highland and the desert (about 52,700 hectars), and in the Jordan Valley (about 31,600 hectars).

It's clear the importance of groundwater in Jordan's overall water resources plan to meet its current water demand. Yet there is a shortage of about 40% in the groundwater supply to reach the current total water demand. The 2005 estimates of available water supplies in Jordan from various sources is 816 MCM (275 MCM from Groundwater, 56 MCM groundwater recharge, 395 MCM surface water, 80 MCM from WWTP effluent, and 10 MCM from desalinated water). The projected increase in the water demand form the three major sectors (99% of the total water demand) in Jordan are presented in Table 4.

Table 4. Previous, Current and Projected Water Demands in MCM (M. Mohsen)

Use	Year			
	1999	2005	2010	2020
Domestic	231	382	434	611
Industrial	37.6	81	99	146
Agriculture	521	858	904	890
Total	789.6	1321	1436	1647

A quick comparison of the water supply in 2005 (used as a reference for the comparison) with water demand in 1999, 2005, 2010 1 and 2020 (see Table 5) reveals major water deficit in all years analyzed expect in 1999. It's clearly demonstrated that the problem of water shortages in Jordan is a chronic problem for years to come. If the current domestic, agricultural and industrial practices are not addressed, the water supply in Jordan will deplete in quantity and quality with time. This will also make the problem of water shortages even worse than actually shown in Table 5. Overdraft of groundwater and surface water is creating a tremendous stress on the water supply in Jordan. Large losses from surface waters (i.e. the Dead Sea) are also a problem that the Jordan has to address in order to at least to reduce these losses.

Table 5. Water Management and Projections in MCM

Year	Available Water Supply	Demand	Deficit
199	801	789.6	+11.4
2005	816	1321	505
2010		1436	620
2020		1647	831

Accomplishment

In order for Jordan to balance its water budget, support the growth plans envisioned in the country, and provide the basic element of life to Jordanians, the government needs to take certain steps to increase the water supply and reduce demands.

Increasing supply should be the most important objective of Jordan's water planners. In order to achieve this objective, the government is forging ahead with major joint projects with neighboring countries (Egypt, Syria, Israel, and Palestine) and applying water conservation practices. The steps the government is proposing to meet and exceed the water demand is listed below.

1. Building Al-Wehda dam will add 100 MCM to the water supply in Jordan. The project is on hold until a peace treaty is forged between Syria and Israel.
2. The main source of additional water supply in Jordan will come from the Dead Sea-Red Sea channel project (or the Peace Conduit). This project is in its early phases. The environmental assessment study and feasibility study were just awarded to French and British companies. When completed, this project will provide Jordan with 570 MCM in 2022. The project is in co-operation between Jordan, Egypt, Israel, and Palestine with the financial support form the world community (the United States of America, the European Union, the World Back and other financial agencies). This is a major piece in the water supply puzzle for Jordan to meet its future water supply.
3. The Disi Project will increase the water supply from the Disi basin (fossil basin) by 100 MCM by the year 2011, which is projected to be depleted in 50 years. This is a temporary fix but it's necessary.
4. More surface water can be harvested by employing better water management practices and building small earthen dams. The exploitation of additional surface water will add 139 MCM to the current 395 MCM.
5. Employing non-traditional water management practices will increase water supply. Some of these practices include but not limited to: improvement of the effluent quality form WWTP by employing new technologies and improve water retention in the WWTP stabilization ponds. These practices will add about 89 MCM in 2020 to the current level of 80 MCM.
6. Invest in desalination technology utilizing sustainable energy sources like solar and wind energies. Jordan implemented two projects that will add 65.5 MCM of available water in 2020 to the current levels of desalinated water of 31 MCM.
7. Utilizing surface runoff to recharge groundwater will add about 26 MCM above the current recharge amount of 56 MCM.

Evaluation of the completed and proposed projects and the implementation of the strategies suggested by Jordan's government one can see that Jordan will be able to or close to meet its water demands by 2020. Until then, Jordan needs to apply short-term fixes like:

1. Improve the portable water infrastructure which will save about 30-40% of the water that is being lost.
2. Enforce existing and propose stricter laws on sewerage and industrial effluent to municipal WWTPs.
3. Increase outreach efforts to citizens and provide incentives to water conservation efforts especially from the agricultural sector.

Impacts of Mining in the Upper Zambezi River Basin: an overview of the Zambian Copperbelt

Imasiku A. Nyambe
Professor and Coordinator, Integrated Water Resource Management Center, C/o School of Mines, University of Zambia, Great East Road, Lusaka 10101 Zambia;
PH 260-955-793600; FAX 260-211-294086 / 290165;
e-mail:inyambe@unza.zm

ABSTRACT: The Zambezi River Basin (ZRB) is the largest river basin in Southern Africa, covering some 1.37 million square kilometers across eight countries: Angola, Botswana, Malawi, Mozambique, Namibia, Tanzania, Zambia, and Zimbabwe. It is home to approximately 30 million people who rely on the river for drinking water, fisheries, irrigation, hydropower production, mining and industry, ecosystem maintenance, and other uses such as tourism at Victoria Falls and wildlife viewing along the river banks. Water management in the basin is especially difficult because there are multiple countries with multiple and competing interests; competing issues other than water that demand time, attention, and money; inadequate basin-level institutional structures; institutional, legal, economic, and human resource constraints within each country; and poor data collection, poor communication, and inadequate training. However, Zambia has a lion's share of the basin with 105.2km^3/ac of water resources covering 75% of the country of a total area of 752,614 sq. km.

Zambia's life line is depended on the Zambezi River Basin's waters, for example, the Kafue River sub-basin is home to the Zambian Copperbelt where huge copper mining have been practiced for almost a century. Further to the west, more new mines have come on line or are about to do so. The middle of the sub-basin occur Lusaka – the capital with a very fast growing population and further down are the large scale sugar-cane farms and industries such as Nitrogen Chemicals of Zambia at Kafue Town. In addition, energy needs, in form of electricity, are drawn from the same Kafue River resulting in competing needs between agriculture (both small & large) and energy. These land uses in addition to growing population have threatened the water resource of the Zambezi River Basin particularly the Kafue River sub-basin both in quantity and quality. Mining in particular has been blamed for water pollution in the Zambezi River Basin. Indeed, recent studies indicate that mining activities have contributed to contaminated soils, stream sediments and water, and agricultural plants such as cassava and sweet-potatoes leaves. These studies have recommended to the Zambian Government as a way of mitigating mining contamination as follows:

- Monitoring and evaluation of long-term trends of contaminated mapped parts of the Copperbelt is highly desirable for the high-quality environmental management.
- A new progressive technology including dust limiting electro-static filters is necessary to reduce the impact of dust fall from smelters and processing plants.
- Reducing the amount of airborne particles that originate from impoundment beaches, capping of beaches by a mixture of clayey laterite and ground limestone is suggested together with overlaping of remedied surfaces with plant residues (i. e. trash conservation or mulching).
- The use of treated municipal seawage to improve the fertility of reclaimed surfaces of tailing impoudments.
- Thickening of tailings should be preferred over wet deposition, combined with high quality seepage barriers and return systems.

1.0 Introduction

The Zambezi River Basin is the largest river basin in Southern Africa, covering some 1.37 million square kilometers across eight countries extending through Angola (18.2%), Botswana (2.8%), Malawi (7.7%), Mozambique (11.4%), Namibia (1.2%), Tanzania (2.0%), Zambia (40.7%) and Zimbabwe (16.0%) (Figure 1).

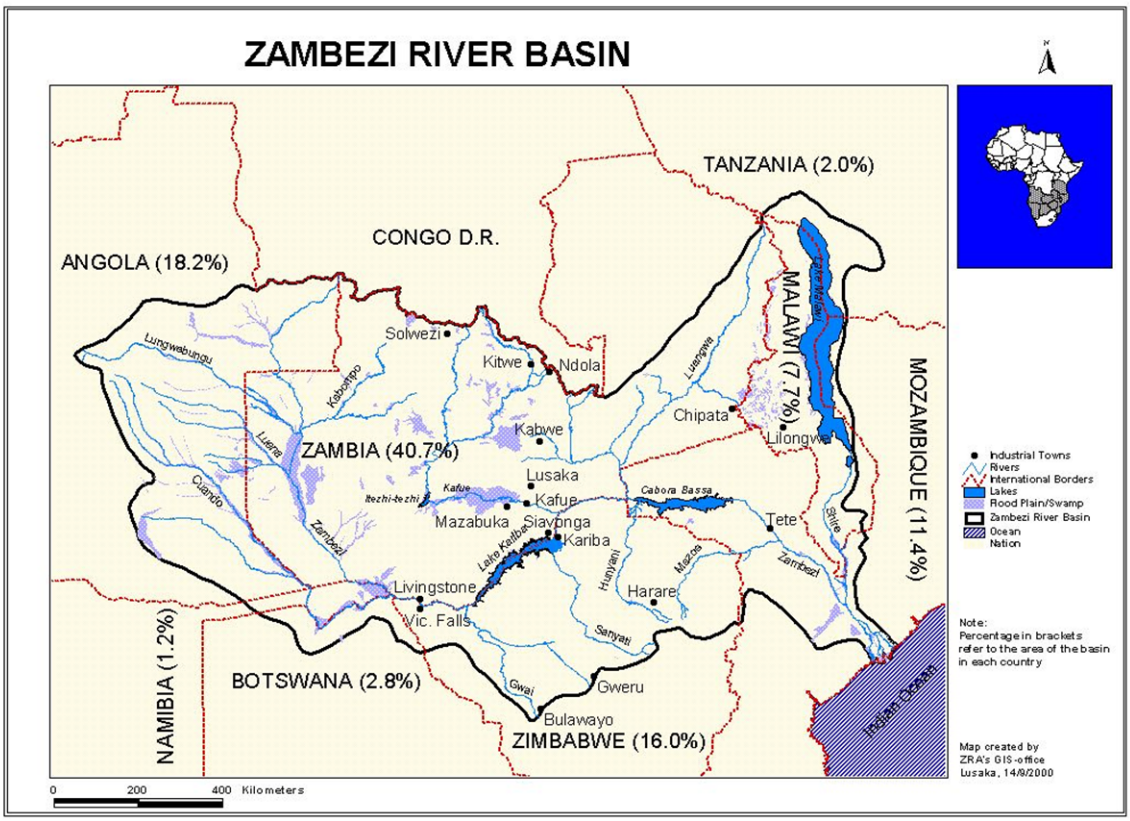

Figure 1: The Zambezi River Basin [adapted from Zambezi River Authority (ZRA), 2000]. Note the area occupied by the Basin in each riparian state)

Renewable water resources in the ZRB as contributed by each riparian country are given in Table 1 (Scholes and Biggs, 2004).

Table 1: Renewable Water Resources by ZR basin country (*after Scholes and Biggs 2004*)

Basin Countries	**Renewable Water Resources**			
	Total (km^3/ac)	**Withdrawals (km^3/ac)**	**Withdrawals % of Total**	**Water 2001 (m^3/person)**
Angola	184.0	0.4	0.19%	13,620
Botswana	14.4	0.1	0.97%	8,471
Malawi	17.3	0.6	3.65%	1,641 [a]
Mozambique	216.1	0.6	0.29%	11,960
Namibia	17.9	0.3	1.51%	10,022
Tanzania	91.0	2.0	2.20%	2,642
Zambia	105.2	1.7	1.65%	10,233
Zimbabwe	20.0	2.6	13.05%	1,560 [a]
[a] Indicates water stress (<1,700 m^3/person)				

From Figure 1, it is clear that Zambia has a lion's share of the basin's surface area covering 75% of the country's total area of' 752,614 sq. km whereas Table 1 indicates that Zambia takes 3rd place in the total water resource of 105.2km^3/ac after Angola (184.0km^3/ac) and Mozambique (216.1km^3/ac).

Zambia's life line is depended on the Zambezi River Basin's waters, for example, the Kafue River sub-basin is home to the Zambian Copperbelt where huge copper mining have been practiced for almost a century. Further to the west, more new mines have come on line or are about to do so. The middle of the sub-basin occur Lusaka – the capital with a very fast growing population and further down are the large scale sugar-cane farms and industries such as Nitrogen Chemicals of Zambia at Kafue Town. These land uses in addition to growing population have threatened the water resource of the Zambezi River Basin particularly the Kafue River sub-basin both in quantity and quality. Mining in particular has been blamed for water pollution in the Upper Zambezi River Basin of the Kafue River sub-basin (Figure 2).

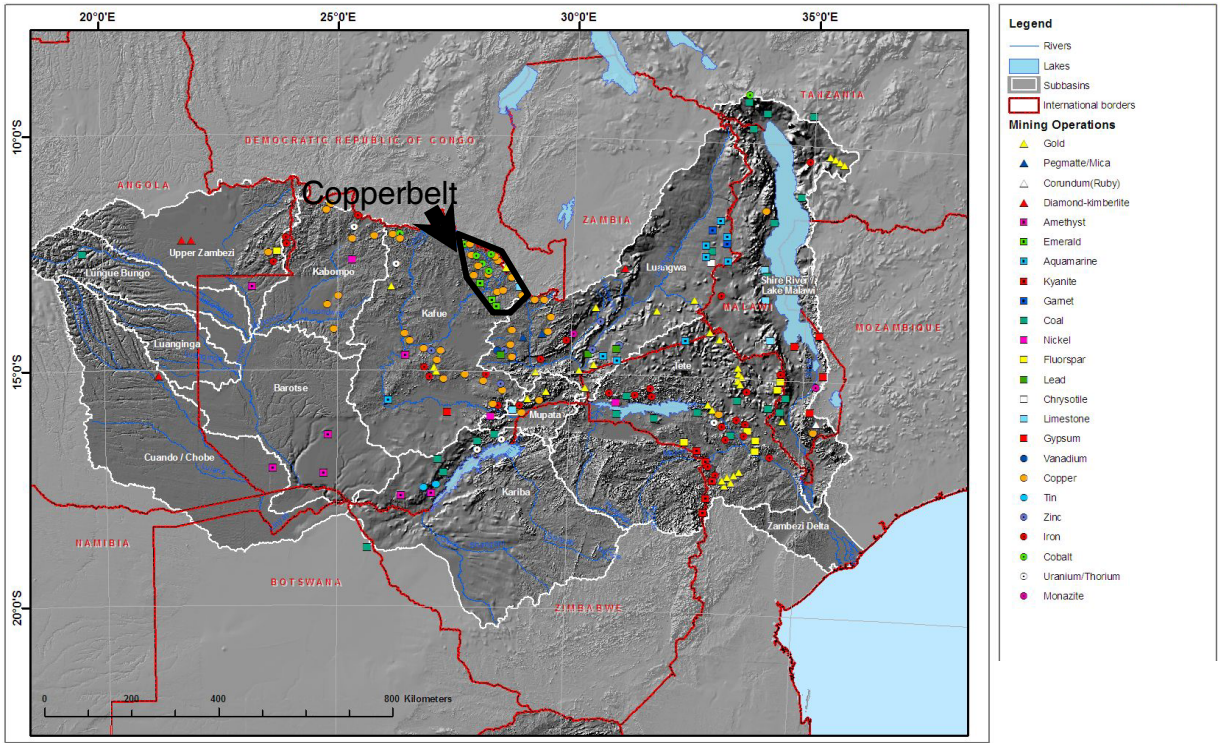

Figure 2: Zambezi River Basin showing location of Zambian Copperbelt (modified from Euroconsult Mott MacDonald, 2007)

This paper therefore looks at the water and stream sediment of the Zambian Copperbelt as impacted by mining and whether it is practical to have standard water quality for the entire Zambezi River Basin.

2.0 Mining on the Zambian Copperbelt

Zambia is an irregularly shaped, land-locked country which contains vast mineral resources. The most important of these are the copper and cobalt metals mined on the Zambian Copperbelt (Figure 3).

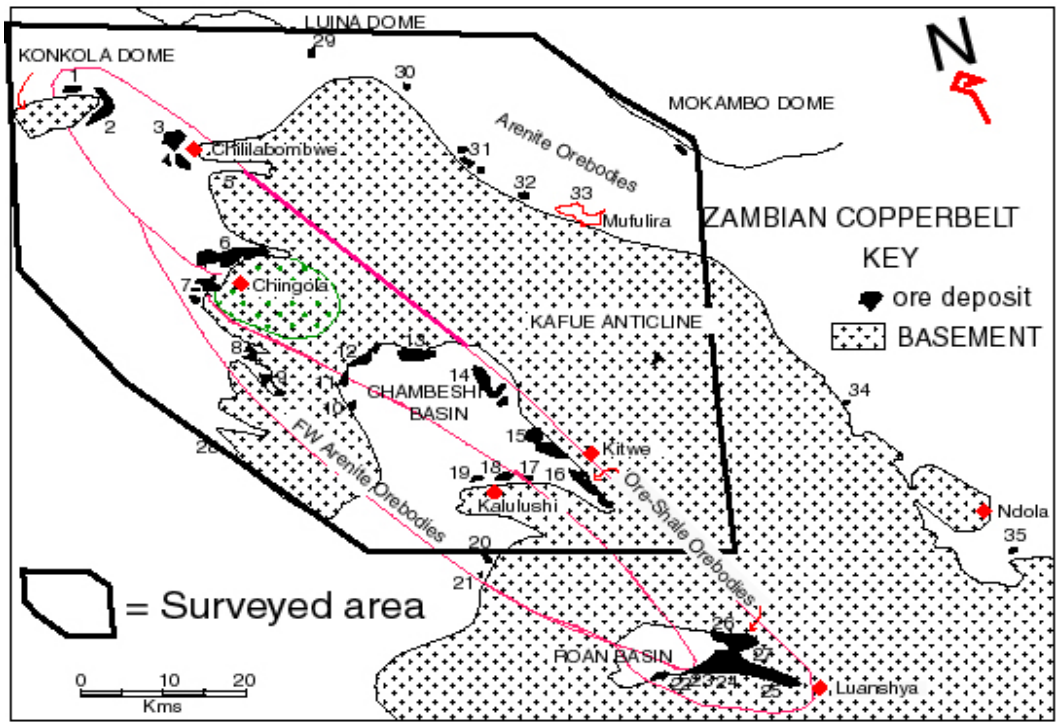

Figure 3: Map of Zambian Copperbelt showing the mining copper ore districts of Chililabombwe (Konkola Mine), Chingola (Nchanga Mine), Mufulira (Mufulira Mine), Chambeshi (Chambeshi Mine), Kalulushi (Chibuluma Mine) Kitwe (Nkana Mine) in the studied area.

For many years, copper mining has supported the social and economic development of the country accounting for about 93% of all Zambia's foreign exchange earnings in 1991, but declined to 72% in 1995. Minerals of all types accounted for 9.8% of export earnings in 1992. On the overall, the Mining Industry was the main contributor to the country's Gross Domestic Product (GDP), contributing an average of 35% (1965-1970), which significantly reduced to an average of 8% during the period 2000 to 2005 rising up to 11.8% in 2006 (Figure 4). For example, in 2004, mining contributed K 2,550 Billion to the total GDP of K32, 141 Billion i.e. 8% of GDP.

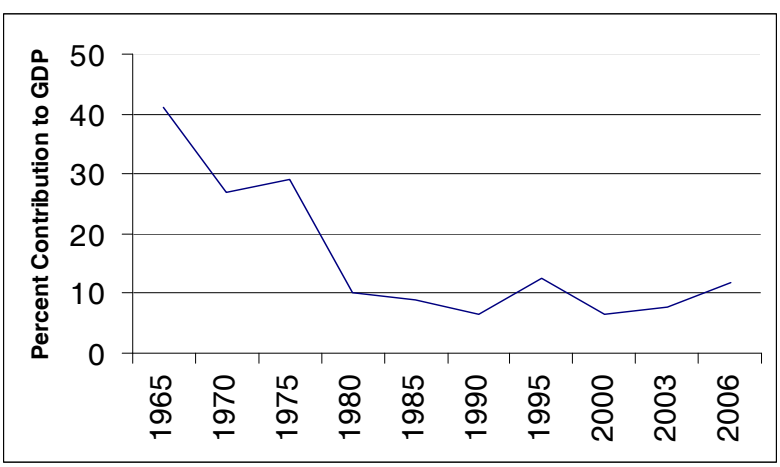

Figure 4: Percent Contribution of Mining to GDP (Source: Central Statistics Office)

Since 1914 to 2002, Zambia has produced enormous tonnages of copper (Figure 5).

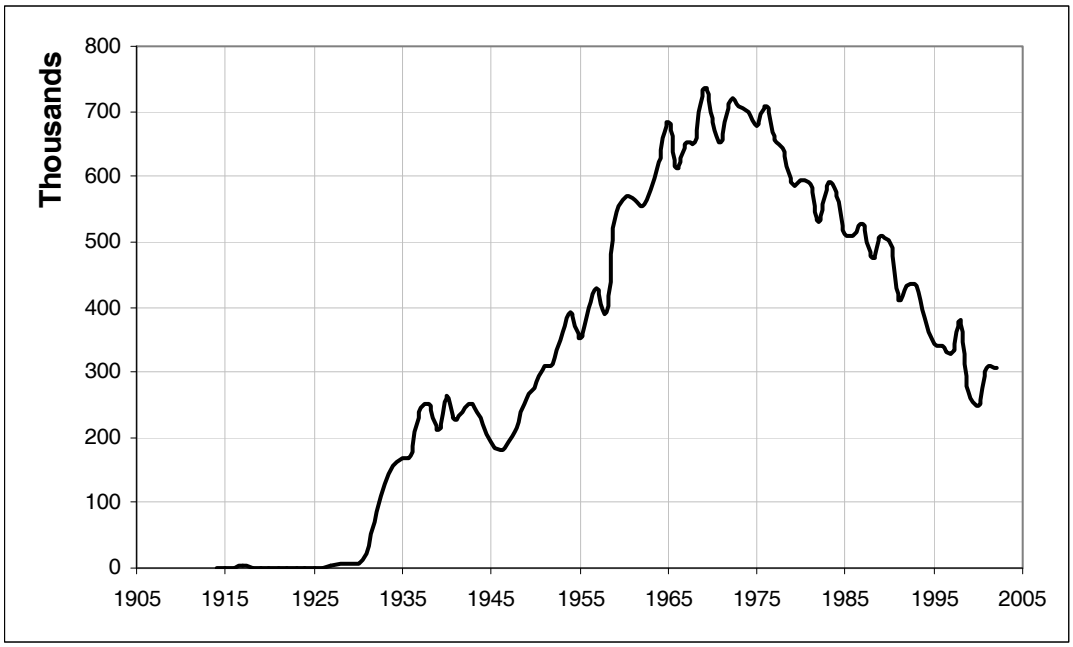

Figure 5: Copper production in Zambia (1914-2002) (Nyambe and Kawamya, 2005)

With these huge copper tonnages, over 600,000 tones between 1964 and 1980 for example, meant that the mining companies had to have licenses to discharge waste into the environment. For example, former Zambia Consolidated Copper Mines Limited, held 9 licenses, to discharge tailings effluent into public streams. It further held 25 licenses to operate tailings dams, 7 licenses to operate domestic waste disposal sites, 7 licenses to operate slag dumps and 8 licenses to transport tailings to tailings dams. The mining activities have led to some pollution of surface and ground waters, degradation of arable land and siltation.

3. Environmental Impacts

Increased levels of mining activities coupled with many years of mining particularly copper has impacted negatively on the surface cover, especially the large-scale mining operations on the Copperbelt (e.g. Nchanga Open Pit and Nkana Smelter (Figure 6a & b).

Open-cast operations have a huge tonnage of overburden consisting of waste rocks and overburden disposed of in waste dumps, overburden dumps and waste rock dumps (Figure 6a). There are 32 overburden dumps in Zambia's mining industry containing 1.899 million tones of overburden and covering an area of about 206,465ha.Waste rock is generated in underground shaft mining. There are 21 waste rock dumps with approximately 77 million tones of waste rock. They cover an area of 388 ha. Slag is waste material produced from smelting of concentrates. It is delivered for disposal in molten or granulated state. There are 9 slag dumps containing 40 million tones of slag. They cover an area of 279 ha. There 45 dumps/dams containing 791 million tones of tailings covering an area of approximately 9,562ha. As at 2005, a total of 216,257 ha were covered by overburden, slag, tailings and waste rock dumps occupying land that could otherwise be used for other purposes.

(a)

(b)

Figure 6: (a) Nchanga Open Pit on the Copperbelt and (b) Overview of Nkana Smelter on the Copperbelt.

Underground mining operations have also impacted negatively on the environment affecting an area of 4,000 ha that is prone to subsidence and thus protected. De-watering from underground workings adds about 500,000m ^{3}/day of water into the Kafue River, a major Zambian river that flows through this mining zone. The river is the source of water for household (including drinking water) and industrial use.

These mining activities have a broad range of effects on the environment and the ecosystem (terrestrial systems, river drainage patterns & human health) that result, for example, from tailings (slimes), slag and minor amounts of toxic hazardous chemical wastes as sources of chemical pollution to water resource due mainly from oxidation of the sulfides.

Processing facilities consisting mainly of crushers, concentrators, smelters and refineries produce among others tailings that feed into tailing impoundments (Figure 7a) providing dust fallout (Figure 7b) on dry sections ("beaches") affecting plant leaves to a distance of a few kilometers from the source of pollution, whereas their dams leak, discharging a pulp rich in iron. The contents of Cu in these precipitates vary between 800 and 2 500 ppm, Co between 780 and 1 900 ppm As 2.7 up to 350 ppm, and Pb 14 and 270 ppm (Kříbek and Nyambe, 2004).

(a)

(b)

Figure 7: (a) Tailing impoundment – wet part; (b) dry part providing dust fallout affecting plant leaves

Effluents from the mines have already been blamed for loss of aquatic life down-stream along the Kafue River locally. For example, cattle losses have been reported due to consuming copper-rich sediment (and possibly vegetation) stirred up at the time of drinking near the Mwambashi River (ZCCM, 1982).

Recent studies undertaken by Kribek et. al, (2002, 2004, and 2006) indicate that main sources of strong anthropogenic contamination with heavy metals (As, Hg, Co, Cu, Pb and Zn) are:

- industrial water released from processing plants and smelters,
- solid and gaseous emissions from smelters,
- seepage through the tailings impoundment dams,
- wash-out of fine-grained material from spoil banks,
- airborne particles from beaches of tailings pond and, airborne particles from crushers.

Contamination of surface waters is ascribed to (i) siltation that results from washout of fine particles from dumps and ore-processing plants, (ii) overflow of water from tailing facilities, (iii) leakage of water through the tailing facilities dams and (iv) the drainage of technological waters from smelters and acid plants.

The contamination of the Copperbelt region by cobalt (Co), copper (Cu), manganese (Mn), selenium (Se), sulphates (SO_4), calcium (Ca) and magnesium (Mg) markedly exceeds the permissible values for surface waters in the European Union. The pH of waste waters from ore dressing plants employing chemical technologies fluctuates between 2.04 and 3.62 when insufficiently limed. The contents of metals in these acid waters exceed the permissible values for surface waters in the European Union by ten times. Limits for cadmium (Cd), nickel (Ni), selenium (Se) and zinc (Zn) also exceed the standards. The contents of toxic elements in stream sediments reach 1,296 ppm As, 3,660 ppm Co, 1257 ppm chromium (Cr), 65 460 ppm Cu (Figure 8), 6.47 ppm Hg, 48 ppm molybdenum (Mo), 360 ppm Ni, 1 370 ppm Pb, 3 590 ppm Zn and 2.1 % sulphur total ($S_{tot.}$). Fortunately, the acid neutralising capacity of river sediments and riverbed rocks is high and the contamination of water significantly decreases downstream of the contaminated sources.

These studies have also shown that on the Copperbelt, soils are general elevated in copper because of the high natural background levels. In contaminated areas contents of copper in fresh agricultural products of cassava and sweet potato leaves reach as much as 253.8 ppm, cobalt 18.9 ppm, arsenic 7ppm, nickel 3.4 ppm, lead 5.04 ppm and zinc 161 ppm.

The elevated natural background levels of copper on the Copperbelt, for example, cannot be substituted with a standard from Mongu in the Barotse flood plains of western Zambia that is entirely made up of Kalahari quartz-rich sands. This will definitely condemn the entire Copperbelt as inhabitable. For the Zambezi River Basin, regional standards are thus recommended.

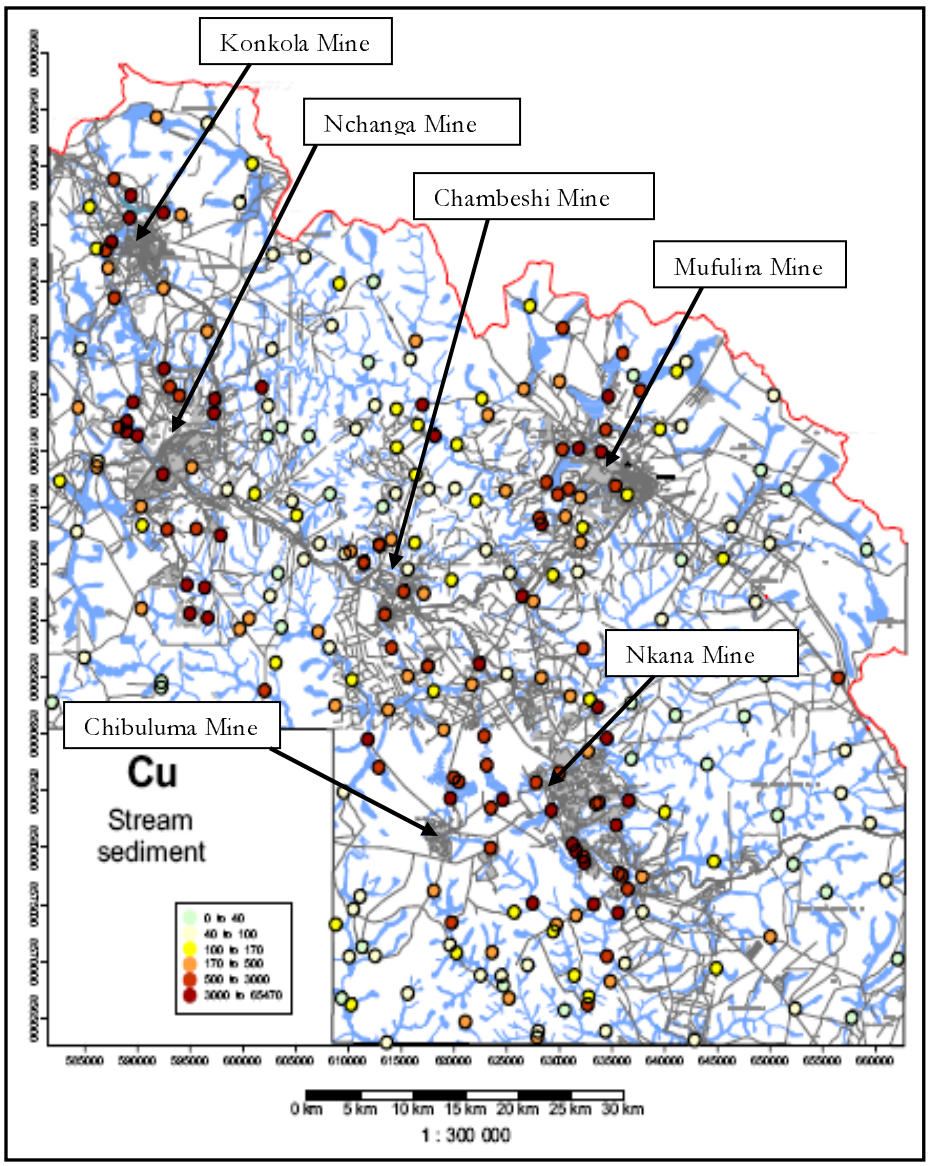

Figure 8: Copper (Cu) in stream sediments. Note high values are related to an operating mine with a maximum up to 65 460 ppm Cu.

4. Observations and Recommendation

Mining activities have indeed contaminated water and stream sediments and in some cases agricultural plants such as cassava and sweet-potatoes leaves have been affected. The significant decrease in contamination levels and the high background levels for a given metal e.g. copper in this case is an indication that a blanket figure for water quality cannot be used for the entire Zambezi River Basin. For example a value of a metal from a district where such a metal does not occur cannot be applied in a district where it occurs despite that they occur in the same basin. Use of local standards per region or district is recommended.

It is therefore useful as recommendations to the Zambian Government to mitigate mining contamination as follows:

- Monitoring and evaluation of long-term trends of contaminated mapped parts of the Copperbelt is highly desirable for the high-quality environmental management.
- A new progressive technology including dust limiting electro-static filters is necessary to reduce the impact of dust fall from smelters and processing plants.
- Reducing the amount of airborne particles that originate from impoundment beaches, capping of beaches by a mixture of clayey laterite and ground limestone is suggested together with overlaping of remedied surfaces with plant residues (i. e., trash conservation or mulching).
- The use of treated municipal seawage to improve the fertility of reclaimed surfaces of tailing impoudments.
- Thickening of tailings should be preferred over wet deposition, combined with high quality seepage barriers and return systems.

Improving the Water Quality of One of the World's Great Lakes: Tai Lake Case Study of Environmental Responsibility in the Developing World

D. P. Albers, PE[1]

[1]Ecology and Environment, Inc., 368 Pleasant View Drive, Lancaster, New York, 14086; PH (716) 684-8060; email: dalbers@ene.com

ABSTRACT

China's Tai Lake is one of the world's great lakes. Located in eastern China near the city of Shanghai, over 30 million people live within the lake's watershed. In 2007 Tai Lake experienced a major algal bloom, which resulted in the suspension of water supplies to Wuxi City. In response, the Chinese central government tasked the China Development Bank (CDB) with creating an environmental loan program to assist in improving the lake's water quality.

Ecology and Environment, Inc. (E & E) was hired by the CDB to assist in identifying loan opportunities that could be used to improved Tai Lake's water quality. A principle finding was the willingness of local authorities to fund large-scale environmental projects. Another significant finding was the recognition within the watershed of the need to shift funding away from wastewater treatment plants and toward measures to intercept polluted runoff from non-point sources.

The approach presented in this paper provides a model for developing countries to create effective and comprehensive environmental loan programs and the supporting strategies needed to help ensure their success.

INTRODUCTION AND APPROACH

This case study provides an example of how a proposed large-scale environmental loan program was developed for China, a rapidly developing nation facing severe environmental challenges. Tai Lake, which is located in eastern Chine near the city of Shanghai, is one of the world's great lakes: the lake has a surface area of greater than 2,300 square kilometers (900 square miles), and over 30 million people live within its watershed (see Figure 1). The lake basin is a resource of national significance, and it is afflicted with serious water quality problems. For several years the water quality of Tai Lake has been below the goals set by China's Ministry of Environment. The most significant issues affecting water quality are algal blooms, high levels of nutrients in the lake's waters, and high levels of oxygen demand. These issues are the direct result of the region's recent industrial, agricultural, and

Figure 1. Tai Lake Basin Map

residential development and represent significant challenges to improving the water quality of Tai Lake.

In 2007 Tai Lake experienced a major algal bloom, which resulted in the suspension of water supplies to Wuxi City. In response, the Chinese central government (in coordination with other efforts) tasked the China Development Bank (CDB) with creating an environmental loan program to assist in improving the lake's water quality. Major international development banks have been making environmental loans to China for decades. This effort reflects China's desire to create a similar environmental loan program for a major Chinese bank.

Comprehensive planning and secure sources of project funding are needed if the problems affecting Tai Lake are to be effectively addressed. Significant planning efforts have been made. Additional coordination will focus efforts on addressing the causes of the lake's water quality problems to achieve lasting improvements.

Ecology and Environment, Inc. (E & E) was hired by the CDB to assist in the development an environmental loan program to address the water quality problems faced by Tai Lake. Our understanding of these problems was developed through a combination of site visits, literature and data reviews, and interviews with government officials and scientists. We then reviewed remedies that had been applied in developed nations to lakes with similar problems.

Based on our findings, a summary of the general causes of the lake's poor water quality was developed and presented to the CDB staff so that they could understand the types of problems that environmental projects should focus on to improve Tai Lake's water quality. Next, projects proposed by municipal and provincial governments to address the water quality problems in Tai Lake were summarized and evaluated for their likely impact on water quality. This was done using an evaluation procedure developed to rank the proposed projects. E & E then developed a work plan for the next phase, which involved developing a coordinated water quality management strategy for Tai Lake that includes all of the major stakeholders. Finally, we developed a detailed approach for an environmental loan program and presented the approach to the CDB.

WATER QUALITY UNDERSTANDING

Although the region depends on Tai Lake for most of its water supply, the water quality in much of Tai Lake is so poor that the water is, in places, not even fit for use as irrigation water. The most prominent water quality problem in Tai Lake—large blooms of blue-green algae—is caused by high levels of phosphorus. The high phosphorus levels are resulting in eutrophication of the lake, which has been accelerating in recent years.

The data relating to sources and quantities of nutrients entering the lake are incomplete and contradictory. No single agency is collecting or coordinating this information, and existing data collection arrangements do not adequately cover the agricultural areas from which the largest nutrient flows likely come.

It is clear from the available data, however, that rapid economic development, urbanization, and population growth in the Tai Lake basin have caused a large increase in water demand for residential, agricultural, and industrial purposes, and has resulted in the discharge of significant amounts of untreated and partially treated wastewater into the lake basin. Industrialization of the region began in the 1970s, and by the year 2000, 460 million cubic meters of domestic wastewater, 1 billion cubic meters of industrial wastewater, and an unknown but large volume of non-point source wastewater (e.g., agricultural runoff) was being discharged into the lake annually. Treatment capacity has increased significantly, but it has not kept up with the need.

CURRENT PROJECTS

The governments in the Tai Lake basin have been working diligently to develop water quality improvement projects for several years. An extensive list of projects that could have a positive impact on the water quality of Tai Lake was developed based on trips to the Tai Lake basin, projects proposed by the local governments and projects identified in the 11th Five-Year Plan (MEPA, 2007). This list contained over 300 projects in various stages of development and was organized into the following project types:

- Effective stop-gap measures that could reduce the steep decline in the lake's water quality and safeguard drinking water supplies;
- More and better wastewater treatment plants;
- More effective treatment of potable water;
- Control of runoff from agricultural lands;
- Focused interventions on industrial discharges based on contaminants of concern; and
- Alternate sources for drinking water.

The criteria we used to evaluate and rank projects for funding and implementation are summarized below. We ranked each criterion for each project based on the presumed likelihood the proposed project would meet the criteria and computed an overall score for each project.

- Magnitude of Impact
- Cost-Effectiveness
- Long-term Effectiveness

- No Environmental Harm
- Induced Impacts
- Location/Proximity Benefits
- Amenity Enhancements
- Proven/Reliable
- Implementable
- Status of Project Planning/Design

COORDINATED WATER QUALITY MANAGEMENT STRATEGY

We developed a coordinated water quality management strategy to meet the goals established in the 11th Five Year Plan to clean up Tai Lake. These goals include the following:

- Improve Tai Lake water quality to protect drinking water
- Control industrial pollution sources to meet discharge standards
- Effectively control all water pollution discharges to the lake
- Strengthen the water quality monitoring and water pollution alarm system

The following short-term objectives are based on meetings and with local and national environmental agencies:

- Improve lake water quality from below Class V to Class V
- Improve the water quality of the eastern portion of the Lake from Class V to Class IV
- Halt the trend in increasing eutrophic levels in Tai Lake
- Improve the quality of the major drinking water sources and transport canals to Class III
- Improve the percent compliance with water quality standards in rivers and canals from 18.6% to 40%

The following long-term objectives were also based on meetings and with local and national environmental agencies:

- Improve lake water quality to Class IV
- Improve the eutrophic level of the lake
- Improve the percent compliance with water quality standards in rivers and canals to 80%

To achieve these objectives, we developed a strategy based on a review of several large international water quality programs, incorporating the best parts and most applicable approaches to the situation at Tai Lake, while paying close attention to lessons learned from those programs.

Based on our review, we recommended the creation of a management structure to properly plan and coordinate the efforts needed to achieve the short- and long-term water quality objectives set for Tai Lake. To help ensure success, this body should include representatives from the major stakeholders that would be involved in the overall program.

Some of the functions of this management body include:

- Coordinating the efforts of cities, provinces, and various government agencies involved in the effort to improve the water quality of Tai Lake;
- Reducing or eliminating duplications of efforts; and
- Reducing the difficulties in sharing information about successes and failures associated with the various projects.

We suggested calling this group the "Tai Basin Water Quality Steering Committee." Working under the Steering Committee, a newly created "Tai Basin Program Management Office" comprising the Technical Resource, Research, and Finance Groups would manage day-to-day concerns such as administration and strategy implementation. The Technical Resource Group would oversee the Design and Construction sub-groups, while the Research Group would house the Modeling and Monitoring sub-groups. This proposed management structure is presented in Figure 2.

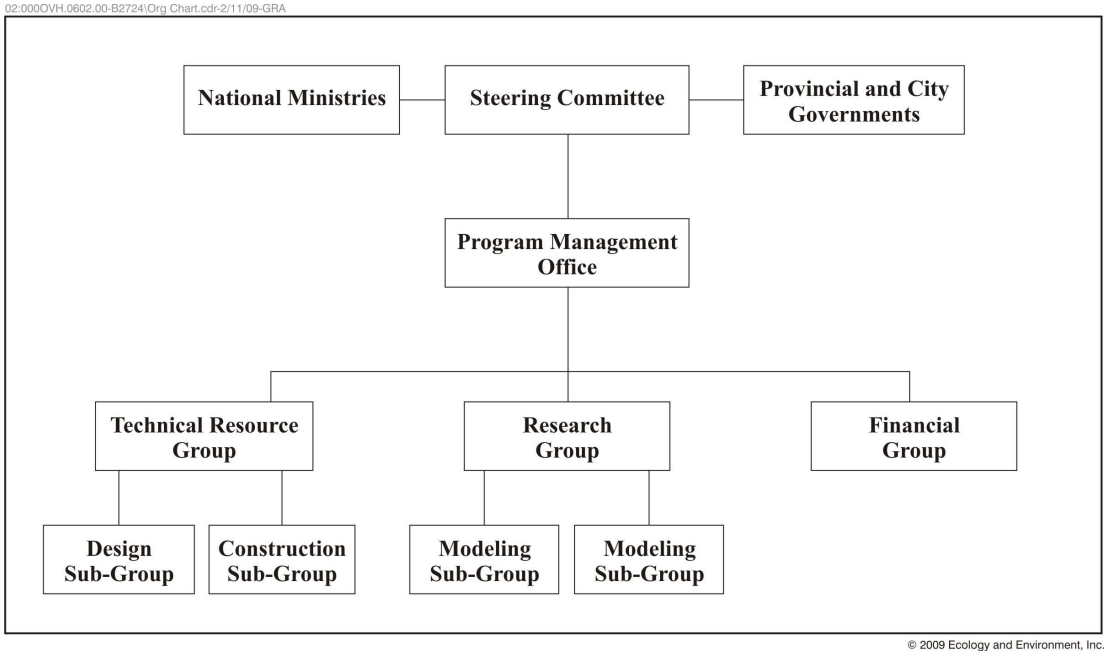

Figure 2. Proposed Tai Lake Water Quality Management Program Structure

The Steering Committee. The Tai Basin Water Quality Steering Committee would provide executive-level management for the Water Quality Management Program and

act as a high-level consultation and coordination body. A principal function of the Steering Committee would be to coordinate the numerous water quality improvement efforts that are now dispersed among many national ministries and agencies, several provinces, numerous large cities, and many smaller cities, and it would work to resolve intergovernmental conflicts on water quality issues. The Steering Committee should have sufficient power to enforce its decisions. It would also ensure the close coordination of the water quality management program with regional economic, environmental, and social development programs.

The Program Management Office. The main role of the Tai Basin Program Management Office (PMO) would be to develop and undertake the Water Quality Implementation Plan. In undertaking the implementation plan, the PMO would deal with day-to-day management affairs, including human resources, administration, public notification and press releases, resource administration (buildings, equipment, laboratories, etc.), day-to-day problems, and crisis management. It would also gather the data necessary to gauge the success of the program and make suggestions to the Steering Committee about how the program might be altered to be more successful.

The Technical Resource Group. The main role of the Technical Resource Group would be to review project designs and monitor construction of water quality management projects. This group would report to the PMO and would be comprised of two major sub-groups: the Design Sub-Group and the Construction Sub-Group.

The main role of the Design Sub-Group would be to review the technical designs of projects with regards to their technical adequacy. The goals of the Design Sub-Group would be to ensure that proposed project designs are technically sound, that they would address the water quality problem they are intended to address, and that lessons learned from previous projects can be incorporated into the designs of newly proposed projects.

The main role of the Construction Sub-Group would be to provide oversight and monitoring during project construction. The goals of this sub-group would be to ensure the proper utilization of resources and the completion of the construction work as presented in earlier planning and design stages.

The Research Group. The main role of the Research Group would be to provide a scientific understanding of the root causes of Tai Lake's water quality problems and a scientific method for predicting the relative effectiveness of various management strategies. The Research Group would be a consortium of government research organizations, universities, and industrial research organizations. This group would report to the PMO and would be comprised of two major sub-groups: the Monitoring Sub-Group and the Modeling Sub-Group.

Monitoring provides accountability for management actions. A coordinated and comprehensive monitoring network would provide the information required by the managers to make informed decisions, adapt their actions as needed, and provide effective stewardship of Tai Lake's water resources. It is anticipated that the bulk of the Tai Lake monitoring effort would be conducted by various organizations already involved to some extent in monitoring Tai Lake's water quality. The goal of the Monitoring Sub-Group would be to coordinate and standardize these various efforts and to centralize the collected data.

The goal of the Modeling Sub-Group would be to develop descriptive tools relating pollutant sources to water quality impacts and to use these tools to predict the effectiveness of alternative pollution control strategies.

The Financial Group. The main role of the Financial Group would be to identify funding sources and to match available funding to proposed projects. The Financial Group would also assess whether proposed projects are financially viable and sustainable. The Financial Group would ensure that entities proposing to implement water quality projects are financially capable and, where necessary, would provide guidance and recommendations to improve their financial management systems.

ENVIRONMENTAL LOAN PROGRAM APPROACH

Having determined, in principle, which projects the CDB and the local governments wish to pursue as part of the comprehensive program to improve water quality in Tai Lake, the next tasks would be to prepare the projects for funding, obtain the necessary funding, and then implement the projects. The project preparation phase begins with an initial concept for a project backed by feasibility studies. To determine whether a proposed project is feasible, sustainable, and suitable for CDB funding requires considerable effort on the part of the Implementing Entity (i.e., the entity that would construct and operate the project), consultants, local government officials, and CDB staff.

This effort is divided into two parts. The first part of the project preparation process is to undertake a detailed review and assessment of each potential project to determine its initial suitability for CDB financing. This assessment would consist of the following types of activities:

- Technical analysis
- Environmental impact assessment
- Social and health impact analysis
- Resettlement assessment
- Public consultation
- Financial analysis
- Economic analysis

- Creating a management information system
- A managerial and organizational review
- Creating a Project Performance Monitoring System
- Recommending loan covenants and loan review procedures

Based on the results of the review and analysis work described above, the CDB would make a determination as to whether the proposed project is potentially suitable for funding. If suitable, a detailed loan report would be written for the consideration of the CDB Board of Directors. The loan report would include a description of the project and a discussion of the need for the project, its objectives and goals, the necessary inputs and outputs, associated activities and milestones, and a summary of the reviews listed above.

After the loan report for a specific project has been approved and funding has been put in place, project-specific implementation activities begin (e.g., final design, tendering, and construction). The purpose of these activities is to provide assurances to CDB (and the Tai Lake Water Quality Steering Committee) that each project approved for funding is designed appropriately, constructed according to the design, constructed to a high standard of quality, and constructed safety. The successful completion of these activities would ensure that the constructed project functions as intended and results in the expected improvement in water quality in Tai Lake.

SUMMARY

To select appropriate project types and projects to improve water quality in the Tai Lake basin, it was necessary to identify and understand the various factors affecting water quality in the lake. Therefore, E & E undertook a high-level qualitative investigation of the causes of the poor water quality in the lake. The investigation included a review of numerous studies, examination of environmental data, and meetings with various local experts in water management, pollution control, and civil engineering. In addition, since many cities in the Tai Lake basin are actively working to develop projects to correct the water quality problems, we examined many of the recent restoration plans and actions taken to restore the lake.

The water quality problems in the Tai Lake basin are serious but not unique: over the years, many developed countries have tackled similar problems. An assessment of the restoration programs undertaken by these countries, as well as the effectiveness of the measures included in those programs, provided another basis for understanding appropriate projects and management structures to improve water quality in Tai Lake basin.

Based on our understanding of the causes of poor water quality in the Tai Lake basin and the successful restoration measures used in developed countries, we have developed a framework that the CDB can use to evaluate loan applications for Tai

Lake water quality project. This framework involves applying the evaluation criteria developed to rank the projects in terms of their likely achievements.

Once restoration projects have been selected for CDB financing, the proposed environmental loan program would need to be implemented. As part of the loan program, the projects would be monitored to ensure they are properly designed, constructed, and implemented. This would ensure that the individual projects provide their anticipated results and that the ultimate goal of enhancing water quality in the Tai Lake basin is achieved.

This case study presents an approach to improve the water quality of a large lake in a heavily populated part of one of the world's leading developing nation. It also presents the first attempt by a Chinese state bank to create a large-scale environmental loan program, which is a major milestone in the development of environmental policy in China. The approach presented here provides a model for developing countries to create effective and comprehensive environmental loan programs and the supporting strategies needed to ensure their success.

ABSTRACT

The Khorezm province of Uzbekistan, located in the Aral Sea Basin, suffers from severe environmental and human health problems due to decades of unsustainable land and water management. Agriculture is the dominant land use in Khorezm, and agricultural runoff water has impacted many small lakes. In this water-scarce region, these lakes may provide a water source for irrigation or fish production. Samples have been collected from 13 of these lakes since 2006 to assess water quality, the aquatic food web, and possible limits to aquatic production. Lake salinity varied from 1 to >10 g/L both between and within lakes. Although hydrophobic contaminants concentrations were low (82-241 pg toxic equivalents/mL in June 2006, October 2006, and June 2007), aquatic species diversity and relative density were low in most lakes. Ongoing work is focused on 4 lakes with pelagic food webs to estimate fish production and assess anthropogenic impacts on the food web. Lake sediment cores are also being examined for organic contaminants, and hydrology is being assessed with stable isotopes.

INTRODUCTION

The Khorezm province of Uzbekistan is located in the Aral Sea Basin, where decades of unsustainable land and water management have led to severe environmental and human health problems and concerns (Allouche 2007). Agriculture is the dominant land use in Khorezm (Wehrheim and Martius 2008), and agricultural runoff water has impacted many small lakes in the province. In this water-scarce region, these lakes may provide a suitable source of water for irrigation or fish production. This study involves collecting and assessing information on the hydrology, water quality, and ecology of these lakes to evaluate their potential for such uses. The project is a collaboration between scientists and students in Uzbekistan, the United States, and Germany.

APPROACH

Since May 2006, we have collected and measured monthly data from as many as 13 lakes. These data include pH, nutrient and major ion concentrations, and depth profiles of water temperature, dissolved oxygen, and specific conductivity. We also collected zooplankton, aquatic macroinvertebrate, and fish samples twice per year in 2006 and 2007 for stable isotope analysis and characterization of the food webs of the lakes. Beginning in August 2007, sampling was modified to focus on 4 lakes with pelagic food webs and nutrient bioassays were added to the monthly sampling regime to examine nutrient limitation over time in the lakes. In summer 2008, shallow piezometers were installed to monitor the exchange of water between shallow groundwater and the lakes. Pressure transducers monitored water level in the piezometers and the lakes, and water samples were collected from wells, piezometers, nearby water bodies, and the lakes on a weekly basis. In addition to the nutrient and ion analyses, these samples were analyzed for stable isotopes of water (hydrogen and oxygen). To measure the toxicity of hydrophobic organic contaminants to aquatic organisms, passive organic samplers (Huckins et al. 1990, 1993) were deployed three times in the lakes and the Amu Darya, and in summer 2008 they were also deployed in piezometers at three of the lakes. We have also taken some preliminary lake sediment cores to examine the history of the lakes in terms of sedimentation and anthropogenic chemical inputs associated with agriculture to the lakes. Training of Uzbek and American students on field and laboratory work has been an important component of the project.

PRELIMINARY RESULTS

The lakes varied in salinity from 1 to over 10 g/L both between and within lakes depending on the lake and season. Concentrations of hydrophobic contaminants in the lakes were low (120-210 pg toxic equivalents (TEQ; Rosen et al., 2006)/mL in June 2006; 82-160 pg TEQ/mL in October 2006; and 83-241 pg TEQ/mL in June 2007). However, results from one of the piezometers in Summer 2008 showed moderate levels of toxicity (approximately 400 pg TEQ/mL is considered moderate). A 100 cm sediment core taken near the edge of one of the lakes showed relatively

constant concentrations of DDT (average 0.007 mg/kg), γ-HCH (0.0012 mg/kg), and their degradates with depth below a depth of about 15 cm depth, with lower concentrations above 15 cm depth (DDT average of 0.004 mg/kg; γ-HCH average of 0.0007 mg/kg). Age dating of this core using ^{137}Cs and ^{210}Pb indicates that the total sediment package represented over 100 years of sedimentation, but interpretation of the age dating profile is ongoing. New cores have also been taken near the center of the lakes.

Despite low concentrations of hydrophobic organic contaminants in lake water columns, aquatic species diversity and relative density were low in most lakes examined. Ammonium and nitrate concentrations in the lakes were higher in the spring in 2007 and 2008 when agricultural fields in the vicinity of the lakes were being leached with excess water. Phosphorus concentrations were highest in 2006 and much lower in 2007 and 2008. Water isotope and major ion analyses have been completed, and preliminary results indicate that groundwater was a major source to one of the lakes during much of the summer of 2008. Food web samples are currently being analyzed to assess food web structure and composition.

Since the project began, seven Uzbek and two American students have been part of the project. Many have participated in training by the senior Uzbek and American personnel related to sampling and analysis procedures. All of the students have also interacted with German and Uzbek students working on related projects through our German collaborator.

FUTURE WORK

Ultimately, the combined datasets will be used for assessing the hydrology of the lakes, examination of possible land management options, and estimation of the economic, ecologic, and water quality impacts of such changes on the lakes. In addition, the project team recently received funding to take additional lake sediment cores and perform microbial experiments to examine processes which might be reducing pesticide concentrations in lake waters and sediments. This information will be useful not only for understanding current and future conditions in the lakes, but also the historical usage and development of these lakes.

ABSTRACT

Construction and operation of dams have two main effects on streams. At first it increases detention time and then leads to thermal stratification. Changing of water quality is the result of these effects and the outflow has different physical, chemical and biological characteristics from inflow.

In this study thermal regime in proposed Bakhtyari reservoir was simulated with CE-QUAL-W2 model. The inputs are reservoir topography, hydrological and meteorological data. As there is no chance to calibrate or verify the model, they will be done in monitoring and operation period. Three different inflow scenarios were simulated based on dry, normal and wet year .Simulation results represent that in dry year stratification starts at April and remains up to September, but the results of normal year indicates that Stratification is between May and November. In wet year because of short detention time, thermal gradient variation is different from dry and normal year and temperature of middle layers imitate inflow water temperature. In all scenarios a stagnant layer could be seen in downward of outlet structure(700mASL).It is concluded that in dry years which dam has a major effect in inflow regime, turnover is mostly conform thermal stratification theories in reservoirs.

Key words: Bakhtyari dam , thermal stratification, modeling , CE-QUAL-W2

INTRODUCTION

In recent decades and by beginning of new century, one of earth planet's inhabitant population's worries and particularly countries located in dry lands such as our country is water problem in a way that availability to water with appropriate quality and quantity has been converted to a challenge(Soltani 1384).As it was customary from the past, reserving water by construction of dam for provision of water for agricultural consumption, industry, potable water, controlling flood, production of aquatic electric energy, quality control and … seems necessary (karamuz 1382).Flowing water under affection of phenomena such as deaeration, cellular breathing , mixing etc. has uniform quality. But surface water flow reservation could cause of unfavorable effects on water quality of the river (Soltani 1384).The most important changes which may occur on reservoirs is thermal stratification. Anyhow other changes such as eutrophication, evaporation, reservoir basin effects , dissolved solids , dissolved gas , smell problem, etc.are such issues which affect on water quality of reservoir (Soltani 1384).

The preliminary step in study of bio-physical processes within reservoir, is understanding thermal stratification and the consequence of formation, as temperature affects decomposition of organic materials and increasing rate of chemical reactions and on the other hand affects the time varying concentration of these materials(Tajrishi 1385).Temperature related features and stability of reservoirs could be predicted by use of mathematical modeling and in case of environmental problem, can be taken remedial way for decreasing problems by various ways.

Use of multilevel outlet structures, destroying of reservoir's stratum or mixture, aeration of outflow water by use of hydraulic jumping creation and so on are recommendable examples of remedial ways in various ages of a dam from study to utilization (Tajrishi 1385).

Before dam construction, a few studies have been done by researchers on thermal stratification, because it needs calibration by future sampling in reservoir. Gunduz et al by use of two dimensional model(CE-QUAL-W2) simulated quality related behavior of proposed Isikli reservoir for provision of potable water. This model used for determination of potential water quality deterioration by entering of various contaminants charges and its resultants compared with potable water quality standards in order to determining of reservoirs water control managements strategies and watershed area (Gunduz et. Al., 1998).Encon consultant company by use of one dimensional model "DYRESM" studied effects of Yusufeli dam -which was under construction in Turkey- on thermal stratification of reservoir (ENCON,2006).

With regarding to Bakhtiari dam reservoirs shape which its length to width is high (approximately 1:60) and has dendrite like shape, the CE-QUAL-W2 model has been used which has the capability of two dimensional simulation of reservoir in depth and lengh.In this article effect of various programming scenarios of inflow water resources to reservoir in formation of thermal stratification has been surveyed by use of this model.

Study Region

Bakhtyari dam is located in west south of Zagros chain mountains' skirt over a river under the same name in border of Lorestan province (right wing) and Khuzestan

province (Left wing).Surface of basin area is 6503 Sq Km and maximum altitude of the area is 4080 m from the free sea level. At normal level reservoir's altitude is 830 m in ratio to sea level, lake total volume is 4845 cubic million meters and live storage of that is 2647 cubic meters, area at full supply level is 55 Sq Km,length of that about 60 Km and maximum depth at dam wall is 300 meters. Six unit of turbine each of them in capacity of 250 megawatts and in total 1500 megawatts will be installed in power generation section of dam.

MATERIALS AND METHODS

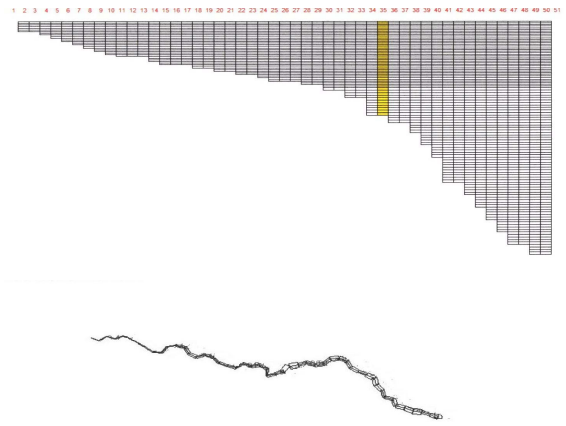
For simulation of reservoirs water quality CE_QUAL-W2 model has used.CE-QUAL-W2 is a two dimensional (longitudinal-depth) hydrodynamic and quality related model. Due to lateral homogeneity assumption, it is appropriate for long water bodies. Development and completing of this model has been begun from three decades ago and has been used for reservoirs, lakes and estuaries in all over the world. This two dimensional model based on finite difference, has ability of simulation of vertical and longitudinal distribution of thermal energy and chemical and biological parameters which has been selected in water bodies. also in water bodies, it simulates appropriately volume, density, vertical and longitudinal concentration of quality parameters. Hydrodynamic simulation engine, impose effects of density changes on flow. Quality modules have the ability of simulation of about 30 quality parameters along with temperature and cyclic pattern of temperature. It also has the below ability: A) simulation for long time period B) Several branches modeling in water body with geometrical complexity C)Multiple joints of water bodies D)variable Longitudinal and height related distances in segmentation. Model along with multi assumption and approximate which is applied for simulation of hydrodynamic processes, transformable and quality based issues has limitations. The model is get used to solve equations in vertical and longitudinal directions, but ignore lateral changes. There is no algorithm for momentum in vertical direction and results for bodies with high vertical acceleration may not be accurate. Water quality parameters which is represented by models has complex interactions. Several processes such as transfer and accumulation of sediments, poisonous materials and dynamic sediment oxygen demand would not be simulated. (William2007)

Four series of data related to reservoir's geometry, simulation period, boundry condition and meteorological parameters have been used for modeling.

Reservoir's Geometry

Topographic and Geometrical information and of Bakhtyari reservoir has been excerpted from topological maps in scale of 1:20000.

For define of reservoir's geometry in model, water body has been divided to 51 pieces with a length of 1.5 Km and 2 and 3 meters depth layers. (Fig.1)



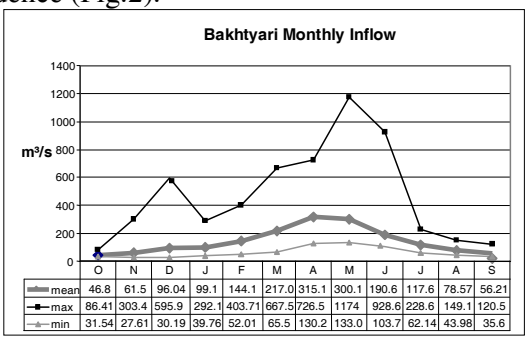


Fig.1 lateral and up view of reservoir's geometry

Simulation Time Period

With regard to that various aquatic years, dry, wet and normal are registered in statistical periods, for each aquatic year, a two year simulation period is included of first year belonging to loading and the second year belonging to water taking from reservoir has been assumed. Information regarding to inflow flow rate to reservoir and outflow flows from the reservoir excerpted from" environmental Impact Assessment" report which has extracted from" water resources programming and optimum energy production". For surveying of yearly varying, three aquatic year of very dry, normal and very wet have been entered separately in model input for comparing of thermal profiles.

Model Boundry Condition

Upward boundry conditions are defined in the model by inflow rate to reservoir and inflow water temperature and downward boundry condition is defined by outflow rate from outlet structure. Hydrological information extracted from water measurement station of TangPanj, which is located in proximity of Bakhtyari river and Cesar river incidence (Fig.2).

	O	N	D	J	F	M	A	M	J	J	A	S
mean	46.8	61.5	96.04	99.1	144.1	217.0	315.1	300.1	190.6	117.6	78.57	56.21

Fig.2-Mean, maximum and minimum of bakhtyari river monthly flow

Meteorological Data

Meteorological data included of air temperature degree, dew point temperature, wind speed and direction and cloud coverage. Required meteorological data has been extracted from Tangpanj and Aligoodarz stations. In this simulation, Meteorological information in a monthly period has been entered into model and has been used from 2004-2005 aquatic year information. With regard meteorological report of the project which indicates the similarity of various year air temperature, monthly mean values for two continuous years has been entered into the model.

Due to the lack of the reservoir and lack of availability of information about reservoir water temperature and level, model calibration is made at the time of reservoir shaping. Based on previously made studies (Mohammadi Khalf Badam 2004, Williams2007), two factors of wind direction to reservoir' and shades resulted from plants coverage from the surroundings are the most affecting factors on layering phenomenon which both factors with regard to collected data are determined.

Management Scenarios:

In order to simulate Bakhtaran thermal behavior based on mean probable changes in inflow flow rate into reservoir, three scenarios has been defined. In first scenario reservoir thermal behavior due to inflow water decreasing based on one of a very dry year had been simulated. The given year has been 1970-1971.In the second scenario thermal gradients in mean inflow rate into reservoir has been surveyed. For this purpose normal aquatic year of 1988-1989 has been selected. In third scenario thermal regiment of reservoir for the year of 1993-1994 which was very wet year has simulated. Outlet structure level in all scenarios was selected 700 meters above sea level.

RESULTS

Figure 3,4,5 depicting vertical water temperature profile for 12 months of the year near the dam wall. for dry, normal and wet year, respectively.

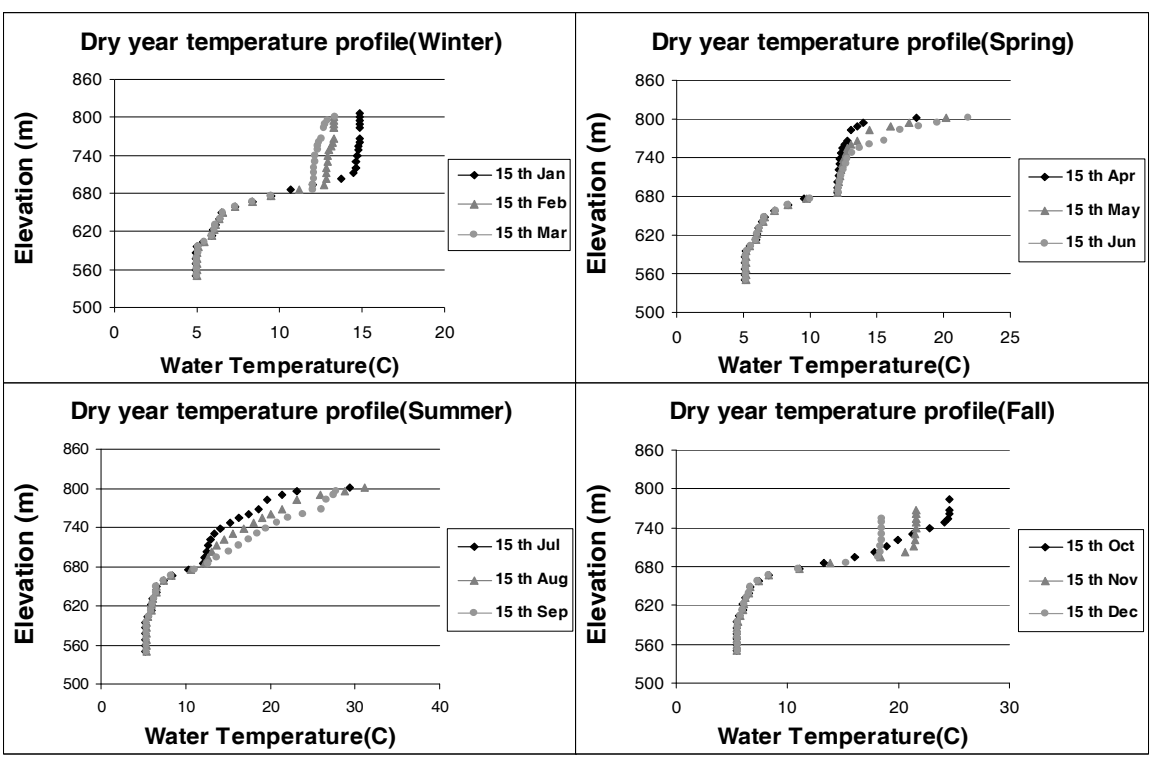

Fig.3-Dry year vertical temperature profile

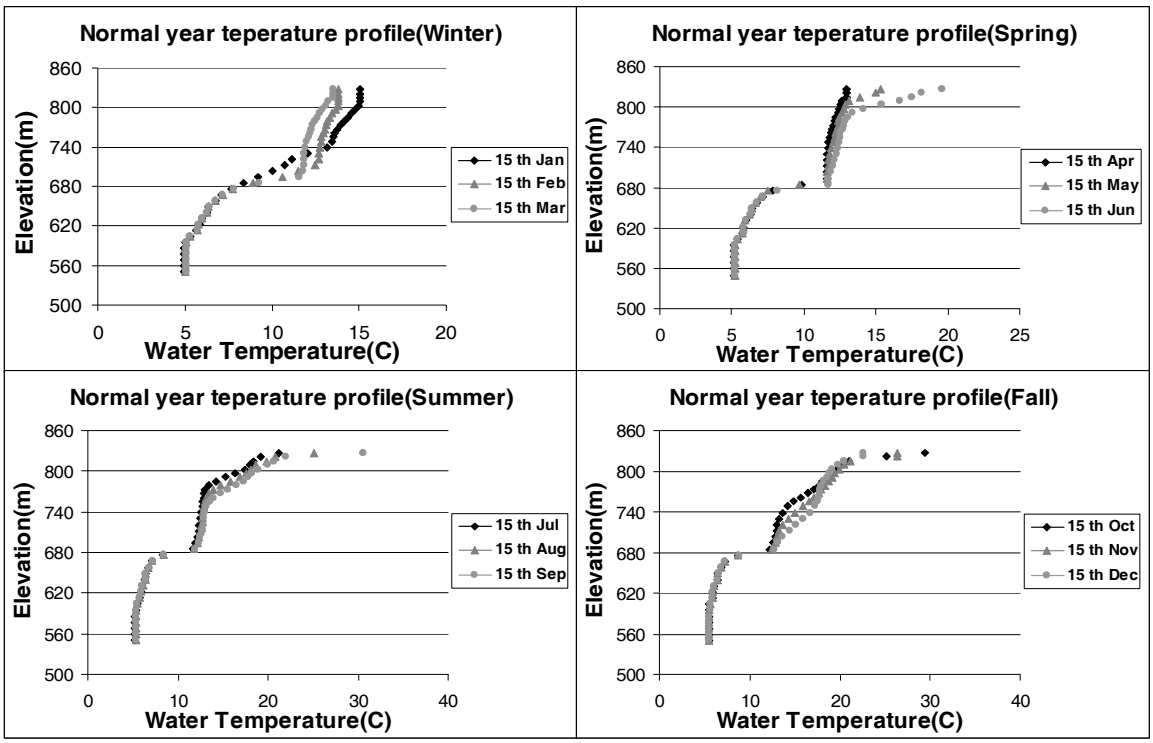

Fig.4-Normal year vertical temperature profile

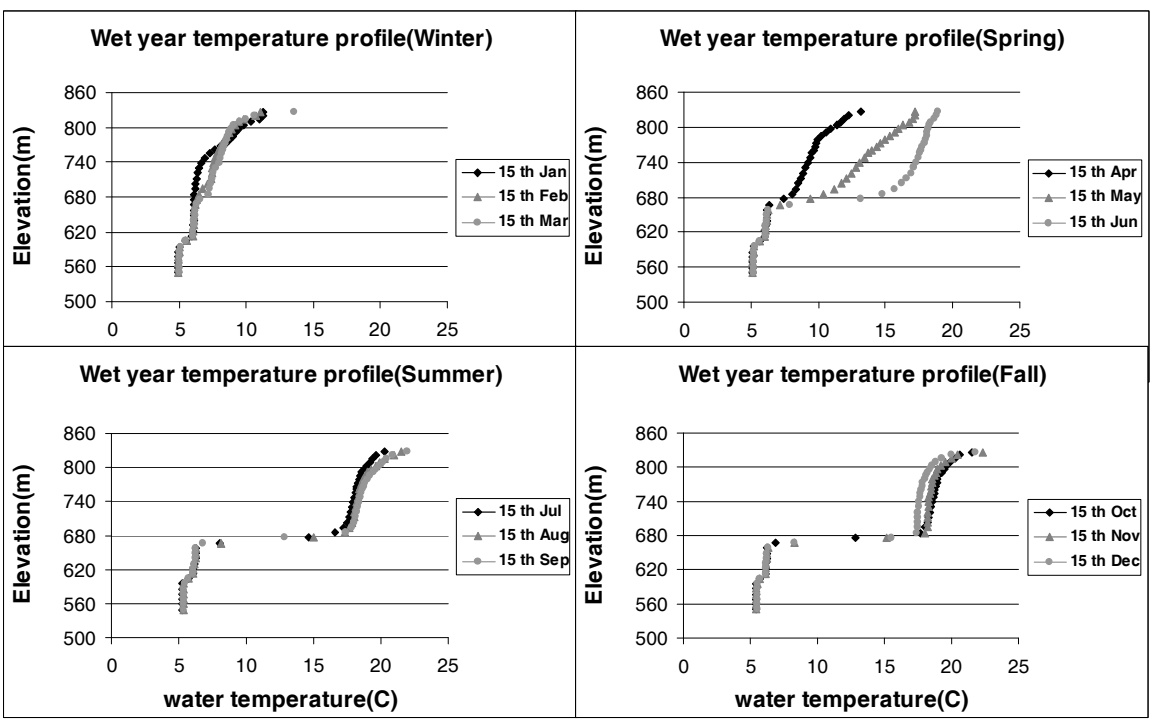

Fig.5-Wet year vertical temperature profile

Discussion and conclusion

It is observed that under 700 meters level which is selected as outlet structure level, temperature profile have stagnant behavior and seasonal changes could not be observed on that and water temperature would be uniform and about 5 degree centigrade. At preliminary test it has determined that depth of this stagnant area is a function of changes in outlet structure level.

Fig.3 show that in dry year from the beginning days of April, layer forming has been begun from high altitudinal level and would maximize up to mid of September, in a way that 16 degree changes of temperature in depth of 100 meters is observable and surface water could reach to 30 degree centigrade. From the mid of September up to January depreciation of stratification would be commenced and again an isothermal layer would begun to form and during temperature decreasing, depth of the layer increase from 35 to 60 meters and January, February and March isothermal conditions are observed about 13 to 15 degree centigrade up to 100 meters depth.Resevoir is warm monomictic and the turnover at the beginning of fall would be happened and stratification is observed about 5 month.

But based on Fig.4 changes are begun from the mid of May and maximize to its magnitude up to November. In a way that 13 degree changes of temperature in depth of 140 meters is observed and surface water temperature is near 27 degree centigrade and depreciation of formed layers would be commenced from last days of March and repeatedly an isothermal layer would begun to form and during decreasing of temperature, depth of the layer would increase from 10 meter to 115 meter and in March and April conditions of thermal uniformity is about 11 to 13 degree and is observed up to depth of 130.Reservoir is warm monomictic and turnover is happened at the beginning of winter and stratification is observed in a 7 month period of the year.

What is perceived from Fig.5 is indicating a layer along with variable thermal gradient which has temperature about 9 to 13 degrees centigrade in April up to 15 to 22 degree centigrade in beginning of winter. It seems like that, except from surface water which is a function of monthly variation of temperature, middle layers are mostly depends on inflow water and reservoir. Due to difference in operation with dry and normal years, expectable stratification would not be come true.

In comparison between two scenarios of normal and dry year it could be concluded that, with regard to long detention time in dry year, thermal gradient is high, but the period of that is shorter. The reason of shortness of stratification could be referred to reaching of a low flow rate of water period and taking of water from middle layers which give absorption opportunity of sun light to upper layers. As well as it can be concluded that , more effects of dam on aquatic regiment (dry year), more is the expectation of circumstances closeness to lake like situation and yearly circulations more would be under affection of geometrical conditions, winding and as a whole effective processes on layer formation. But by decreasing dam effect in flow regiment (wet year), outflow water quality more would be under effect of inflow regiment and reservoir's effects whether on hydrodynamic parameters such as temperature or quality parameters such as dissolved oxygen , nitrogen and phosphorus changes in depth and etc. would decrease.

Physiological and Yield Response of Green Bell Pepper to Soil Moisture Sensor Controlled Drip Irrigation

Lincoln Zotarelli, Michael D. Dukes. Agricultural and Biological Eng. Department, University of Florida. PO Box 110570, Gainesville, FL, 32611, ph: (352) 392-1864. lzota@ufl.edu; mddukes@ufl.edu.

The objectives of this study were to evaluate the physiological and yield response of pepper to different soil moisture thresholds using soil-moisture-sensor (SMS) irrigation control. Irrigation treatments were set at specific threshold of volumetric-water-content (VWC) which was allotted five irrigation windows/day and bypassed events if the VWC exceeded the established threshold. Treatments were: threshold of 4, 8, 12%VWC single irrigation-drip at center of the bed (SS); threshold of 8, 12%VWC with double drip-irrigation (SD); $TIME_{2h}$ with fixed 2hr irrigation/day and $TIME_{4x24}$ with 4 fixed events of 30min/day. The use of SMS reduced irrigation water applied (81; 118; 138; 112; 201; 341 and 260mm for SS_4; SS_8; SS_{12}; SD_8; SD_{10}; $TIME_{2h}$ and $TIME_{4x24}$, respectively). For the same order, the pepper yield was 26; 31; 35; 30; 42; 33; 41 Mg/ha. Water and NO_3-N captured in lysimeters were lower on SMS irrigation controlled compared to TIME based irrigation commonly used by producers.

Keywords: *nitrogen leaching, vadoze zone, fertigation, drainage lysimeters, best management practices*

Introduction

Vegetables are a major component of Florida agriculture encompassing about 72,000 ha for production with a crop value of 1.5 billion dollars. Bell pepper is the second most important vegetable produced in Florida in terms of value. With a crop value of 209 million dollars, the average acreage annually planted with bell peppers in Florida is 7,500 ha. Vegetable crops in Florida are irrigated due to the coarse-textured soils with low water holding capacity and soil organic matter content(Carlisle et al. 1988). Since irrigation and fertilization are intrinsically linked, appropriate irrigation management is required for these soils in order to avoid nitrate leaching. Despite the N-fertilizer rate recommendation for mineral soils with drip irrigation in Florida of 224 kg N ha^{-1}, growers may opt to apply excessively high N rates to minimize risk of yield reduction due to nitrogen limitations. In addition, on sandy soils, proper irrigation management is decisive to maximize yield, fertilizer and water use efficiency for vegetable crop production. On the other hand, significant reductions in water availability for irrigation use in southeast U.S. have increased the importance of implementation of water conservation practices in agriculture. Agricultural practices such as the use of plastic mulch, drip irrigation and quantitative irrigation scheduling are common in Florida, and they provide growers with a viable option to reduce crop water requirements and thus conserve water resources. Even with these advances, there remains a need for advancement in irrigation management by using real-time monitoring techniques combined with high frequency irrigation application methods based on actual plant water requirements. The use of frequent but low volume irrigation applications via drip irrigation is superior to the more traditional scheduling of few large applications (Locascio 2005). In the past few years, sensor technology that permits continuous on-farm monitoring of soil water status has become increasingly accessible to commercial producers. Soil moisture

sensors (SMS) measure volumetric soil water content (SWC), which can be used to more accurately balance specific crop water requirements. The use of SMS–based irrigation systems can maintain soil water status within upper and lower limits determined by type of soil and crop preventing over irrigation and saving water (Dukes and Scholberg 2005; Zotarelli et al. 2008; Zotarelli et al. 2009) . The objective of this study was therefore to identify suitable irrigation scheduling methods, drip irrigation system design to reduce crop water use and to evaluate their effect on pepper development and yield. We hypothesized that alternative irrigation designs and improved irrigation management will reduce irrigation water requirements of intensively managed pepper production systems.

Materials and Methods

A field experiment was carried out at the University of Florida, Plant Science Research and Education Unit, near Citra, FL, during the spring of 2008. The soil has been classified as Candler sand (Buster 1979). These soils contain 97% sand-sized particles in the upper 1 m of the profile (Carlisle et al. 1988) with a field capacity in the range of 0.10-0.12 ($v\ v^{-1}$) in the 0-30 cm depth (Icerman 2007). The area was rototilled and raised beds were constructed with 1.8 m between bed centers. Granulated fertilizer was incorporated into the beds at a rate of 112 kg ha^{-1} of P_2O_5. Beds were fumigated (80% methyl bromide, 20% chloropicrin by weight) 13 days before transplanting at a rate of 604 kg ha^{-1} after placement of drip tape and plastic mulch in a single pass. Irrigation was applied via drip tape (Turbulent Twin Wall, 0.20 m emitter spacing, 0.25 mm thickness, 0.7 L hr^{-1} at 69 kPa, Chaplin Watermatics, NY). Water applied by irrigation and/or fertigation was recorded by positive displacement flowmeters (V100 16 mm diameter bore with pulse output, AMCO Water Metering Systems, Inc., Ocala, FL, USA). Weekly manual meter measurements were manually recorded while data from transducers that signaled a switch closure every 18.9 L were collected continuously by data loggers (HOBO event logger, Onset Computer Corp., Inc., Bourne, MA, USA) connected to each flow meter. Pressure was regulated by inline pressure regulators designed to maintain an average pressure in the field of 69 kPa during irrigation events. The plots were 15 m long, and a tractor mounted hole puncher was used to make 50 mm wide openings at 30 cm intervals in twin staggered rows with each approximately 7 cm from the bed center. A weather station located within 500 m of the experimental site provided precipitation, temperature, relative humidity, solar radiation and wind speed data and this information was used to calculate daily reference evapotranspiration (ET_0) according to FAO-56(Allen et al. 1998). Crop evapotranspiration (ET_c) was based on the product of ET_0 and the crop coefficient (K_c) for a given growth stage (Simonne et al. 2007) and values were reduced by 30% to account for the effect of plastic mulch on crop ET (Amayreh and Al-Abed 2005) until the plant canopy was 80% full cover of raised bed area. Pepper transplants (*Capsicum annuum* var. "Brigadier") were set on 9 April 2008. Weekly fertigation consisted of injecting dissolved fertilizer salts into fertigation lines. All plots received 247 kg ha^{-1} of K_2O as potassium chloride and 12 kg ha^{-1} of Mg as magnesium sulphate. The experimental design had seven irrigation treatments randomized within four blocks. The N-rate corresponded to 220 kg ha^{-1} of N applied as calcium nitrate (Olson et al. 2005).

The irrigation treatments were identified as single drip irrigation (SS) in the center of the bed and double drip (SD) beside plant rows. The irrigation treatments were regulated by the commercial RS500 soil moisture sensor (SMS) controller manufactured by Acclima, Inc. (Meridian, ID). The RS500 unit controls irrigation application by bypassing time clock initiated irrigation events if soil moisture was at or above a preset threshold of volumetric water content

(VWC) depending on irrigation treatment (Table 1). The soil moisture sensor probes were installed at a 45 degree angle between two plants that measured the soil moisture in the top 0.15 m of the bed. Timed irrigation windows were specified as five possible events per day, starting at 8:00 am, 10:00 am, 12:00 pm, 2:00 pm, and 4:00 pm for 24 minutes each (2 hr/day total). Two reference treatments were established, a time-based irrigation treatment with one fixed 2 hr ($TIME_{2h}$, approx. 6 mm/day) irrigation event per day and fixed 4 irrigation events per day of 24 min ($TIME_{4x24}$, approx. 4.8 mm/day), both with a single drip line. An overview of irrigation treatments are outlined in Table 1.

Table 1. Outline and description of irrigation treatments along with threshold volumetric water content (VWC), total cumulative and daily irrigation application depth.

Treat. codes	Irrigation description	Threshold VWC	Max. irrigation	Max. daily	Number of irrigation events		
		$m^3\ m^{-3}$	frequency (events/d)	irrigation (mm)	Sched.	Irrigated	Skipped
SS_4	Acclima Digital TDT RS-500	0.04	5	6.0	266	77	189
SS_8	Acclima Digital TDT RS-500	0.08	5	6.0	266	106	160
SS_{12}	Acclima Digital TDT RS-500	0.12	5	6.0	266	117	149
SD_8	Acclima Digital TDT RS-500	0.08	5	6.0	266	172	94
SD_{12}	Acclima Digital TDT RS-500	0.12	5	6.0	266	171	95
$TIME_{2h}$	No soil moisture sensor, daily fixed time irrigation	-	1	6.0	54	54	0
$TIME_{4X24}$	No soil moisture sensor, reduced daily fixed time irrigation	-	4	5.0	216	216	0

Plots were harvested on 62 and 76 days after transplanting (DAT). The harvested area consisted of a central 10.5 m long region within each plot. Pepper fruits were size graded into culls, medium, large, and extra-large. Marketable weight was calculated as total harvested weight minus the weight of culls. Irrigation water use efficiency (IWUE) expressed in kg of fruit per m^{-3} of irrigation applied was calculated. Plant biomass accumulation was evaluated by harvesting two representative plants per treatment replicate at transplanting, 23, 34, 49 and 68 DAT. Vegetative and reproductive plant parts were separated. Leaf area was determined for each sample using a LI-300 (Li-cor, Lincoln, Nebraska). Shoot and fruit tissues were dried at 65 ^{o}C for subsequent dry weight determination. Leaf stomatal conductance (g) was measured with a diffusion porometer (Model AP4, Delta-T Devices, Burwell, Cambridge, UK). Measurements were performed at middle of vegetative stage and at begging of the flowering stage. Four leaves (two sunlit, two shaded) were sampled from the upper part of pepper plants, giving twelve measurements per treatment (Verhoef 1997). The results of stomatal conductance were multiplied by the corresponding plant leaf area for each treatment and the results presented in mmol s^{-1} $plant^{-1}$.

The volumetric water content of the top soil of the production beds was monitored by coupling time domain reflectometry (TDR) probes (CS-615, Campbell Scientific, Inc. Logan, UT, USA) with a datalogger (CR-10X, Campbell Scientific, Inc., Logan, UT, USA). Soil

moisture probes were placed in the beds at two subsequent soil layers which recorded soil moisture values. The upper probe was inserted at an angle in order to capture soil moisture in the top 0.15 m of the profile and the lower probe was inserted vertically below the upper probe recording soil moisture between 0.15 m and 0.30 m. Drainage lysimeters were installed 0.75 m below the surface of the bed three years prior to the bed formation. Leachate extraction via a vacuum pumping system occurred weekly, one day before each fertigation event. Total leachate volume was determined gravimetrically, and subsamples collected from each bottle were analyzed for NO_3-N so that total N loading rates could be calculated. Soil solution and soil core extracts were stored at –18 ºC (0 ºF) until nitrate and nitrite analysis. Samples were analyzed using an air-segmented automated spectrophotometer (Flow Solution IV, OI Analytical, College Station, TX) coupled with a Cd reduction approach (modified US EPA Method 353.2).

Statistical analyses were performed using PROC GLM procedure of (SAS 2002)to determine treatment effects for yield, IWUE and stomatal conductance. Means separation testing was performed as needed using Duncan's Multiple Range Test at a confidence level of 95%. For repeated measurements such as plant biomass accumulation volume leachate nitrate leaching, the PROC MIXED procedure of SAS with residual maximum likelihood estimation approach and least squares means of fixed effects were pair-wise compared.

Results and Discussion

The cumulative rainfall at the final harvest was 174 mm. Overall temperatures increased over time, during establishment period average temperature was 19 ºC and the minimum temperature dropped below 10 ºC on several occasions. During the plant vegetative and reproductive stages the average daily temperature was 25 ºC, with maximum temperatures ranging between 27 and 35 ºC and minimum temperature ranging between 11 and 23 ºC.

In the first 23 days after transplanting, a plant establishment phase was characterized by the application of approximately 5.5 mm day^{-1} divided in 4 irrigation events, totaling 123 mm applied to each treatment. After the pepper plants were well established, the irrigation treatments were initiated. Each soil moisture sensor controller was programmed to bypass irrigation if the probe read soil moisture at or above the set threshold at the beginning of an irrigation window. During the crop season, programmed irrigation events were skipped which significantly reduced the amount of water applied to soil moisture sensor (SMS) based treatments (Fig. 1). The volume of irrigation increased in order $SS_4 < SD_8 < SS_8 < SS_{12} < SD_{12} < TIME_{4x24} < TIME_{2h}$ (Fig. 1). For the same order, the water savings compared to $TIME_{2h}$ treatments corresponded to 76%; 67%, 65%, 60%; 41% and 24%, respectively. The daily application rates can be translated to 1.5, 2.1, 2.2, 2.6, 3.8 and 4.9 mm d^{-1}, respectively. The cumulative ETc for the period after the plant establishment was 170 mm (Fig. 1), which indicates that only treatments SD_{12}, $TIME_{4x24}$ and $TIME_{2h}$ received amount of irrigation water above the cumulative ETc at end of the season.

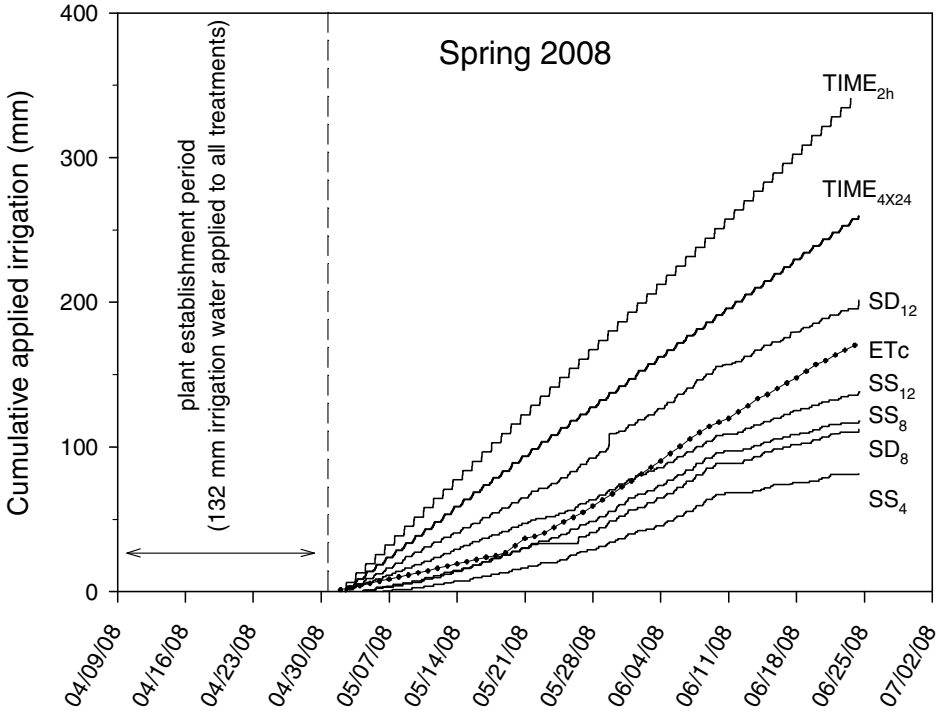

Fig.1. Cumulative irrigation and estimated evapotranspiration (ET_c) after initial plant establishment as affected by different irrigation scheduling and soil moisture sensor irrigation treatments during spring 2008.

The soil moisture content as measured by TDR probes had a noticeable increase in soil moisture after each irrigation event throughout the growing season (Fig. 2). Soil moisture sensor based irrigation treatments irrigated for short periods of time which resulted in a relatively small increase in soil moisture, consequently decreasing the volume of percolate. On the other hand, the $TIME_{2h}$ treatment was irrigated for a longer time period which resulted in very pronounced soil moisture fluctuations (Fig. 2 bottom row). These spikes in soil moisture were only temporary, as excess soil moisture that rapidly drained in this sandy soil (Fig. 3). Soil moisture content returned to field capacity within 12 h. The spikes also indicate that the soil water content as measured by the TDR probes rapidly reaches a point above the soil water holding capacity in the soil upper layer, inducing percolation to deeper soil layers, and explaining the higher percolate values for the $TIME_{2h}$ treatment compared to the other treatments (Fig. 3 left). In fact, similar spikes in soil water content were observed at below15 cm showing appreciable soil water percolation though the soil profile throughout the entire production. In terms of soil water availability to plants, the $TIME_{2h}$ treatment initially may provide more favorable growth conditions since the soil remains wetter, thus reducing potential water stress. However, excessive water percolation also may reduce N retention and crop N supply and thereby reduce yield for pepper (Fig. 4).

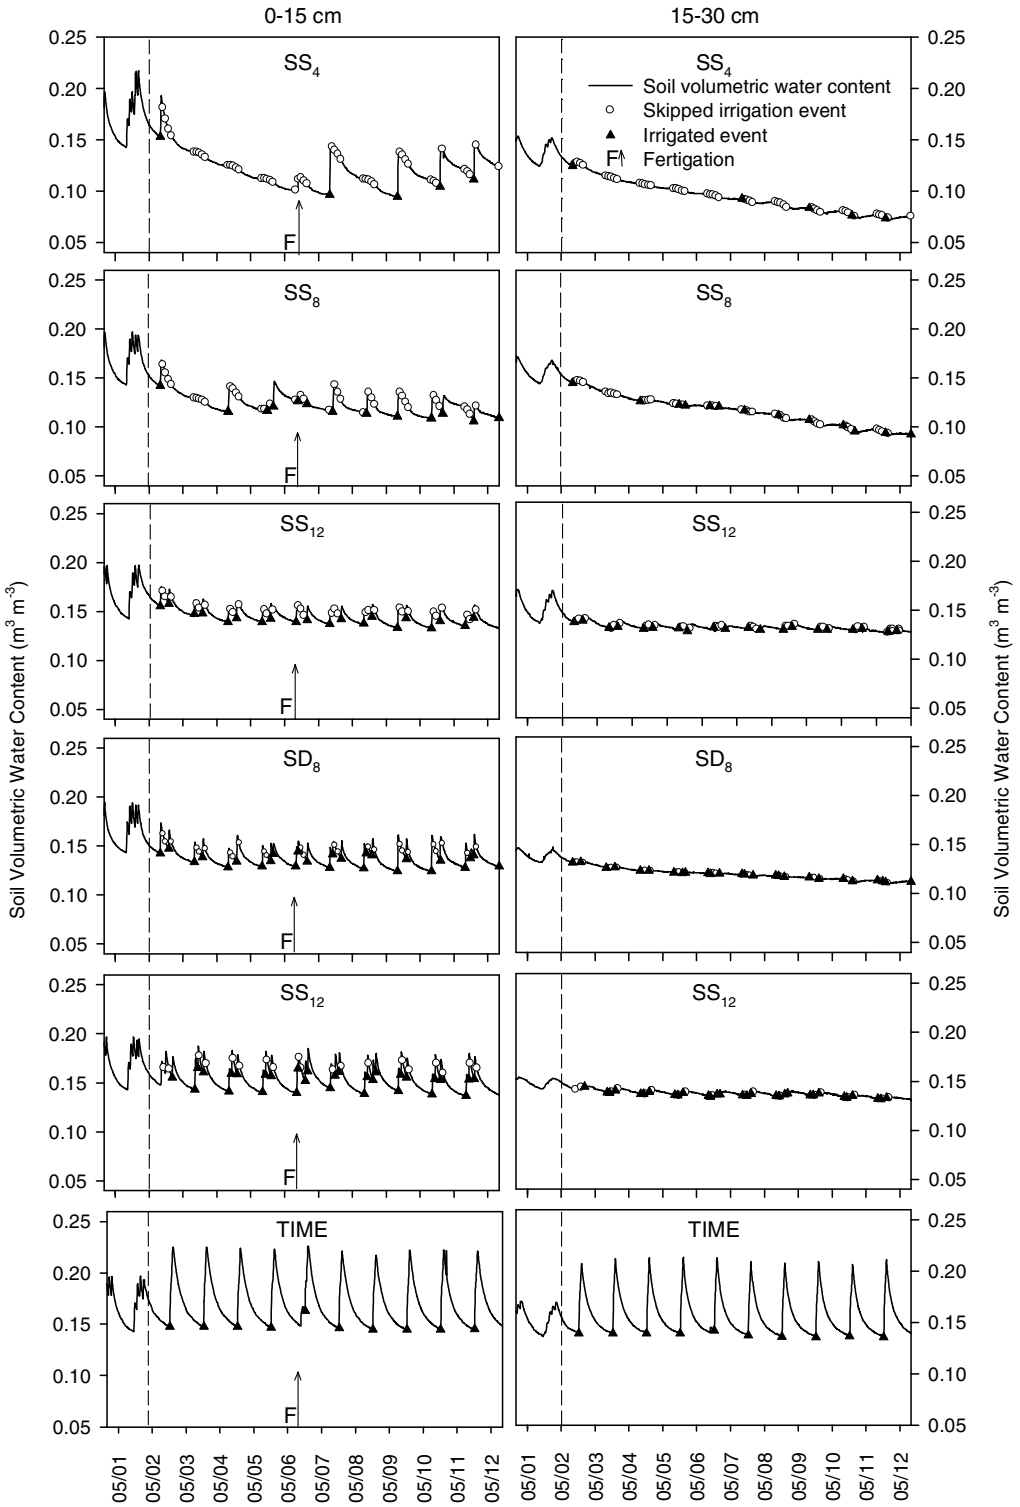

Fig. 2. Soil volumetric water content measured at 0-15 cm (left graphs) and 15-30 cm depth (right graphs) with schedule irrigation events during pepper vegetative development in spring of 2008. The dotted line represents the initiation of soil moisture sensor treatments.

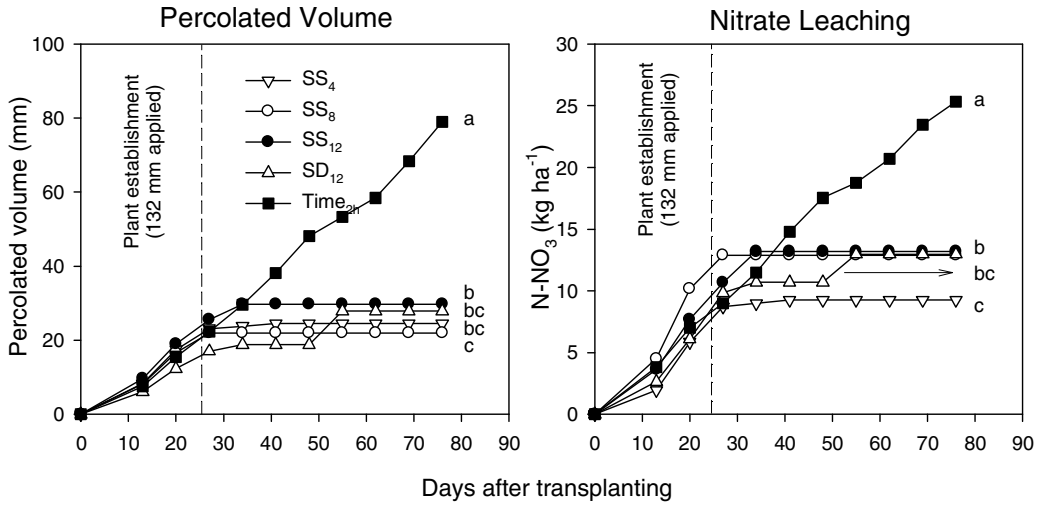

Fig.3. Cumulative leachate volume (left) and cumulative NO_3-N mass leached for different irrigation scheduling and soil moisture sensor irrigation treatments during spring 2008. Treatment means followed by same letter are not different according to Duncan's Multiple Range Test at $P \leq 0.05$.

The overall leachate amounts since the transplanting date were 24, 22, 30, 27 and 80 mm, for SS_4, SS_8, SS_{12}, SD_{12} and $TIME_{2h}$, respectively. However, most of the water percolation occurred during the establishment period, except for $TIME_{2h}$, which percolated about 7-8 mm wk^{-1} (Fig. 3 left). Cumulative nitrate leaching at the end of the crop season was significantly higher for $TIME_{2h}$ with 25 kg NO_3 ha^{-1} leached. The measured values for SS_4, SS_8, SS_{12} and SD_{12} ranged from 9 to 13 kg NO_3 ha^{-1} following the same patterns observed for percolated volume (Fig. 3 right).

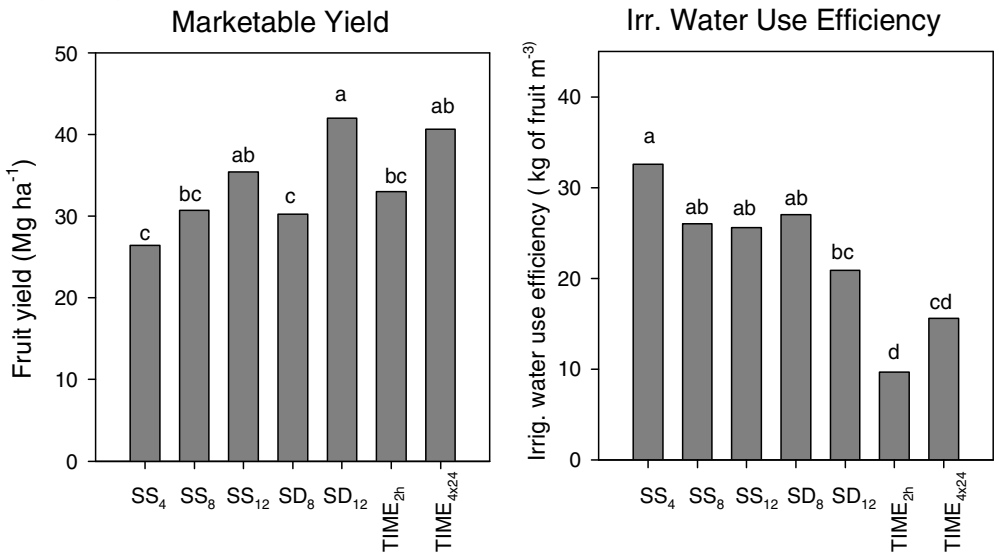

Fig. 4. Pepper total and marketable yield (culls minus total yield) and irrigation water use efficiency as affected by different irrigation scheduling and soil moisture sensor irrigation treatments during spring 2008. Treatment means followed by same letter are not different according to Duncan's test at $P \leq 0.05$.

Irrigation treatments had an important impact on IWUE and pepper yield (Fig. 4). The use of SMS with 12% VWC threshold and $TIME_{4x24}$ significantly increased marketable pepper yield when compared to the other treatments (Fig.4). Pepper yield obtained in these experiments were in the range of those reported in the literature for sandy soils in Florida.

The use of SMS control at 12% VWC threshold increased the water use efficiency of peppers without reducing yield compared to $TIME_{2h}$. Overall shoot (leaves and stem) dry weight ranged between 1.4 and 1.9 Mg ha^{-1} with no differences between treatments (Fig. 5 bottom). A reduced leaf area was observed for SS_4 and SS_8 treatments, while other treatments showed a leaf area above 3400 cm^2 $plant^{-1}$. Interestingly, the leaf area for $TIME_{2h}$ treatment reached a plateau around 50 DAT, indicating earlier plant maturity, which may be associated to the excessive leaching and lack of nitrogen, compared to the other treatments (Fig. 5 top). On the other hand, the reduction in leaf area for treatments SS_4 and SS_8 was related to the soil water availability and irrigation water distribution. Besides the reduced number of irrigation events for SS_4 and SS_8 compared to the other SMS treatments, the amount of water applied to these two treatments was not enough to wet soil between 15-30 cm and VWC decreased below 10% several days after the treatments started (Fig. 2 right column).

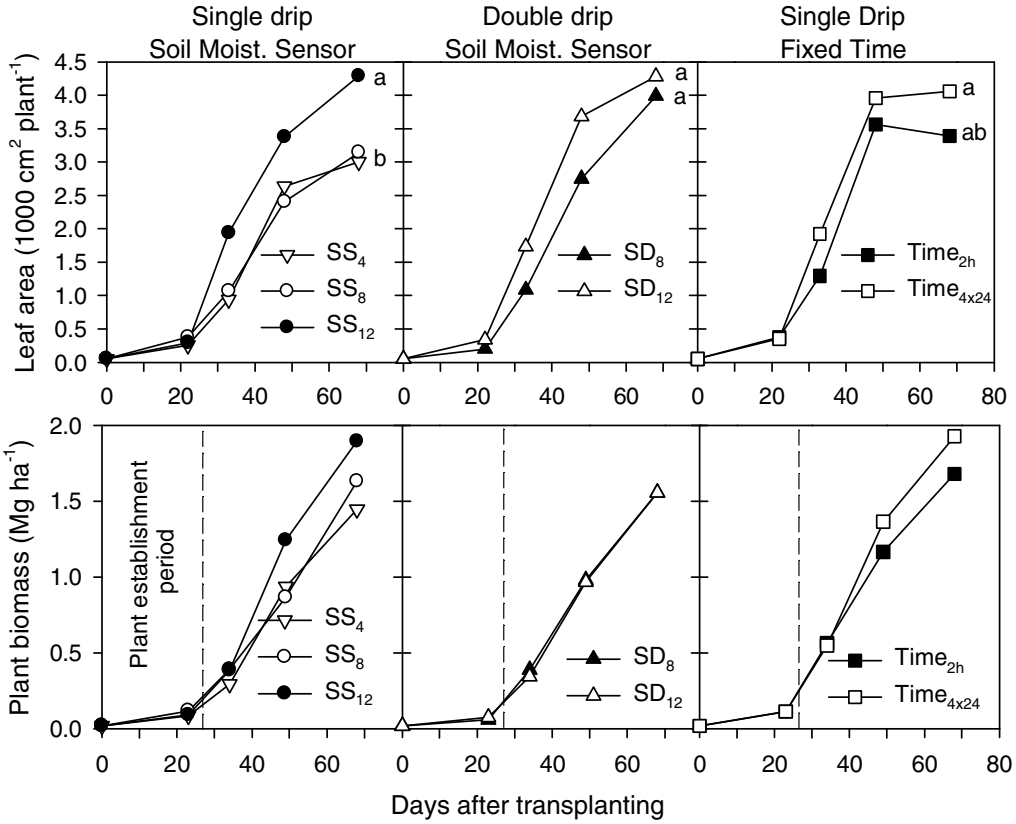

Fig.5. Leaf area (top row) and cumulative plant biomass (bottom row) of pepper as affected by different irrigation scheduling and soil moisture sensor irrigation treatments during spring 2008.

The irrigation frequency reported for treatments SS_{12}, SD_8 and SD_{12} resulted in higher levels of VWC (15-18%) at 0-15 cm and 15-30 cm soil layer (11-14%) without excessive drainage (Fig. 3). The soil moisture patterns influenced directly leaf stomatal conductance. Initially at 33 DAT, leaf stomatal conductance ranged between 7 to 15 mmol s^{-1} $plant^{-1}$, but no

patterns leaf stomatal conductance was correlated to the irrigation treatments (Fig. 6 left). During the flowering at 48 DAT, leaf conductance was again measured (Fig. 5 right, notice different scale for axis), and the $TIME_{4x24}$, SD_{12} and SS_{12} showed the higher leaf stomatal conductance and these results followed the similar patterns of yield results. Furthermore, more frequent measurements within a day and in season are required to reduce the large uncertainty of approximately 20% (Bragg et al. 1991) in conductance data estimated using porometry.

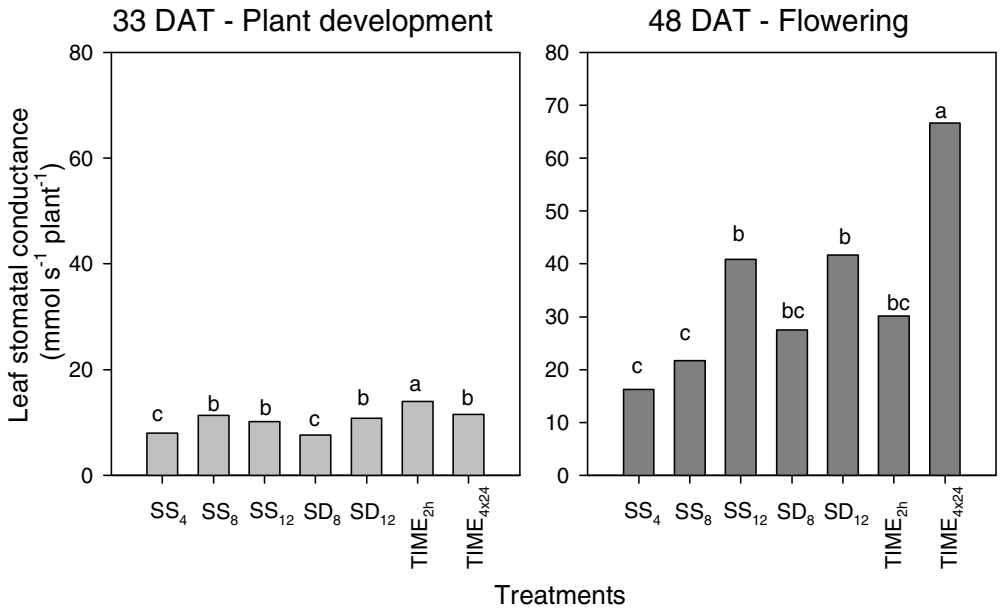

Fig.6. Pepper leaf stomatal conductance as affected by different irrigation scheduling and soil moisture sensor irrigation treatments during spring 2008. Treatment means followed by same letter are not different according to Duncan's test at $P \leq 0.05$.

Conclusion

Soil-moisture sensor (SMS) based irrigation systems in pepper significantly reduced the applied irrigation resulting in 41%-60% less irrigation water applied compared to fixed time irrigation ($TIME_{2h}$) without reducing yield. Soil moisture sensor controller thresholds below 8% of volumetric water content significantly reduced the amount of water applied, but also resulted in a significant decrease of marketable yields. The treatment ($TIME_{4x24}$) with four fixed irrigation events a day resulted in similar marketable yields as SD_{12}, SS_{12}, but with lower irrigation water use efficiency. The use of double drip improved water distribution across bed, which resulted in an increase of leaf area for SD_8 compared to SS_8 treatment, however, no additional yield benefit was measured due to the use of double drip comparing SS_{12} and SD_{12} to SS_8 and SD_8.

Water Production Functions for High Plains Crops

Thomas Trout, Gerald Buchleiter and Walter Bausch

USDA-Agricultural Research Service, 2150 Centre Ave., Bldg D, Fort Collins, CO. 80526; PH 970-492-7419; email: Thomas.trout@ars.usda.gov.

ABSTRACT

Declining water supplies is the critical resource issue for irrigated agriculture in the High Plains and much of the western U.S. Farmers need to maximize production per unit water consumed to remain economically viable and sustain irrigated agriculture. The Agricultural Research Service (ARS) Water Management Research Unit is developing water production functions for High Plains crops that can help farmers make decisions for allocating limited water supplies among crops. The Unit has developed an irrigated research farm to measure total water balance for a 4 crop rotation (wheat, corn, sunflower, dry beans). The goal is to develop water production functions based on consumptive use, relate yields to soil water deficits and plant stress indicators, and improve existing plant growth models to more accurately reflect water stress effects. Results for the first year corn crop show both grain and total biomass yields nearly proportional to water consumptive use with water use efficiencies of 2.4 and 3.9 kg/m^3, respectively.

INTRODUCTION

Population growth, environmental needs, water table declines, and reduced precipitation, possibly due to climate change effects, are resulting in reduced water supplies for irrigated agriculture in the High Plains and much of the western U.S. These trends will likely continue. As our understanding of the hydrology of the region has improved, it has become apparent that increases in irrigation system efficiency alone will not create sufficient water supplies to meet future water needs. Irrigated area will likely decline, jeopardizing the viability of rural agricultural economies throughout the High Plains.

Sustaining irrigated agriculture will require maximizing economic output per unit of the most limiting resource – water. This will require both conversion to higher value crops, which has been occurring for several years in California and the southwestern U.S., and maximizing productivity per unit of water consumed.

Many studies have shown that the marginal productivity per unit of irrigation water applied tends to increase as water application declines. This may be due either to increased efficiency of water use (less deep percolation and evaporation losses from irrigation and better utilization of precipitation), or to a physiological responses in plants that increases productivity per unit water consumed. The first effect is likely, but, as stated above, may not produce the needed additional water supplies. Past studies that show a linear relationship between yield and water consumption

(Doorenbos and Kassam 1986) indicate that there may not be water productivity efficiency gains from decreasing water use.

The objective of this project is to measure water productivity (production per unit water use) of four crops common in the high plains under a range of water application and consumption amounts. Precision water application and measurement systems are used to separate out irrigation efficiency and crop water productivity. Plant responses to water stress are monitored to better understand physiological responses and to provide indicators of levels of stress. Plant growth models will be compared with the results and modified to better model stress effects, so that the results can be extended to other environments and conditions.

METHODS

A 16 ha field research facility northeast of Greeley, CO was developed to enable the precision field measurements required to accomplish the above objectives. Four blocks (one per crop) were laid out near the center of the facility with 4 replications and 6 water treatments. Each block has 6 outside buffer rows. Each plot includes twelve 40 m long rows (76 cm spacing), of which the center four are used for measurements. The predominately sandy loam soils in the plot area were mapped according to apparent electromagnetic measurements and with visual surveys of open irrigation pipe trenches. Soil cores were sampled to 2 m to determine soil types and water holding characteristics.

Four crops – winter wheat, field corn, sunflower (oil), and dry beans (pinto) are rotated through the four blocks. Crops are planted, fertilized, and managed for maximum production under fully irrigated conditions. All blocks are managed with no or minimum tillage except for one 7.6 m end of each replication across all plots which is conventionally tilled to allow comparison of the water balance under the two tillage systems.

Six water treatments are applied to each crop:

- #1 – 100%: fully meet predicted water requirements
- #2 - 85%: 85% of treatment #1
- #3 - 70%: 70% of treatment #1
- #4 - 70%: 70% of treatment #1
- #5 - 55%: 55% of treatment #1
- #6 - 40%: 40% of treatment #1

Treatment 3 is applied proportional to treatment #1 at each irrigation. Treatments #2, 4, 5, and 6 are targeted to be seasonally proportional to treatment #1 but the water applications are distributed in response to critical growth periods (Stewart et al. 1975, Stegman 1982). This results in applications below the treatment amount between establishment and reproductive stages and during plant maturation stages, and application above the treatment amount during the critical reproductive stage. This water management scenario is designed to maximize production per unit of water applied. Comparison of treatments 3 and 4 will indicate the advantages of this

scenario. All treatments are irrigated equally during the germination and plant establishment period.

Irrigation water is delivered to the corner of each plot and applied through polyethylene header pipes to drip irrigation tubing (Point Source Irrigation 41T163-12 [16 mm thick walled tubing with 1.1 L/h conventional inline emitters on 30 cm spacing])[1] laid on the soil surface near each plant row. Flow rates and volumes to each treatment are measured with turbine flow meters (BadgerMeter Recordall 1 ½" Turbo 160 meters with RTR transmitters). Irrigation applications to each treatment are controlled and recorded with Campbell Scientific CR 1000 data loggers. A portable sprinkler system (Nelson Poly 2000 with R10 Turbo heads on 9 m spacing) is used as needed to germinate crops and incorporate herbicides. Water is supplied from groundwater (1.9 dS/m), stored in a 22,000 L storage tank, and pressurized with a pressure-controlled variable frequency drive booster pump.

An automated weather station is located at the edge of the plots near the center of a 0.5 ha grass plot. Hourly data from the station is used to calculate ASCE Standardized Penman-Monteith alfalfa reference evapotranspiration (ETr). Soil water content (SWC) in each plot between 15 and 200 cm depth is measured by neutron attenuation (503 Hydroprobe, Campbell Pacific Nuclear) from an access tube in the center of each plot. Soil water content in the surface 15 cm is measured with a MiniTrase portable TDR system (SoilMoisture). Irrigations are scheduled using measured soil water depletion and predicted soil water depletions based on ETr measurements.

Plant measurements are taken periodically to indicate responses to the water treatments. Plant growth stage is assessed visually. Canopy cover is measured both with a photosynthetically active radiation sensor (AccuPAR LP-80, Decagon Devices), and a NIR,R,G digital camera (ADC, TetraCam Inc.). Spectral radiometers and an infrared thermometer mounted on a mobile platform (along with the TetraCam camera) measure canopy reflectance and temperature, respectively (Fig 1). Stomatal conductance is measured with a porometer (Model SC-1, Decagon Devices), and leaf water potential with a plant water status console (Model 3000, SoilMoisture, Inc.). At the end of the season, seed yield and quality and total biomass is measured from an approximately 70 m^2 area in the center of each plot.

Two adjacent 2 ha fields are each planted to one of the four crops so that each crop is grown in alternate years. Bowen Ratio energy balance instrumentation is installed in the center of each field to estimate actual crop ET. The crop in the field is irrigated to meet full water requirements, and the measured ET is compared to calculated water use in the 100% treatment. The measured ETc is also used to calculate a crop coefficient for the crop under well watered conditions. The fields adjacent to these fields and the plot areas are used as buffer areas and for variety trials under water stress conditions.

Figure 1. Mobile radiometer platform used to measure reflectance and canopy temperature from 7.2 m above the ground.

Results will be compared with three types of models. A simple water balance spreadsheet is used to track ET and SWC and to schedule irrigations. This model estimates ETc (FAO 56 methodology), surface evaporation, and deep percolation losses and compares measured and predicted SWC. The FAO AquaCrop model (Steduto et al. 2007, Raes, et al. 2007) is a semi-empirical model designed to predict crop water production functions. We will calibrate the model with initial results and verify its accuracy against future year data. The RZWQM2 model (Ma et al. 2000, Ahuja et al. 2000) is a process-based soil and plant model. It will be coupled with the DSSAT (Jones et al. 2003) suite of plant models and compared with measured results. Once the various components of the model are verified (soil water balance, ETc, plant growth, yield), it will be used to project the field results to other conditions and environments and generate data for economic comparisons of alternative water management options. The RZWQM2 model produces a single stress parameter to describe water stress. We will attempt to relate this stress parameter to our measurements of plant stress and add measurable stress indicators that could be used as triggers for deficit irrigation scheduling.

RESULTS

This project began in 2008 so we have completed one crop year. We will present 2008 results for corn in this paper. Due to land preparation requirements (deep ripping and land planing), the first year crop was not planted "no-till". Nitrogen fertilizer applications, based on soil samples and agronomic practices, were split between preplant broadcast (50 kg/ha), sidedress at planting (33 kg/ha), and water-applied nitrogen (34 kg/ha). DeKalb 52-59 AF2 (VT3) corn seed was planted May 12 at 80,000 seeds per ha. Germination was nearly 100%.

The corn, which was sprinkle irrigated May 21 (20 mm), emerged about June 1 and received 30 mm of precipitation on June 6. This was the last measureable rainfall until Aug 6, allowing fully controlled water treatments throughout the vegetative stage. Ten irrigations (287 mm) were applied to the 100% treatment and 7 irrigations (110 mm) to the lowest water treatment in this interval. On Aug 4, soil water deficits to 90 cm depth varied from about 40 mm in the 100% treatment to 90 mm in the driest two treatments. Figure 2 shows the dramatic effects of the water stress treatments on corn vegetative growth.

Figure 2. Comparison of corn growth condition on July 31 just before entering the reproductive growth stage. Rows at the left and background are treatment 1; rows at right (short with curled leaves) are treatment 6.

Table 1. Water application and consumptive use for the six irrigation treatments for the 2008 corn crop. Applications are divided between vegetative (Veg) and reproductive (Repro) growth stage (before/after Aug 3). Percents are relative to treatment #1. Soil water content (SWC) change is to 0.9 m depth from June 10 to Oct 9.

Tmnt	Target	Irrigation Application			Irrig. + Precipitation			Evapotranspiration			Transpiration			Deep Perc.	Surface Evap.	SWC Change

The corn tasseled and entered the reproductive stage about Aug 3. A 42 mm rainfall on Aug 6 replenished the soil water in all treatments to start the reproductive stage, and 95 mm rainfall on Aug 14/15 filled the 0.9 m root zone profile in all treatments. Irrigation treatments were re-started on Aug 26 and continued until a rainfall on Sept 12. First frost occurred Oct 12 and the crop was harvested Nov 6.

Table 1 lists water applications and consumption for the 6 treatments. The 100% treatment received 437 mm of irrigation and 230 mm of rainfall, of which about 117 mm was lost below the root zone; and evapotranspired about 564 mm, of which about 50 mm was estimated to be surface evaporation. Although the range of irrigation applications exceeded the range of treatment targets, the range of ETc and transpiration (T) was reduced due to the August rainfall. The soil water storage change from the beginning to end of the season was relatively small in all treatments due to late season rainfall.

Although the low water treatments were severely stressed in July and early August and successful pollination seemed questionable, the well-timed rainfalls allowed even the driest treatment to produce viable yields. Seed yields varied from 12.9 Mg/ha (205 bu/ac) for tmnt #1, an above average yield for the area, down to 8.6 Mg/ha (137 bu/ac) for treatment #6. The harvest index increased only slightly with increasing deficits (from 0.58 to 0.62). Figure 3 shows the water production relationship for the crop. The relationships for both total biomass and seed yield are fairly linear over the range tested. The intercepts of both the biomass and grain yield vs. ETc and T are small meaning that the responses are nearly proportional and the water productivity (yield per unit water) is nearly constant over the range. The grain yield averaged 2.7 and 2.4 kg per m^3 of water and biomass yield averaged 4.4 and 3.9 kg/m^3 of water transpired and evapotranspired, respectively. For the 2008 year, the grain yield per unit irrigation water applied increased from 3.0 kg/ m^3 for treatment #1 up to 6.4 kg/ m^3 for treatment #6. These values will vary widely with precipitation amount and timing.

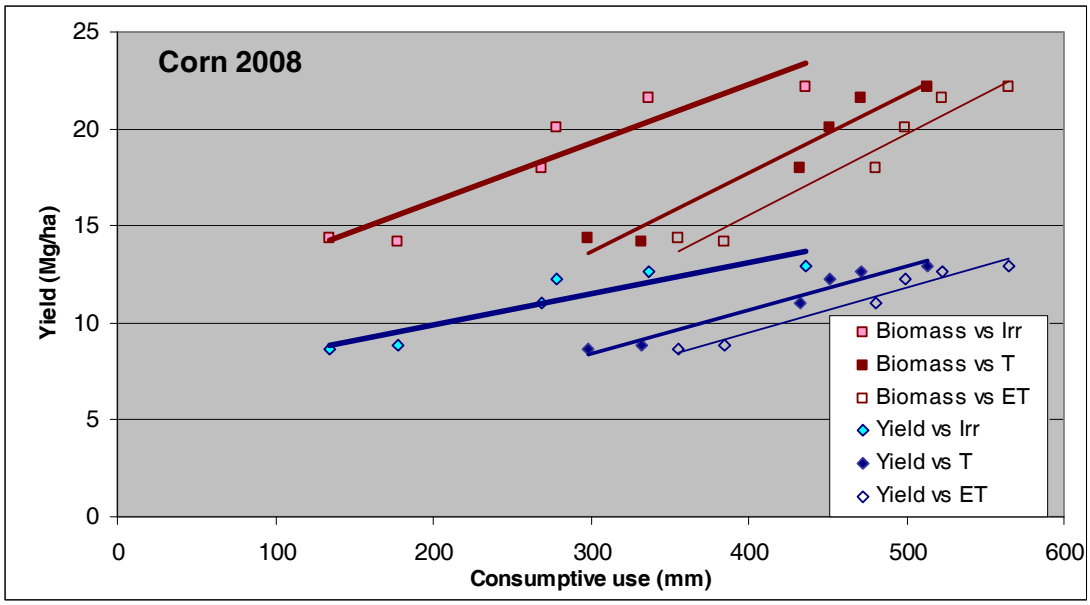

Figure 2. Water production functions for 2008 corn. Red lines are total biomass (dry wt.). Blue lines are grain yield (15.5% moisture content). Yields are plotted relative to irrigation amount (Irr), crop transpiration (T), and crop ET (ET). Lines are linear least squares regression fits to the 6 data points.

DISCUSSION

Many water production function studies in the High Plains have related production to irrigation water applied, and they show increasing productivity with decreasing irrigation applications, as we measured in this study. This is because deficit irrigation increases the effective use of precipitation, may increase irrigation efficiency by reducing deep percolation and soil evaporation losses, and may result in soil water mining. However, since the impact of irrigation on the regional hydrology is often more closely related to water consumed than irrigation water applied (assuming unconsumed water returns to useable supply sources such as groundwater or return flows to streams), consumptive use should be the more relevant parameter. By relating production to consumptive use, the results can be transferred to other environments and irrigation methods.

These results which show that water productivity does not change with consumptive use indicate little opportunity to increase water productivity through deficit irrigation. Even though stress during the vegetative stage resulted in dramatically reduced vegetation (Fig. 2), the reduction in stress during reproduction resulted in relatively good yields from deficit irrigated plots and relatively constant water productivity for both biomass and grain. Whether these results are borne out over a range of environmental conditions will be determined by future results.

Abstract

Containerized plant production represents an extremely intensive agricultural practice and a large amount of water and chemical fertilizer is applied. Hydo-physical characteristics such as water infiltration, texture and structure, particle size distribution affect the quality of the media used in containerized agricultural systems and the water availability to plants. Water retention characteristics depend on particle size distribution as well as the composition of the media used. Materials with coarser particles allow faster percolation of water and also retain relatively higher amounts moisture per unit weight due to higher porosity But drain faster due to less surface area.. Faster drainage can result into air flow through coarser materials causing the media to dry. As the media desaturates, hydraulic conductivity is reduced. The objective of this study was to analyze the different media used by nurseries to characterize the physical properties which would explain the soil-water interactions. In this study we measured soil's hydraulic conductivity in the laboratory using three methods, constant head permeability test, falling head permeability test and tension Infiltrometer. The results were compared in relation to particle size distribution characteristics of samples. The results of the study indicate that the four common media being used in nurseries in South Florida have distinct hydro-physical properties. The result of this should assist the land managers while selecting the Best Management Practices.

Introduction

Florida is the second-leading horticulture state in the nation. Florida greenhouse/nursery sales are more than $1.6 billion annually. Containerized plant production represents an extremely intensive agricultural practice and a large amount of water and chemical fertilizer is applied. Considering that three national parks (Everglades, Biscayne and Big Cypress) in south Florida surround agriculture, a major challenge in agricultural production is the development of appropriate technology that combines optimum crop production with environmental protection. Non-point source water pollutants (nutrients, pesticides, and other chemicals) resulting from agricultural areas have been implicated as a source of water quality degradation in southern Biscayne Bay. In 1996, the United States Environmental Protection Agency published an interim report on South Florida Ecosystem Assessment. The report stated that the nutrient loading from agricultural and urban areas had significantly increased nutrient concentrations,

particularly phosphorus. The report also indicated that discharging phosphorus at the current control target of 50 μg/L would continue to allow eutrophication of over 95% of the Everglades marshes.

Farming methods can alter soil mechanisms such as soil structure, porosity, as well as the hydraulic conductivity and water retention. Transition to container production is driven by market demands and numerous production advantages including greater production per acre, faster plant growth, higher plant quality, and lack of dependence on arable land (Colangelo and Brand, 2001). In agriculture systems, environmental conditions affect the longevity of fertilizer availability and release. Because environmental conditions fluctuate, regular monitoring of the medium's nutrient status is essential. Lack of essential elements will result in slow and aesthetically unacceptable growth. Conversely, excessive nutrient concentrations result in root injury, hindering the plant's ability to absorb water and nutrients; which increases the potential for environmental contamination (Water Quality Handbook for Nurseries). Leaching of nutrients is a major field of study and a major concern in agricultural practices, and the ability of a soil to hold nutrient depends on the mechanics and dynamics of its interaction with water which in turn acts a major source of nutrient transport. Extent of leaching depends directly with the hydraulic conductivity. The mass leaching is substantially reduced when the hydraulic conductivity lowers for a stabilized soil and substantially increases when the hydraulic conductivity is increased.

The objective of this study was to analyze the different media used by nurseries to characterize the physical properties which would explain the soil-water interactions. The study involved measuring soil's hydraulic properties in the laboratory by three methods (i.e., constant head permeability test, falling head permeability test and tension Infiltrometer. The results were compared in relation to the particle size distribution of each sample.

Materials and Methods

The samples analyzed where from four different nurseries across South Miami-Dade county Florida, Pine Island Mix, Nursery Mix, Greenhouse mix and Costa farms mix. The characteristics of the study samples are illustrated in Table1. The samples have high organic content. This is in contrast to soil in the region which have a high percentage of clay, sand, loam and silt. The high organic content of the four nursery samples is due to the efforts of the nursery operators who add certain media in the soil sample to increase the moisture retention capacity.

Pine Island	**Nursery Mix**	**Greenhouse Mix**	**Costa Farms**
Hardwood Fines	Pine Bark (50%)	Pine Bark (37.5%)	Pine Bark
Pine Bark Fines	Sand (10%)	Sand (7.5%)	Sand
Eco-Soil	Coir Pith (40%)	Coir Pith (30%)	Coir Pith
Dolomite	Dolomite	Perlite (25%)	Dolomite
Talstar	Micro Mix	Dolomite	Styrofoam
Minors		Micro Mix	
Total Organic Content (65.17 %)	Total Organic Content (39.13 %)	Total Organic Content (62.29 %)	Total Organic Content (48.8 %)

Table 1. Materials in nursery mixtures under study.

The study involves the following experimental procedures to develop characterize selected physical properties of nursery mixtures:

1. Sieve Analysis: Fisher Scientific (US Standard Sieve Series).
2. Constant Falling Head Permeability Test: ELE International Permeameter.
3. Falling Head Permeability Test: ELE International Permeameter.
4. Infiltration: Tension Infiltrometer Soil Measurement System Tension Infiltrometer.

It has long been recognized that hydraulic conductivity is related to the grain-size distribution of granular porous media (Freeze and Cherry, 1979). Knowledge of saturated hydraulic conductivity of soil is necessary for modeling the water flow in the soil, both in the saturated and unsaturated zone, and transportation of water-soluble pollutants in the soil. Permeability is the ease with which the water flows through a soil medium. Tension Infiltrometer measures the unsaturated hydraulic properties of a given soil sample. Water is allowed to infiltrate soil at a rate which is lower that free fall rate of water through a column, which is accomplished by maintaining a negative pressure on the water.

Methodology

- Sieve Analysis:

A defined amount of oven dry soil sample was subjected to a stack of 13 sieves ranging from 38.1mm to 0.075mm. The duration of the sieve shaking process was kept at a constant value of 15 minutes for all the four samples. After the allotted time of 15 minutes for the shaker, the individual sieves were analyzed for their respective weights and the several parameters were calculated, Cumulative percent of soil retained on the nth sieve, Cumulative percent of soil passing through the nth and the Weight gain of soil during sieve analysis.
Unlike the usual soils mixtures which tend to lose some mass during the course of the experiment, the nursery mixtures gained some weight during the course of the experiments which was about 20 minutes from the time of coming out of the oven to the final step of measuring the individual sieve weight.

Sr. No	Sample	Initial mass of soil	final mass of soil	coefficient of uniformity (Cu)	coefficient of gradation (Cc)	Weight Gain during the sieve analysis
		gm	gm			%
1	Pine Island	350	359.5	7.257	0.626	2.71
2	Nursery mix	300	302.2	2.738	0.721	0.73
3	Green house Mix	225	227.7	3.385	0.816	1.20
4	Costa Farms	200	201.6	8.276	0.920	0.80

Table 2: Sieve analysis coefficients.

- Constant Head Permeability Test:

Constant Head Permeability Test were conducted with ELE International Permeameter model EI25-0623 (Loveland, Colorado). This Instrument consists of a transparent acrylic cylinder that holds the soil sample which is to be tested. The permeameter has two different opening one at the top and the other at the bottom for the continuous movement of fluid. To distribute the flow over the entire cross-sectional area of the permeameter two Porous stones are used at either ends of the cylinder. Since the flow of water through the media may cause actual movement of the soil particle or even the soil fragments, a spring is placed on the top porous stone to pack/contain the soil media movement .the constant head permeability test requires a constant flow of water through the medium, hence to fulfill the requirement a Constant-head supply device which is just a large funnel, with an overflow held up over the permeameter. Once the assembly is in place oven dry soil specimen is filled upto about two-thirds the length of the tube. The spring packing of the oven dry sample enable the calculation of the dry density:

$$\rho_d = \frac{W}{AL}$$

Where, W is the Weight of the Specimen in the Permeameter: L is the Length of specimen *(*cm) and A is the Area of specimen ($A = (\pi/4)\, D^2$, cm^2).
Upon the measurement of time and the constant head the hydraulic conductivity of the particular sample can be calculated as:

$$K = \frac{QL}{Aht}$$

Where, Q is the Volume (cm^3), t is the Time of collection (s) and h being the Head difference (cm)

- Falling Head Permeability Test:

Falling Head Permeability Test were conducted with ELE International Permeameter model EI25-0623 (Loveland, Colorado)The equipment and assembly is similar to the Constant Head permeability test but unlike the Constant-head supply device, the head is allowed to fall with the help of a burette instead of the funnel assembly. The hydraulic conductivity is calculated as:

$$K = \frac{aL \ln \frac{h_1}{h_2}}{At}$$

Where, a = area of falling head tube (cm^2); L=final length of specimen (cm); A=area of specimen (cm^2); t = falling time (sec); h_1= initial drop height (cm) and h_2= final drop height (cm).

- Infiltration Test

Infiltration tests were conducted with tension infiltrometers by Soil Measurement Systems model SW-080B which has a 20 cm base plat that was separated from the water tower. Tension Infiltrometer measures the unsaturated hydraulic properties of a given soil sample. Water is allowed to infiltrate soil at a rate which is lower than the free fall rate of water through a column, which is accomplished by maintaining a negative pressure on the water. This is done to prevent the infiltration through cracks and wormholes, which would otherwise give high hydraulic conductivity values, which are not representative of the soil matrix (SMS Infiltrometer manual). Tension Infiltrometer measures the unsaturated hydraulic properties and the infiltration rate decreases as the soil becomes saturated till it attains a stabilized rate. The range of tensions attainable in the Infiltrometer is between 0 and –30 cm H2O, and each cm corresponds to 1 mbar pressure. Therefore at tensions close to zero, the infiltration rate should be approximately equal to saturated hydraulic conductivity of the soil.

When similar infiltration experiments involving two different negative pressures are performed the saturated hydraulic properties of the soil can be computed. The experiments when performed with a slight negative pressure difference (negative pressure of 5 vs. 40) yield nearly identical infiltration results, but the distinct behavior was eminent when the negative pressure difference was increased (negative pressure of 5 vs. 40). The volume of water entering the soil per unit time (cm^3/hr) can be computed as:

$$Q(h_X) = \pi r^2 K_{sat} \exp(\alpha h_X)\left[1 + \frac{4}{\pi r \alpha}\right]$$

Where, Q is the volume of water entering the soil per unit time (cm^3/hr); K is the hydraulic conductivity (cm/hr); α is coefficient (cm^{-1}) and h is the tension (cm). Also

$$K(h) = K_{sat} \exp(\alpha h)$$

Different negative pressures (h_x) provide different Q values, upon comparing two different Q values for the same medium hence

$$\alpha = \frac{\ln\left[\frac{Q(h_2)}{Q(h_1)}\right]}{h_2 - h_1}$$

The above equations can be used to generate a variety of values for the varying negative pressure. The saturated hydraulic conductivity value calculated and the saturated hydraulic conductivity value measured directly with the Infiltrometer might not be the same (SMS Infiltrometer manual).

Table 3. Tension Infiltrometer parameters and observation

Sr. No	Sample	Negative pressure -h1 (cm)	Negative pressure -h2 (cm)	Infiltration Rate at h_1 cm/hr	Infiltration Rate at h_2 cm/hr	Tension Infiltrometer (cm/hr)
1	Pine Island	154	40	6.12	32.04	7.2
2	Nursery mix	181	50	24.4	33.6	57.6
3	Green house Mix	153	40	23.6	36.4	25.2
4	Costa Farms	135	40	22.8	28.8	21.6

*Average of experiment done twice.

- Moisture retention capacity Evaluation

The moisture retention capacity and moisture absorption rate of the Nursery mixture is alarmingly high compared to usual soil media as evident form the sieve analysis, where the oven dry soil sample absorbs moisture from the surroundings which increases the total weight of a sample by a mean of 1.5% in a span of 20 minutes.

Table 4. Moisture gain during sieve analysis of the nursery mixtures

Sr. No	Sample	Weight Gain during the sieve analysis (In 20 minutes) %
1	Pine Island	2.71
2	Nursery mix	0.73
3	Green house Mix	1.20
4	Costa Farms	0.80

The saturated water retention capacities of the media were estimated using two different procedures, the first consists of adding water to the soil till it saturates and the second is to submerge the soil sample in water till it absorbs moisture to reach saturation. The amount of oven dry soil sample for each experiment was 50 grams. To prevent the intermixing and loss of the soil media Cheese cloth was used. The error related to the cheese cloth‘s ability to absorb water were duly noted and evaluated to get the best possible Moisture retention measurement of the Nursery mixture. The Moisture retention capacity of the media was computed as

$$\text{Saturation Water Content (\%)} = \frac{W - S - E}{S} \times 100$$

Where, W is the total weight of the saturated specimen (g); S is the soil sample weight (g); E is the error due to the cheese cloth. The high water retention capacity may be attributed to the high organic content of the Nursery mixtures.

Results

The media samples under study have been enriched by the nurseries to satisfy their respective needs and the major requirement was to retain as much moisture as the sample can. Hence a lot of organic contents where added like pine barks, manure with only fraction of sand. And a simple water saturation experiment illustrates the following results in Table 5. Figure 1 presents the particle -size distribution of the nursery mixtures. All four mixtures had similar particle size distribution, in general.

Table 5. Water saturation characteristics of the nursery mixtures.

Sr. No	Sample	Saturation Water Content (%)
1	Nursery mix	138.3 ± 13.2
2	Green house Mix	155.3 ± 3.3
3	Pine Island	213.2 ± 16.6
4	Costa Farms	201.2 ± 5.8

*Average of 3 tests

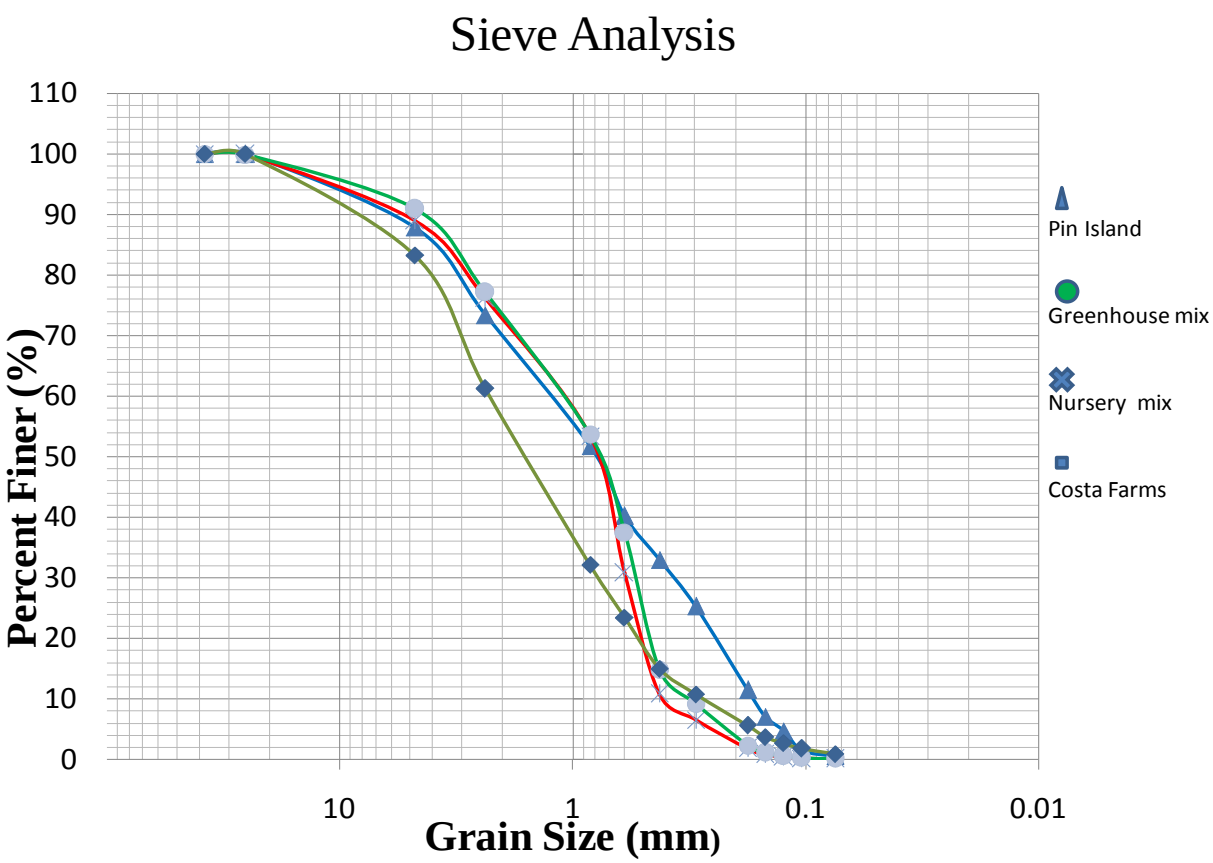

Figure 1. Particle -size distribution of the nursery mixtures.

To characterize the hydraulic conductivity of different size particles within the nursery mixtures, each sample was divided into 3 different particle size ranges by sieving. The sieving process consisted of a small sieve (0.425mm - Pan), medium sieve (2mm - 0.6mm) and large sieve (38.1mm- 4.75mm). The constant head permeability experiments provided the dry density and the hydraulic conductivity of each particle size mixture as presented in Figures 2 and 3. The decrease in particle size results in the increase of dry density and in the decrease of hydraulic conductivity. The hydraulic conductivity of the sample medium as whole follows the particle size analysis behavior, for example the Pine Island sample has larger particle size distribution hence the hydraulic conductivity is similar to the hydraulic conductivity of the lager sieve range of Pine Island sample. Tension infiltrometer was used to measure the unsaturated hydraulic properties of the nursery soil samples. Since saturated hydraulic was required, the experiments were performed with two different negative pressure. The experiments were performed in containers simulating the conditions in containerized agriculture systems. Figure 4 presents the plots of cumulative infiltration versus time. The hydraulic conductivities of the three different methods yield the results which are presented in Table 7.

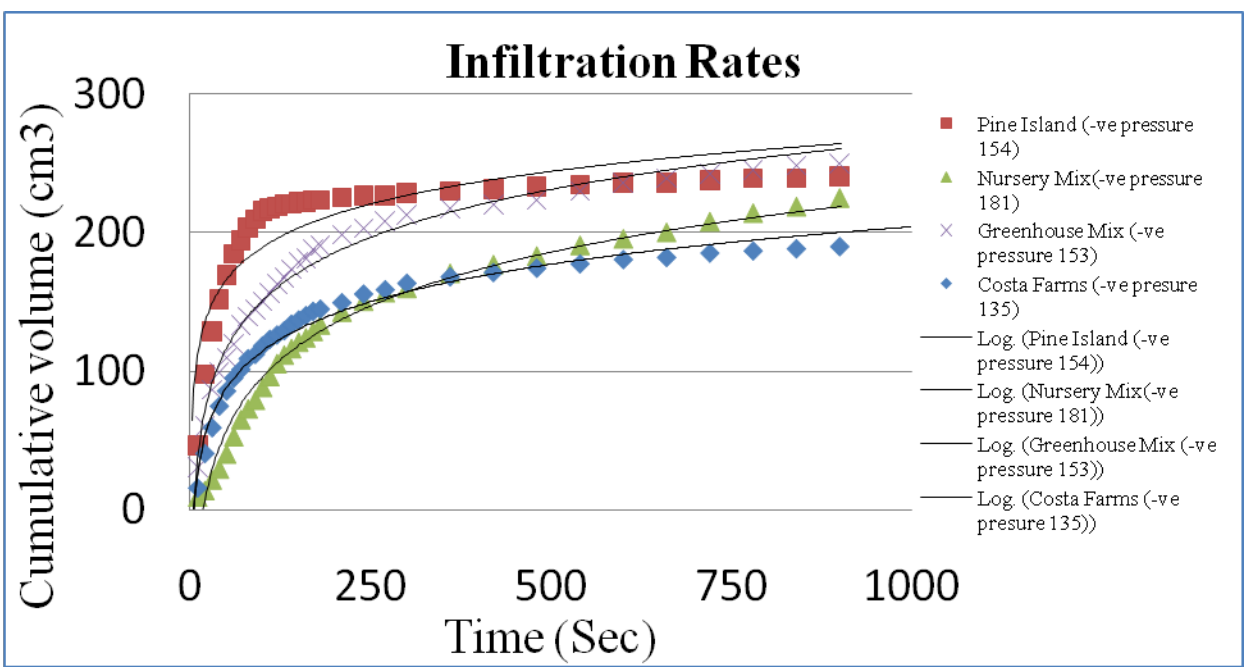

Figure 4. Results from tension Infiltrometer tests

Table 6. Equation of the Infiltrometer fit curves.

Sample	Curve Fit Equation	
Nursery mix	y = 39.01ln(x) - 65.14	R^2 = 0.981
Green house Mix	y = 49.81ln(x) - 78.45	R^2 = 0.986
Pine Island	y = 55.90ln(x) - 161.2	R^2 = 0.974
Costa Farms	y = 33.92ln(x) + 33.76	R^2 = 0.767

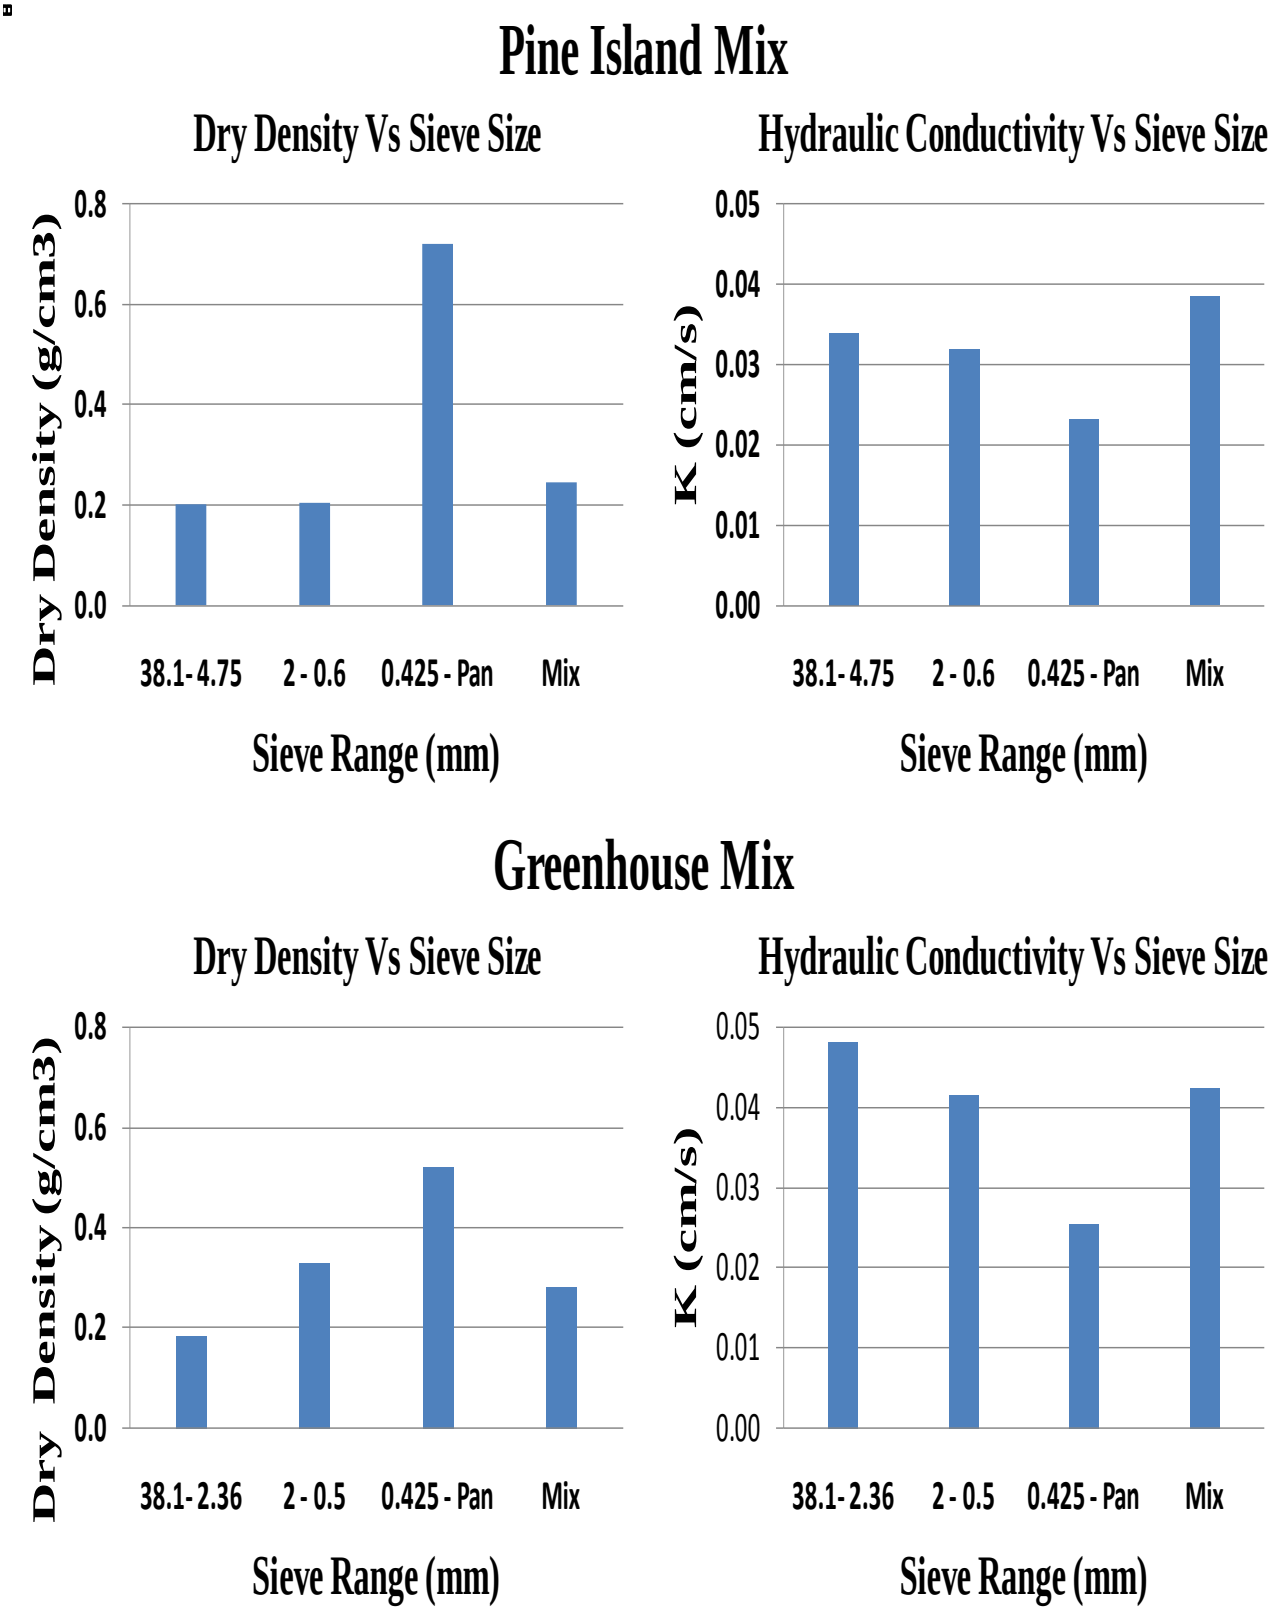

Figure 2. Variation of dry density and the hydraulic conductivity in relation to particle size in Pine island Mix and Greenhouse Mix samples.

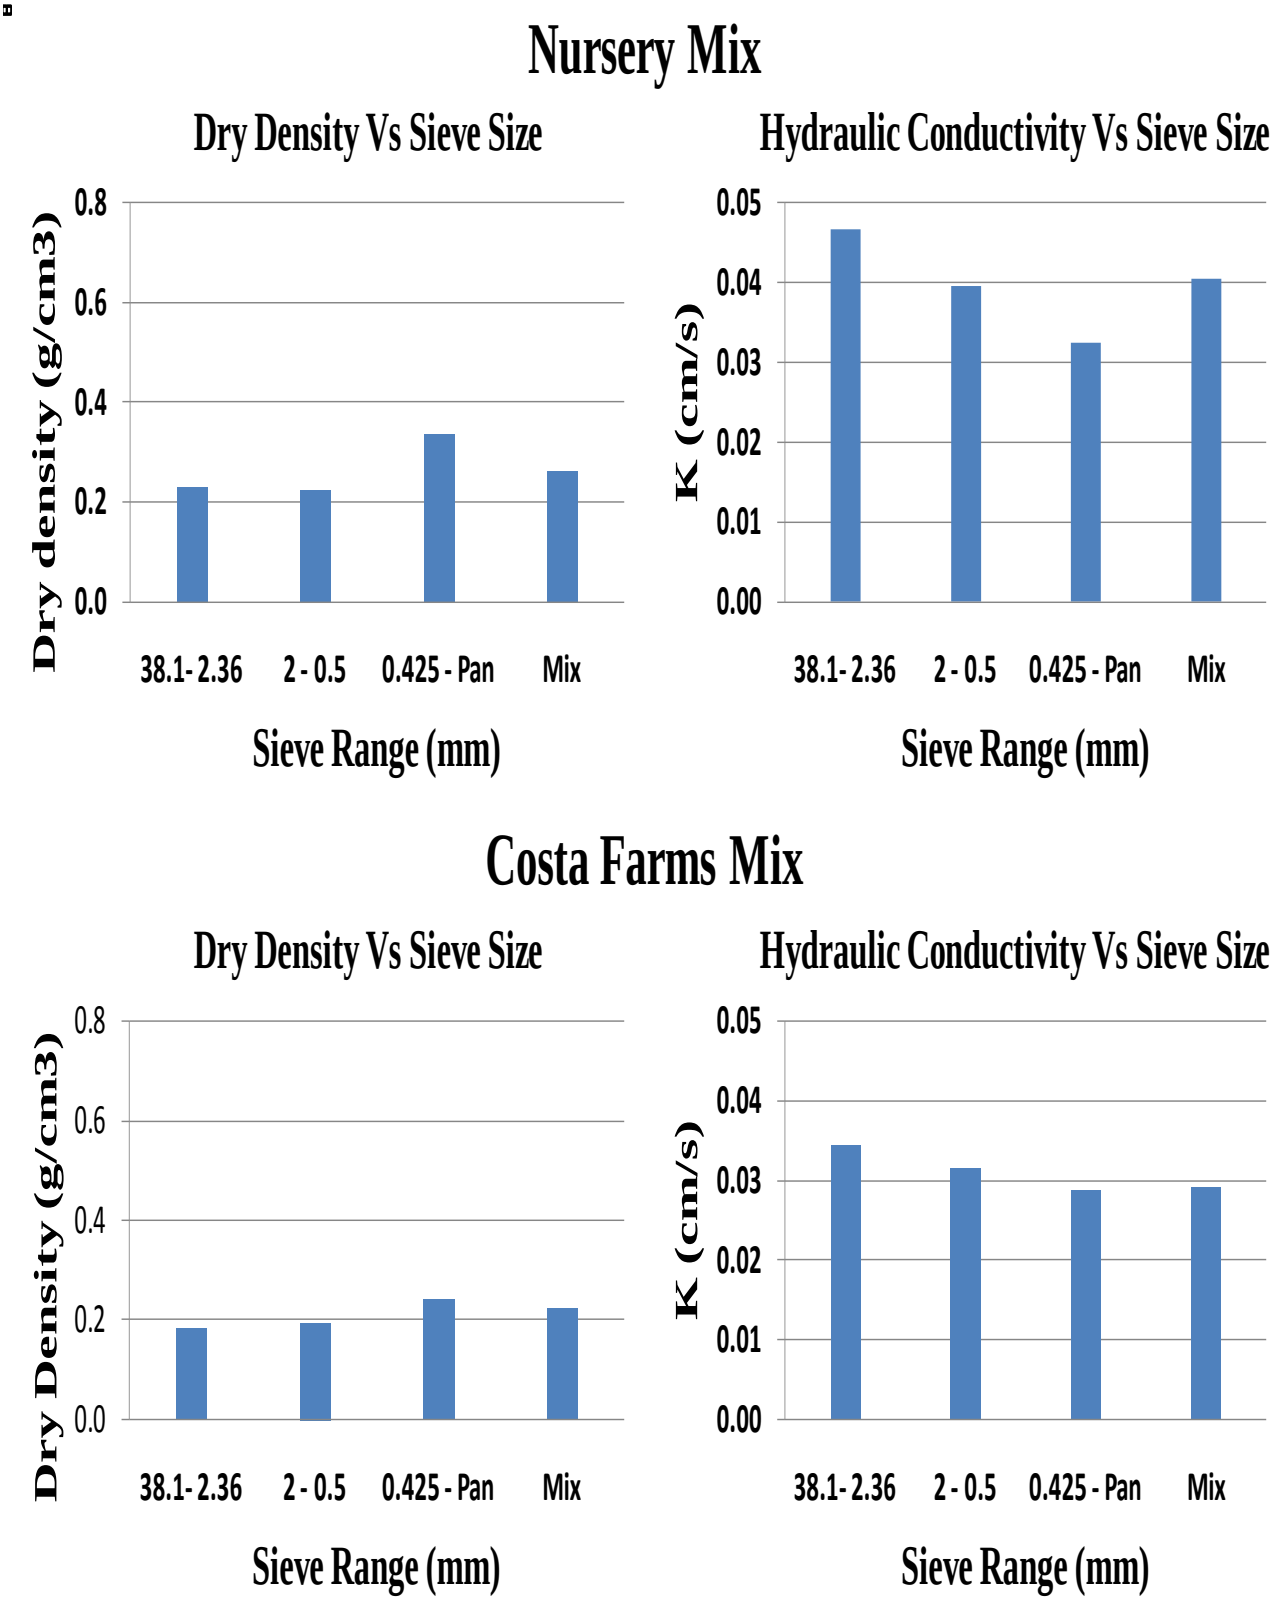

Figure 3. Variation of dry density and the hydraulic conductivity in relation to particle size in Nursery Mix and Costa Farms samples.

Table 7. Saturated hydraulic conductivity of nursery mixtures measured by three different test methods.

Saturated Hydraulic Conductivity	Pine Island	Nursery Mix	Greenhouse Mix	Costa Farms
Constant Head Permeability Test (cm/hr)	136.8 ± 21.6	151.2 ± 18	144 ± 5.76	104.4 ± 7.2
Falling Head Permeability Test (cm/hr)	381.6 ± 41.7	334.8 ± 23.2	280.8 ± 36.6	403.2 ± 17.8
Tension Infiltrometer (cm/hr)	7.2	57.6	25.2	21.6

* Constant Head Permeability Test was performed 6 times, Falling Head Permeability Test 4 time and Tension Infiltrometer 2 times.

Conclusions

Hydro-physical characteristics such as water retention and hydraulic conductivity of four different nursery mixtures were characterized by laboratory experiments. Effect of particle size on hydraulic conductivity was analyzed after separating each sample by using three 3 different size sieve sizes. The hydraulic conductivity measurements varied significantly between different test methods. The results of these types of characterization can provide a scientific basis for understanding of the non-point source water pollution from containerized horticultural and floricultural production systems and assist in the development of the Best Management Practices (BMP) for operation of environmentally sustainable agricultural enterprises in South Florida.

ABSTRACT

The water use characteristics of *Camelina sativa*, an oilseed crop, were evaluated in an irrigation experiment in Maricopa, Arizona. Camelina (cv. Robinson) was grown between November 2006 and April 2007 in plots, each 10 by 17 m. Thirty-two of the field plots were replicated in a randomized block design consisting of irrigation treatments of four levels of soil water depletion: 40, 50, 65, and 75%. Six supplemental plots evaluated water stress at 85% soil water depletion. Weekly soil water content measurements were obtained over a soil profile of 1.9 m for all plots using neutron probes. In January 2007, following initial irrigations uniformly applied to all treatments, treatments received one to four additional surface irrigations. The camelina extracted soil water to a depth of 1.5 m. The seasonal evapotranspiration, calculated from soil water balance data, varied from 285 mm for the water stress plots to 371 mm for the 40% treatment. Excluding the water stress plots, seed yields for treatments varied from 950 to 1130 kg ha^{-1}, though differences were not significant. Mid-season camelina crop coefficients were on the order of 1.13 to 1.20. A camelina crop coefficient curve is presented as a function of days after planting.

INTRODUCTION

Camelina sativa (L.) Crantz is an oilseed crop that is currently being investigated by U.S. industry as a source for biodiesel, but has a number of other potential industrial and food applications as well (Vollmann et al., 2007). Camelina has a relatively short growing season when sown as a summer annual in northern Midwestern U.S. areas, e.g., 80 to 100 days (Putnam et al., 1993), but in Northern and Central Europe the season length is reportedly longer ≈120 days (Zubr, 1997). Camelina has also been shown to perform well as a biannual winter crop in certain areas (Putnam et al., 1993). Prior research has listed several attractive agronomic attributes of camelina (see, e.g., Putnam et al., 1993; Vollmann et al., 2007). These include the ability to grow well at low-fertility inputs (e.g., seasonal application of 60 kg N ha^{-1}) and under saline soils. It can survive frost and freeze cycles after emergence, is competitive with annual weeds, needs little insect control, and has drought-avoidance characteristics.

Researchers at the USDA-ARS research center in Maricopa, AZ, are working with industry to develop several alternative crops, including camelina, for production in the arid southwestern U.S. Successful commercialization efforts of camelina could ultimately create opportunities for growers in the area with limited cropping alternatives. Camelina commercialization may also create new areas of production with limited competition from major commodity crops. However, little is known about the crop's water use characteristics and yield response to irrigation. Consequently, we currently lack the information that will lead to appropriate irrigation management for its production in the desert Southwest (French et al., 2009). Thus, a field experiment was conducted to evaluate camelina water use and yield under irrigated conditions in the desert southwestern U.S. The main objectives were to determine: (1) the crop's soil water use characteristics, (2) crop evapotranspiration (ETc), and (3) yield response to variable irrigation levels. Experimental objectives also included development of camelina crop coefficients compatible with the FAO-56/ETc guidelines (Allen et al., 1998) and applicable to southwestern U.S. growing conditions.

METHODS AND MATERIALS

A camelina irrigation experiment, the first of a two-year field investigation, was conducted from November 2006 to April 2007, on a laser-leveled, 1.25 ha field site (fig. 1) located at the University of Arizona, Maricopa Agricultural Center, in central Arizona (33˚04'N, 111˚58'W, 361 m above M.S.L.). The field soil is a Casa Grande series (Typic Natrargids, fine-loamy, mixed, hyperthermic) with predominantly sandy clay loam texture. Crops grown at the site in the years prior to the experiment were wheat, oats, barley, and jojoba. On 06 November 2006, camelina seed was broadcast-planted to dry soil over the entire field at a rate of 8.2 kg ha^{-1}. The seed, a 'Robinson' variety, was supplied by Technology Crops International (TCI, www.techcrops.com). Immediately after planting, measurements were made to mark 40 plots, each 10 m x 17 m in area, within the site (fig. 1).

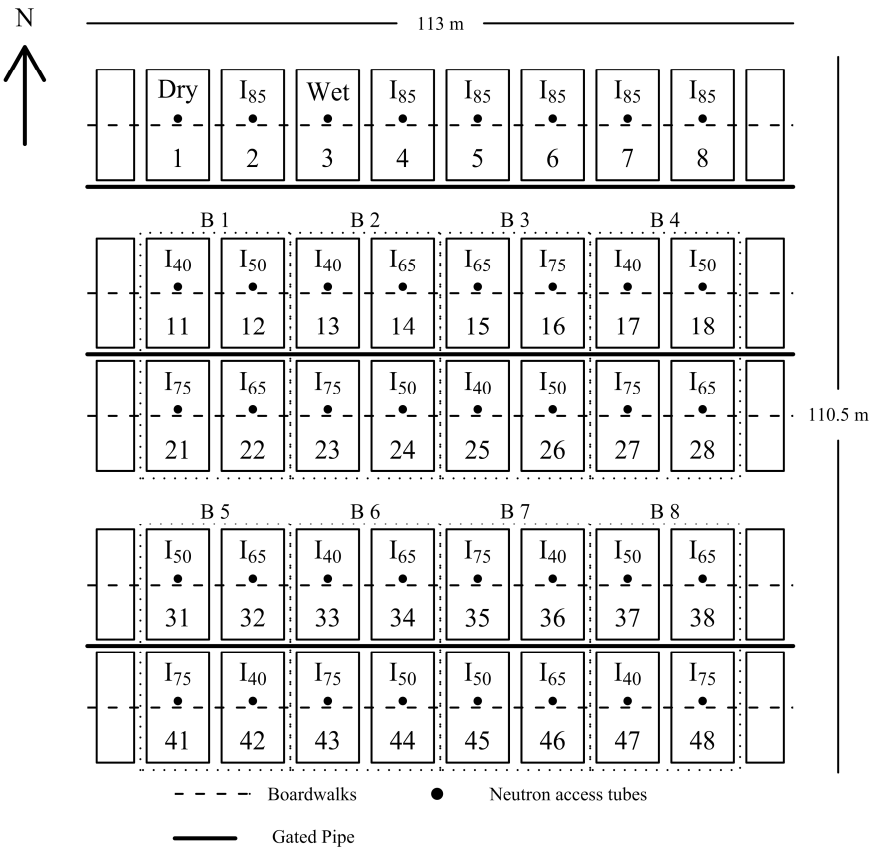

Figure 1. Camelina experiment field site at Maricopa, Arizona, showing 40 plots, each 10 m x 17 m. Treatment identifiers at the top of each plot correspond to irrigation soil water depletion levels: I_{40} at 40%, I_{50} at 50%, I_{65} at 65%, I_{75} at 75%, and I_{85} at 85%. Block design is indicated by dotted-lines with identifiers B1-B8. The top row that includes six of I_{85} plots was not blocked.

A tractor-mounted Giddings[3] soil sampler (Model 25-TS, Giddings Machine Company, Windsor, CO) was then used to install neutron access tubes to a depth of 2.0 m in 38 of the plots (fig. 1). During the installation of the access tubes, soil samples in each plot were extracted in 0.3-m increments to a depth of 1.8 m. The soil samples were then taken to the laboratory and analyzed for -33 kPa (field capacity) and -1500 kPa (wilting point) soil water retention using pressure membrane extractors (Model 1000, Soilmoisture Equip. Corp., Santa Barbara, CA) and soil particle size fraction using the hydrometer method (Gee and Bauder, 1986). Following access tube installation, border dikes were formed to separate plots and to control surface irrigation water applications to plots. Three gated pipe irrigation systems, 152-mm diameter, were installed in the east-west direction extending the length of the field (indicated by heavy east-west lines in fig. 1). Irrigation water was controlled by valves located on the west end of each system, and gated-ports spaced

[3] Mention of products and trade names does not imply endorsement by USDA

1.0 m apart were used to control water application to individual plots. In-line propeller water flow meters were used to measure the amount of water applied to plots during the season. Raised mid-plot boardwalks (dashed lines in fig. 1) were also installed to provide non-destructive access to plots.

Starting on 14 November 2006, prior to the first irrigation of the dry-planted camelina, frequent monitoring of volumetric soil water contents were begun for all plots. Soil water contents (θ_v) were measured from 0.1 to 1.9 m in 0.2 m increments using field-calibrated neutron moisture gauges (Model 503, Campbell Pacific Nuclear, CPN, Martinez, CA). Since neutron gauge accuracies can be unreliable at the 0.1 m depth, the neutron data were supplemented by measuring soil water contents for the 0 to 0.3 m soil surface using a time domain reflectometry (TDR) system (Trase1, Soilmoisture Equip. Corp., Santa Barbara, CA), where the TDR rods were placed 0.5 m away from the access tube in each plot. For each plot, the θ_v measurements made during the season were combined with field capacity (θ_{fc}) and wilting point (θ_{wp}) soil water content data determined in the laboratory to estimate soil water depletion percentage (SWD_p). The SWD_p, expressed as a percentage of total available water, was calculated as:

$$SWD_p = [(\theta_{fc} - \theta_v)/(\theta_{fc} - \theta_{wp})] \times 100$$

A randomized block experimental design was employed to investigate four irrigation treatments each replicated eight times. The 32 plots used in the blocked irrigation study were 11-18, 21-28, 31-38, and 41-48 (fig. 1). Eight other plots (1-8) not included in the blocked irrigation treatment design were used for other experimental purposes, i.e., unplanted dry and wet soil plots (1 and 3) and planted plots, imposed with severe water stress (2, 4, 5, 6, 7, and 8). Thus, data from these water stress plots, though omitted from analysis of variance procedures, will be presented for reference purposes. Plants in the two soil plots were removed by herbicide applications, whereas planted buffer areas on the east-west sides of the field and alleyways between plots north to south (fig. 1) provided cropped surfaces outside of plot areas. To obtain uniform crop emergence and establishment, all plots were irrigated three times (15 and 21 November 2006, and 5 December 2006) early in the season before irrigation treatments were begun. Layout size and field logistics did not allow testing effects due to fertilization. Consequently, on 5 December 2006, all plots were fertilized with 50 kg N ha^{-1} by injecting 32% solution urea-ammonium-nitrate (32%) through the irrigation system.

After crop establishment, irrigation for treatments were governed by measured SWD_p where the four levels selected, 40, 50, 65, and 75%, corresponded to treatments defined as I_{40}, I_{50}, I_{65}, and I_{75}, respectively (fig.1). The depletion level used for the six stress plots in the northern portion of the field was 85% (where stress treatment is denoted as I_{85}). For irrigation scheduling purposes, soil water depletion levels were based on a conservative crop rooting depth of 0.7 m. When the median measured SWD_p at the 0.7-m depth for replicates within a treatment reached the specified level, irrigations were then applied to all treatment plots with water depths approximately

1.1 times the depth needed to restore an individual plot to field capacity. Consequently, plots within a given treatment, though irrigated on the same day, often received different irrigation application depths due to differences in soil water depletion prior to irrigation and water holding capacities among plots.

Weekly photographic data were collected on 13 occasions to document camelina canopy cover fractions. A digital camera was mounted at the end of a 2.6-m hand-carried aluminum pole, allowing nadir-views for all plots with a field of view of about 1.6 m x 1.2 m. Pixel resolution was better than 1 mm at mid-season canopy heights of about 0.5 m. Image data were originally collected in raw mode, then converted to 3-band (red, green, blue) TIFF format. Weekly fractional crop cover estimates for each plot were generated using a green index classification method developed and presented by French et al. (2009).

Camelina evapotranspiration (ETc) rates for plots were estimated throughout the growing season using soil water balance procedures described in Hunsaker et al. (2005). For each plot, ≈ weekly estimates of ETc were calculated by the change in soil water content from one measurement date to the next over an estimated effective root extraction depth, accounting for water gains in the soil profile from irrigation and rainfall, and water losses below the root zone. The ETc data, combined with estimated fractional cover and plant height for a given plot, and the FAO-56 grass reference evapotranspiration (ETo) provided by a nearby MAC farm AZMET weather station (Brown, 1989), were used to back–calculate basal crop coefficients (Kcb, Allen et al., 1998) following procedures developed by Hunsaker et al. (2005):

$$Kcb = ETc/ETo + Ke$$

where Ke is the soil evaporation coefficient and all other parameters are as defined above.

On 19 April 2007, seed yield samples were harvested from each plot using a Hege plot combine (Wintersteiger AG, Austria) equipped with a 1.5-m cutter bar. The samples were harvested within designated areas measuring approximately 24 m^2 in the south half of each plot (south of the boardwalk in fig. 1). Unfortunately, seed was lost while harvesting plot 28 (treatment I_{65}), and this particular plot will be omitted from data analyses. Each harvest area was individually marked and measured for total area and all seed yields were subsequently adjusted to 0% moisture. Total oil content was measured with a TD-NMR mini-spectrometer (Model mq20, Bruker Optics Inc., Billerica, MA).

RESULTS AND DISCUSSION

The November-planted camelina crop was 156 days old when harvested on 19 April 2007. However, it was initially anticipated that a winter-planted camelina crop in Arizona would about 120 days or less from planting to harvest and that this would then allow field preparation for our rotation to cotton by mid-March, 2007. Even

though irrigations to the treatments were terminated by early March, subsequent air temperatures were not high enough to fully dry the seed until mid-April. The early March cut-off of irrigation water to the crop likely affected final yields, which averaged about 1300 kg ha^{-1} for the 50% top-yielding plots. Thus, our yields were considerably lower than those reported elsewhere, e.g., 1574 to 2248 kg ha^{-1} as reported by Vollmann et al. (2007) in eastern Austria. Limitations to camelina yield for the longer than expected growing season in Arizona may also have been induced to some extent by insufficient nitrogen application. However, the average total oil content, 41%, for the Arizona crop was comparable to other total oil contents reported (Zubr, 2003; Vollmann et al., 2007).

Water application schedules for the five irrigation treatments are summarized in table 1. All treatment plots were irrigated three times (15 and 21 Nov. 2006, and 5 Dec. 2006) early in the season before irrigation treatments were begun. More irrigation water was needed during the initial irrigation for the I_{85} treatment plots to achieve uniform coverage for germination in those plots. After the irrigations of 5 December, in which all plots were also fertilized with 50 kg N ha^{-1}, the I_{40}, I_{50}, I_{65}, and I_{75} received another 4, 3, 2, and 2 irrigations respectively, whereas the I_{85} received only one more irrigation. Between planting and harvest, the field site received a total of 38 mm of rain.

Mean soil water content profiles presented for the I_{40} treatment show that crop soil water extraction was confined to the upper 0.7 m soil profile through about mid Jan. 2007 (fig. 2a). During this early season period, water from irrigations gradually moved downward in the soil profile to about 1.3 m. After mid Jan., camelina extracted stored soil water at deeper depths (fig. 2b). By 5 March 2007, soil water extraction had occurred to about 0.9 m. Following the final irrigation to I_{40} (6 March), the camelina depleted soil water as deep as 1.5 m by early April.

Based on the above evaluation of camelina soil water profiles, ETc was calculated by the soil water balance using a 1.5-m root zone. As there was no observed movement of water below 1.5 m for any treatment, deep drainage was assumed to be negligible.

A statistical difference occurred between irrigation treatments for seasonal ETc, calculated from 15 Nov. 2006 through 1 April 2007. The I_{40} (371 mm) and I_{50} (354 mm) treatments both had greater seasonal ETc than for the I_{65} treatment (table 2), whereas the ETc for the I_{50} was not significantly different from that for I_{75}. Unlike seasonal ETc, neither final yield nor water use efficiency (final yield per unit of evapotranspiration) was significantly different between treatments (table 2). However, within-treatment yield was highly variable compared to that for seasonal ETc. Consequently, these results indicated that seed yield was independent of irrigation schedule and crop water use. Results for the I_{85} treatment, though outside of the experimental design, suggested a substantial decrease in both ETc and yield ($\approx$ 20 % reduced compared to other treatments) may occur when only a single irrigation is given after emergence.

Table 1. Irrigation event dates and mean irrigation depths for camelina treatments during the 2006-07 growing season at Maricopa, Arizona.

Treatments	I_{40}	I_{50}	I_{65}	I_{75}	I_{85}
Date	Treatment mean irrigation depth (mm)

[b] One plot in this treatment was inadvertently irrigated twice on 5 Dec. 2006.

Table 2. Camelina irrigation treatment means for seasonal crop evapotranspiration (ETc), seed yield (Y), and water use efficiency (WUE_{ETc}) for the 2006-07 season.

	Treatments[a]				
Variable	I_{40}	I_{50}	I_{65}	I_{75}	I_{85}[b]
Crop evapotranspiration, ETc (mm)	371a (0.06)	354ab (0.09)	325c (0.09)	333bc (0.04)	285 (0.09)
Seed yield, Y (kg ha^{-1})	1058a (0.21)	1077a (0.32)	950a (0.27)	1130a (0.29)	857 (0.48)
Evapotranspiration water use efficiency, WUE_{ETc} (kg m^{-3})	0.28a (0.18)	0.30a (0.32)	0.28a (0.23)	0.34a (0.28)	0.30 (0.48)

[a] Treatment coefficients of variation for variables are shown in parenthesis below means.
[b] Note I_{85} is excluded from the analysis of variance since it was not part of the block design.
a, b, c Treatment means followed by different letters in a row are significantly different at the 0.05 level according to the Tukey (HSD) test.

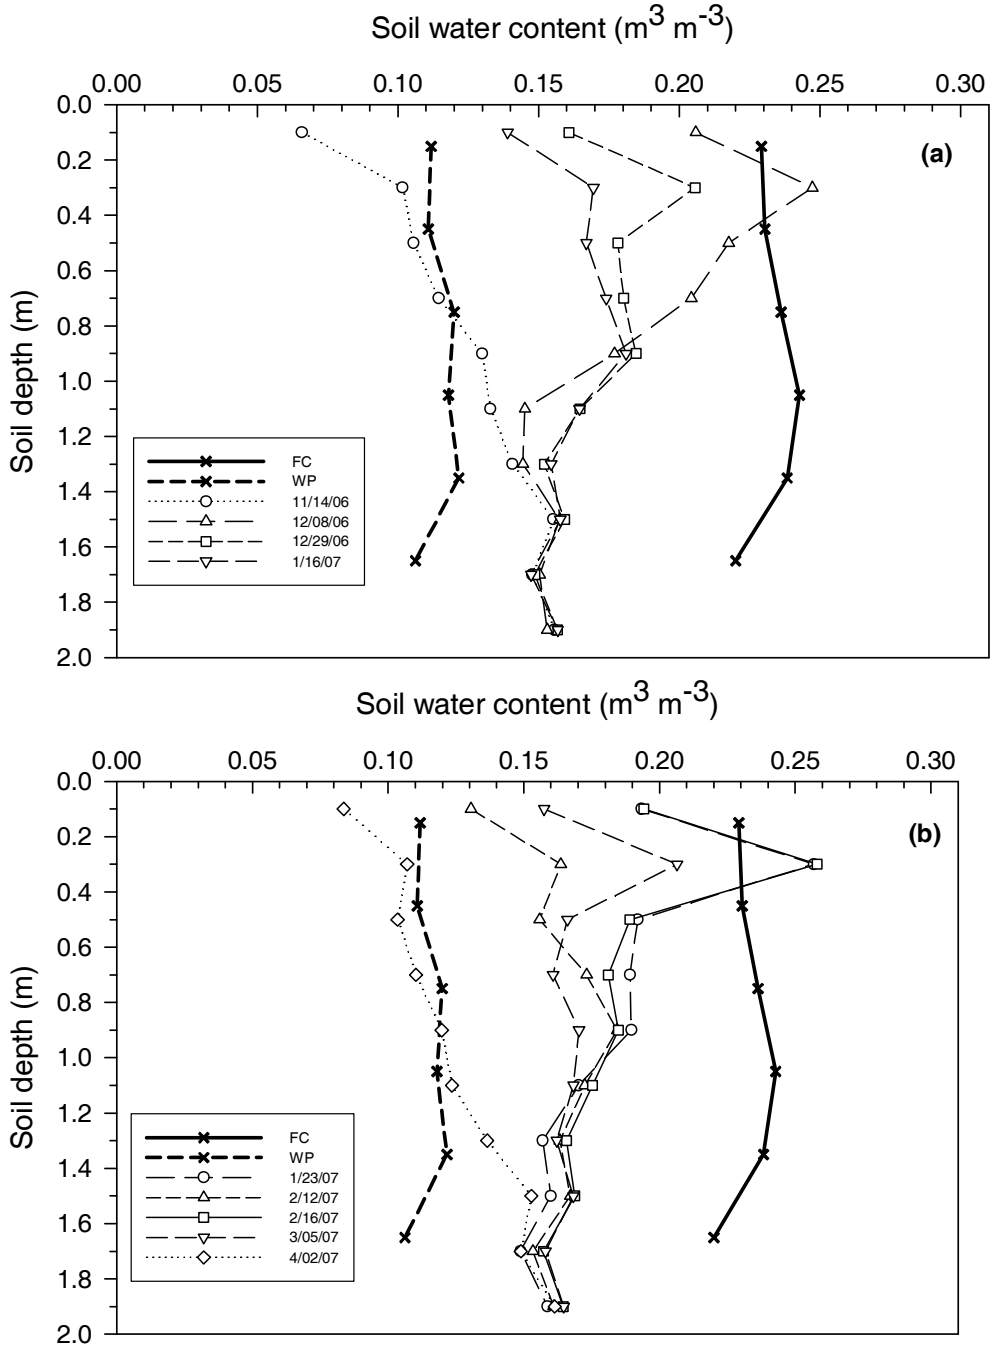

Figure 2. Mean soil water content profiles and mean field capacity (FC) and wilting point (WP) for the I_{40} treatment during the (a) early and (b) late camelina season.

Data for the 50% top-yielding plots (16 plots) were used to back-calculate basal crop coefficients (Kcb) and then derive a camelina Kcb curve as a function of days after planting (DAP). The Kcb increased slowly for the first 50 DAP (fig. 3). This trend is likely explained by retarded growth during the cold temperatures in December and January. The Kcb increased more rapidly after 50 DAP to maximum Kcb values at about 100 to 120 DAP. The effects of different treatment irrigation scheduling regimes beginning 63 DAP (17 Jan. 2007) induced higher Kcb variability than during the early season. In general, the Kcb for the I_{65} and I_{75} were lower than those of the more frequently irrigated treatments, I_{40} and I_{50}, once irrigation treatments were initiated. While different models could be employed to describe Kcb as a function of DAP, a 4th order polynomial regression model appeared to provide a reasonable representation (fig. 3). The 4th order model agreed well with data during the early season and estimated negligible Kcb after 140 DAP. The model also predicts maximum Kcb values from 1.13 to 1.20 from 100 to 120 DAP.

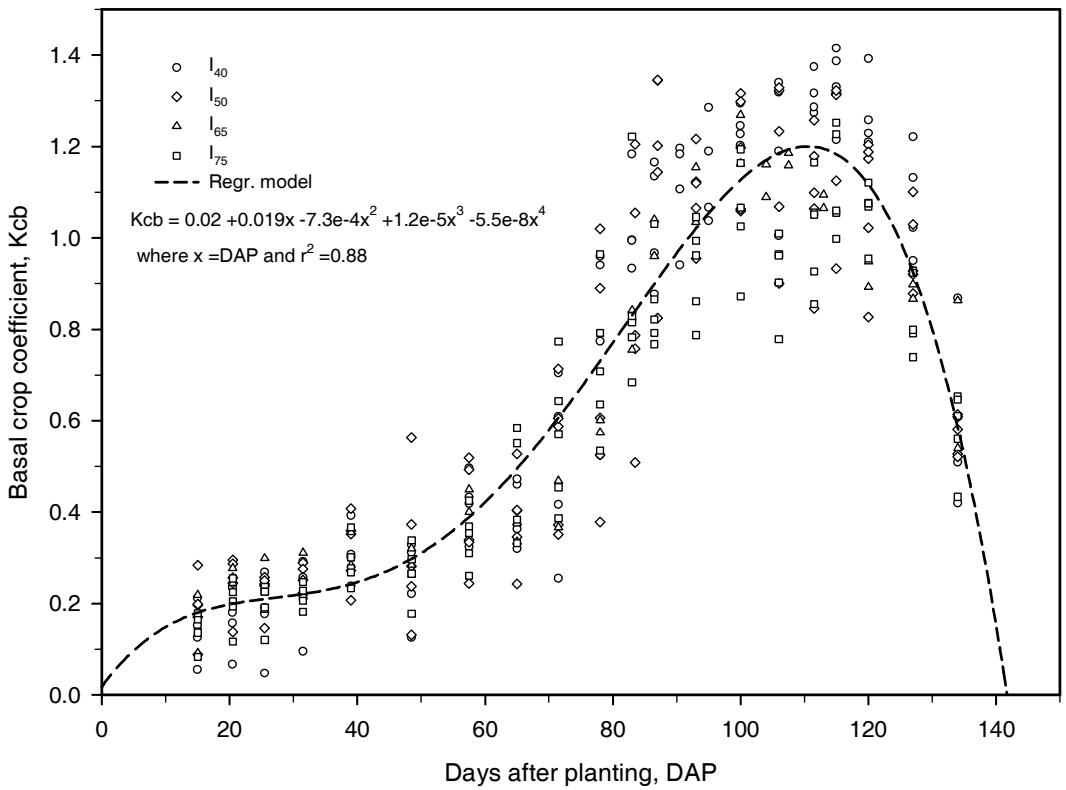

Figure 3. Camelina basal crop coefficients (Kcb) for 16 treatment plots with days after planting (DAP) and Kcb regression model as a function of DAP.

CONCLUSIONS

An irrigation field experiment with camelina sativa was conducted in Maricopa, Arizona during 2006-07 to evaluate the crop's water use and ETc crop coefficients. Results from this initial camelina experiment indicated that differing levels of irrigation affected total evapotranspiration. However, the different amounts of water applications and ETc achieved did not significantly affect final seed yields, which varied from 950 to 1130 kg ha^{-1}, for blocked treatments. A preliminary Kcb curve for camelina as a function of days after planting was derived from the experimental data. Subsequent camelina investigations underway in Arizona utilized fertilization levels and planting dates markedly different from those of this experiment and will be used to extend these results to a wider range of conditions.

[1] Irrigation Scheduling for Deficit Irrigation

Norman L. Klocke, P.E.[2], Loyd R. Stone[3], Dale A. Bolton[4]

ABSTRACT

Many irrigators face the prospect that they will not be able to fully irrigate their crops. In these cases, they still need to schedule their water applications to make the best economic use of available water. Major scheduling questions for deficit irrigation include: (1) will pre-season irrigation be beneficial; and (2) when should irrigation be started and stopped during the growing season. Traditional irrigation scheduling has been developed for irrigation systems that can supply the full irrigation requirements of the crop and produce maximum crop yields. Irrigation schedules are based on current crop water requirements and predict irrigation needs in the immediate future. Irrigators practicing deficit irrigation need to predict irrigation schedules in advance of the growing season and make appropriate adjustments based on potential crop yields and economic returns. A computerized decision tool, the Crop Yield Predictor (CYP) has been developed to predict yields from alternative irrigation schedules. The user determines soil water status before or during the cropping season and formulates a potential schedule of irrigation dates and amounts. Soil water holding capacity and irrigation system water delivery capacity are constraints on the ability to supply water to the crop. CYP uses a daily soil water balance coupled with computations of effective evapotranspiration (ETe) to predict crop yields from regional yield-ET relationships. Multiple executions of CYP with alternative irrigation schedules lead to the schedules that project optimum net economic returns from the management scenarios.

INTRODUCTION

Maximum net economic returns for irrigators with adequate water supplies usually have corresponded to irrigation management to obtain maximum crop yields. Irrigation in excess of crop water needs reduces net economic return, but the marginal increases in crop yields usually covered marginal production costs. When water supplies cannot match crop needs and deficit irrigation management is anticipated, optimum net economic return from irrigation is the appropriate measure of best management (English et al. 2002). Crop selection for optimum net return may involve multiple crops in rotation, a single crop with reduced irrigation, or irrigation on a smaller area (Martin et al. 1989). In addition to crop selections, irrigation needs to be allocated among crops, using crop production functions and production costs for optimum economic return (English, 1981, Martin et al. 1989, Klocke et al. 2006).

Scheduling irrigation events during the growing season for crops that have a non-limited water supply has involved the estimation of non-stressed crop ET (ETc) from current weather parameters, producing a reference ET (ETr) that is modified with a crop coefficient (Kc) to account for changing crop growth stages. A soil water balance of ETc, effective precipitation, net irrigation, drainage, runoff, and run-on produces daily values for available

soil water (ASW). For irrigation schedules with the goal of crops with no water stress, irrigation needs are calculated to keep ASW between field capacity and an ASW content that does not cause stress, usually 50-60% of the ASW remaining in the active root zone. The starting dates for irrigation events are established by calculating the days until the crop will experience stress at the point of the end of the irrigation cycle (no later than starting date) and when there is room to store the irrigation event amount at the point of the beginning of the irrigation cycle (no sooner than date) (Kansas State University, 2007)

When the water supply for irrigation is less than the water required for non-stressed conditions, water deficits can be anticipated. Irrigation schedules for deficit irrigation need to anticipate the potential for crop yields and net economic returns prior to and during the growing season. The major irrigation scheduling decisions for deficit irrigation are: (1) whether or not pre-season irrigation is needed (Stone et al. 2008), and (2) when irrigation growing season irrigation should start and stop. Between the start date and stop date, irrigation systems often operate on a fixed frequency depending on the capacity of the well to supply water.

The objective for this study was to develop an interactive decision model that would help users to predict optimum irrigation schedules for crops that are expected to experience water stress. The model predicted ASW during the growing season, crop yields, and the net economic return for the crop with the proposed irrigation schedule. Model users could simulate alternative irrigation schedules for years with less than average, average, and more than average precipitation.

MODEL DESCRIPTION

The CYP was an adaptation of the Kansas Water Budget (KSWB) model (Khan et al., 1996 Stone et al., and Stone et al., 2006). The KSWB was a coupled model of a daily soil water balance and an estimation of daily evapotranspiration (ET) (figure 1). The ET side of the model started with a reference ET (ETr) using the equation of Jensen and Haise (1963) with inputs of average daily maximum and minimum air temperature, average daily solar radiation, and an expression for latent heat of vaporization (Wright, 1982). Maximum ET (ETm) was derived from ETr with a bare-soil water coefficient during the non-growing season and a crop coefficient (Kc) during the growing season (Doorenbos and Pruitt, 1977). ETm values assumed that the crop was not stressed by soil water content, atmospheric conditions, disease, or lack of nutrients. ETm was modified with a soil water stress coefficient (Ks) during the growing season to produce actual ET (ETa). The soil Ks values were developed according to the function reported by Jensen et al. (1970):

$$Ks = \ln(ASW + 1)/\ln(101) \quad [1]$$

where ASW is available soil water (%).

ETa transferred to the soil water balance side of the model:

$$SW_E = SW_B + P_E + I_N - ETa - D_P \quad [2]$$

where SW_E was total SW at the end of each day; SW_B was total SW at the beginning of each day; P_E was the daily average effective precipitation from 30 years of weather records minus

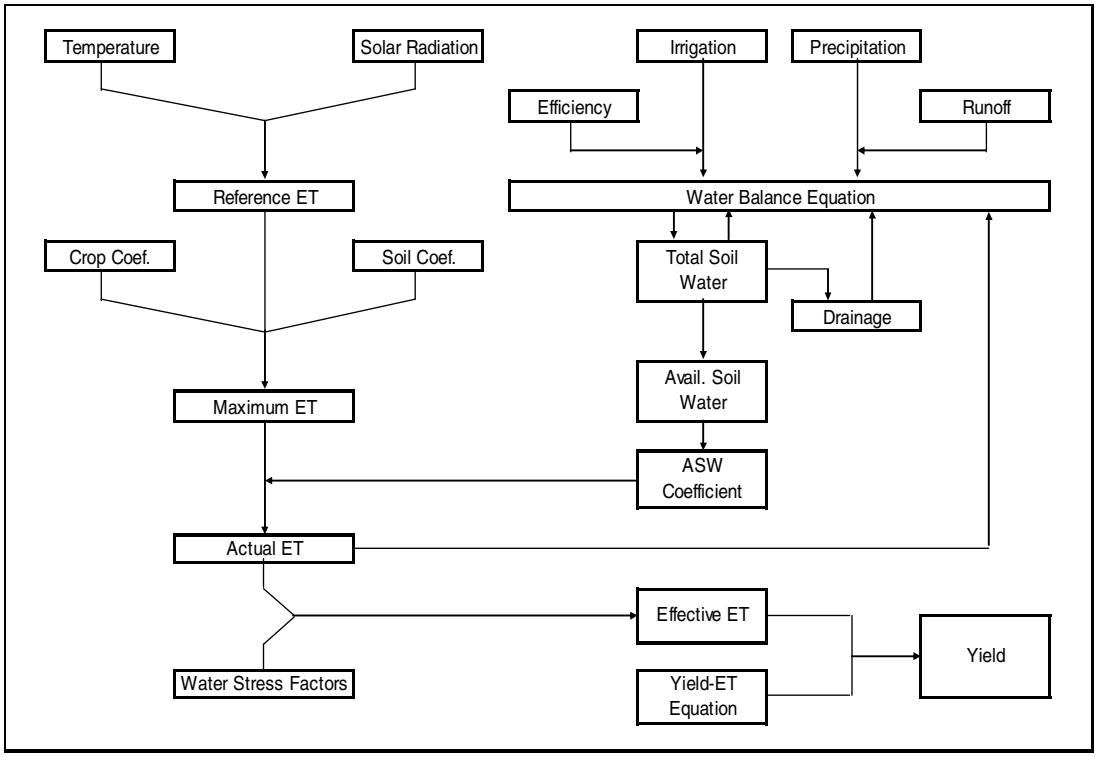

Figure 1. Flow chart for Kansas Water Budget adapted to Crop Yield Predictor

runoff, I_N was net irrigation that infiltrated into the soil and D_P was drainage from the 1.83 m soil profile. Daily drainage was calculated by using the Wilcox method as described by Miller and Aarstad (1972). Daily drainage for a Ulysses silt loam soil (Stone et al., 1987) was:

$$D_P = 42.7(TSW/729)^{18.06} \quad [3]$$

where TSW is total soil water of the 1.83 m profile (mm).

Effective ET (ETe) was derived from ETa using the ratio of ETa and ETm along with the crop's sensitivity to water stress during the stages of growth, including vegetative, flowering, seed formation, and ripening. ETe for corn that actually contributed to crop yield (Ye), was calculated with:

$$Ye\ [Mg\ ha\text{-}1] = -11.5\ [Mg\ ha\text{-}1] + 39.8\ [Mg\ ha\text{-}1\ mm\text{-}1]\ X\ ETe\ [mm] \quad [4]$$

USER INPUTS FOR CYP

Reference evapotranspiration was calculated daily by CYP for the geographic location selected by the user. Average daily maximum air temperature, minimum air temperature, and solar radiation for each default location were calculated from thirty years of weather data for each location. The average daily weather factors for each location were used to calculate daily reference evapotranspiration (ETr) from Jensen and Haise (1963). ETr was for a well watered crop with full canopy cover in semiarid and arid regions. ETr was

increased to account for advective energy when the average maximum air temperature was more than 33°C.

Annual precipitation was determined by the model user. Precipitation probability values were also available for each default location. Precipitation amounts for occurrence 2 out of 10 years, 5 out of 10 years, and 8 out of 10 years were suggested so the user could simulate wet, normal, or dry years.

Soil texture was selected by the user from a listing of silt loam and loamy sand soils. The ASW storage capacity and volumetric soil water contents at field capacity and permanent wilting were displayed for each soil texture.

Irrigation system efficiency was defined as the ratio of water infiltrated (net irrigation) and the water pumped or supplied to the field (gross irrigation). The user entered irrigation efficiency and the program supplied suggested efficiencies for types of irrigation systems.

Crop selection was for corn, grain sorghum, sunflower, soybean, winter wheat or alfalfa. CYP furnished default dates for growing season milestones, but the user could change the defaults for to match other crop cultivars. Kc values and water stress factors were adjusted for the days in each growth stage.

Irrigation schedule was a series of dates for irrigation events and the corresponding gross irrigation amounts. Irrigation dates and amounts could be entered into the program directly or imported from an Excel file. Multiple irrigation schedules could be developed in Excel for input into the program. The program also could generate uniform frequency schedules from user entries of (1) starting dates and ending dates for the growing season irrigation events, (2) irrigation season gross irrigation, (3) gross irrigation for each irrigation event, where the gross irrigation was the same for all irrigation events, (4) area irrigated, and (5) irrigation system pumping capacity.

Runoff was the percentage of daily precipitation that did not infiltrate. The user could enter the runoff percentage or CYP calculated a runoff factor using crop type, total annual precipitation, and soil texture.

Initial available soil water could be entered for any date by the user and CYP used it for water balance calculations from that date forward. Default ASW on January 1 was determined by CYP from annual precipitation and total irrigation for the growing season.

Crop prices and production operating costs could be entered to predict net economic return without considering fixed costs from the projected crop yield:

$$\text{Net Return} = \text{Price X Yield} - \text{Operating Costs.} \qquad [5]$$

CYP OUTPUTS

Effective crop evapotranspiration (ETe) was the crop's evapotranspiration that contributed to crop yield. ETe was calculated with coefficients that modified ETr to account for crop growth stage (Kc), crop water stress from less than optimum soil water content (Ks), and the crop's susceptibility to stress during different growth stages. ETm was the crop's ET with no water stress and only dependent on crop growth stage; ETa was the crop's ET when soil

water stress reduced ETm; and ETe was the crop's ET that also included the influence of growth stages on stress susceptibility.

During the non-growing season a bare soil evaporation coefficient modified ETr to generate daily evapotranspiration values.

Crop yield (Ye) was calculated from linear relationships of yield as a function of ETe, which were developed form long-term field studies in west-central Kansas.

Maximum Potential Yield (Ym) was calculated with the yield-ET relationships using ETm for the non-stressed condition.

Relative Yield (Yr) was the ratio of Ye and Ym. The predicted relative yields may be more important to the model user than field yields. The user could use expected maximum field yields and simulated relative yields to calculate deficit irrigated yields.

Daily drainage was calculated using a Wilcox-type drainage equation (Miller and Aarstad, 1972) that was field calibrated for each soil texture.

Daily available soil water was charted by CYP from a soil water balance of:

$$ASW_t = ASW_{t-1} + \text{effective precipitation} + \text{net irrigation} - \text{drainage} - ETe$$

The model user can visually inspect the daily ASW charts to find its relationship to field capacity and permanent wilting.

MODEL TESTING

Field data. Crop yields, daily ASW, and ETa for continuous corn were predicted with CYP and compared with field results from a cropping system study conducted at the West Central Research and Extension Center of the University of Nebraska at North Platte, Nebraska (41.1°N, 100.8°W, 860 m above sea level) (Schneekloth et al. 1991 and Hergert et al. 1993, and Klocke et al., 2007). The average annual precipitation is approximately 508 mm, which is 36% of annual reference ET (ETr). Approximately 80% of the annual precipitation occurs during the summer growing season, which extends from late-April until mid-October. Predominant soil texture was Cozad silt loam (Fluventic Haplustoll) with pH of 7.5. Plant available soil water holding capacity was 0.17 m^3 m^{-3} for volumetric soil water contents from 32% for field capacity to 15% for permanent wilting over 0 to 3 m of soil depth. The land slope was less than 1%.

There were three water treatments: full irrigation, limited irrigation, and non-irrigated. The full irrigation treatment was scheduled to meet full crop ET by replacing soil water extractions. The limited irrigation treatment received an annual irrigation allocation of unless there was sufficient soil water to achieve full water needs. Limited irrigation was scheduled to favor applications during critical growth stages for crop development. Irrigation was reduced or withheld during the vegetative period and concentrated on reproduction and grain fill.

Soil water was measured weekly to a depth of 1.8 m in 0.3 m increments with the neutron attenuation method (Evett and Steiner, 1995). Precipitation, net irrigation, and changes in soil water from one measurement to the next were used to calculate weekly ETa. Drainage

was assumed to be minimal within the one week sampling interval of soil water and was not included in the soil water balance. Water runoff and run-on to the plots were observed to be zero.

CYP testing. Continuous corn data from the North Platte location for 1994 and 1995 were compared with simulations by the CYP. Daily irrigation events, precipitation events, and ETr from the field study were used as inputs to the CYP. ASW storage capacity, field capacity and permanent wilting soil water characteristics for a Ulysses silt loam soil were used for the simulations with CYP.

Annual precipitation amounts for 1994 and 1995 were nearly the same but the monthly values were quite different (table 1). January through May, 1994 had less precipitation than 1995, but July and August 1995, months with more crop water needs, had very little precipitation.

Table 1. Precipitation (mm) for North Platte, NE.

Year	Jan-Mar	Apr	May	Jun	Jul	Aug	Sep	Oct-Dec	Annual	May-Sep[+]
1994	11	45	26	89	126	25	19	86	428	285
1995	23	76	128	74	43	0	62	10	416	307
Avg.	41	43	74	80	75	54	45	57	468	328

[+]Growing season precipitation

With more than normal precipitation during July and August, 1994 less irrigation was required in 1994 than 1995. Simulated corn yields were less than field measure yields in 1994, but simulated yields for limited and full irrigation treatments in 1995 were more than in 1994. The simulation of these yield better approximated field yields (table 2). The relative yields may be more important than the actual yields because the model user can use their expected fully irrigated yields and the relative yields to estimate deficit yields. Simulated maximum yields can be calculated from ETm.

Table 2. CYP simulated and North Platte field corn yields.

Year	Irrigation Treatment	Irrigation	Simulated Yield	Field Yield	Yield Deviation Field-Sim.	Simulated Relative Yield	Field Relative Yield
		mm	Mg ha^{-1}	Mg ha^{-1}	%	%	%
1994	Dryland	0	5.8	7.4	22	80	76
1994	Limited	76	7.0	10.0	30	95	103
1994	Full	152	7.3	9.6	24	100	100
1995	Dryland	0	2.3	3.2	28	20	32
1995	Limited	152	8.8	8.2	-7	77	81
1995	Full	381	11.5	10.2	-13	100	100

Soil water contents from the field study, the discrete data points, were compared with CYP simulations, which were daily estimations (figures 2 and 3). Field and simulated soil water contents were similar in 1994 over the dryland, limited, and full water treatments. Limited irrigation field data were less than the simulated estimations during the middle of the growing season. The dryland and limited irrigation treatments compared well in 1995

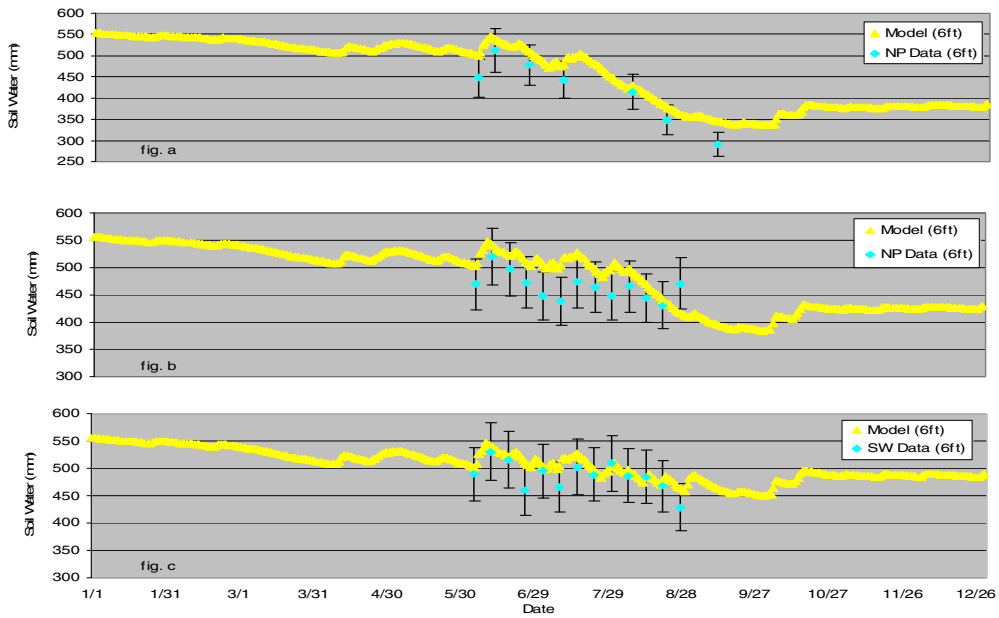

Figure 2. Total soil water simulated from CYP and measured in the plots for dryland (a), limited (b), and full (c) water treatments with ±10% deviation for each field SW measurement for 1994.

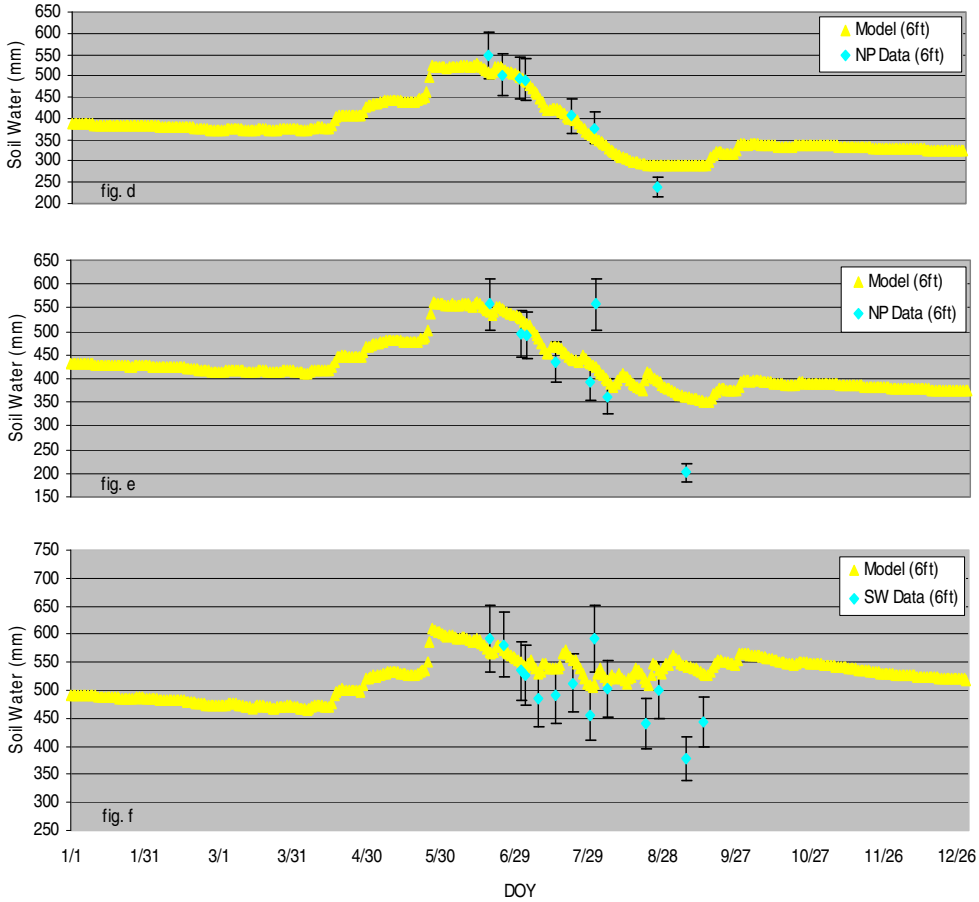

Figure 3. Total soil water simulated from CYP and measured in the plots for dryland (d), limited (e), and full (f) water treatments with ±10% deviation for each field SW measurement for 1995.

except for two outlying field data points in the limited irrigation treatment. Field data for the full irrigation treatment tended to be more than simulated during the early growing season and lower during the end of the growing season. These comparisons are encouraging for the application of CYP for simulations.

CONCLUSIONS

The Crop Yield Predictor (CYP) has been adapted from the Kansas Water Budget (KSWB) to become and interactive model where the user can enter a western Kansas location, annual precipitation, soil texture, crop type, a potential irrigation schedule, runoff, initial soil water (SW) content, crop production costs, and commodity prices to predict grain yield, relative grain yield, daily SW content, daily drainage, daily crop ET and net economic returns. Alternative irrigation schedules and annual precipitation can be entered into CYP to predict changes in results. The alternative schedules can guide CYP users in choosing irrigation starting dates ending dates and irrigation frequencies.

Simulated and measured grain yields relative to fully irrigated yields for each year compared better than actual yields. CYP simulated and measured soil water contents showed similar trends through the growing season with better agreement with the dryland water treatment than the fully irrigated treatment.

ABSTRACT

In the US Mid-South, annual rainfall is generally sufficient for limited crop production, but periods of drought during the growing season make irrigation essential for optimum yields. However, factors such as cloudy weather, rainfall, and temperature swings caused by the movement of weather fronts all complicate irrigation scheduling. The Arkansas Irrigation Scheduler has been in use for over twenty years in Arkansas and surrounding states, with the current version released in 2008. The current version retains most of the objectives of the earlier versions, with the exception of being field-, rather than system-based, allowing users to view the soil water status of more of their fields at one time and group the fields as they feel most appropriate. Other changes made the program easier to learn, allowed the user to take advantage of more extensive weather data if it is available, and made the program applicable to more areas than before. Crop coefficient functions developed in the region are needed, but are not currently available. Future versions of the program may be limited to the internet, but no internet version is currently available for public use. In addition to improving yields, using the program to properly schedule irrigation can save energy and therefore money by reducing unnecessary pumping, and help to alleviate water shortages being experienced in many agricultural areas.

INTRODUCTION

The US Department of Agriculture's National Agricultural Statistics Service (NASS) divides the US into 20 Water Resource Areas, with the Lower Mississippi (WRA 08), also called the Mid-South, containing portions of Missouri, Kentucky, Arkansas, Tennessee, Mississippi, and Louisiana. The region has a humid subtropical climate and irrigation has been a fairly recent addition to many farmers' production systems. For example, the 2002 Census of Agriculture showed that Arkansas was the fourth leading state in terms of irrigated land (USDA-NASS, 2004), but as recently as 1975

approximately 95 % of the soybean and cotton harvested in the state were produced without irrigation (USDA-NASS, undated).

In the Mid-South, annual rainfall is generally sufficient for limited crop production, but periods of drought during the growing season make irrigation essential for optimum yields. Timely irrigation has been shown to increase yields of corn (Vories et al., 1993) and cotton (Vories et al., 2007), and irrigation has also been shown to reduce corn earworm damage and aflatoxin production (Smith and Riley, 1992). However, irrigation scheduling, the correct timing of irrigation during the growing season, is more difficult in humid regions like the Mid-South than in arid locations. Factors such as cloudy weather, rainfall, and temperature swings caused by the movement of weather fronts all complicate irrigation scheduling. Weather conditions in humid regions vary greatly from year to year, and even within a year, and the variability must be accounted for.

Too often, people in the Mid-South decide when to irrigate by the appearance of the crop; however, by the time stress is visible on the plants, the yields have probably already been reduced from the lack of water. Someone with quite a bit of experience can do a good job with the "feel method," or examining the soil in the root zone. In fact, one study reported that after "calibrating" with a tensiometer, better results were obtained by feel than with other scheduling methods (Phipps, 2003). However, more objective methods are usually needed for effective irrigation management.

Most commonly used methods either measure or estimate the soil water content. Evett (2007) provided an in-depth discussion of soil water and many of the methods for available for measuring soil water content. Although many types of instruments have been developed to measure soil water content, using many different kinds of technology, all have drawbacks. In addition, the highly variable soils in the region have limited the use of soil water measurements for irrigation scheduling.

The complexity of scheduling irrigation can be greatly reduced by the use of publicly available computer programs. Henggeler (2002) summarized eight programs developed in locations ranging from Arizona to North Dakota and varying greatly in complexity and input requirements. One of the programs discussed by Henggeler (2002) was the Arkansas Irrigation Scheduler (AIS), which was developed in the 1970s and early 1980s under the leadership of Dr. James Ferguson to aid Arkansas farmers in managing irrigation. Arkansas producers were just beginning to irrigate their crops, rather than depending solely on rainfall to meet the crop's water needs. In fact, during the years 1972 through 1981, the first ten years with separate records collected for irrigated and nonirrigated crops in Arkansas, an average of only 8% of the soybean and 14% of the cotton crops were irrigated (USDA-NASS, undated).

The program has gone through many changes as both knowledge and personal computing power have advanced. The earliest versions were mainframe-computer based (Yar, 1984), since personal computers (PCs) were fairly rare and not very powerful at that time. An early PC version of the program was written in BASIC for

the Radio Shack TRS-80[1] computers (Radio Shack Corporation, Fort Worth, Tex.) in many University of Arkansas Cooperative Extension Service (CES) and some farm offices. Several updated versions were released by CES for the MSDOS operating system, and the most recent versions were written in FoxPro for Microsoft Windows (Microsoft Corp., Redmond Washington). The initial program was only for use with stationary center pivot systems, but later versions included support for towable center pivot systems (Edwards, 1986). Support for furrow, flood, and graded border irrigation were included in subsequent revisions. Cahoon et al. (1990) reported five objectives for the AIS: 1) to be user friendly and easily operated; 2) to require minimal input data; 3) to be applicable to Mid-South climatological conditions and crops; 4) to be system-based as opposed to field-based; and 5) to be useful as a prediction tool, as opposed to a monitoring tool. While increases in computing power have reduced the need to be system based, the other four objectives still apply.

ARKANSAS IRRIGATION SCHEDULER PROGRAM DESCRIPTION

Like many scheduling programs, the AIS uses a water-balance approach to scheduling irrigation, similar to managing a checkbook. The system balance represents the soil water deficit (SWD), the difference between the soil's existing moisture content, summed over the rooting depth, and the moisture content of the soil at its well drained upper limit (~24 hours after surface water was removed). Deposits to the system include rainfall and irrigation. Withdrawals from the system include crop evapotranspiration (ET_c), runoff, and deep percolation below the root zone. Deep percolation is considered negligible when the SWD > 0 and is therefore not considered in the program. Rooting depth is not used explicitly in the program, but is implicit in the choice of a maximum allowable SWD. Cahoon et al. (1990) provided a detailed description of the program and that information will not be repeated. Instead, this report will deal primarily with changes made to the program since their article was written.

User friendly and easily operated. Each winter from 2005 through 2008 a group of program users met to discuss ways to improve the program for the next release. One of the most commonly heard comments was that the program should operate similarly to other Windows-based programs, making it easier for new users to learn to operate the program. Therefore, many of the changes were intended to make the program more user friendly as stated in objective 1. An updated version was released in 2008 (version 2.2.166) that included improvements to incorporate knowledge gained since the 2000 release of version 1.1w, to feature more intuitive operation similar to other Windows-based programs, and to be more universally applicable, rather than just aimed at users in Arkansas and surrounding states.

Require minimal input data. The program was developed for Arkansas producers, and much of the funding for developing and supporting the program was provided by Arkansas soybean producers through their checkoff funds. One of the problems

[1] Mention of trade names or commercial products in this publication is solely for the purpose of providing specific information and does not imply recommendation or endorsement by the U.S. Department of Agriculture or University of Arkansas.

facing Arkansas farmers when the AIS was developed was a lack of detailed weather information, which was one reason for objective 2 (to require minimal input data). Even though many states have networks of electronic weather stations with data available to the public, no such system was employed in Arkansas. However, producers in the states surrounding Arkansas also used the program and many researchers use the program as well. Therefore, the program needed to be flexible enough to meet the needs of producers with little weather information available and researchers or producers in other states with access to more weather data.

Rainfall. Several changes have dealt with rainfall and how it is considered in the daily water balance. As before, the program doesn't attempt to estimate runoff; instead the user is asked to input the effective rainfall, or the amount in excess of runoff. Knowing net rainfall would be advantageous, since considerable runoff can result from the thunderstorms common in the Mid-South. However, much more detailed information concerning topography and soil would be necessary than is currently required of the user. Furthermore, the resulting estimate would probably not be highly accurate. The relatively flat topography in most of the region increases the likelihood that rainfall will be effective at reducing the SWD before running off of the field.

In addition, the limit reported by Cahoon et al. (1990) that rainfall could replace no more than 90% of the estimated SWD was removed from the program. The numerical value of the limit seemed somewhat arbitrary given the wide range of rainfall amounts and intensities common in the region. In addition, the fact that rainfall could never eliminate the SWD seemed to be a point of confusion for program users.

Another change had to do with the lower limit for rainfall amount effective in reducing the SWD. Cahoon et al. (1990) ignored daily rainfall amounts < 5 mm. Their modified crop coefficient used to calculate ET_c included a soil surface wetness coefficient that served to raise the modified crop coefficient to 1 on the day of irrigation or a rainfall > 5 mm, to account for evaporation of water from the wet surfaces of the soil and/or leaves. They also included a lesser surface wetness coefficient on the following day. Rainfall < 5 mm was felt to be offset by the increased evaporation. However, an 8 mm rainfall could be reported as two 4 mm rainfalls and be ignored by the program, or it could be reported as one 8 mm rainfall and be accounted for in the program depending on the timing of the rain relative to the measurement. Later program revisions eliminated both the 5 mm limit and effect of the surface wetness coefficient on the second day. For small rainfalls, the impact of the wetness coefficient was limited by the rainfall amount (i.e., a 2 mm rainfall could not increase ET_c by more than 2 mm).

Reference evapotranspiration. Since one of the problems facing Arkansas farmers was a lack of detailed weather information, the program developers needed to estimate reference evapotranspiration from minimal data. Cahoon et al. (1988) used regression analyses to investigate relationships for estimating pan evaporation, which was measured at several sites in the region. Pan evaporation was related to a short grass reference evapotranspiration (ET_o) using a pan coefficient of 0.86. They developed quadratic equations for six locations in or near Arkansas (Fig. 1) of the form:

$$Pan = C_1 + C_2(T_{max}^2) + C_3(T_{max}) + C_4(DL) \quad (1)$$

where:
Pan = daily pan evaporation;
T_{max} = maximum daily temperature;
DL = day length;
C_1, C_2, C_3, C_4 = regression coefficients.

Day length was calculated from the latitude of the site and the day of the year, so that only rainfall and T_{max} were entered daily by the user. Other relationships were investigated, but Equation 1 appeared to provide the best combination of acceptable accuracy and minimal input data. Furthermore, it was believed that small day-to-day errors would be reduced somewhat during the days between irrigations (i.e., a small negative error one day would be partially offset by a small positive error the following day).

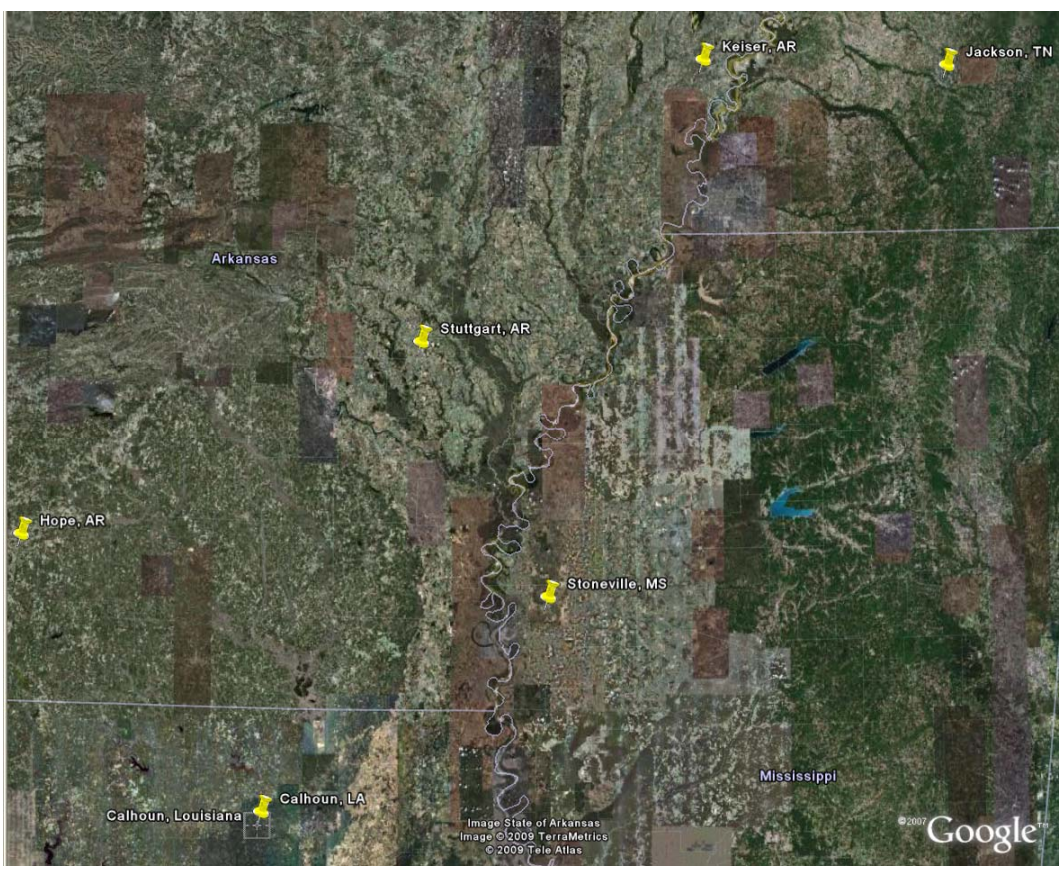

Figure 1. Locations of climatological data analyses for pan evaporation estimates.

Before 2008, producers or researchers with extensive weather data were only able to use T_{max} and rainfall data and required to select one of the six locations (Stuttgart, Keiser, and Hope, Ark.; Jackson, Tenn.; Stoneville, Miss.; and Calhoun, La.) most similar to their own location for estimating ET_o. Many researchers and some farmers from nearby states, including Louisiana and Missouri, had access to data from electronic weather stations that provided more extensive weather data than was

available to most Arkansas producers. Therefore, the latest version of the program allows users to input a value for ET_o directly using estimates derived from some other method believed to be more accurate, rather than having the program estimate one. Those with limited data can still allow the program to estimate ET_o in the same way as before. Therefore, while only minimal input data are still required to use the program, the change allows the user to take advantage of additional data when it exceeds the minimum required.

Long-time program users must exercise care if they change to another method of ET_o estimation, even if it provides more accurate estimates. Vories and Tacker (2006) reported that ET_o values calculated with the AIS for Keiser, Ark., were consistently higher than values calculated with the Standardized Penman-Monteith equation (ASCE-EWRI, 2004). Hypothetical irrigation schedules developed from the ET_o values resulted in consistently earlier first irrigations and two additional irrigations were scheduled each year with the AIS values. Vories et al. (2009) reported agreement between ET_o values from the AIS and from observed pan evaporation from the National Climatic Data Center (NOAA, undated) using the pan coefficient used in the AIS (0.86). However, both were higher than the values calculated using the standardized Penman-Monteith equation (ASCE-EWRI, 2004). Some of the differences could be accounted for by varying the maximum allowable SWD for different ET_o estimation methods. Farmers are currently advised to adjust the maximum allowable SWD to best fit individual fields as they become more familiar with using the AIS, and similar adjustments could be especially important if a different ET_o estimation method is used. However, for most producers in Arkansas and many other areas, using more data-intensive methods is not an option until more detailed weather data become widely available.

Applicable to Mid-South climatological conditions and crops. While the program will be applicable to more areas than before, it is still intended primarily for use in the Mid-South or areas with similar humid climates as suggested in objective 3. Wet soil conditions typical of winter and early spring simplify the choice of a starting SWD. In addition, small errors that accumulate over time from the use of limited weather data will usually be erased by rainfall or in some cases by surface irrigation. However, better crop coefficient functions are needed for the Mid-South. Lysimeter-based functions have not been developed in the region, so some of the functions were adapted from different climates. Weighing lysimeters have been installed by the US Department of Agriculture's Agricultural Research Service (ARS) in Stoneville, Miss., (Fisher, 2004) and by Louisiana State University in Saint Joseph, La. (Clawson and Hendrix, 2007). Both systems have been used to study cotton ET_c, but will likely be available for other crops in the future. Similarly, photographic techniques being developed (Purcell, 2000; Trout and Johnson, 2007) may result in simpler methods for developing crop coefficients than using weighing lysimeters. Until better functions are developed, irrigators in the Mid-South must rely on published values and experimental data from other regions.

System-based as opposed to field-based. Recent versions of the program have changed from system-based (obj. 4) to field based. In the early versions, computer memory and storage restricted the program to only consider a small number of fields.

A representative situation was selected as a four-field system, representing quadrants of a stationary center pivot field, halves of two towable center pivot fields, or four fields sharing one well for surface irrigation. Recommendations were made for when to irrigate each of the fields in the system. More powerful PCs allow many more fields to be considered simultaneously. Being able to view the soil moisture status of most or all of the fields on a farm at the same time was believed to be more advantageous than retaining the system base. The user could then choose to group the fields in whatever way best fit the situation.

Useful as a prediction tool, as opposed to a monitoring tool. The program has kept its utility as a prediction tool, rather than just a monitoring tool (obj. 5). The predictive capability of the program is one of its most important assets under Mid-South conditions, where multiple crops are often irrigated from the same water supply. In addition, irrigation decisions are often coordinated with pesticide applications or other field operations. User's can project irrigation needs for the next ten days, assuming no rainfall and the expected T_{max}.

Other factors. Even with improvements to the AIS, users must remember that many things can still affect the accuracy of the program output. In addition to excessive rainfall, runoff can result from application rates on the outer portions of a center pivot that are too high for the soil. An application efficiency of 90% is assumed for sprinkler irrigation and cannot be changed by the user. However, since runoff-inducing application rates waste water and energy, they should be avoided. With furrow irrigation, soil crusting, irrigating every other middle, or irrigating a field with appreciable slope may result in less than saturated conditions following irrigation, even though the assumption in the program is SWD = 0 (Cahoon et al., 1990).

Another assumption in the program is no standing water (i.e., all rainfall or irrigation applied in excess of the SWD will run off the field). Standing water can cause the soil to remain saturated for several days, stressing the crop and continuing to affect water use after the standing water is removed. Estimates for water use in the program are based on a healthy, well watered crop. A crop that has been drought stressed or experienced oxygen stress from standing water may never recover to the expected water use rate. However, between the humid climate and the relatively flat topography, standing water is often unavoidable, particularly in lower portions of the fields.

Internet version. CES has decided to move most of their supported software to the internet. While the internet has been used for program distribution for several years, most of the programs were downloaded from the website and operated on the user's computer. However, future plans are for programs to run on the server without residing on the user's computer. Advantages to such a system include: "bugs" can be repaired without having to contact users and provide "patches" or updated versions; the user is always assured of using the latest version of the program; and the user doesn't have to bother with installation and setup of the software on their computer. However, the main disadvantage is that the program cannot be used without internet service. Users without internet service would not be able to use the program, and users with relatively slow dial-up service might not be willing to wait the time

necessary to run the program for many fields. Although the internet version is in beta testing, no internet version is currently available for public use.

Finally, the current version of the program is applicable to more areas than before, and offers improvements for users already familiar with the program. Using the program will aid producers in determining the optimum irrigation schedule for their situation. In addition to improving yields, properly scheduling irrigation can save energy and therefore money by reducing unnecessary pumping. Reducing unnecessary pumping can also help to alleviate water shortages being experienced in many agricultural areas.

SUMMARY

The AIS has been in use for over twenty years in Arkansas and surrounding states, with the current version released in 2008. The current version retains most of the objectives of the earlier versions (user friendly and easily operated, requires minimal input data, applicable to Mid-South climatological conditions and crops, and useful as a prediction tool, as opposed to a monitoring tool). The one changed objective was to be field-, rather than system-based, allowing users to view the soil water status of more of their fields at one time and group the fields however they feel most appropriate. Other changes made the program easier to learn, allowed the user to take advantage of more extensive weather data if it is available, and made the program applicable to more areas than before. Changing only the ET_o calculation method was shown to suggest fewer irrigations per year in one study. Therefore, previous users that take advantage of more extensive weather data will need to exercise care to see if other changes such as maximum allowable SWD are also needed. Crop coefficient functions developed in the region are needed, but are not currently available. Future versions of the program may be limited to the internet, if service becomes extensive enough to reach all of the users. However, no internet version is currently available for public use. In addition to improving yields, using the program to properly schedule irrigation can save energy and therefore money by reducing unnecessary pumping, and help to alleviate water shortages being experienced in many agricultural areas.

ABSTRACT

A number of states have developed advisory software to assist farm managers with irrigation scheduling. The fundamental procedures for irrigation scheduling are relatively straightforward and simple, but the diversity of the programs that have recently been developed is remarkable and significant. The range of analytical options offered by these programs is increasing; some have evolved from simple irrigation scheduling programs into comprehensive and sophisticated irrigation planning and management programs, driven in part by the accelerating competition for water. The next generation of irrigation management software will need to address the challenge of optimizing irrigation management; i.e. maximizing net economic returns rather than maximizing yields. But the software to do that is inherently very complex, and development of such software is beyond the resources of most individual states or agencies.

This paper provides an overview of existing and developing irrigation management programs in the U.S. and suggests some potential components of the next generation of irrigation management software.

INTRODUCTION

The Natural Resources Conservation Service (NRCS) is the lead agency of the United States Department of Agriculture charged with carrying out the Department's conservation mission on private lands. The agency addresses the resource concerns of landowners with an individually designed conservation plan composed of conservation practices. One of the natural resource concerns that the conservation plans can address is inefficient use of water on irrigated lands.

Among the 160 plus NRCS conservation practices is the "irrigation water management" practice. Irrigation scheduling and irrigation water management are among the preferred tools NRCS has for assisting a landowner in mitigating the inefficient use of irrigation water.

In 2008, NRCS applied the Irrigation Water Management Conservation Practice on 1,307,457 acres nationwide (NRCS, 2008). The NRCS has encouraged the use of irrigation scheduling software through both technical and financial assistance to landowners. In addition, some developers of irrigation schedulers have received financial assistance from the agency. Other developers have received indirect assistance through the encouragement or requirement of using a specific irrigation scheduler.

IRRIGATION GOALS

Determining when and how much to irrigate is fundamental to the operation of any irrigated farm. Optimizing an irrigation schedule can have a variety of goals, including (Martin, 1990):

- maximizing net return,
- minimizing irrigation costs,
- maximizing yield,
- optimally distributing a limited water supply,
- minimizing groundwater pollution or
- optimizing the production from a limited irrigation system capacity.

Current irrigation schedulers often assume that the sole goal of the irrigator is to maximize yield. In this case, the scheduler looks at the immediate situation, i.e. when is the next recommended irrigation. This assumes that the water is available on that date. The irrigator usually is not given guidance of how best to manage several fields in a water limited environment. Going forward, we can expect US irrigators to be in a water limited situation more frequently, and effective schedulers will need to be able to recommend an irrigation schedule based on the irrigator's selected goal and the amount of water the farmer has available.

SCHEDULING STRATEGIES

Every irrigated farm uses some type of decision making process to schedule irrigations, though that process may be as basic as "water is delivered every seventh day". Table 1 indicates that the current preference of deciding when to irrigate is based on the "crop condition" or "feel of soil". All other methods have a relatively low level of use.

Table 1. Methods Used in Deciding When to Irrigate (USDA, 2004)

Respondents could choose more than one method.	1998	2003	% of 2003 value	% Change 1998-2003
Number of irrigated farms	223,932	220,163		-1.7%
Any method	220,770	220,163	100.0%	-0.3%
Condition of crop	163,303	175,560	79.7%	7.5%
Feel of soil	90,434	76,731	34.9%	-15.2%
Soil moisture sensing device	17,869	14,452	6.6%	-19.1%
Plant moisture sensing device	(NA)	3,193	1.5%	
Commercial or government scheduling service	7,238	14,190	6.4%	96.0%
Reports on daily crop-water evapotranspiration (ET)	10,841	15,323	7.0%	41.3%
Scheduled by water delivery organization	22,567	26,537	12.1%	17.6%
Personal calendar schedule	40,338	42,551	19.3%	5.5%
Computer simulation models	2,237	1,285	0.6%	-42.6%
When neighbors begin to irrigate	(NA)	14,080	6.4%	
Other	15,601	19,298	8.8%	23.7%

Scientific irrigation scheduling follows one of three strategies (Jones, 2004):

- Soil water measurement
- Soil water balance calculations
- Plant 'stress" sensing.

Irrigation schedulers typically use the checkbook method to calculate the daily soil water balance and recommend irrigations dates and amounts. The checkbook method of irrigation scheduling is one variation of the soil water balance strategy, and can be represented mathematically as (Howell, 2007):

$$\Theta z_{i+1} = \Theta z_i + (P_i - Q_{roi}) + I_{ni} - ET_i - Dz_i$$

where Θz_i is the soil water content on day i integrated over the root zone depth z, P is rainfall, Q_{ro} is runoff, I_n is net applied irrigation, ET is the crop water use from the root zone, and D_z is the deep percolation beneath the root zone at depth z.

The checkbook method requires inputs of crop ET, effective rainfall, and irrigation depth. The development of state and regional weather and evapo-transpiration networks has allowed irrigators to have access to daily evapo-transpiration values. However, the checkbook method, even when integrated with a weather/ET network, typically relies on the irrigator to record and enter the effective rainfall and irrigation events. Even if the crop ET data is completely accurate, the irrigator may have difficulty in determining the effective precipitation or the net irrigation depth. Errors can be introduced into the checkbook method early and often.

Consequently, it is universally recommended to field truth the results of irrigation schedulers. Errors are cumulative in the checkbook method, and unless an effective rainfall or irrigation fills the root zone to field capacity, measuring the soil moisture is critical to ensure that the scheduling calendar reflects what is happening in the field.

IRRIGATION SCHEDULING SOFTWARE

To facilitate the calculations required for the checkbook method, a variety of organizations have developed irrigation scheduling software. This section highlights selected schedulers. All of these schedulers discussed use some form of the soil water balance calculation to predict the next date and amount of irrigation. Table 2 summarizes the schedulers.

AZSCHED

AZSCHED (Martin, 2003, 2005) was developed by the University of Arizona; it has most of the features common to schedulers. The software is standalone; the user downloads the program and runs it off of a personal computer. The program connects to the AZMET weather network to access real time ET data. There are 28 crops in the AZSCHED database. The program uses growing degree days rather than days after planting to determine the crop stage.

Arkansas Scheduler

The Arkansas Scheduler (Tacker, 2006) is designed for the irrigated crops in the mid-south, and can be used to schedule irrigations of cotton, soybeans, grain sorghum or corn. Arkansas Scheduler allows the user to import ET data, but does not access any weather network. In the absence of ET data, it will calculate a daily ET value based

on the day's maximum temperature. It also has a predictive function; the user can enter in the forecasted weather and Arkansas Scheduler will develop an irrigation calendar.

Wateright

Wateright (C.I.T., 2009) is a web application created by the Center for Irrigation Technology in Fresno, CA. It has a wide area of application because of its ability to access the ET networks of California (CIMIS), and Oregon, Washington and Idaho (Agrimet). The user is able to schedule a total of 15 fields, and the results are shown in tabular form. The soils data is limited to seven soil types e.g. "fine sandy loam". If the weather station selected is in California, the user can choose from among 63 crops. For fields in the Pacific Northwest, Wateright has access to the crop database of Agrimet. Wateright also provides the option of specifying a cover crop with its own crop coefficient; the cover crops also can have their own start and stop dates. The user can also select the criterion for the irrigation schedule, e.g a schedule based on the management allowable depletion, a preferred length of irrigation set, or a preferred irrigation rotation.

KanSched

KanSched2 (Clark, 2002) (Rogers, 2006) was developed by Kansas State University. This is a standalone program. It has been used successfully as a research tool in at least one instance (Dogan, 2006) and has been adopted for use by NRCS as the preferred scheduling tool in Kansas. It does not access an online ET network, though this does have one advantage because it can be used easily outside of its "design' area. The program has 19 internal crops, and the crop coefficients can be edited so that virtually any crop can be modeled. It uses generic soil names and data, e.g. clay loam, for its available water capacity, but, again, this data can be easily edited. Notable features include its graphing output and its irrigation pumping cost tool.

NDAWN (North Dakota Agricultural Weather Network) Irrigation Scheduler

The NDAWN Irrigation Scheduler (Scherer, 2008) is a web-based application for use in North Dakota. It uses a soil water balance algorithm to determine the soil water deficit in the effective root zone on a daily time step. The application has a GIS interface that allows the user to delineate the field of interest based on aerial photographs; the soil information is then immediately imported. The user is able to make a selection from three nearby weather stations for ET data. The soil data includes available water capacity from the NRCS Soil Data Mart, and this information is automatically added to a table so the user doesn't have to enter it.

A tabular irrigation schedule is then produced, with historical ET data for dates in the future. The user must enter the precipitation and irrigation events, and has the option of adjusting the soil moisture content as needed. The soil water balance is calculated for the three major soils of the delineated field.

IMO (Irrigation Management Online)

IMO (Irrigation Management Online) (Hillyer, 2007) is a web application that is currently in field testing. While the original development was centered in Oregon, the developers are now working cooperatively with the University of California,

Washington State University and the University of Idaho to utilize IMO in those states. IMO incorporates sophisticated analytical and decision support capabilities not found in conventional irrigation decision support software, including:

- modeling of application efficiencies and crop yields, both of which are normally assumed *a priori* in conventional irrigation management but must be explicitly analyzed for partial irrigation,
- conjunctive management of all fields that share a single source of water (as opposed to the conventional approach of managing each field independently) in order to facilitate optimal allocation of limited water among multiple fields,
- explicit modeling of uncertainties coupled with a Bayesian decision model for irrigation management under uncertainty,
- linking of simulation models to enterprise budget spreadsheets tailored to the economic circumstances of individual farms to facilitate rapid economic assessment of alternative water use strategies and associated crop yields.

Additionally the developers anticipate moving to 'controlled' open source code options that would permit local users to adapt the system to accommodate local circumstances, science and preferred practices while still insuring the integrity of the system.

Citrus MicroSprinkler Irrigation Scheduler

The Citrus MicroSprinkler Irrigation Scheduler (FAWN, 2009) was developed by the University of Florida and is hosted on the Florida Automated Weather Network site. It is an easy to use web application for citrus. It accesses the Florida Automated Weather Network's 35 weather stations. The user enters some basic data about the tree spacing of a mature citrus orchard, the irrigation system, and selects one of nine available soils. The web application then returns a statement on the recommended timing of the irrigation events for the next two weeks. For example, the result may be: "Irrigate every 5 days for 11 hours and 2 minutes."

TrueISM

Often left out of the discussion of irrigation schedulers are the efforts of private software firms. One such effort is sponsored by the El Dorado Irrigation District (EID) in northern California. EID uses the TrueISM software (Taylor, 2009) that was specifically developed for the irrigation district by TruePoint Solutions. This software is a web application and resides on one of the EID servers. There are two main sub-components to the current software package. The first is the day-to-day operations where a majority of the tasks are automated including weather data downloads and grower report delivery by e-mail. The second component is the field application where all of the data logger information and neutron probe readings are recorded on a tablet computer. At the end of the day this tablet is connected to the network and the prediction database updated. The software then re-calculates all of the irrigation predictions automatically based on the most recent data. The district has developed accurate irrigation system efficiencies for each farm based on the dense network of soil moisture sensors and irrigation flow measurement devices. The farmer has the option of waiting for the weekly e-mail, or accessing the most current information online.

THE NEXT GENERATION (NG) OF IRRIGATION SCHEDULERS

Irrigation scheduling software development will continue. As a starting point for discussion on where the development should lead, several suggestions are listed here.

1. The NG irrigation schedulers will be online applications. Although there will continue to be a need for legacy software, the ability to access real time online data requires that the user have an internet connection. Fortunately, the number of farmers without broadband internet will continue to decline. One attractive aspect of online applications will be the ability to evaluate the real time use of the software.
2. The NG irrigation schedulers will be able to access relevant on-line databases that expand the functionality of the software. Among the relevant databases are:
   - weather networks that report daily ET and real time rainfall and weather forecasts,
   - soil databases,
   - aerial photography,
   - water rights databases, and other information that is important for individual watersheds and irrigation districts.

   Many of the current schedulers are capable of accessing several existing ET networks. The NDAWN irrigation scheduler accesses the NRCS soils database and aerial photography. Leveraging the work of other agencies, particularly federal and state databases, will create added value, and generate support from those agencies.
3. The NG irrigation schedulers will allow for the quality weighting of various inputs. Currently, most schedulers replace calculated soil moisture data with measured soil moisture data, assuming the measured soil data is flawless. In fact, all data points have some inherent error. Determining the relative uncertainty of all data will be an important function.
4. The NG irrigation schedulers will have integrated crop yield models. In addition, they will allow the user to make decisions based on the current economic situation, i.e. commodity and water prices.
5. The NG irrigation schedulers will allow for deficit irrigation, and in fact, allow the farmer to choose among several goals in order to optimize irrigation.
6. The NG irrigation schedulers will schedule whole farms, and their multiple fields and water sources.
7. The NG irrigation schedulers will allow irrigation districts and watershed organizations to access water use information to improve planning.
8. The NG irrigation schedulers will be integrated with irrigation hardware. For example, the scheduler will be linked to the flow meters, rain gauges and soil moisture monitoring devices of the farm, so that this data does not have to be entered manually. This will provide a feedback loop so that the scheduler can be a data management tool that mitigates the uncertainties inherent in data collection. For example, although not fully integrated, TrueISM inputs soil moisture data gathered on a tablet computer in the field and automatically updates its irrigation schedule.

Table 2. Irrigation Scheduler Summary

Program Name and Version	Standalone or WebApp	Weather Network	Area of Use	Crops & Coeffficients	Soil Information Available	Other interesting information
KanSched2 2.1.8	Standalone	ET data entered manually	Anywhere, but crop coefficients are for Kansas	19 internal crops, plus ability to add/edit custom crop coefficients	11 generic soil textures e.g. clay loam. Can be edited.	Good Soil Moisture Charts. Pumping Cost tool.
NDAWN Irrigation Scheduler	WebApp	NDAWN: 70 stations, mostly in ND.	North Dakota	9 crops	Soil information seamlessly imported when field is delineated	User delineates field from aerial photography
AZSCHED 1.17	Standalone	AZMET: 28 active stations in January 2009, all in AZ.	Arizona	24 crops	User enters the available water capacity for the soil.	Uses growing degree days to monitor crop status
Wateright	WebApp	CIMIS and Agrimet	California, Oregon, Washington, Idaho	63 crops in CA. In the Pacific Northwest the number varies based on the Agrimet station	7 generic soil textures	Wide variety of crops and locations
IMO (Irrigation Management Online)	WebApp	Agrimet	Oregon, Washington, Idaho	It uses the ET crop data provided by Agrimet, which varies by station	11 generic soil textures, plus can create new soil type	Good graphing capabilities.
Arkansas Scheduler 2008	Standalone	ET data entered manually	Arkansas	cotton, corn, soybeans, grain sorghum	5 generic soil texture class	Projection aspect: user enters expected weather
Citrus MicroSprinkler Irrigation Scheduler	WebApp	FAWN: 35 stations in Florida	Florida	Citrus only	9 soils	One page entry, one click and the user gets the result.
TrueISM (as configured for the El Dorado Irrigation District)	WebApp	1 CIMIS station	El Dorado Irrigation District (EID), Placerville, CA	41 crops	All 42 soils of the EID	Interactive Soil Triangle, accurate system efficiency database

Woodruff Irrigation Charts

J.C. Henggeler [1]

[1] Department of Biological Engineering, University of Missouri, PO Box 160, Portageville, MO 63873; PH (573) 379-5431; FAX (573) 379-5875; email: henggelerj@missouri.edu

ABSTRACT

The Woodruff Irrigation chart method of irrigation scheduling began as a graphical chart solution of when to irrigate for a specific crop, location, planting date, and soil in Missouri. It has been expanded to a web-based chart maker that can be used for corn, cotton, and soybeans in Missouri and adjacent states. Survey data indicates that irrigators who use the Woodruff charts increase their yields over non-schedulers by 14.0 bu/ac more corn, 104 lbs/ac more cotton, and 10.7 more bu/ac soybeans. In southeast Missouri approximately 16%, 6%, and 5% of corn, cotton, and soybean irrigators use the Woody method, while 12%, 17%, and 7% use the ***Arkansas Scheduler***. Total impact since 2001 is estimated to be $54 M.

INTRODUCTION

Dr. "Woody" C.M. Woodruff was born in1910 in Kansas City and passed away in 2003 still maintaining an active presence in agronomic research. He had worked for the University of Missouri's Agronomy Department since 1929. He graduated from the University of Missouri College of Agriculture in 1932. He received has master's degree in agronomy from the University of Missouri-Columbia in 1939 and after civilian wartime service completed his doctorate in 1953.

He was a many-talented man. Because of his keen mind, he served with the United States Army Signal Corps doing research during World War II on radar systems and airborne magnetic submarine detectors. He was primary a soil chemist, and developed the Woodruff buffer equation commonly used in soil analysis. He was the first person to break the 100-bushel per acre yield level on corn. He did this by reverse analysis determining the number of kernels per acre needed and the amounts of N, P and K required to provide kernel mass to attain 100 bu/ac. He later said that he was lucky because the first season right after Word War II when he did this had well-timed rains.

He was keenly aware of weather patterns and their effect on yield. He determined that yield suppression in corn can occur if the previous season has received too much rain. He showed that this was due to micro-nutrients becoming tied up in chelates that caused the micro-nutrients not to be readily available to corn next season. This awareness of the problem of too much late-season moisture led to a tool he developed to help irrigators so that they would not over-irrigate crops. This became know as the Woodruff Chart, or as what we in Missouri call the Woody chart.

BACKGROUND

The Woodruff chart consists of a graph containing two parallel lines that serve as a graphical means to schedule irrigation. The top one represents the accumulative crop water use of the crop. The bottom line indicates when drought would occur and is offset a vertical distance equal to the available water holding capacity of the soil. Thus, the X axis (horizontal axis) of the graph represents time, while the Y axis (vertical axis) represents inches of water.

Original Woodruff chart. Woodruff had determined that the average daily water use of corn was 0.15 inches per day (ipd), but since he knew that it was important to end the season with some amount of available storage, he used the value of 0.14 ipd to develop the curve of accumulation. Also, his study of weather patterns in central Missouri indicated that in 95% of all years soil moisture was adequate through May, so the irrigation chart starts in June. Figure 1 shows the original double-line graphic that was used in Missouri guidesheet from the 1970s (Woodruff, 1975).

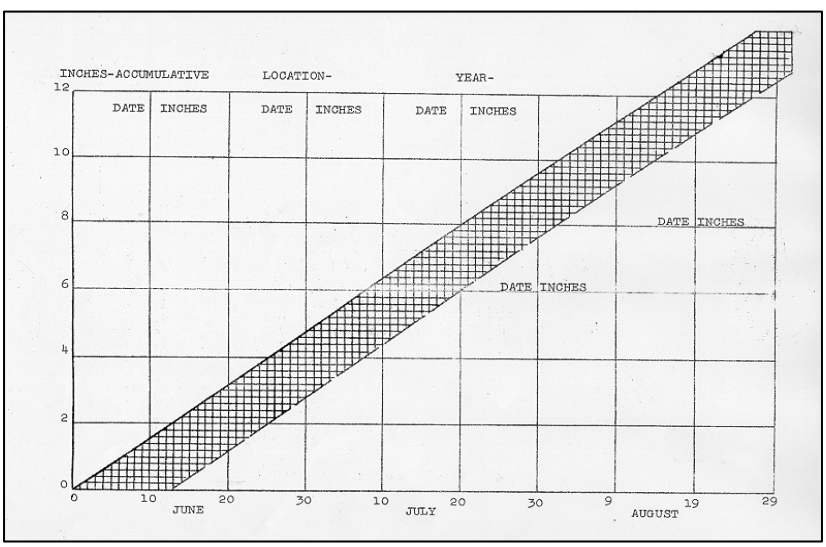

Figure 1. A Woodruff graph as it appeared in a Missouri guidesheet from the 1970s.

To schedule irrigations, the user merely pencils in the rainfall amounts in an up-and-down fashion on the day they occur, using the same vertical units that the crop water use curve is plotted with. The second and subsequent rainfall events are penciled in on the graph on their appropriate date and start at a level equal in elevation to the top of the last penciled in rainfall event, creating a stair step pattern. Irrigation occurs before the stair step crosses the bottom (drought) line. Irrigation amounts are penciled in the same manner as rainfall events. If a rainfall or irrigation amount takes the stair step across the top line (accumulative water use), any portion above the accumulative curve is considered deep percolation, and is discounted. In this case, the irrigator

begins the stair step, not at the top of the rainfall line, but at a level equal to where the rainfall line and the accumulative water use line cross.

Woodruff charts had great popularity with Missouri irrigators, most of whom had little irrigation experience.

Updating the Woodruff chart method. As mentioned, the original chart was developed specifically for corn planted about May 1 and grown on claypan soils in central Missouri making it site-, crop-, and date-sensitive. In the 1980s agricultural engineers at the University of Missouri expanded the concept with a BASIC computer program that allowed weather data to be an input variable. Also, additional crops, emergence dates and soils could be utilized. A value of 80% of Blaney-Criddle evapotranspiration (ET_{BC}) was used as the reference value (Gregory and Schottman, 1982). This method did not construct a chart, but instead used a generated table.

Existing Woodruff chart method. The current Internet Woodruff site was opened up to growers in June, 2001. The system was designed to require minimal data from the irrigator, who on one of the opening screens (Figure 2), chose crop, soil type, irrigation method, and county in Missouri.

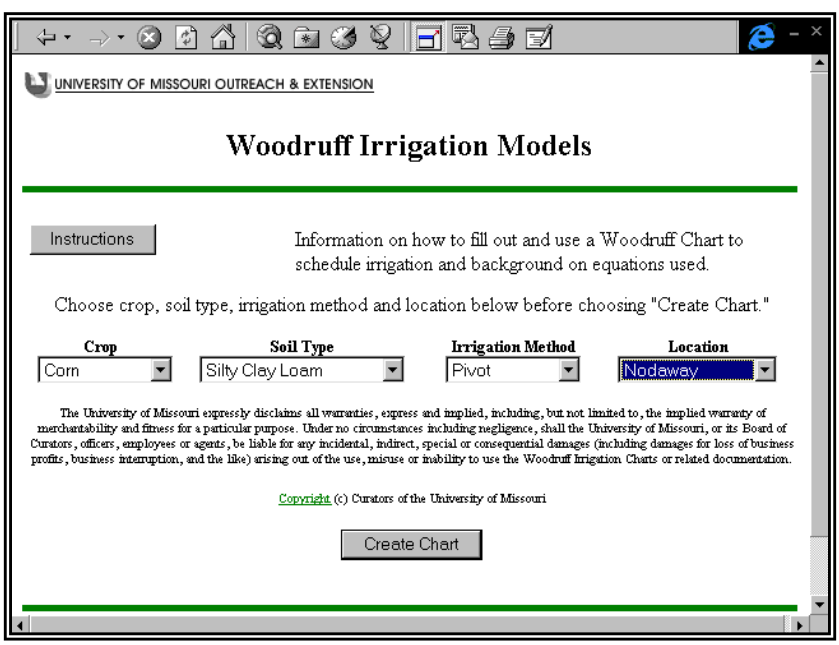

Figure 2. Opening query screen of the Woodruff Irrigation Chart Internet site.

The ET_{BC} equation is used in the Internet version. Daily values of evapotranspiration are calculated using a splining function on published 30-year monthly mean values of daily maximum and minimum temperatures. Latitudinal values are used to calculate daylight hours, part of the Blaney-Criddle equation. A database was established that

contains, for each Missouri county, latitude, daily maximum temperature, daily minimum temperature, and daily ET_{BC}.

The next screen that a viewer sees (Figure 3) asks for additional information including emergence date, field name, acreage and Relative Maturity or Maturity Group, depending on whether corn or soybeans had been chosen. It was found that "field name" was important as some growers had a number of various fields that Woodruff charts were printed up for. Acreage data was asked for so that developers could measure total impact.

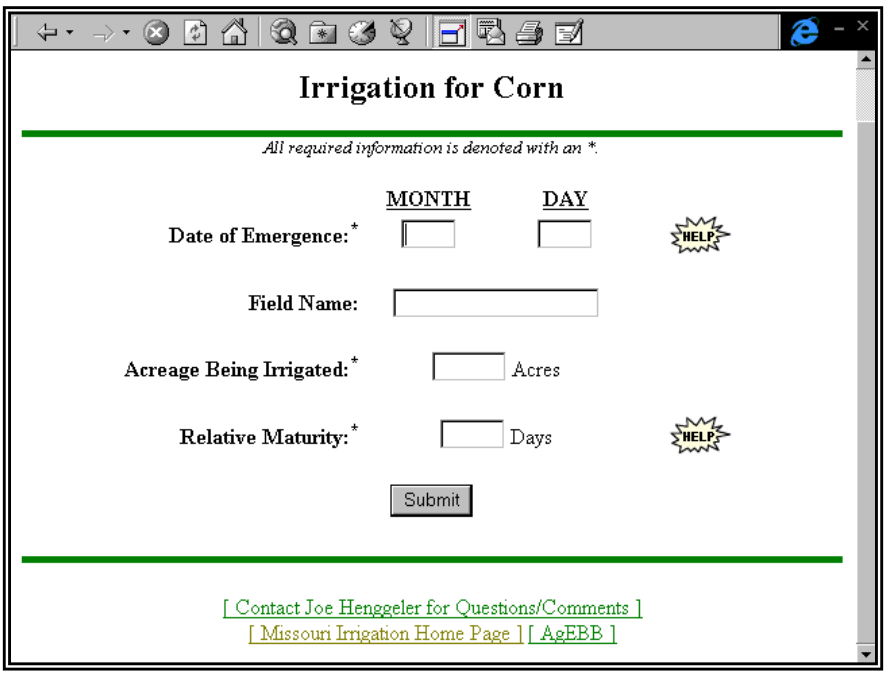

Figure 3. The second query screen that collects data for developing the Woodruff chart.

The final screen (Figure 4) before the graph is created, presents computer-suggested data including date crop will cease up-taking water, estimated water holding capacity of the soil, the ideal soil moisture status at the end of the season, and the deficit at which to trigger irrigations. These values are derived from data already supplied by the user, and can be adjusted if needed to be.

Cessation of crop water use. The final maturity of the crop is based on empirical relationships. Corn maturity is based on an estimate of corn Heat Units (HUs) (base 50° with 86° degrees as upper limit on maximum) to reach "black layer" that uses the Relative Maturity of the hybrid in use. Once the required HU value is calculated, the associated historical weather file is used to determine the date this will occur. A grower can change this date if he feels that it is not correct. The crop coefficient curve is based on % of HUs.

For soybeans, final maturity (R8) is based on a derived empirical relationship using Maturity Group, latitude and date of emergence. Again, once emergence and date of R8 are determined, a coefficient curve is developed based on standard Hus (60-degrre base).

Cotton is by nature a perennial, so cessation of its water use is dependent on either the occurrence of sufficiently cold enough weather or the application of crop desiccants. For Missouri conditions, the occurrence of 55°F-weather in the fall is close in time to normal applications of crop termination chemicals. Once the emergence date and the date of the first 55° fall weather (determined by interrogating the county data file) are known, the seasonal Heat Units (base 60 with no upper limit on maximum) can be calculated. Daily crop coefficient values are based on % of seasonal Heat Units experienced up to that date.

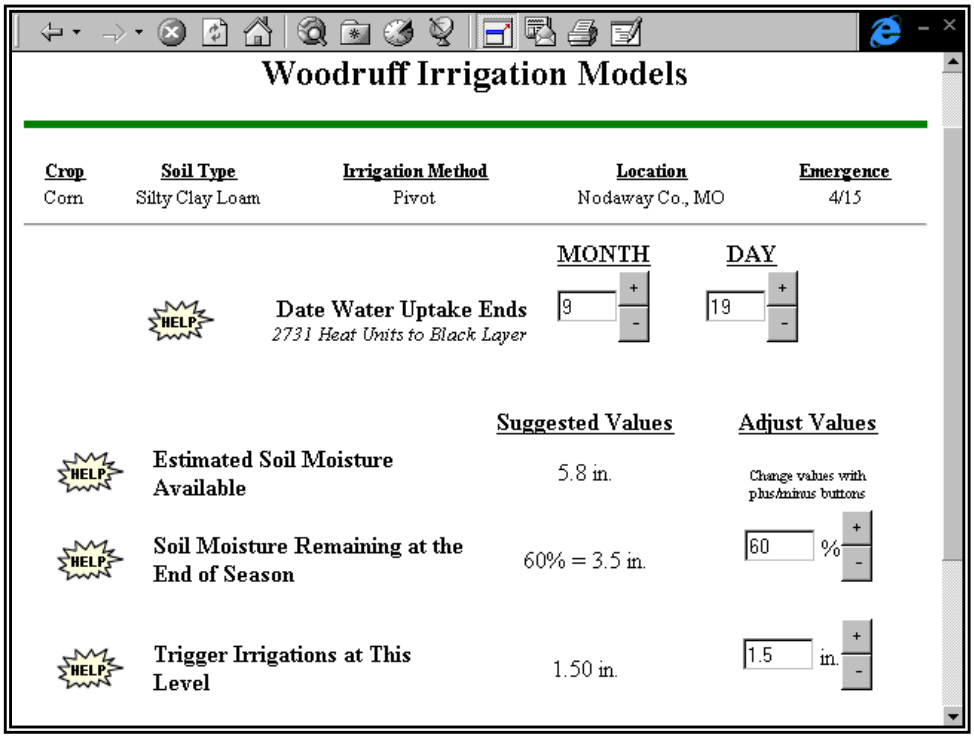

Figure 4. The last query screen that collects data for developing the Woodruff chart and allows for default estimates to be modified.

Irrigation trigger points. The soil type, crop, and method of irrigation determine the irrigation trigger (a.k.a., deficit) to default to (Table 1). This value represents the off-set between the bands in the chart. These suggested values are based on empirical research done by the University of Arkansas and are employed in their computer program, ***Arkansas Scheduler*** (Ferguson, 2000).

A sample Woodruff chart for 119-RM corn, emerging on May 1 in Clay County, MO is seen in Figure 5. Full information on crop coefficient values used and other items are found in the documentation section of the web-based program. The site of the program is:

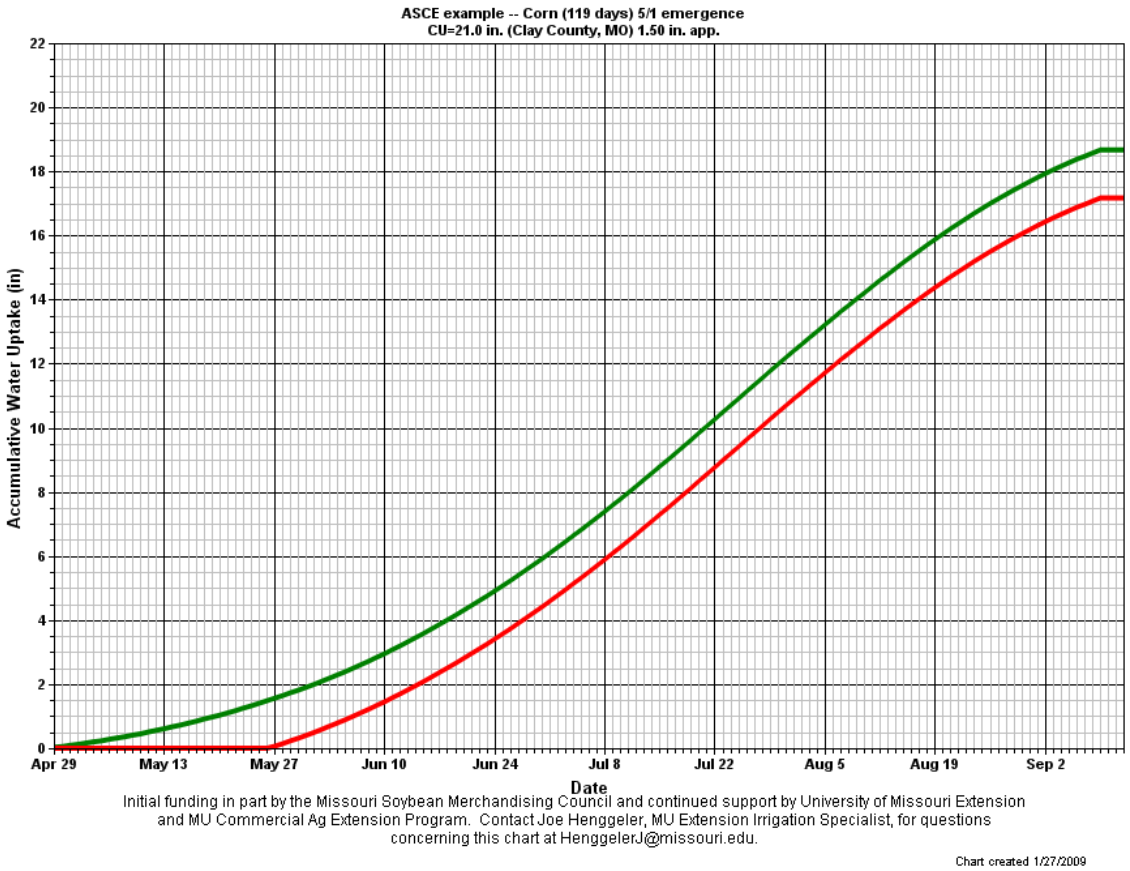
http://agebb.missouri.edu/irrigate/woodruff/

Table 1.Default irrigation deficits for various crops, soil types and irrigation methods.

Soil Type	CORN		SOYBEAN		COTTON	
	Pivot	Flood	Pivot	Flood	Pivot	Flood
	-------- inches per irrigation application ----------					
Coarse Sand	0.75	1.00	1.00	1.50	1.00	1.50
Fine Sand	1.00	1.50	1.50	2.00	1.50	2.00
Loamy Sand	1.00	1.50	1.05	2.00	1.05	2.00
Sandy Loam	1.25	1.75	1.75	2.25	1.75	2.25
Fine Sandy Loam	1.25	1.75	1.75	2.25	1.75	2.25
Very Fine Sandy Loam	1.25	1.75	1.75	2.25	1.75	2.25
Clay	1.25	1.75	1.50	2.00	1.50	2.00
Clay Loam	1.25	1.75	1.50	2.00	1.50	2.00
Silty Clay	1.50	2.00	2.00	2.50	2.00	2.50
Silty Clay Loam	1.50	2.00	2.00	2.50	2.00	2.50
Silt Loam	1.50	2.00	2.00	2.50	2.00	2.50

IMPACT

The two prime scheduling methods in Missouri are the computer program ***Arkansas Scheduler*** developed by the University of Arkansas (Ferguson et al., 2000) and the Woodruff chart.



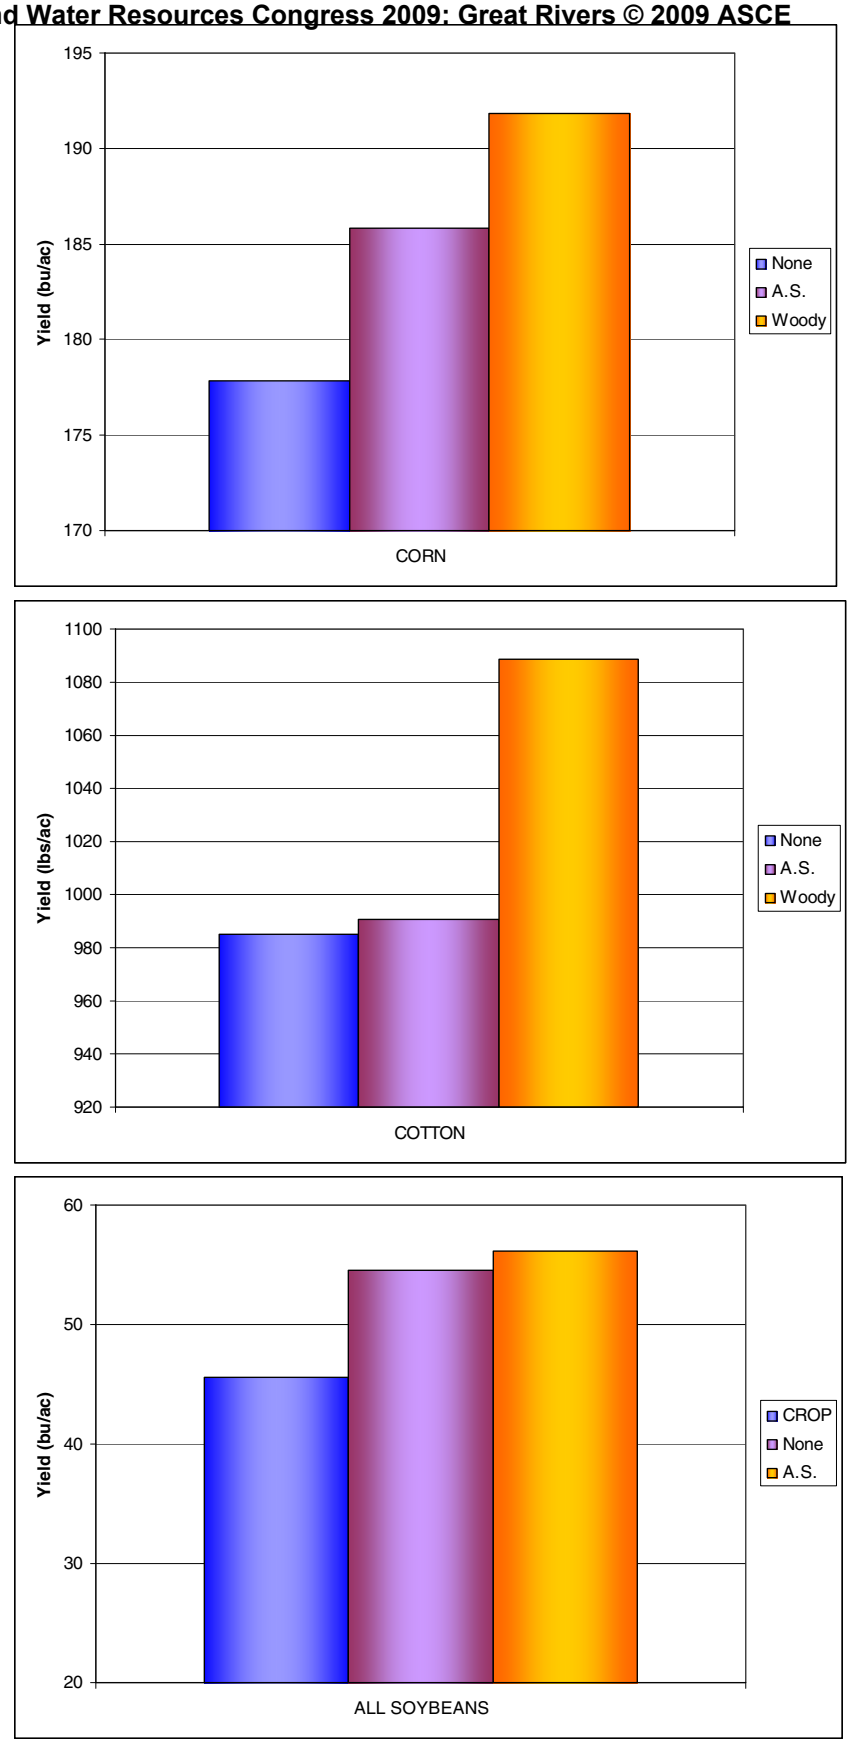


Figure 5. A sample Woodruff chart for 119-RM corn, emerging on May 1 in Clay County, MO.

The **Bootheel Irrigation Survey** (**BIS**) was initiated in 1987 and collects data from irrigators in southeast Missouri. Since 2000 the **BIS** has collected data on the method of irrigation scheduling the farmer used. Survey data indicates that irrigators who use the Woodruff charts increase their yields over non-schedulers by 14.0 bu/ac more corn, 104 lbs/ac more cotton, and 10.7 more bu/ac soybeans. In southeast Missouri approximately 16%, 6%, and 5% of corn, cotton, and soybean irrigators use the Woody. Figures 6 a through c show the yields of non-schedulers, users of the ***Arkansas Scheduler***, and users of the Woodruff irrigation charts.

Using the information on yield increase, % of users, and amount of irrigated acres it is estimated that the Woodruff irrigation website has increase the gross profits of Missouri irrigators by $54M since its inception in 2001. This is based on increased gross profits of $30M, $7M, and $17M for corn, cotton, and soybean, respectively.

Figures 6a,b,c. Irrigated yields of corn (6a), cotton (6b), and soybean (6c) for non-schedulers (None), users of Arkansas Scheduler (A.S.), users of Woodruff charts (Woody) for period 2001-2008.

Abstract

The optimum (profit maximizing) level of irrigation water use is usually less than the yield maximizing level, particularly when water has an associated opportunity cost. However, the amount of analysis required to implement a profit maximizing strategy is usually too time consuming to be practical for most farmers. Furthermore the practical operational constraints imposed on typical irrigation practices are usually too complicated to be fully encapsulated in software.

Oregon State University and the NRCS have cooperatively developed a web-based, user-directed application for optimum irrigation management. This system has already completed two years of field trails and has a demonstrated capacity for delivering conventional irrigation schedules. The system is now entering a second phase of development where we are adding new analytical tools that enable easy generation of optimum irrigation schedules. This system, known as Irrigation Management Online (IMO), explicitly analyzes irrigation efficiency and yield reductions for deficit irrigation, performs simultaneous, conjunctive scheduling for all fields in the farm that share a limited water supply, and employs both ET and soil moisture measurements in a Bayesian decision analysis to enhance the accuracy of the irrigation schedules. To mitigate the complexities of irrigation constraints the system has been designed so that the user is an integral part of the irrigation optimization procedure.

Relevant theoretical background on irrigation optimization has have been articulated in papers by (English et al., 2002) and (English and Orlob, 1978). The system described herein is comprised of two key elements: (i) a general model of irrigation system performance that analyzes the ultimate disposition of applied water, the spatial distribution of water, and corresponding yield responses to applied water; (ii) a web based advisory program for optimal irrigation scheduling that analyzes farm water demands in individual fields and aggregate farm water demand, allocates farm water supply according to the management rules stipulated by the user, and facilitates the development of optimum irrigation schedules. These two elements are described in greater detail below.

The Irrigation Efficiency Model (IEM)

The Irrigation Efficiency Model was initially designed to model the relationship between sprinkler irrigation intensity, water losses and crop water use. IEM was originally developed by Oregon State University and the New Zealand Ministry of Agriculture and Fisheries (English, 1992), then further developed and refined with funding from a USDA National Research Initiative grant (Isbell, 2005). The model is implemented in C# and uses a variant of the MODCOM simulation framework (Hillyer, 2003). The implementation is modular and has been designed with the anticipation of future extensions and modifications. Complete details of IEM's functions are described by (Isbell, 2005) and are also available online at http://oiso.bioe.orst.edu. What follows is a brief description of the four key features of IEM.

Calculated Efficiency. IEM functions as a soil water balance model, tracking irrigation and precipitation inputs, estimating potential crop ET, adjusting the potential ET to account for low soil moisture or wet surface conditions, and partitioning ET into its component parts of evaporation and transpiration using the algorithms outlined in FAO 56 (Allen et al., 1998). A system diagram of the water balance is shown in Figure 1. When soil moisture is depleted to a user-specified level of allowable depletion, the model calculates the gross irrigation requirement, expressed as the amount of irrigation required to replenish soil moisture to a user specified refill level. Calculations of gross irrigation requirements are based on net irrigation requirement and an assumed application efficiency provided by the user. Subsequently, when an irrigation event occurs, IEM simulates *actual* application efficiencies by modeling the principal determinants of irrigation losses, spatial

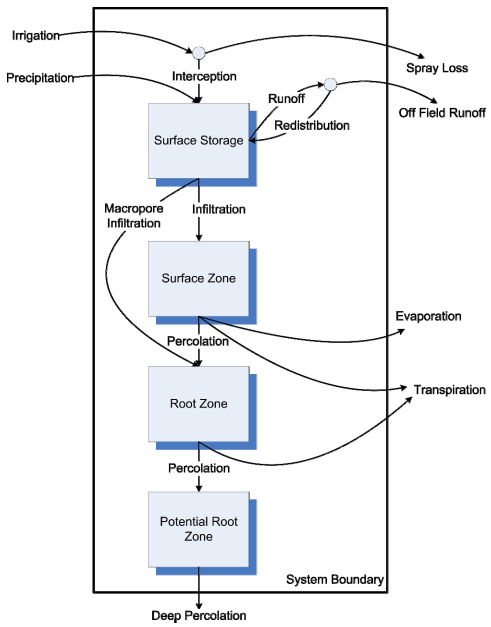

Figure 1. IEM System Diagram

variability of soil characteristics, irrigation timing and adequacy, patterns of applied water, wind effects on spray losses, wind distortions of sprinkler patterns, variability of surface infiltration rates, and surface water accumulations and associated redistribution. By simulating these factors the model analyzes the disposition of applied water in terms of evaporative losses, deep percolation, and runoff in addition to water stored in the crop root zone.

Spatial Variability. All irrigation systems are, to some degree, non uniform in their application of water. Furthermore, soil physical properties vary throughout a field. These two sources of non-uniformity combine to produce varying levels of available water in the field. It has also been demonstrated (Isbell, 2005) that the statistical distribution of cumulative crop ET will change shape with varying levels of irrigation intensity. Given such progressive distortions of ET patterns (and therefore yield) simulation of spatial variability will be of central importance in estimating the statistical characteristics of yield predictions. IEM attempts to quantify this variability through a Monte Carlo approach. The water balance model described above is replicated with varying soil physical properties. During any irrigation event each replicated water balance receives a different depth of applied water based on the uniformity characteristics of the irrigation system. Figure 2 shows the simulated distributions of crop ET from a field irrigated at 60%, 80%, and 100% of potential ET. By using this method IEM is able to simulate the distribution of crop ET without assuming *a priori* the distribution of available water. This method does, however, require that we be able to quantify the magnitude of spatial variable physical properties. At present this issue is left to the user's judgment, although default values are provided.

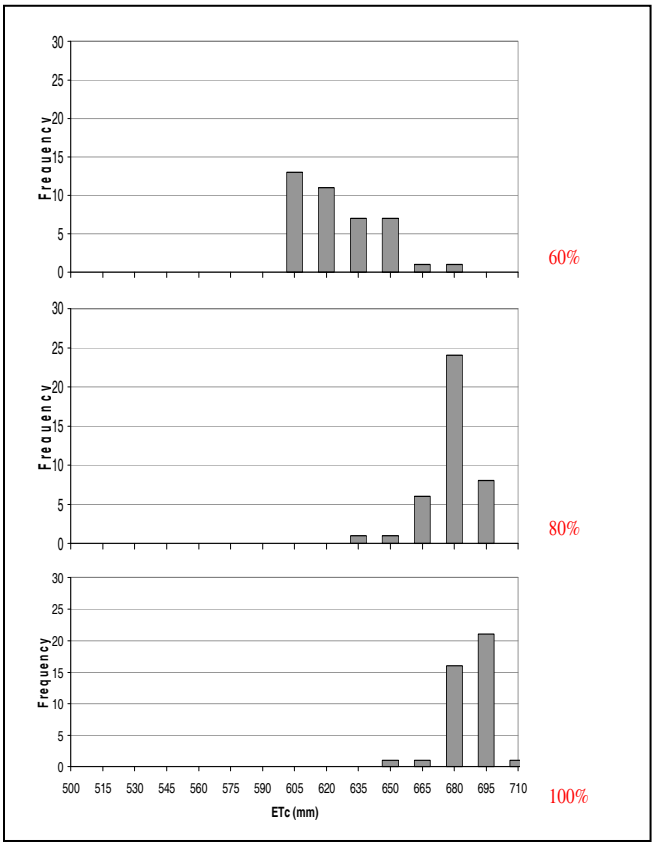

Figure 2. Histograms of Cumulative Crop ET at varying levels of Irrigation Intensity

Yield Modeling. Currently IEM uses the procedure described in FAO Irrigation and Drainage Paper No. 33 to estimate yield reduction from under irrigation. Also, a model described by (Solomon, 1985) is used to estimate yield reductions associated with over irrigation. Though FAO 33 is a widely used model, the authors experience and the experience of many others with the use of this model under ordinary field

conditions has been unsatisfactory. During the last few years, a team of climate, crop, soil, irrigation, and water scientists from various countries have been working under the auspices of FAO to develop a new crop-water production model to replace the FAO 33 model. The new FAO model, known as "AquaCrop, is a simple, accurate, robust, menu-driven and user-friendly program that is designed for a wide range of users. The model is being calibrated for a variety of crops based on experiments conducted in a number of countries (Raes et al., 2006). We intend to integrate the AquaCrop model into IEM once it has been calibrated for a sufficient number of crops.

Combining Soil Moisture Estimates. Figure 3 shows a histogram of measured 'field capacities' in a small area (one acre) of a silt loam soil that illustrates the innate variability of soil water holding characteristics (Isbell, 2005). This variability has two important implications. First, since net irrigation requirements are commonly based in part on field capacity, the variability indicated by Figure 3 implies that net irrigation requirements depend upon which part of a heterogeneous field is considered the 'control' sector for scheduling purposes. Secondly, since it is common practice to rely on soil moisture measurements to determine 'true' soil moisture, the variability shown in Figure 3 implies that such soil moisture measurements must be treated as highly uncertain. These two conclusions are known to experienced irrigation managers, and they illustrate the rationale for simulating spatial variability.

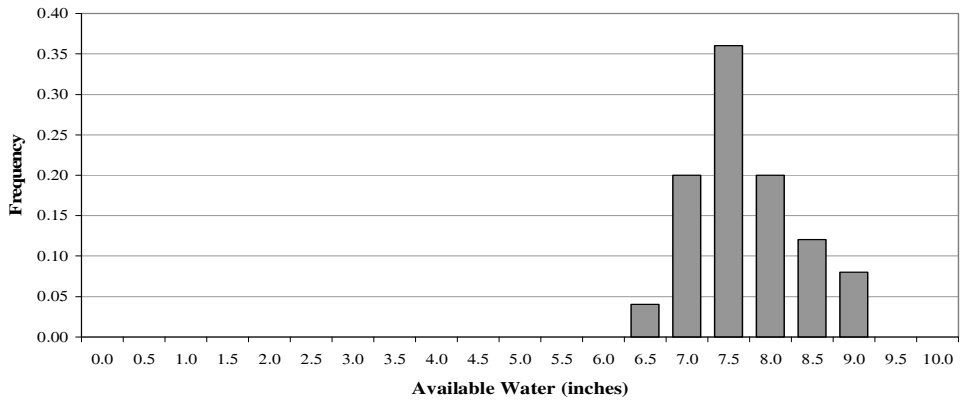

Figure 3. Measured 'field capacities' in a relatively homogeneous silt loam soil

Reference ET, even under the best conditions, is still an estimate and will have some associated error. It is clear that both estimated ET and measured soil moisture are subject to error, but at the same time both embody valuable information. Rather than arbitrarily dismissing one in favor of the other, a more rational approach is to estimate the uncertainty of each, and then derive a hybrid estimate that weights each source of data according to its estimated uncertainty. Bayes Rule provides a way of integrating the information about each estimator to derive an a-posteriori estimator of depletion that is both more precise (reduced variance) and more accurate. The analysis involves using the statistical distribution of one estimator (or source of information; e.g., cumulative ET) as a prior probability distribution for depletion, and then using the other estimator (e.g., as obtained from soil moisture measurements) to update that distribution, creating an a-posteriori distribution of the estimated depletion. Space

does not permit duplicating the complete details of this analysis, the reader is referred to (English et al, 2008) for more complete details of the procedure.

Irrigation Management Online

A web based irrigation advisory service known as Irrigation Management Online (IMO)[1] has been cooperatively developed by Oregon State University and the National Resource Conservation Service. IMO is currently undergoing its third year of field trails and has been successfully used in Oregon, Washington, and Idaho. The service has a demonstrated ability to provide conventional scientific irrigation scheduling advice. Development of IMO has proceeded in two phases. The first phase, now largely complete, involved development of a tool that enables farm managers to actively search for irrigation strategies that minimize water use and allow management of irrigation when water supplies are limited. The second phase, now underway, involves development of user interface tools that allow farm managers to actively search for optimal irrigation strategies and analyze their potential impact on yields and net economic returns. A complete description of all of IMO's features is not possible with the space restrictions here. Instead we will describe some of the features relevant to optimum irrigation scheduling and some of the features that make IMO different from other irrigation scheduling applications.

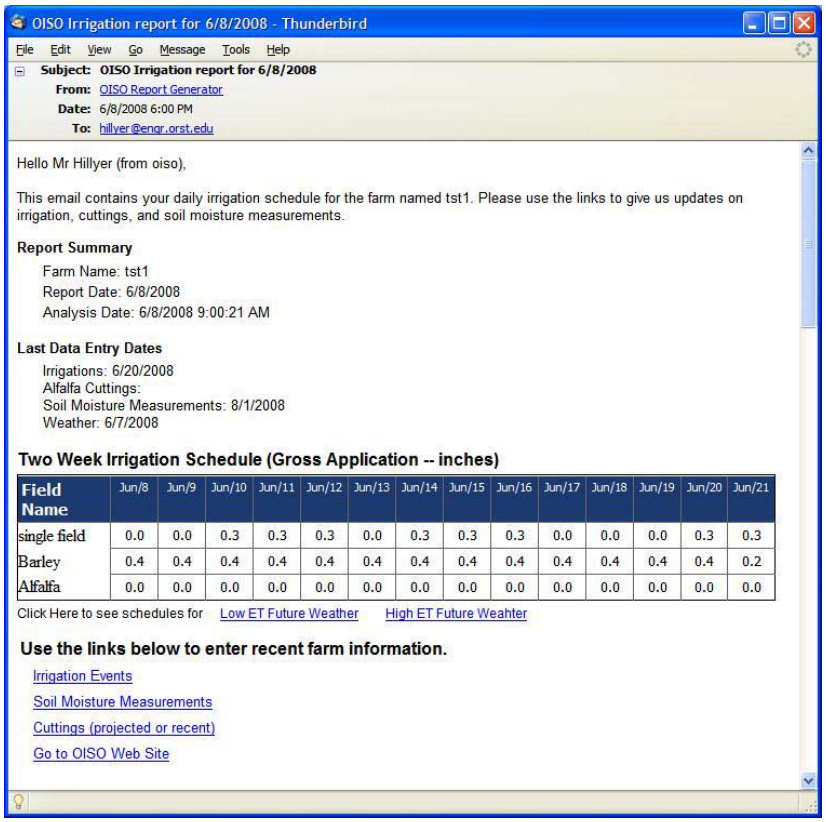

Figure 4. Sample Email

[1] IMO was formerly known as Oregon Irrigation Scheduling Online (OISO) and some of the figures in this document retain references to that name.

IMO was designed with the KISS principle in mind. Collecting information from the user is usually one of the more complicated and/or frustrating steps in using any application. To address this problem all setup information is collected through a series of wizards. These wizards provide explanations for each piece of information collected and, wherever possible, reduce the amount of information required for setup. The wizards both reduce the effort required to setup a farm and inform the user about the terminology and concepts used by IMO.

A second simplifying feature of IMO is automatic weather downloads. Part of the setup process involves choosing a site and source of weather data. Once this choice has been made IMO will automatically download updated weather information and use it to generate new irrigation schedules. The system is currently configured to use weather data from either the USBR AGRIMET weather network or IFPNet (Dalles, OR). We are actively working to extend the system to connect to the CIMIS network in California for a pilot program there.

Once a farm has been setup the user is kept informed via daily emails from the website. A sample of one such email is shown in Figure 4. These emails include inquiries about recent irrigation operations and links that bring the user back to the data input pages of the website. These emails serve as a recurring reminder to the farm manager to evaluate their water use and plan for short term supply limitations.

One feature that distinguishes IMO from other systems is forecasting of crop water demand that extends from the current date to the projected end of season. An example forecast for a single field is shown in Figure 5. This graph shows the projected soil moisture, soil moisture measurements (black squares), precipitation, past irrigations, and proposed future irrigations that are recommended by IEM.

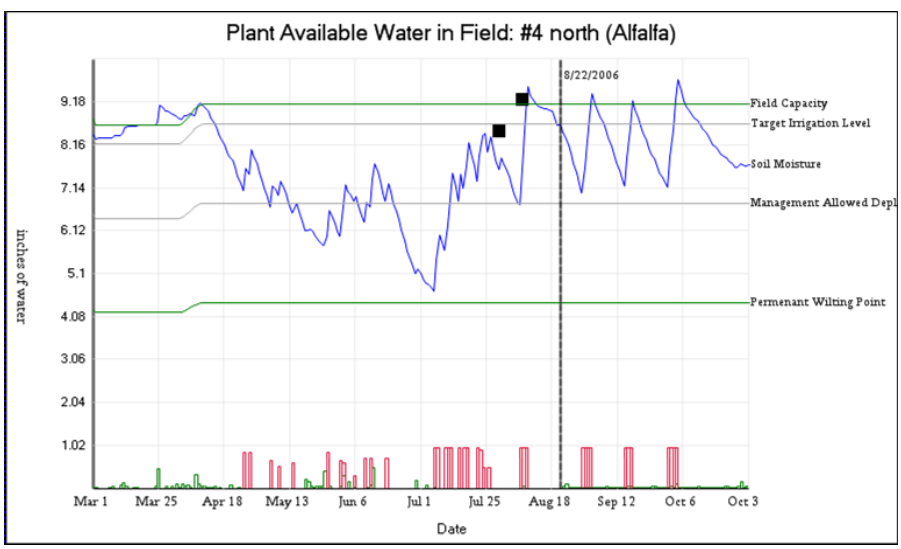

Figure 5. Sample Soil Moisture plot produced by IMO

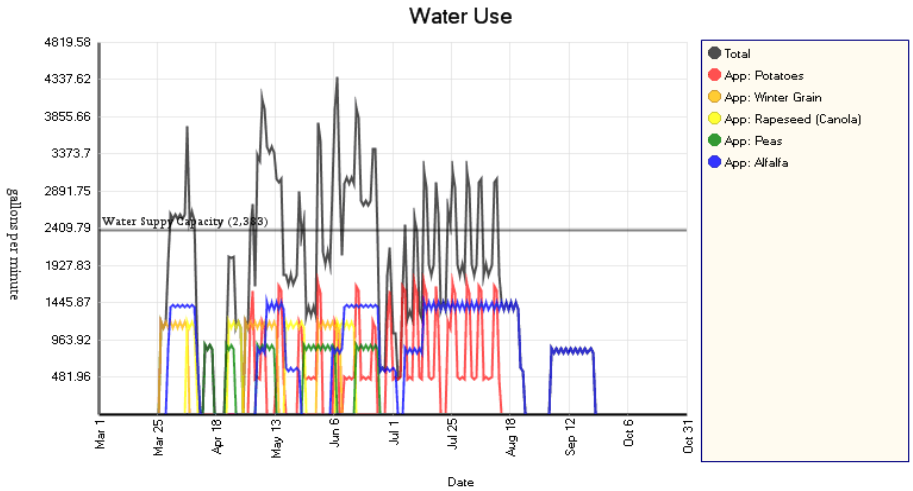

Figure 6. Full Season water use plot produced by IMO

Managing Long Term Constraints. An example seasonal water use plan from a cooperating farm is shown in Figure 6. The different coded lines show projected irrigation dates and delivery rates (gallons per minute) for irrigation of five crops on seven fields of various sizes with a variety of irrigation systems. The resulting aggregate farm water demand, summed for all fields, is also shown (upper line). Total farm water delivery capacity, about 2400 gpm, is shown as a horizontal line. As the graph indicates, the water demand would exceed supply for much of the season, particularly in May and June, so the initial water use plan shown here is not feasible. Several changes might then be proposed to deal with this water shortage; (i) a small field of alfalfa in its last year of production could be fallowed, (ii) a second field of alfalfa could be deficit irrigated, (iii) alfalfa cutting dates could be shifted slightly, and (iv) a field of winter wheat could be deficit irrigated.

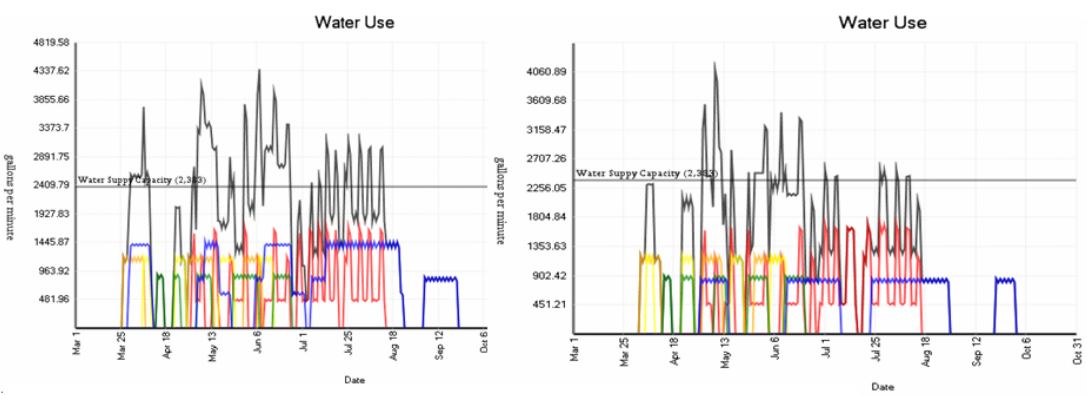

Figure 7. Original (left) and revised (right) water use plots

Figure 7 is a comparison of the initial water demand graph (left) with the resulting revised graph (right) produced after inputting the proposed changes into IMO. The proposed changes would substantially reduce overall demand, and shorten most periods of excess demand, making the water shortages more manageable. The irrigation schedule might then be adjusted on a day-by-day basis, shifting irrigations

from high demand days to days when capacity is under-utilized. These day-by-day adjustments are performed using an interactive two week schedule described in the next section.

Another long term management feature is the ability to use multiple weather profiles for estimating water use. When a farm is set up IMO uses the selected weather station to generate a historical weather data set that represents high, average, and low ET years. Then, whenever forecasts are produced, IMO uses IEM to generate three different forecasts corresponding to the high, average, and low ET weather profiles. This feature allows farm managers to see a range of water use scenarios and plan accordingly. Figure 8 shows three soil moisture graphs that show the irrigation forecast for a field of Alfalfa based on the historical weather downloaded from the AGRIMET station in Powel Butte, OR.

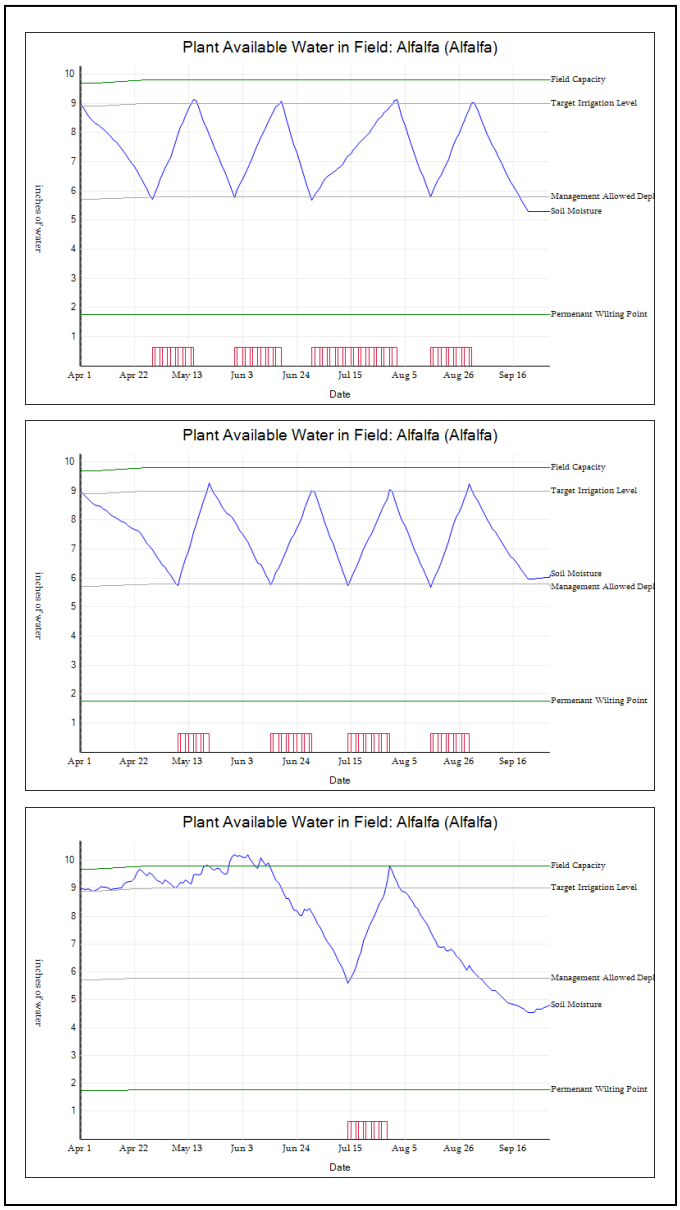

Figure 8. Forcast Irrigation schedules for high (top), average (middle), and low (bottom) ET estimates.

Managing Short Term Constraints. Figure 9 shows a sample two week irrigation schedule generated by IMO. The bottom row of the table indicates that the irrigation demand is exceeding the supply capacity of the water management unit[2]. The user can edit this schedule by moving some events around, deleting some of them, or adding new ones. All of this data entry is performed via drag-and-drop style interaction with the two week schedule. After sufficient manipulation the schedule will appear as shown in Figure 10. Note that now the bottom row indicates (via a change in color) that the supply constraints are not being

[2] Color is used on the website to emphasize the excess condition.

exceeded. After performing these manipulations IMO will re-evaluate the soil moisture calculations for each field and present the user with revised estimates of soil moisture conditions, water use, and predicted yields.

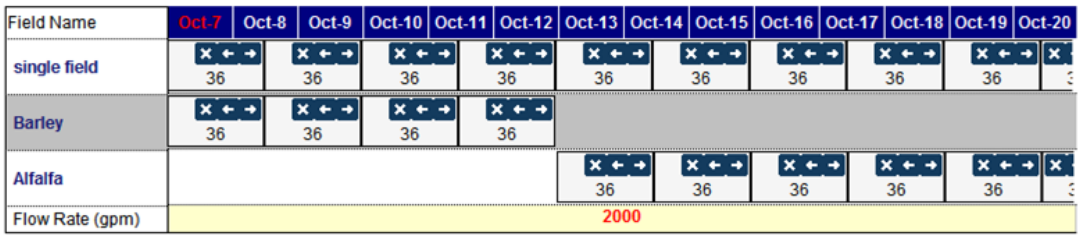

Figure 9. Editable Calendar Schedule screenshot

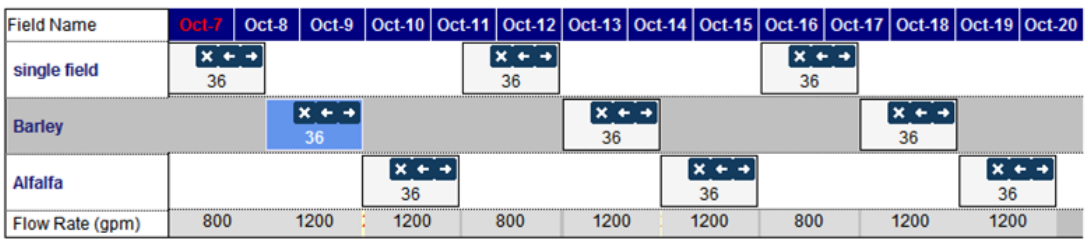

Figure 10. Editable Calendar Schedule screenshot (after editing)

Economic Analysis. We have recently added an economic analysis component to IMO. Each farm manager has different preferences regarding how they track costs relating to irrigation. The IMO website cannot possibly accommodate every person's preferences in this regard. The economics package is implemented as an Excel spreadsheet that downloads information from the IMO website. Excel allows the user the flexibility to setup and enumerate their costs in a way that is convenient to them and it eliminates the security concerns associated with storing sensitive financial information on a web server. Once the initial setup is complete (performed via VBA macros) a Web Service is used by the spreadsheet to download updated information on number of irrigations, total water use, and yield estimates projected to the end of the season. This update procedure can be performed by the user each time they want to re-evaluate their irrigation operations. The spreadsheet and Web Service are currently in a beta form and will be field tested during the coming year.

Conclusion

IEM is a robust numerical model that estimates efficiency of irrigation by modeling the disposition of applied water. This model uses well established algorithms and procedures for estimating consumptive use of water, stress related reduction in consumptive use, and for yield estimation. Furthermore, the model explicitly accounts for spatial variability of non-uniform irrigation and soil physical properties. The model is also able to combine ET based estimates and measurement based estimates of soil moisture to provide more accurate results.

IMO is a web-based advisory service for irrigation management. The website provides farm managers with a set of tools that enables them to actively search for optimum irrigation strategies. The system is being used in a pilot program for implementation of conventional irrigation scheduling and optimum irrigation strategies when water supplies are limited or expensive. Originally developed for use in Oregon, IMO is now being field tested inWashington, Idaho, and California.

ABSTRACT

The crop coefficient is the ratio of actual ET to reference ET and is heavily controlled by the amount of vegetation present to transpire water. This relationship can be used to estimate values for the crop coefficient as functions of the amount of ground covered by vegetation. A method established in the FAO-56 publication is expanded in this paper to estimate the crop coefficient from the fraction of ground cover and height of vegetation. In addition, when estimates of average background soil evaporation are made, then the 'mean' or single crop coefficient can be estimated. Estimates from the method are compared with measured crop coefficients reported for a number of vegetable crops during the crop development periods. Results are promising.

INTRODUCTION

The two-step crop coefficient (K_c) x reference evapotranspiration (ET_{ref}) method has been a successful and dependable means to estimate evapotranspiration (*ET*) and crop water requirements. The method utilizes weather data to estimate *ET* for a reference condition and multiplies that estimate by a crop coefficient that represents the relative rate of *ET* from a specific crop and condition to that of the reference. The reference condition is generally *ET* from a clipped, cool season, well-watered grass (ET_o) or from a taller full-cover alfalfa crop (ET_r). The calculation of *ET* from these surfaces has been standardized by FAO (Allen et al., 1998, 2006) and the American Society of Civil Engineers (ASCE-EWRI 2005).

The K_c ET_{ref} approach provides a simple, convenient and reproduceable way to estimate *ET* from a variety of crops and climatic conditions (Doorenbos and Pruitt, 1977, Wright 1982, Snyder et al., 1989a,b, Allen et al., 1998). Crop coefficient 'curves' have been developed and reported for a wide range of agricultural crops (Allen et al., 1998, 2007). The K_c is regarded as generally transferable among regions and climates under the assumption that the ET_{ref} accounts for nearly all variation

caused by weather and climate and the K_c represents the relative fraction of ET_{ref} that is governed by amount, type and condition of vegetation. These characteristics are more consistent for agricultural vegetation than, for example, natural vegetation, and thus the K_c values are more consistent and accuracy of the K_c ET_{ref} approach is usually highest for agricultural applications. Therefore, tabular values for K_c are often successfully used over a wide range of agricultural applications. The developed K_c curves or values represent the ratios of ET_c to ET_{ref} during various growth stages.

Conversely, the vegetation amount, height and density of many systems including natural vegetation, orchards, and residential and rural landscapes is highly variable, even during the middle part of the growing season, so that substantial uncertainties exist with tabularized values for these systems. Under these conditions, K_c values can be more accurately estimated by basing the estimates on the fraction of ground covered or shaded by vegetation, the height of the vegetation and the amount of stomatal regulation under moist soil conditions. The value for K_c for conditions of low soil water availability is generally determined by reducing the K_c estimate via a stress coefficient K_s using a daily soil water balance model.

This paper describes a relatively simple approach for estimating the K_c value based on a physical description of the vegetation. The method traces to the FAO-56 publication (Allen et al., 1998) with extensions made to account for background evaporation from soil and better seamlessness of the procedure. The procedure is intended for estimating both basal and average K_c for natural vegetation, orchards and landscape systems for different portions of the growing season based on amount of vegetation present and background evaporation from soil.

BACKGROUND

Basal Crop Coefficient. Basal crop coefficients, K_{cb}, represent primarily the transpiration component of *ET* and a small evaporation component from soil that is visibly dry at the surface. The use of K_{cb} over long periods requires adjustment for evaporation from wet soil during periods following rain or irrigation. The total crop coefficient, K_c is computed from K_{cb} as:

$$K_c = K_s K_{cb} + K_e \quad (1)$$

where K_s is a dimensionless 'stress' coefficient whose value is dependent on available soil water and K_e is a coefficient that adjusts for increased evaporation from wet soil following rain or irrigation. The procedure in eq. 1 has been referred to as the 'dual' K_c approach (Allen et al., 1998, 2005). The value for K_s is 1 unless available soil water limits transpiration, in which case it has a value less than 1. The values for K_e create "spikes" in the K_c curve as shown in fig. 1. Estimation of K_e for bare soil conditions is described in Wright (1982) and Allen et al., (1998, 2005).

Single Crop Coefficients. In basin-wide water balance studies or irrigation systems planning, use of 'single' crop coefficients that imbed averaged effects of evaporation from wet soil are more useful and convenient than computing a daily K_c based on K_{cb}, K_s and K_e. The single crop curve, K_{cm}, shown in fig. 1 lies above the basal curve by an amount that depends on the frequency of soil wetting. The K_{cm} is in essence a 'time-averaged' K_c as opposed to the 'dual K_c'. When a single crop coefficient is used, usually no additional adjustment is made for the effects of surface soil wetness. Adjustments are made for the effects of limited soil water as:

$$K_c = K_s K_{cm} \tag{2}$$

where K_s is calculated from Allen et al., (1998, 2005). Values for K_{cm} during partial crop cover depend not only on the amount and type of vegetation cover, but on frequency of precipitation and irrigation and whether irrigation wets all or part of the soil surface. K_{cm} curves can be generated from K_{cb} curves for known or simulated precipitation or irrigation frequencies following the dual K_{cb} approach and daily timestep.

Segmented Crop Coefficient Cuves. Figure 1 shows realistic K_c curves that have smooth, continuous transitions during the growing season. K_c curves have often been constructed, for simplicity in construction and estimation, using the FAO segmented approach shown in fig. 2 where the continuous seasonal curve is broken into four linear segments representing the initial, development, midseason and late season periods (Doorenbos and Pruitt, 1977, Allen et al., 1998, 2005). The appeal of the FAO style curve is that only three key values for K_c need to be determined: $K_{c\ ini}$ during the initial period, $K_{c\ mid}$ during the midseason period, and $K_{c\ end}$ at the end if the late season period. Values for $K_{c\ ini}$, $K_{c\ mid}$ and $K_{c\ end}$ are listed in FAO-56 (Allen et al. 1998) and Allen et al., (2007). The FAO style curve can be applied equally well to basal and single K_c applications in both dual and single mode. Examples of successful application of the FAO style K_{cb} curves in dual model include Hunsaker (1999), Tolk and Howell (2001), de Medeiros (2001), Hunsaker et al. (2002, 2003, 2005), Howell et al. (2004), Mutziger et al. (2005) and Allen et al. (2005a, 2007).

The procedures for constructing K_c curves presented in the following apply to both grass and alfalfa reference bases. Therefore, distinction is made between those K_c that apply to grass reference and those that apply to the alfalfa reference by denoting the former as K_{co} and the latter as K_{cr}. The two types of K_c's should not be interchanged, since those for the grass reference basis tend to be 20 to 30% larger than those for the alfalfa reference basis because ET_r tends to be 20 to 30% stronger than ET_r.

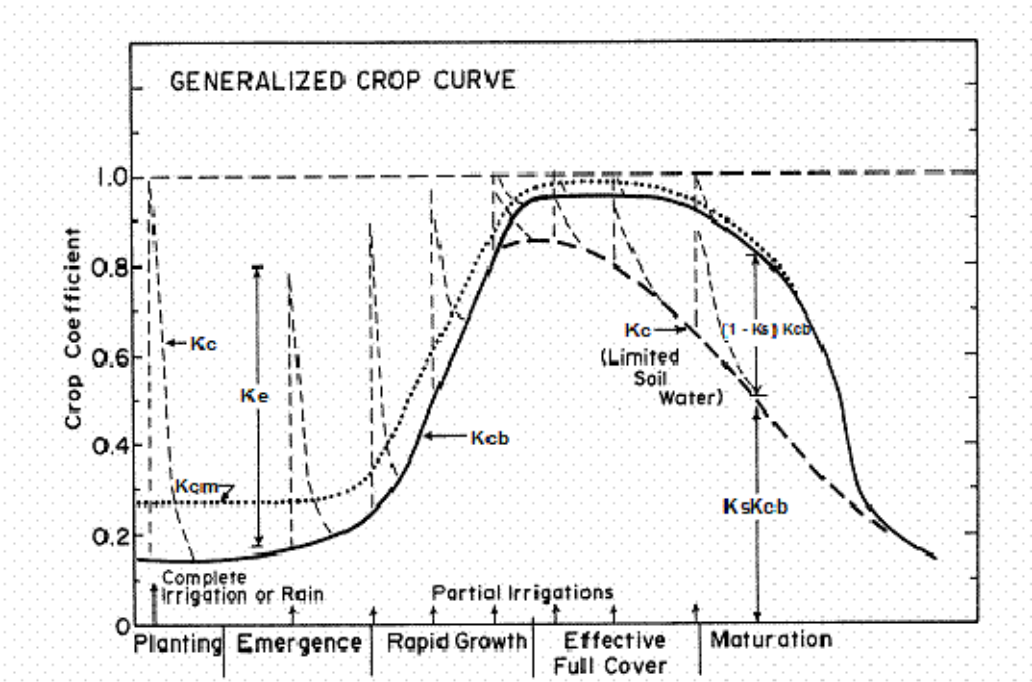

Fig. 1. Generalized crop coefficient curves over a growing season showing the effects of increasing K_c during midseason caused by plant development, wet soil surface and (long-dashed curve) limited available soil water (after Wright 1982; Jensen et al. 1990).

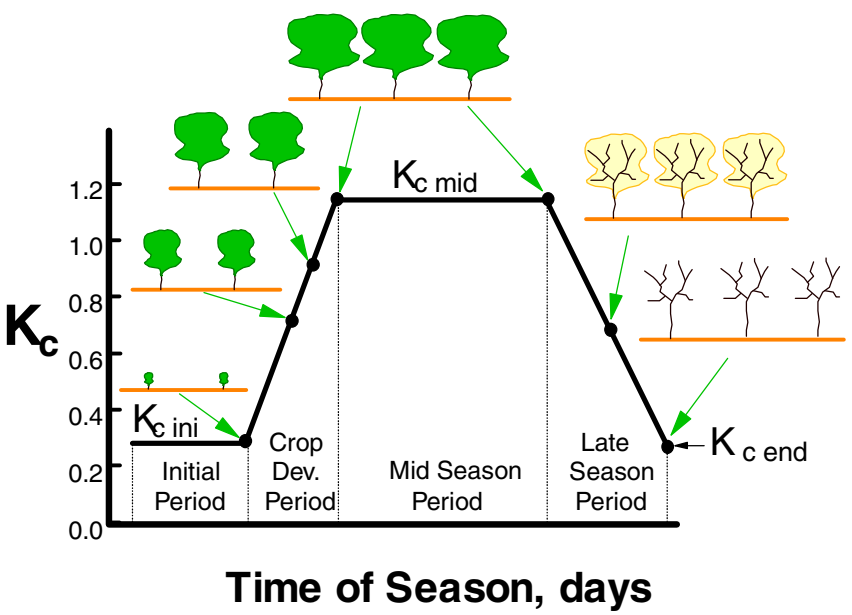

Fig. 2. FAO segmented crop coefficient curve and four growing stages (after Allen et al. 1998).

Adjusting K_{co} for Climate. The ratio of ET_c to grass ET_o for many crops increases as wind speed increases and as minimum daily relative humidity decreases (Doorenbos and Pruitt, 1977). This is due primarily to differences in roughness between taller agricultural crops and the clipped grass reference. The result is a higher K_{co} value caused by increased roughness and perhaps leaf area making the aerodynamic aspects of vapor transport more important and significant. The adjustment to K_{co} is generally required only for coefficients based on the grass ET_o reference. No adjustment for climate is necessary for coefficients based on the alfalfa ET_r reference because of the greater roughness of alfalfa that is more similar to most crops (Wright, 1982, Pereira et al. 1999). The FAO procedure for adjusting K_{co} values uses mean daily minimum relative humidity and wind speed. For climates with RH_{min} greater than or less than 45% or with mean wind speeds at 2 m over grass (u_2) that are more than or less than 2.0 m s^{-1}, the standardized values for all $K_{co\ mid}$ and $K_{cbo\ mid}$ from FAO-56 and for $K_{co\ end}$ and $K_{cbo\ end} > 0.4$ are adjusted as:

$$K_{co\ mid/end} = K_{co\ mid/end\ (table)} + \left[0.04\left(u_2 - 2\right) - 0.004\left(RH_{\min} - 45\right)\right]\left(\frac{h}{3}\right)^{0.3} \qquad (3)$$

where $K_{co\ mid/end(table)}$ is the value for $K_{co\ mid}$, $K_{cbo\ mid}$, $K_{co\ end}$ or $K_{cbo\ end}$ for the standardized climate and h is the mean maximum plant height, m, during the midseason period, or full cover period. Eq. 3 is valid for h to 20 m (Allen et al., 1998, 2005). The values for RH_{min} and u_2 need only be approximate values averaged over the midseason and late season periods.

ESTIMATING K_C CURVES FROM FRACTION OF GROUND COVER

Natural vegetation systems tend to have extensive variability in vegetation density, plant height, and water availability, both within a single expanse and between expanses of the same vegetation. Therefore, the distribution of K_c and thus ET populations can be broad, as shown in fig. 3, where a frequency distribution of ET for the month of June and calendar year for cottonwood and salt cedar populations along a 100 km stretch of the Middle Rio Grande valley is shown as derived from satellite-based energy balance (Allen et al. 2007b). ET from salt cedar showed larger variance due to its tendency to grow across a broad range of water availability (water table depth), soil types and salinity conditions, whereas cottonwoods, which exhibited a smaller variance in the population of ET, are typically found close to stream channels and consistent water supply. Wide variation was also noted for tree population density, which added to variance in the populations of ET.

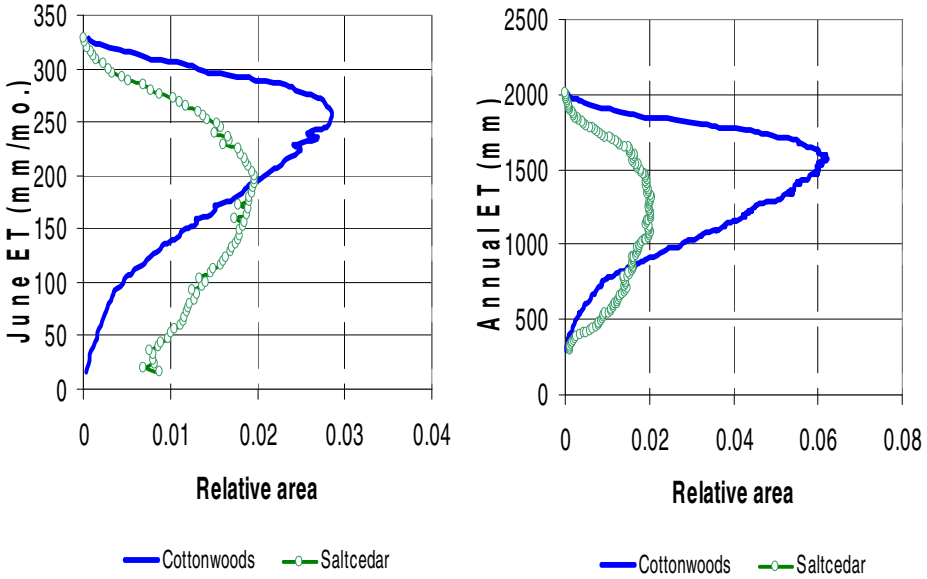

Fig. 3. Frequency distributions of ET from 6,000 ha of cottonwood and salt cedar along the Middle Rio Grande in New Mexico during June and all of 2002.

For expanses of vegetation large enough that an equilibrium boundary is established so that general one-dimensional equations such as the Penman-Monteith apply, a maximum upper limit on *ET* is established due to the law of conservation of energy. Therefore, for large expanses of vegetation (larger than about 500 to 2000 m^2) , the K_c development process has upper limits for K_{cr} of about 1.1 for the alfalfa reference and upper limits for K_{co} of about 1.3 for the grass reference. K_c's for smaller expanses (< 500 m^2) should also adhere to these limits when the vegetation height and leaf area is less than or equal to that of surrounding vegetation and soil water availability is similar. Only under conditions of "clothesline effects" (where vegetation height exceeds that of the surroundings) or "oasis effects" (where vegetation has higher soil water availability than the surroundings) will peak K_c's exceed the limits stated. The user should exercise caution when extrapolating ET measurements from small vegetation stands or plots to large stands or regions, as overestimation of ET may occur.

The upper, energy-constrained limit on K_c can be used to advantage in estimating K_c for vegetation for which the K_c is unknown, by using it to set the upper limit for vegetation having full or nearly full ground cover. The value for K_c reduces when plant density or leaf area fall below full ground cover which, in some cases has been defined as when leaf area index, *LAI,* < 3. Because the K_c tends to decrease in proportion to the amount of vegetation, the basal K_{cb}, which correlates with amount of vegetation because it represents mostly transpiration, can be expressed in terms of a density coefficient, K_d, where:

$$K_{cb} = K_{c\min} + K_d \left(K_{cb\,full} - K_{c\min}\right) \quad (4)$$

where K_{cb} is the approximation for K_{cb} for conditions represented by the density coefficient, K_d, $K_{cb\ full}$ is the estimated basal K_c during peak plant growth for conditions having nearly full ground cover (or $LAI > 3$), and $K_{c\ min}$ is the minimum basal K_c for bare soil ($K_{cb\,min} \sim 0.15$ under typical agricultural conditions and $K_{cb\,min} \sim 0.0$ to 0.15 for native vegetation, depending on rainfall frequency). The density coefficient K_d can be estimated as a function of measured or estimated leaf area index LAI or as a function of fraction of ground covered by vegetation. The density coefficient is defined in eq. 7.

For tree crops having grass or other ground cover, eq. 4 can take the form:

$$K_{cb} = K_{cb\,cover} + K_d \left(\max\left[K_{cb\,full} - K_{cb\,cover}, \frac{K_{cb\,full} - K_{cb\,cover}}{2} \right] \right) \quad (5)$$

where $K_{cb\ cover}$ is the K_{cb} of the ground cover in the absence of tree foliage. The second term of the *max* function reduces the estimate for $K_{cb\,mid}$ by half the difference between $K_{cb\ full}$ and $K_{cb\ cover}$ when this difference is negative. This accounts for impacts of shading by vegetation having K_{cb} that is lower than that of the surface cover due to differences in stomatal conductance. Eq. 4 and 5 can be applied to estimate K_{cb} during any period, including the midseason period. The value for K_{cb} from Eq. 4 and 5 should be applied as a basal coefficient using the dual $K_{cb} + K_e$ method, since the actual K_c may increase to 1.0 for ET_r or 1.2 for ET_o following precipitation even if the estimated K_{cb} is small, due to surface evaporation from among sparse vegetation. In addition, K_c should be reduced via K_s when soil water is low.

The approach of Eq. 4 and 5 can be similarly applied to estimate a single K_{cm} coefficieint for any period having less than full vegetative cover by accounting for the effect of evaporation from predominately exposed areas of soil among the vegetation, much the same as is done in the dual $K_{cb} + K_e$ approach:

$$K_{cm} = K_{soil} + K_d \left(\max\left[K_{c\,full} - K_{soil}, \frac{K_{c\,full} - K_{soil}}{2} \right] \right) \quad (6)$$

where K_{soil} represents the average K_c from the non-vegetated (exposed) portion of the surface and reflects the impact of wetting frequency, soil type and relative ET rate (i.e., ET_o) during the same period as K_d and $K_{c\ full}$. The K_{cm} represents an average K_c value that considers the mean impact of evaporation from soil, as does $K_{c\ full}$, representing K_c.from a fully covered soil with some background evaporation. K_{cm} can be used to represent the midseason or other period as defined by K_d, K_{cm} and $K_{c\ full}$.

For large stand size (greater than about 500 m^2), $K_{cb\ full}$ for use with ET_o can be approximated as a function of mean plant height and adjusted for climate following Allen et al. (1998):

$$(for\ ET_o)\ .....\ K_{\text{cb full}} = F_r \left(\min\left(1.0 + 0.1h,\ 1.20\right) + \left[0.04(u_2 - 2) - 0.004(\text{RH}_{\min} - 45)\right]\left(\frac{h}{3}\right)^{0.3} \right) \quad (7a)$$

For use with alfalfa reference ET_r, $K_{cb\ full}$ can be estimated as:

$$(for\ ET_r)\ .....\ K_{\text{cb full}} = F_r\ \left(\min\left(0.8 + 0.1h,\ 1.0\right)\right) \quad (7b)$$

where h is mean maximum plant height in m, u_2 is the mean value for wind speed at 2 m height during the mid-season in m s^{-1}, and RH_{min} is the mean value for minimum daily relative humidity during the mid-season in %. The climatic correction is not required for $K_{\text{cb full}}$ when used to derive the K_{cb} for ET_r because of the aerodynamic and canopy characteristics of the alfalfa reference crop. $K_{c\ full}$ can generally be estimated as equivalent to $K_{cb\ full}$ or equal to $K_{cb\ full}$ + 0.05 following Wright (1982) and Allen et al., (1998).

The value for $K_{c\ full}$ represents a general upper limit on $K_{cb\ mid}$ for tall vegetation having full ground cover and LAI > 3 under full water supply. Eq. 7a and 7b produce general approximations for the increase in $K_{cb\ full}$ with plant height and climate. The estimate from eq. 7 may need adjustment downward if the vegetation exhibits more stomatal control on transpiration than is typical for agricultural crops, for example, for types of trees or natural vegetation.

Density Coefficient. The density coefficient describes the increase in K_c with increase in amount of vegetation. The shape of the K_d curve is curvilinear with LAI or fraction of ground cover because of effects of microadvection of convective and radiative energy from exposed soil and height of vegetation. Where *LAI* can be measured or approximated, K_d can be approximated under normal conditions using an exponential function by Allen et al. (1998):

$$K_d = \left(1 - e^{[-0.7\,LAI]}\right) \quad (8)$$

where *LAI* is defined as the area of leaves per area of ground surface averaged over a large area with units of $m^2\ m^{-2}$. Only one side of 'green,' healthy leaves that are active in vapor transfer is counted. The relationship in eq. 8 is similar to one used by Ritchie (1974).

Where estimates of the fraction of ground surface covered by vegetation, f_c, are available, the K_d is estimated similar to Allen et al. (1998) as:

$$K_{\mathrm{d}} = min\left(1, M_L\, f_{c\,eff}, f_{c\,eff}^{\left(\frac{1}{1+h}\right)}\right) \tag{9}$$

where $f_{c\,eff}$ is the effective fraction of ground covered or shaded by vegetation [0.01 - 1] near solar noon, M_L is a multiplier on $f_{c\,eff}$ describing the effect of canopy density on shading and on maximum relative ET per fraction of ground shaded [1.5 – 2.0], and h is the mean height of the vegetation in m. Estimation of $f_{c\,eff}$ was described in Allen et al. (1998). For canopies such as trees or randomly (nonrow) planted vegetation, $f_{c\,eff}$ can be estimated as:

$$f_{c\,eff} = \frac{f_c}{\sin(\beta)} \qquad \leq 1 \tag{10}$$

where β is the mean angle of the sun above the horizon during the period of maximum ET (generally between 11.00 and 15.00) and f_c is the fraction of surface covered by vegetation as observed from directly overhead. f_c is often determined from visual inspection. However, digital image analysis or other measurement means can be employed. Generally, $f_{c\,eff}$ can be calculated at solar noon (12.00), so that β can be calculated as:

$$\beta = \arcsin\left[\sin(\varphi)\sin(\delta) + \cos(\varphi)\cos(\delta)\right] \tag{11}$$

where parameters φ and δ are latitude ($-\pi/2 \leq \varphi \leq \pi/2$) and solar declination in radians. Allen et al. (1998) provided equations for estimating β for row crops as a function of row orientation. A schematic showing f_c, $f_{c\,eff}$ and β is shown in fig. 4.

Fig. 4. Schematic showing extent of f_c, $f_{c\,eff}$ and β for tree vegetation where f_c is the fraction of surface covered by vegetation as measured from directly overhead.

The M_L multiplier on $f_{c\,eff}$ in eq. 9 imposes an upper limit on the relative magnitude of transpiration per unit of ground area as represented by $f_{c\,eff}$ (Allen et al. 1998) and is expected to range from 1.5 to 2.0, depending on the canopy density and thickness. Parameter M_L is an attempt to simulate the physical limits imposed on water flux through the plant root, stem and leaf systems. The value for M_L can be modified to fit the specific vegetation.

Fig. 5 shows values for K_d over a range of $f_{c\,eff}$ and a range of h for M_L = 1.5 and for M_L = 2 when h = 5 m, showing the effect of h and M_L on the estimate. Only K_d for h greater than about 1 m is impacted by varying the value for M_L from 1.5 to 2.0. The estimates by eq. 9 closely reproduce individual functions previously suggested by Fereres (1981) for orchards (using M_L = 2.0) and Hernandez and Suarez (1988) for vegetables. The function by Fereres (1981) is the same as one recommended by Snyder and Eching (2005).

Eq. 9 suggests that as h increases, total leaf area and resulting net radiation capture will increase, thereby increasing K_c. In addition, as h increases, more opportunity for microadvection and radiation of heat from soil to canopy occurs and turbulent exchange within the canopy increases for the same amount of ground coverage. Both of these increases increase the relative magnitude of K_{cb} or K_c. Values for K_{cb} or K_c can be scaled from estimates by Eq. 6 or 7 in proportion to the health and leaf condition of the vegetation at termination and the length of the late season period (i.e., whether leaves senesce slowly or are killed by frost). The f_c parameter and h are probably the simplest indices to estimate in the field.

When the mean stomatal control by the vegetation is greater than that characteristic of agricultural vegetation, Allen et al. (1998) suggested that the estimate by Eq. 6 or 7 be reduced by about 10 or 20 percent for each doubling of leaf resistance above 100 s m^{-1}. A more specific reducer for effects of stomatal control was introduced by Allen et al. (1998) where a stomatal resistance factor F_r was developed based on the FAO Penman-Monteith equation assuming full cover conditions:

$$F_r \approx \frac{\Delta + \gamma(1 + 0.34u_2)}{\Delta + \gamma\left(1 + 0.34u_2 \frac{r_l}{100}\right)} \qquad (12)$$

where r_l is mean leaf resistance for the vegetation in question [s m^{-1}], Δ is the slope of the saturation vapor pressure vs. air temperature curve, kPa C^{-1}, and γ is the psychrometric constant, kPa C^{-1}. Factor F_r is multiplied against the estimate for $K_{cb\,full}$ in Eq. 7 to reduce its value. The standard value for F_r is 1.0, which is applicable to most agricultural crops, where r_l is approximately 100 s m^{-1}. Values for r_l for many agricultural and non-agricultural plants can be found in Körner *et al*. (1978) and Allen *et al*. (1996).

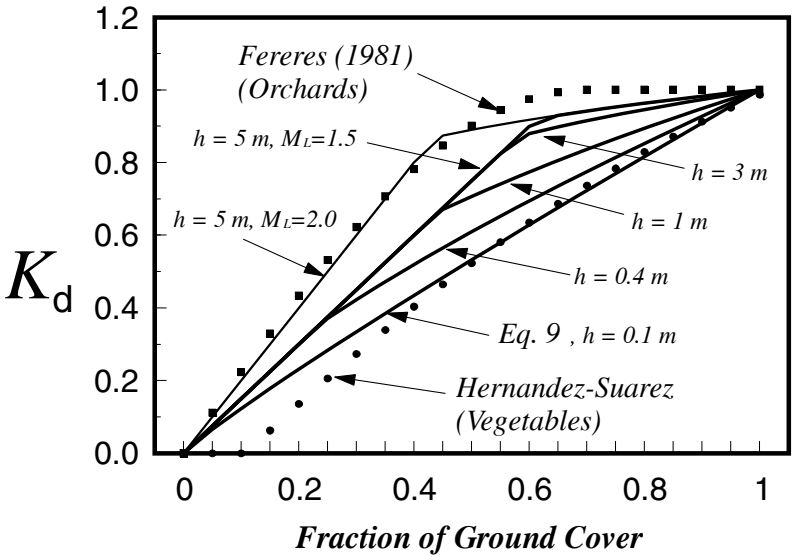

Fig. 5. Density coefficient, K_d, estimated from eq. 9 with M_L = 1.5 over a range of fraction of ground cover and various plant heights, and compared with estimates by Fereres (1981) for orchards and Hernandez-Suarez (1988) for vegetables.

COMPARISON OF K_C FROM EQ. 6 BASED ON K_D FROM EQ. 9 WITH DATA

The close agreement with Fereres (1981), Snyder and Eching (2005) and Hernandez and Suarez (1988) suggests that the general form of Eq. 9 is appropriate for a range of vegetation types and heights. The estimation of K_c from Eq. 6 using $K_{c\ full}$ from Eq. 7a and K_d from Eq. 9 was further compared with K_c data and regression equations reported by Grattan et al., (1998) and Hanson and May (2006). Grattan et al., (1998) reported the progression of K_c during plant development for seven vegetable crops in California as measured using Bowen ratio systems. They expressed K_c as a function of percent of ground cover, which is equivalent to f_c so that their data can be compared directly to that from Eq. 6 and 9. Hanson and May (2006) additionally reported a polynomial equation for K_c vs. f_c for tomatoes in California.

Eq. 6 for K_c was applied rather than Eq. 5 for K_{cb} since some background soil evaporation appeared to be present for some of the crops. $K_{c\ full}$ was estimated as equivalent to $K_{cb\ full}$. In addition, f_c was used in Eq. 9 rather than $f_{c\ eff}$ because specific dates of vegetation development were not reported. Because the sun angle during late spring is high, differences between f_c and $f_{c\ eff}$ will be small. The parameters used in Eq 6, 7a and 9 for the vegetable crops are summarized in Table 1 as are root mean square error (RMSE) for the Eq. 6/9 combination and for the original regression equations of Grattan et al. (1998). Comparisons of Eq. 6/9, the regression

equations by Grattan et al., and the Grattan et al. data are shown in Figure 6 for the seven crops. Vegetation height was varied over time in Eq. 9 in proportion to the maximum estimated height times the ratio of specific f_c to f_c at full cover reported by Grattan et al., (1998), with the exception of cantaloupe, which was assumed to have nearly constant height due to its vine nature. Maximum values for h were taken from tables in Allen et al., (1998). A standard climate was assumed due to lack of reported data by Grattan et al. (1998). Due to the relatively short height of the crops, the adjustment for climate in Eq. 7a would be small.

Table 1. Parameters used in Equations 6, 7 and 9 to simulate the crop coefficients measured by Grattan et al. (1998) and Hanson and May (2006).

Crop	**Arti-choke**	**Beans**	**Brocolli**	**Lettuce**	**Canta-loupe/ Honey -dew**	**Onion**	**Straw - berry**	**Tomato**
K_{soil}	0.15	0.50	0.15	0.15	0.15	0.40	0.05	0.15
M_L	2.0	2.0	2.0	2.0	2.0	2.0	2.0	2.0
Max h, m	0.6	0.4	0.3	0.3	0.3	0.4	0.2	1.2
h vs. t	in prop. to *fc*	in prop. to *fc*	in prop. to *fc*	in prop. to *fc*	Constant	in prop. to *fc*	in prop. to *fc*	in prop. to *fc*
u_2, ms^{-1}	2	2	2	2	2	2	2	2
RH_{min}, %	45	45	45	45	45	45	45	45
no. obs.	11	27	34	39	35	14	10	--
$RMSE_{Grattan}$	0.09	0.09	0.13	0.16	0.09	0.10	0.05	--
$RMSE_{Eq.\ 6/9}$	0.15	0.10	0.14	0.17	0.10	0.11	0.10	--

The agreement between K_c from Eq. 6, 7a and 9 and the data of Grattan et al. (1998) was nearly as good as the fitted regression equations reported by Grattan et al. (1998), with the exception of artichokes where the Grattan regression fit the data better with its stronger curve (Fig. 6a). The accuracy of K_c from Eq. 6, 7a and 9 appears to be within the measurement error of the reported K_c data. When K_{soil} = 0.15, Eq. 6 reverts to Eq. 4 that was developed for the basal K_c. The larger values required for K_{soil} in Eq. 6 for beans and onion suggest that the soil surface was relatively moist for these two crops, as evidenced by values for measured K_c at low f_c. The publication of Hanson and May (2006) did not report the measurement data so that only their regression equation was compared against the product of Eq. 6, 7a and 9. The two estimates compared closely, suggesting that Eq. 6, 7a and 9, using readily estimated physical parameters can be used to estimate K_c if visually assessed or other estimates of f_c are available.

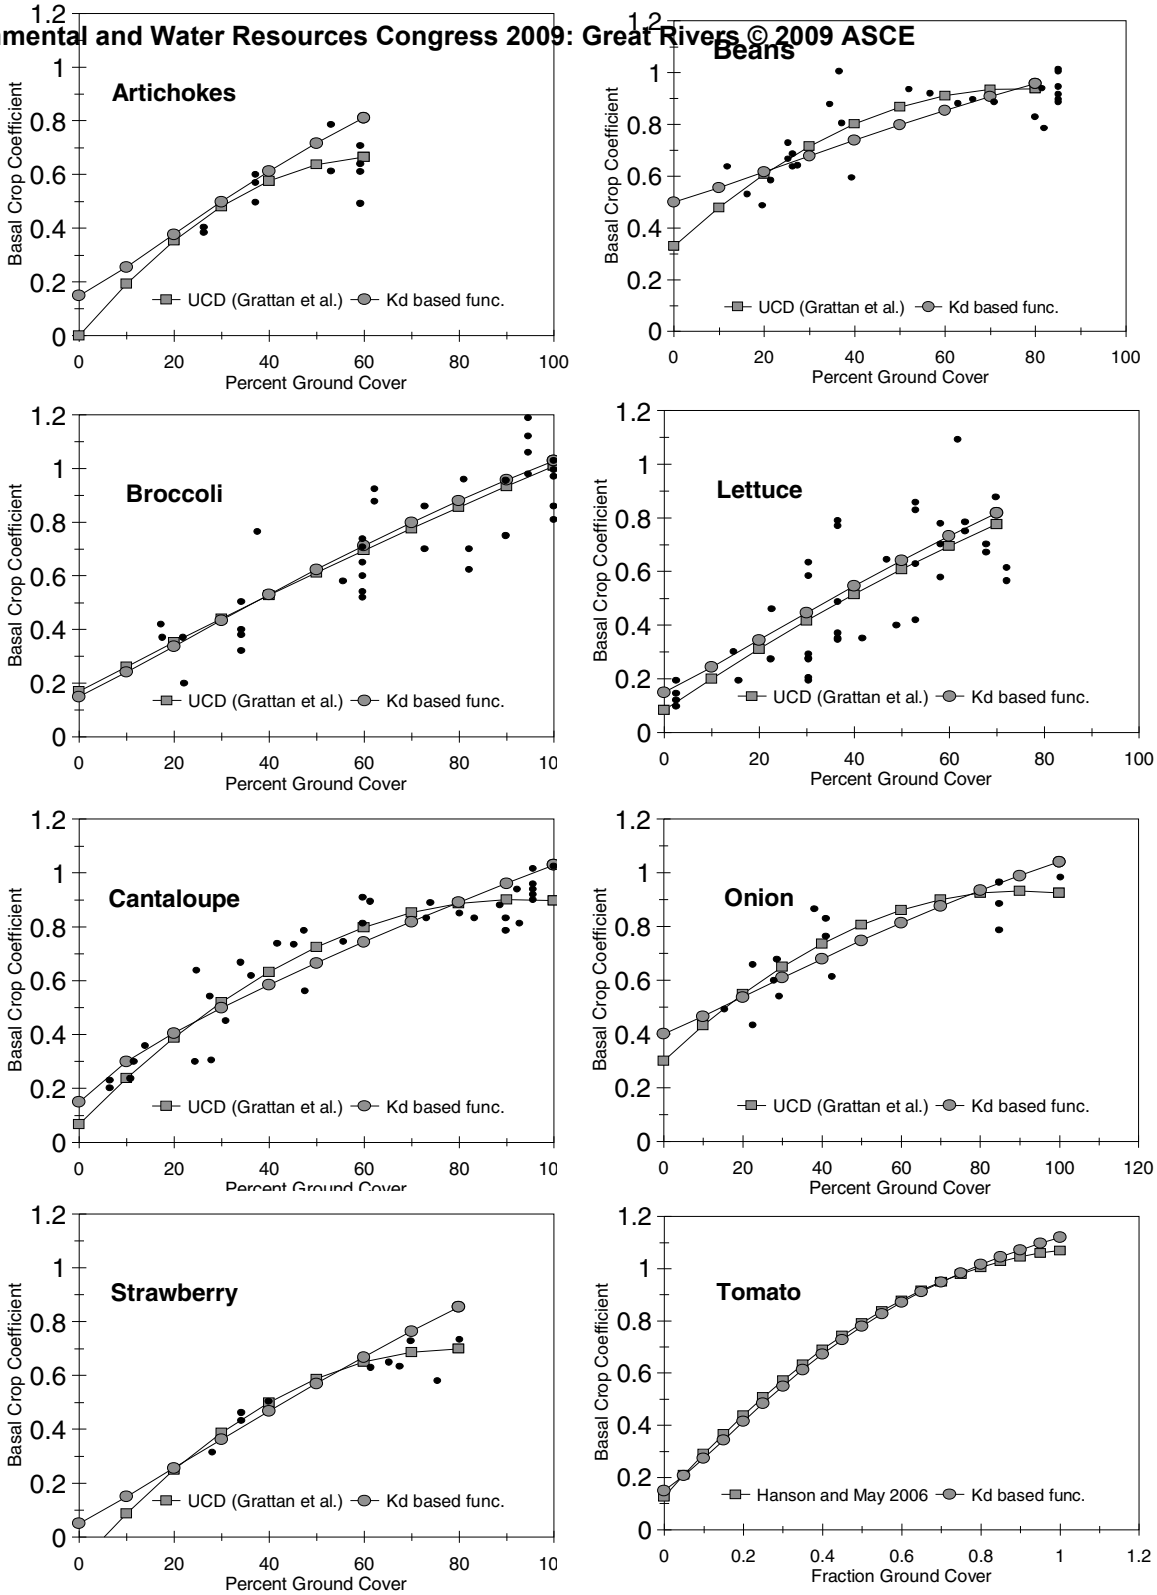

Fig. 6. K_c vs. f_c for seven vegetable crops in California reported by Grattan et al. (1998) (a-g) and tomatoes in California by Hanson and May (2006) (i), showing data and regression equations by Grattan et al. and Hanson and May (2006) with K_c estimated using Eq. 6, 7a and 9.

CONCLUSIONS

The crop coefficient is the ratio of actual ET to reference ET and is heavily controlled by the amount of vegetation present to transpire water. This relationship can be used to estimate values for the crop coefficient as functions of the amount of ground covered by vegetation. A method established in the FAO-56 publication is expanded in this paper to estimate the crop coefficient from the fraction of ground cover and height of vegetation. In addition, when estimates of average background soil evaporation are made, then the 'mean' or single crop coefficient can be estimated. Estimates from the method are compared with measured crop coefficients reported for a number of vegetable crops during the crop development periods. Results are promising.

Manure Application to Soybeans in the Chesapeake Bay Watershed

William F. Ritter[1]

[1]Professor of Bioresources and Civil and Environmental Engineering, Bioresources Engineering Department, University of Delaware, Newark, DE 19716. email: writter@udel.edu.

ABSTRACT

Corn and soybeans are major crops grown in the Chesapeake Bay watershed. The watershed has significant numbers of poultry, dairy and swine in certain areas. Land application of manure is a standard practice in the watershed. Over the years phosphorus concentrations have built up in manure applied soils because application rates have been based upon crop nitrogen requirements. In some cases research has shown manure application will increase soybean yields. One of the environmental concerns of applying manure to soybeans is the risk of increasing nitrate concentrations in the groundwater or tile drainage. Another concern is the buildup of phosphorus in the soil, which may cause phosphorus leaching on sandy soils or increase phosphorus loads in surface runoff.

INTRODUCTION

Today the livestock and poultry industry has become much more concentrated than in the 1960s. The broiler industry is concentrated in the southeastern and south-central states. Georgia, Arkansas, Alabama, Mississippi and North Carolina account for more than 60% of all broiler production in the U.S (Paudel and McIntosh, 2005). Several counties on the Delmarva Peninsula account for 18% of the product. Iowa, North Carolina and Minnesota account for 54% of the hog production in the U.S. (USDA, 2008).

As livestock and poultry operations have become larger and more concentrated, manure management has become more intensive and challenging. In many cases producers cannot use all the manure produced on their own farms and transportation costs for manure are a concern. Ideally corn and cotton are ideal crops for the application of swine and poultry manure. In many areas where swine and poultry are produced, corn and soybeans are the major crops grown. With excess manure produced in some areas, this has led to the application of manure applied to soybeans. Soybeans are a legume crop which fix nitrogen, so the nitrogen in the manure may not be efficiently used. Also if manure is applied to soybeans based upon nitrogen needs of the crop, phosphorus application rates will exceed crop uptake needs. This paper will discuss the potential environmental effects and summarize research on the utilization of manure on soybean production as it relates to water quality.

IOWA BAN ON LEGUINE MANURE APPLICATION

In 2003 a number of environmental organizations in Iowa proposed banning the application of liquid swine manure to soybeans. For several years the Iowa Environmental Protection Commission (EPC) considered banning the practice of applying liquid manure to soybeans. After several years of public comment and a number of hearings the EPC voted in April 2008 by a 5-2 vote to establish the rate of liquid manure application on land to be planted to soybeans in a manure or nutrient management plan at 112 kg/ha of available nitrogen. The rule took effect May 14, 2008. The 112 kg/ha does not apply on or after June 1 of each year, but the rate of 0.063 kg of N per kg of soybean yield applies. Many farmers in Iowa apply liquid manure or nitrogen fertilizer in the fall or early spring in Iowa.

IMPACT ON YEILD

The average soybean yield in Iowa in 2006 was 3089 kg/ha and is estimated to have a nitrogen removal of 194 kg N/ha (Helmers et al., 2008). Varel et al (1992) found soybeans can remove up to 200 kg N/ha. The amount of nitrogen that can be fixed by soybeans over a growing season has been reported to range from 70 to 120 kg N/ha (Tisdale and Nelson, 1975). Soybeans may be unable to fix the total quantity of nitrogen needed for yields obtained under optimal growing conditions today. These comparisons should be made with care, however, because soybean yields today are higher than in 1975.

There have been a number of studies reported in the literature where manure applications have increased soybean yields. Rakshit (2002) applied liquid swine manure to multiple plots at nitrogen target rates of 112 and 224 kg N/ha. Soybean yields increased at all sites receiving manure but only three of the five sites had a statistically significant yield increase. Schmitt et al. (2001) applied swine manure at sever field locations in Minnesota to multiple soybean cultivars at zero, low and high rates of nitrogen. Low rates ranged from 43 to 230 kg N/ha and high rates ranged from 72 to 460 kg N/ha. Soybean yields increased at three of the seven field locations with increasing manure nitrogen application rates. Yields increased on sites having low available soil nitrogen during mid-June.

Adeli et al. (2005) applied broiler litter and commercial fertilizer to soybeans on a Leeper silty clay loam soil in Mississippi. Treatments were broiler litter application at the rates of 0, 40, 80 and 160 kg N/ha of plant available nitrogen and commercial fertilizer applications at broiler litter equivalent nitrogen rates. Soybean grain yield and nitrogen uptake rate increased with increasing broiler litter and fertilizer application rates. Soybean grain yields and nitrogen uptake rates were significantly greater from broiler litter application than from commercial fertilizer applications. Soybean yields for broiler litter application ranged from 2770 kg/ha for the 40 kg N/ha application rate to 3180 kg/ha for the higher broiler application rate.

RESIDUAL SOIL NITRATE AND GROUNDWATER QUALITY

Rakshit (2002) found when the swine manure application rate was less than 200 kg N/ha, post harvest nitrate profiles at all the sites revealed only one instance where concentrations were above the non-manure soil nitrate levels. Schmidt et al. (2000) in a study evaluating the impact of swine manure application nodulating and non-nodulating soybeans found post harvest soil nitrate concentrations followed a quadratic relationship. The results indicate increases of 4, 17 and 35% increases in post-harvest soil nitrate levels from 0 to 120 cm with application rates of 56, 112 and 168 kg N/ha, respectively when compared to 0 kg N/ha.

Kanwar et al. (2006) reported on a six year study at the Iowa State University Northeast Iowa Research Farm in Floyd County where liquid swine manure was applied to plots in a corn-soybean rotation. Swine manure was applied at the rate of 168 kg N/ha before soybeans. The manure was applied in the fall. Tile drainage samples were analyzed for nitrates. The fall applied manure resulted in the highest average nitrate concentration in tile water compared to other fertilizer and manure treatments. The average six-year nitrate concentration for the corn-soybean rotation was 39.8 mg N/l and for the soybean-corn rotation 36.6 mg N/L. Average yearly concentrations ranged from 20.7 to 70.4 mg N/L. Spring application of manure in no-till corn only resulted in the lowest average nitrate concentration of 16.2 mg N/L.

In a four year study in Pocahontas County, Iowa, liquid swine manure was applied at a rate of 168 kg N/ha before both corn and soybeans and compared to a rate of 224 kg N/ha applied every other year before corn. The total of 336 kg N/ha application rate every two years versus the 224 kg N/ha application rate every two years resulted in average nitrate concentrations increasing in the tile drainage on an average from 17 to 23 mg N/L, a 35% increase that was statistically significant (Helmers et al., 2008).

Adeli et al. (2005) found no significant differences in residual soil nitrate concentrations following two years of soybean production where broiler litter and fertilizer were applied at 0, 40 and 80 kg/ha of available nitrogen. At an application rate of 160 kg N/ha of available nitrogen, residual nitrate concentrations increased in the top 30 cm of the soil profile. At the high application rate soil residual nitrate concentrations were significantly greater with commercial fertilizer than broiler litter. Nitrates did not leach below the 90 cm depth.

Vasilas (1997) conducted a two-year study to evaluate the effect of timing of broiler litter application to soybeans. The study was conducted at the University of Delaware Research and Education Center in Sussex County on Ingleside sandy loam soil. Broiler litter was applied in November, January, March and two weeks prior to planting in May. Broiler litter was applied at a rate of 9 Mg/ha. The experimental design was a randomized complete block with three replications. Two groundwater sampling wells 3.6 m deep were installed in each plot. Monthly groundwater samples were taken from June 1994 to May 1996.

When groundwater sampling started, nitrate concentrations were below 10 mg N/l Nitrate levels in the November and January applications increased to above 10 mg N/l in November 1994. The May and March applications caused nitrate levels to increase to above 10 mg N/l in January 1995 and April 1995, respectively. For each sampling date the November and January applications generally had the highest groundwater nitrate concentrations. In February 1996, the nitrate concentration for the November application was almost 30 mg N/l. Post harvest soil nitrate concentrations in 1995 were 60 mg/kg at the 60 to 90 cm depth and 101 mg/kg at the 90 to 120 cm depth for the November application.

Vasilas (1997) concluded from the study that timing of the broiler litter application was unlikely to affect soybean yields and that the recovery of broiler litter nitrogen by soybeans is low. This means the potential for groundwater contamination is high. In order to maximize the recovery of broiler litter nitrogen by soybeans, application of the broiler litter should be close to the planting date and double cropping winter wheat or planting a cover crop after harvesting the soybean to recover the soil residual nitrogen.

DELAWARE STUDY

Methods And Materials: Broiler litter was applied to four large plots 0.25 ha in size in 194 and 1995 at the University of Delaware Research and Education Center in Sussex County. Manokin soybeans were planted in 75 cm rows at a rate of approximately 350,000 seeds/ha in late May each year. One plot was used as a control where no broiler litter was applied. The other three plots received 2.24, 4.48 and 9.6 Mg/ha of broiler litter each year. The nutrient content of the broiler litter varied somewhat from year to year. In 1994, nitrogen application rates for the three treatments with broiler litter were 73, 146 and 292 kg N/ha. In 1995, nitrogen application rates were 115, 230 and 460 kg N/ha. Phosphorus application rates were 66, 132 and 264 kg P_2O_5 /ha in 1994 and 12, 24 and 48 kg P_2O_5/ ha in 1995. No commercial fertilizer was applied to the control plot. The plots were located on a Klej loamy sand soil. From 1989 to 1991 the plots were used for a winter cover crop non-irrigated corn study. For that experiment three monitoring wells were installed in each plot at a depth of 4.5 m. All monitoring wells were constructed from 3.25 cm PVC pipe with the bottom 0.75 m screened with 2.5 mm slot size PVC screen. The monitoring wells were installed by the auger drilling method. The annulus around all wells was sealed with bentonite. Two background monitoring wells were also installed.

In 1992 and 1993 soybeans were planted on the four plots but no experiments were conducted. In 1996 soybeans were also planted, but no broiler litter or fertilizer was applied.

Groundwater samples were collected every two or three months from November 1993 to October 1996 and analyzed for nitrates by the Bioresources Engineering Water Quality Laboratory. All monitoring wells were sampled with a battery operated

peristaltic pump. The wells were pumped dry and allowed to recharge before a sample was taken. Water table depth measurements were taken each time groundwater samples were taken. Nitrates were analyzed by the ion chromatograph method.

Groundwater Quality: Average nitrate concentrations for the different treatments are presented in Table 1. Nitrate concentrations where 9.6 Mg/ha of broiler litter was applied for two years increased somewhat. There was no trend in nitrate concentrations for the other broiler litter treatments or the control. Average nitrate concentrations for the control ranged from 7.25 to 11.1 mg N/l. Nitrate concentrations for 2.24 and 4.48 Mg/ha broiler litter application rates decreased in 1995 and 1996 when compared to concentrations in 1993 and 1994 before the broiler was applied. In February, 1994 the average nitrate concentration for the 4.48 Mg/ha treatment was 11.1 mg N/l. In September of 1994 the nitrate concentration decreased to 7.20 mg N/l for the remainder of the sampling period. For the 9.6 Mg/ha treatment nitrate concentrations reached a high of 15.9 mg N/l in November of 1995. Nitrate concentrations in the two background wells were below 10 mg N/l.

Table 1. Average Groundwater Nitrate Concentrations (mg N/l) for Broiler Litter Application

	Broiler Litter Rate (Mg/ha)			
Sampling Date	2.24	4.48	9.6	Control
11-12-93	6.42	12.2	9.42	8.27
2-28-94	7.13	11.1	10.7	9.69
4-26-94	9.50	10.2	9.05	10.3

7-25-95	5.65	5.51	10.5	10.1
9-29-95	7.39	5.86	12.9	9.61
11-20-95	5.73	6.65	15.9	10.4
1-3-96	7.31	7.12	15.0	11.1
3-26-96	4.84	4.67	13.5	10.0
5-31-96	4.42	4.94	12.7	10.0
7-25-96	3.74	7.09	10.7	7.53
10-2-96	3.49	4.69	10.8	7.25

Rainfall varied considerably during the growing season from 1994 to 1995. In 1994 a total of 553 mm of rainfall occurred during the growing season while in 1995 the

rainfall was 276 m. In 1994 soybean yields for the different treatments ranged from 1781 to 2059 kg/ha and in 1995 they ranged from 510 to 886 kg/ha. Both years the control had the lowest yield.

In 1994, the total rainfall was 758 mm after the manure was applied. The high rainfall probably caused the nitrates on the high rate broiler litter applications to leach to the groundwater as indicated by the higher groundwater nitrate concentrations in January, 1995. For the lower application rate treatments, probably most of the mineralized nitrogen was taken up by the soybean plants since yields were normal for dry land soybeans grown on sandy soils in Delaware. Although during the growing season rainfall was low in 1995, 277 mm of rainfall occurred in October and November. It is surprising nitrate concentrations did not increase in the groundwater for all three broiler litter treatments in January 1996 because of the low soybean yields in 1995.

PHOSPHORUS

A 5925 kg/ha soybean crop will remove 35kg/ha of phosphorus (P_2O_5) 170 kg/ha of nitrogen and 62 kg/ha of potassium (K_2O). Soybeans will use the phosphorus in the manure, but if either broiler litter, liquid swine manure or dairy manure is applied to soybeans at a rate of 112 kg/ha of nitrogen, phosphorus will build up in the soil. If liquid swine manure from a grower-finishing operation was applied at a rate of kg N/ha, the phosphorus application rate may be 77 kg/ha (P_2O_5). With broiler litter, a 112 kg N/ha nitrogen application rate could result in a phosphorus application rate of 70 kg/ha (P_2O_5). For semi-solid earthen basin dairy manure, a 112 kg N/ha nitrogen application rate may result in a 54 kg/ha phosphorus (P_2O_5) application rate (MWPS, 2000). Adding phytase to the broiler or swine ration may decrease the phosphorus in the manure by up to 25 to 30% (Sutton and Humenik, 2003) Long term buildup of phosphorus in the soil would be of a concern with surface runoff and also on sandy soils phosphorus leaching may occur. Maryland, Pennsylvania, Delaware and Virginia all have nutrient management regulations based upon phosphorus. If the soil tests high or very high in phosphorus no more phosphorus can be applied than what is removed by the crop based upon a three year average.

CONCLUSION

There are some benefits to applying manure to soybeans and some negative aspects. On the positive side, manure can supply nitrogen phosphorus, potassium and other nutrients for the crop and reduce commercial fertilizer cots. In some cases manure application may increase soybean yields. With a corn-soybean rotation incorporating manure into cornstalks instead of soybean stubble will reduce the erosion potential because of the greater residue cover with corn stalks.

Manure application to soybeans will increase the risk of nitrate losses to groundwater or tile drainage. Applying manure in a corn-soybean rotation to both crops to meet

nitrogen needs or even applying manure at a rate of 112 kg/ha to soybeans will result in a buildup of phosphorus in the soil.

If manure is applied to soybeans it should be applied as close to planting as possible. Manure should not be applied in the fall of the year to soybeans. A winter cover crop such a rye or winter wheat should be used to remove the residual nitrogen since nitrate leaching will occur during the winter months and early spring.

ABSTRACT

On-line irrigation scheduling consultant software is being developed for producers within the Belle Fourche Irrigation District (BFID). This project, which is funded for 3 years by a Conservation Innovation Grant (CIG) through the Natural Resources Conservation Service (NRCS), is entering its second irrigation season.

The BFID is a gravity-fed, canal-based system located in western South Dakota. Recurring droughts often limit the amount of water available for irrigation in the BFID. The purpose of this project is to provide producers with a reliable, easy-to-use means to monitor and schedule irrigations that will conserve water and reduce the amount of sediment-laden irrigation return flows that are discharged into the adjacent Belle Fourche River, historically listed as impaired for total suspended solids (TSS) by the South Dakota Department of Environment and Natural Resources (SD DENR).

The on-line irrigation scheduling consultant software allows producers with internet access to create a secure, personalized Web page that provides irrigation scheduling advice for a particular field. The software collects daily weather data and uses it to estimate rainfall and calculate crop evapotranspiration (ET) utilizing the American Society of Civil Engineers (ASCE) Penman method and locally adapted crop coefficients. Irrigation delivery amounts entered online by the producer are added to the rainfall estimates for that location. The irrigation scheduling software then calculates a soil water balance and irrigation schedule for soil types in the field. Soil moisture sensors installed at two depths are recorded to provide on-line tracking of relative soil water changes throughout the irrigation season. The producer has the option to adjust the calculated soil water balances or measured rainfall amounts based on his observations at the field.

The results of the first year of irrigation scheduling were used to evaluate the on-line software and methods. User feedback is also being collected to fine tune the on-line user interface. The second season of irrigation will expand the user base and be used to further evaluate the software.

KEYWORDS: Irrigation, Evapotranspiration, Soil Moisture, Computer Software, NRCS

INTRODUCTION

The Belle Fourche Project is located immediately north of the Black Hills in western South Dakota (Figure 1). The Belle Fourche Irrigation District (BFID) serves over 480 individual producers who irrigate 57,183 acres. Typical irrigated farms in the BFID are small to medium in size (100–300 acres) and are family owned. Alfalfa and hay production accounts for about 65 percent of crop production, with small grains and corn accounting for most of the remainder of crops produced. Irrigation methods are almost entirely surface irrigation.

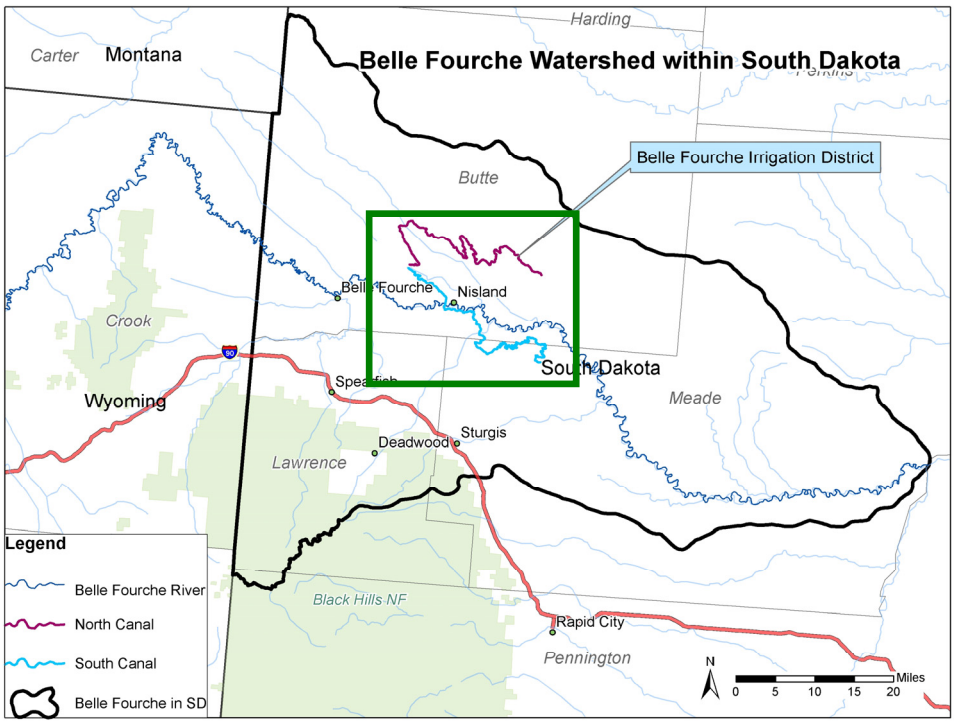

Figure 1. Location of the Belle Fourche Irrigation District within the Belle Fourche River Watershed.

The Belle Fourche River has been historically listed as impaired for total suspended solids (TSS) by the South Dakota Department of Environment and Natural Resources (SD DENR). The project began when the BFID participated in the Belle Fourche River TSS Total Maximum Daily Load (TMDL) study. The study determined that a significant portion of the TSS entering the river could be eliminated by reducing the amount of unused irrigation waters flowing into the river and its tributaries (Figure 1). Horse Creek, also impaired because of excessive TSS, receives much of the irrigation return flows originating in the BFID. The TMDL recommended that reductions in return flow be accomplished through canal automation, updating their water order and billing system, and implementing on-farm improvements such as scientific irrigation scheduling and converting surface irrigated fields to sprinkler irrigation.

Recurring droughts often limit the amount of water available for irrigation in the BFID. Research has documented how scientific irrigation water management (IWM) can improve water conservation and productivity. In the Steele et al. [2000] study, savings of 30 percent of the seasonal irrigation depths were achieved using IWM versus grower practices. Scientific IWM considers factors such as soil water-holding capacity, crop water use, and allowable depletions necessary to apply the optimum amount of water needed for crop production.

When water is limited, IWM allows the best use of irrigation water by applying water during the most critical crop growth periods. Studies on corn in North Dakota, Kansas, and Nebraska have shown deficit irrigation can save water with minimal yield reduction. Melvin and Payero [2003] stated, however, that "the deficit irrigation strategy is the most challenging to manage." Heeren et al. [2008] modeled 30 irrigation strategies with a simulated center pivot at Nisland, South Dakota (located within the BFID). They found that it is critical to use specific scheduling strategies to achieve the greatest water and production efficiency. Thus it is critical to use scientific irrigation scheduling to achieve the greatest productivity with the available water.

Shearer and Vomocil [1981] found that adoption of scientific irrigation scheduling was well accepted by growers but the practice was not sustained once technical support was reduced. Leib et al. [2002] determined that the number of irrigators using scientific irrigation scheduling, even with the availability of consultants for technical support, may have been as low as 18 percent as of 1998. Technical service providers in many parts of the country provide IWM assistance but serve a relatively small number of growers. Dr. Hal Werner, consultant available to the project, conducted extension educational efforts on IWM for over 30 years. His experience indicates that use of scientific irrigation scheduling will be limited unless user-friendly methods are available to the producer.

Presently, irrigation scheduling for most farmers relies largely on past practice. Even though it is generally accepted that scientific scheduling can increase water efficiency, scientific input is minimal because of constraints of training, experience, time, and other resources. This is in spite of the fact that tools are now widely available for scientific irrigation scheduling, including evapotranspiration (ET) information and stand-alone scheduling software. Many locations publish ET and crop water use information on the Web; however, an interactive Web-based irrigation scheduler that requires minimal input and effort from the producer is not available at this time for producers in the BFID.

Consultants to the project developed the software logic and framework that would be implemented by this project. The software includes the ASCE Penman and locally adapted crop coefficients. The software model considers on-site ET, rainfall, irrigation amount, soil water capacity, soil water balances, and forecasted ET to plan irrigation amounts and timing.

METHODS

The goal of this 3-year project is to implement a Web-based, interactive irrigation scheduling calculator that is customized to each producer's crop, planting date, soil type, rainfall and irrigation amounts, and method of irrigation. The calculator will allow any producer with internet access to create a personalized Web page with irrigation information for a particular field. To accomplish this, an extensive real-time weather network was implemented that ties into an existing radio network the BFID uses to monitor structure settings and flow throughout the BFID. The weather network includes four full-weather stations that provide the necessary inputs to calculate daily evapotranspiration (ET) using the American Society of Civil Engineers (ASCE) Penman method and also nine rainfall monitoring sites (Figure 2).

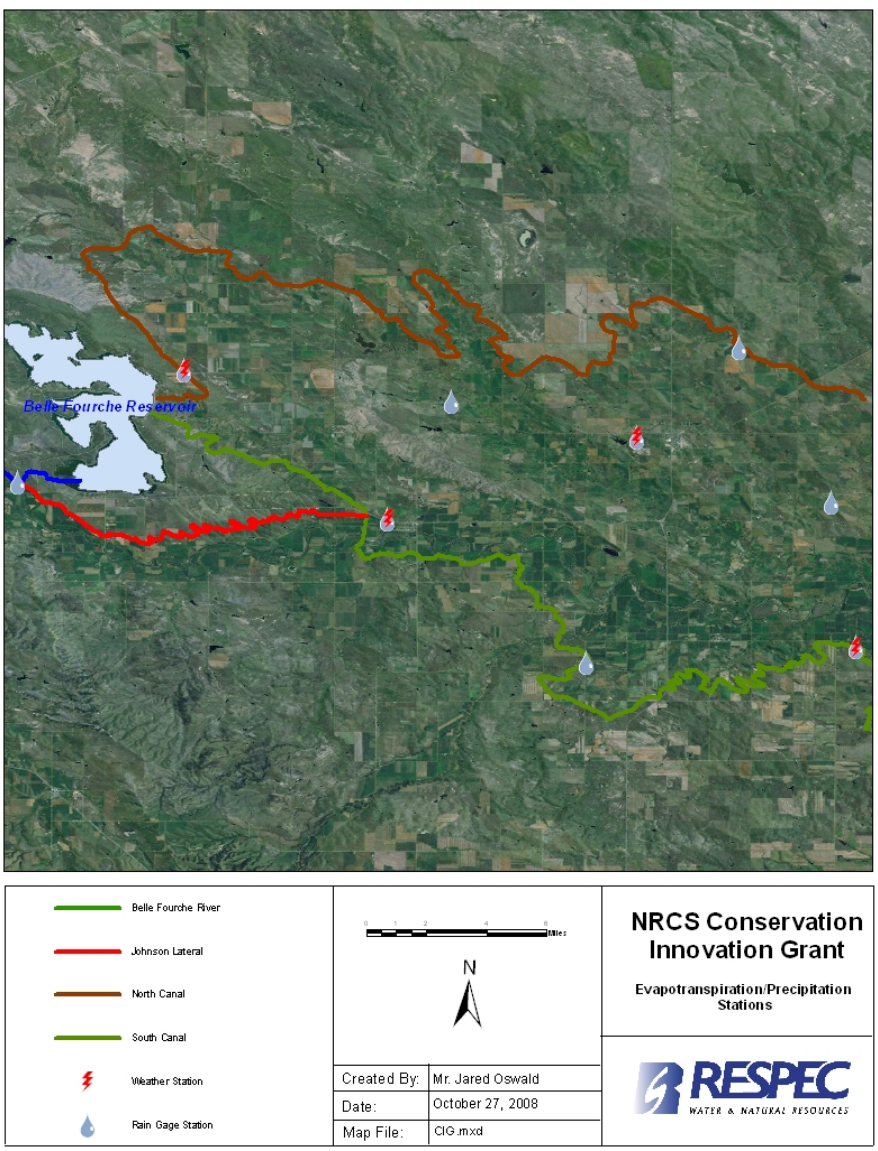

Figure 2. Location of the weather stations and rain gages throughout the Belle Fourche Irrigation District.

Producers are able to establish site-specific irrigation scheduling for each crop and irrigated field on their farm using the on-line scheduling application. Currently, scheduling routines have been developed for alfalfa (both new crop and established), corn, barley, and wheat.

At the beginning of the growing season, the producer must log on to their personalized Web page and then, using a custom Web mapping application, draw a polygon around the field that they plan to use with the on-line scheduler. Once the producer selects the location of their field and inputs the current crop and planting date, the database system retrieves the water-holding capacity of the soil and calculates the total area to be irrigated. It also assigns the appropriate rain gage and weather station along with BFID lateral that supplies water to the field. From that day forward throughout the irrigation season, the on-line irrigation consultant software will calculate and track crop water use and soil water balances for each soil type in the field.

The on-line irrigation consultant software provides projections of future crop water use that allows the producer to plan irrigations and water deliveries. This is accomplished by averaging the crop water use from the previous 3 days and projecting that amount on the next 4 days. This prediction is essential because there can be up to a 3-day lag from when the producer orders water from the BFID to when it actually arrives at the field.

The producer is required to enter the amount and timing of irrigation deliveries. Ten-minute readings from soil moisture instruments installed at ¼ and ¾ of the crop rooting depth are collected weekly and are provided online as a means to track relative soil water changes throughout the irrigation season. The on-line scheduling application provides the producer with the ability to input actual rainfall amounts when those are measured on site. They can also adjust the calculated soil water balance based on soil moisture measurements or field inspection.

ANALYSIS

Development and testing of the irrigation scheduling consultant software during the first year of this project precluded use by producers during the first irrigation season. Instead, the irrigation scheduling routine was developed using Microsoft Excel. The tracking of the calculated field soil water balance along with the soil water tension, measured with Watermark® blocks, was provided via email on a weekly basis.

During the first irrigation season, the producers based their irrigation decisions more on the information being provided to them from the soil moisture sensors rather than the soil water balance being calculated using weather, rainfall, and the irrigation model. This was partially because the information was provided on two separate graphs using two different scales—tension in centibars for the measured balance and soil water balance in inches for the calculated balance. Producers also stated that they

were more comfortable with something that was concrete and visible rather than the equations in the model. Because of the expense of not only buying the soil moisture data loggers and sensors but also the expense of collecting the data, the success of the on-line irrigation scheduling consultant application as an economical, systemwide application depends on the producers trusting the calculated balance while using the measured balance from soil moisture sensors as occasional ground truth.

After the irrigation season was completed, project staff attempted to devise a method of in-season indexing these two datasets. This was done to identify any discrepancies between the calculated and measured soil water balance and also for a visual aid that would allow the producers to correlate the two forms of information. It was hypothesized that the calculated values should lie somewhere in between those measured at the two rooting depths since the calculated value is essentially an average of the entire soil profile.

An initial analysis was completed on a relatively small 23-acre field with established alfalfa (Figure 3). The field contains a soil with a water-holding capacity of 2.12 inches per foot, which is assumed to be homogeneous throughout its 4-foot rooting depth. The soil moisture sensors are located in the northeast corner of the field. Irrigation is delivered via gated pipe from the west end of the field and travels from southwest to northeast.

Figure 3. Aerial imagery of a 23-acre field used for initial analysis.

The 2008 irrigation season was wetter than normal, with 14.89 inches of rainfall occurring between April 15 and September 1 in a region that normally receives approximately 13 inches of annual precipitation. The producer irrigated the field twice during the growing season, July 12–15 and August 25–28. For the purpose of the calculated water balance, the irrigation volume was distributed uniformly across the entire field while assuming a 50 percent application loss.

To index the two datasets, the measured values of soil moisture tension and the calculated values of soil water deficit were divided by their full scale range, or range of available water from 0 to 100 centibars, to determine the percentage of soil water deficit (Figure 4). The full scale value was assumed to be 75 percent of field capacity (6.4 inches) for the calculated water deficit in this soil type, based on literature. The percentage of soil water deficit measured and calculated tracked similarly until irrigation was delivered from July 12–15. At this point, the soil moisture sensors recorded zero centibars of tension (soil was saturated) and the calculated deficit dropped to approximately 20 percent and then immediately began to rise again. This caused the calculated percent deficit after this point to be much greater than the measured percent deficit. Assuming the Watermark® sensors were correct in measuring saturated soil, a reindexing algorithm was applied that reset the calculated percent deficit to 0 percent when the average reading of the two soil moisture sensors was below 10 centibars of tension (Figure 5). With this correction, the calculated value stayed within the range of the 1-foot and 2-foot sensors for nearly the entire irrigation season. The anomaly that coincides with the final irrigation is because an implement tire track was created inadvertently upstream of the soil moisture station, causing water to be diverted around the sensors. The 3-foot sensor responded to the irrigation amount, but at a later date than was predicted.

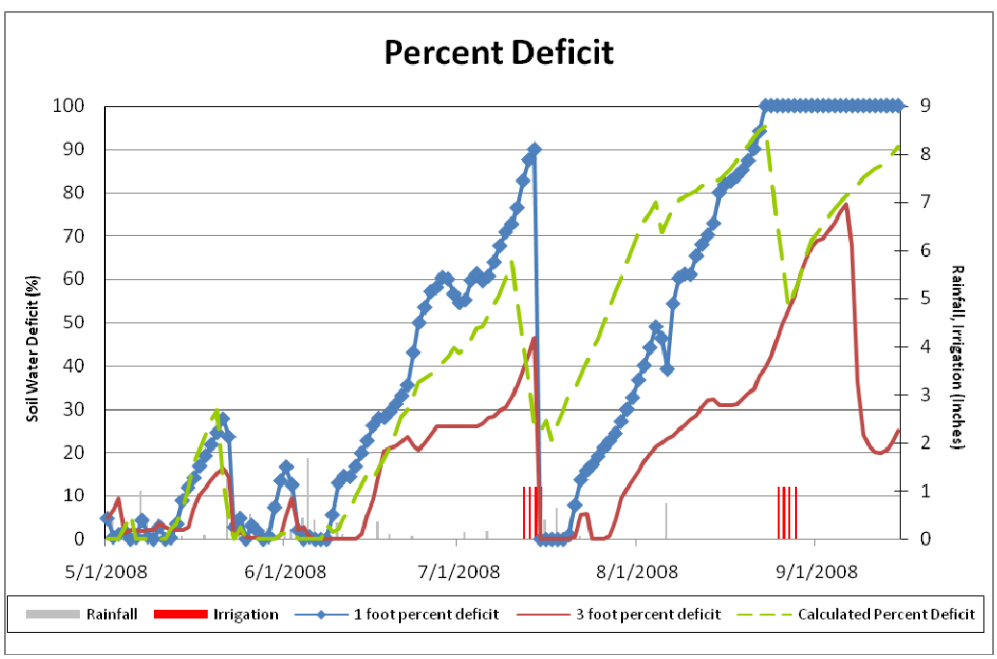

Figure 4. Measured and calculated values of soil water deficit.

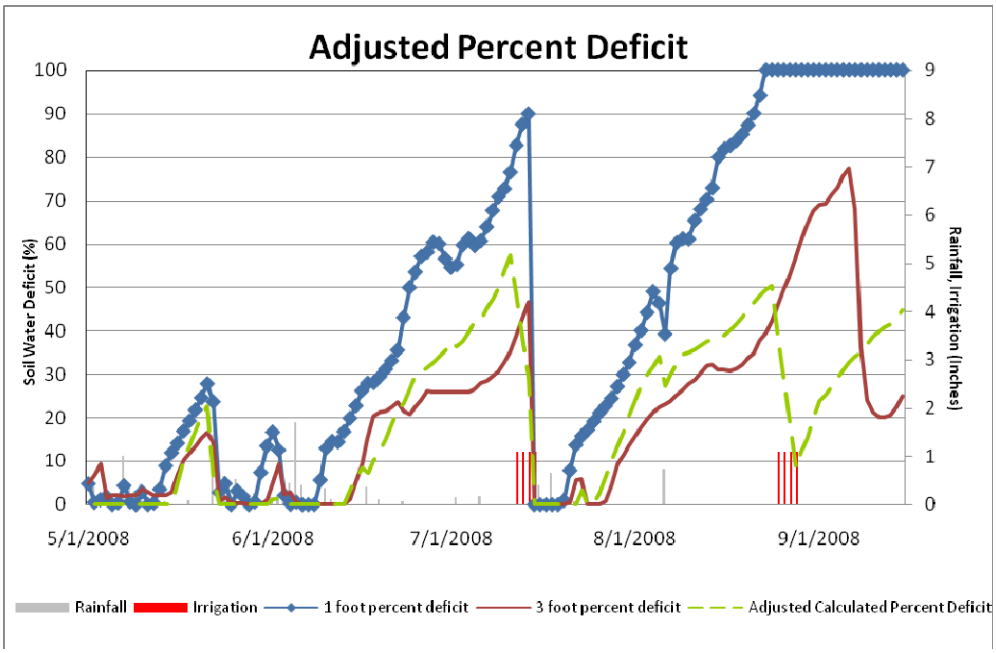

Figure 5. Percentage of measured and calculated soil water deficit with calculated being adjusted to 0 percent when the average of the two sensor readings is below 10 centibars of tension.

The effectiveness of using this indexing method is directly correlated to the reliability of the soil moisture information. There were several soil moisture stations that reported erroneous information that could not be used to compare to the water balance that is being calculated, as in the values reported in Figure 6.

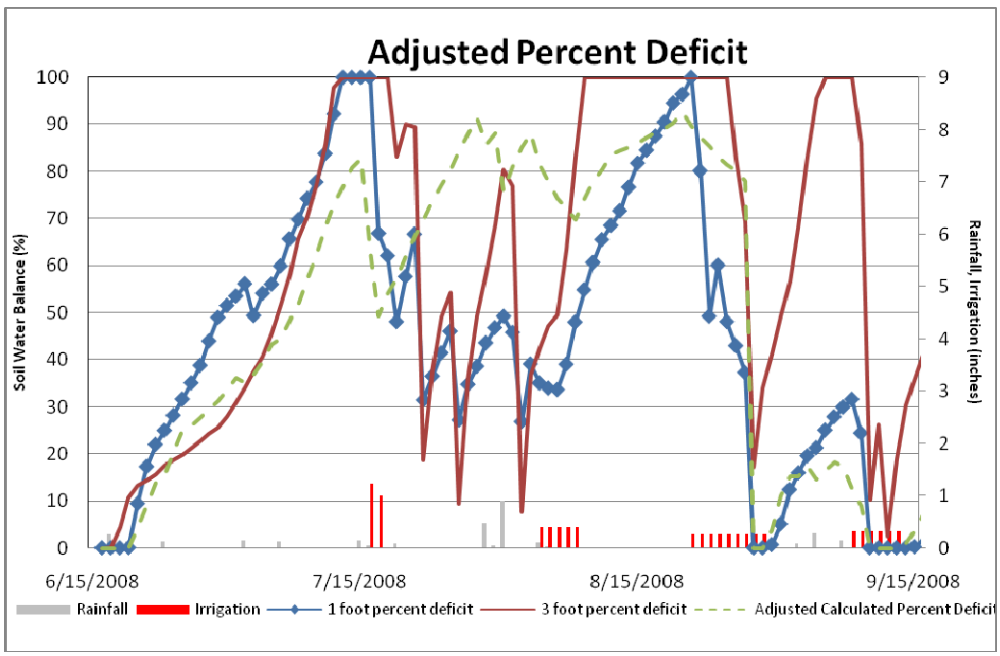

Figure 6. Adjusted percent deficit for a soil moisture station with erroneous readings.

SUMMARY

The goal of this 3-year project, funded by a Conservation Innovation Grant (CIG) through the Natural Resources Conservation Service (NRCS), is to develop a reliable, Web-based irrigation scheduling tool that is easy for producers in the Belle Fourche Irrigation District to set up, understand, and maintain. The Web-based application was being developed and tested during the first irrigation season, so cooperating producers were provided with calculated soil water balances that were developed using the model logic from the Web-based application input into a Microsoft Excel spreadsheet. Producers were also provided with readings from Watermark® soil moisture sensors placed at ¼ and ¾ of the crop's effective rooting depth.

After the irrigation season was completed, project staff devised a method of comparing the measured and calculated soil moisture balances that would identify any discrepancies between the two datasets and also provide a visual aid that would allow the producers to correlate the two forms of information. The two sets of data were normalized by dividing the calculated values of soil water deficit in inches and measured values of soil moisture tension in centibars by their full range (range of plant available water from field capacity to 100 centibars) and were represented as a percentage of the soil water deficit. The calculated soil water deficit was then set to zero when the soil moisture sensors had an average tension of less than 10 centibars.

In the first year, producers had a tendency to rely more heavily on the measured soil moisture information than what was being calculated using weather data collected from a network of weather stations and rain gages. This was justified in the fact that the calculated balance before indexing was often much higher than what would be expected, especially following irrigation applications. Because of the expense to the producer of not only buying the soil moisture data loggers and sensors but also the expense of collecting the data, the success of the on-line irrigation scheduling consultant application as an economical, broad-reaching application depends on the producer trusting the calculated balance and using the measured balance as an occasional ground truth.

The goal for the next 2 years of the project will be to deploy the Web-based application and continues to monitor if the indexing method developed after the first year continues to apply. Gravimetric tests will be run on all soil types so the inches of available water from 0 to 100 centibars is represented more precisely rather than relying solely on literature values.

Agricultural Drainage Management Systems Task Force (ADMSTF)

A Partnership Group that Promotes and Implements Drainage Management Systems on Cropland in the Mississippi River Basin to Improve Water Quality of Drainage Flows.

James L. Fouss[1] and Michael Sullivan[2]

ABSTRACT

The Agricultural Drainage Management Systems (ADMS) Task Force was initiated during a charter meeting in the fall of 2002 by dedicated professional employees of Federal, State, and Local Government Agencies and Universities. The Agricultural Drainage Management (ADM) Coalition was established in 2003 by drainage industry officials, trade associations and non-government organizations. These two groups formed a working partnership to promote and implement drainage water management systems that can significantly improve the quality of drainage water flows from agricultural cropland. Earlier research had shown that a large percentage of the nitrate-nitrogen that migrates down the Ohio and Mississippi Rivers comes from surface and subsurface drainage discharge from agricultural cropland in the Midwest region. An initial primary goal of the partnership groups was to reduce the loss and transport of fertilizer nutrients, particularly nitrate-nitrogen, from drained agricultural croplands in the Midwestern States on a farm-by-farm basis. They installed and conducted field demonstrations for farmers to promote and encourage them to install and implement drainage water management practices (controlled-drainage) for both new drainage installations and by retrofitting their existing drainage systems with drainage outlet controls. Previous research that had been conducted at multiple locations to evaluate controlled-drainage systems documented that the decrease in nitrate-nitrogen loss in drainage discharge was almost directly proportion to the reduction in drainage outflow volume accomplished by installing control structures on the drainage outlets. A 50% reduction in drainage outflow and nitrate loss was a common research finding at most of these locations. The desired ultimate goal of the ADMSTF and ADMC partnership efforts was to implement drainage water management on a large enough scale (watershed-by-watershed) in the Midwest to decrease transport of excess nutrients through the Mississippi River drainage basin to the Gulf of Mexico. EPA and USGS had reported this source of nitrate-nitrogen as one of the major sources contributing to the persistent formation of the large hypoxic zone ("dead zone") in the Gulf of Mexico.

Background and Need for Change in Agricultural Drainage Management Practices

In agricultural cropland areas where soil profiles have seasonal shallow water tables, a centuries old management practice has been to install subsurface (tile) drainage systems to reduce the duration of excess soil-water occurrences in the root-zone that damage crop growth and yield. The subsurface drainage practice provides other beneficial benefits as well, including improved filtration, reduced surface runoff and thus less soil erosion, and improved crop growth and yield when compared to the same or similar soil without a subsurface drainage system (Skaggs and van Schilfgaarde, 1999). It has been known for many years that subsurface drains reduce the losses of phosphorus and sediment from agricultural cropland, however, the loss of nitrate-Nitrogen was found to increase in sub-drainage outflows because of leaching from the soil profile by the subsurface drainage system (Gilliam et al., 1999). The nitrate leaching into subsurface drains has been studied, but during the last two decades concerns have been raised about the increasing size of hypoxic zone formed each year in the northern Gulf of Mexico (and elsewhere around the world). This concern has focused a renewed interest and need for additional subsurface drainage studies. The new studies provided a focus on drainage management because drainage of the soil profile was needed for optimum agricultural production, but a way needed to be found to avoid or greatly reduce the losses of fertilizer nutrients (especially nitrate-Nitrogen) with the drain outflows to surface receiving waters and streams. The original focus of the ADMS Task Force activities was the 8-State Midwest area including MN, IA, MO, IL, IN, OH, MI, and WI, because earlier EPA and USGS reports indicated that this region was the major source of the nitrate-Nitrogen lost from agricultural cropland that was carried down the Mississippi River System to the northern Gulf of Mexico and contributed to formation of the hypoxic zone.

The Concept of Nutrient Reduction by Drainage Water Management

There are two components involved to explain the nutrient reduction in the drainage outflow with drainage water management (controlled drainage); see example implementation in Fig. 1. First, the outflow drainage volume reduction by DWM results in a decreased discharge of nutrients (mostly nitrates) in almost direct proportion to the percent that the drain volume outflow is reduced (Gilliam et al., 1979; Evans et al 1989; Skaggs et al., 1994; Thomas et al., 1995). Second, by elevating the drainage outlet, any resulting decrease in the depth to the water table will cause the soil to become anaerobic and thus increase denitrification (Gilliam et a., 1979; Evans et al., 1989b; Kliewer and Gilliam, 1995; Thomas et al., 1995; Drury et al., 1997; Power et al., 2000). These effects of these two outcomes work together rather than separately, thus enhancing the reduction in nutrients discharged from the drain outlet.

Drainage water management research has shown reductions in nitrate outflow from subsurface drainage system by about 50% (Meek et al., 1970; Gilliam et al., 1979; Gilliam and Skaggs, 1986; Evans et al., 1989b; Skaggs and Chescheir, 1999; USDA-ARS, 2002; Fausey, 2004). In Sweden, Westrom et al. (2001) reported that during a dryer than normal or average year, nitrate loads in drainage outflow were reduced by 78% to 94% from drainage water management plots when compared to conventional drainage. Skaggs and Cheschier (1999) predicted with the DRAINMOD-N model that drainage water management reduced nitrate losses most effectively in closely spaced, deeper drains.

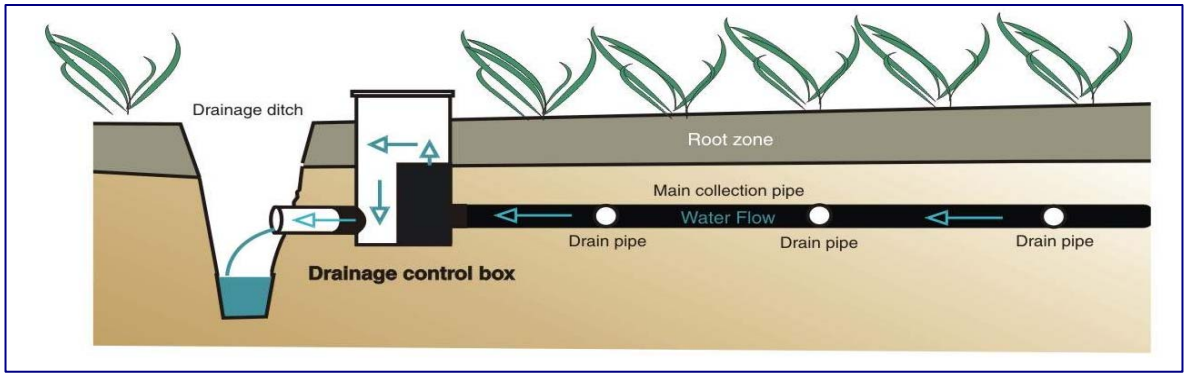

Fig. 1. Conceptual Drainage Outlet Control Structure in Subsurface Drain Main

As drainage water management (controlled-drainage) holds more water is in the soil profile, denitrification occurs, reducing nitrate concentrations in the saturated portion of the soil (Meek et al., 1970; Jacinthe, et al., 1999; Power et al., 2000). Jacinthe, et al. (1999) reported that during a 130 day study, 24% to 43% of the nitrogen present was denitrified when the water table was controlled at 10 cm below the soil surface.

The majority of nitrate load decrease observed from drainage water management is due to the volume of water and the nitrates in that water being held back within the soil profile (Gilliam et al., 1979, Evans et al., 1989b; Gilliam et al., 1999; Evans and Skaggs, 2004).

Drainage water management has the advantage that it does not require land to be removed from production because the soil profile is utilized for both water storage and creates the conditions for denitrification. A disadvantage is that drainage water management can only be used on relatively flat fields (i.e., 1% slope or less is preferred), but some recent technological flow-control developments may make it applicable to lands of greater slopes.

The ADMS Task Force and its Organizational Membership and Meetings

The Task Force was formally established in early 2003 as a technical work group (TWG) of USDA's Partnership Management Team (PMT) to assist in addressing and resolving water quality issues on agriculturally drained lands. The PMT was a collaborative effort among the USDA Agricultural Research Service (ARS); Natural Resources Conservation Service (NRCS); and the Cooperative State, Research, Education, and Extension Service (CSREES). Agricultural drainage management was one of 14 priority national research and technology development needs that were already identified by NRCS under the PMT Need-Request System, before it became a TWG.

Besides the principal Federal Government Agencies, ARS, NRCS, and CSREES that made up the PMT, other Federal Agencies that took an active part were the Environmental Protection Agency (EPA) and the U.S. Geological Survey (USGS). The main cooperative state agencies were the Minnesota Department of Agriculture and some Midwest State Departments of Environmental Quality (DEQ).

The Land Grant Universities in the Midwest had several members of their faculty, researchers, extension specialists, and instructors who initially took a very active role in the formation and activities of the Task Force, such as Iowa State University, University of Minnesota, University of Illinois, Purdue University, The Ohio State University, North Carolina State University, and Louisiana State University. By the second year of the ADMSTF, the University of Missouri, Michigan State University, and University of Wisconsin.

The Technical Committee and leadership of the ADMSTF was provided by a Chair – responsible for Technology, co-Chair – responsible for Implementation (these may be two co-Chairs), and an Executive Secretary – responsible for Education and Extension. In the first few years the Technology was handled by ARS, Implementation by NRCS, and Education and Extension by one of the Land Grant University professors in association with CSREES.

Although the ADM Coalition members were not official members of the ADMS Task Force (to avoid any legal conflicts of interest when voting on action items) they were invited to attend and participate in the discussions at Task Force meetings. Many of the ADMC members were representatives of drainage materials manufacturers and most were also members of the Corrugated Polyethylene Plastic Pipe Assoc. (CPPA) of the Plastic Pipe Institute, Inc. (PPI). At some of the Task Force meetings local drainage contractors were invited to attend and some made formal presentations or put on field demonstrations for the Task Force. Some drainage and water management consultants, who were members of the ADMC, often attended Task Force meetings to keep up to date with the technology. In addition, representatives from several non-Government Organizations have attended TF meetings, such as the National Corn Grower's Association; Sand County Foundation; IN Drainage District Association; IA Drainage District Association; Gulf of Mexico Program; Lower Mississippi River Basin Sub-Committee on Hypoxia; National Association of Conservation Districts (NACD); The Fertilizer Institute; The Nature Conservancy (TNC); and Ducks Unlimited. From 2002-2009, Task Force meetings have been held in IA (3), OH (4), IL (2), IN (2), FL, MN (3), LA, and NC, for a total of 17 meetings.

ADMS Research Findings

On behalf of the Task Force, Dr. Wayne Skaggs (c/o NCSU) completed a summary of past research findings. This summary report emphasizes that "Drainage Water Management" includes conventional drainage, controlled drainage, and subirrigation. While the emphasis has been on subsurface drainage, drainage water management includes surface drainage as well. Over the years the terms "water table management", "water table control", "reversible drainage", and "controlled and reversible drainage" have been coined to describe drainage systems that have facilities for some level of management, as opposed to passive, conventional drainage systems. Recently the term "drainage water management" has been proposed as a descriptive and politically acceptable term that can be used to describe any and all combinations of the above practices.

The report supports the conclusion -- based largely on the research in Ohio, Illinois, North Carolina, Michigan, and Louisiana -- that drainage water management can effectively reduce water flow and nitrate-Nitrogen loading during the non-growing season by an annual average of 30 to 60 percent. Producers can also receive an economical benefit from reduced losses of

inputs. Moreover, by using additional drainage management during the growing season, producers can mitigate dry spells or drought by capturing more water within the soil profile, mitigating yield reductions by 10-15 bushels of corn per acre. For example, research results from a 4.5-year field study, comparing controlled drainage to other drainage treatments in Northwest Ohio, showed that controlled drainage treatment reduced drainage outflows to about 60 percent of conventional drainage flows and nitrate-nitrogen loadings by more than 45 percent compared to conventional drainage; see Fig. 2.

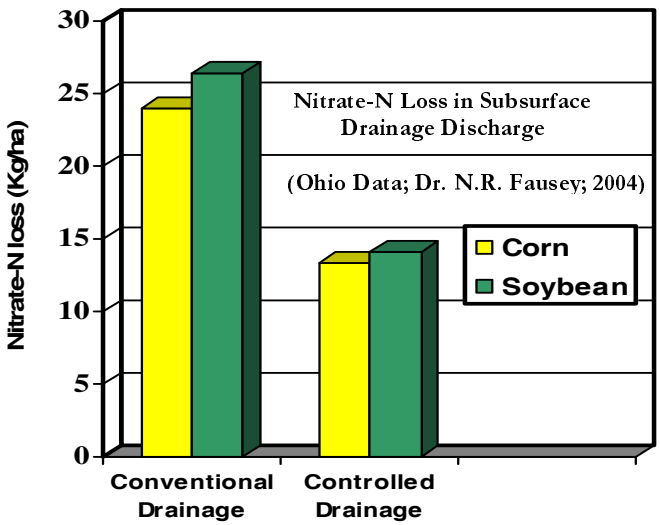

Fig. 2. Research Findings from Northwest Ohio

Field Implementation of Agricultural Drainage Management

Based on research findings documenting the water quality benefits of drainage water management, NRCS has provided funding for demonstrating the practice and further documenting benefits through the NRCS Conservation Innovation Grants Program (CIG) over the past several years. Six National CIG projects with almost $3 million in federal funds have been approved since 2004.

Technical and financial assistance has been made available to producers for implementing drainage water management through the Environmental Quality Incentives Program (EQIP) and the Conservation Security Program (CSP). Since 2004, approximately 56,000 acres have been planned and 23,000 acres implemented for drainage water management nationwide. Drainage water management practices have been planned on approximately 14,600 acres and applied on 6,700 acres within the 8-state focus area of the Task Force.

Challenges exist, however, in achieving widespread acceptance and adoption on the cropland potentially suitable for drainage water management. Producers have shown interest in drainage water management but mainly for the potential to increase yields that is not well documented. Technical capacity is limited for developing sound drainage water management plans – to help address this, Illinois NRCS offered an EQIP Ground and Surface Water Conservation Project in 2007 targeting development of drainage water management plans.

Recent ADMS Accomplishments

The Task Force worked with NRCS to develop a Fact Sheet for products and revised the Practice Standard 554, "Drainage Water Management," which highlights, in particular, the use of "control structures" that are placed in the main lines of subsurface drainage systems. The Fact Sheet points out that users need to consider drainage water management as part of conservation management system (CMS). Conservation practices such as drainage water management are normally implemented as part of a CMS that includes other practices such as nutrient management, riparian buffers, cover crops, filter strips, wetlands, etc. as needed to address identified natural resource concerns. Standards for the practices are available in the NRCS electronic Field Office Technical Guide (eFOTG; 2004): http://www.nrcs.usda.gov/Technical/Standards/nhcp.html

The Task Force has also developed a website on The Ohio State University computer system that contains the Charter, Action Plan, Goals and Objectives, Fact Sheet, and Flyer: http://www.ag.ohio-state.edu/~usdasdru/ADMS/ADMSindex.htm Other information such as an education and extension bulletins, recent summary of research findings, and linkages to other drainage water management conferences, activities, and meetings will be added to the website.

The Task Force organized its first technical session in 2004 entitled "*Drainage Water Management for the Midwest"* with a series of papers presented at the American Society of Agricultural Engineers (ASAE) **8th International Drainage Symposium**. The Task Force continues to plan, organize and participate in other conferences and symposiums that provide detailed engineering and scientific information on drainage water management practices and systems along with the latest status on Task Force projects and activities.

A recent research modeling/simulation accomplishment by Task Force members involved a preliminary evaluation of the potential water quality impact of applying drainage water management in an 8-state region of the Midwestern U.S. (Jaynes and Thorp, 2008; Thorp, et al. 2008). Their simulations were made with the hybrid model RZWQM-DSSAT,[3] to predict both conventional subsurface drainage and drainage water management performance in terms of hydrologic and nitrogen cycles over a 25-year period of historical weather at 48 locations across the 8-state region (MO, IA, MN, MI, WI, IL, IN, OH). They showed the DWM was suitable for about 7.2 million ha of cropland in the corn belt region. Their simulated average reduction in drain flow with DWM for the region was 151 mm/yr, and the regional reduction over the long term was predicted at 53%. This predicted reduction in nitrogen load down the Mississippi River System to the Gulf of Mexico was about 7% of the proposed 45% reduction by the year 2015 as recommended by the EPA National Research Council (NRC).[4] They estimated costs and indicated that the DWM practice was cost effective for reducing N-load at $1.53/kg-N/yr, and this was less than for other practices or methods compared (Jaynes and Thorp, 2008). The predicted regional reduction in nitrate-nitrogen losses through the drains was 18.9 kg-N/ha/yr, and the regional percent reduction over the long term was 51% (Thorp et al., 2008).

[3] The RZWQM-DDSAT hybrid model combines the Root Zone Water Quality Model with components of the Decision Support Systems for Agrotechnology Transfer model (Ma et al., 2005; Ma et al., 2006).
[4] Recent EPA reports indicate the year 2015 may no longer be realistic to reach the 45% reduction target goal.

Joint ADMC and ADMSTF Projects and Future Activities

NRCS developed a Drainage Water Management (DWM) Practice Standard 544 and conservation practice standards for the Midwestern States to provide cost-sharing assistance through NRCS to farmer's who implement DWM on their farms. When farmers began to ask more questions about how well DWM would work on their farms and in their soils, the ADMC and partnering members of the ADMSTF in the 5 States of IA, MN, IL, IN, and OH applied for and was granted a $1 million NRCS Conservation Innovation (CIG) Grant to install and conduct DWM demonstration projects on paired field-size demonstration sites in each of the 5 States. This CIG project is now in its third year of the 3-year grant period, and data collected will demonstrate the effectiveness of the DWM Systems for reducing nitrate loss is drainage outflows, reducing drainage volumes, and effects on crop yields. Rainfall is measured (monitored) at all demonstration sites and water table depth monitored at each DWM site. All sites have a satellite link that allows downloading of site data to remote PC equipment. Field Days and Workshops on DWM are conducted at each of these demonstration sites for farmers, contractors, consultants, State and Federal government agencies, and the General Public. Future endeavors to be undertaken by the Task Force will include promoting complementary conservation practices that can be combined with DWM, such as winter cover crops to further reduce the potential of nitrate loss from the cropland sites following annual crop harvest, and improvements in fertilizer application methods or fertility management practices. Other projects have evaluated the reduction in nitrate in subsurface drainage discharge by biofilters, saturated buffers, recycling of drainage water, and diversion of the drainage waters through wetland resource areas to reduce nitrate-load.

The Task Force is concentrating first on transferring drainage management technologies in demonstration projects in areas with suitable tile drainage systems. As these areas are identified, the Task Force will work with local sponsors and producers to develop and implement economically feasible research and demonstration projects. These will include the use of other management practices in combination with multiple drainages management practices. To further refine the existing technology, data will be gathered from these areas by conducting research and monitoring at the sub-watershed scale. A part of the project design would be to create the monitoring strategy for each project to assess water quality, such as reducing nonpoint source pollution; agronomic affects, such as yield changes and other crop growth attributes; water conservation effects for varying management strategies; soil quality affects for varying management strategies; and economic attributes, such as economic return on investment from drainage water management practices and systems. The researchers will collaborate with the landowner and local drainage district personnel to ensure the best-designed project and that no off-site problems with water drainage would develop.

The Task Force also is working to increase technical assistance, education, and extension activities. For example, ARS technical specialists are being asked to identify the best locations in the states on which to focus drainage water management projects identify pollutants to address, identify opportunities for wildlife habitat enhancement, and provide information to landowners. The Task Force plans to work with NRCS to draft practice standards at the state level for the projects. The Task Force is also interested in opportunities to cooperate with education and extension programs to educate landowners, conservation groups, and local and

state farm groups on drainage water management options that could be deployed in certain areas across a particular state. This will be instrumental in building support for the effort as well as in identifying potential landowning participants.

DENITRIFYING BIOREACTORS FOR TREATMENT OF TILE DRAINAGE

Laura E. Christianson[1], Alok Bhandari[1], Matthew H. Helmers[1] and Martin St. Clair[2]
[1]Department of Agricultural & Biosystems Engineering, Iowa State University, Ames, IA
[2]Department of Chemistry, Coe College, Cedar Rapids, IA

Abstract

Much of the hypoxia in the Gulf of Mexico has been attributed to agricultural nonpoint pollution sources in the Midwestern states. There is, therefore, a critical need to develop practical and cost effective methods to reduce nitrate loadings from these areas. As the hypoxic zone is thought to be larger this year than ever before, the time is ripe for new technologies to reduce nutrient loads in the Mississippi River. Denitrifying drainage bioreactors can provide cost-effective treatment of tile water at the field scale while requiring minimal system maintenance. These bioreactors consist of a trench filled with an available carbon source (usually woodchips) that is readily colonized by bacteria and fungi capable of utilizing nitrate as an electron acceptor. A handful of such bioreactors have been installed in the US Midwest and have shown good nitrate removal. This poster describes the design, field installation, and cost estimates of full-scale denitrifying bioreactors.

Background

The history of artificial agricultural drainage in the US middle west began in the 1800's and has grown to include more than 20.8 x 10^6 ha in Midwestern states (Dinnes et al. 2002). Increased use of fertilizers over the past 60 years has resulted in elevated concentrations of nitrate in agricultural drainage, often above the drinking water limit (Baker et al. 1975; Kalita et al. ; Mirek 1999) with annual nitrate loadings to surface waters of tens of kg per ha (Jaynes et al. 2008). Nitrate from agricultural sources has been identified as a major source of non-point source pollution, and nitrate loadings in the Mississippi River are key causes of water quality impairment in the Gulf of Mexico (Rabalais et al. 1996) with the hypoxic zone in the Gulf expected to be the second largest this year (NOAA 2008).

The magnitude and intensity of agricultural nitrate losses depends upon many management factors such as tillage (Kanwar 2006), cropping (Kanwar 2006; Mirek 1999), fertilizer type (Kanwar 2006), and tile drain spacing (Kladivko et al. 2004). Several options have been proposed to reduce nitrate loadings to surface waters including more soil testing, abandoning drainage systems, increased use of wetlands, better crop rotations, increased use of cover crops, and better fertilizer application rate, placement and timing (Dinnes et al. 2002; Jaynes et al. 2004). However, regardless of better management strategies, nitrate concentrations in drainage waters can still exceed the drinking water standard (Baker et al., 1975), because in addition to management factors, precipitation timing and organic matter mineralization can affect nitrate loss (Randall and Goss 2001; Kanwar 2006; Kladivko et al. 2004).

In watersheds where agriculture is a major land use, high nitrate mass loadings to surface waters often result. For example, in the Embarrass River watershed in Illinois where 70-85% of the land is cropped, annual total nitrogen losses were 39 kg N/ha (Kovacic et al. 2000). Jaynes et al. (1999) documented that nitrate losses in an Iowan agricultural watershed ranged from 4-66 kg N per ha annually. Similarly, Kalita et al. (2006) found that Illinois drainage water nitrate losses ranged from 23-33 kg NO_3-N/ha/yr with average concentrations (range of 15-20 mg/L) above the drinking water limit. Such nitrate losses have been documented for several decades, with early work by Baker et al. (1975) showing that the nitrate nitrogen concentrations in drainage water ranged from 2.3-44.2 mg/L with an average of 21 mg/L. While nitrate concentrations from individual drains are relatively consistent on a day-to-day basis (Baker et al. 1975), nitrate concentrations can vary by season as Mirek (1999) found that drainage nitrate-nitrogen concentrations were highest in the spring and lowest in the summer (spring: 14.7 mg/L, summer: 9.8 mg/L, fall: 11.5 mg/L, winter: 11.7 mg/L). Note that drainage volumes also vary by season which has implications for mass loadings. Mirek (1999) documented the greatest drain flow volumes during the spring and the least drain flow during the summer.

Denitrifying Bioreactor Technology.

Although denitrification, or nitrate-removal, occurs naturally in soil, the rapid transport of drainage water in tile drains decreases the available time for the nitrate to be depleted before the water is discharged into a receiving stream (Kellman 2005). Edge-of-field treatment systems can be designed to intercept tile drainage and remove nitrate biologically by the action of soil microorganisms. Biological denitrification requires the presence of suitable bacteria, nitrate, a carbon or energy source, and the absence of oxygen (Korom 1992). In the simplest terms, denitrifiers "breathe" the nitrate and "feed on" the carbon source.

Denitrifying bioreactors such as those filled with woodchips ('woodchip bioreactors'), provide a new option for nitrate removal from agricultural drainage. This can be accomplished by directing tile flow into an underground trench containing woodchips as a carbon source for denitrification activity. Denitrifying bioreactors for agricultural drainage are based loosely on the concept of flow-through denitrification systems proposed for treatment of septic effluent (Robertson and Cherry 1995) and for groundwater remediation (Schipper and Vojvodic-Vukovic 2000; Schipper et al. 2005). Jaynes et al. (2004) compared various nitrate reduction strategies including deep tiles, denitrification walls, phytoremediation, and usage of a cover crop and observed that the denitrification wall had the highest nitrate removal with no yield losses or land taken out of production. Bioreactors occupy a land area that is typically $1/10^{th}$ that of wetlands (Kovacic et al. 2000). Van Driel et al. (2006) recently showed that bioreactor nitrate removal rates could be an order of magnitude higher than those associated with wetlands.

The first bioreactor for agricultural drainage was installed in Ontario, Canada and consisted of three 200 L barrel reactors that were partially buried in a stream bank 100 m from a tile outlet. Influent nitrate-nitrogen concentrations (2-6 mg/L) were reduced to nearly zero inside the organic matter and sand filled barrels (Blowes et al. 1994). Early research on denitrifying bioreactors has also been conducted at the University of Illinois (Appleford et al. 2008; Cooke et al. 2001; Wildman 2001) and the USDA-ARS National Soil Tilth Lab in Ames, Iowa (Jaynes et al. 2008; Moorman 2008, personal communication).

The USDA National Soil Tilth Lab bioreactors have been modeled most closely after denitrification wall research with their design consisting of flow-through woodchip walls

adjacent to tile lines. Their wall treatment resulted in a nitrate reduction of 55% (results averaged over five years) with no detrimental effect on crop yields (Jaynes et al. 2008). The placement of these walls on each side of the tile line, however, limits the practicality of this design for widespread field implementation. The Soil Tilth Lab has also conducted laboratory scale bioreactor studies involving carbon source for the bioreactor (Greenan et al. 2006) and production of nitrous oxide (Moorman 2008, personal communication).

The University of Illinois has done substantial work on bioreactors. Rodrigue (2004), documented that a bioreactor (0.9 m wide and 1 m deep below 0.97 m soil; drainage area: 13 acres) experienced variations in effluent nitrate most likely due to fluctuations in microbial activity. Effluent nitrate concentrations exceeded 10 mg/L nitrate-N, but only after large storm events (Rodrigue 2004). Wildman (2001) reported that a field reactor was only $1/8^{th}$ of the required size but still achieved 100% nitrate reduction. Other bioreactors deployed in Illinois have been successful in removing 50-60% of nitrate concentration in drainage waters (Appleford et al. 2008).

Bioreactor Design

It is thought that designing a denitrification bioreactor for eight to ten hours of retention time (RT) is sufficient for denitrification of most agricultural drainage waters in Iowa (Van Driel et al. 2006). Retention periods that are too long will encourage sulfate reduction and RTs which are too short will result in insufficient denitrification. Another major consideration is that it is impractical to design a bioreactor to treat 100% of agricultural drainage flow throughout the entire drainage season. To do so would require a bioreactor of uneconomical proportions. Van Driel et al. (2006) has argued that designing a reactor to handle peak flows is not cost-effective while designing for base flows that occur during the growing season is most appropriate. Therefore, it is thought that designing these systems to treat approximately 20% of the peak flow will result in the treatment of the majority (approximately 70%) of total annual flow. In this case, the peak volume is estimated to be the drainage design coefficient for which many drainage systems in Iowa have been designed, usually about 1.3 cm/day (0.5 inches/day).

Based on these considerations, designers must find a balance between the RT, percentage of peak flow to be treated and design volume. Ideally, an RT of eight hours with treatment of 20% of peak flow will result in a volume that is not to big so as to be impractical. The porosity, hydraulic conductivity, and head gradient across the bioreactor all affect these values.

A special note must be made for the distinction between the volume of the bioreactor versus the volume of carbon needed for denitrification to be sustained for a significant length of time (years to decades). The amount of carbon needed is determined by the stoichiometry of denitrification; it is well established that about 1 kg of carbon is needed to denitrify about 1 kg of nitrate (Blowes et al. 1994; Robertson and Cherry 1995). The total volume of the bioreactor based on the retention time and percent of peak flow is usually far more than the amount of carbon needed for actual denitrification. Because the carbon source in denitrifiers, usually woodchips, may be difficult to obtain and expensive in large quantities, the idea naturally follows that inert materials (gravel, etc.) may be mixed in with the carbon source to make up the required volume in the bioreactor excavation while still allowing the sufficient carbon (Wildman 2001).

Recent Bioreactor Installations

Within Iowa, a handful of such bioreactors have been installed to treat a variety of drainage areas under differing *in situ* conditions (table 1). The oldest, a bioreactor near Pekin, Iowa, was installed by Iowa State University and the Iowa Department of Agriculture and Land Stewardship in 2004. This bioreactor is 0.5m x 30.5m (1.5ft x100 ft) and treats drainage from 1.2 ha (3 ac). Another bioreactor that has been operating for several years is the bioreactor installed in the Lime Creek watershed in Buchanan County, Iowa by a local watershed group for approximately $2,050. This bioreactor is 1.5m x 12.2m (5ft x 40ft) with a drainage treatment area of approximately 40.5 ha (100 ac). The first year of data indicated nitrate reduction increased within the bioreactor over the course of the summer months (May through September) (figure 1). In figures 1 and 2, “near bioreactor outlet” refers to a sampling well within the bioreactor approximately 5 m from the outlet. Outlet concentrations in this case

were elevated, most likely due to backflow into the outlet control structure from bypass flow. Sulfate reduction follows this same temporal pattern within the bioreactor meaning that sulfate reducing bacteria are utilizing the carbon source in addition to the denitrifiers especially in late summer (figure 2). This additional process may possibly decrease the longevity of this bioreactor.

Table 1: Denitrification bioreactors in Iowa

Location	Funding Organization	Length	Width	Depth	Drainage Treatment Area
Pekin, Iowa	Iowa State University and Iowa Department of Ag and Land Stewardship	30.5 m	0.5 m	1.2 m	1.2 ha
Buchanan County, Iowa	Local watershed group	12.2 m	1.5 m	1.2 m	40.5 ha
Central Iowa	Iowa Soybean Association	15.2 m	7.6 m	Approx. 1.8 m	16.2 ha

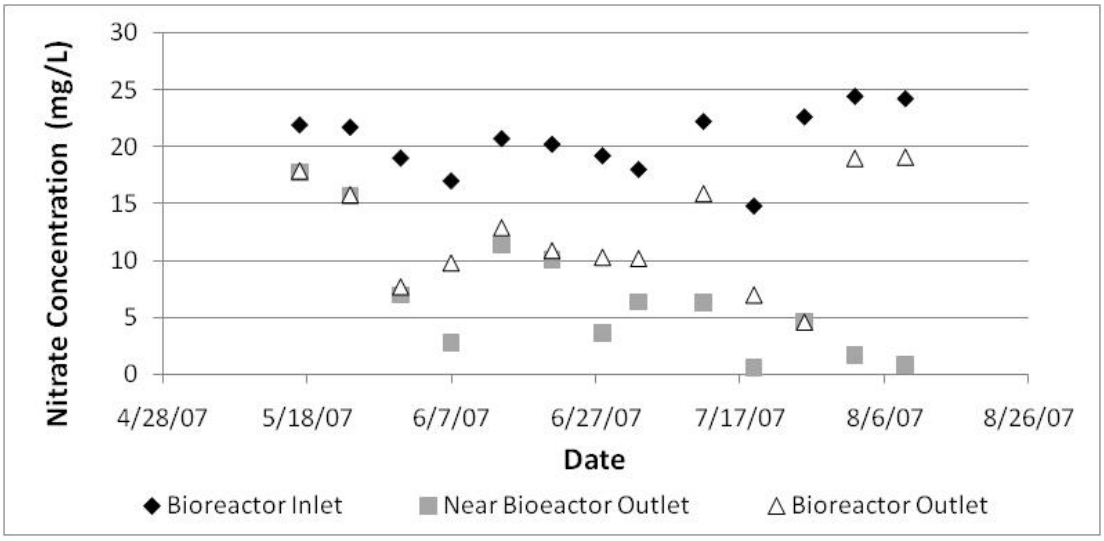

Figure 1: Lime Creek nitrate concentrations throughout bioreactor for summer 2007

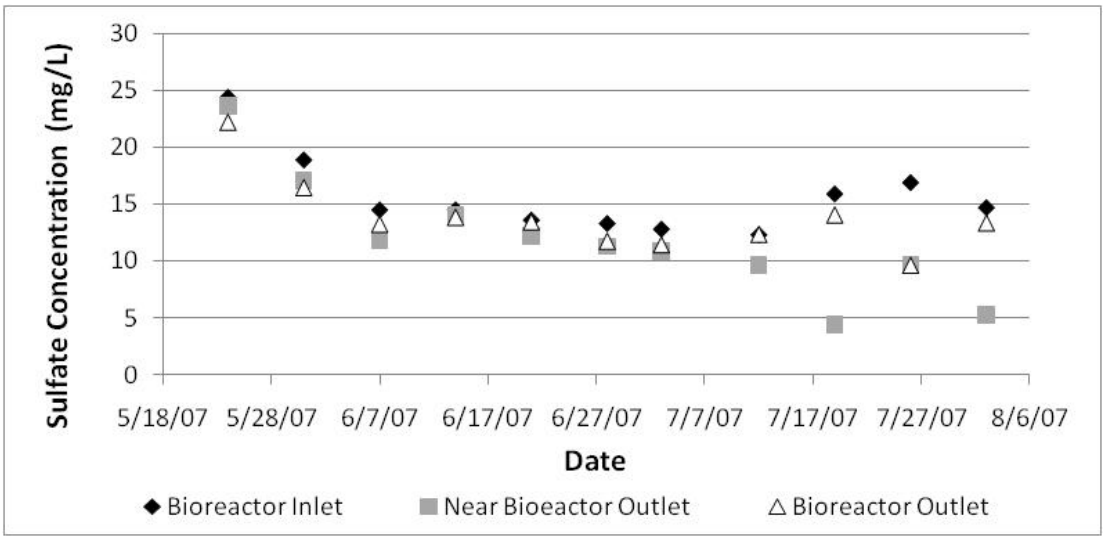

Figure 2: Lime Creek sulfate concentrations throughout bioreactor for summer 2007

The Iowa Soybean Association organized and funded the most recent bioreactor installation of a 7.6m x 15.2m (25ft x 50ft) rectangular bioreactor in central Iowa. Preliminary data has shown initial losses of organics in the effluent. Many researchers have documented these flushing losses especially during start-up (Diaz et al. 2003; Robertson and Cherry 1995; Vogan 1993; Volokita et al. 1996). The cost of this bioreactor was estimated at approximately $8000 (Iowa Soybean Association 2008, personal communication). Capital cost per unit drainage area for this bioreactor was $495/ha ($200/ac). Approximately half of the woody material obtained for this bioreactor was free and consisted of shredded woody debris provided by a local city government. The other half of woody material included conventional woodchips (approximately 76.5 m^3 or 100yd^3) bought for $975 including transportation costs.

One of the obstacles for bioreactor installation has been the ability to locate and hire a contractor who has an opening in his schedule during a window when soil conditions allow for excavation. Another hurdle has been encountered in locating enough woodchips. It is important to have access to a woodchip supplier who is both close in proximity and can provide reasonably priced woodchips. Moreover, the quality of woodchips should be consistent between batches so as to allow for some consistency between loads. Lastly, regarding implementation, the location of the bioreactor at the chosen site is important. An additional

denitrification bioreactor not mentioned above was located in a very sandy soil. Because of this, while there is significant inflow, there is very little outflow. It is thought that it would have been better to install a plastic liner in this bioreactor to attempt to reduce the leaching out of this system.

Conclusions

Denitrification bioreactors in Iowa and the Midwest have shown good potential to be an additional technology to add to the existing slate of nitrate reduction options such as wetlands and in-field management. With further research into the hydraulic and biological processes that occur within bioreactors, it is believed their performance can be enhanced. Though challenges remain for design and installation, increased understanding of the basic science of these systems combined with increased experience of *in situ* applications will help make this a viable option for many landowners.

Abstract

Subsurface drainage systems installed throughout much of north central region of Iowa have provided substantial crop production benefits. However, most of these systems were installed in the early 1900's and as such they are reaching their design life. With the aging infrastructure of these systems, better economic conditions, and the potential for more financial gains for better drainage; there will need to be significant rehabilitation that occurs in the future. This paper will discuss some of what is known about the existing infrastructure in this area, some potential opportunities for future redesign, and potential economic returns of drainage district redesign. The future redesign would need to include environmental as well as economic considerations and might include the integration of drainage and wetland systems. While this paper focuses on a specific location, the concepts should have relevance to many areas where existing drainage infrastructure is aging.

Keywords. Subsurface drainage; drainage design

Introduction

Subsurface drainage is a common water management strategy for agricultural productivity in areas with poorly drained soils and seasonal high water tables. This is especially the case in the north central region of Iowa. This is an area where local drainage districts were formed in the early 1900's to provide outlets to landowners in flat poorly drained areas with no natural outlet on their property. In many areas the existing drainage outlet or main may be significantly undersized such that the water cannot be removed quickly enough to minimize crop damage even if there is adequate field drainage installed. Also, these systems are nearing or exceeding their design life, so there will likely be significant maintenance, rehabilitation, or redesign of these systems in the future. This comes at a time when there is the potential for financial gains with better drainage. This paper discusses some of what is known about the existing infrastructure in this area, some potential opportunities for future redesign, and potential economic returns of drainage district redesign.

Background

Within Iowa there are approximately 3.6 million ha that have been artificially drained (Baker et al., 2004). About two-thirds of this drainage area is within organized drainage districts. Based on the soil conditions (mineral) and field crops grown in this area along with the need for surface inlets in most cases, the modern design standards would call for a drainage coefficient of between 1.27 to 2.54 cm/day (1/2 to 1 inch/day). A 1980's study (Schult et al., 1981) investigated drainage conditions in parts or all of 10 counties studied in north central Iowa. Of an estimated 395,098 ha (975,551 acres) in the study area, 76,031 ha (187,732 acres) were considered to be naturally well drained soils needing no artificial drainage. On the remaining 319,067 ha, 273,542 ha (675,414 acres) were estimated to have a high level of field drainage (drainage coefficient of at least 1.27 cm/day), 31,353 ha (77,415 acres) were estimated to be at an intermediate level of field drainage (drainage coefficient of at least 0.95 cm/day), and 14,171 ha (34,990 acres) were estimated to have no tile drainage. While the majority of the area was estimated to have adequate field drainage, nearly all the area was estimated to have inadequate outlet capacity through the drainage main. Of the 319,067 ha (787,819 acres) that were potentially drainable in the study area, approximately 95% of the area (302,952 ha) was estimated to have a drainage district outlet capacity that was less than 0.95 cm/day. So, while in most cases adequate field drainage existed, the actual drainage of most fields was estimated to be constrained by the drainage district system.

Based on this 1980's study, they estimated based on surveys of farmers that within the study area 68% of the maximum yield was being realized but if all drainage district outlets were sized to at least a 0.95 cm/day drainage coefficient 90% of the maximum yield could be realized (Kanwar et al., 1983). While it has been estimated that significant yield improvement could result from improved outlet capacity of these drainage district systems there have been few upgrades to the design capacity. Drain outlet improvements have been hampered by poor economic conditions as well as a requirement for the majority of landowners to approve additional drainage taxes to pay for improved systems. Improvements in grain commodity prices may increase the interest in drainage main improvement and it is important to understand potential impacts of drainage main rehabilitation on crop yields and water flow.

While the 1980's study provides a basis for evaluating the impacts of drainage main improvement, we used a drainage model, DRAINMOD, to evaluate the potential impacts of drainage main design. The field scale deterministic hydrologic model, DRAINMOD (Skaggs, 1978) simulates a soil-water regime of surface and subsurface drainage systems, and predicts surface runoff, infiltration, evapotranspiration, subsurface drainage and seepage (vertical and lateral) from subsurface drained landscapes. The daily precipitation, maximum and minimum temperature for a period from 1945 to 2004 (Fig. 1) were used from the Humboldt weather station, located in Humboldt County, IA. The average monthly temperature varied from -9°C in January to 23°C in July. The average monthly precipitation varied from 20 mm in January to 120 mm in June with an average annual precipitation of 785 mm. The rest of the input parameters such as soil, crop, and trafficability parameters were the same as

summarized by Singh et al. (2006). For drainage system design, a drain spacing of 24 m was used which is consistent with recommendations for many soils in north central Iowa (Anonymous, 1987) and the drainage coefficient was varied to evaluate the impact of drainage outlet design on water flow and crop production on a field-scale. Using the crop production estimates, an example county in north central Iowa was used to evaluate the potential impacts of drainage redesign on crop production. This example county had approximately 101,250 ha (250,000 acres) in drainage districts with an average drainage capacity of 0.46 cm/day.

Results and Discussion

Based on the DRAINMOD simulations, as expected, average annual subsurface drainage over the 60 year simulation period is predicted to increase as drainage coefficient increases and, conversely, as drainage coefficient increases surface water runoff is predicted to decrease (Figure 1). Potential increases in subsurface drainage would have water quality implications since increased subsurface drainage would be expected to increase the export of water soluble contaminants with nitrate-nitrogen of particular concern. However, decreased surface water runoff would be expected to decrease export of those contaminants most closely associated with sediment export (e.g., phosphorus, pesticides, and bacteria).

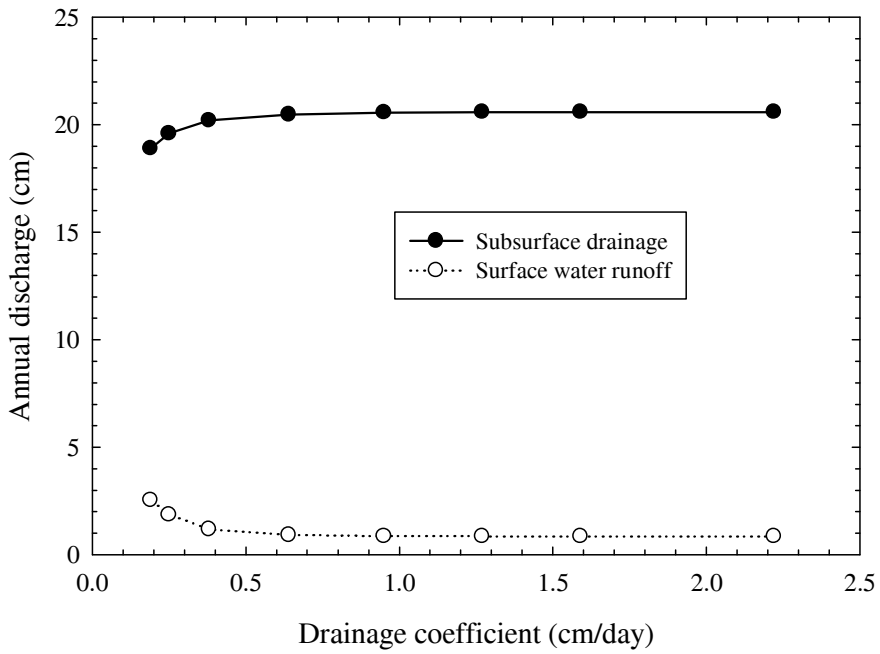

Figure 1. Predicted impact of drainage outlet coefficient on surface runoff and subsurface drainage.

Also, as expected, increases in drainage coefficient is expected to have a positive impact on crop production with average predicted relative yield increasing from about 87% at a drainage coefficient of 0.46 cm/day to a relative yield of about 97% at a drainage coefficient of 0.95 cm/day (Figure 2). Using the predicted relative yield values shown in Figure 2 along with the drainage capacity estimations for the

example county, the overall yield increase of improving the drainage from existing conditions to a drainage coefficient of 1.27 cm/day was estimated to be 7.7%. This value assumes that well-drained soils would not benefit from improved outlet capacity and that drainage districts with a very low drainage coefficient would have disproportionate benefits. Considering a potential 7.7% increase in yield for both corn and soybeans, a base corn yield of 11,915 kg/ha (190 bushels/acre) and a base soybean yield of 3,695 kg/ha (55 bushels/acre), and 65% corn area with 35% soybean area; drainage redesign in this example county (101,250 ha) would be predicted to provide an annual increase of 63.6 million kg (2.5 million bushels of corn) and 10.6 million kg (0.39 million bushels) of soybeans.

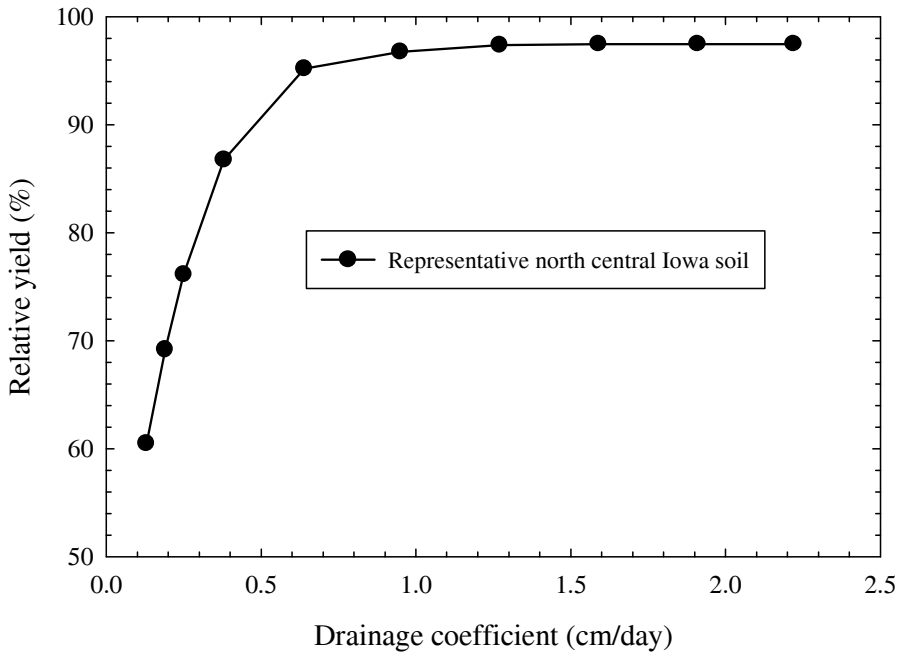

Figure 2. Predicted impact of drainage outlet coefficient on relative crop yield.

An additional factor to consider in upgrading the outlet capacity is the possibility for improved drainage in farmed wetland areas where farmed wetlands are partially drained wetlands that may contain some tile and can often be farmed. However, the degree of drainage in continuously cropped farmed wetlands cannot be improved beyond what it was in 1985, when Swampbuster took effect in the United States. So, while improving the outlet capacity may provide increased crop production for the majority of the drainage area and potentially reduce surface runoff there could be potential concern with improved drainage of continuously cropped farmed wetlands in addition to nitrate loss. Overall, the current situation results in poor drainage conditions for the prior converted cropland, and relatively unproductive farmed wetlands that are continuously farmed with little value as cropland or as wetland.

A potential strategy to mitigate concerns regarding drainage and wetland protection would be to integrate nitrate-removal wetlands into the redesigned drainage systems. In this type of integrated system, the water from the drainage district would be routed

through a wetland prior to release to a downstream waterbody. Using this type of integrated strategy, wetlands would be specifically sited to capture and treat drainage water and these wetlands would also provide important ecological functions on the landscape while providing a better outlet condition for prior converted cropland.

Conclusions

Subsurface drainage is essential for crop production in north central Iowa but currently many of the systems are not optimally designed relative to crop production. Many of the systems have a drainage coefficient that is well below the recommended design standards and the systems are likely reaching the end of their design life. So, with recent increased commodity prices there may be renewed interest in drainage outlet improvements. As discussed, a redesign of the drainage systems could have significant positive impacts on crop production and there is the potential to reduce surface water runoff. However, the potential increase in nitrate-nitrogen export from improved drainage would need to be considered in this redesign and nitrate-removal wetlands could provide an opportunity for treating the drainage water before discharging to downstream waters. In addition, these nitrate-removal wetlands may provide improved ecological functioning compared to continuously cropped farmed wetlands that are likely present in many of these drainage areas of north central Iowa.

Alfalfa reference ET from a weighing lysimeter and estimates from the ASCE Standardized Reference ET Equation in the Arkansas Valley of Colorado

Allan Andales[1], Dale Straw[2], Thomas Ley[2], Abdel Berrada[1]
[1] Department of Soil and Crop Sciences, Colorado State University, Fort Collins, CO 80523-1170; email: Allan.Andales@colostate.edu
[2]Colorado Division of Water Resources

ABSTRACT

The American Society of Civil Engineers (ASCE) standardized reference ET equation has been prescribed for use in the Arkansas Valley of Colorado for estimation of reference evapotranspiration (ET) and subsequent estimation of crop consumptive use. In 2006, a precision weighing lysimeter (mechanical lever scale – load cell combination) was installed at Rocky Ford, Colorado to verify the performance and predictive accuracy of the ASCE standardized ET equation for calculating alfalfa reference (tall reference) ET values. The undisturbed soil monolith is contained in a tank that is 3 m x 3 m in area and 2.4 m deep. The standard deviation of the weight measurements was less than 0.02%, based on calibration of the load cell with known weights. Alfalfa was established on the lysimeter and surrounding field (4 ha) in 2007. Instrumentation for micrometeorological measurements as well as soil temperature, soil heat flux, and soil moisture measurements were installed. Calculated ET from the ASCE standardized equation (ET_{rs}) and ET measured from the lysimeter (ET_r) were compared during periods in the 2008 season when the alfalfa crop on the lysimeter and surrounding field were considered to be in reference conditions. Calculated ET_{rs} agreed well with ET_r from the lysimeter when wind conditions were relatively calm and vapor pressure was relatively stable. However, ET_{rs} tended to be greater than ET_r under advective conditions. Also, calculated ET_{rs} was notably less than ET_r from the lysimeter on a number of days late in the growing season. The underlying causes of these differences need further investigation.

INTRODUCTION

Accurate estimates of crop consumptive use (evapotranspiration) are needed to effectively manage irrigation in the Arkansas River Basin of Colorado and to maintain compliance with the Arkansas River compact with Kansas. The American Society of Civil Engineers (ASCE) standardized Penman-Monteith equation (PME) (Allen et al., 2005) has been approved by the U.S. Supreme Court as the method of determining evapotranspiration (ET) for compact compliance, but has not been tested in the Arkansas Basin. A validated ASCE-PME can be a widely-applicable tool for irrigation management in the Arkansas River Basin of Colorado.

An accurate way to quantify actual ET rates from a crop is to use a precision weighing lysimeter that directly measures ET based on changes in weight of an intact soil monolith containing an actively growing crop. In 2006, construction of a precision weighing lysimeter was completed at Rocky Ford in the Arkansas River Basin of Colorado. One purpose of the lysimeter is to provide accurate measurements of crop ET for the evaluation of the ASCE-PME for conditions in the Arkansas River Basin. The objective of this paper is to present a preliminary evaluation of the performance of the ASCE-PME compared to hourly alfalfa ET measurements from the weighing lysimeter in 2008.

DESCRIPTION OF THE LYSIMETER

The lysimeter is located at the Arkansas Valley Research Center (38° 2´ 17.30´´ latitude and 103° 41´ 17.60´´ longitude), approximately 3.2 kilometers east of Rocky Ford in Otero County, Colorado (NW1/4 Sec 21, T23S, R 56W). The elevation at the site is approximately 1,274 m above mean sea level. The soil type is Rocky Ford; coarse-loamy, mixed, superactive, mesic Ardic Argiustoll.

The long-term average annual precipitation at the site is 300 mm, with May through August having the highest rainfall. The total average annual snowfall is 589 mm. The annual average minimum temperature is 2.4 °C and the annual average maximum temperature is 21 °C. The last spring frost (0.3 °C) occurs on or before May 1 and the first fall frost on or before October 5 in 50% of the years; thus the average length of the growing season for warm-season crops like corn is 158 days.

The crop lysimeter was patterned after the lysimeters at Bushland, Texas operated by USDA-Agricultural Research Service. Marek et al. (1988) provide details of the lysimeter design. The lysimeter consists of an inner tank with dimensions of 3.0 m x 3.0 m surface area x 2.4 m depth and an outer containment tank. Installation and calibration of the crop lysimeter was completed in 2006. The inner tank was filled with undisturbed soil (soil monolith) from the same field where the lysimeter is located (Fig. 1). The soil tank moves freely within the outer tank and the top edges of the two are separated by a few millimeters. The chamber between the two tanks houses the weighing mechanism, the drainage tanks, data loggers and has standing room for half-a-dozen people. The weighing mechanism consists of a mechanical lever scale-load cell combination (mV V^{-1} output; 0.02% accuracy). Based on calibration of the load cell to measure the weight of the inner tank containing the soil monolith, a unit change in load output (1 mV V^{-1}) is equivalent to 76 mm of water. Thus, changes in load cell output are simply multiplied by 76 to obtain the amount of water lost through ET or amounts of water gained through precipitation or irrigation. Water that percolates through the soil monolith is collected in two drainage tanks suspended from the scale frame that supports the soil tank, so that there is no overall weight change registered by the scale as water drains into the tanks. One tank collects water from the internal portion of the monolith and the other tank collects water from the perimeter of the monolith. Berrada et al. (2008) provide details on the installation, calibration, and management of the crop lysimeter.

Figure 1. The inner tank plus soil being lowered inside the containment tank of the crop lysimeter. Photo taken by Michael Bartolo.

The crop lysimeter and surrounding field were seeded with alfalfa (Genoa variety) on 9 August 2007. The dimensions of the surrounding field are 158.5 m x 256.1 m (4.06 ha). Instrumentation for measuring rainfall, wind speed and direction, air temperature, humidity, incoming and reflected radiation, photosynthetically active radiation, and canopy temperature were installed above the lysimeter (Fig. 2). Soil temperature sensors were installed at 0.01 m, 0.04 m, 0.5 m, 1.0 m, and 2.0 m below the soil surface of the monolith. Heat flux plates were also installed 0.1 m below the soil surface. Two 3.8-cm diameter electromechanical steel tubes (EMT) were installed in the monolith to monitor soil water content with a neutron probe. Also, soil temperature sensors and neutron probe access tubes were installed adjacent to the lysimeter. The lysimeter load cell and sensor outputs are logged by a Campbell Scientific CR-7 data logger mounted in the underground chamber. Detailed descriptions of the sensors and their placement were given by Berrada et al. (2008).

Figure 2. View of the crop lysimeter looking to the east. The manhole for accessing the data logger, weighing mechanism, and drainage tanks is on the left; and micrometeorological sensors are mounted above the lysimeter.

METHODS

The lysimeter load cell output was recorded every 10 seconds throughout the 2008 growing season. Fifteen-minute averages of the load cell output were used in the calculation of ET. The difference between beginning and ending load cell outputs (mV V^{-1}) on each hour were multiplied by 76 mm mV^{-1} V to obtain hourly rates of ET (mm h^{-1}).

The alfalfa crop on the lysimeter and the surrounding field were managed similarly. Both the lysimeter and surrounding field were furrow-irrigated at the same times (Table 1). Furrow irrigation of the lysimeter was done manually with the use of a metered hose to approximate water application rates on the surrounding field. Furrow spacing was 0.76 m, with 4 furrows on the lysimeter.

Table 1. Irrigation dates and amounts for the lysimeter (4/1/2008 – 9/1/08).

Date	Net irrigation amount (mm)
April 2	114
May 12	119
June 20	121
July 1	165
July 25	164
August 4	146
Total	829

Alfalfa on the lysimeter and surrounding field was harvested three times: 6/11/2008; 7/21/2008; 9/1/2008. After each cutting, alfalfa canopy height was about 0.08 m, which was significantly below the standard reference height of 0.50 cm specified by the ASCE-PME. For purposes of comparing ET_r from the lysimeter and ET_{rs} from the ASCE-PME, we assumed that the alfalfa crop was approximately at reference conditions when the observed height was greater than 0.30 m. The alfalfa height remained below 0.30 m for about 2 to 3 weeks after each harvest. We assumed that ET_r from the lysimeter was comparable to the ASCE-PME ET_{rs} values during the following periods, when alfalfa crop height was at least 0.30 m: 4/30/2008 – 6/10/2008; 6/30/2008 – 7/20/2008; and 8/3/2008 – 8/31/2008.

The hourly version of the ASCE-PME (Allen et al., 2005) was used to calculate alfalfa reference ET_{rs} using hourly averaged micrometeorological data recorded directly above the lysimeter. The hourly ASCE-PME is given below.

$$ET_{rs} = \frac{0.408\Delta(R_n - G) + \gamma \frac{C_n}{T + 273} u_2 (e_s - e_s)}{\Delta + \gamma(1 + C_d u_2)}$$

where:

ET_{rs} = standardized reference crop evapotranspiration for tall surfaces (mm h^{-1}),

R_n = calculated net radiation at the crop surface (MJ m^{-2} h^{-1}),

G = soil heat flux density at the soil surface (MJ m^{-2} h^{-1}),

T = mean hourly air temperature at 1.5 to 2.5-m height (°C),

u_2 = mean hourly wind speed at 2-m height (m s^{-1}),

e_s = saturation vapor pressure at 1.5 to 2.5-m height (kPa),
e_a = mean actual vapor pressure at 1.5 to 2.5-m height (kPa),
Δ = slope of the saturation vapor pressure-temperature curve (kPa $°C^{-1}$),
γ = psychrometric constant (kPa $°C^{-1}$),
C_n = 66; numerator constant for tall reference and hourly time step (K mm s^3 Mg^{-1} h^{-1}) and C_d = 0.25 (daytime), 1.7 (nighttime); denominator constants for tall reference and hourly time step (s m^{-1}).
Units for the 0.408 coefficient are m^2 mm MJ^{-1}.

Hourly ET_{rs} values calculated from the ASCE-PME were compared to hourly ET_r values measured from the lysimeter on days when alfalfa crop height was at least 0.30 m. Agreement between ET_{rs} and ET_r values were evaluated with the following statistics:

- RE = relative error of mean (%); zero is best
- RMSE = root mean square error (mm); average error of hourly ET_{rs}
- d = index of agreement (0 – 1; see Willmott, 1981); 1 means perfect agreement between ET_{rs} and ET_r
- p-value = probability of ($T \leq t$) from a 2-tailed t-test comparing means; p-value > 0.05 indicates mean ET_{rs} is not significantly different from mean ET_r (from lysimeter) at 0.05 significance level.

RESULTS AND DISCUSSION

The cumulative alfalfa ET measured from the lysimeter (4/1/2008 – 9/1/2008) was 1042 mm (Fig. 3). In contrast, precipitation during the same period was only 196 mm. The irrigations applied during the season (Table 1) typically penetrated down to 50 cm below the monolith surface (Fig. 4) but could not refill the deeper soil layers in mid-season. However, the irrigation on August 4 plus several rainfall events later in August penetrated down to 190 cm.

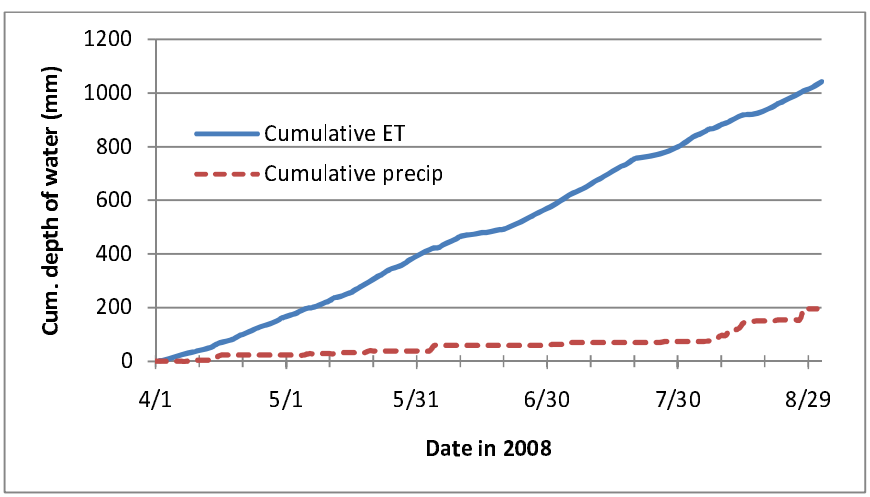

Figure 3. Cumulative alfalfa ET and precipitation on the lysimeter in 2008.

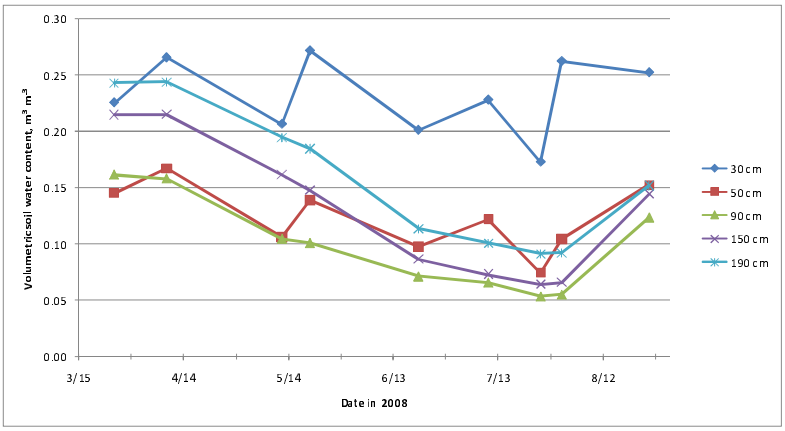

Figure 4. Volumetric soil water content at selected depths in the lysimeter for 2008.

Figures 5 to 8 show representative comparisons of hourly ET computed from the ASCE-PME (ET_{rs}) versus ET measured from the lysimeter (ET_r) for three different days during the 2008 season, when the alfalfa crop on the lysimeter and surrounding field was considered to be in reference condition. June 7 (Fig. 5) is an example of a day (early season) when ET_{rs} and ET_r matched well throughout the day. Wind conditions were relatively calm and vapor pressure was relatively stable (Fig. 8). Consequently, relative error and RMSE were low and the index of agreement (d) was close to 1.

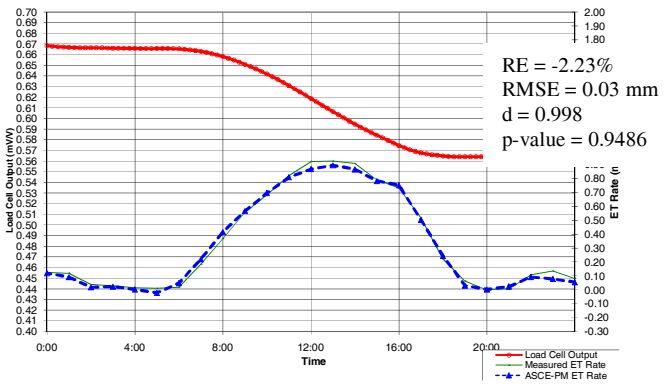

Figure 5. ET rate and lysimeter load cell output on 7 June 2008 (before 1st alfalfa cutting).

June 2 (Fig. 6) was also early in the season but had elevated afternoon temperatures, higher afternoon wind speeds, and a drop in vapor pressure (Fig. 8). The drop in solar radiation after 1200 h (Fig. 8) indicated increased cloud cover, which was reflected in the drop in both the lysimeter and ASCE-PME ET rates. However, the ASCE-PME seemed to be overly sensitive to higher wind speed and decreased vapor pressure that occurred after 1400 h. The equation over-predicted ET under these conditions (Fig. 6). Relative error and RMSE were considerably higher

and d was lower compared to those on June 7. The late afternoon to early evening (1600-2000 h) ET rates from the lysimeter ranged from 0.25 to 0.72 mm h^{-1} on June 2 compared to a range of 0.00 to 0.70 mm h^{-1} for the same period on June 7 (Fig. 5). On June 2, the strong winds that came after 1400 h came from the WSW (235-250 azimuth from true N). The source of this advected hot dry air was a large expanse of dry prairie in the aforementioned direction from the lysimeter.

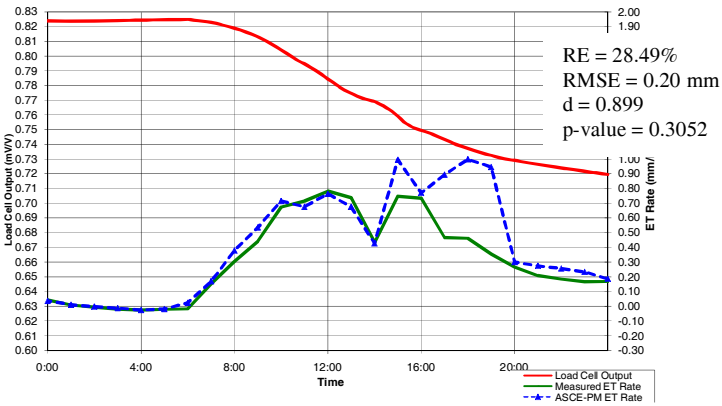

Figure 6. ET rate and lysimeter load cell output on 2 June 2008, showing overestimation of afternoon ET_r by ASCE-PM equation.

Figure 7 shows a comparison late in the season (August 28) where the computed ET_{rs} from the ASCE-PME was notably less than the measured ET_r from the lysimeter during midday. This under-prediction was noted on a number of days late in the season. No unusual weather conditions were evident (Fig. 8). However, the increased soil water content of the monolith profile (Fig. 4) and the 0.6 m alfalfa canopy height that was slightly higher than ASCE-PME standard height (0.5 m) may have contributed to the underestimation. The underlying causes of these differences need further investigation.

In all the comparisons between ET_r from the lysimeter and ET_{rs} calculated from the ASCE-PME, the p-values were greater than 0.05. This indicated that the calculated alfalfa ET rates from the ASCE-PME were not statistically different from the ET rates measured from the lysimeter (at 0.05 significance level).

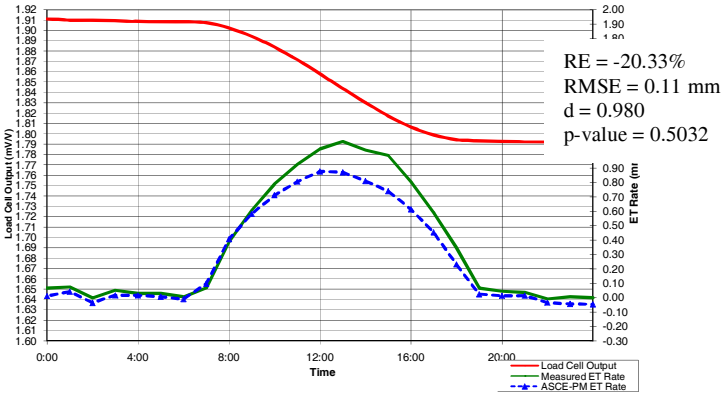

Figure 7. ET rate and lysimeter load cell output on 28 August 2008, showing mid-day under-estimation of ET_r by the ASCE-PM equation. Alfalfa crop height was about 0.6 m.

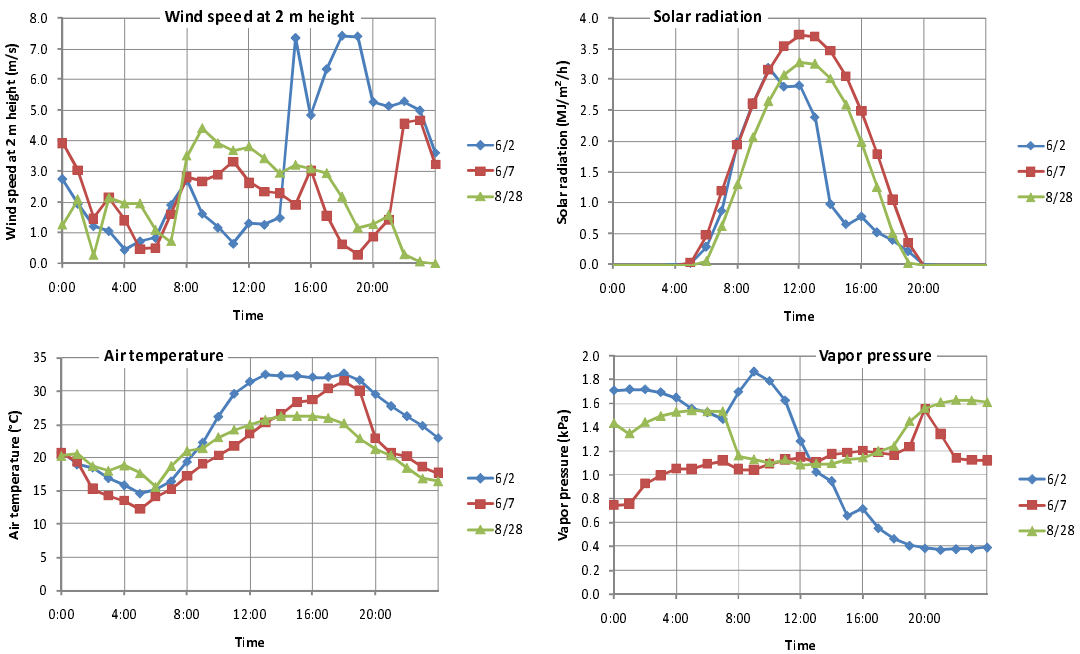

Figure 8. Comparisons of primary weather variables among the three sample dates.

CONCLUSION

This paper presented preliminary comparisons between hourly alfalfa reference ET calculated from the ASCE-PME and measured values in 2008 from a newly installed precision weighing lysimeter at Rocky Ford, Colorado. The ASCE-PME gave alfalfa ET estimates that agreed well with lysimeter measurements when sensible heat advection was not significant. The equation tended to over-estimate hourly ET rates when high wind speeds (> 5 m s^{-1}) occurred with elevated air

temperature and decreased vapor pressure. On the other hand, the equation under-estimated mid-day alfalfa ET rates on some days late in the season, possibly because of the assumed canopy height (0.5 m) being less than the actual canopy height and/or soil water and root water uptake dynamics that are not accounted for. Further studies are needed to evaluate the accuracy of the ASCE-PME in estimating alfalfa reference ET for different conditions in the Arkansas River Basin.

Abstract

In the fourth report in the case of Kansas v. Colorado (No. 105, Original, U.S. Supreme Court), regarding compliance with the Arkansas River Compact, the Special Master hearing the case recommended specific changes by which Arkansas River streamflow depletions at the Colorado-Kansas Stateline are determined. One of the major changes was the recommendation to move away from the modified Blaney-Criddle method and adopt a reference crop evapotranspiration-mean crop coefficient approach to determine crop consumptive use estimates for input to the computer model used to determine compact compliance. This paper discusses some of the steps the State of Colorado has taken to comply with this recommendation.

Introduction

The lower Arkansas River Valley of southeastern Colorado is characterized as a long, relatively narrow and shallow valley, extending approximately 260 km (160 mi) from below Pueblo Reservoir near Pueblo, Colorado on the western end, to the Colorado-Kansas Stateline on the eastern end, east of the town of Holly, Colorado (Figure 1). Within the lower Arkansas River Valley east of Pueblo there are approximately 260,000 acres of irrigated cropland. Forage crops, specifically alfalfa, are predominant, followed by grains (corn, wheat, sorghum) and vegetables (onions, peppers, melons).

Historically, the modified Blaney-Criddle method has been used to determine crop consumptive use, or potential crop evapotranspiration (PET) estimates for input to the Hydrologic-Institutional (HI) Model. The HI Model was developed to determine depletions to usable Arkansas River streamflows at the Colorado-Kansas Stateline

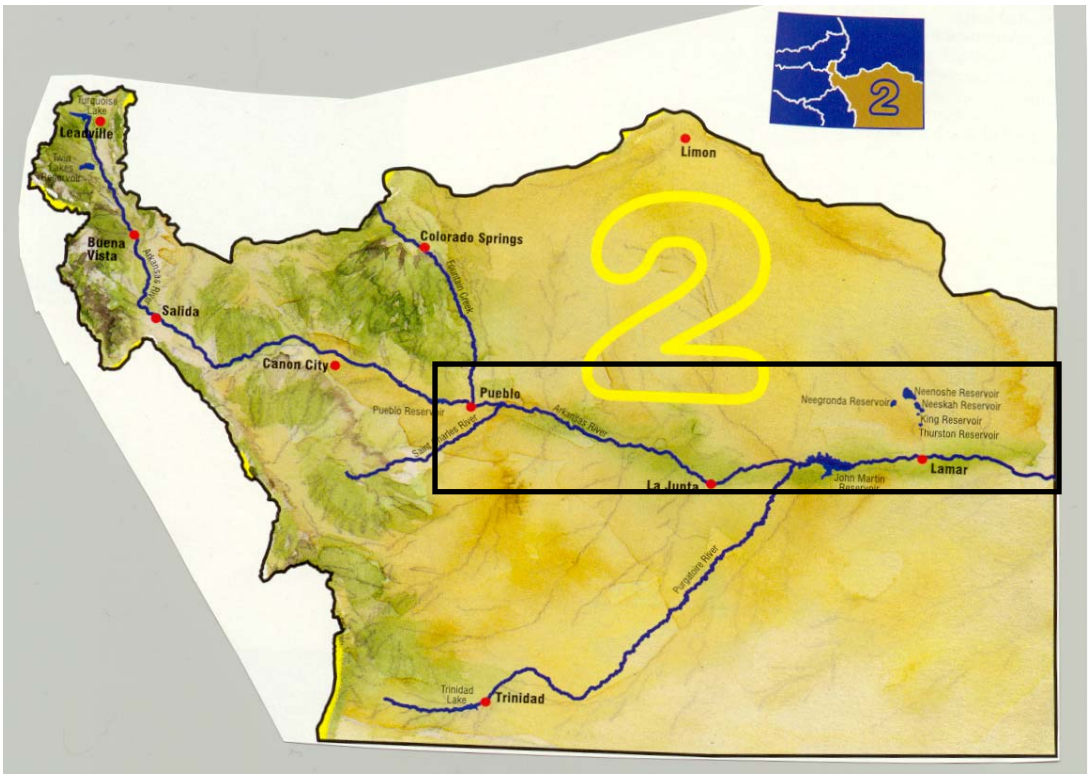

Figure 1. Lower Arkansas River Valley in Southeastern Colorado.

caused by post-Compact well pumping in Colorado, and evaluate whether the State of Colorado is in compliance with the Arkansas River Compact between the two States. The HI Model uses estimates of potential crop water use to predict diversions for irrigation by ditches in Colorado and to calculate actual crop water use. Modified Blaney-Criddle crop consumptive use estimates were developed using monthly maximum and minimum air temperature data from six NOAA Cooperative Observer weather station network sites located near Pueblo, Rocky Ford, La Junta, Las Animas, Lamar, and Holly, Colorado. These long term NOAA Coop stations are relatively evenly distributed down the Arkansas River Valley from Pueblo to the Colorado-Kansas Stateline.

In his fourth report (Littleworth, 2003) in the case of Kansas v. Colorado (No. 105, Original, U.S. Supreme Court), regarding compliance with the Arkansas River Compact, the Special Master hearing the case recommended specific changes by which PET was to be determined, for both the historical period, and for annual updates. Based on expert testimony regarding the inaccuracy of the Blaney-Criddle method, and the increasing availability of electronic weather station data in the area, the Special Master recommended that crop consumptive use estimates for input to the HI Model should be based on a reference crop ET-mean crop coefficient approach. Specifically, the ASCE standardized reference evapotranspiration equation (ASCE-EWRI, 2005) and available electronic weather station data should be used to estimate tall (alfalfa) reference crop ET_{rs}, and alfalfa-reference based mean crop coefficients adapted for the major crops grown in the area used to compute crop ET.

This paper will discuss:

1) evaluation of existing automated electronic weather station sites at the time of the Special Master's recommendation, various weather station siting issues, and steps taken to improve the network of electronic weather stations within irrigated agricultural areas of the Arkansas Valley of southeastern Colorado;
2) cooperation and collaboration with the State of Kansas to evolve and improve processes in the review and quality assurance of the weather data used in the ASCE standardized equation to compute tall crop (alfalfa) reference evapotranspiration, $ET_{rs;}$
3) brief review of the development of mean crop coefficients used to estimate crop ET for the major crops produced in the area.

Further discussion and background of steps taken by the States of Colorado and Kansas to implement this recommendation are discussed in companion papers in these proceedings (Andales et al., 2009, Book and Brengosz, 2009; Brengosz, 2009; Ley et al., 2009).

Weather Data Requirements

All versions of the Penman combination equation, including the ASCE standardized reference ET equation (ASCE-EWRI, 2005), require detailed weather data. Ideally, these weather data (intended for reference ET estimation) should be collected at weather stations sited over well-watered, clipped grass surfaces in open, irrigated settings. For daily estimates, required daily weather data are total daily solar radiation, daily maximum and minimum air temperature, mean daily dewpoint temperature or actual air vapor pressure as determined from measurements of relative humidity, and mean daily wind speed at 2 m above the surface. Beginning in the early to mid-1980's, automated electronic weather station networks were installed in agricultural areas of Nebraska and California. Since then, additional States have installed similar networks, including, for example, Washington State PAWS, Oklahoma Mesonet, and the Texas North Plains PET network. In Colorado, the Colorado Agricultural Meteorological Network (CoAgMet) began in the early 90's (Duke, 1996). Many of these weather station networks collect data for the purpose of, among others, computing reference ET and crop ET for crops of interest in their respective areas. These data should not be taken at face value, but carefully assessed using recommended data integrity and quality control procedures. Such procedures must also evaluate the weather collection site and local and regional environment to determine if the weather data were collected in the prescribed reference environment. These issues are discussed further below.

Weather Station Site Assessment

It is recommended that weather data intended for reference ET estimation be collected at weather stations sited over well-watered, clipped grass surfaces in open,

irrigated settings (Allen et al, 1998; ASABE, 2004; Allen, 1996). Reference ET (and therefore crop ET) estimates will be artificially high when weather data are collected in environments that are drier than these reference conditions (Brown and Ley, 1993; Ley, et al., 1996). Specifically, when located in environments that are drier than the reference condition, weather stations will measure increased air temperatures, reduced water vapor in the air, and potentially greater wind speeds, resulting in increased reference ET estimates compared to the reference environment. In such cases, a greater portion of the energy available is used in sensible heating of the air and soil and less in evaporation (which results in cooling and humidification of the air) because of the reduced amount of environmental moisture available for evaporation. This effect has generally been termed an aridity effect.

Each weather station proposed for use in calculation of reference ET estimates should be visited and assessed as to potential aridity effects. Siting information to note include whether the station is located in a generally irrigated agricultural environment, what the local siting conditions are out to a radius of several hundred feet, what the ground cover is immediately under and around the station and how is it maintained, and what the condition is of the fetch (surface and moisture characteristics of the land) in the primary upwind direction. Deviations from prescribed reference conditions described above indicate that the weather data collected at the site need to be carefully evaluated for aridity effects. This includes a very careful evaluation of the relative humidity data and the relationship between daily minimum air temperature and dewpoint temperature (ASCE-EWRI, 2005). Suggested procedures for correcting weather data for potential aridity effects are given in Allen (1996) and ASCE-EWRI (2005). Any corrections to the weather data should be noted and maintained as part of the record.

At the time of trial testimony, and the Special Master's subsequent formulation of recommendations regarding crop ET methodology, circa 2002, only 4 CoAgMet stations were in existence in the lower Arkansas River Valley (Vineland, Avondale, Rocky Ford, and Lamar01). Of these, the Vineland, Avondale, and Rocky Ford sites were found to be located in irrigated environments, while the Lamar01 station was found to be located in a dry, rangeland environment about 5 miles south of irrigated land near Lamar CO. As a result, the Lamar01 data have generally been considered unusable for reference ET computation. This left essentially two CoAgMet weather stations: Avondale and Rocky Ford to represent the lower Arkansas Valley, from Pueblo CO to the Colorado-Kansas Stateline. The Avondale and Vineland CoAgMet stations are only about 6 miles apart, and for reasons discussed later, the Vineland station data are only used to fill in for missing data at Avondale. Figure 2 is a satellite image of the lower Arkansas River Valley of Colorado showing the current locations of CoAgMet weathers stations. In 2002, the Special Master's recommendation was to determine crop ET for the entire valley using only the Avondale and Rocky Ford stations located in the western half of the lower valley.

Mean monthly ratios of crop ET (computed using ASCE standardized alfalfa reference ET and mean crop coefficients) to modified Blaney-Criddle crop

consumptive use, for the 7-year period: 1994-2000 and for 10 different crops, were developed to calibrate the modified Blaney-Criddle method to the ASCE standardized reference ET-mean crop coefficient method. The Avondale CoAgMet site was used to calibrate the Pueblo NOAA site, while the Rocky Ford CoAgMet site was generally used to calibrate the Rocky Ford, La Junta and Las Animas NOAA sites for the historic period. The trend in calibration factor change between Pueblo and Rocky Ford was used to develop extrapolated calibration factors for use at Lamar and Holly. Calibration factors were applied to modified Blaney-Criddle crop consumptive use estimates for the historic compact period, 1950-1993, to adapt them to standardized reference ET-mean crop coefficient-based crop ET estimates. For the period 1994-2004, Avondale and Rocky Ford CoAgMet data were directly used to compute alfalfa reference ET and subsequently, crop ET at those sites. However, again, the extrapolated calibration factor trend was used to calibrate the NOAA sites from Rocky Ford east to the Stateline for this period.

Weather Station Density

A question of the "representativeness" of the Avondale and Rocky Ford CoAgMet weather stations of conditions in Lamar and Holly, much less La Junta and Las Animas immediately arose. Hubbard (1994) investigated the spatial variability of daily weather variables measured at 24 locations of the High Plains Automated Weather Data Network of the central US during the period 1988-92. The coefficient of determination, r^2, the ratio of the explained variation to the total variation between parameter values at pairs of locations, was computed through regression techniques and then plotted as a function of time of year for given separation distances between stations. To explain 90% of the variation in daily weather variables between sites, Hubbard found that a 60-km (37 mi) station spacing was needed for maximum temperature; 30-km (19 mi) spacing for minimum temperature, relative humidity, solar radiation, and reference ET; 20-km spacing (12.5 mi) for soil temperature, and 10-km (6.2 mi) spacing for wind speed. Seasonal weather differences were observed to strongly affect spatial variability.

Spatial dependence structure of multivariate time series at several locations in space (i.e., electronic weather station data collected at several locations) can be analyzed through an evaluation of the cross-correlations between the multiple series. For example, a multivariate autoregressive model of order one, AR(1), of a state variable (weather parameter or reference ET) describes a state-space process with lag-zero and lag-one correlation in space and lag-one temporal correlation (Bras and Rodriguez-Iturbe, 1985). Lag-zero spatial correlation describes the spatial coherence of a given variable measured on the same day at a number of sites. Lag-one spatial correlation describes the spatial coherence of a given variable measured at one site with the same measured variable at a number of other sites on the previous day. Lag-one temporal correlation describes the temporal dependence structure of a given variable measured at one site with the same measured variable at the same site on the previous day. Ley (1995) developed multivariate AR(1) models of daily weather variables (max, min and dewpoint temperatures, solar radiation, and wind run) and daily alfalfa reference

ET for a 33-station agricultural weather network in Eastern Washington for the period 1989-91. Spatial variability was analyzed by plotting lag zero cross-correlation coefficient matrixes of the standardized zero-mean detrended residuals of each variable versus a matrix of interstation distances. These plots revealed that for spatial cross-correlation of no less than 0.95 (which for comparison to results of Hubbard (1994) is equivalent to a coefficient of determination of $r^2 = 0.90$); maximum interstation distances for the weather variables and reference ET were: maximum temperature approximately 50 km (31 mi); minimum temperature approximately 10 km (6 mi); dewpoint temperature approximately 10 km (6 mi); solar radiation approximately 30 km (19 mi); wind run approximately 6 km (3.7 mi); and reference ET approximately 20 km (12.5 mi). The narrower station distances are attributed to the more complex topography and influence of prevailing weather patterns in eastern Washington as compared to the High Plains area of Hubbard's study.

Hill and Ley (Appendix C, 2002) used these same procedures to evaluate spatial variability of electronic weather station data collected over the 7-year period 1994-2000 at the Avondale, Vineland, and Rocky Ford CoAgMet weather station sites and the Kansas State University site at Garden City KS. Assuming a minimum acceptable lag zero cross-correlation coefficient equal to 0.90 (somewhat more relaxed than the two studies previously described), Hill and Ley showed the Rocky Ford CoAgMet station could be considered an appropriate predictor as follows: maximum temperature for all NOAA locations east to the state line; minimum temperature, dewpoint temperature, solar radiation and alfalfa reference ET for La Junta and Las Animas NOAA locations, but not Lamar and Holly; daily wind run for the La Junta NOAA location, but not Las Animas, Lamar and Holly. The La Junta and Las Animas sites are within 26 miles east of Rocky Ford, however, Lamar is 60 miles east and Holly is about 86 miles east of Rocky Ford. These results indicated the Rocky Ford CoAgMet station does not provide representative reference ET estimates for computing crop ET for all locations of the Arkansas Valley from Rocky Ford east to the Colorado-Kansas Stateline.

Two new CoAgMet stations had just been established at about the time of the Special Master's recommendation in 2002: Lamar02 and Holly01. The Special Master recommended the data collected at these stations be evaluated and used as well. These sites and the data collected during 2002-2004 were evaluated. In each case, the weather stations were established in large un-irrigated fields on the fringe of irrigated areas. The Lamar02 data were considered usable for reference ET, but it was felt there was some aridity impact due to the local dry environment surrounding the station. The Holly01 site was considered to be too heavily impacted by dry, advected air and it was agreed to not use the data from this site for reference ET estimation.

Weather Station Network Development

Beginning in the spring of 2005, the CoAgMet weather station network in the lower Arkansas River Valley of Colorado was the focus of considerable enhancement.

Based on the analyses of spatial variability of weather variables by Hill and Ley (2002) and problems with the Lamar02 and Holly01 sites described above, a network of weather stations usable for reference ET purposes was developed (Figure 2). The established stations at Avondale, Vineland, and Rocky Ford remained in place. New electronic weather stations were established at Fowler, in the irrigated area between La Junta and Las Animas, and in the irrigated area east of Las Animas, between Las Animas and Lamar. The Fowler station was located on a golf course. The La Junta and Las Animas stations were located in large irrigated alfalfa fields. The Lamar02 site was moved, and is now known as Lamar04. It is located in a large irrigated alfalfa field. The Holly01 site was also moved and is called Holly02. It is also located in a large irrigated alfalfa field. Due to cooperator interest in the weather data, the Holly01 site was eventually re-established with another weather station. Supplies of spare sensors and parts (anemometer bearings) were procured to support maintenance. Routine weather station site visits were initiated for the purpose of maintaining vegetation growth in the immediate vicinity of the stations and to check/clean sensors. Since 2005, minor modifications have been implemented: the Avondale station was moved approximately 175 m north of its old location in June 2007 due to two new center pivots installed to the SW and NW that were irrigating the station. The Lamar04 station was moved approximately 30 m south of its old location in June 2007 to obtain separation distance from the corn crop that had been planted on the immediate north side of the old location.

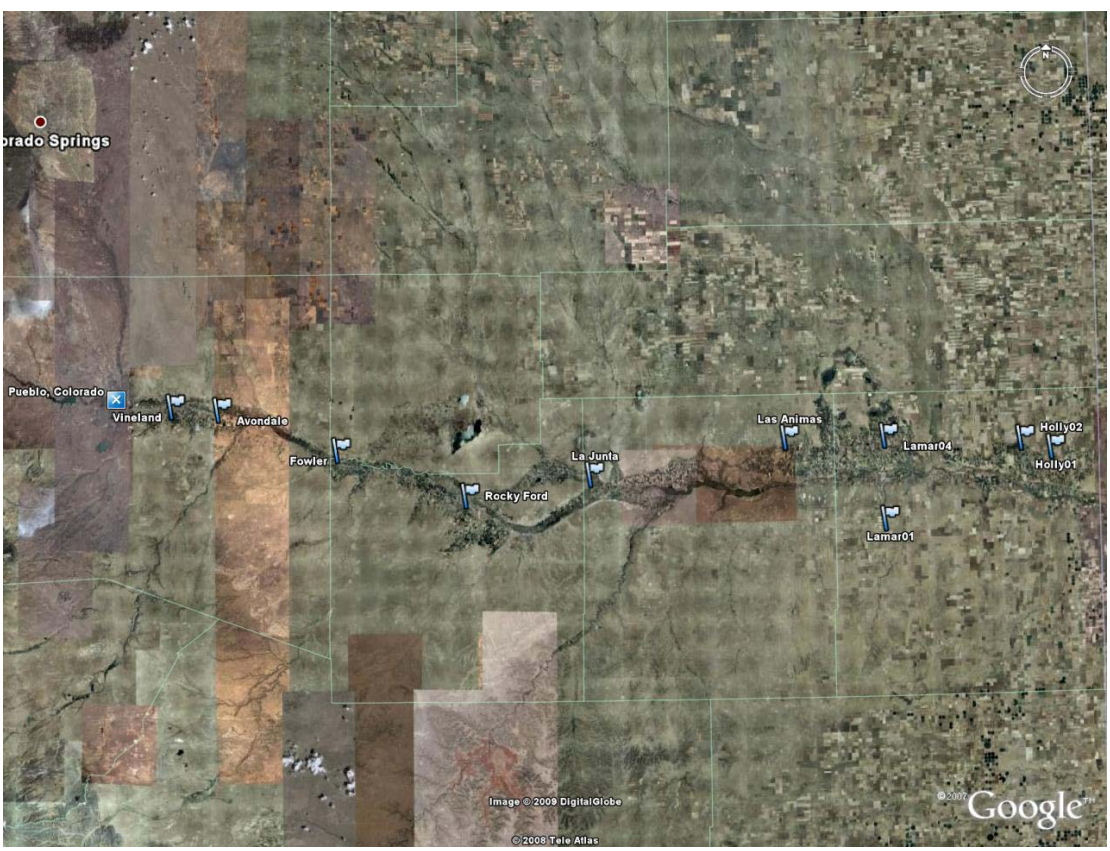

Figure 2. Current (2009) CoAgMet electronic weather station network in the lower Arkansas River Valley of Colorado.

When enough good quality weather data have been collected at Lamar04 and Holly02 (i.e., 5 years minimum), the two States have agreed to develop new calibration factors to re-calibrate the modified Blaney-Criddle method at each of the Lamar and Holly NOAA sites. New crop ET estimates for the period 1950-2004 will be used in the HI Model to determine if significant differences between the two calibration methods result.

Locating weather stations in irrigated alfalfa fields, as opposed to the recommended irrigated clipped grass, was considered necessary due to a lack of large irrigated grass fields or pastures in the lower Valley. The effects of the growing, and harvested, alfalfa on wind speeds measured at 2 m above the ground surface have been identified as a concern. A study of these effects was initiated in 2008 and results are reported in Ley et al. (2009).

Weather Data Integrity Assessment

Faulty weather measurement sensors (poor calibrations, poor or inadequate maintenance practice, sensor failure etc.) and inadequate weather data quality control/quality assurance procedures can result in inaccurate reference ET estimates. Procedures and guidelines for assessing the integrity of weather data for reference ET estimation have been developed (Allen, 1996; ASCE-EWRI, 2005; Allen et al., 1998). Methods for "correcting" data collected by poorly calibrated sensors, for adjusting temperature data collected at non-reference sites to reflect reference conditions, and for filling in missing weather data are also described in these same references. Officials for both the States of Colorado and Kansas have independently performed weather data integrity assessments using some combination of the methods referred to above and summarized below. In most cases, very similar "corrected" data sets have been developed. Where differences are found, further interaction between the two States occurs until a final data set agreeable to both sides is developed. Any corrections to the weather data are noted and maintained as part of the record.

Generally, the following steps are taken to assess weather data integrity at a single station. Trends among neighboring stations are similarly assessed. Missing data are often filled in using checked weather data from a neighbor station or regression analyses of a given weather parameter during identified good periods of data from neighboring weather stations.

1) Graph daily maximum and minimum air temperatures to check for obvious outliers (data values which do not follow the trends of the preceding or following periods) and/or inconsistent trends.
2) Graph daily minimum air temperature and daily dewpoint temperature together over time. Check for outliers and inconsistent trends in dewpoint temperature. In an irrigated reference environment, dewpoint temperature should generally be within 2-5 °C below minimum air temperature, although during periods of annual crop development, when the crops in the area are

providing less than 70% ground cover, some local aridity impact due to sensible heating is often evident and acceptable. Figure 3 shows a comparison of measured daily minimum air temperature and dewpoint temperature at the Las Animas CoAgMet station during 2007. The small differences between the two data sets, particularly during the growing season, indicates this is a well-watered reference type environment.

3) Graph daily maximum and minimum relative humidity (RH) to assess the performance of the RH sensor and potential calibration problems. If the daily maximum RH values consistently exceed 100% by 3-5% then a sensor or sensor calibration problem should be suspected. The same would be true of extended periods of maximum daily RH less than 80-85% if the station is located in an irrigated reference environment. Figure 4 is an example of an obvious RH sensor problem during the first part of the year, and replacement of the sensor during 1995 at the Rocky Ford CoAgMet site.
4) Graph daily solar radiation data and compare with expected clear sky short wave solar radiation for the site. Both States have adopted methodology for clear sky short wave solar radiation given in Appendix D of ASCE-EWRI (2005), which considers effects of sun angle and water vapor on absorption of short wave radiation, and separates the components of beam and diffuse radiation. Measured solar radiation should be expected to be nearly equal to clear sky solar radiation values on clear days. If there are obvious periods when the maximum measured solar radiation does not approach or is in excess (by more than ±3-5%) of the clear sky values a sensor calibration problem should be suspected and the data "re-calibrated". Figure 5a shows measured daily total solar radiation at the Rocky Ford CoAgMet station during 2008 versus the clear sky envelope. Due to relatively low values during most of January-September as compared to the clear sky curve, a calibration factor of 1.04 was determined and applied to the measured data. The resulting "re-calibrated" total daily solar radiation data are shown in Figure 5b.
5) Graph daily mean wind speed and check for periods of consistently low readings that might indicate bearing fatigue, or for periods in mid to late summer when crops in nearby fields have begun to mature and may be sheltering the weather station and wind sensor. Figure 6 is a comparison of mean daily wind speeds during 2003 at Avondale and Vineland. These sites are only about 5 miles apart and should experience relatively the same wind. The Vineland site is perennially surrounded by corn crops within a few meters on two or three sides. The wind speed differences seen in Figure 6 from about day 170 to day 255 are due to sheltering of the anemometer as the corn grows to full height (mid June) and up until harvest (mid September).

Crop Coefficients

ASCE-EWRI (2005) suggests that published sets of crop coefficients may be used with the ASCE standardized equation, as long as the basis for the crop coefficient and the reference crop, i.e., alfalfa or grass, is consistent. Mean crop coefficients

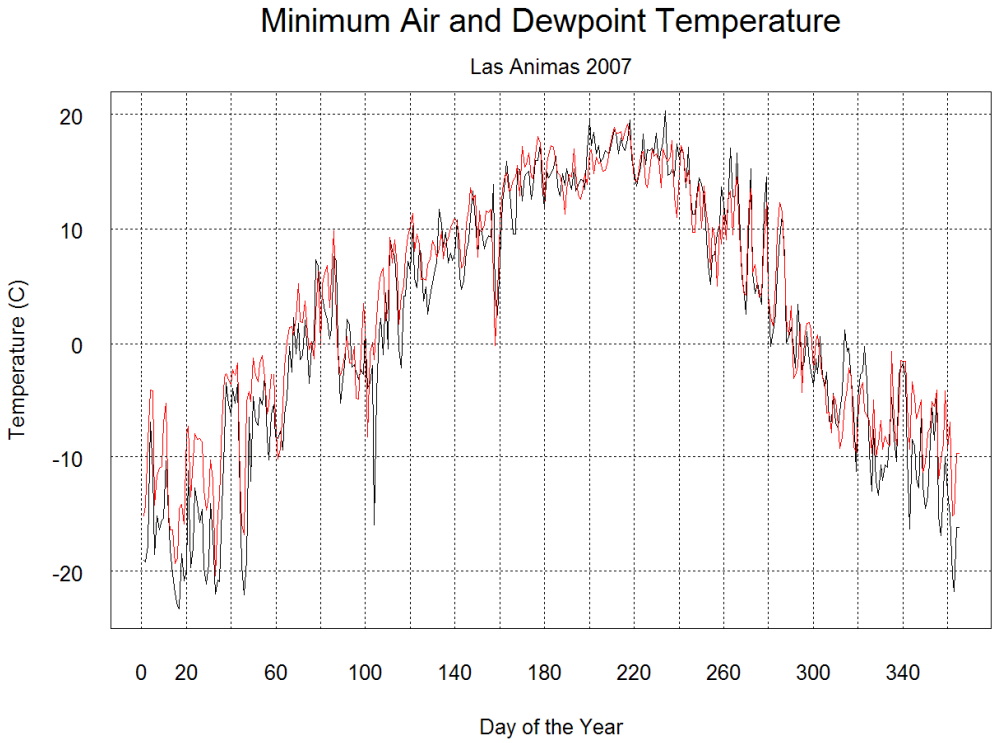

Figure 3. Comparison of measured minimum air temperature (black) and dewpoint temperature at Las Animas CoAgMet station during 2007.

ultimately adopted are based on Table 6.9 of ASCE Manual 70 (Jensen et al. 1990), adjusted for the differences in crop planting, development and harvest dates between southeastern Colorado and Kimberly, Idaho. The Manual 70 crop coefficients were developed specifically for 1982 Kimberly Penman equation which gives alfalfa reference ET estimates. The ASCE standardized equation for the tall (alfalfa) reference crop differs from the 1982 Kimberly Penman in that ASCE standardized equation assumes a constant 0.50 m tall hypothetical reference (alfalfa) while the 1982 Kimberly Penman does not. As a result, the ASCE standardized tall reference equation tends to predict higher than the 1982 Kimberly Penman equation during the spring and fall months (Mar-May, Sept-Oct) and predicts equal to or slightly lower during the peak summer months (Jun-Aug). Thus, the adopted mean crop coefficients were adjusted to account for the differences between the two methods.

The Special Master did understand and recognize that improvements in the computation of crop consumptive use can be made. Specifically,

> "This is not to say that the Kansas' values, as calculated with the Penman-Monteith equation and crop coefficients, can never be changed. As more information is developed on conditions in the Arkansas River Valley, adjustments made in accordance with recognized professional procedures may be appropriate." (Littleworth, 2003).

The State of Colorado in cooperation with Colorado State University has undertaken the design, construction, and operation of precision weighing lysimeters located at the Colorado State University Arkansas Valley Research Center near Rocky Ford, Colorado. The purpose of the lysimeter project is to research and develop crop coefficients for use with the ASCE standardized reference ET equation for climate conditions and crops produced in southeastern Colorado. A companion paper in these proceedings (Andales et al., 2009) describes lysimeter research work accomplished to date.

Interstate Collaboration in the Arkansas River Compact Compliance Process:
The "Nuts and Bolts" of Developing PET for Canal Service Areas
for Input to the H-I Model

ABSTRACT

The Hydrological-Institutional (H-I) Model is a computer model used to determine compliance with the Arkansas River Compact. The States of Kansas and Colorado complete an annual update of the model to compute the effects of well pumping on Stateline river flows. The annual update process requires the two States to agree on the crop mix, weather data and potential evaporation (PET) estimates for the canal service areas (among other things). The H-I Model is highly sensitive to the crop evapotranspiration input, so the update of this input data set is given particular attention by both States. This paper describes the evolution of the PET estimates over time, and the steps involved in the annual update process, emphasizing the collaboration and cooperation that occur in order to reach a final PET data set.

INTRODUCTION

The Arkansas River Compact (Compact), ratified in 1949, allocates the water supply of the river between the States of Colorado and Kansas. In 1985, Kansas sought enforcement of its compact rights in the United States Supreme Court. The case is now awaiting approval of the Proposed Decree by the Court. The history of Kansas v. Colorado (No. 105, Original, U.S. Supreme Court) is discussed in more detail in another paper in these proceedings (Book and Brengosz, 2009). The end of the case signaled a shift in the interactions between the two States, from "litigation mode" which is necessarily adversarial, to "update and monitoring mode", which requires cooperation and collaboration. One of the areas in which cooperation is essential is the annual update of the H-I Model.

THE H-I MODEL IN KANSAS V. COLORADO

In this case, the H-I Model, in the FORTRAN language, was developed in the late 1980s and submitted to court by Kansas at the trial in 1990. It was intended to calculate the depletions to useable flow in the Arkansas River at the Colorado-Kansas Stateline, caused by well pumping after the Compact was signed. Both States adopted it for modeling in the case, and it is now being used to determine if Colorado

is in compliance with the Compact. The model is updated annually, but compliance is determined on the basis of a rolling ten-year accounting period.

The model contains twenty-three water users under canals diverting from the Arkansas River, located from near the city of Pueblo to near the Stateline. Fourteen users are upstream of John Martin Reservoir and nine are downstream. John Martin Reservoir represents a break-point in the valley, physically and operationally. Canal service areas range from about 600 acres to more than 90,000 acres. Input data and parameters, such as streamflow, canal diversions, precipitation, and irrigation pumping, are read in from a file containing 34 data sets. The file PET.DAT, which is, inexplicably, data set 50, contains the monthly crop PET for each user. Surface water delivered to farms from the canals for irrigation use is subject to on-farm lateral losses, surface runoff and deep percolation losses. The remaining surface supply, as well as effective precipitation and pumped groundwater (a separate input data set), is available for consumptive use by the crops. The H-I Model then simulates consumptive use by crops, soil moisture storage and on-farm losses as part of the overall calculation of Stateline flows.

In the model's original incarnation, crop PET for the years 1950-1985 was calculated with the Modified Blaney-Criddle formula (USDA, SCS 1970), and was later updated through 1999 during the continuing litigation. The Modified Blaney-Criddle formula was well-accepted in water rights matters in Colorado at the time the trial began. The Blaney-Criddle method requires only average monthly temperature data, which is readily available from numerous weather stations in the cooperative observer network of the National Oceanic and Atmospheric Administration/National Weather Service (NOAA/NWS) for long periods of record. The PET estimates for the model were based on six NOAA/NWS weather stations distributed across the valley, near the Colorado towns of Pueblo, Rocky Ford, La Junta, Las Animas, Lamar, and Holly. Figure 1 is a map of the model area showing the river, irrigated areas and weather stations.

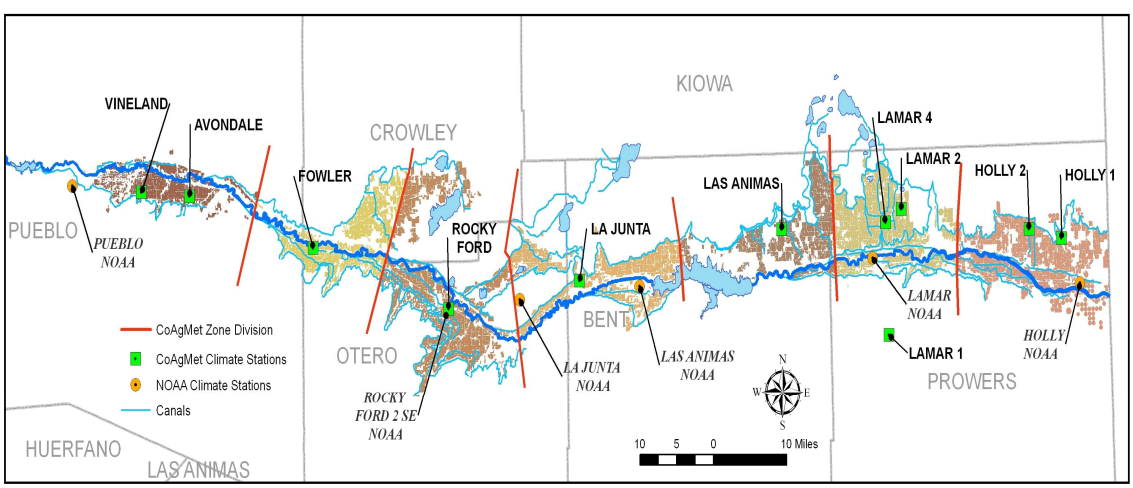

Figure 1. Location Map of Irrigated Areas and Weather Stations
(Irrigated parcels and zone divisions are from Colorado Division of Water Resources)

During the decades of litigation, the science of computing crop evapotranspiration (ET) was advancing. The Penman-Monteith and the 1982 Kimberly Penman methods gained favor in the engineering community, but few weather stations collected the more extensive data need for these newer methods. In 1992, the first weather stations collecting the necessary data in the Arkansas Valley were installed at Avondale and Rocky Ford. By 2002, there were four such stations (at Vineland, Avondale, Rocky Ford and Lamar01) that were part of the Colorado Agricultural Meteorological Network (CoAgMet). At trial in 2002, the engineers for Kansas recommended that the Penman-Monteith Method be used for calculation of PET for model input. The form of the Penman-Monteith equation used by the Kansas engineers was the standardized form that had been recommended in 2000 by the ASCE Task Committee on Standardized Evapotranspiration Calculations. This later became the ASCE Standardized Reference Evapotranspiration Equation (ASCE-EWRI, 2005). During this trial phase, the CoAgMet stations were evaluated for their suitability for use in the Penman-Monteith equation in the Arkansas Valley. As more fully described in another paper in these proceedings (Ley et al., 2009a), Vineland and Lamar01 were determined to be unusable for calculating reference ET. The two States agreed to use the two remaining CoAgMet weather stations, Avondale and Rocky Ford. Some Vineland data were used to fill in missing data at Avondale. In his fourth report in 2003 (Littleworth, 2003), the Special Master recommended the use of the ASCE standardized Penman-Monteith (ASCE std. Penman-Monteith) for development of crop consumptive use estimates that are input to the H-I Model for both historical and future years, using the Avondale and Rocky Ford stations.

ADJUSTMENT OF HISTORICAL BLANEY-CRIDDLE INPUT

The H-I Model had been calibrated to the PET input based on the Blaney-Criddle Method. Because there are significant differences in the PET results from the Blaney-Criddle Method and the Penman-Monteith Method, the model was recalibrated to the new input (Spronk & Papadopulos, 2002). In addition, adjustment was needed for the 1950-1994 PET input, years for which the data needed to calculate Penman-Monteith were not available. To achieve a consistent data set, the Blaney-Criddle PET values were "calibrated", or adjusted, to more closely resemble the Penman-Monteith values by applying monthly adjustment factors for each crop and weather station.

The adjustment factors, which are the ratio of the monthly Penman-Monteith Crop PET to the Blaney-Criddle Crop PET, were derived from the period of overlapping record at the time of the derivation, approximately 1993-1999, at the NOAA and CoAgMet stations. The Penman-Monteith at the Avondale/Vineland CoAgMet station was used to adjust the Pueblo NOAA station Blaney-Criddle. The CoAgMet station at Lamar was not used to calculate adjustment ratios. The Rocky Ford CoAgMet Penman-Monteith was used to adjust the Blaney-Criddle at all the remaining NOAA stations at Rocky Ford, La Junta, Las Animas, Lamar, and Holly, a distance of about 90 miles.

The Penman-Monteith/Blaney-Criddle monthly adjustment factors ranged from 0.28 for Winter Wheat in November at Rocky Ford, to 8.13 for Hay/Pasture in March at Pueblo. The adjustment factors were close to 1.0 for the peak growing months of each crop, but differed by a greater amount at the start and end of the growing seasons (Franzoy, 2001). The adjustment ratios for each station were presented at trial in 2002, and were agreed to by both States after several exchanges of expert reports in the case. An example of the ratios for alfalfa and winter wheat are shown in Table 1.

Table 1. Example of Blaney-Criddle to Penman-Monteith Adjustment Ratios

Crop	Month	Pueblo	Rocky Ford, La Junta & Las Animas	Lamar & Holly
Alfalfa	Apr	3.04	2.27	2.16
	May	1.45	1.34	1.28
	Jun	1.23	1.17	1.11
	Jul	1.01	1	0.95
	Aug	0.95	0.95	0.9
	Sep	1.1	1.02	0.97
	Oct	1.12	1.23	1.17
Winter Wheat	Mar	5.59	2.72	2.46
	Apr	1.85	1.56	1.41
	May	1.43	1.34	1.21
	Jun	2.62	2.67	2.41
	Jul			
	Aug			
	Sep	0.91	0.85	0.77
	Oct	0.65	0.56	0.5
	Nov	0.41	0.31	0.28

There was a question about whether data from Rocky Ford was appropriate for adjusting the Blaney-Criddle values all the way to the Stateline, and general agreement by the parties that more stations were needed because of the long distance. Colorado actively worked to encourage the expansion of the CoAgMet network, and was successful in establishing new stations. However, as discussed by Ley et al. in their paper in these proceedings, there were issues relating to the siting of the CoAgMet stations, particularly those downstream of John Martin Reservoir, and how they would be used in calculation of future PET input data and adjustment of the Blaney-Criddle estimates. There were several more years of discussion, and location and relocation of weather stations, needed to resolve these issues, culminating in the PET Agreement in 2005.

2005 PET AGREEMENT

In 2005, the State Engineer for Colorado, Hal Simpson, and the Chief Engineer for Kansas, David Pope, entered an agreement (the PET Agreement) regarding the computational procedures for PET used in the H-I Model, and a method for adjusting SCS Blaney-Criddle values in the future when more weather stations were

operational. The PET Agreement, Appendix B.2 of the Decree (Littleworth, 2008) confirms the use of the adjustment ratios proposed at trial for the 1950-1993 PET estimates for canal areas upstream of John Martin Reservoir (Pueblo NOAA with Avondale/Vineland CoAgMet and Rocky Ford NOAA with Rocky Ford CoAgMet). For 1994-2004, PET would be calculated directly by the ASCE std. Penman-Monteith method at the Avondale/Vineland and Rocky Ford CoAgMet stations. For calculations in 2004 and into the future, it was anticipated that three new CoAgMet stations would be installed at Fowler, La Junta and Las Animas, and the PET would be calculated directly. The States agreed to jointly develop a new distribution of canal service areas to the weather stations when acceptable data became available from the new stations. In 2008, the new stations were incorporated into the distribution as shown on Figure 1.

For canal areas located downstream of John Martin Reservoir, the1950-2002 Blaney-Criddle PET estimates at the Lamar and Holly NOAA stations were adjusted with the Rocky Ford CoAgMet station. For 2003-2004, PET would be calculated directly by the ASCE std. Penman-Monteith method at the Lamar02 CoAgMet station, and this would be used for the entire area downstream of John Martin Reservoir. For 2005 and 2006, PET would be calculated directly by the ASCE std. Penman-Monteith method at the Lamar02, Lamar04 and Holly02 CoAgMet stations. It was thought by the parties that at the end of 2009, there would be at least five years of overlapping data at the Lamar and Holly NOAA and CoAgMet stations, and new Blaney-Criddle to Penman-Monteith ratios could be calculated for the 1950-2002 data. However, as Tom Ley indicated in another paper in these proceedings (Ley et al., 2009a), the stations were moved during the time frame specified in the Agreement, and some of the data are not of sufficient quality for this purpose. The Holly station in particular had persistent data problems through 2007. This has been an area of ongoing discussion, and will be another area of opportunity for cooperation as the 2008 data are reviewed for the update in 2009.

ANNUAL UPDATES

The States of Kansas and Colorado complete an annual update of the model to compute the effects of well pumping on Stateline river flows. Although all input data sets are updated, the Stateline flows calculated by the H-I Model are highly sensitive to the crop PET input. Because of this sensitivity, the update of the PET input data set is given particular attention by both States. Every step of this process includes collaboration between the States. The update process requires the two States to agree on the crop mix, weather data and final PET estimates for the canal service areas.

The Decree and the PET Agreement form the framework within which the annual updates are done. The PET Agreement specifies which weather stations will be used. Because several weather stations have been relocated more than once, this has not been as straightforward as it appears, and the States have cooperatively agreed to defer some parts of the schedule in the PET Agreement in order to accomplish the objectives of the Agreement. The Decree in Appendix B.1 addresses the

methodology for calculating the county crop distribution, evaluating and correcting data from the weather stations, and calculating the PET, and sets out the schedule of the annual updates.

Colorado's engineers collect and compile the data and create the updated data sets, and provide them to the Kansas engineers by March 31. The Kansas engineers review the material from Colorado and proceed with their own analysis, and provide the model results and any proposed modifications to the data sets to Colorado by May 15. In acknowledgement of the give-and-take nature of this process, the Decree specifies that if the States have not reached agreement on H-I Model results by June 1, they shall be submitted to the "Dispute Resolution Procedure" prescribed in Appendix H of the Decree. In the updates that have been performed so far, the States have agreed on the PET input in sufficient time to avoid this situation.

THE PET UPDATE PROCESS

Overview

Although the Decree states that Colorado is responsible for the data compilation and creation of the update data set, Kansas engineers collaborate in the update of all the data sets in order to check the information provided by Colorado on March 31 each year. The calculations are done by engineers for the two States with different tools, adding to the confidence in the final results. The "two States" are in reality several persons who review the data, "crunch the numbers", and exchange results in order to ultimately agree on an input data set. For Colorado, they are Thomas Ley and Dale Straw of the Colorado Division of Water Resources, and Robert Hill of Utah State University. For Kansas, three employees of Spronk Water Engineers perform this work: Dale Book (President), Mary Kay Brengosz (Senior Water Resources Engineer), and Angela Schenk (Assistant Hydrogeologist). Both States have also had the benefit of input from Dr. Richard Allen of the University of Idaho.

The steps involved in the annual update process for the PET data set are:

1. Weather data assessment and correction.
2. Calculation of Reference ET.
3. Calculation of crop PET at the weather stations.
4. Determination of the county-wide crop distribution.
5. Determination of irrigated acreage under each canal.
6. Distribution of the crop ET to the canal service areas.

At each step, there can be differences of opinion and interpretation. The canal/user PET results are input to the Model to compute the actual crop ET, based on available water supply.

The Kansas engineers use the Ref-ET program developed at the University of Idaho (University of Idaho, 2000) to calculate the reference ET, and a series of spreadsheets to process the results and produce the input data set. The Colorado engineers use the S-Plus program for the weather data integrity assessment and for calculation of the ASCE std. Penman-Monteith equation (coded by Tom Ley). The S-Plus output is daily weather and reference ETr, which are input to a spreadsheet where the monthly mean crop coefficients are applied to produce the monthly crop PET. A series of "C" language programs developed by Dale Straw are used to produce the input data set. (Ley, 2009b) The two methods give almost identical results when using the same input data. The results are shared with and reviewed by each State's engineers. Comparison of the results helps to pinpoint areas of differences in the data integrity assessment. The cooperative review and calculation by the two States has become an important component of the process.

Weather Station Data Assessment and Correction

Daily weather data are used with the ASCE std. Penman Monteith equation to compute daily alfalfa reference ETr at each weather station. Before use in the equation, the data are reviewed and corrected. "Data Correction" is a concept unfamiliar to engineers in many areas of practice. There is a well-deserved attitude of suspicion towards, and a taboo against, altering data to better fit the desired outcome. However, correcting the data is precisely what is required to ensure that use of the ASCE std. Penman-Monteith equation will result in a good, representative reference ETr for the weather station. Faulty or missing data, whether from sensor error, battery failure, operator error, or other causes, should be corrected or replaced with values that are reasonable for a given weather station. Even before any data are collected, the location of a weather station is important. The PET Agreement specifies that the States will cooperate in the siting of weather stations. In practice, Colorado has sited the weather stations and Kansas has not objected. However, the multiple locations of the Holly station (Holly01 and Holly02) and the Lamar station (Lamar02, Lamar02 and Lamar04) since the locations were first evaluated could be interpreted as an extreme example of the concept of data correction, in that the stations have been moved to provide data that is more representative of reference conditions.

The Decree provides that data corrections to faulty or missing data identified by the Colorado engineers during the data integrity assessment or by the Kansas engineers during their review of the data shall be corrected or estimated using standard engineering principles. The report of the ASCE Task Committee (ASCE-EWRI, 2005), in Appendices D and E, provides procedures for siting a weather station, and for assessing and correcting the various weather parameters. Both States follow these procedures in general, but the results can be different depending on the actual

procedure used for data replacement or adjustment. Data adjustment can include using an average of surrounding days, replacing with data from a nearby station, or using a regression based on one or more nearby stations. The process of selecting a proper location for the weather stations and assessing the daily data is described more fully in another paper in these proceedings, (Ley et al., 2009a).

Data integrity assessment and correction is the most time-consuming part of the annual PET update. This was especially true in the first rounds of the update process, where multiple years were processed. Review of daily data for each parameter is tedious, and evaluation of the weather parameters, especially the solar radiation data, is subject to some interpretation, and therefore some disagreement between the States. The areas most subject to interpretation have been wind speed and solar radiation. For example, is a period of low solar radiation readings just an extended cloudy period, or is something wrong with the sensor? Is the wind speed regionally low during a certain period of time, or is there tall vegetation, a pile of hay bales, or a structure obstructing the anemometer? Are there other conditions at the site that do not meet reference conditions? Even if the States agree that adjustments to a certain parameter are needed, they must then agree on when to apply the adjustments and how much should they be.

Calculation of Reference ET

After the data assessment and corrections, the calculation of alfalfa reference ET is fairly straightforward since the Decree specifies the ASCE std. Penman-Monteith will be used. However, through each State's detailed review of the other's work, some issues have been identified. Although the ASCE std. Penman-Monteith equation was developed for wind measurements at a height of 2 m over a smooth grass surface, some of the CoAgMet stations are located over and near tall alfalfa. Tom Ley, Rick Allen and Marvin Jensen investigated this issue in 2008 at two CoAgMet sites and a lysimeter operated by Colorado State University, and they will report on their investigation in another paper in these proceedings (Ley et al., 2009c). Another issue that has arisen in this case is the impact of soil and irrigation water salinity and irrigation management practices and their relation to reference crop conditions. The Special Master considered this issue and decided that an adjustment for salinity should not be made to the PET, but should instead be accounted for in the irrigation efficiency of individual canals, if needed.

The daily values of reference ETr are summarized to monthly totals for further use in development of the input data set. The engineers on both sides of this case are indebted to the ASCE Committee for developing and publishing the ASCE std. Penman-Monteith Equation, and to the researchers through the preceding decades who contributed to the development of the equation. They have provided a tool that is capable of hourly estimates of evapotranspiration when used with accurate data. However, field conditions are not as controlled as research conditions, and the developers may be appalled that we have taken their elegant and carefully tuned hourly equation and are using it as the equivalent of a year-at-a-glance calendar.

Calculation of Crop ET

The summarized monthly reference ETr is used to calculate crop ET for nine different crops plus a winter (or non-growing season) ET in the months November through March, and the results are summarized to a monthly PET for each crop at each weather station.

Crop Coefficients

The crop coefficients for the Penman-Monteith Method that were ultimately adopted at trial in 2002, and are still being used, are based on Table 6.9 of ASCE Manual 70 (Jensen et al, 1990) adjusted for the differences in climate and crop planting/harvest dates in Colorado compared to Kimberly, Idaho, and further refined for differences between the Kimberly Penman and ASCE std. Penman-Monteith equations. The crop coefficients are shown in Table 2. Gene Franzoy, a consultant for Kansas, developed the crop coefficients in consultation with Dr. James Wright who had developed the Manual 70 coefficients, Dr. Robert Hill who was a consultant for Colorado, and several other locally-based researchers who supplied invaluable information on local harvest and planting dates (Franzoy, 2001).

County-wide Crop Mix

The Decree requires that the crop distribution for each user be derived from county agricultural statistics, unless more detailed records are available for individual canal systems. In practice, more detailed information has not been available. The two States use the county crop statistics from the National Agricultural Statistics Service's Colorado Field Office each year to develop a crop mix for each canal/user.

Differences in interpretation of the county statistics are resolved before proceeding. The crop statistics for the year being updated may not be available by the deadlines specified in the Decree, so a place-holder value, usually the same value as the previous year, is used until the revised data are available. The Decree requires that when final crop statistics become available, the States shall make a revised H-I Model run based on the final crop statistics, if the States are in agreement on the other aspects of the data sets.

Irrigated Acreage

Appendix B.4 of the Decree documents another agreement between the States to resolve issues relating to the periodic updates of irrigated acreage. In order to analyze and document changes in irrigated areas that would affect the model results, Colorado acquires Landsat satellite imagery every five years (the last year was 2008) and annual aerial photographs from the United States Department of Agriculture (USDA) Farm Service. In addition, Colorado's farm verification program investigates twenty percent of the wells and their associated acreage each year, so that all are reviewed every five years. The engineers for Kansas review the information provided by Colorado and provide feedback on any changes in parcels that have been proposed by Colorado.

Canal/User PET

Allocation of canal service areas to weather stations is done by assigning area-weighted irrigated areas under each canal to the nearby weather stations and to each county (Tables 3 and 4). When the model was developed, GIS was not a readily available tool. The area-weighting factors were developed using paper maps and visual inspection. The early county-to-canal weighting factors, used in the crop distribution allocation, have not changed since they were developed, but a change could be needed if there is a significant change in irrigated parcels over time. The early canal-to-weather station weighting factors were used until 2008, when the Fowler station was added to the process, and the latest locations of the remaining weather stations were included. The current method of determining the canal-to-weather station is based on a GIS map analysis by Colorado in 2008, and the then-current weather station locations. Another change in weather station locations is not anticipated, but could be possible.

The canal/user PET is calculated with the annual crop distribution (weighting factors by county) and the crop PET (weighting factors by weather station) for nine crops, plus a winter (or non-growing season) ET in the months November through March. Calculation of canal/user PET is done collaboratively by the two States. Different tools are used and the States compare and agree to each other's estimates of user PET for input to the H-I Model. The Kansas team imports the crop PET at each station into a spreadsheet that distributes the PET to canal areas based on the weightings. The method used by the Colorado team runs the PET through a series of "C" programs that give almost identical results when used with the same data.

The winter ET is still calculated by the Blaney-Criddle method with a crop coefficient of 0.2. Winter ET is applied to all the user acreage in the months December through February. The growing season for several crops extends into March and November, so the winter ET cannot be applied to 100% of the acreage in these months. In November, the winter ET is applied to the total acreage less the percentage of winter wheat in the user's crop distribution. In March, winter wheat, pasture grass, alfalfa and spring grain have begun growth, so the winter ET is applied to the total acreage less the percentage of these crops. The total PET for March and November is thus the sum of the crop ET on the cropped acreage and the winter ET on the uncropped acreage.

The engineers for Kansas proposed in 2008 that the winter ET be calculated with the Penman-Monteith method instead of Blaney-Criddle. The Kansas engineers also suggested further investigation into adjustment of wind speeds measured over alfalfa. The Colorado engineers had already begun planning such an investigation, and it was performed in 2008. The results of that study are the subject of another paper in these proceedings (Ley et al., 2009c). These will be areas for discussion between the States in 2009 or future years.

ONGOING OPPORTUNITIES FOR COOPERATION

Because of the process defined in the Decree and the PET Agreement, many areas of disagreement have already become areas of cooperation and collaboration. The annual update process, at least regarding the issues already resolved, becomes smoother every year. The people on both sides have become familiar with each other's approaches and personalities, as well as each State's viewpoints. This makes it easier to anticipate areas of agreement which may require less review, and focus on potential areas of disagreement, which will require a closer look. In general, disagreements in the annual PET update process have been resolved in an amicable and timely manner. However, because of the ongoing evolution and improvement in the science of ET, potential advancements in the equipment at the weather stations, changes in cropping patterns and land and water use, it is almost certain that new issues will arise in the future. Although past agreement is not a certain predictor of future solutions, all of us who are involved in the annual updates hope that future legal action can be avoided on the issue of PET if we continue the collaboration that has served us well in past years.

ABSTRACT

Crop Evapotranspiration (ET) is an important element in hydrological modeling in river basins with significant irrigation. The State of Kansas currently participates in ongoing modeling in two river basins for the purpose of monitoring compliance with interstate compacts: the Arkansas River in Colorado and Kansas and the Republican River in Kansas, Nebraska and Colorado.

The decree in *Kansas v. Colorado* (No. 105, Original, U.S. Supreme Court) provides for annual updates of the Arkansas River Hydrological-Institutional Model (H-I Model) to compute the effects of well pumping and offsets on Usable Stateline flows. The model was originally developed for the litigation, and has been modified for use in monitoring compact compliance. The Republican River Groundwater Model was developed through negotiation as part of a settlement in the case of *Kansas v. Nebraska & Colorado (*No. 126 Original, U. S. Supreme Court*)*. The Republican River model is used each year to determine the Calculated Beneficial Consumptive Use attributed to groundwater pumping in the Republican River Basin in the States of Nebraska, Colorado and Kansas. The settlement stipulation requires that each state calculate the crop irrigation requirement by county and compare those estimates to the pumping. This paper discusses the development and function of crop ET in each setting.

INTRODUCTION

Enhancement of crop evapotranspiration (ET) is the goal of irrigation and an important hydrologic parameter to quantify when assessing impacts of water use on streamflows and basin water supply in the western United States. The estimation of crop ET has been used for design and operation of irrigation systems and planning water resource projects for many years. The science of ET is well established, and collection of climatologic data for purpose of crop management is widespread. Formulas to determine crop water use have evolved into sophisticated methods, as water scarcity leads to more careful use of water for crops.

Hydrologic modeling involves complex relationships of the movement, distribution and consumption of water supply. Water supply projects often involve reservoir storage and conjunctive use of ground and surface water. The use of water for irrigation results in partial consumption of the water supply, with a residual returning to the drainage and stream system. Water is stored in the root zone and aquifers as it flows through the irrigation process, to be "reused" again downstream in the system. It is these processes of application, soil moisture storage, crop consumption, percolation through the aquifer to the stream as return flow and diversion or storage downstream that make up essential elements of the hydrologic model of a stream system used for irrigation supply.

Crop ET determination has been applied for many years to quantify the consumptive use of irrigation water, for the purpose of facilitating water rights transfers. The basic principal of limiting future consumption of water to historical crop consumption has been a staple of water rights engineering as water supplies are shifted from irrigation to municipal and industrial uses in stream systems of limited supplies. Methods of analysis range from deterministic methods to compute crop ET and return flows to more sophisticated stream system models, with calibrated parameters to match streamflow or water level measurements. This paper discusses the application of two such calibrated models, one in the Arkansas River basin and one in the Republican River basin, and the role of crop ET in each. Both models are being applied in the context of administration of interstate compacts, where methods have been established to assess compact compliance.

ARKANSAS RIVER COMPACT

The Arkansas River Compact (Compact) allocates the water supply of the river between the States of Colorado and Kansas. Ratified in 1949, the Compact required protection of water uses existing at the time of the Compact in the two States as additional development occurred. Since 1949, additional water development consisted of groundwater development in each state and construction of two federal reservoirs in Colorado. Although some municipal and industrial use of water occurs in the basin in both states, the primary use of water, as in most western states, is for irrigation. The Compact did not provide a fixed allocation to either of the states, but instead provided for maintenance of conditions enjoyed by the water uses existing at the time of the Compact. The Compact was reached after a long history of litigation between the two States dating back to 1907. The Compact was centered on the allocation of benefits of John Martin Reservoir, constructed during the 1940's to provide supplemental water supply in Colorado and Kansas, and prescribed the operations of the reservoir.

The Arkansas River in Colorado and Kansas is fully allocated and was extensively developed for irrigation by the time of the Compact. The basin is characterized by water shortages after the snowmelt runoff season in most years and throughout dry years. Construction of reservoir storage provided supplemental supplies, but water available for storage was still less than demand, as John Martin Reservoir was

emptied in most years before the irrigation season ended. Groundwater pumping was developed to supplement the surface water supplies in both states after the Compact.

Kansas v. Colorado (No. 105, Original) was initiated in the United States Supreme Court in 1985 for enforcement of Kansas' compact rights. The case has been brought to a close, pending the Court's issuance of a final decree, which has been prepared and submitted to the Court by the Special Master, Arthur L. Littleworth. (Littleworth, 2008). Because of the provisions in the Compact requiring protection of water uses in place as of 1949 from effects of post-compact water uses, it was necessary to develop analyses of such effects over the variable hydrologic conditions that have occurred since the time of the Compact. This ultimately led to the development and use of a hydrologic basin model to assess impacts of water use in Colorado at the Stateline.

Physical Setting

The Arkansas River begins in the headwaters of the eastern slope of the Rocky Mountains in Colorado and flows generally west to east across the eastern high plains into Kansas, across most of that state and into Oklahoma. However, it is the western reach that was most extensively developed for irrigation beginning in the late 1800's, and continuing into the 1970's with construction of federal reservoirs and development of groundwater by wells. The Arkansas River Compact between the states of Kansas and Colorado requires that development and use of water in Colorado not diminish the flow allocated to Kansas under the Compact. The water crossing the Stateline to Kansas is normally used within the western reach down to Garden City or a short distance downstream, where the river alluvium overlies and recharges the Ogallala Aquifer. The river has normally been dry at Dodge City, approximately 120 river miles east of the Stateline, since the early 1970's, except during periods of very high streamflow. The river begins to flow again in the vicinity of Great Bend, Kansas.

At issue in Kansas v. Colorado was the effect of post-compact use by groundwater pumping in Colorado on Stateline flows. Most of the groundwater development occurred in the 150-mile reach of the river extending from Pueblo to the Stateline and was limited to the alluvial aquifer along the mainstem of the Arkansas River (Figure 1). Major tributaries in this reach are sparse. Fountain Creek drains the Pikes Peak area and enters the river at Pueblo. The Purgatoire River drains the southern Front Range, extending to New Mexico, and flows in the Arkansas River at Las Animas, just upstream of John Martin Reservoir. The basin water supply is largely derived from snowmelt in the headwaters. Streamflow from rainfall is relatively limited and of short duration most years. A shallow aquifer of sands and gravels along the river extends about three miles wide with depths of less than 100 feet.

The reach between Pueblo to the Stateline was extensively developed for irrigation prior to the turn of the 20th century. Canals and reservoirs in Colorado are allocated water from the river on the basis of dates of appropriation, with the "senior" rights

entitled to appropriations before more "junior" water rights are entitled to divert. By 1900, the dependable flow in the western reach had been appropriated in Colorado and a number of off-channel reservoirs had been constructed. Downstream diversions depended on runoff and return flows for water supply. Between Pueblo and the Stateline, about 300,000 acres have been irrigated from a number of canals. Due to the limited and variable water supply, wells were developed for supplemental supply wherever the aquifer would produce usable well capacities. Twenty three canals diverted flows from the river. All of the canals had water rights with dates of appropriation that were integrated into Colorado's administrative system to allocate water along the entire length of the river in the State.

Figure 1: Arkansas River Basin Location Map (Littleworth, 2008)

The primary crops irrigated are alfalfa, corn, sorghum and small grains. The region is also famous for the melons and vegetables grown in parts of the valley, where dependable water rights were secured and favorable soils exist. The climate is considered arid, noted for high winds, clear days and high temperatures during the peak of the summer. Elevation ranges from approximately 4,700 feet at Pueblo to approximately 3,300 feet at the Stateline.

When John Martin Reservoir was constructed and placed into operation, supplemental water supply was provided for eight canals downstream in Colorado and eight canals in Kansas. Some of the smaller canals were subsequently taken out of operation and their water supply was obtained from wells. With a conservation capacity of approximately 350,000 acre-feet, the reservoir does not fill most years and was typically drained by late summer.

The Arkansas River Compact specified how the supply stored in the reservoir would be divided between Colorado and Kansas. The outlet gates are closed in the winter and all inflows are stored. The Compact divided the water supply in John Martin Reservoir 60% to Colorado and 40% to Kansas, measured at the Stateline, 60 miles downstream of the reservoir. When the reservoir was empty, administration of the river reverted back to the pre-compact condition and water was allocated to canals in Colorado by appropriation date, and return flows and stream gains flowed into Kansas. An agreement entered in 1980 between the states established separate accounts in the reservoir which encouraged more carryover storage from year to year since then.

Hydrologic Model

The technical issues involved in Kansas v. Colorado were complex. It was necessary to define the standard of compliance and the "compact condition" against which new water uses could be quantified. The addition of John Martin Reservoir into the system at the time of the Compact rendered the pre-compact stream conditions obsolete for purposes of measuring allocations. This meant it was not possible to use the pre-compact water supply, diversions and stateline flow to develop index flows. The complex operation of the priority system in Colorado meant that water supplies were variable from canal system to system, depending on the seniority of the water rights and available flow. The yield of the Arkansas River is also quite variable from year to year. Since the canals on the lower end of the system divert mostly return flows, their supplies are dependent on upstream operations in addition to intermediate runoff conditions. Finally, the Compact provision protecting Kansas uses existing at the time of the Compact was conditioned on flows being usable in Kansas, such that upstream depletion of streamflow deemed unusable in Kansas was allowed under the Compact.

All of this complexity in the system of canals and reservoir, administration of water rights, the operations of John Martin Reservoir and consideration of conditions in Kansas resulted in the need for a hydrologic model of the river from Pueblo to the Stateline. The purpose of the model was to determine the effect of post-compact groundwater pumping in Colorado on Stateline flows into Kansas. The model has been referred to as the H-I Model, in reference to the hydrologic and institutional processes simulated by it. The model simulates the surface water system and processes groundwater interaction with the river through response functions derived from a separate groundwater flow model.

The H-I Model was developed initially to quantify the effects of the groundwater pumping in Colorado since the time of the Compact through the date of the filing with the court (1985), and subsequently extended to the present in several phases. After it was determined that the groundwater development had resulted in compact violations, controls were necessary in Colorado to obtain compact compliance. The model has evolved into a tool for measuring compliance. The model and its use going forward for assessing the adequacy of replacement operations in Colorado is

documented in the proposed decree pending before the Supreme Court (Littleworth, 2008).

Colorado promulgated Rules in 1996 to require that any continued pumping would be subject to providing offsets so that depletions of Stateline flows prohibited by the Compact would be mitigated. Sources of offsets could include irrigated acreage retirement, reservoir water, net of historical return flows, or transmountain water from the western slope not native to the Arkansas River, usually return flows from the first use.

The model is to be used each year to measure the combined effect of post-compact pumping and operation of replacement plans in Colorado on Stateline flows. Data for actual water supply, climate data, reservoir operations and groundwater pumping are compiled each year and input to the model. The model operates by using measured streamflow supplies, and predicts diversions and storage for pre-compact canals and reservoirs in Colorado. The model contains calibration parameters that were used to calibrate the model to historical streamflows and canal diversions.

Crop ET in the H-I Model

A major module of the model is the simulation of crop water demand and use. The model computes crop water consumptive use and return flows, based on the water supply predicted to be available to the irrigated land. The difference between stream diversions and return flows is commonly referred to as stream depletion, which is a measure of consumptive use by irrigated crops and the delay of return flows reaching the stream.

The crop water demand, or potential ET, is an important model parameter for computing the actual crop ET, limited by the available water supply. Other important model parameters for determining the actual crop ET are irrigated area and water supply. Potential crop ET is calculated outside of the model and used as a model input. The process to calculate crop water demand is a comprehensive combination of climatological data, reference crop ET, application of crop coefficients and derivation of a composite demand for each canal based on cropping patterns across the model domain (Brengosz, 2009). The model uses the crop water demand to compute a demand for water from the river for the canals. The water supply in the river is allocated to the canals and reservoirs based on their demands, locations and relative priorities. Groundwater pumping is added to the supply available for lands served by wells. The total available water supply is applied to meet the crop water demand to determine actual crop ET. The structure of the model, to determine crop water use based on the crop water demand and water supply, reflects the generally water-short condition of the study area.

Potential crop ET was originally computed for the model using the Modified Blaney-Criddle formula, which was developed by the U.S. Department of Agriculture (USDA), Soil Conservation Service (SCS) (USDA-SCS, 1970). This method has had

wide acceptance for calculating historical crop water demand in settings where weather data were limited. The only data requirements were mean monthly temperature at several locations within the study area. Monthly precipitation is also an input to the model and effective precipitation is computed by a routine in the model.

As it became apparent that the H-I Model would be used going forward in time to assess compact compliance, the State of Kansas recommended that the methodology being used to compute the potential crop ET be improved to incorporate available weather data sufficient for application of the Penman-Monteith formula. This proposal was submitted to the Special Master in a trial phase dealing with future remedies, in 2002.

Since the time of the first submittal of the H-I Model to the Special Master in 1990, a weather station network had been installed in the Arkansas River Valley in Colorado, maintained by the Colorado Agricultural Meteorological Network (CoAgMet). The use of Penman-Monteith for reference crop ET had become more streamlined, with progress being made on the development of the ASCE Standardized Reference ET equation, by the ASCE Task Committee on Standardization of Reference Evapotranspiration (ASCE-EWRI, 2005). ASCE Manual 70, Evapotranspiration and Irrigation Water Requirements, had been published in 1990, which described various methods of ET estimation and evaluated and compared the accuracy of various methods under various climatic conditions (Jensen et al., 1990).

The conversion of the method used to estimate potential crop ET from Modified Blaney-Criddle to Penman-Monteith for the H-I Model involved a number of considerations. Because the potential crop ET was a model input, the change did not require any modifications to the structure of the H-I Model. The primary issues that needed to be addressed included the source, sufficiency and reliability of weather data, adaptation of crop coefficients that would be applicable for the study area and any recalibration issues for the H-I Model.

1. The sufficiency and reliability of weather data are discussed in papers presented in these proceedings by Brengosz and by Ley, et al. (Brengosz, 2009 and Ley et al., 2009). Data from four weather stations were available in the study area in 2000. Three of the sites had data for seven years of record available at the time of conversion. Additional weather stations subsequently have been added to the network since 2000 and are now utilized in preparing annual updates.

2. Crop coefficients for application to the Arkansas River Valley were derived from ASCE Manual 70 for use with alfalfa reference crop ET. Adjustments were made for the local growing season conditions in the Arkansas River valley (Franzoy, 2001).

3. The potential effect of the implementation of the Penman-Monteith method on calibration of the H-I Model was addressed by comparing the results from

Penman-Monteith with those obtained with Modified Blaney-Criddle for the overlapping period of record, seven years for most of the weather stations. ASCE Manual 70 had documented differences in the ability of each method to predict crop ET, which indicated an overall difference between the two methods for arid climates. This difference was substantiated by the comparison made for the Arkansas River valley.

The H-I Model was calibrated over the period of 1950 – 1994, using the prior estimates as input. To provide a set of potential crop ET input to the model for the calibration period that would be consistent with the extensions of the model past 1994 using Penman-Monteith, the potential crop ET estimates for 1950 – 1994, obtained with the Modified Blaney-Criddle formula, were transformed to values consistent with Penman-Monteith results. This was accomplished by deriving monthly adjustment factors for each crop and weather station. The H-I Model was then recalibrated with the transformed potential crop ET data.

The evidence submitted by Kansas and Colorado at trial is described in the Special Master's fourth report (Kansas v. Colorado, No. 105 Original, 2003) (Littleworth, 2003). The Special Master considered extensive evidence and decided a number of issues involving the adoption of Penman-Monteith for use in the H-I Model. He concluded that Blaney-Criddle tended to underestimate potential ET in arid locations. He also concluded that Penman-Monteith was generally the method recommended by the scientific community when adequate data were available. He noted data issues were reasonably addressed with integrity assessments and appropriate adjustments which could be relied on into the future, with the expectation that data collection methods would also improve with time.

Issues raised at trial for consideration of the change were related to the applicability of results computed with Penman-Monteith formula to real-world conditions in the field when computing actual crop ET. This is an issue that continues to be important for modeling applications, here and elsewhere: to what extent can results obtained from direct application of the Penman-Monteith and commonly used crop coefficients be accepted without adjustment, or if adjustments are needed, what information or data are necessary to substantiate any adjustments? The H-I Model of course accounted for the availability, or shortage, of water supply because that was the underlying structure of the model. The issues of effects of irrigation management and water quality on crop water use were addressed with evidence and testimony. The Special Master decided that the results of the equation could be used in the model in this case without downward adjustment for real world conditions and management.

The Arkansas River in eastern Colorado is somewhat remarkable for high concentrations of salinity. However, the water supply continues to be a valuable resource for irrigated agriculture in the region, implying that water users have adapted management to the water quality. The issue of the effect of water quality on crop yield and ET was considered by the Special Master. He concluded that the interrelationships of water quality, soil salinity, irrigation management and crop yield

were complex and a relatively simplified adjustment to potential crop ET rates was not appropriate for this modeling application, suggesting that reduced irrigation efficiency to account for leaching practice would be sufficient for this model.

The technical issues considered in this case are examples of details that may need to be considered for direct use of reference or crop specific ET results in other hydrologic models. As the Special Master noted, "While experts speak in terms of 'equations', the mathematical certainty that one might be led to expect from this terminology is not real. Clearly, under some conditions, adjustments are made to reflect local conditions, and these adjustments are not without subjective input." (pg 73, Fourth report) (Littleworth, 2003).

Current Status of Arkansas River Model

The Special Master's findings that the Penman-Monteith equation should be used to compute crop potential ET for input to the H-I Model laid the groundwork for the ongoing updates to the modeling done by the two states each year. The Draft Decree and Appendices provide specifications for annual updates, including schedules, data requirements and procedures for making future changes to the methods (Littleworth, 2008). The decree contains specifications for climate data to be used, crop coefficients, and weather data integrity assessment and correction procedures. Model results are currently updated through year 2007.

REPUBLICAN RIVER COMPACT

The Republican River Compact allocates the water supply of the Republican River Basin between the States of Nebraska, Kansas and Colorado by percentages and tributary basin. The basin is located in the high plains, from eastern Colorado, through southwestern Nebraska and northwestern Kansas (Figure 2). The river flows into Kansas near Hardy, Nebraska, continuing to its confluence with the Smoky Hill River near Junction City, Kansas. Streamflow is derived principally from baseflow and precipitation runoff. The Republican River Compact was adopted in 1943. Water development for irrigation has included early surface water diversions, construction of several federal reservoirs and canal systems, and groundwater development throughout the basin. Much of the basin is underlain by the Ogallala Aquifer. The largest reservoir, Harlan County Reservoir, located about 65 miles upstream of the final crossing of the Kansas-Nebraska Stateline, is a joint project between the Corps of Engineers and Bureau of Reclamation, supplying water to lands in both Nebraska and Kansas.

The State of Kansas brought an action for enforcement of the Republican River Compact in 1999 to the U. S. Supreme Court (Kansas v. Nebraska and Colorado, No. 126 Original). The Republican River Compact allocated beneficial consumptive use to each of the States. Compact compliance is assessed by tabulating the consumptive uses in each state, computing the allocable water supply by adding the stream gage

flows to the computed consumptive uses and comparing each states use to its allocation.

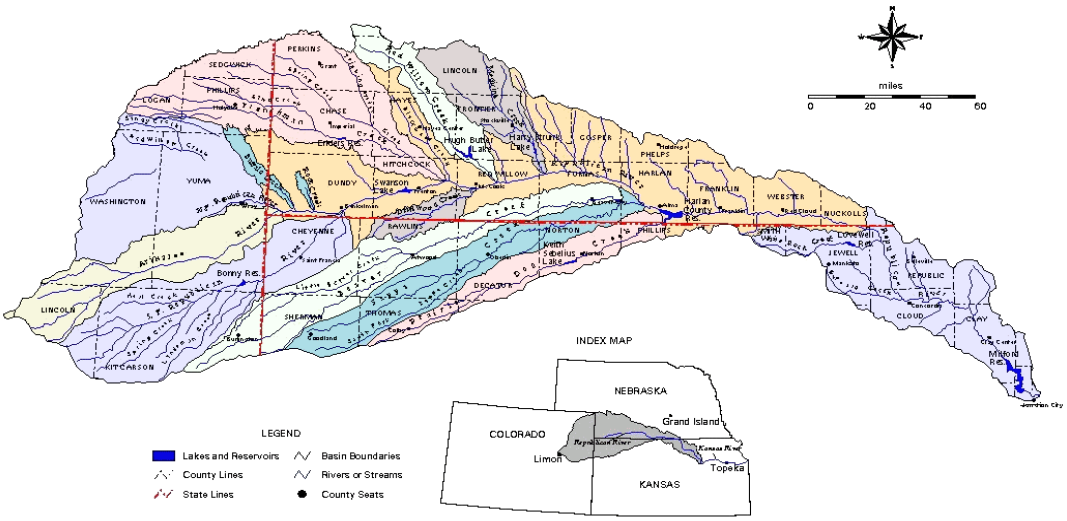

Figure 2: Republican River Location Map based on Appendix C.1 of McKusick, 2003.

In this case, the Special Master issued a ruling requiring that effects of groundwater pumping on streamflows be included and accounted for within each State's allocations. The three states then entered negotiations to resolve issues related to measuring compact compliance. An important element of the settlement was the development and acceptance of a groundwater model used to compute the effects of pumping in each state on streamflows. The Final Settlement Stipulation was submitted to the court in December, 2002 and the Groundwater Model was finally adopted in September, 2003 (McKusick, 2003).

ET Calculations for Republican River Compact

The Groundwater Model is used each year to compute the streamflow effects of pumping in each state. The updates and accounting are accomplished through the Republican River Compact Administration. The methods and data requirements are specified in the Accounting Procedures and Reporting Requirements, Appendix C to the Final Settlement Stipulation. Model documentation is contained in Appendix J to the Final Settlement Stipulation and the Final report of the Special Master. The model determines the effects of pumping for irrigation supply by using the concept of net pumping. Total pumping and recharge of applied water are input to the model.

Crop ET is not an explicit input or result from the model. The Accounting Procedures contain a requirement for each state to annually tabulate and provide estimates of crop irrigation requirement, on a county format. This information has

been and continues to be developed by each State using the Hargreaves method for reference ET, calibrated to the Penman-Monteith equation. The reference crop ET derived with Hargreaves is used with locally derived crop coefficients to obtain the crop specific ET values. Composite values are then obtained by county, using county-wide crop statistic data. Effective precipitation is computed from the monthly totals of potential crop ET and precipitation, using the methods set out in Technical Release No. 21 (USDA, 1970).

Abstract

The ASCE Standardized Reference Evapotranspiration Equation expects the weather station wind speed data to represent that occurring at a height of 2 m over and downwind of a smooth measurement surface such as clipped grass. The Task Committee on the Standardized Equation provided guidance for adjusting wind speed measured at height other than 2 m, or, for situations when the wind speed is measured over and downwind of 0.5 m alfalfa. The latter adjustment attempts to account for the effects of both grass and alfalfa crop characteristics (height, roughness) on the wind profile. A more physically representative approach to adjust wind speeds at various heights and various weather measurement surface conditions to equivalent wind speed at 2 m height over clipped grass is tested. Wind speeds were simultaneously measured during the 2008 growing season at 2-m and 3-m heights above ground surface over variable height alfalfa at two Colorado Agricultural Meteorological Network (CoAgMet) electronic weather stations and at the research alfalfa lysimeter installation at the Colorado State University Arkansas Valley Research Center. These wind speed measurements were adjusted to estimated wind speed at 2 m over grass, and compared.

Introduction

In his fourth report (Littleworth, 2003) in the case of Kansas v. Colorado (No. 105, Original, U.S. Supreme Court), regarding compliance with the Arkansas River Compact, the Special Master hearing the case recommended specific changes by which Arkansas River streamflow depletions at the Colorado-Kansas Stateline are determined. One of the major changes was the recommendation to use the ASCE Standardized Reference Evapotranspiration Equation (ASCE-EWRI, 2005) as the

method to determine reference crop evapotranspiration and the basis for determining crop consumptive use. Steps taken by the States of Colorado and Kansas to implement this recommendation are discussed fully elsewhere in these proceedings (Book and Brengosz, 2009; Brengosz, 2009; Ley et al., 2009). One activity undertaken by the State of Colorado, in cooperation with the Colorado Climate Center, was to expand and improve the collection of weather data suitable for use in the Standardized Equation. To this end, new Colorado Agricultural Meteorological Network (CoAgMet) electronic weather stations were installed, or existing stations moved, into large, private, commercial irrigated alfalfa fields in the lower Arkansas Valley of Colorado. Locating stations in irrigated alfalfa fields was done because of the need to collect weather data for the Standardized Equation in an irrigated environment with adequate fetch (ASCE-EWRI, 2005), and because of a lack of large irrigated grass or pasture fields that could be used for this purpose.

American Society of Agricultural and Biological Engineers Engineering Practice EP505: Measurement and Reporting Practices for Automatic Agricultural Weather Stations recommends that wind speed be measured at 2 m or 3 m height over uniform, low cover vegetation such as grass (ASABE, 2004). The standard wind speed measurement height on CoAgMet weather stations is 2 m above the surface. Some weather station networks measure wind speed at 3 m to avoid or minimize effects of measurement surface vegetation height.

The parameterization of the ASCE Standardized Reference Evapotranspiration Equation (ASCE-EWRI, 2005) expects the wind speed measurement, if not measured at 2-m height over and downwind of a smooth measurement surface such as clipped grass, to be translated to an equivalent value. Specifically, the zero plane displacement, 0.08 m, used in the Standardized Equation for the tall reference crop, is for a weather measurement surface similar to clipped grass, with vegetation height of 0.12 m. The purpose of this was to accommodate a majority of weather stations collecting data over a smooth surface like grass. The Task Committee on the Standardized Equation provided guidance in Appendix B of EWRI-ASCE (2005) for adjusting wind speed measured at height other than 2 m, or, for situations when the wind speed is measured over and downwind of 0.5 m tall alfalfa using standard logarithmic wind speed profile theory. Equation B.14c (ASCE-EWRI, 2005) was developed to adjust wind speed measured over and downwind of 0.5 m alfalfa to an equivalent wind speed over clipped grass for use in the Standardized Equation.

$$u_2 = u_z \frac{\ln\left(\frac{2-d}{z_{om}}\right)}{\ln\left(\frac{z_w-d}{z_{om}}\right)} = u_z \frac{\ln\left(\frac{2-0.08}{0.062}\right)}{\ln\left(\frac{z_w-0.335}{0.062}\right)} = u_z \frac{3.44}{\ln(16.3z_w-5.42)} \quad \text{(B.14c)}$$

where u_2 is wind speed at 2 m above ground surface (m s^{-1}), u_z is wind speed at height z_w over 0.5 m alfalfa (m s^{-1}), d is zero plane displacement height (m) taken as 0.67 h, and z_{om} is aerodynamic roughness length (m) taken as 0.123 h, where h is crop height

(m). The d and z_{om} values in the denominator are for the 0.5 m alfalfa weather measurement surface, while the d and z_{om} in the numerator are a combination of the zero plane displacement for clipped grass (0.08) and roughness length for 0.5 m alfalfa (0.062). This combination is an attempt to account for the effects of both grass and alfalfa crop characteristics (height, roughness) on the wind profile. However, there is some question on whether Eq. B.14c functions correctly in translating wind speed measured over a rough surface such as full cover alfalfa to an equivalent for a smooth grassed standard weather surface.

The States of Colorado and Kansas have agreed to temporarily use Eq. B.14c with a seasonal average alfalfa crop height of 0.3 m to adjust the 2-m wind speed data collected at the CoAgMet weather stations located in commercial alfalfa fields. This results in a nominal 1.7% upwards adjustment to measured wind speeds. It is felt that the true ratio of 2-m wind speed measured over clipped grass to 2-m wind speed over alfalfa will exceed this value on a seasonal average basis, and potentially significantly exceed it, during periods when alfalfa is growing at reference conditions. This paper presents the results of initial studies to better define the adjustment of wind speed data measured at 2-m above ground surface over variable height alfalfa.

Background

The second and third authors have performed a considerable amount of research along with Dr. James L. Wright, USDA-ARS (retired), in the development of Penman and Penman-Monteith type evapotranspiration equations, including the ASCE Standardized Reference ET Equation. Much of this work was done at the USDA-ARS research facility in Kimberly Idaho using alfalfa as the reference crop and with wind measurement over a standard grassed weather station surface. This ultimately influenced the final values for surface resistance used in the Standardized Equation, and thus, the wind data input to the equation should be collected over grass (or adjusted to a grass condition) (Allen et al., 1989; Allen and Wright, 1997; ASCE-EWRI 2005). In that case, the wind profile adjusted to grass should be constructed using zero plane displacement and roughness for grass, which, as discussed above, may not be properly done in Eq. B.14c.

A suggested better approach (than Eq. B.14c) to adjust wind data collected over non-standard measurement surface conditions to an equivalent wind at 2 m over clipped grass is to use the full wind speed translation algorithms presented in Allen and Wright (1997) that correctly account for impacts of height and roughness of vegetation of each surface. These algorithms apply the concept of 'blending height' where the wind profiles over the measurement surface and the surface to which wind is being translated are both extended upward to the top of the internal (or inertial) boundary layer, IBL, over each respective surface. At this elevation, the wind speeds (or at least friction velocity) can be assumed to be equal for both surface conditions. The wind speed at the top of the IBL is then extrapolated downward from this height to the surface to which the wind speed is being translated. Equation 13 of Allen and Wright (1997), repeated here as Eq. 1, illustrates this translation algorithm:

$$u_{z,v} = u_{z,w} \frac{\ln\left(\frac{z_{IBL,w} - d_w}{z_{om,w}}\right)\ln\left(\frac{z_{IBL,v} - d_R}{z_{om,R}}\right)\ln\left(\frac{z_v - d_v}{z_{om,v}}\right)}{\ln\left(\frac{z_w - d_w}{z_{om,w}}\right)\ln\left(\frac{z_{IBL,w} - d_R}{z_{om,R}}\right)\ln\left(\frac{z_{IBL,v} - d_v}{z_{om,v}}\right)} \quad (1)$$

where $u_{z,w}$ is the measured wind speed (m s^{-1}) at a weather station at height z_w (m) having vegetation type W, and $u_{z,v}$ is the equivalent wind speed (m s^{-1}) estimated to have occurred at height z_v (m) above a surface of vegetation type V. $z_{IBL,w}$ and $z_{IBL,v}$ are the heights (m) of the IBL over the weather measurement surface (W) and over the surface (V) to which wind is being translated. d_w, d_R, and d_v are the zero plane displacement heights (m), taken as 0.67 h, for the weather measurement vegetation, the regional vegetation, and, the vegetation of surface V. $z_{om,w}$, $z_{om,R}$, and $z_{om,v}$, are aerodynamic roughness lengths (m) taken as 0.123 h, for the weather measurement vegetation, the regional vegetation, and, the vegetation of surface V. The variable h is vegetation height (m) for each surface condition (W, R, and V).

Eq. 1 is a multiplicative combination of the basic logarithmic wind speed profile relationship and extrapolates wind measured at z_w upward to $z_{IBL,w}$, then from $z_{IBL,w}$ upward to $z_{IBL,R}$, then from $z_{IBL,R}$ downward to $z_{IBL,v}$, and finally from $z_{IBL,v}$ downward to z_v. The intermediate steps to extrapolate up from the weather measurement surface IBL to the regional internal boundary layer and back down to the IBL for surface V is necessary when the heights of the IBL's for the weather measurement surface and for surface V are expected to be different from each other due to different vegetation roughness and fetch lengths for each condition. The regional IBL is assumed to occur directly above the IBL's of the two underlying surfaces and integrates the effects of surface conditions for a large area on the regional wind speed profile. One limitation of the approach of Eq. 1 is that it assumes that neutral boundary layer buoyancy conditions hold. This is generally the case for reference and agricultural conditions when vegetation is near full-ground cover (Allen and Wright, 1997) and the same assumption is used in the derivation and application of the standardized reference ET equation (ASCE-EWRI 2005).

Use of Eq. 1 requires estimating the thickness or height the IBL for each surface condition and the region. The thickness of the IBL depends on the size of the area having similar surface properties, including roughness, vegetation characteristics, and moisture conditions. Allen and Wright (1997) present an approach developed by Brutsaert (1982) to approximate the growth of the IBL over an individual field downwind of a surface discontinuity. Their Eq. 14 is repeated here as Eq. 2:

$$z_{IBL} = d + 0.33 z_{om}^{0.125} x_f^{0.875} \quad (2)$$

where z_{IBL} is the height of the IBL over a surface having roughness, z_{om}, and zero plane displacement, d, at a horizontal distance downwind, x_f, of a substantial change

in surface or vegetation characteristics, all in (m). Surface roughness, z_{om}, and zero plane displacement, d, are approximated as 0.123 h, and 0.67 h, respectively, where h is vegetation height (m).

It should be noted that when the weather station measurement surface (W) and the surface to which wind speed is being translated (V) are both alfalfa with the same fetch conditions, then Eq. 1 reduces to the standard wind speed profile adjustment equation, which is simply an adjustment for wind speed measurement height. The leftmost part of Eq. B14c (as presented above) shows this adjustment, where the d and z_{om} values in both the numerator and denominator are for variable height alfalfa. For example, the adjustment could be from wind speed measured at 3 m above ground surface over alfalfa to 2 m above ground surface over alfalfa.

Methods and Materials

Concerns on the effects of full canopy alfalfa on wind speed measured at 2 m above the ground surface prompted the outfitting of three weather stations along the Arkansas River valley of southeastern Colorado that were in the interiors of alfalfa fields with additional wind speed measurement instrumentation at 3-m height. The three stations comprised two CoAgMet stations located in large alfalfa fields, Las Animas and Holly 02, and the meteorological station at the research alfalfa lysimeter site at the Colorado State University Arkansas Valley Research Center (CSU-AVRC) near Rocky Ford. The outfitting was completed in early June 2008 (see Table 1). In all instances, RM Young Wind Sentry cup anemometers were used at both 2-m and 3-m heights above the ground surface. The existing 2-m height cup anemometers were serviced with new upper and lower shaft bearings and were cleaned at the time of the installation of the 3-m height anemometers, which were all brand new. The CSU-AVRC lysimeter installation is also equipped with a RM Young Wind Monitor (propeller anemometer with integrated vane). The CoAgMet stations are equipped with CR-10X data loggers programmed to measure attached sensors every 10 seconds. Final wind speed data values stored in the CoAgMet database are the mean hourly wind speed (m s^{-1}) and the daily wind run (km d^{-1}). The CSU-AVRC lysimeter meteorological instrumentation is measured by a CR-7X data logger programmed to measure on a 6-sec interval. Final output data includes 5-minute, 15-minute, and daily average wind speed (m s^{-1}).

The typical growth pattern of alfalfa (green chopped or harvested for hay) in the lower Arkansas Valley of Colorado is for spring greenup to begin in late March/early April. Four harvests are usual, occurring approximately the first week of June, the middle of July, the end of August and mid to late October. Fall dormancy and or killing frosts occur by late October. Alfalfa crop growth and harvest data were documented at the CSU-AVRC site, and monitored and documented with photos at the two CoAgMet sites. Cutting dates were obtained from the cooperators at the CoAgMet sites. See Table 1. Crop height curves through the season were approximated at each site using these data, and a simple linear-segmented crop height model similar in structure to the simple single crop coefficient model described in

Table 1. 3-m anemometer installations and crop growth dates during 2008 at the three study sites.

Site	Lat	Long	Elev (m)	3-m anem. installation date	Spring Greenup	First harvest	Second harvest	Third harvest	Fourth harvest
CSU-AVRC	38.04	103.70	1274	Jun 12	Apr 1	Jun 11	Jul 19	Aug 29	Nov 3
Las Animas	38.15	102.86	1187	Jun 4	Apr 1	Jun 14	Jul 22	Aug 28	Nov 11
Holly 02	38.14	102.24	1088	Jun 4	Mar 20	May 30	Jul 8	Aug 21	Oct 18

FAO-56 (Allen et al., 1998). Crop height during the initial growth stage was taken as 0.12 m, and during full canopy stage as 0.50 m, except during the last growth cycle of the season, when maximum alfalfa height attained was only about 0.35 m at all sites. Crop growth between harvests was broken into 3 or 4 intervals, the initial period, rapid development, full canopy, and late. The initial period is normally 5-7 days, except during the first cycle when growth is slower due to cooler temperatures. Rapid development occurs over about 20 days, and full canopy and late stages are from 10-15 days during the mid-season. The impact of alfalfa vegetation height on reducing the ratio of wind speed measured at 2-m height above ground surface to that made at 3-m height above ground surface became more pronounced as the alfalfa grew.

Eqs. 1 and 2 were used to translate both the 2-m and 3-m measured mean daily wind speeds (m s^{-1}) at each site to an equivalent 2-m mean daily wind speed (m s^{-1}) over clipped grass, termed adjusted 2-m and adjusted 3-m mean daily wind speeds in the discussion of results. The alfalfa weather station measurement surface (crop height) at each site varied with time as described above. The fetch of similar surface conditions in each case, i.e., x_f, in Eq. 2, was taken as 200 m for all three deployments, although in the case of CSU-AVRC, there were corn fields or plots 83 m to the north and 100 m to the south of the meteorological instrumentation on the lysimeter field. East and west fetch distance was well over 200m.

An additional measure of wind speed was made at the Rocky Ford CoAgMet station during 2008, over a surface that approximates a standard clipped grass surface. However, these wind data were not reliable for 2008 because corn research plots were located in the near vicinity of the anemometer (5-60 m to the south and west/NW). During June – mid October, when the corn on the plots was taller than about 1 m, sheltering effects on wind speed measurements from the CoAgMet station were evident. Therefore, and unfortunately, the wind speed measurements from the grassed Rocky Ford CoAgMet station could not be used for comparison and as a reality check for the alfalfa wind speed data that were translated to an equivalent wind speed at 2 m over grass.

Eq. 1 was applied to translate measured wind speeds to values representing equivalent wind speeds expected to have occurred over 0.12-m grass having 200 m of

fetch and at the 2-m height (i.e., conditions for a standard weather station). The regional condition in each case was taken as having 1000 m of irrigated fetch with an average vegetation height of 0.5 m. The 0.5 m height represents a mixture of agricultural crops including alfalfa, field corn, grains and vegetables.

Eq. 1 was also applied in reduced form (as discussed above) to translate the 3-m measured wind speeds over alfalfa to estimated 2-m wind speeds over alfalfa at each site. The estimated 2-m wind speeds were then compared to the measured 2-m wind speeds. This translation allows a check on the whether the logarithmic adjustment holds over the alfalfa fields and that the assumption of neutrality is generally valid.

Results

The measured 3-m mean daily wind speed is plotted against measured 2-m mean daily wind speed (upper graph), and the adjusted 3-m mean daily wind speed is plotted versus the adjusted 2-m mean daily wind speed (lower graph), for each of the three sites, respectively, in Figures 1, 2, and 3. Wind speeds typically increase as one moves west to east in the Lower Arkansas Valley of Colorado. For the period June 15 to Oct 31, 2008, the cumulative daily wind run measured at 2-m and 3-m height, respectively, was 23,143 km and 26,577 km at CSU-AVRC; 33,511 km and 37,379 km at Las Animas; and, 33,900 km and 39,180 km at Holly02. The average ratio of measured 3-m to 2-m mean daily wind speeds for this period was 1.148 at CSU-AVRC; 1.116 at Las Animas; and, 1.156 at Holly02. During this period, CSU-AVRC had 62 days, Holly02 had 63 days, but Las Animas had only 41 days when the alfalfa height was 0.35 m and taller. This partially explains the smaller 3-m to 2-m wind speed ratio at Las Animas for the period.

The factor, computed using Eqs. 1 and 2, to adjust the measured 2-m wind speed to the standard weather station condition ranged from 1.00 to 1.18 for alfalfa crop heights of 0.12 m and 0.50 m, respectively, at all 3 sites. The average adjustment factor for April 1 to October 31 across all three sites was 1.09. Conversely, the factor to adjust the measured 3-m wind speed ranged from 0.92 to 1.03 for crop heights of 0.12 m and 0.50 m, respectively, with an April 1-October 31 average adjustment factor of 0.98 across all three sites. The 3-m adjustment factor ranged from 0.98 to 1.03 during periods when the alfalfa crop could be considered at full canopy, 0.30 to 0.50 m in height.

An objective of this study was to adjust measured 2-m and 3-m wind speeds so that the adjusted wind speeds from both heights, representing equivalent wind speeds measured at 2 m over 0.12 m grass, was the same and reflected wind speeds expected over a grassed surface. In Figures 1-3, the measurements made at 2 m over the ground surface for alfalfa were increased following adjustment, and acquired values similar to those derived when adjusting the 3-m measurements over alfalfa to 2 m over a standardized grass surface. Table 2, part (A) is a summary of the measured and adjusted 2-m and 3-m wind speed data for all three sites for the study intervals

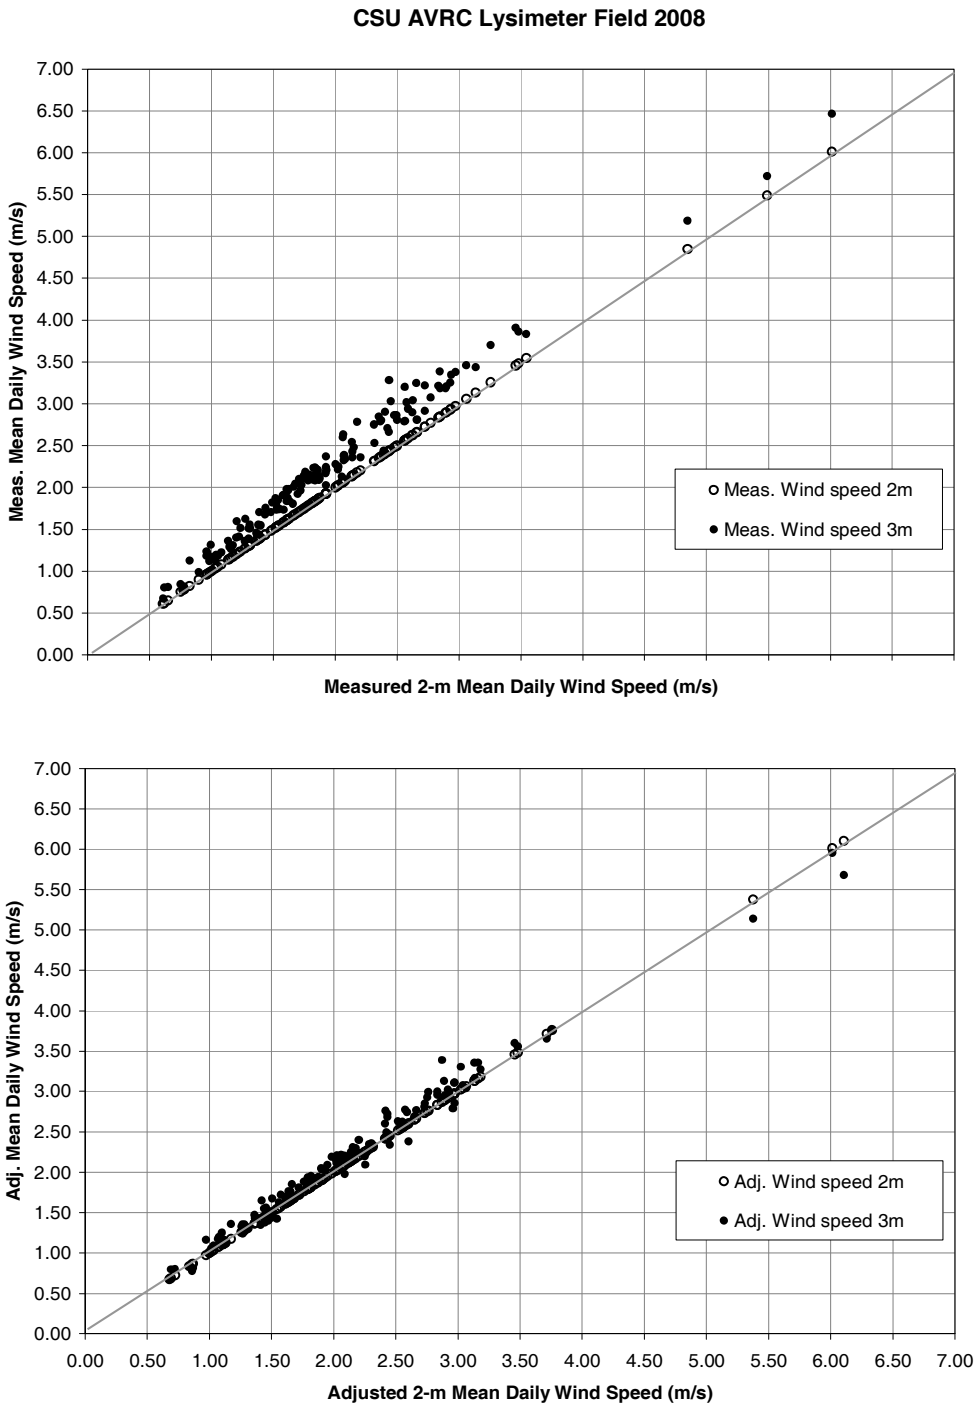

Figure 1. Comparison of measured 2-m and 3-m mean daily wind speeds (upper graph) and adjusted 2-m and 3-m mean daily wind speeds (lower graph) at CSU AVRC.

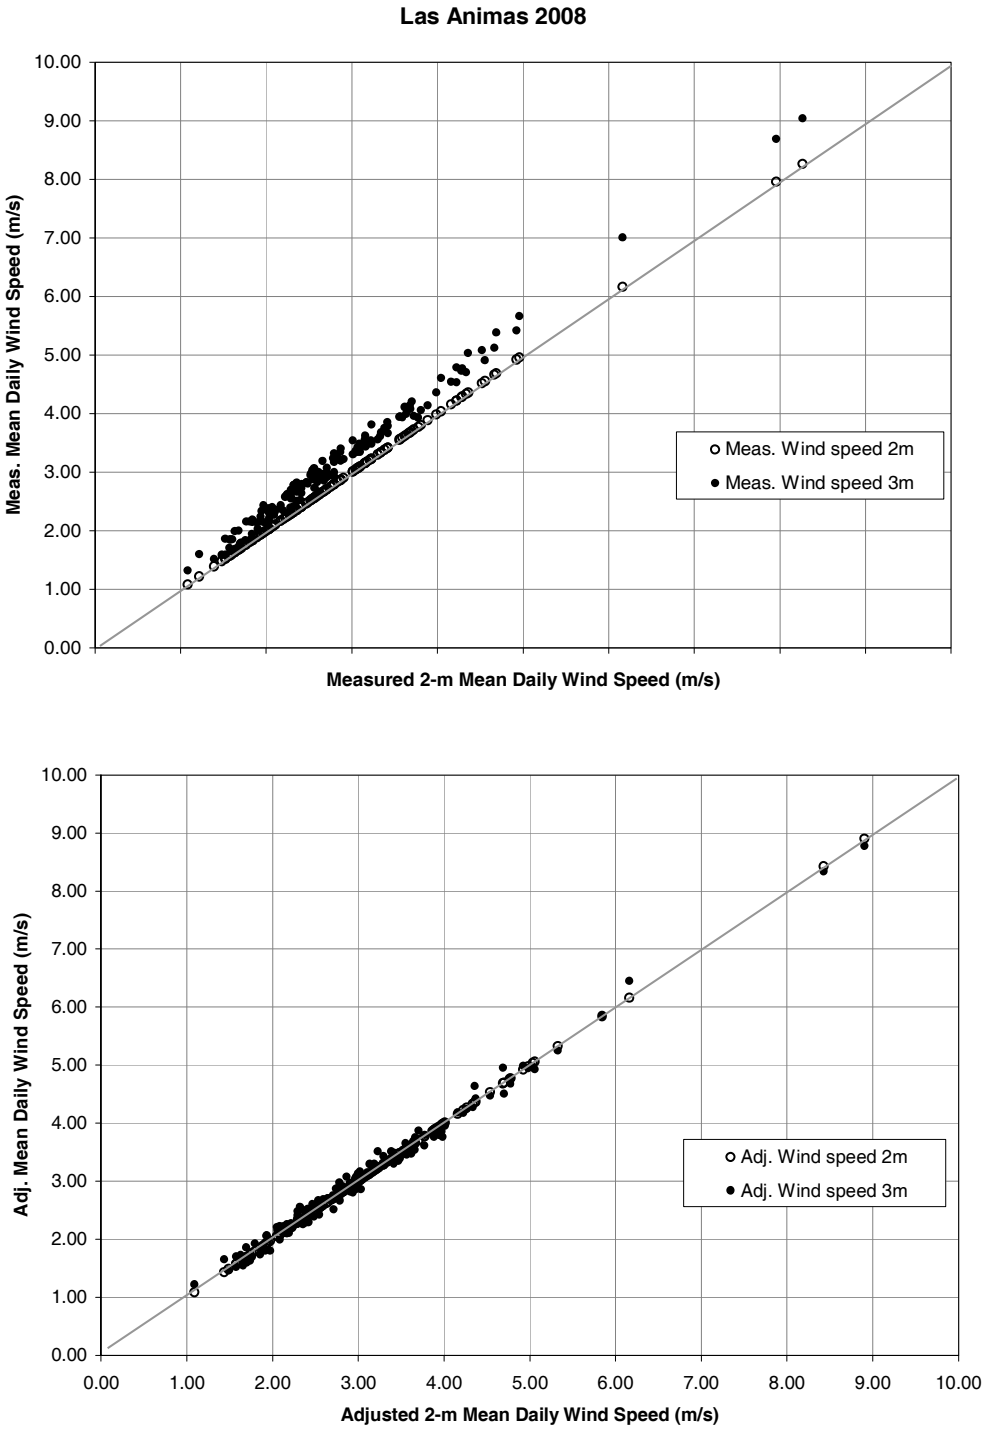

Figure 2. Comparison of measured 2-m and 3-m mean daily wind speeds (upper graph) and adjusted 2-m and 3-m mean daily wind speeds (lower graph) at Las Animas CoAgMet station.

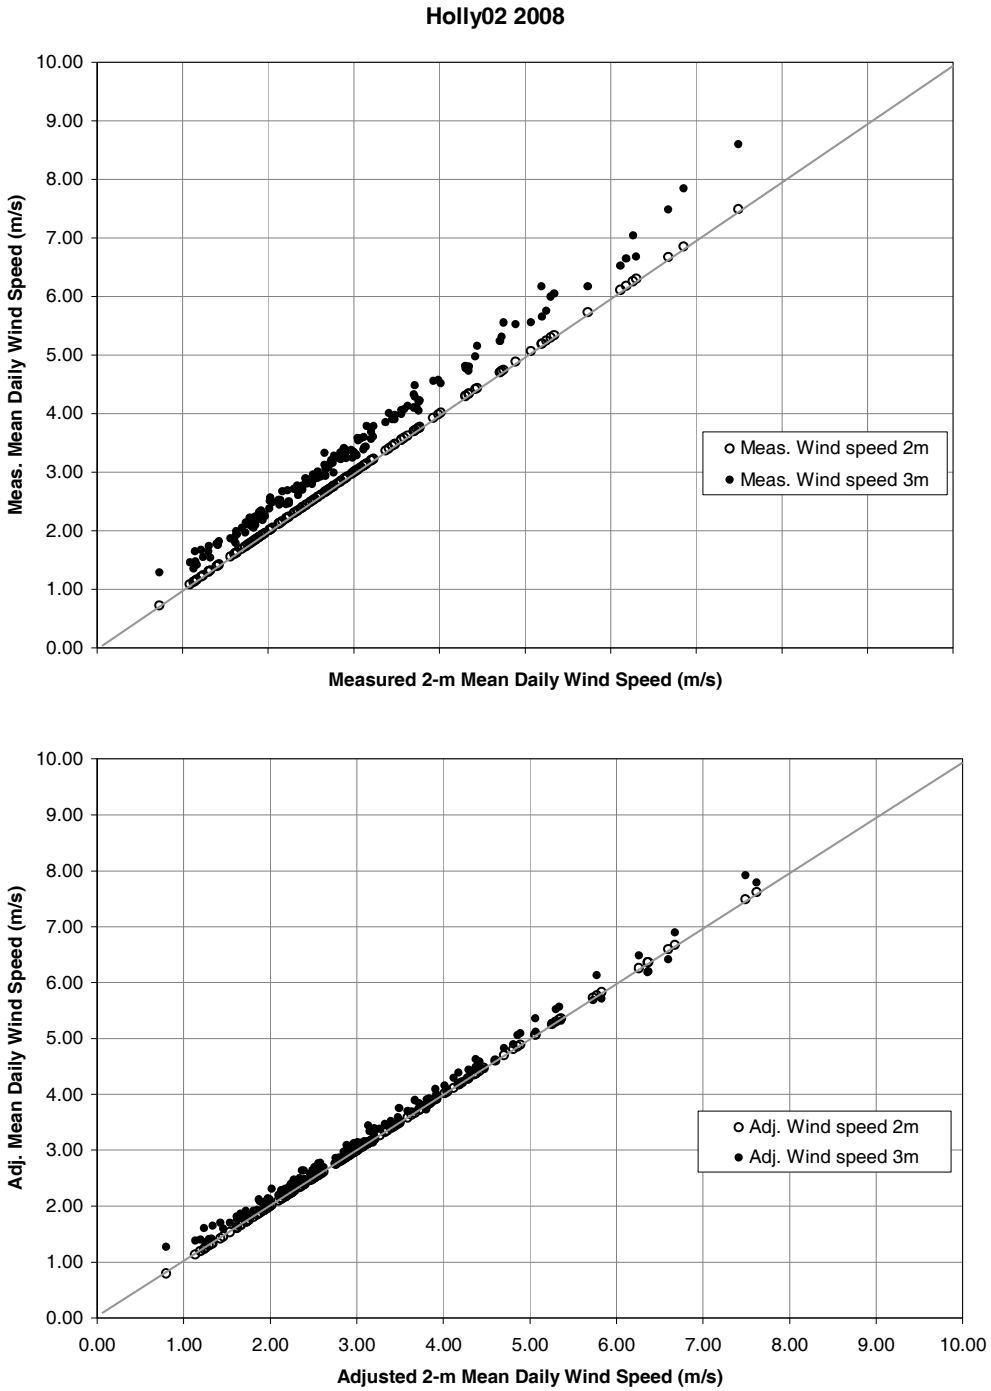

Figure 3. Comparison of measured 2-m and 3-m mean daily wind speeds (upper graph) and adjusted 2-m and 3-m mean daily wind speeds (lower graph) at Holly02 CoAgMet station.

indicated. These results and lower graph in each of Figures 1-3 show the adjustment method is relatively effective and internally consistent, in that the adjusted wind speeds are similar. For example, the results in Table 2 show the mean difference between the measured 2-m and 3-m daily wind speeds was 0.28 m s^{-1} at CSU-AVRC, 0.33 m s^{-1} at Las Animas, and 0.43 m s^{-1} at Holly02. After adjustment using Eq. 1, the mean difference between the adjusted 2-m and 3-m daily wind speeds was 0.07 m s^{-1} at CSU-AVRC, 0.02 m s^{-1} at Las Animas, and 0.12 m s^{-1} at Holly02. The adjustment procedure reduced the difference by 75% at CSU-AVRC, by 94% at Las Animas, and by 72% at Holly02. The variability of the performance of the adjustment algorithm suggests additional investigation is needed on the sensitivity of the error closure to the values used for regional fetch length, regional vegetation height, the estimation method for the height of the IBL's, etc.

The last column of Table 2 indicates the standard deviation of the average difference between the adjusted daily 2-m and 3-m wind speeds to be within 3-5% of the mean adjusted 2-m wind speeds.

At CSU-AVRC, adjustment statistics were also computed for a subset of days, designated as CSU-AVRC (subset) in Table 2, when mean daily wind direction was from either of two 90-degree sectors: NE to SE or SW to NW. This was done to determine if the corn crops to the north and south of the lysimeter field affected the measured and adjusted wind speeds. The measured and adjusted mean daily 2-m and 3-m wind speeds were slightly less for the subset of days at CSU-AVRC. The standard deviation of the daily difference between adjusted 2-m and 3-m wind speeds was also slightly less. Filtering days from the data set when the mean wind direction was from the areas of the corn fields does not appear to have much impact on the results.

Least squares linear regression relationships were computed for each of the adjusted 2-m and 3-m wind speeds versus the measured 2-m wind speed at all three sites. As well, least squares linear regression relationships were computed for adjusted 3-m wind speed versus the adjusted 2-m wind speed at all three sites. At CSU- AVRC, these linear regressions were computed for both the full data set and the wind direction-filtered subset of days. Results are summarized in Table 3. The values for r^2 were high, as expected, due to the large covariance between wind speed measurements at the two heights. In general, no improvement in r^2 was found for the CSU-AVRC subset, when the data were filtered for wind direction. The individual site regression equations, or the overall mean regression equations for adjusting 2-m wind speed measured over alfalfa and presented at the bottom of Table 3, part (A) may provide a simple means for adjusting wind speeds collected over variable height alfalfa to equivalent wind speeds for the standard weather station conditions when nothing is known about alfalfa growth periods and harvest dates, especially in the case where wind speed measurement height is to be standardized at 2 m, as in the case of CoAgMet. Adjustments to measured 2-m wind speeds over alfalfa using the overall mean regression equation developed using the CSU-AVRC subset compared to those made using the full logarithmic wind speed profile translation algorithm, Eq.

Table 2. Comparison of measured mean daily wind speeds, adjusted mean daily wind speeds, average difference between adjusted wind speeds, standard deviation of the difference, and standard deviation of the difference as percent of mean adjusted 2-m mean daily wind speed at the three study sites: (a) comparison for Eq. 1-adjusted 2-m and 3-m mean daily wind speeds, (b) comparison for Eq. 1-adjusted 2-m mean daily wind speed and regression equation adjusted 2-m mean daily wind speed, and (c) comparison for 2.7 m mean daily wind speeds over alfalfa with Eq.1 adjusted 2-m mean daily wind speeds (grass equivalent).

regression of adjusted 3-m wind speed versus the measured 2-m wind speed (both over alfalfa)				
slope	0.98	0.99	0.99	0.99
intercept	0.10	0.09	0.05	0.14
r^2	0.99	0.98	0.99	0.99

1, with time variable crop height data, resulted in less than ±1% difference in the adjusted seasonal mean daily wind speed. See Table 2, part (B).

The results shown in Table 3, part (B) are best fit equations for the data plotted in the lower graph of each of Figures 1-3 (with the exception that the CSU-AVRC subset data have not been plotted). The r^2 values are generally higher in this case compared with those in Table 3, part (A), because the time-variable impacts of alfalfa vegetation height are factored out, i.e., both data sets have been adjusted to the same datum (grass roughness). These regression results (with slopes near 1.00 and small intercepts) indicate the wind speed translation algorithm (Eq. 1) is internally consistent, i.e., the adjusted 3-m wind speeds are nearly the same as the adjusted 2-m wind speeds.

Table 3, part (C) shows the results of regressions of the measured 3-m wind speed adjusted to a 2-m height above ground over alfalfa versus the measured 2-m wind speeds above ground over alfalfa at each site. These results indicate the logarithmic wind profile adjustment holds over the alfalfa fields and that the assumption of neutrality is generally valid.

Estimate of neutral wind speed measurement height over alfalfa. The range of the adjustment factors to adjust the 2-m and 3-m mean daily wind speeds measured over alfalfa (as computed using Eq. 1) to equivalent mean daily wind speed at 2 m over grass suggests there is an intermediate height for wind speed measurement above ground surface over variable height alfalfa that is neutral and approximates wind speed at 2 m over grass without need for adjustment. By setting $u_{z,w}$ equal to $u_{z,v}$ in Eq. 1, one can solve directly for z_w, the alfalfa wind speed measurement height as a function of the alfalfa crop height. The result is a z_w time series reflecting the alfalfa growth and harvest periods. Neutral, seasonal mean wind speed measurement height over alfalfa that is equivalent to mean wind speed measured at 2 m over grass was computed in this fashion for the periods of data collection at all three locations in 2008. The mean neutral alfalfa weather station wind speed measurement heights were 2.73 m for CSU-AVRC, 2.67 m for Las Animas, and 2.70 m for Holly02; or, across all three sites, the average is 2.70 m. Anemometers deployed at this height in actively growing and harvested alfalfa fields (having similar growth and harvest patterns as the study area, Table 1) would be expected to measure wind speeds over alfalfa that do not need adjustment prior to computing alfalfa reference ET_{rs}. This was evaluated by adjusting the measured 2-m wind speeds at each location to a height of 2.70 m using logarithmic wind profile adjustment for height (discussed previously), and comparing the resultant values with the Eq.1 adjusted 2-m wind speeds (that represent equivalent wind speed at 2 m over grass). Results are shown in Table 2, part (C), in the format similar to previously discussed results. The results show there is very good agreement between the two sets of wind speed estimates at all three sites (average differences near 0.00), but with more scatter/dispersion in the differences, (similar or larger values for the std. deviation of the differences).

Impacts on computed reference ET. ASCE standardized equation alfalfa reference ET_{rs} was computed for the period of data collection during 2008 at all three sites using the following wind speed data sets: a) measured 2-m mean daily wind speed, b)

measured 3-m mean daily wind speed, c) Eq. 1 adjusted 2-m mean daily wind speed, d) Eq. 1 adjusted 3-m mean daily wind speed, and e) mean daily wind speed adjusted using the overall mean regression equation for all sites with the CSU-AVRC wind direction-filtered subset of days (i.e., Equiv. 2-m wind speed over grass (m s^{-1}) = 1.04 * measured 2-m wind speed over alfalfa (m s^{-1}) + 0.12). Results are presented in Table 4. The period of data collection at each site essentially covers three alfalfa growth cycles. Computed ET_{rs} using measured 3-m mean daily wind speed is from 4.3-5.6% greater, using adjusted 2-m mean daily wind speed is from 1.4-3.2% greater, and using adjusted 3-m mean daily wind speed is from 3.1-4.5% greater than when computed using the measured (over alfalfa) 2-m mean daily wind speed. Using the regression-equation adjusted mean daily wind speed (based on the general equation listed earlier in this paragraph) results in an increase of computed alfalfa reference ET by 2-3% compared to using measured (over alfalfa) 2-m mean daily wind speed. The 'true' ET_{rs} values, (i.e., as computed using measured wind speed at 2 m above ground surface over clipped grass), would likely have been in the range of 2 to 4% greater than the ET_{rs} calculated using the wind speeds collected at 2-m height above ground surface over the alfalfa crops. On average, ratios of the 3-m to 2-m unadjusted wind speeds averaged about 1.15, as noted earlier, and ratios of ET_{rs} using these two wind data sets averaged about 1.05. This suggests that, in the context of weather data along the Arkansas River, the 15% increase in measured wind speed from 2-m to 3-m height causes the seasonal ET_{rs} estimate to increase by 5%, or a ratio of about 1 to 3.

Table 4. Comparison of computed Standardized Alfalfa Reference ET for measured and Eq. 1 adjusted 2-m and 3-m mean daily wind speed data sets, and regression equation adjusted mean daily wind speed data. Values in parentheses are the ratio of the ET_{rs} value to the ET_{rs} computed using the measured 2-m mean daily wind speeds.

Standardized Alfalfa Reference ETrs (mm)						
Site	Period (DOY)	Meas. 2-m mean daily wind speed	Meas. 3-m mean daily wind speed	Adj. 2-m mean daily wind speed	Adj. 3-m mean daily wind speed	Regression equation adj. mean daily wind speed
CSU-AVRC	165-305	999	1042 (1.043)	1013 (1.014)	1030 (1.031)	1019 (1.020)
Las Animas	157-305	1058	1110 (1.049)	1092 (1.032)	1098 (1.038)	1090 (1.030)
Holly02	157-305	975	1030 (1.056)	1003 (1.029)	1019 (1.045)	1001 (1.027)

Summary and Conclusions

Wind speed data measured at 2-m and 3-m height above ground surface over variable height (growing) alfalfa during 2008 at three sites in the lower Arkansas Valley of Colorado were adjusted to represent wind speeds expected at 2 m over 0.12-m grass having 200 m or more fetch. Wind speed translation algorithms were applied where the wind profiles over the measurement surface and the surface to which wind is

being translated are both extended upward to the top of the internal boundary layer over each respective surface. At this elevation, the wind speeds (or at least friction velocity) are assumed to be equal for both surface conditions. The adjustment method was found to be internally consistent—i.e., the adjusted 2-m and 3-m wind speeds at each site were nearly equal in value. This requires, however, careful documentation of alfalfa growth and harvests at the alfalfa weather station. The sensitivity of the method to weather measurement surface fetch, and the vegetation height of the general region, which affects the height of the internal boundary layer over the measurement surface and the translation surface, needs further study.

Measured 3-m wind speed over alfalfa was adjusted to 2-m height above ground over alfalfa and compared to the measured 2-m wind speeds above ground over alfalfa at each site. Results indicate the logarithmic wind profile adjustment holds over the alfalfa fields and that the assumption of neutrality is generally valid.

Ideally, adjusted wind run should be compared to measured 2-m wind run over 0.12-m grass at a standard weather station with 200 m or more fetch. The Rocky Ford CoAgMet site, which is near the CSU-AVRC lysimeter site, approaches these conditions, however, measured wind speed data at this site during 2008 were affected by nearby corn crops.

Adjustments made to wind speed measured at 2-m height above ground over alfalfa to translate the measurements to that expected at 2-m height above ground over clipped grass ranged from 1.00 to 1.18, when the alfalfa height ranged from 0.12 m to 0.50 m. The seasonal (Apr 1-Oct 31) average adjustment factor was 1.09. The maximum, 1.18, and average, 1.09, upward adjustment factors are substantially greater than the 1.7% upward adjustment calculated using Eq. B.14c (ASCE-EWRI, 2005) with seasonal average alfalfa height of 0.30 m. Eq. B.14c appears to underestimate the required adjustment, and we recommend that it not be used to adjust wind speed measured over a rough surface such as alfalfa to the standardized smoother surface of clipped grass that is expected by the standardized reference ET equation.

A single mean regression relation developed using data collected in 2008 may be a suitable method to adjust wind speeds collected over variable height alfalfa to represent wind speeds at 2 m over 0.12-m grass with 200 m of fetch, especially in cases where nothing is known about alfalfa growth periods and harvests at the weather station, and when standard wind speed measurement height is 2 m. Such regression equation-based adjustments when compared to those made using the full logarithmic wind speed profile translation algorithm, Eq. 1, with time variable crop height data, resulted in less than ±1% difference in seasonal mean daily wind speed. This approach needs further study and would benefit from an additional year or two of data to assess variability.

A mean neutral wind speed measurement height over alfalfa (for the alfalfa growth conditions of this study), i.e., which produces equivalent wind speeds at 2-m over grass, of 2.70 m was determined through manipulation of the full wind speed adjustment algorithm expressed here as Eq. 1. Measured 2-m wind speeds over

alfalfa adjusted for height to 2.70 m compared well with Eq. 1 adjusted 2-m wind speeds (grass equivalent).

ABSTRACT

Evapotranspiration and net irrigation water requirement estimates were updated in 2007 by Allen and Robison (2007; Allen et al., 2007) for agricultural areas in Idaho. ET calculation procedures were employed that use an updated procedure to calculate crop coefficients that considers the impact of surface wetting by irrigation and precipitation on total evapotranspiration. ET was calculated for daily, monthly and annual timesteps for 123 weather station locations across Idaho for complete, available periods of record. ET estimates were made for all times during the calendar year including winter to provide design and operation information for managing land application of agriculture, food processing and other waste streams and to provide full-calendar year estimates of E and ET for hydrologic studies and to estimate beginning of growing season soil water content.

Crop evapotranspiration, abbreviated ET_c, was calculated on a daily timestep basis for improved accuracy. Daily calculation timesteps allowed for the calculation of evaporation of water from wet soil surfaces following precipitation or irrigation events. ET_c for monthly, growing season and annual periods were summed from the daily calculations. The FAO-56 method for estimating evaporation from bare, wet soil, was utilized where a daily water balance was computed for the top 10 cm of soil as a means for reducing evaporation losses as the soil surface dries. Precipitation runoff was estimated using the NRCS Curve Number method where antecedent moisture was computed from the daily surface soil water balance.

Snow cover data as observed at many of the NWS stations were used to modify winter time estimates of evaporation caused by high albedo of snow and energy required for heat of fusion and was also used during adjustment of cumulative growing degree days for winter wheat during winter.

INTRODUCTION

Evaporation during nongrowing (wintertime) periods varies widely, based on availability of moisture, freezing of soils, snow cover, impacts of surface organic mulches (dead vegetation) and availability of energy for evaporation. Quantification of winter time evaporation is important when performing hydrologic water balances and when estimating effectiveness of wintertime precipitation in recharging the soil profile to supply water to vegetation during the subsequent growing season. Evaporation losses during winter, following soil wetting events, reduces the effectiveness of precipitation in recharging soil profiles.

Few studies have measured and documented wintertime evaporation. Wright (1991, 1993) conducted a series of wintertime measurements of evaporation using the dual precision weighing lysimeter systems at Kimberly. The following figures 1 and 2 show mean K_c values derived by Wright (1991) that correspond to evaporation during nongrowing (winter) seasons at Kimberly over a six year period from 1985 – 1991. The lysimeter surface conditions included clipped fescue grass on one lysimeter that was dormant during the winter period and various 'bare soil' conditions on the other lysimeter that represented soil conditions in between annual agricultural crops. The bare soil conditions included disked wheat stubble, disked alfalfa, disked soil, alfalfa and winter wheat. The basis for the mean K_c values in the figures is the ASCE standardized Penman-Monteith method (original K_c's by Wright were transformed to the ASCE PM basis). The ASCE PM alfalfa reference ET_r standard represents 0.5 m tall green alfalfa, even during winter (the crop is a hypothetical potential reference). The K_c at Kimberly during winter time rarely reached 1.0. However, mean K_c (K_{cm}) did typicalloy approach or exceed 0.8 during Dec. 1988 - Mar. 1989 for the disked soil, a period having a nearly continuous distribution of precipitation.

THE CROP COEFFICIENT APPROACH

A common approach for ET is the crop coefficient – reference ET method, where a reference ET_r is multiplied by a crop coefficient. The reference ET_r represents ET from a defined, fully vegetated surface such as full-cover alfalfa or clipped cool season grass and incorporates the influence of weather on the ET quantity. The K_c is defined as the ratio of actual or potential ET by a specific crop or land-cover condition to ET_r. The K_c therefore incorporates plant and cultural factors that cause ET to vary from ET_r. These factors are typically related to stage of vegetation development and wetting by irrigation or precipitation. The K_c ET_r method is widely used due to its simplicity, reproducibility, relatively good accuracy, and transportability among locations and climates. The method, when applied carefully, can produce estimates of ET that are sufficiently accurate for irrigation systems design and operation.

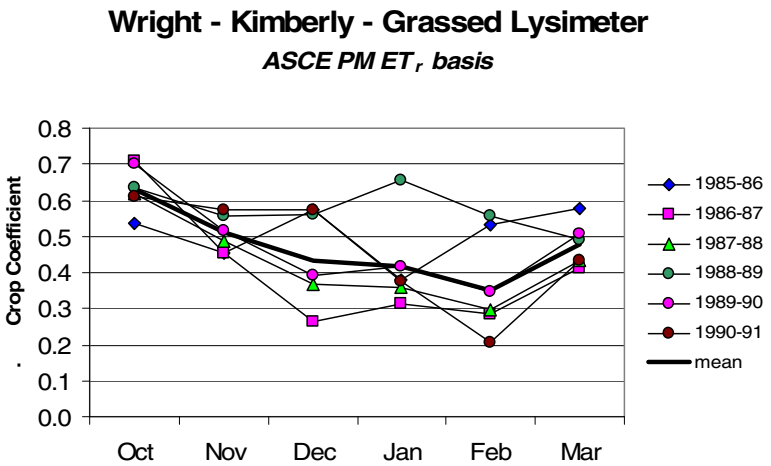

Figure 1. Mean monthly K_c measured by Wright (1993) from a grassed (dormant) lysimeter during nongrowing periods at Kimberly, Idaho converted for use with the ASCE Penman-Monteith alfalfa reference ET_r equation.

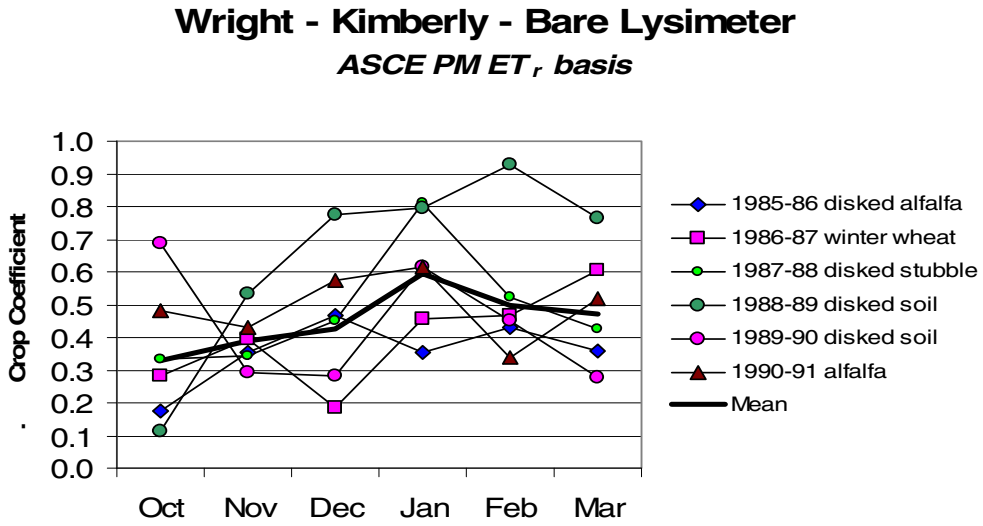

Figure 2. Mean monthly K_c measured by Wright (1993) during nongrowing periods at Kimberly, Idaho for various types of surface cover, converted for use with the ASCE Penman-Monteith alfalfa reference ET_r equation.

Two approaches to K_c have historically been applied. The first approach uses a 'mean' K_c where all time-averaged effects of evaporation from the soil surface are averaged into the K_c value. The mean K_c represents, on any particular day, average evaporation fluxes expected from the soil and plant surfaces under some 'average' wetting interval (by rain or irrigation). The second K_c approach is the 'dual' K_c method, where the K_c value is divided into a 'basal' crop coefficient, K_{cb}, and a separate component, K_e, representing evaporation from the soil surface. The basal crop coefficient represents ET conditions when the soil surface is dry, but with sufficient root zone moisture present to support full transpiration. The K_e component

is calculated separately, according to actual or simulated wetting events and is then added to the K_{cb} to produce the total K_c. Generally, a daily calculation time-step is required to apply the dual K_c method. The form of the equation for actual $ET_{c\ act}$ in the dual K_c approach is:

$$ET_{c\ act} = \left(K_s\, K_{cb} + K_e\right) ET_r \tag{1}$$

where K_{cb} is the basal crop coefficient [0 - ~1.0 when used with ET_r], and K_e is a soil water evaporation coefficient [0 - ~1.0 when used with ET_r]. All K terms are dimensionless. K_{cb} is defined as the ratio of ET_c to ET_r when the soil surface layer is dry, but where the average soil water content of the root zone is adequate to sustain full plant transpiration. K_e quantifies the evaporation component from wet soil in addition to the evapotranspiration represented in K_{cb}. K_s is a reduction coefficient for when there is stress caused by low soil moisture [0 - 1] (dimensionless). K_s reduces the value of K_{cb} when the average soil water content of the root zone is not adequate to sustain full plant transpiration. K_s = 1.0 when there is no water stress.

The dual K_{cb} approach is considered to be a superior approach for estimating wintertime evaporation than the mean K_c approach because the evaporation process is dominated by frequency of wetting events and relative wetness of the surface soil layer. A daily soil water balance is required to calculate K_s, since its value can change daily as soil water contents decline. This soil water balance incorporates the full effective root zone as simulated on a particular date during the growing season and an evaporation layer during the nongrowing season. A separate soil water balance estimates K_e where only the water content of the upper 0.1 m of soil is simulated, since it is this upper soil layer that supplies water for direct evaporation from the soil surface. The calculation of the crop coefficient curve during the growing season followed general practice of FAO-56 and Allen et al., (2005).

The daily water balance calculations and the calculation of K_s and K_e follow directly the procedure established in the FAO-56 publication (Allen et al., 1998) and extended by Allen et al., (2005). Departures from the Allen et al., (2005) FAO-56 procedure were made for the Idaho application to account for use of alfalfa reference ET_r rather than grass reference ET_o that is generally applied with the FAO-56 procedure. The general model for K_e (Allen et al. 1998) for use with the basal crop coefficient is:

$$\begin{aligned} &K_e = K_r\,(\,K_{c\,max} - K_s K_{cb}\,) \\ &\textit{such that} \\ &K_e \le f_{ew}\ K_{c\,max} \end{aligned} \tag{2}$$

where $K_{c\ max}$ is the maximum value of K_c following rain or irrigation, K_r is a dimensionless evaporation reduction coefficient [0-1] that in the FAO-56 dual K_c approach, is expressed as a function of the cumulative depth of water depleted by evaporation from the soil. Parameter f_{ew} is the fraction of soil surface from which

most of the evaporation occurs and is generally taken as the fraction of soil surface that is both exposed to drying and is 'wetted' during the wetting event. The use of cumulative depth of evaporation to estimate K_r tends to stretch out drying periods when ET_{ref} is low and shorten them when ET_{ref} is high.

The FAO-56 K_c approach represents a compromise between complexity and general application by conducting a daily water balance of the upper soil layer where upward flux of water or vapor to the layer from below is considered to be negligible or is ignored, and the effective depth of the evaporating layer is specified as the depth of soil that dries, on average, to a threshold dryness point. In the case of the FAO procedure, the threshold point is taken as the mean soil water content half-way between air dry and wilting point. This is an arbitrary dry point, but one that is relatively straight forward for field application and one that is reproducible. The maximum depletion depth for the layer provides a consistent stopping point for the evaporation cycle to ensure conservation of mass and can be customized for each application to fit observations.

The FAO procedure assumes that evaporation takes place in two stages following Ritchie (1971): the energy limiting stage 1, and the falling rate stage 2. When the soil is wet (in stage 1), the evaporation reduction coefficient in eq. 2, K_r = 1.0. When the water content in the effective evaporation layer begins to limit evaporation (in stage 2), K_r decreases. The value for K_r is set to zero when the total amount of water in the effective evaporation layer is depleted during the drying cycle. Assuming the soil is at field capacity (θ_{fc}) shortly after rainfall or irrigation and that it can dry to halfway between 0 and the wilting point (θ_{wp}), the total amount of water that can be depleted by evaporation (*TEW*) from the effective evaporation layer during a drying cycle is estimated as:

$$TEW = 1000\,(\theta_{fc} - 0.5\,\theta_{wp})\,z_e \tag{3}$$

where *TEW* is the 'total evaporable water' in mm, θ_{fc} and θ_{wp} are $m^3\ m^{-3}$ and z_e is the effective depth of the surface layer that is dried by evaporation in m. The cumulative depth of evaporation, D_e, at the end of stage 1 is defined as readily evaporable water (*REW*) and normally ranges from 5 to 12 mm depending on soil texture (Ritchie 1972).

Downward adjustment of *TEW* was recommended by Allen et al. (1998, 2005b) during extended periods of low ET_{ref} (i.e., ET_o < 5 mm d^{-1}) commonly experienced during nongrowing periods. During cool conditions, for example during winter or other cool periods, less radiation energy is available for heating the soil surface layer and evaporate water, and total effective *TEW* representing a drying event will typically be smaller than during a warm period. Allen et al. (1998) suggested using ET_o as a surrogate for temperature and radiation conditions to reduce the value for *TEW*. When ET_o < 5 mm d^{-1}, *TEW* is estimated as:

$$TEW = 1000(\theta_{fc} - 0.5\theta_{wp})z_e\sqrt{\frac{ET_o}{5}} \quad (4)$$

where ET_o is an average representing the general estimation period. A monthly average for ET_o was used. Varying ET_o on a daily basis is not recommended since it will cause *TEW* to vary daily, which can cause numerical inconsistencies. The value for REW was limited to less than or equal to 0.7 ($TEW_{applied}$).

During the falling rate stage when $D_e > REW$, evaporation is estimated to be proportional to the amount of water remaining in the surface soil layer, and K_r becomes:

$$K_r = \frac{TEW - D_{e(i-1)}}{TEW - REW} \quad (5)$$

where $D_{e(i-1)}$ is the cumulative depth of evaporation at the end of day $(i - 1)$, or the previous day.

Estimation of K_e requires a daily water balance for the f_{ew} fraction of the surface soil layer:

$$D_{e,j} = D_{e,j-1} - (P_j - RO_j) - \frac{I_j}{f_w} + \frac{E_j}{f_{ew}} + T_{ei,j} + DP_{ei,j} \quad (6)$$

where $D_{e,j-1}$ and $D_{e,j}$ are cumulative depletion depth at the ends of days j-1 and j [mm], P_j and RO_j are precipitation and precipitation runoff from the soil surface on day j [mm], I_j is the irrigation depth on day j that infiltrates the soil [mm], E_j is evaporation on day j (i.e., $E_j = K_e\ ET_{ref}$) [mm], $T_{ei,j}$ is the depth of transpiration from the exposed and wetted fraction of the soil surface layer on day j [mm], and $DP_{ei,j}$ is the deep percolation from the f_{ew} fraction of the soil surface layer on day j if soil water content exceeds field capacity [mm]. Assuming that the surface layer is at field capacity following heavy rain or irrigation, the minimum value for $D_{e,j}$ is zero. The limits imposed on $D_{e,j}$ are consequently $0 \le D_{e,j} \le TEW$. The irrigation depth I_j is divided by f_w to approximate the infiltration depth to the f_w portion of the soil surface. Similarly, E_j is divided by f_{ew} because it is assumed that all E_j (other than residual evaporation implicit to the K_{cb} coefficient) is taken from the f_{ew} fraction of the surface layer. It is recognized that soil water content can exceed field capacity for a few days following a large wetting event and that some drainage in soil occurs at very small rates at water contents below field capacity. To some extent, impacts of these simple assumptions can be compensated for in setting the value for z_e or *TEW*.

CALCULATING WINTERTIME EVAPORATION

In estimating K_c for nongrowing season periods, a basal $K_{cb} = 0.1$ was used for bare soil conditions, for surfaces covered with some amount of mulch, and for dormant turf/sod systems. The K_{cb} represented conditions when these surfaces had a

dry soil surface, but with sufficient moisture at depth to supply some diffusive evaporation. The evaporation (K_e) component was estimated separately in the daily soil water balance, where $K_{c\ max}$ during the nongrowing period was set at 0.9 for bare soil, 0.85 for mulched surfaces and to 0.8 for dormant grass cover. The lower value for grass is to account for insulative effects of the grass and higher albedo. The *third surface cover class* of 'mulch', was used to represent surfaces that are part way between bare and grassed conditions. The assumed effective fraction of 'cover' f_{ew} used during estimation of K_e was 0.7 for dormant grass, 0.4 for mulch and 0 for bare soil. The use of a low value for K_{cb} permitted the K_e function in the daily calculations to increase the value for total K_c according to wetting frequency by rain and snow.

An effective 'rooting zone' of 0.10 m was used for the fraction of surface under the cover. For all surfaces, a daily soil water balance was conducted and a stress coefficient is applied when soil water content drops below a critical value for the upper 0.10 to 0.15 m. Thus, actual K_c reduced below K_{cb} when both the ground surface and subsurface soil were dry.

The nongrowing season (winter) period was defined as the period beginning at the end of a K_{cb} curve representing the growing cycle for a specific crop or the occurrence of a killing frost, and ending at greenup or planting of the same crop the following year (or Oct. 1 in the case of winter wheat). All land use types, including agricultural, landscape, horticultural and natural vegetation, were assigned one of the three winter cover conditions (dormant grass, bare soil or mulch classes) for estimating evaporation losses during winter.

Adjustment for snow cover. Snow cover depth and new snowfall are reported for a number of National Weather Service cooperature stations. Snow cover information was used to adjust the K_c ($K_{c\ max}$) value to account for higher albedo of snow and absorption of heat by melt. The following algorithms were applied:

$$K_{c_multiplier} = 1 - K_{radiation_term_winter} + \frac{(1 - albedo_{snow})}{(1 - albedo_{surface})} K_{radiation_term_winter} \quad (7)$$

where $K_{RadiationTermWinter}$ represents the weighting of (or contribution to) winter time reference ET estimates by the radiation term of the Penman-Monteith method, $albedo_{snow}$ is the mean albedo of snow cover and $albedo_{surface}$ is the mean albedo of the bare surface. $K_{RadiationTermWinter}$ is equivalent to:

$$K_{radiation_term_winter} = \frac{\Delta}{\Delta + \gamma\left(1 + \frac{r_s}{r_a}\right)} \quad (8)$$

where Δ is slope of the saturation vapor pressure-temperature curve, γ is the psychrometric constant, r_s is surface resistance to vapor flow and r_a is aerodynamic resistance to heat and vapor flow above the surface. The intent of Eq. (7) is to adjust the ET_r estimates by the Penman-Monteith method, which is parameterized to estimate ET for a vegetated surface to those that would have occurred from snow cover. The primary adjustment is for albedo of the surface, which is higher for snow cover. For ease of calculation, $K_{RadiationTermWinter}$ was calculated as a function of day of year based on a relation derived using full years of Kimberly weather data and the ASCE standardized Penman-Monteith equation:

$$K_{RadiationTerm} = 2.2E-08\ J^3 - 2.42E-05\ J^2 + 0.006J + 0.011 \quad (9)$$

An additional reduction in evaporation of 30% was made to account for absorbed latent heat of fusion of any melting snow prior to evaporation. Albedo of snow was set at 0.8 in calculations and albedo of the surface was set to 0.25.

Occaisionally, some stations reported snow fall (daily), but did not report observations of accumulated snow cover. In these cases, estimated depth of snow on the ground was made by accumulating snow fall and applying a simple melt rate function:

$$Snow_accumulation_i = Snow_accumulation_{i-1} + \frac{Snowfall}{2} - Melt_i \quad (10)$$

$$Melt = 4\ T_{max} \quad (11)$$

where *snow_accumulation* is snow depth accumulation in mm, *Snowfall* is reported snowfall depth for the day in mm, *Melt* is melt rate in mm/day and T_{max} is daily maximum air temperature in ^oC. The *snow_accumulation* parameter was calculated for all stations and periods and was used if it exceeded reported snow depth, as a precaution. The reported depth of snowfall was halved to reflect consolidation of the snow cover. The snow melt rate function was based on about 50 years of snowcover observations for Ashton, Idaho.

INFILTRATED PRECIPITATION

Runoff during precipitation events is strongly influenced by soil texture, soil structure, sealing and crusting of the soil surface, land slope, local land forming (tillage and furrowing), antecedent moisture, precipitation intensity and duration. Generally, estimation of runoff during precipitation is fraught with uncertainty. For general purposes, runoff can be estimated using the USDA-NRCS Curve Number approach. The NRCS curve number is simple to apply and is widely used within the hydrologic, soils and water resources communities. Required data are daily precipitation depth and computation of a daily soil water balance by which to select the antecedent soil water condition.

Once the surface runoff depth is estimated using the curve number procedure, the depth of rainfall infiltrated is calculated as:

$$P_{inf} = P - RO \tag{12}$$

where P_{inf} is the depth of infiltrated precipitation [mm], P is the measured precipitation depth [mm], and RO is the depth of surface runoff [mm]. If the soil will not hold the amount infiltrated, the remainder goes to deep percolation.

EXAMPLES OF WINTERTIME ESTIMATES

Examples of calculated K_{cb} and $K_{c\ actual}$ curves ($K_{c\ actual} = ET_{c\ actual} / ET_r$), including wintertime evaporation are shown in Figure 3 for a crop of spring wheat and potatoes during the 2004 calendar year near Ashton. The $K_{c\ actual}$ traces include the evaporation (K_e component) that appear as 'spikes' above the K_{cb} curves following precipitation and irrigation events. The $K_{c\ actual}$ during winter time peaked at about 0.6 for the spring wheat crop that was assumed to have a mulched soil surface during the nongrowing season and at 0.8 or less for the potato crop that was assumed to have a bare soil surface during the nongrowing season. $K_{c\ actual}$ peaks during winter were reduced when snow cover was noted to account for higher reflectance of the snow (January – March for 2004). $K_{c\ actual}$ was below K_{cb} when soil stress was estimated to occur during the nongrowing season or prior to initiation of irrigation (generally begun when $K_{cb} > 0.22$). The duration of K_e spikes (time-wise) tends to increase during spring and fall as weather cools and more days are required to dry the soil surface. Even though the value estimated for $K_{c\ actual}$ was relatively high during the nongrowing season, the actual ET rate was relatively low (bottom figure in Figure 3) due to the low value for reference ET_r, which represents the drying power of the atmosphere and energy available for evaporation.

An example of a time series of daily K_c over a multiyear period is shown in Figure 4 for six crop categories at Parma, Idaho for the 1988-1990 period. The K_c values shown are the basal K_{cb} curve (solid line) and actual K_c curve (symbols). During processing, these K_c values were converted to crop ET_c by multiplying by reference ET_r. The difference between actual K_c and basal K_{cb} when K_c exceeds K_{cb} represents evaporation from the bare or partially covered soil surface. K_c is occasionally below K_{cb} when there is insufficient soil moisture to support the evaporation process. Even though values for total K_c are 'high' during winter following wetting events, the resulting ET_c is relatively low, since ET_r averages less than 1 mm d^{-1} during much of winter. This was demonstrated in Figure 3. The values for K_c during winter varied with crop type due to assumptions made regarding the type and nature of cover during winter (mulch, bare soil or dormant sod-like surface).

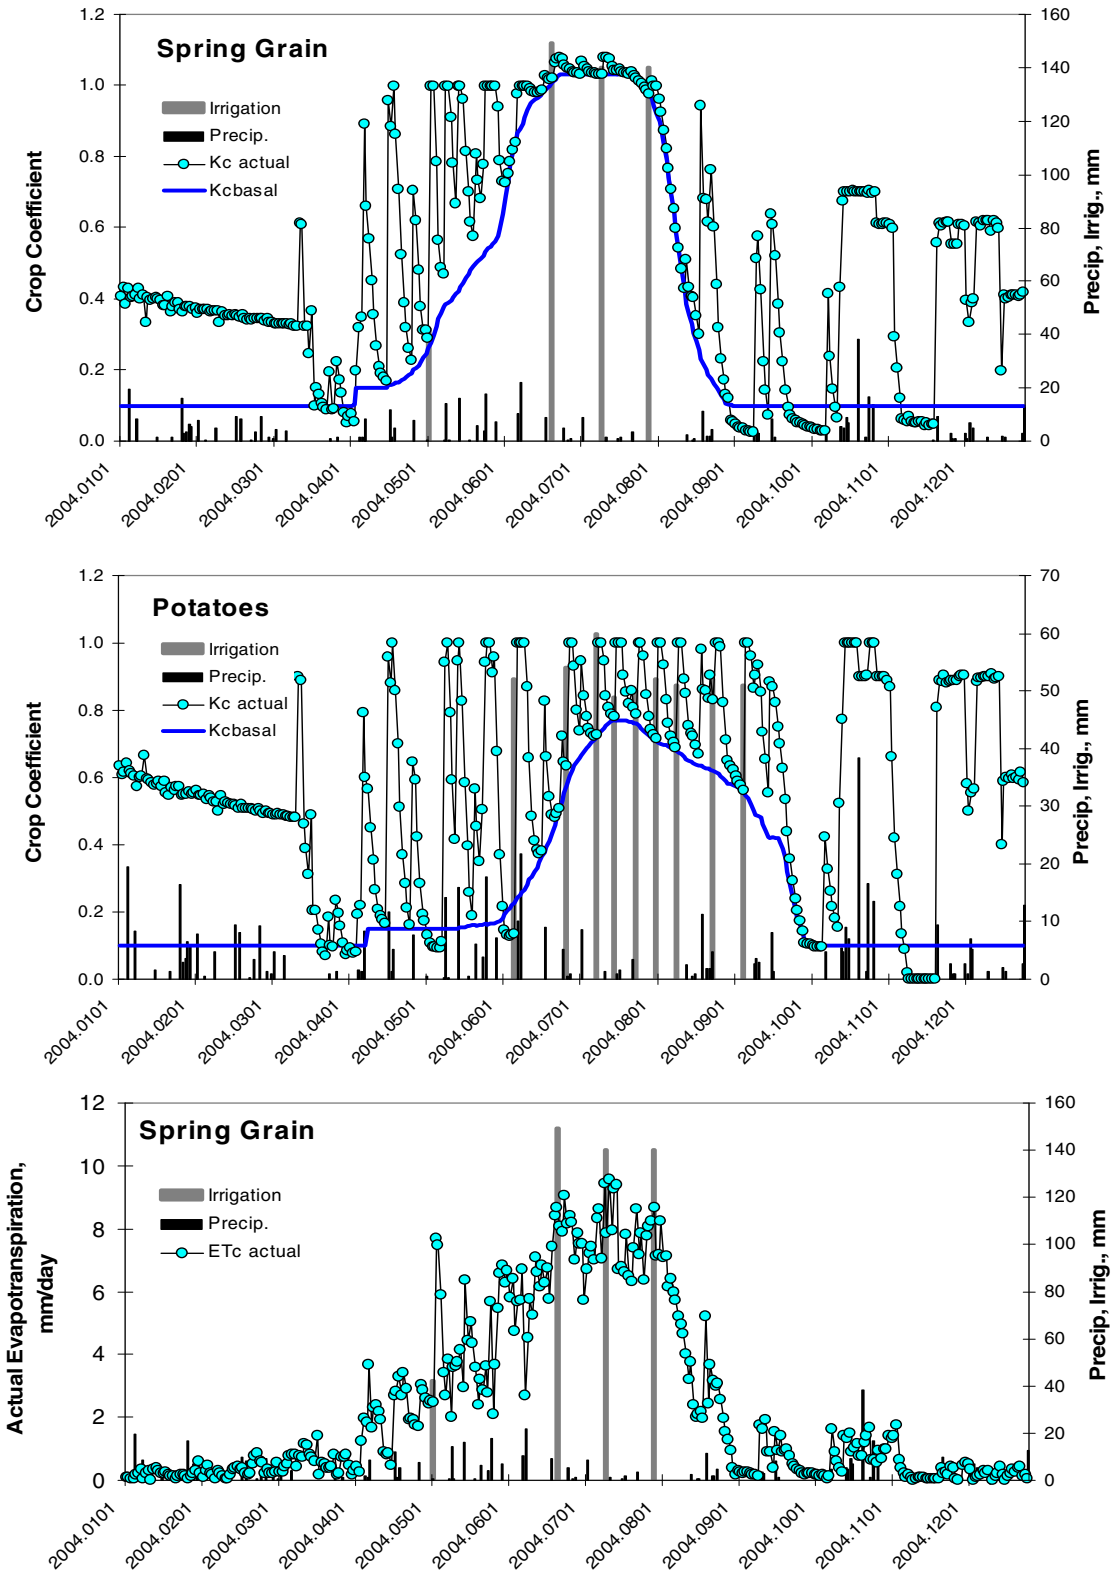

Figure 3. Example K_{cb} ('Kcbasal') and $K_{c\ actual}$ curves for spring wheat and potato crops near Ashton during 2004. Simulated irrigation events are shown as vertical bars. The $K_{c\ actual}$ traces include the evaporation (K_e component) that appear as 'spikes' above the K_{cb} curves following precipitation and irrigation events. Also shown in the bottom figure is daily actual ET_c for the spring grain.

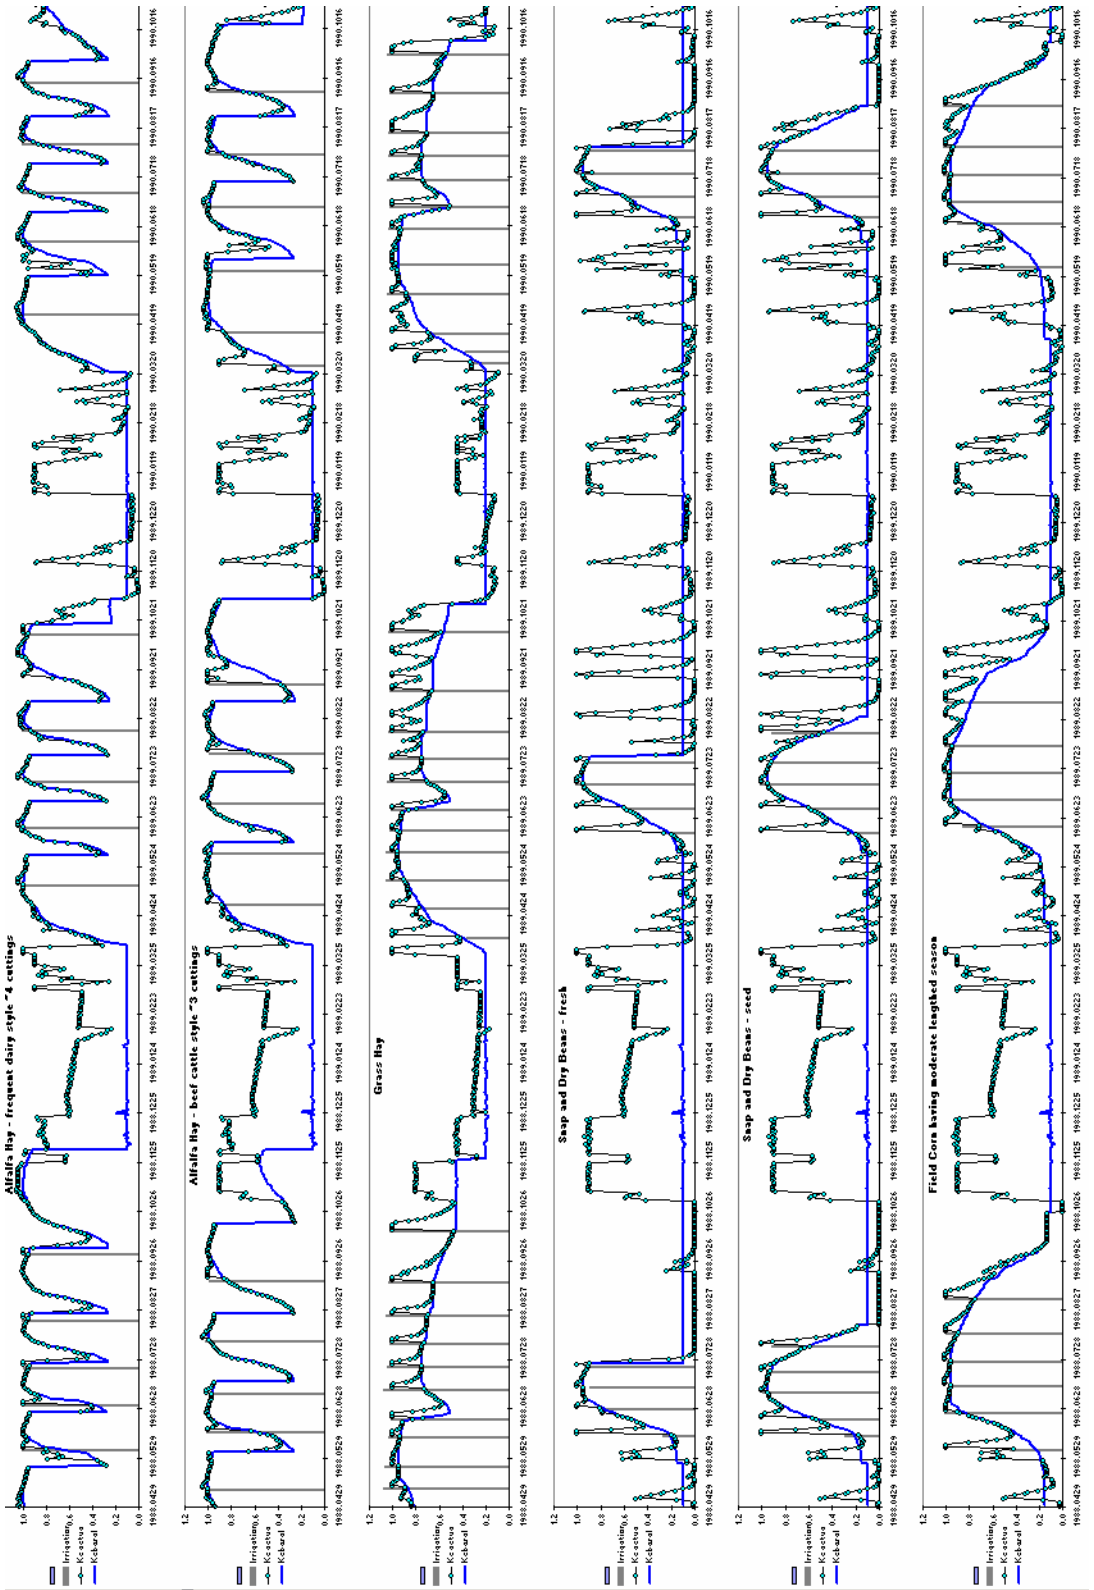

Figure 4. A time series of daily crop coefficients for alfalfa hay (top two crops for frequent and less frequent cutting), grass hay (third crop), dry beans harvested fresh (fourth), dry beans harvested dry (fifth) and field corn (bottom) over a three year period (1988-90) including wintertime at Parma.

COMPARISON OF ESTIMATES AGAINST THE WRIGHT LYSIMETER DATA

Figures 5 and 6 below show simulations from the "ETIdaho" calculations of Allen and Robison (2007) for Kimberly, Idaho for the same years as shown in Figures 1 and 2, estimated using a daily time step and the dual K_{cb} approach described above and using reference ET calculated using the ASCE PM for alfalfa reference based on National Weather Service data (maximum and minimum air temperature only, with dewpoint, solar radiation and wind speed estimated).

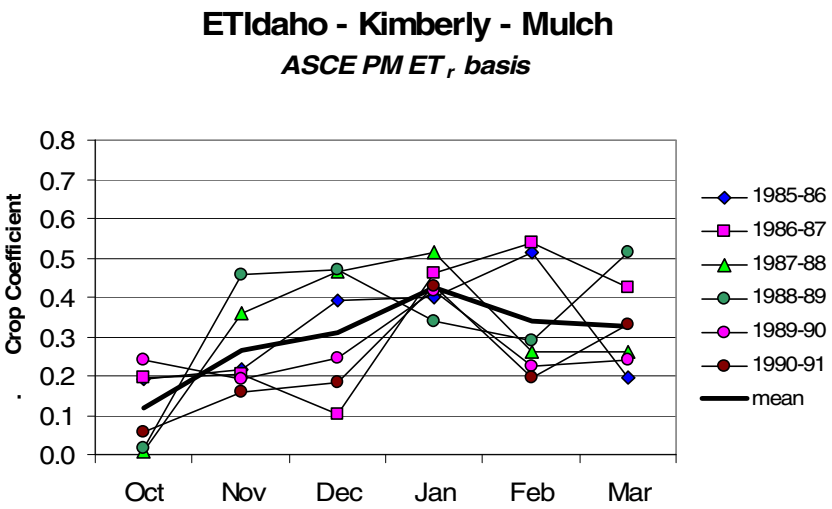

Figure 5. Monthly K_c for mulched soil cover condition during winter at Kimberly, Idaho for the same years as shown in Figure 1, estimated using a daily time step and the dual K_{cb} approach.

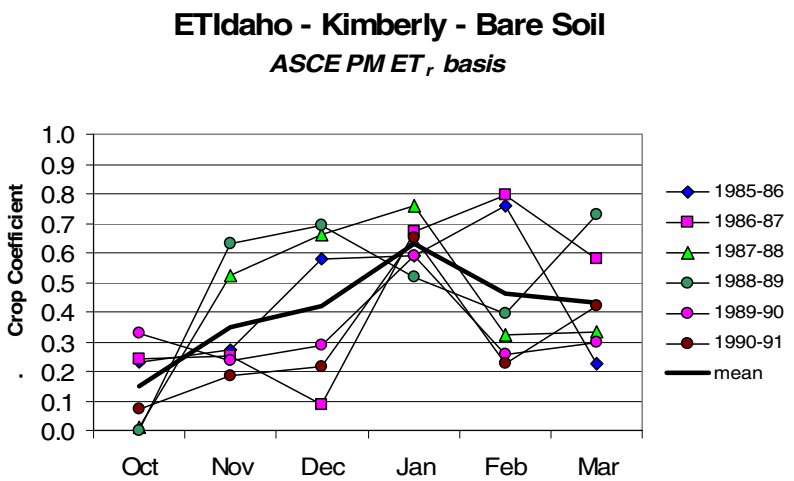

Figure 6. Monthly K_c for bare soil during winter at Kimberly, Idaho for the same years as shown in Figure 2, estimated using a daily time step and the dual K_{cb} approach.

The estimates for the mulched cover (Figure 5) are similar to those measured by Wright (1993) for the dormant turfgrass (Figure 1), although somewhat lower, especially during October, when the ETIdaho routine estimated lower ET due to the assumption of no irrigation. The lysimeters at Kimberly were irrigated. The estimates for bare soil (Figure 6) follow the measurements shown in Figure 2 relatively closely, with similar year to year variation in K_c caused by variation in precipitation amounts and frequencies as well as snow cover. Estimates by ETIdaho for dormant turf were lower than measurements shown in Figure 1 due to lack of irrigation assumed in ETIdaho for the cover.

SUMMARY AND CONCLUSIONS

The FAO-56 method for estimating evaporation from bare, wet soil, was utilized at 123 locations in Idaho over a more than 100 year period of record at some sites. A daily water balance was computed for the top 10 cm of soil as a means for reducing evaporation losses as the soil surface dries. Available water holding capacity and texture of soil for each station was determined using information from the National StatsGo soils information data base using a GIS analysis of the national soil data base for the area assigned to each station. Precipitation runoff was estimated using the NRCS Curve Number method where antecedent moisture was computed from the daily surface soil water balance. The curve number was determined from soil texture based on the StatsGo soils data base. Snow cover data as observed at many of the NWS stations were used to modify winter time estimates of evaporation caused by high albedo of snow and energy required for heat of fusion and was also used during adjustment of cumulative growing degree days for winter wheat during winter. Monthly winter evaporation estimated for Kimberly over a six year period compared relatively well with lysimeter measurements reported by Wright (1993).

ABSTRACT

Evapotranspiration (ET) of water is a primary component of the hydrologic cycle and is becoming more significant as increasing demands are placed on finite water supplies in Nevada and across the western U.S. Local, state, and federal water resource agencies have a great need for accurate estimates of net irrigation water requirements for evaluating irrigation development, transfers of irrigation water for municipal use, and litigation of water rights applications and protests. The major objective of this study is to update estimates of crop ET and net irrigation water requirements for Nevada. Estimates of ET and net irrigation water requirements are made for all major crops grown in Nevada at over 200 locations using National Weather Service weather stations located throughout the state. The methods for estimating ET follow the new ASCE-EWRI Standardized Penman-Monteith approach, while the net irrigation water requirement for crops is estimated using a dual crop coefficient and daily soil water balance approach. Results show that in central and northern parts of Nevada, the net irrigation water requirement for alfalfa, the primary crop grow in Nevada, is less than the typical permitted amount of irrigation water rights of 4 ac-ft/ac, indicating that if irrigators wish to change or sell their water rights to more consumptive uses, they would not be able to transfer the entire water right. These revised estimates of ET and net irrigation water requirements for various crops will be used for updating basins water budgets and establish the amount of irrigation water that is available for water transfers in the future.

INTRODUCTION

Irrigation water requirements are primarily controlled by the evapotranspiration (ET) of agricultural crops. Quantifying the amount of ET for a particular type of vegetation and region is necessary for proper design of irrigation systems, basin water balance estimates, and irrigation water management, review and litigation of water right applications and disputes, all of which continue to receive high priority attention. In the past, the State of Nevada has based ET and net irrigation water requirement estimates on a combination of reports, mainly from the USDA Nevada Irrigation Guide (USDA-SCS, 1992), State of Nevada Report No. 3 (Pennington, 1980), and studies used in hearings associated with the Alpine Decree (Mahannah, 1979; Hill, 1979; Guitjens and Mahannah, 1977). These publications primarily utilized temperature based Blaney-Criddle, modified Blaney-Criddle, Jensen-Haise, and Penman equations for computing reference ET, as well as correlation of estimated consumptive use with crop yields, and soil moisture balance (depletion) estimates of ET, resulting in a wide range of estimates. While these reports have been extremely useful, their dated methods and limited spatial coverage have created a need to update ET and net irrigation water requirement estimates with large spatial coverage using newly available standardized methods.

The major objective of this report is to update crop ET and net irrigation water requirement estimates for Nevada. Estimates are made for major crops grown in Nevada using more than 200 National Weather Service stations located throughout the state, providing sufficient spatial coverage for estimating the spatial distribution of crop ET and net irrigation water requirements, however, in this paper only alfalfa ET and net irrigation water requirements will be discussed.

EVAPOTRANSPIRATION CALCULATION APPROACH

The approach applied in this study for computing crop ET is the common crop coefficient – reference ET approach, where the reference ET is multiplied by a crop coefficient for estimating the actual ET of a vegetative surface. There are many methods available for estimating the reference ET, ET_o, while many are simple temperature-based techniques, others are data intensive as required for more physically based models. Estimates of ET_o vary widely among the methods, and there is considerable debate as to which is the more correct method. Generally, the lack of weather variables such as incoming solar radiation, dew point temperature, and wind speed needed for more physically based models of ET_o has led to the use of simple temperature based methods, even though investigators are often aware that more physically based methods result in more accurate and representative estimates of ET_o. Given that the number of weather stations that collect incoming solar

radiation, relative humidity, and wind speed are extremely limited, there is a great need to utilize basic National Weather Service (NWS) data of maximum and minimum temperature and precipitation and apply an ET_o method that is robust and currently accepted in the literature and scientific community to estimate state-wide crop ET and net irrigation water requirements.

The Penman-Monteith method for calculating ET_o is currently accepted as a standard method (ASCE-EWRI, 2005) for calculating a standardized and consistent value for ET_o, referred to here as ET_{sz}. The Penman-Monteith method, however, requires weather variables that are not routinely measured at NWS stations. Recent advancements in estimating weather variables such as incoming solar radiation (Thornton and Running, 1999; ASCE-EWRI, 2005), generalization of dew point temperatures representative of irrigated areas (ASCE-EWRI, 2005; Allen et al., 1998; Allen and Robison, 2007) and regionalizing of wind speed (Allen and Robison, 2007) have proven useful for estimating ET_{sz} using the Penman-Monteith equation while maintaining sufficient accuracy and spatial coverage for state-wide application. The grass reference Penman-Monteith equation has been widely applied by Arizona and California State agencies for computing consumptive use (i.e. AZMET and CIMIS), as well as the U.S. Bureau of Reclamation for their Lower Colorado River Accounting System (LCRAS) model, therefore the State of Nevada has adopted the daily time step grass reference evapotranspiration equation (ET_{os}) as the basis for computing crop ET and net irrigation water requirements, which is used in this study.

Given that ET_{sz} refers to ET from a reference crop that is actively growing, not limited by soil moisture, and is at full cover and peak height, the ratio of actual ET to the ET_{sz}, otherwise known as a crop coefficient (K_c) representing specific crop types, must be applied to adjust the ET_{sz} to simulate the actual ET of a particular crop or surface (ET_{act}). The majority of crop coefficients in the literature were derived from research weighing lysimeter measurements of actual ET from stress-free crops and calculated ET_{sz} at the lysimeter sites, mainly from Davis, CA, and Kimberly, ID (Doorenbos and Pruitt, 1977; Wright, 1981, 1982). This study utilizes a dual crop coefficient and daily soil water approach to compute the ET_{act}, where the K_c value is separated into a 'basal' crop coefficient, K_{cb}, and a soil evaporation coefficient, K_e (Allen et al., 2005). The heritage of many of the K_{cb} values used in this study can be traced to Wright (1982).

METHODS

Standardized Penman-Monteith Equation

As a part of a standardization effort, the ASCE Penman-Monteith (ASCE-PM) equation and associated equations for calculating aerodynamic and bulk surface

resistance have been combined and condensed into a single equation that is applicable to both grass and alfalfa surfaces by changing standardized constants (ASCE-EWRI, 2005). The ASCE-PM equation is intended to simplify and clarify the presentation and application of the method. As used in this analysis, the term ET_{os} refers to the standardized grass reference ET. Calculation of parameters required in the ASCE-PM equation was accomplished using guidelines from ASCE-EWRI (2005). Methods for estimating variables of daily incoming solar radiation, dew point temperature, and wind speed required are discussed below.

NCDC Weather Data Assembly

Weather station data from the NWS used in the computation of ET_{os} and net irrigation water requirements include daily maximum and minimum air temperature and precipitation, and observations of snowfall and snow cover depth for some stations. These data are officially collected and housed by the National Climatic Data center (NCDC) of the National Oceanic and Atmospheric Administration (NOAA). Data are generally available from the NCDC from about 1930 onwards, however lengths of records vary widely from station to station, ranging from less than 1 month to 120 years. Limiting weather station datasets to those stations having at least 4 years of complete annual records resulted in over 200 usable weather stations in Nevada.

Incoming Solar Radiation Estimation

Time series estimates of solar radiation (R_s) for each NWS station were calculated following an empirical method described by Thornton and Running (1999), which is based on the difference between daily maximum and minimum air temperature. The general premise of the method is based from the principle that during cloud cover maximum air temperatures generally decrease, and the minimum temperature is increased due to increased downward emission and reflection of long wave radiation by clouds at night (Allen, 1997). Application of the Thornton-Running equation to NWS station temperature data has produced satisfactory results when compared to measured R_s at 14 nearby weather stations. The average ratio of daily estimated to measured R_s for all 14 stations is 1.02 with a standard deviation of 0.05, while the average RMSE for daily estimated R_s is 3.75 $MJ/m^2/d$. In general, the Thornton-Running equation provides reasonable estimates over the ranges of R_s experienced and during all months of the year. The Thornton-Running equation was applied in similar applications for Idaho by Allen and Robison (2007).

Dewpoint Temperature Estimation

Dew point temperature (T_{dew}) is defined as the temperature at which a parcel of air must be cooled to become saturated with water vapor. The dewpoint temperature can be used to represent the humidity of the lower air mass, for example the relative humidity (RH) is at 100% when the air temperature is at the dewpoint. Because NWS stations do not record relative humidity, the estimated T_{dew} is used to represent the humidity of the lower air mass. In an irrigated setting T_{min} will usually approach T_{dew}, especially in the early morning when winds are calm and soil moisture is high. Weather stations located in non-irrigated settings typically record higher maximum air temperatures and lower daily RH than those located in irrigated areas due to the lack of available water, causing the net radiation to be partitioned into sensible heat instead of latent heat or ET. The use of humidity data collected from non-irrigated settings can cause overestimation of ET_{sz} to as much as 20-26% (Brown, 2001; ASCE-EWRI, 2005).

The daily T_{dew} at each NWS weather station is estimated in this study as $T_{dew} = T_{min}-K_o$, where T_{min} is the daily minimum air temperature (^oC) and K_o is an offset coefficient (^oC) and is synonymous with the dew point depression. It is common in arid and semiarid regions to have a T_{dew} of 2 to 5 ^oC below T_{min} under well watered conditions (Allen, 1996). Rather than assign NWS stations spatially constant mean monthly K_o values, spatially distributed mean monthly K_o values were derived and assigned to NWS stations. There are very few weather stations in Nevada that measure RH in irrigated areas, therefore mean monthly K_o values were computed from weather stations located in irrigated areas from the AZMET (Arizona Meteorological Network), CIMIS (California Irrigation Management Information System), AGRIMET, and Utah Agriculture Weather Network, as well as U.S. Geological Survey (USGS) micrometeorological stations located in irrigated areas in Nevada from studies by Maurer et al., (2006) and Allander et al., (2009) (Figure 1a). Calculated mean monthly K_o values for the different weather stations are shown in Figures 1b, where it is apparent that mean monthly K_o values vary depending on the location. For instance, in southern locations the K_o value for a given month is greater than in northern locations, primarily due to the temperature, length of growing season, amount and seasonality of precipitation, and magnitude of regional advection of dry air. Mean monthly K_o values were ultimately assigned to NWS stations by spatial interpolation using inverse distance weighting, averaging spatially interpolated K_o surfaces to individual hydrographic areas, and then assigning NWS stations respective mean monthly spatially averaged hydrographic area K_o values. Measured mean monthly K_o values were assigned to NWS stations in basins where measurements occurred. For illustration purposes the spatial distribution of mean annual K_o is shown in Figure 1c.

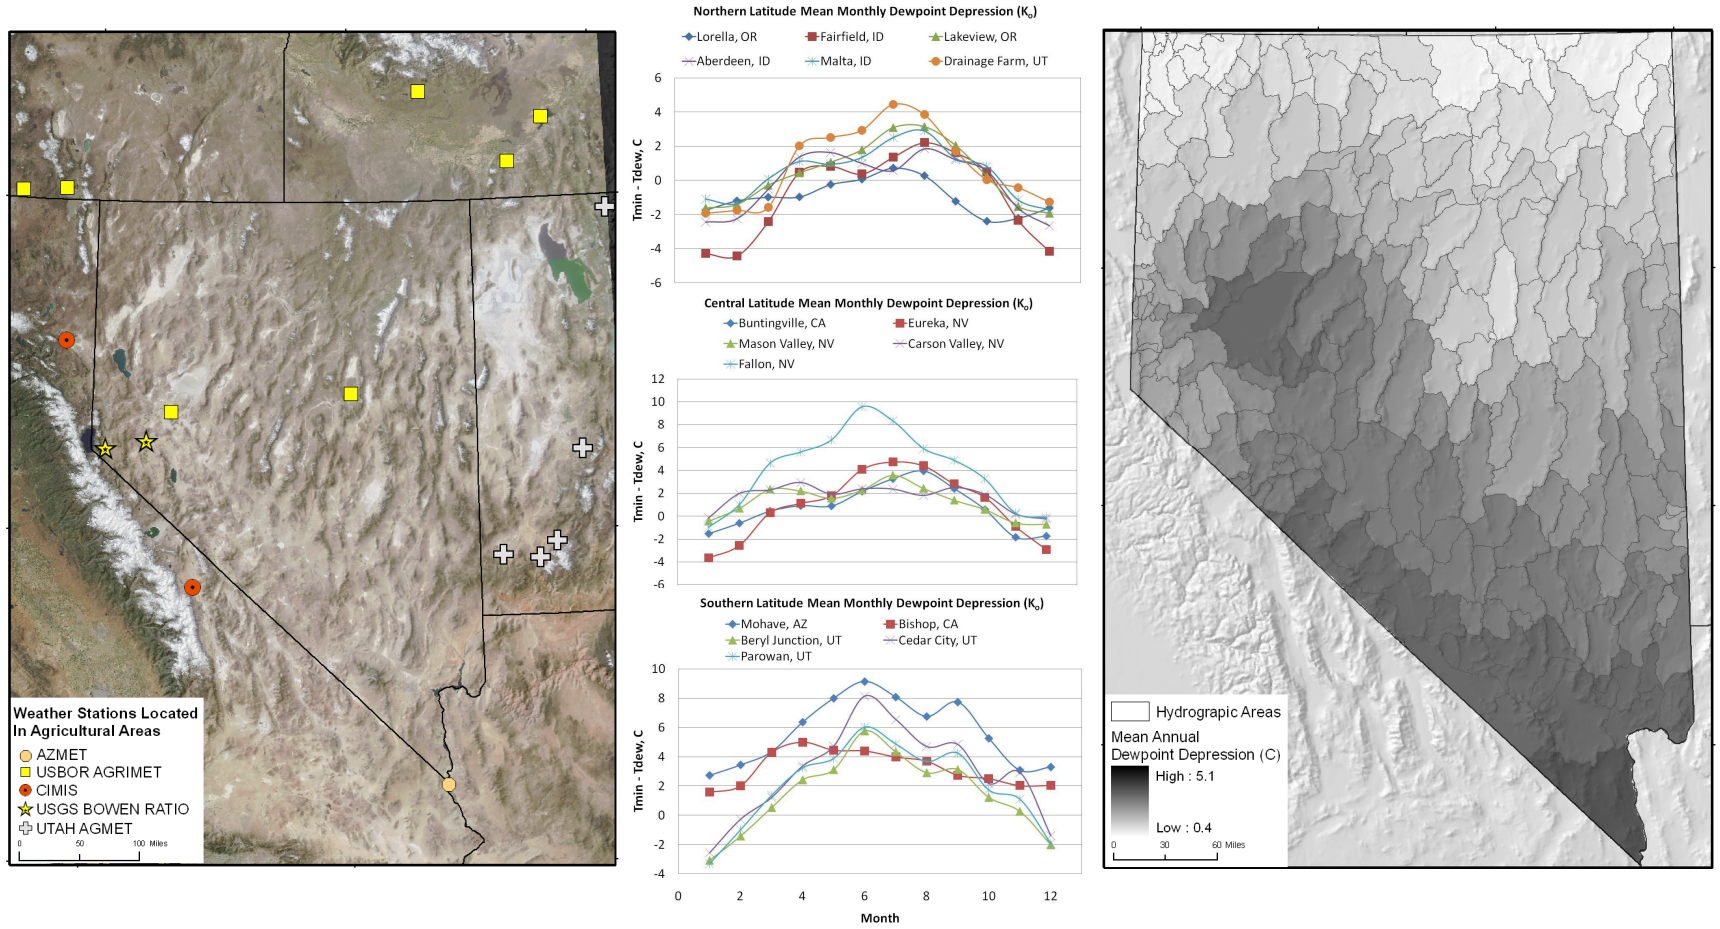

Figure 1a-c. (a)Weather stations measuring RH located in irrigated areas used for calculation of and spatial interpolation of dew point depression (K_o). (b) Mean monthly K_o for southern, central, and northern weather station locations shown in figure 1(a). (c) Spatially averaged mean annual K_o illustrating the extreme spatial variability of K_o (i.e. T_{min}-T_{dew}).

As expected, southern locations have a larger dew point depression (i.e. larger K_o value) while northern areas have a smaller dew point depression. This spatial trend is likely due to regional scale advection of dry air, and more specifically the climatology that governs regional scale advection such as the amount of valley floor precipitation, energy balance from the natural vegetation on valley floor areas, and typical air mass origins or jet stream patterns. Using weather stations located in irrigated areas as the basis for computing mean monthly K_o values likely minimizes local advection effects while preserving regional advection effects that most irrigated areas in Nevada are likely experiencing due to the arid climate and smaller scale irrigation projects. For example, the mean monthly K_o for Fallon, central Nevada, is significantly higher than surrounding stations shown in Figure 1b. After a detailed analysis of K_o from surrounding stations in the Fallon area that are located in non-irrigated settings, the mean annual K_o at these stations is above 8°C, while the Fallon AGRIMET site is reporting a mean annual K_o of 4°C. This finding suggests that the Fallon AGRIMET K_o can be interpreted as being 'representative' of the K_o occurring in the irrigated project area. The irrigated areas surrounding the AGRIMET site in Fallon are highly discontinuous, as there are many fallowed fields. However, this is a common occurrence in the Fallon project area, therefore the Fallon AGRIMET site is likely 'seeing' the effect of regional advection more than other areas in central Nevada that have more continuous irrigated areas and receive more annual precipitation.

Wind Speed Estimation

Wind speed (U) is not measured at NWS stations except at airport stations, therefore wind speed from NWS airport stations and weather stations from a variety of networks located on valley floor areas with sufficient period of record, totaling 60 stations, were used to compute the mean monthly wind speed. The mean monthly wind speed at each NWS station was estimated as

$$U_2 = U_{2mean \cdot monthly_i}$$

where U_2 is the estimated daily 2 meter height wind speed for each NWS station, and $U_{2\ \text{mean monthly i}}$ is the measured mean monthly 2 meter height equivalent wind speed or hydrographic area spatially averaged 2 meter wind speed. Similar to the assigning of K_o values to NWS stations with no measurements within the hydrographic basin, spatially interpolated mean monthly wind speed surfaces were generated using inverse distance weighting and were then spatially averaged to hydrographic areas,

where NWS stations were assigned respective spatially averaged mean monthly wind speed values.

Crop Evapotranspiration

Actual crop ET, ET_{act}, in this study is calculated as

$$ET_{act}=(K_sK_{cb} + K_e)ET_{os}$$

where ET_{os} is the grass reference ET, K_{cb} is the basal crop coefficient, and K_e is the soil water evaporation coefficient. K_{cb} and K_e are dimensionless and range from 0 to 1.4 when used with ET_{os}. When the soil water content is less than that needed to sustain full rates of transpiration a stress coefficient, K_s, is applied ranging from 0 to 1. K_s is equal to 1 when there is no water stress, as is the case for fully-irrigated crops during the irrigation season as opposed to rain fed crops or native vegetation. A daily soil water balance is required to calculate K_s, which incorporates the available soil moisture for the simulated effective root zone. An additional soil water balance is maintained for the estimation of K_e, and is limited to the upper 0.1m of the soil since this zone is assumed to be the only layer that supplies water for direct evaporation from the soil surface. Further details of the daily water balance used in this study can be found in Allen et al.,(2005) and Allen and Robison (2007).

The K_{cb} curve represents impacts on ET stemming from changes in vegetation phenology, which can vary from year to year depending on the start, duration, and termination of the growing season, all of which are dependent on temperature conditions during spring, summer, and fall periods. Depending on the crop, the start, duration, and termination of the growing season are estimated each year according to a 30-day moving average temperature or a cumulative growing degree method prior to the start date, with specified temperatures defining the killing frost. For alfalfa, spring green up was estimated when cumulative growing degree day (CGDD) since January 1 reached 300 ^oC-days using a temperature base of 0^oC. The cumulative growing degree day was normalized following Wright (2001) by the quantity of CGDD required to advance the K_{cb} curve from green up to effective full cover and harvest.

Three different alfalfa K_{cb} curves were constructed according to the cycle of growth, that being a initial cycle curve, a intermediate or mid cycle curve, and a late cycle curve according to Wright (1981, 1982) and lysimeter records in Kimberly, ID (Figure 2). Implementation of three different K_{cb} curves for alfalfa is consistent with the fact that the first cycle or cutting of alfalfa has the largest yield and hence water consumption, with subsequent cuttings having less yield, and the final cutting having the least amount of yield. The CGDD values for the first growth cycle are accumulated beginning at green up of the crop in spring, and from the time of cutting

for all subsequent growth cycles. The killing frost temperature of -7°C defines termination of the growing season for alfalfa.

Calibration of CGDD values controlling the simulation of the green up and cutting dates was accomplished by minimizing the error in simulated vs actual green up and cutting dates documented from previous studies in Nevada, and 'typical' green up and cutting dates obtained from farmers located in southern, central, and northern Nevada (Table 1). The best fit CGDD value from January 1 until green up was 300 °C-days, while the best fit CGDD value for time from green up until the first cutting was 880 °C-days, and CGDD value of 740 °C-days since the first cutting until the next cutting. These CGDD values gave promising results across the state considering the extreme spatial variation of air temperature. Details on the development of the curves shown in Figure 2 and CGDD calculations are given in Allen and Robison (2007) and Allen et al., (2007). The alfalfa reference-based curves of Allen and Robison were converted to grass reference-based curves in this Nevada application by dividing by 1.20, which is the standardized ratio for alfalfa to grass reference for the standard climate condition proposed by FAO (Allen et al., 1998) where mean wind speed at 2 m is 2 m/s and mean daily minimum relative humidity is 45%. Departures from the standard climate condition are however accounted for by adjusting the daily K_{cb} value upward based on the estimated daily RH and wind speed following procedures outlined in FAO-56 (Allen et al., 1998).

RESULTS

Estimated ET_{os} vs Calculated ET_{os}

Assessing the error in estimated ET_{os} using estimates of R_s, T_{dew}, and U_2, verses using measured data is of significant concern because estimation of these weather variables provides the ability to use NWS stations for sufficient spatial coverage and statewide application. To address this issue a comparison was made between estimated ET_{os} at NWS stations and calculated ET_{os} at nearby stations located in irrigated areas that measure the full suite of weather variables. Results of the comparison indicate that the ratios of annual estimated ET_{os} to calculated ET_{os} range from 1.01 to 1.06, with an average of 1.04, and an average RMSE for daily estimated ET_{os} of 0.95 mm/d (Table 2). These results are acceptable considering the overall error and that estimated ET_{os} is entirely dependent on spatially interpolated dew point depression, wind speed, and estimated R_s using T_{max} and T_{min}. The bias in slightly overestimating ET_{os} is attributed to a small bias of NWS station reported local temperatures.

Table 2. Estimated ET_{os} vs calculated ET_{os} at NWS and nearby irrigated area weather stations that measure the full suite of weather variables.

Actual Crop ET and Net Irrigation Water Requirements

Actual crop ET (ET_{act}) was calculated at a daily time step for the period of record for all NWS stations using the ASCE-PM equation and dual crop coefficient and soil water balance approach following Allen et al., (2005), Allen and Robison (2007), and Allen et al., (2007). An example of the daily ET_{act} for Fallon, NV, during 2002 is illustrated in Figure 3, which also illustrates cutting effects and the response of the K_c curve (K_{cb}*K_s+K_e) to precipitation and simulated irrigations due to the evaporative component of the K_c curve. The mean annual net irrigation water requirement of alfalfa for all NWS stations analyzed were computed for the last 30

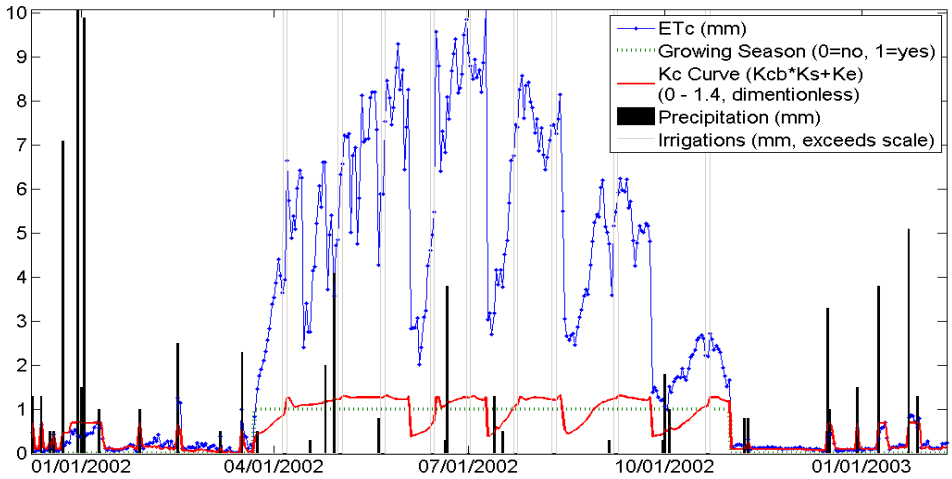

Figure 3. Simulated alfalfa ETc using the NWS Fallon, NV weather station. The computed Kc curve, simulated irrigations, and measured precipitation are also shown to illustrate the response of the K_c curve due to wetting events and cuttings.

years of record available. Results were then spatially distributed and averaged to hydrographic area boundaries for illustration purposes only (Figure 4). The net irrigation water requirement is defined as the ET_{act} – precipitation residing in the root zone, and represents the amount of additional water that the crop would evapotranspire beyond precipitation residing in the root zone if water were made available at the right time during the growing or non growing season. The net irrigation water requirement is synonymous with the net consumptive use. Figure 4 illustrates the large spatial variation in the net irrigation water requirement of alfalfa, primarily due to the extreme spatial variability in air temperature affecting the ET_{os} and growing season length. In southern parts of Nevada, the net irrigation water requirement is larger than the typical permitted irrigation water right of 5ft/yr (1,524mm/yr), and in central and northern areas of Nevada the net irrigation water requirement is less than the typical permitted irrigation water right of 4ft/yr (1,219mm/yr).

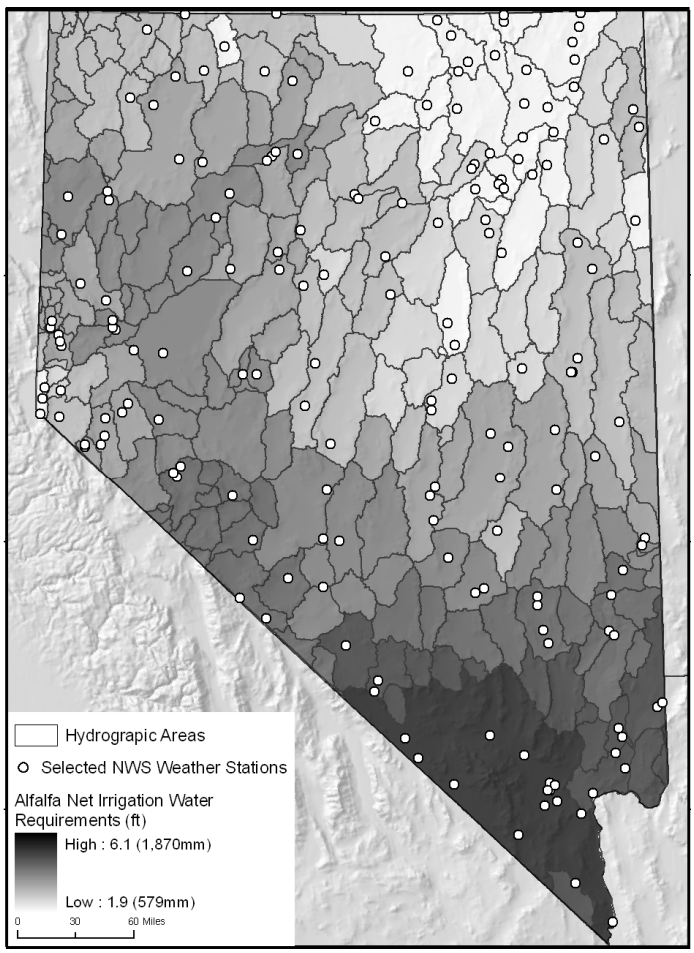

Figure 4. Mean annual alfalfa net irrigation water requirements (net consumptive use) and NWS stations used for computations. Results are spatially averaged to hydrographic area for illustration purposes only.

CONCLUSIONS

The objective of this study was to update crop ET and net irrigation water requirements for assessing water transfers from agriculture to new uses. In order to provide adequate spatial coverage, NWS stations were used; however NWS stations do not measure all weather variables needed for application of the widely accepted standardized ASCE-PM equation. Therefore, solar radiation was estimated at NWS stations with acceptable levels of error, and mean monthly measurements of dew point depression and wind speed from weather stations located in irrigated areas and valley floor areas, respectively, were assigned to NWS stations by spatially distributing mean monthly measurements. Estimates of ET_{os} vs computed ET_{os} using weather stations that measure the full suite of weather variables are in good agreement and provide confidence in weather variable estimation methods and net irrigation water requirement estimates. Results indicate that in central and northern parts of Nevada, if irrigators decide to change their irrigation water right to a new use by fallowing their fields, Nevada water law allows for the irrigation water right available for transfer to be reduced to the net irrigation water requirement (i.e. net consumptive use). These revised estimates of ET and net irrigation water requirements for various crops will be used for determining the amount of irrigation water that is available for water transfers in the future, as well as assist in basin water budget studies.

ABSTRACT

The snow pack of Sierra Nevada, Southern Spain, melts during spring and early summer feeding ancestral irrigation canals in the region called Alpujarra. This study compared the traditional supply, based on proportional division, with the actual supply, based on up-downstream priority, in a representative watershed in the Alpujarra. A combination of three models was used for the analysis. Snow melt and runoff were simulated using the Snow Runoff Model and satellite images to determine snow cover. A second model (based on a water balance with capacity constraints) simulated the distribution of water either following proportional supply or up-downstream priority. Crop irrigation requirements were simulated using the FAO approach. The equity inherent to the proportional supply did not diminish adequacy overall. Because of the reuse of return flows in the watershed, irrigation efficiency at the watershed scale was significantly greater than irrigation efficiency at the irrigation canal scale.

INTRODUCTION

Irrigation in Spain flourished in the Middle Age. The Muslims introduced in Southern and South-eastern Spain not only new irrigation techniques, but also the concept of collective management in the governance of the water resources. The actual organization of the water users' associations in Spain is based on the principles that were developed at that time. Moreover, some irrigation systems and their organization have remained almost unchanged in mountainous areas of Southern Spain. Alpujarra is one of those areas. Traditionally, water was divided based on proportional supply among canals and then rotated within the canals. These water distribution rules (reported in historical documents dated in the XVI century) have been in use until today, but the whole system is declining rapidly.

Another feature of these systems was integrated water management. In fact, the new paradigms of water and irrigation management (Mateos et al., 1998; Mateos, 2008; Clemmens et al., 2008) were implicit in the ancestral systems of the Alpujarra. First, the excess of water in sectors of the system were reused downstream. Second, when supply

was greater than demand, natural springs were recharged to extend the availability of water into the dry season.

The performance of these systems may be quantified using indicators defined by several authors (Molden and Gates, 1990; Malano and Burton, 1998; Mateos et al., 2002).

This study analyses using simulation models and performance indicators the integrated water management of a representative watershed (the Poqueira River) in the Alpujarra. The traditional proportional supply is compared with the actual supply, which is based on up-downstream priority.

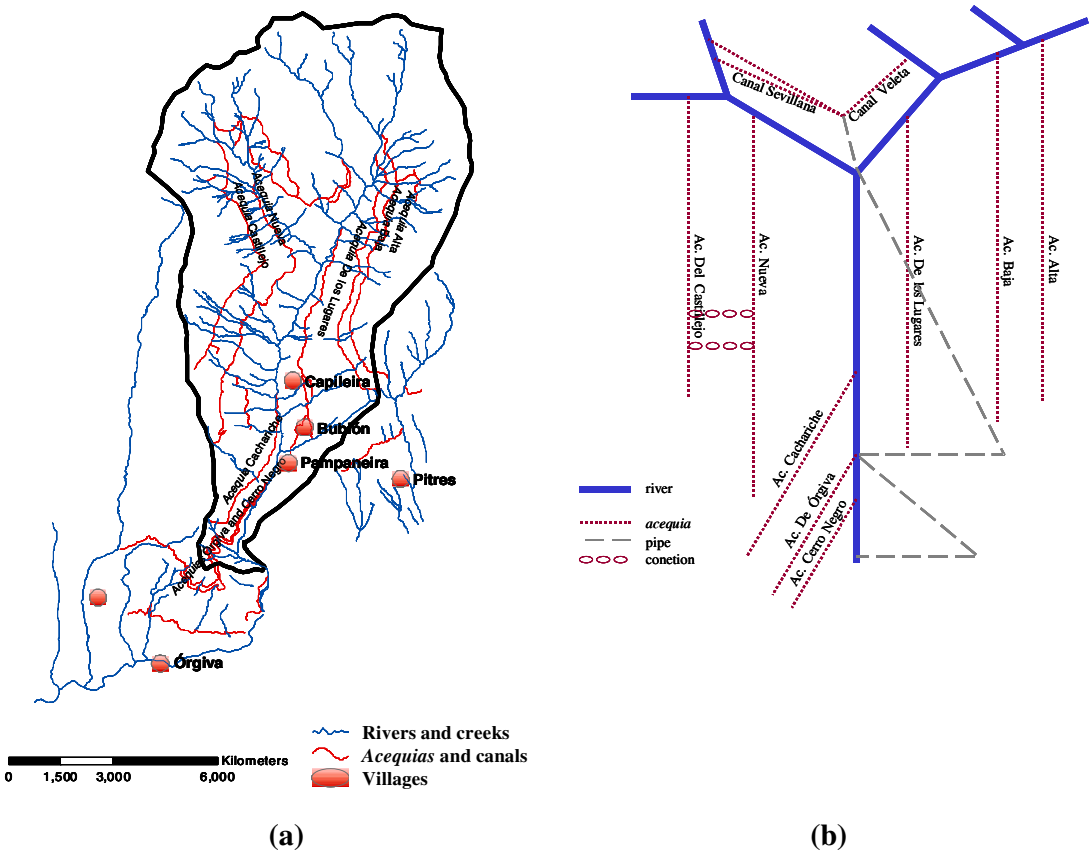

Figure 1. Map of the study watershed (a) and sketch of the fluvial and *acequias* networks (b)

THE STUDY WATERSHED

The study was carried out in the Poqueira River watershed (Fig. 1a). This watershed covers 90 km^2 of mountainous land in the southern face of Sierra Nevada, Southern Spain. Its altitude varies from 400 m a.s.l where the Poqueira River joins the Guadalfeo River to 3479 m a.s.l. at the summit of the Mulhacén peak. Mean annual rainfall in the Poqueira watershed varies from 450 mm in its lowest part to about 1000 mm in the mountain

summits. The rainfall distribution along the year is typical of a Mediterranean climate; the summer is dry and maximum precipitation occurs between November and February. Above 2000 m, 75% of the precipitation is as snow.

Table 1. Characteristics of the *acequias* and canals in the study watershed, including number of *pagos* and number of turns

Acequia	Length (m)	Area (ha)	Lining	Capacity ($L\ s^{-1}$)	*Pagos*	Turns
del Castillejo	8332	803	Unlined	200	6	11

Canal Sevillana	2837		Concrete			
Canal Veleta	1906		Concrete			

The Poqueira watershed has a complex water conduit network consisting of *acequias*, canals that transport water to hydropower plants, and pipes (Fig. 1b). The total length of open canals (*acequias* plus hydropower canals) is 73.7 km. Table 1 gathers the main characteristics of the *acequias* and canals. There are five *acequias* for irrigation within the watershed: Castillejo, Nueva, De los Lugares, Cachariche and Cerro Negro (Fig. 1). Other two *acequias* run along the eastern slope of the watershed, *acequias* Baja and Alta, transferring water to the watershed of the Trevélez River, where they divert water to the neighbour watershed (Fig. 1). The *acequia* Órgiva also transfers water by crossing the western slope of the watershed and transposing to the watershed of the Chico River, where it flows to irrigate the lowland of the nearby village, Órgiva (Fig. 1).

The irrigated crops are mainly vegetables (abundant in *acequia* Cerro Negro, the most active in the watershed) and pasture for animal grazing (abundant in *acequia* Castillejo). Nevertheless, an increasing proportion of the irrigable land is being abandoned, mainly in *acequia* Cachariche. *Acequia* de los Lugares was built for irrigation purposes too, but it supplies water for domestic use to the villages Capileira, Bubión and Pampaneira.

The water supplied by an *acequia* is divided into irrigation sectors locally called *pagos*. The number of *pagos* in the *acequias* of the Poqueira watershed is 5 or 6 (Table 1). Each *pago* has the right to a number of hours or days during the rotation, (which duration varies) with a variable time period between 8 and 15 days (Table 1). Within a *pago*, water is rotated among farms from upstream to downstream. The canal master controls the water turns. The rules governing water distribution are precise and they have long tradition, so they are observed tacitly by all farmers.

The flow rate at the head of the *acequias* is determined by the water availability at the river where they derive from, and by the agreements that regulate the water use in the watershed. Nowadays, these agreements are not always equitable: in the dry year 2005, when the water was insufficient to satisfy all the demand, only the downstream *acequias* farmers suffered the scarcity. More just rules governed water distribution in the past.

An activity related to the *acequias* is dedicated to hydropower production. Three power plants are connected in cascade by means of pipes starting at a basin at 2100 m of altitude (Fig. 1b). There is an agreement between the electricity company and the farmers of *acequia* Nueva, according to which as the discharge in the creek decreases the diversion for hydropower production must be reduced, giving priority to the *acequia* Nueva.

MATERIALS AND METHODS

Three models were combined for the simulation study: the Snow Runoff Model, the crop irrigation requirements model, and the water distribution model.

The Snowmelt-Runoff Model (SRM) was designed to simulate and forecast daily stream flow in mountain basins where snowmelt is a major runoff contributor. SRM was developed by Martinec (1975) in small European basins. Each day, the water produced from snowmelt (calculated on a degree-days base) and from rainfall is computed, superimposed on the calculated recession flow and transformed into daily discharge from the basin (Martinec et al., 2005). Model variables are derived from actual observations of temperature, precipitation, and snow covered area. Model parameters can either be derived from measurements or estimated by hydrological judgement taking into account the basin characteristics, physical laws, and theoretical or empirical relationships. The application of SRM involved the determination of snow cover using images collected with the sensor MODIS on board of the satellite Terra. Temperature and precipitation data were obtained from a weather station located in the village of Lanjarón.

The crop irrigation requirements were calculated using a soil water balance equation. Two water contents were used to characterize each soil class: the drained upper limit or field capacity and the lower limit of plant extractable water or wilting point. Drainage below the root zone was computed as the excess of water over field capacity. Crop evapotranspiration was calculated from reference evapotranspiration and crop coefficients (Doorembos and Pruitt, 1977; Allen et al., 1998). Reference evapotranspiration was estimated by the Hargreaves equation (Hargreaves and Sammani, 1985). The balance equation was used to calculate net irrigation as the depth of water needed to refill the soil profile when the water content reached the allowable depletion. Net irrigation was divided by an application efficiency accounting for percolation and runoff losses.

For the purpose of formulating the water distribution model, the watershed was divided in three subsystems, each consisting of the water source (the point were snow melt runoff is assumed to concentrate), natural channels, *acequias*, canals and *pagos*. The water distribution model was based on the principle of the water balance at the nodes of the distribution network accounting for capacity constraints. The capacity of each *acequia* and

canal (Table 1) was calculated based on Manning's equation. Filtrations along the *acequias* and canals were estimated as a function of their construction material and length (Table 1). The simulation step was daily. The turns within each *pago* were simulated according to the traditional organizational rules (Table 1).

The division of water among *acequias* and canals was simulated according to two distribution modes: proportional supply (the traditional mode) and supply according to up-downstream priority (the current mode). Under proportional supply the available water at one node was divided proportionally to the irrigable area downstream each of the two branches starting at that node. Under the division by priority, the available water was diverted to the *acequias* or canals until filling their capacity, thus the water rights had an up-downstream priority. Then, the volume simulated for each *pago* was compared with the irrigation requirements calculated previously. The excess of water at the *pagos* or *acequias* was circulated according to the diagram in Fig. 1b. From here on, proportional supply will be denoted by PRO and supply according to up-downstream priority, by PRI.

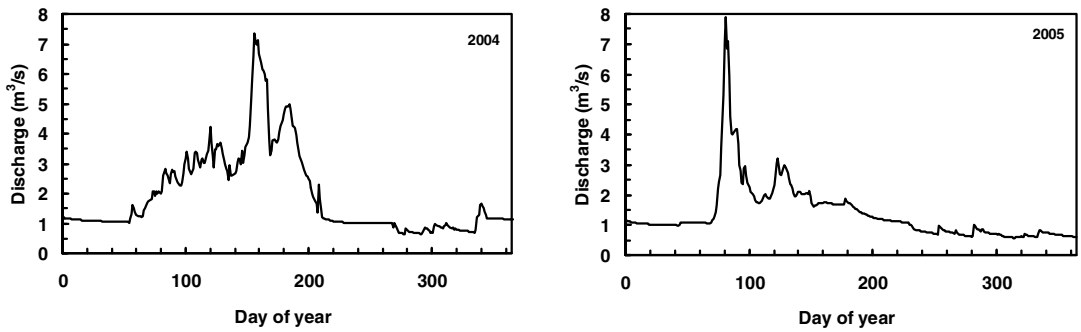

Figure 2. Simulated runoff hydrographs for the study watershed in 2004 and 2005

RESULTS AND DISCUSSION

The snow melting period varied in the years of study (2001 to 2005) notably. Typically it started during March and it ended during June or July, resulting in periods between two and four months. The runoff hydrographs reflected the occurrence of intense rain events and of snow meeting peaks consequence of temperature increases (Fig. 2). 2001, 2003 and 2004 were wet years, with annual runoff volumes between 45.99 and 60.19 hm^3, whereas 2002 and 2005 were dry years, with runoff volumes 30.86 and 34.39 hm^3, respectively.

Simulated volumes that were diverted to the canals system were greater the wet years, for both distribution modalities: 14.04 hm^3 in 2001 or 2004 and 14.33 hm^3 in 2003, for PRO, and between 11.31 hm^3 in 2001 and 11.80 hm^3 in 2003, for PRI; whereas the smaller volumes corresponded to the dry years: 10.71 hm^3 in 2005 and 11.83 hm^3 in 2002 for PRI and 7.38 hm^3 in 2005 and 10.11 hm^3 in 2002 for PRO (Table 2).

The mean, simulated volume flowing in the watershed was 45.67 hm^3. Under PRI, the mean volume diverted to the canals system was 12.99 hm^3, representing 28.4 % of the available volume. Whereas under PRO, this averaged volume was 10.39 hm^3 only, or 22.7

% of the volume available in the watershed. This difference was expected because under PRO a fraction of the available water was allowed to flow at the outlet of the watershed. While the runoff volume simulated in 2005 at the outlet of the watershed was 1.19 hm^3 under PRI it was 3.48 hm^3 under PRO. In a wet year as 2001, the runoff volume at the outlet of the watershed reached 25% of the available volume, with little difference between both distribution modalities.

Table 2. Simulated volume of water, hm^3, diverted to the canals system and to some specific *acequias* of the study watershed in the period March to August, years 2001 to 2005, for the two water distribution modalities considered (PRO: Proportional supply and PRI: supply according to an up-downstream priority)

Year		Total	Castillejo	Nueva	Lugares	Cachariche	Cerro N.
2001	PRI	14.04	1.88	2.13	2.15	2.60	1.99
	PRO	11.31	1.65	1.68	1.37	1.83	2.05
2002	PRI	11.83	2.14	2.09	2.64	1.96	0.18
	PRO	10.11	1.87	1.52	2.24	0.61	1.93
2003	PRI	14.34	1.89	2.19	2.26	2.60	1.90
	PRO	11.80	1.63	1.98	1.69	1.50	2.05
2004	PRI	14.04	2.14	2.63	2.64	1.97	1.07
	PRO	11.34	1.97	2.09	2.32	0.75	1.78
2005	PRI	10.71	1.56	1.05	1.58	2.59	1.42
	PRO	7.38	1.20	0.81	0.78	0.77	2.05

The total volume of water diverted to the canals system depended on the water availability and the distribution modality. However, the share of water for each canal depended on its location within the watershed as well. The *acequias* located in the upper part of the watershed diverted under PRI a greater share of water than under PRO (Table 2), and vice versa. Compare for instance the volumes diverted to the *acequias* Castillejo (the highest) and Cerro Negro (the lowest) (Table 2).

The return flows of the irrigated land plus the intentioned diversions for recharging natural springs varied from year to year and depended on the distribution modality as well. In the wet years, the volume of return flows that were re-circulated were 0.04 hm^3 and 0.02 hm^3 for PRI and PRO, respectively, while in the dry years these volumes were halved.

These differences among years and between distribution modalities had differential effects on the irrigation performance of the different canals. For instance, the relative irrigation supply for *acequia* Castillejo (the highest) and *acequia* Cerro Negro (the lowest) in 2003 (wet year) and 2005 (dry year) showed a contrasting evolution along the irrigation campaign. In *acequia* Castillejo, the relative irrigation supply (RIS, defined as the ratio between the diverted water and the irrigation water required for maximum yield) under PRO decreased with respect to the RIS under PRI as the season progressed. This decrease corresponded with the RIS increase under PRO with respect to the RIS under PRI observed in *acequia* Cerro Negro. Moreover, note that the contrast was in the dry year more marked than in the wet year. This contrasting performance indicated that PRO, contrary to PRI, approached the water distribution that avoids water excess and crop water deficit.

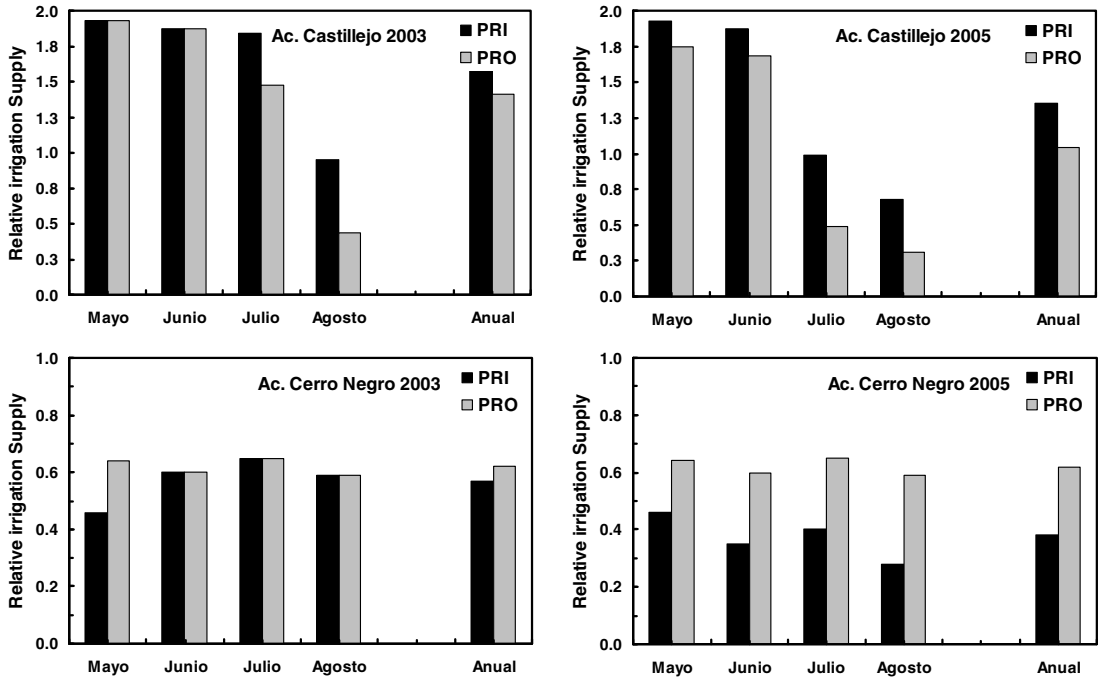

Figure 3. Relative irrigation supply in *acequias* Castillejo and Cerro Negro, years 2003 and 2004, for the water distribution modalities PRO (proportional supply) and PRI (supply according to an up-downstream priority)

Table 3. Equity among the *acequias* of the three subsystems and the whole system of the study watershed, years 2001 to 2005, for the water distribution modalities PRO (proportional supply) and PRI (supply according to an up-downstream priority)

Year	Subsys. Toril		Subsys. Mulhacén		Sunsys. Poqueira		Whole system	
	PRI	PRO	PRI	PRO	PRI	PRO	PRI	PRO
2001	0.50	0.55	0.89	0.94	0.26	0.43	0.54	0.53
2002	0.56	0.64	0.74	0.98	0.00	0.78	0.39	0.67
2003	0.49	0.48	0.88	0.96	0.25	0.52	0.58	0.67
2004	0.47	0.52	0.73	0.92	0.18	0.70	0.53	0.69
2005	0.72	0.72	0.65	0.90	0.18	0.75	0.25	0.42

As it should be expected, PRI resulted in equity significantly greater than PRI (Table 3). Equity (EQ) is defined herein as one minus the quotient between the average of the absolute differences between the irrigation water depths and their average (numerator), and the average of the irrigation water depths (denominator). Globally, the difference between EQ under PRI and PRO widened in the years of less precipitation, exactly when equity is more important.

Note that, although distribution capacity is not discussed herein, both RIS and EQ were conditioned by it. The same occurred with efficiency (E, defined as the quotient between the diverted volume minus the return flow and the diverted volume), which resulted under PRO higher than under PRI (Table 4). Again, the difference of this indicator applied to

both distribution modalities was under dry years greater than under wet years. This interaction is affected by the distribution capacity of the *acequias*, which it not discussed herein.

But perhaps the most interesting point regarding E is the difference between the efficiency of the subsystems and that of the whole system. The later is always greater than the former, reflecting the water reuse within the watershed.

Table 4. Efficiency in the *acequias* of the three subsystems and the whole system of the study watershed, years 2001 to 2005, for the water distribution modalities PRO (proportional supply) and PRI (supply according to an up-downstream priority)

Year	Subsys. Toril		Subsys. Mulhacén		Sunsys. Poqueira		Whole system	
	PRI	PRO	PRI	PRO	PRI	PRO	PRI	PRO
2001	0.74	0.80	0.83	0.85	0.73	0.91	0.90	0.96
2002	0.74	0.83	0.82	0.86	0.61	0.97	0.92	0.99
2003	0.75	0.85	0.83	0.88	0.72	0.94	0.90	0.98
2004	0.75	0.89	0.82	0.88	0.71	0.97	0.93	0.99
2005	0.75	0.82	0.84	0.89	0.71	0.96	0.87	0.98

CONCLUSIONS

The results showed that the equity inherent to the traditional proportional supply overall did not diminished the relative irrigation supply of the land irrigated from each of the irrigation canals. Moreover, the relative irrigation supply of the downstream irrigation canals improved in the dry years with little effect on the relative irrigation supply of the upstream canals. It was concluded that the abandonment of the agricultural activity in the Poqueira watershed and the relaxation of the ancestral irrigation organisational rules is degrading the irrigation performance. On the other hand, thanks to the integrated use of water and to the reuse of return flows, irrigation efficiency at the watershed scale was significantly greater than at the scale of irrigation canal. The study case illustrated a paradigm of water governance and integrated management that should enlighten scientists, engineers and professionals dealing with the world water crises.

ABSTRACT

The eddy correlation (EC) method has been recommended as one of the standard methods for measuring actual evapotranspiration. One of the challenges in interpreting eddy correlation measurements is that the balance between various energy components measured and the total energy received can sometimes be off by up to 30%. An independent measurement of sensible heat flux by scintillometry is often used to resolve this energy balance closure problem.

An EC system was set up at a 47 ha commercial corn field in southeastern North Dakota in 2008. Net radiation, latent heat flux, sensible heat flux, soil heat flux and other weather parameters were measured continuously at a 30-min interval during the growing season. A Scintec Boundary Layer Scintillometer 900 (BLS900) was temporarily deployed for seven days when clear sky conditions were satisfied. During the synchronous experiment, both systems were adjusted to at least 1 m above the canopy and collected data at an increased frequency of every minute. The EC system was placed at approximately the midpoint of the scintillometer path. The comparison of sensible heat fluxes measured by the two methods showed good agreement. The results will be used to validate the eddy correlation system in an attempt to reconcile the closure of energy balance.

INTRODUCTION

Sensible heat (H) is the transfer of heat energy driven by temperature difference between the surface and the air. Latent heat (LE) is released when water condenses and is required for evaporation. Thus we have the latent heat of vaporization, i.e., the heat required to evaporate water. In a vegetated area, LE is determined by the evapotranspiration rate, and the direct measurement of evapotranspiration by eddy correlation (EC) method has been widely used and accepted as one of the standard methods for LE determination (Farahani et al., 2007). The EC

station can be deployed over a large area above the crop or tree canopy, which overcomes the actual surface conditions. However, one of the challenges with EC is to reconcile the measurements of various energy components. The unbalanced energy amount can be off by up to 30% of the total measured energy (Wilson, et al., 2002). It is normally assumed that the unbalanced energy is evenly distributed between sensible and latent heat fluxes, according to the Bowen Ratio (H/LE) (Twine et al., 2000, Jia et al., 2007). Therefore an independent estimate of sensible heat flux can help to determine the unbalanced energy and reduce the error.

Scintillometry measures atmospheric scintillation caused by refractive index fluctuations and applies the Monin-Obukhov Similarity principle to derive the sensible heat flux from the structure parameter of the temperature (Hemakumara et al., 2003; Lagouarde et al., 2006). This is the only micrometeorological method, though indirect, that can be used to provide an estimate of sensible heat flux averaged over a distance and over a continuous time period (DeBruin et al., 1995; DeBruin, 2002; Meijninger and DeBruin, 2000). It can operate over a variety of landscape scales. Kleissl et al. (2008) measured sensible heat flux over a homogenous area with natural vegetation using six large aperture scintillometers deployed at different heights and locations and found only 10% differences in the results. Asanuma and Iemoto (2007) compared sensible heat flux measured by eddy correlation and a large aperture scintillometer, but indicated that an accurate measurement of sensible heat flux depends on additional temperature and wind speed measurements as well as an estimate of the roughness length.

During the growing season of 2008, an eddy correlation system was used to measure actual ET in a maize field over a subsurface drainage. A large aperture scintillometer (LAS) was set up with the eddy correlation station for a comparison. This paper describes the experimental setup and presents preliminary comparison of the sensible heat flux measured by the two methods.

MATERIALS AND METHODS

Experimental Site

The experiment was conducted in 2008 over a 47 ha maize field at Fairmount, Richland County, ND. An eddy correlation system was set up (46.00895^{o} N, 96.60368^{o} W, 296 m above the sea level) at the southwest quarter of the field, at which a subsurface drainage system was installed in the fall of 2002. A scintillometer (BLS900, Sentic, German) was setup with the EC station in the middle of transect between the transmitter and the receiver. The path length was 584 m. Figure 1 shows the schematic layout of the instrumentation setup.

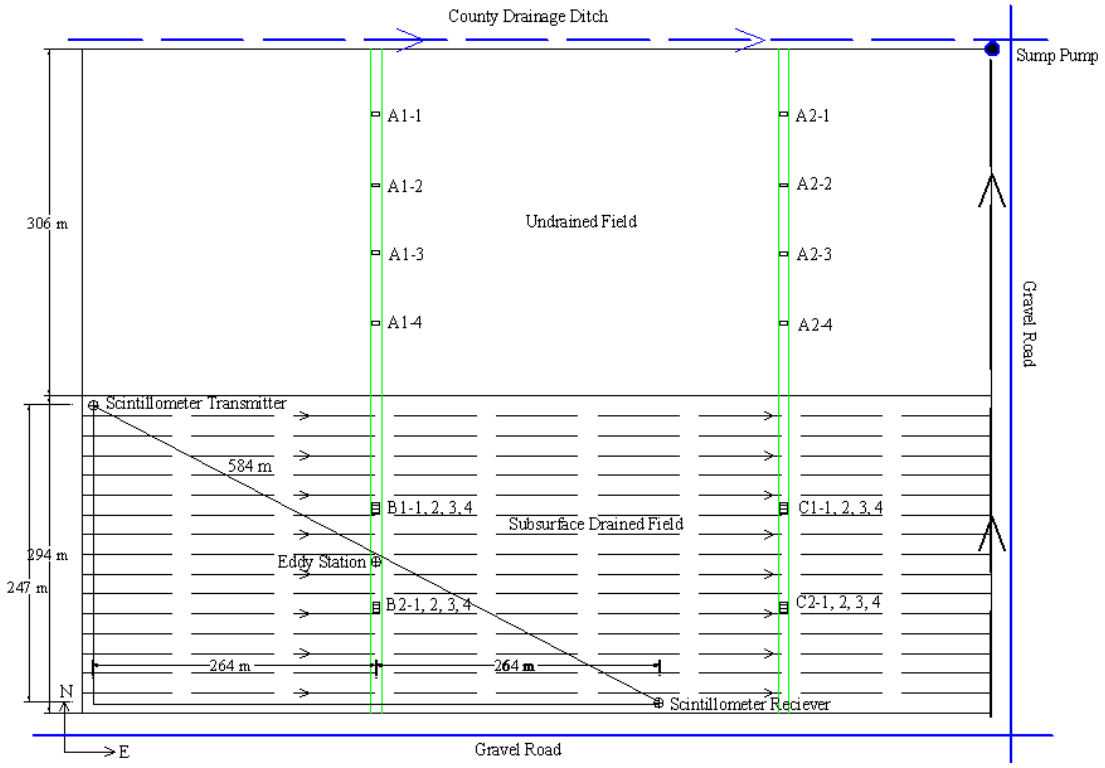

Figure 1. Schematic diagram of the experimental setup.

The EC station consists of a CSI (Campbell Scientific Inc., Logan, UT) CSAT3 3-D Sonic Anemometer and a CSI KH20 Krypton Hygrometer. The sampling frequency was 10 Hz and 1 to 2 min moving averages were used during the comparison with the scintillometer. The same average was applied to the meteorological measurements, such as net radiation, temperature, soil temperature, soil moisture, etc.

The scintillometer used in this study is a Large Aperture Scintillometer, model BLS900, manufactured by Scintec Inc., Germany. The BLS900 transmitter emits radiation through 924 light emitting diodes (LED) on two disks. The LEDs can operate in 4 different pulse repetition rates from 1Hz to 125 Hz; in this study, the rate was set at 5 Hz. The BLS900 is insensitive to transmitter vibrations because of its large emitting surface area and relatively large disperse angle.

During the experiment, the path length of scintillometer was fixed at 584 m, but its height along with that of EC was adjusted according to the maize height (Figure 2). The EC and LAS comparison was conducted on July 5, 8, 9, 13, 14 and August 5 and 6, 2008.

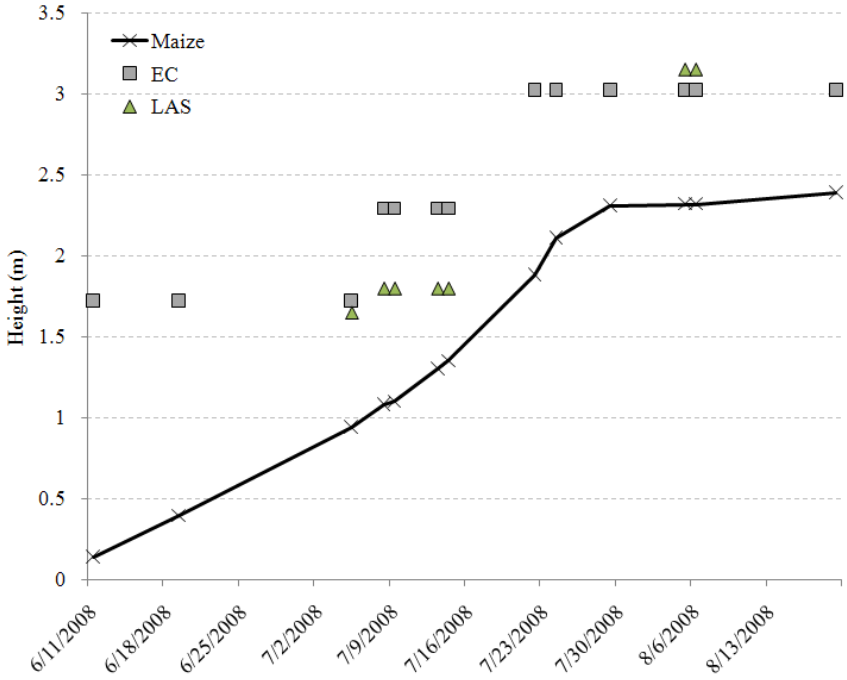

Figure 2. Arrangement of crop and instrumentation heights during the 2008 growing season at Fairmount, ND.

Sensible heat flux calculation

The description of EC method used in this research has been detailed by others (Sumner, 2001, Jia et al., 2006, 2007) and will not be repeated in this paper. Sensible heat flux estimation from scintillometer measurements have been addressed by Clifford et al. (1974), Hill et al. (1992), Hill (1997), and Lagouarde et al. (2006). In this paper, we only review the equations used for H estimation by the BLS900 large aperture scintillometer.

The refractive index (C_n^2, $m^{-2/3}$) integrated along the optical path was directly provided by the BLS900 processing unit. The structure function constant of temperature (C_T^2, $K^2\ m^{-2/3}$) can be calculated using

$$C_n^2 = \alpha_1^2 \frac{p^2}{T^4} C_T^2 \qquad (1)$$

where α_1 is wavelength dependant proportionality factor. At wavelength 880 nm, α_1 is 0.005759 $K\ Pa^{-1}$; p is the air pressure in Pa; and T is air temperature in K. This equation was listed in the manufacturer manual (Scintec, 2007).

The Bowen ration (β) correction listed by others (Wesely, 1976; DeBruin et al., 1995; Lagouarde et al., 2006) was not applied. The use of scintillometer is intended to compare the H

by LAS (H_{LAS}) with H by EC (H_{EC}). The use of β from EC will not allow the independent estimation of H_{LAS}. As stated by Savage (2009), when β is small, the correction for H is large, but the absolute value of H is small. When the β is large, the correction for H is small with possible little impact on the estimated energy balance.

Once C_T^2 is known, the temperature scale T_* can be calculated from a universal function $f_1[(z\text{-}d)/L_m]$ based on Monin-Obukhov similarity theory (MOST):

$$C_T^2 = T_*^2 (z-d)^{-2/3} f_1[(z-d)/L_m] \qquad (2)$$

where z is the height of the optical beam above ground in m. The d term is the zero displacement height in meters and can be determined from 0.67h, where h is the mean maximum height of the plant canopy in meters (ASCE, 1996).

The temperature scale T_* is used to calculate the H_{LAS}:

$$H = \rho C_p u_* T_* \qquad (3)$$

where ρ is air density in kg m^{-3} and C_p is specific heat of air in J kg^{-1} K^{-1} (1.225 J kg^{-1} K^{-1}).

The friction velocity, μ_*, can be obtained from surface to air application based on measured wind speed at height z, and an integrated stability correction function for momentum transfer:

$$\mu_* = k u_z \left[\ln \frac{z-d}{z_{om}} - f_2\left(\frac{z-d}{L_m} \right) \right]^{-1} \qquad (4)$$

where k is the von Karman constant, 0.41, u_z is wind speed at height z in m s^{-1}, and z_{om} is momentum roughness height of the surface and is estimated from 0.123 h.

The L_m term is the Obukhov length. When neglecting the latent heat flux correction, it is a function of friction velocity μ_*, and temperature scale T_*.

$$L_m = -\frac{T\mu_*^2}{kgT_*} \qquad (5)$$

Where T is air temperature in K, k is the von Karman constant, and g is gravitational acceleration, 9.81 m s^{-2}.

The two functional equations in eq. (2) and (4) are based on the status of $(z\text{-}d)/L_m$.

When $(z\text{-}d)/L_m \leq 0$, the boundary layer is under unstable condition:

$$f_1\left(\frac{z-d}{L_m}\right) = a_u\left(1+b_u\left|\frac{z-d}{L_m}\right|^{-2/3}\right) \quad (6)$$

When $(z-d)/L_m > 0$, the boundary layer is under stable condition:

$$f_1\left(\frac{z-d}{L_m}\right) = a_s\left(1+b_s\left|\frac{z-d}{L_m}\right|^{2/3}\right) \quad (7)$$

From De Bruin et al. (1993), constants $a_u = 4.9$, $b_u = 9.0$, $a_s = 4.9$, and $b_s = 0$ will be used in this study.

For the unstable condition with $(z-d)/L_m \leq 0$ (Paulson, 1970),

$$f_2\left(\frac{z-d}{L_m}\right) = 2\ln\left(\frac{1+x}{2}\right) + \ln\left(\frac{1+x^2}{2}\right) - 2\arctan(x) + \frac{\pi}{2} \quad (8)$$

For the stable condition, $(z-d)/L_m > 0$ (Webb, 1970),

$$f_2\left(\frac{z-d}{L_m}\right) = -5.2\left(\frac{z-d}{L_m}\right) \quad (9)$$

where x is calculated from

$$x = \left(1-\frac{16(z-d)}{L_m}\right)^{1/4} \quad (10)$$

In summary, input parameters are refractive index, air temperature, height of the optical beam of the LAS, mean maximal height of the plant canopy, and wind speed through the calculations. The H_{LAS} value is calculated from iteration by assuming an initial value of μ_*. Once the $(z-d)/L_m$ stabilizes after 3-4 iterations, the H_{LAS} value is calculated.

ABSTRACT

Evapotranspiration (ET) of fully-irrigated and deficit-irrigated (no irrigation in July, August, and September) was measured in five alfalfa fields at various locations throughout California. Seasonal ET ranged from 838 to 1,651 mm, which differed from historical seasonal ET. Deficit irrigation reduced ET, but the ET difference between fully-irrigated and deficit-irrigated alfalfa was site specific. Yields were reduced by deficit irrigation.

INTRODUCTION

Alfalfa is California's single largest agricultural water user due to the amount grown, typically about 405,000 ha, and its long growing season. Seasonal alfalfa water applications generally range from 494,000 to 679,000 ha-m. Because of the high water usage, interest exists in better defining the seasonal water use of fully irrigated alfalfa for different climatic areas of California and in midsummer deficit irrigation (no irrigation in July, August, and September) of alfalfa as a strategy for coping with limited water supplies and also as a strategy for providing water for transfer from water-rich areas such as the Sacramento Valley to water-short areas such as the San Joaquin Valley and southern California. In theory, the amount of water available for transfer is the difference between the ET of fully-and deficit-irrigated alfalfa. This midsummer deficit irrigation strategy maintains the relatively high yields of the first part of the year and eliminates irrigations during the summer when yields are small and quality usually is poor.

Previous studies on mid-summer deficit irrigation of alfalfa showed that no irrigation during the midsummer reduced the alfalfa yield, but did not stop all plant growth (Frate et al., 1991, Guitjens, 1993, Ottman et al., 1996, Putnam et al., 2000, Robinson et al., 1994). As a result, some evapotranspiration occurred during the period of deficit irrigation. No information exists on differences in midsummer evapotranspiration amounts between fully-and deficit-irrigated alfalfa.

This study investigated the seasonal ET requirements of fully-irrigated alfalfa and the effect of midsummer deficit irrigation on yield and evapotranspiration in commercial alfalfa fields at various locations in California.

METHODS AND MATERIALS

Alfalfa evapotranspiration (ET) was determined at Tulelake (Klamath Basin), Scott Valley (near Yreka in the intermountain area of northern California), Sacramento Valley (near Davis), Kern County (near Buttonwillow), and the Imperial Valley (near Holtville). All sites were commercial fields except for the Tulelake site, which was located at the University of California Intermountain Research and Extension Center, Measurements were made at the Davis site from 2005 to 2008, and at the other sites in 2007 and 2008.

These sites reflect mid-summer climate conditions ranging from warm summer temperatures in the Intermountain areas (Scott Valley, Tulelake) to very hot summer temperatures (Imperial Valley). Border (flood) irrigation was used at the Sacramento Valley, Kern County, and Imperial Valley sites, while sprinkle irrigation was used at the Scott Valley and Tulelake sites, reflecting the irrigation practices of each area. Most of each field was fully irrigated; a section of each field was deficit irrigated during the mid-summer. The fully-irrigated alfalfa was irrigated according to the irrigators' normal practices.

The ET was determined using the eddy covariance (Tanner et al., 1985) and surface renewal meteorological methods (Paw U and Brunet, 1991; Paw U et al., 1995; Snyder et al., 1996; Spano et al., 1997). The eddy covariance system consisted of a CSAT3 sonic anemometer (Campbell Scientific, Inc.), four Hukseflux self-calibrating soil heat flux plates installed at 8 cm deep, two sets of spatially averaging soil temperature probes (Campbell Scientific, Inc.) installed at 2 and 6 cm deep, two CS616 soil water sensors (Campbell Scientific, Inc.) installed 2.5 cm deep, and a Q7.1 net radiometer (Radiation and Energy Balance Systems, Inc.). The sensors were connected to a CR5000 data logger (Campbell Scientific, Inc.). Logger software from Campbell Scientific, Inc. was used to process the data and to calculate covariances and average flux densities of net radiation (R_n), latent heat (LE), sensible heat (H), and soil heat (G) every 30 minutes. The CSAT3 anemometer also measured horizontal wind speed, wind direction, and air temperature. Relative humidity was measured with a HMP45C temperature and relative humidity probe (Campbell Scientific, Inc.).

The surface renewal system consisted of a Q7.1 net radiometer, two soil heat flux plates (Radiation and Energy Balance Systems, Inc.), one set of spatially averaging soil temperature probes, and two fine wire thermocouples (0.076 mm diameter) (Campbell Scientific, Inc.) mounted about 1.5 m above the ground surface to measure air temperature. The sensors were connected to either a CR23X, a

CR10X, or a CR1000 data logger (Campbell Scientific, Inc.), depending on the site, which recorded high frequency temperature data and low frequency data of other variables. Data archiving and processing to determine the uncalibrated sensible heat flux density is described in Snyder et al (1996). Average flux densities were calculated for a 60 minute time interval (CR10X, CR23X) or a 30 minute interval (CR1000).

Sensible heat data from the EC systems were used to calibrate the SR method. The uncalibrated sensible heat flux determined by the SR system must be corrected for unequal heating between the ground and the measurement height using independent measurements of sensible heat flux such as the EC data.

RESULTS AND DISCUSSION

Fully-irrigated alfalfa evapotranspiration. Daily evapotranspiration of alfalfa was small, generally between 1.4 mm and 2.5 mm per day, at the start of the crop growing season, which varies depending on climate characteristics, increases with time of year to maximum values between 8 and 10 mm per day in June/July, and then decreases to small values at the end of the crop season, as shown in Figure 1 for Scott Valley, Sacramento Valley, and Imperial Valley sites. The growing season of Scott Valley is smaller than those of the Sacramento and Imperial Valley due to its altitude (823 m) and northerly location. In the Imperial Valley, alfalfa evapotranspiration from July to September in 2007 was affected by possible heat stress, reflected by daily ET values smaller than reference ET values. Similar behavior occurred in the Imperial Valley 2008 growing season (not shown). Daily ET decreased during the harvest, but increased rapidly with time after the first irrigation after harvest, reaching maximum values just before the next harvest.

Seasonal evapotranspiration ranged from 838 mm (Scott Valley 2008) to 1,651 mm (Imperial Valley 2008) (Table 1). Seasonal ET values of Scott Valley and Tulelake were greater than the historical ET commonly used for crop water use. Seasonal ET of the Sacramento Valley and Kern County sites was slightly higher than the historical ET, with an average of 1,346 mm for the three year period for the Sacramento Valley. The seasonal ET of the Imperial Valley was smaller than the historical value, possibly due to the heat stress.

Table 1. Seasonal ET of the fully-irrigated alfalfa and historical ET for the experimental sites.

Site		Seasonal ET (mm)	Historical ET (mm)
Imperial Valley	(2007)	1473	1930
	(2008)	1651	
Kern County	(2007)	1422	1245
Sacramento Valley	(2005)	1270	1245
	(2006)	1372	
	(2007)	1397	
Scott Valley	(2007)	991	838
	(2008)	838	
Tulelake	(2007)	1041	838
	(2008)	889	

Crop Coefficients. Crop coefficients were calculated as the ratio of the measured ET to the reference crop ET. Average alfalfa crop coefficients were calculated for each site and compared with the historical crop coefficients (Table 2). Coefficients were not calculated for Scott Valley, where reference crop ET was not available. Crop coefficients were the smallest just after a harvest and largest just before harvest. Values of the average, minimum, and maximum coefficients were similar to those in Doorenbos and Pruitt (1977) except for the Imperial Valley site.

Table 2. Crop coefficients of alfalfa.

Site	Average	Minimum	Maximum
Imperial Valley 2007	0.80	0.43	0.99
Kern County 2007	1.01	062	1.25
Sacramento Valley 2005	0.92	0.49	1.14
Sacramento Valley 2006	0.94	0.56	1.11
Sacramento Valley 2007	1.04	0.65	1.33
Tulelake 2007	0.99	0.50	1.30
Historical (Doorenbos and Pruitt, 1977)			
Humid[1]	0..85	0.50	1.05
Dry[1]	0.95	0.40	1.15
Strong wind	1.05	0.30	1.25

[1] light to moderate wind conditions

Mid-summer Deficit Irrigation. Mid-summer deficit irrigation reduced the ET, but the amount of reduction varied considerably between the experimental sites with differences between fully-and defict-irrigated alfalfa ranging from 5 mm (Tulelake 2007) to 238 mm (Sacramento Valley 2005) (Table 3). The 2007 value for Tulelake reflects the influence of shallow groundwater, which contributed to the ET of the deficit irrigated alfalfa. Only one month of deficit irrigation occurred for Kern County, which resulted in a small difference. The largest differences were found for Sacramento Valley. ET values of the fully-irrigated alfalfa during the period of deficit irrigation were similar for Imperial Valley, Sacramento Valley, and Tulelake.

Yield. Actual yield differences between fully–and deficit-irrigated alfalfa during the period of deficit irrigation ranged from 0.90 (Tulelake 2007) to 8.38 Mg ha^{-1} (Sacramento Valley 2007) (Table 4). The small Tulelake difference reflects the shallow ground water contribution. The differences for Kern County reflect the one month of deficit irrigation. However, experience has shown that a yield of 1.12 Mg ha^{-1} or smaller is not economical to harvest. Yields smaller than 1.12 Mg ha^{-1}were excluded in the practical yield differences. The practical yield differences represent the economical yield loss to the grower.

Table 3.ET differences between fully-and deficit-irrigated alfalfa and fully-irrigated ET during the periods of deficit irrigation.

Site		ET differences (mm)	Full ET during period of deficit irrigation (mm)
Imperial Valley	2007	61	572
Kern County	2006	46	226
	2007	43	356
Sacramento Valley	2005	239	594
	2006	168	538
	2007	119	475
Scott Valley	2007	51	269
	2008	79	320
Tulelake	2007	5	472
	2008	109	627

Table 4. Total yield difference between fully-and deficit-irrigated alfalfa.

Site		Actual yield difference (Mg ha^{-1})	Practical yield difference* (Mg ha^{-1})
Imperial Valley	2007	3.72	3.72
Kern County	2006	1.48	2.31
	2007	1.90	2.60
Sacramento Valley	2005	3.07	
	2006	6.23	8.85
	2007	8.38	10.28
Scott Valley	2007	1.84	3.09
Tulelake	2007	0.90	0/90

* adjusted for yields smaller than 1.12 Mg ha^{-1} not considered economical to harvest.

CONCLUSIONS

These ET measurements generally showed seasonal ET values that are higher than the historical seasonal ET values. The exception was Imperial Valley where the 2007 and 2008 seasonal values were considerably smaller than the historical value. Average crop coefficients were similar to the historical values except for Imperial Valley. Mid-summer deficit irrigation reduced the ET during the period of deficit irrigation, but the differences in ET between fully-irrigated and deficit-irrigated alfalfa were site specific. Yields were also reduced by deficit irrigation.

Water transfer amounts based on ET differences are not practical because of the site-specific responses, which cannot be predicted. Although ET occurred during the periods of deficit irrigation, the source of this water used by the crop was stored soil moisture from the earlier irrigations, prior to the start of deficit irrigation. Also,

this crop water use did not contribute to economical yield levels. The exception was at Tulelake where crop water use of the shallow ground water maintained high yields of the deficit-irrigated alfalfa. Water transfer amounts should be based on the ET of fully irrigated alfalfa during the period of mid-summer irrigation, which can be estimated as the product of crop coefficients and reference crop ET. This ET also more fully reflects the reduction in applied water during the deficit irrigation period.

ABSTRACT

Efficient use of water in agroecosystems requires the accurate quantification of evapotranspiration (*ET*). Explicit combination method (ECM) equations (i.e., the Penman equation and its derivatives) have been widely used and tested. These equations rely on an assumption to remove the surface temperature from the calculation, and the validity of this assumption has been questioned as likely underestimating *ET*, particularly in semiarid and arid climates. Information on the validity of this assumption in subhumid regions is rare. Recursive combination methods (RCM), based on an equation proposed by Budyko, make no assumptions for the surface temperature, but they require iteration to arrive at a solution. The objective of this research was to compare daily *ET* calculated by the ECM and RCM and compare those values to Bowen ratio energy balance system (BREBS)-measured *ET* for a well-watered and maintained grassland near Central City, Nebraska. The results indicated that both equations were sensitive to the value chosen for the surface resistance (r_s). For equivalent values of r_s, *ET* predicted by the ECM was greater than *ET* predicted from the RCM. Using r_s values of 40 s m^{-1} for the ECM and 20 s m^{-1} for the RCM resulted in the best predictive performance for the two methods, and using these values, the ECM performed slightly better. While the RCM may potentially provide more accuracy under some conditions, it was no more accurate than the ECM under these experimental conditions.

INTRODUCTION

Accurate quantification of evapotranspiration (*ET*) is necessary for the efficient planning and use of water resources in agroecosystems. A number of different combination, temperature, and radiation-based equations have been

developed for estimating *ET*. The most accurate and reliable of these are the combination method equations which combine surface energy balance and mass transfer methods for calculating *ET*. The most popular of these are derivatives of the original Penman equation (Penman, 1948). Standardized versions of the Penman-Monteith formulation of the Penman equation have been developed, tested, and recommended for use in calculating *ET* (ASCE-EWRI, 2005).

The Penman equation and its derivatives rely on an approximation of the saturation vapor pressure vs. air temperature relation using the finite difference form of the Clausius-Clapeyron equation to remove the surface temperature from the equation (Sellers, 1965). This results in a single, explicit equation that is easily solved. This method is hereafter referred to as the explicit combination method (ECM). The validity of the assumption necessary to remove the surface temperature from the equation has been questioned (Lascano and van Bavel, 2007). The error due to the approximation is proportional to the difference between the surface and air temperatures, and errors are likely to be largest in arid and semiarid regions (Sellers, 1965). However, information on the validity of this assumption in subhumid areas is rare.

Budyko (1956), as cited in Sellers (1965), independently developed a combination equation that contains two unknowns, the surface temperature and the saturation vapor pressure at the surface temperature. It therefore, requires recursive iteration to arrive at a solution for the surface temperature to use to then calculate *ET*. This method is hereafter referred to as the recursive combination method (RCM). Because the RCM requires iteration to reach a solution, it is somewhat more cumbersome to use than the ECM. However, because it doesn't rely on the linear approximation of the saturation vapor pressure vs. temperature relation, it offers the potential for greater accuracy. Modern computer hardware and software makes the solution of the RCM trivial. The objective of this research was to compare daily *ET* calculated by the ECM and RCM and compare those values to Bowen ratio energy balance system (BREBS)-measured *ET* for an irrigated grassland.

METHODS

Study site and season. Measurements of *ET* and micrometeorological variables were made at an irrigated grassland near Central City, Nebraska (41°17'N, 97°56'W, 577 m MSL), which was maintained as a pasture. The study site is in a transition area from subhumid to semiarid zones. The grassland was approximately 64.7 ha and contained a mixture of cool season grasses [i.e., Tall Fescue (*Festuca arundinacea*) and Kentucky Bluegrass (*Poa pratensis*)]. Significant spring rains and irrigation in the summer kept the pasture well-watered. The pasture was irrigated, when needed, with a center pivot irrigation system and fertilized as needed. The pasture was grazed by cattle throughout most of the growing season, and the grass height varied between approximately 5 and 13 cm throughout the season. The data used for *ET* calculations were from the 2008 growing season, which was defined as May 1 (Day 122) to September 30 (Day 274).

Field instrumentation. Surface energy fluxes were measured using a deluxe version of a BREBS (Radiation and Energy Balance Systems (REBS), Inc., Bellevue, WA), and actual crop *ET* (ET_c) was calculated using the Bowen ratio method. The BREBS was installed near the middle of the study field but away from the pivot point of the center pivot. Fetch distances were at least 200 m or more in all directions. The BREBS included sensors to measure the following variables: air temperature and relative humidity gradients, incoming and outgoing shortwave radiation, net radiation, soil heat flux, soil temperature, soil water content every 30 cm up to 1.8 m in the soil profile, barometric pressure, precipitation, and wind speed and direction. A detailed description of the instrumentation may be found in Irmak and Irmak, (2008); Irmak and Mutiibwa (2008a); and Irmak and Mutiibwa (2008b). All variables were sampled at 30-s intervals and averaged and recorded every hour for energy balance calculations using a Model CR10X datalogger and AM416 Relay Multiplexer (Campbell Scientific, Inc., Logan, UT). The BREBS was closely supervised and general maintenance was provided at least biweekly. The BREBS data were downloaded from the datalogger weekly to biweekly and carefully screened.

Combination equations for calculation of *ET*. The ASCE Standardized Reference Evapotranspiration Equation (ASCE-EWRI, 2005) was used as the ECM for calculating *ET*. Calculations were carried out as described in ASCE-EWRI (2005) for calculation of daily reference *ET* for a grass surface with the exception that the denominator constant (C_d) was modified to allow for varying the surface resistance (r_s). The (Budyko, 1956) equation as cited in (Sellers, 1965) and applied by (Lascano and van Bavel, 2007) was used as the RCM for calculating *ET*. The RCM equation we used for daily *ET* calculations has the form:

$$R_n - G - \frac{0.622\rho\lambda K}{P(r_a + r_s)}(e_s - e_a) - \frac{\rho c_p K}{r_a}(T_s - T_a) = 0 \qquad (1)$$

where R_n is net radiation (MJ m^{-2} d^{-1}), G is soil heat flux (MJ m^{-2} d^{-1}), ρ is air density (kg m^{-3}), λ is the latent heat of vaporization (MJ kg^{-1}), P is air pressure (kPa), r_a is aerodynamic resistance (s m^{-1}), r_s is surface resistance (s m^{-1}), e_s is saturation vapor pressure at the effective surface temperature (kPa), e_a is actual vapor pressure (kPa), c_p is the specific heat of moist air (MJ kg^{-1} °C^{-1}), T_s is the surface temperature (°C), T_a is the air temperature (°C), and K is a unit conversion constant for daily calculations (86,400 s d^{-1}). To make the comparison with the ECM as consistent as possible, R_n, ρ, P, and r_a were all calculated as described in ASCE-EWRI (2005) for daily calculations except that net long-wave radiation, and ρ were calculated using T_s in place of T_a. G was assumed to be zero for daily calculations, and varying levels of r_s were used. Since T_s is not known, it must be solved for by finding the root of the RCM equation. T_s was solved for using the *uniroot* function of R v. 2.8.1 (R Development Core Team, 2008). However, root finding functions from other mathematical software or iterative spreadsheet solvers could also be used to solve the RCM equation for T_s. Once a value for T_s was found, *ET* was calculated from the latent heat flux term of the RCM.

Comparisons between the ECM and RCM. The primary difference between the ECM and the RCM is in the handling of T_s. The RCM uses iteration to solve for T_s, whereas the ECM uses a linear approximation of the saturation vapor pressure vs. air temperature relationship to eliminate surface temperature from the equation, which allows for an explicit solution for *ET*. To compare the impact of this assumption, effective T_s values as solved for in Equation 1 for the RCM and calculated for the ECM using the finite difference form of the Clausius-Clapeyron equation:

$$T_s - T_a = \frac{R_d T_a^{\,2}}{0.622 \lambda e_{sa}} \left(e_s - e_{sa} \right) \tag{2}$$

where R_d is the gas constant for dry air (287 J kg^{-1} K^{-1}), and e_{sa} is the saturation vapor pressure at the air temperature (kPa) (Sellers 1965) were compared. This was done with r_s set to zero in the RCM to remove the impact of the surface resistance term on the solved for T_s. *ET* values calculated using both the ECM and RCM, with the r_s term set to zero in both terms for consistency, were then compared. While the *ET* and micrometeorological data from the grassland were chosen to approximate the reference surface used in the ASCE Standardized Reference Evapotranspiration Equation, the actual surface of the grassland would be expected to vary somewhat over the length of the growing season. The grassland where this experiment was carried out was well-maintained, had relatively uniform height, and was composed of green and actively growing grass vegetation meeting the reference surface criteria. However, given the potential variations in vegetation during the season due to grazing, *ET* was also calculated with varying levels of r_s, using both the ECM and RCM, to evaluate the impact of r_s in both equations when compared with the measured *ET* of the grassland. The performance of the ECM and RCM equations was evaluated using root mean square deviation (RMSD) and two measures recommended by ASCE (1993), which were the cumulative deviation (D_V) and the Nash-Sutcliffe efficiency (NSE).

RESULTS AND DISCUSSION

The effective surface temperature from using the ECM was always greater than the air temperature, and the temperature difference remained fairly consistent over the growing season (Figure 1). The difference between T_s and T_a using the ECM ranged from 0.1 to 3.5°C with a mean difference of 1.1°C. Conversely, T_s calculated using the RCM method was not always greater than T_a, and the difference between T_s and T_a varied over the growing season. T_s and T_a were generally very similar during the early growing season. T_s generally began to exceed T_a around July 1 and generally exceeded the T_s values calculated using the ECM from mid-July to early September. T_s values, as calculated by the RCM, then declined during the remainder of the growing season and were generally less than T_a at the end of the growing season. $T_s - T_a$ using the RCM ranged from −5.1 to 7.6°C with a mean difference of 0.5°C.

ET calculated using the ECM (ET_{os}) was always greater than that calculated using the RCM (ET_{RCM}) when r_s was set to zero in both equations (Figure 2). The

difference ranged from 0.03 to 1.1 mm d^{-1} with a mean of 0.4 mm d^{-1}. ET_{os} and ET_{RCM} were generally much greater than ET_c during the early growing season. From late July through August both ET_{os} and ET_{RCM} were generally very similar to the measured ET_c, which indicates that, during this period, r_s was minimal. During September, ET_{os} and ET_{RCM} began to diverge from ET_c again. Lascano and van Bavel (2007) found that *ET* calculated using the RCM exceeded *ET* calculated with the ECM by 1 to 4 mm d^{-1} when *ET* exceeded 9 mm d^{-1} over a 45 day period during the summer at Lubbock, Texas. However, the regression equation that they developed indicates that ECM-calculated *ET* would exceed RCM-calculated *ET* for values less than 6 mm d^{-1}. Over 75% of the measured daily *ET* values in our study were less than 6 mm d^{-1}.

The value for r_s had a substantial impact on calculated *ET* values from both equations (Figures 3 and 4). ET_{os} exceeded ET_{RCM} for equivalent values of r_s, and thus the performance of the equations for predicting ET_c varied depending on the r_s value (Table 1). The results of this study indicate that an r_s value of approximately 40 s m^{-1} for the ECM and 20 s m^{-1} for the RCM resulted in the best performance for predicting ET_c of the grassland based on the BREBS-measured ET_c data. Using these values the ECM performed slightly better than the RCM with a lesser RMSD and greater NSE, although the D_V for the RCM was slightly less than that for the ECM. The ECM-calculated values generally had less scatter about the 1:1 line when compared with the measured ET_c. The results also indicate that the 70 s m^{-1} value of r_s used in the ASCE Standardized Reference Evapotranspiration Equation for a grass reference surface was too large and resulted in underpredictions of ET_c for the studied grassland. Although conditions of the studied grassland were representative of the standard surface, differences between the grassland and the hypothetical reference conditions and variations in conditions over the growing season may explain the underpredictions using the standard value for r_s.

CONCLUSIONS

ET values calculated using explicit and recursive combination methods were compared against each other and against measured *ET* from an irrigated and well-maintained grassland. The methods differ in their handling of the effective surface temperature, and while T_s was consistently greater than T_a for the ECM, T_s calculated from the RCM showed more variation over the growing season. In this study, *ET* calculated with the ECM exceeded *ET* calculated with the RCM for equivalent values of the surface resistance. The results indicated that an r_s of 40 s m^{-1} for the ECM and 20 s m^{-1} for the RCM resulted in the best predictive performance for estimating ET_c of the irrigated grassland. Using these values, the ECM method based on the ASCE Standardized Reference Evapotranspiration Equation performed slightly better than the RCM and exhibited less scatter. However, both methods performed extremely well, and the overall predicted *ET* for the growing season was within 1% of the overall measured ET_c using both methods. While the RCM may offer the potential of increased accuracy in situations where there are large differences between T_s and T_a, these results indicate that under the conditions of this study the ASCE equation was more accurate. However, both methods were sensitive to value chosen for r_s.

ABSTRACT

In semiarid environments with a shortage of water resources and a risk of overexplotation, it is essential to improve the accuracy of the estimation of crop water requirements to reduce water use and increase water productivity. For this reason, in 1999 three weighing lysimeters were installed in the experimental farm "Las Tiesas" located in Albacete (Central Spain). The facility has a lysimeter for measuring the grass reference evapotranspiration (ET_o), a second for rotating annual crops and third installed in a perennial vineyard for measuring grape water use. Each of lysimeter is surrounded by a one hectare square buffer plot planted to the lysimeter crop. The lysimeters are weighed with a balance beam and load cell configuration, with most of the weight being eliminated using counterweight. The overall resolution of the systems are 250 g or 0.04 mm of water. The measurement frequency is one second, and a reading is registered by a datalogger every 15 min. During the period 2002-2003 the FAO-56 Penman-Monteith (FAO-56 PM) and the ASCE "standardized" version of Penman-Monteith (ASCE PM) hourly equations were evaluated by comparing them with reference lysimeter measurements. In 2003 we measured the water use (ETc) of broccoli as a double crop. Records of grapevine ET were collected from 2002 to 2008 and detailed canopy development information was obtained from 2004 to 2008 growing seasons. In this paper, we present results of grapevine ET measured by a weighing lysimeter during 2008 growing season.

INTRODUCTION

The use of groundwater to supply large surfaces of irrigated land has been the key to agricultural development in a large number of countries over the past few years. In arid and semiarid areas, irrigation using groundwater has transformed good quality land with low productivity (due to drought) into areas of high productivity. Consequently, the income level of the farmers has increased and the rural population base has been maintained (Martín de Santa Olalla et al., 2003). This groundwater use must be sustainable, balancing the extractions with the recharge of the aquifer. Overexploitation of the system has often been practiced in the past, leading to serious environmental damage and contributing to the desertification process (Martín de Santa Olalla and de Juan, 2001).

In the Albacete province (Central Spain) water for irrigation and urban water supplies are still nearly exclusively from groundwater, although the implementation of the new state Water Plans provide for the substitution of some of this pumping by regulated surface water, which will allow a more rational and sustainable exploitation of the system (Montoro et al., 2002).

The semiarid climate of the south central plateau of Spain has limited water resources and recent irrigation development, primarily for maize production, is threatening the groundwater resource. Martín de Santa Olalla et al. (2003) have reported a decline in the water table of the aquifer 08.29 Mancha Oriental, and the problem seems to be increasing. This aquifer is located south-east of the Iberian peninsula, on the eastern side of the La Mancha plains, with a total surface area of 8,500 km^2. The aquifer supplies water to around 115,000 ha of irrigated lands provided with modern irrigation technology. The aquifer also supplies domestic and industrial water for a population of over 275,000. The annual water withdrawal for these purposes is about 500 hm^3 (Montoro, 2008).

In this situation, with a shortage of water resources and a risk of overexplotation, it is essential to improve accuracy in the estimation of crop water requirements to reduce water use and increase water productivity. For this reason, in 1999 three weighing lysimeters were installed in the experimental farm "Las Tiesas" located in Albacete (Central Spain). The facility has a lysimeter for measuring the grass reference evapotranspiration (ET_o), a second for rotating annual crops and third installed in a perennial vineyard.

Initially we conduced two studies to evaluate different equations to calculate daily and hourly ET_o using the measurements obtained by the reference lysimeter. In this research works, the FAO-56 Penman-Monteith method was the most accurate for calculating daily and hourly ET_o (López-Urrea et al., 2006a,b). During the period from 1999 to 2008 the annual crop lysimeter has been used to measure the water requirements of different agronomic crops (maize, sugar beet, barley, broccoli, sweet corn, canola, sorghum, etc.) (López-Urrea et al., 2004, 2006c, 2007, 2008). During the 2002 to 2008 growing seasons the water use of two grapevines (*Vitis vinifera* L. cv. Tempranillo) has been measured with the vineyard lysimeter (Montoro et al., 2008). In this paper, we present some results obtained by this lysimeter facility.

MATERIALS AND METHODS.

These studies were carried out during the period from 1999 to 2008 in the "Las Tiesas" farm, located near Albacete (Central Spain). Its geographical coordinates are: longitude 2º 5' 10" West, latitude 39º 14' 30" North, and its altitude is 695 m above sea level. The climate is semiarid, continental with 320 mm of annual rainfall, mostly concentrated in the spring and fall. Average mean, maximum and minimum temperatures are: 13.7, 24.0 and 4.5 ºC, respectively. For a more detailed description of the climate of the area see López-Urrea et al. (2006a).

The soil is classified as Petrocalcic Calcixerepts (Soil Survey Staff, 2006). Average soil depth of the experimental plot is 40 cm, and is limited by the development of a more or less fragmented petrocalcic horizon. Texture is silty-clay-loam, with 13.4% sand, 48.9% silt and 37.7% clay, with a basic pH. The soil is low in organic matter and in nitrogen, and has a high content of active limestone and potassium.

The reference lysimeter was used during the 2002 and 2003 growing season to evaluate the FAO-56 Penman-Monteith (FAO-56 PM) and the American Society of Civil Engineers version of Penman-Monteith (ASCE PM) equations to estimate hourly ET_o values in the semiarid environment of Albacete (Spain). The lysimeter was installed in the centre of a 10,000 m^2 grassy plot (*Festuca arundinacea* Schreb., cv. "Asterix") maintained in optimum growth conditions for the purpose of measuring reference evapotranspiration values (ET_o). An agro-meteorological station was installed next to

this lysimeter, which had the necessary sensors to record the meteorological data required for calculating ET_o.

To measure the ET_o, we used a weighing lysimeter with continuous electronic data recording (López-Urrea et al., 2006a). The ET_o values were calculated from hourly mass loss minus drainage loss and the mass added from irrigations and/or rainfall. The lysimeter is located in the center of a 100 x 100 m plot, where grass was sown in September, 1998. The whole plot has a permanent sprinkler irrigation system with sprinklers placed on a grid of 15 x 12.5 m that provide a precipitation rate of 8.6 mm h^{-1}. The lysimeter container is 2.7 m long, 2.3 m wide and 1.7 m deep, with an approximate total weight of 14.5 Mg. Efforts were made to keep the crop inside the lysimeter at the same growth rate and plant population as the crop outside to minimize edge effects. Two time domain reflectometry (TDR) soil moisture sensors (model CS615, Campbell Scientific Ltd., Leicestershire, UK) were installed in the lysimeter at the 0.30 and 0.60 cm depths for measurement of soil water content, and two soil temperature probes (model 107, Campbell Scientific Ltd., Leicestershire, UK) were placed at the 0.15 and 0.30 m depths. The lysimeter soil-containing tank sits on a system of scales and a counterweight that offset the dead weight of the soil and the tank. The de-multiplication factor of the system is 1000:1. A steel load cell (model SB2, Epelsa Ind., S.L.) is connected to the system of balances. The system allows measurement of ET_o in the lysimeter with a resolution of 0.04 mm water depth. Additional information about the technical features of the lysimeter may be found in Lopez-Urrea et al. (2006a). The lysimeter readings were checked daily to identify individual readings that could not be explained by natural processes of water input and loss. Data losses sometimes occurred during irrigation and precipitation events and during weight and calibration verifications.

The FAO-56 PM reference equation (hourly time step) evaluated was:

$$ET_o = \frac{0.408\Delta\left(Rn - G\right) + \gamma \frac{37}{T_{hr} + 273} U_2 \left(e^o\left(T_{hr}\right) - e_a\right)}{\Delta + \gamma\left(1 + 0.34U_2\right)}$$

where ET_o is the reference evapotranspiration (mm h^{-1}); Δ is the saturation slope vapour pressure curve at T_{hr} (kPa $ºC^{-1}$); Rn is net radiation at the grass surface (MJ m^{-2} h^{-1}); G is soil heat flux density (MJ m^{-2} h^{-1}); γ is the psychrometric constant (kPa $ºC^{-1}$); T_{hr} is the mean hourly air temperature (ºC); U_2 is the average hourly wind speed (m s^{-1}); $e_o(T_{hr})$ is the saturation vapour pressure at T_{hr} (kPa); and e_a is the average hourly actual vapour pressure (kPa).

The actual vapour pressure (e_a) is determined as:

$$e_a = e^o\left(T_{hr}\right)\frac{RH_{hr}}{100}$$

where RH_{hr} is the average hourly relative humidity (%). The saturation vapour pressure at T_{hr} ($e_o(T_{hr})$) is calculated from:

$$e^o\left((T_{hr}\right) = 0.6108\exp\left[\frac{17.27T_{hr}}{T_{hr} + 237.3}\right]$$

The ASCE PM equation for hourly time steps is expressed as (Walter et al., 2000; Temesgen et al., 2005):

$$ET_o = \frac{0.408\Delta(Rn - G) + \gamma \frac{37}{T_{hr} + 273} U_2 \left(e^o(T_{hr}) - e_a\right)}{\Delta + \gamma\left(1 + C_d U_2\right)}$$

The constant C_d in the denominator is a function of the time step representing bulk surface (r_s) and aerodynamic resistance (r_a), and varies with reference type and time of day. For hourly time steps, the ASCE PM equation has a C_d value of 0.24 during the daytime period (Rn > 0) and 0.96 during the nighttime period (Rn $\leqslant$ 0). All other terms and units are the same as for the FAO-56 PM equation.

Several comparisons were obtained through the simple linear regression analysis technique (Box et al., 1989) and a set of statistics proposed by Willmott (1982): the root mean square error (RMSE) and the index of agreement (d). The RMSE was calculated as:

$$RMSE = \left[N^{-1} \sum_{i=1}^{N} (Pi - Oi)^2 \right]^{0.5}$$

where N is the number of observations, Pi are estimated ET_o values, and Oi are observed ET_o values.

The index of agreement was computed as:

$$d = 1 - \left[\sum_{i=1}^{N} (Pi - Oi)^2 / \sum_{i=1}^{N} \left(|Pi - Oavg| + |Oi - Oavg| \right)^2 \right] \quad 0 \leq d \leq 1$$

Perfect agreement would exist between P and O if d = 1.

To determine actual broccoli ET, we used a weighing lysimeter with continuous electronic data recording. The ETc values were calculated from daily mass loss minus drainage loss and the mass added from irrigations and/or rainfall. The lysimeter is located in the center of a 100 x 100 m plot, where broccoli was transplanted on 4 August, 2003. Plant rows were 0.7 m apart with plants 0.25 m apart within the row. The lysimeter used for rotating annual crops has the similar characteristics as the reference lysimeter.

The 1 ha (100 x 100 m) vineyard was planted in 1999 with Vitis vinifera L. cv. 'Tempranillo' grafted to 110 Richter rootstock at a vine and row spacing of 1.5 and 3 m, respectively (4.5 m^2 per vine). During dormancy, grapevines were pruned to two, 10-node, fruiting canes. The trellis consisted of 1.7 m long aluminium posts driven 0.4 m into the soil and separated 6 m in the row with four vertical wires. The basal wire at 0.4 m above the soil supported the irrigation lateral, the next wire at 0.8 m above the soil supported the fruiting canes, and two more wires at 1.1 and 1.3 m above the soil supported the canopy. Vines were drip-irrigated with 3.5 L h^{-1} emitters spaced every one meter.

Water use of two grapevines was measured with a monolithic weighing lysimeter installed in the centre of the plot. The lysimeter dimensions were 3 x 3 m and 1.7 m deep and the total mass exceeded 18.5 Mg. The lysimeter was weighed with a balance beam and load cell configuration, with most of the weight being eliminated using counterweight. The overall resolution of the system was 250 g or 0.04 mm of

water. The sample frequency was 1 s, and a reading was registered by a datalogger (CR10X, Campbell Scientific Ltd., Logan, Utah, USA) every 15 min.

Two vines were planted in the lysimeter, each one occupying 4.5 m^2, the same as the vines in the rest of the plot. The vines were 1.5 m apart and 0.75 m from either end of the 3 m long lysimeter and 1.5 m from the sides of the lysimeter. The trellis for the vines in the lysimeter was self-contained and not attached to the trellis system used in the rest of the row, to ensure that it was part of the lysimeter mass.

The lysimeter's daily mass change was used to determine ETc. Irrigation (five hours) was always at night commencing at 2100 h and on irrigation days ETc was calculated omitting values during the irrigation period. No drainage was recorded during the study period. The data were downloaded daily for processing.

The ET_o and ETc were used to establish Kc for the grapevines in the lysimeter as a function of age and developmental stage. The Kc reported for 2008 was calculated with the ET_o values using the Penman-Monteith equation.

RESULTS AND DISCUSSION

Hourly reference evapotranspiration equations

Figure 1 presents the regression analysis of hourly values calculated from grass lysimeter measurements. This comparison was conducted from 696 observations from both years that the experimental work was carried out.

The hourly FAO-56 PM equation (Fig 1(a)) performs very well compared to lysimeter measurements. The slope of the straight line is very close to one, and neither overestimations nor underestimations are produced in the range of the values studied. These results differed from those obtained by Howell et al. (2000) who compared FAO-56 PM ET_o against lysimeter ET_o in Bushland, Texas, and observed tendencies in the FAO-56 PM equation to overestimate ET_o for low rates and to underestimate ET_o for high rates.

Figure 1b shows comparison of the hourly lysimeter ET_o values and ET_o calculated by the Standardized PM method. The data agree fairly well up to 0.45 mm h^{-1}, which indicates the good performance of this method for that range of values. However, above 0.45 mm h^{-1}, calculated values slightly overestimate lysimeter measurements.

Table 1 shows the results of this comparison, through simple regression analysis, between lysimeter measurements and the values calculated by both methods, and indicates the calculation of error and the index of agreement. Calculated reference valuaes were taken as dependent variables while the measurements made in the lysimeter, as the independent variable. The hourly FAO-56 PM equation showed very good performance when compared to values measured in the lysimeter. This method, with a RMSE of 0.0796 mm h^{-1} and a 0.9725 index of agreement, neither underestimates nor overestimates lysimetric measurements. These results are even better than in previous papers from the same area, where a comparison was made between daily measured and calculated ET_o values (López-Urrea, 2004; López-Urrea et al., 2006a).

The ASCE PM equation also performed well compared with lysimetric measurements, but produces a small overestimation (4%) with a RMSE of 0.0878 mm h^{-1} and a 0.9683 index of agreement. These results are slightly different from those obtained in a previous paper from Córdoba, Spain (Berenjena and Gavilán, 2005). In that paper hourly FAO-56 and ASCE PM equations were also evaluated and compared with weighing lysimeter data. Hourly ET_o values calculated by the ASCE PM equation underestimated lysimetric measurements by 2%, and had a RMSE of 0.032 mm h^{-1} and

a 0.997 index of agreement, while the FAO-56 PM method underestimated them by 3%, with a RMSE of 0.047 mm h^{-1} and a 0.993 index of agreement.

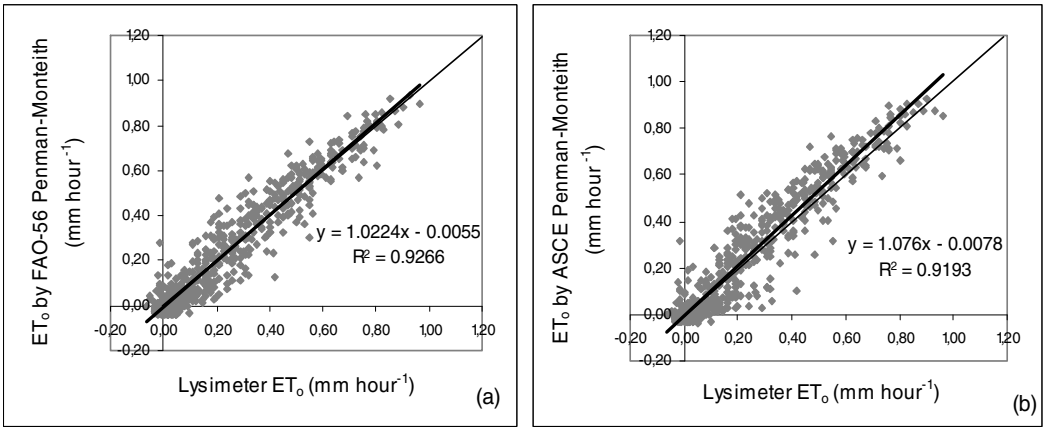

Figure 1. Hourly reference evapotranspiration comparison between the lysimeter and the FAO-56 (a) and ASCE Penman-Monteith (b) equations (hourly time step) during 13 days in 2002 and 16 days in 2003 (April-October).

Table 1. Lysimetric evaluation of hourly FAO-56 and ASCE Penman-Monteith equations.

Calculation method	N	Oavg (mm hour^{-1})	Pavg (mm hour^{-1})	Pavg/Oavg (%)	A (mm h^{-1})	B	R^2	RMSE (mm hour^{-1})	d
					ET_o(estimated) = A + B*ET_o(Lysimeter)				
FAO-56 Penman-Monteith	696	0.2033	0.2023	100	-0,0055	1.022	0.9266	0.0796	0.9725
ASCE Penman-Monteith	696	0.2033	0.2109	104	-0,0078	1.076	0.9193	0.0878	0.9683

N: observation number; Oavg: average of values measured in the lysimeter; Pavg: average of the values estimated by FAO-56 and ASCE Penman-Monteith (hourly time step); A: intercept; B: regression coefficient (slope); R^2: determination coefficient; RMSE: root mean square error; d: index of agreement. Values for A, B and R^2 were highly significant (P<0.01) in all cases.

Evapotranspiration and crop coefficient of broccoli

Figure 2 presents the daily broccoli ET data as well as the water input from irrigation and rainfall. Following transplanting, ETc was high due to daily applications of water, but then it decreased to low values around 15 August. ETc rose very rapidly after that date due to the fast canopy growth, facilitated by the favourable summer temperatures. Peak ETc was reached around 10 September and then declined following the general decrease in evaporative demand as the season advanced.

Figure 3 presents the Kc data, calculated as the ratio of the lysimeter measured ET and the ET_o, calculated with the FAO-56 PM equation. Previous lysimeter studies at the same location have reported a reasonably good performance of this equation (López-Urrea et al., 2006a). The minimum (0.39) and the maximum (1.31) Kc values were observed during the crop establishment stage and in the head emergence period, respectively. Because of the influence on ETc of the frequent surface wetting by irrigation, the Kc values are reported as 5-day averages which were fitted to a second degree polynomial function (Figure 3).

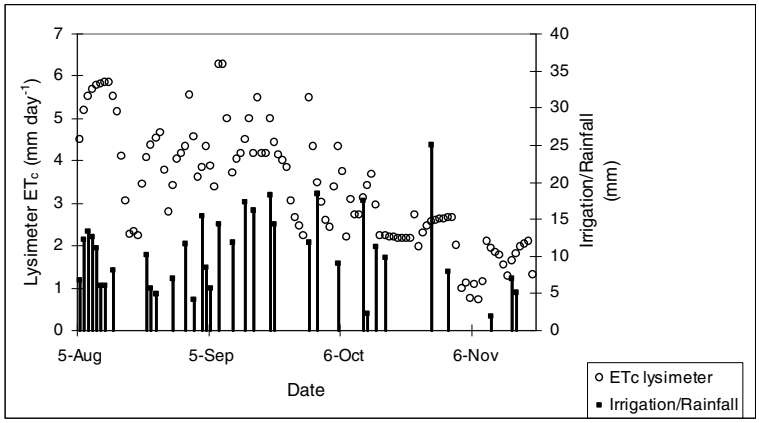

Figure 2. Daily evapotranspiration values measured in the lysimeter. Irrigation and rainfall during the experimental period is indicated with vertical bars.

The Kc curve fitted to the measured data does not follow the conventional shape of the crop coefficient curve recommended for broccoli (Figure 3). For the case of late summer plantings, the initial Kc results from the frequent watering following transplanting under the high seasonal ET_o conditions (Figure 3). Subsequently, the Kc drops and then increases again, reaching maximum values at commercial harvest, without the decline in Kc recommended in Allen et al. (1998) (also shown in Figure 3). In a recent paper, El-Shikha et al. (2007) used Kc values very similar to those in Allen et al. (1998) to compute broccoli ET in a remote sensing study of late fall plantings and spring harvest in Arizona. The slower Kc increase in the crop development phase of the data reported in Figure 3 compared to Allen et al. (1998) recommendations, reflects the sub-optimal autumn temperatures for broccoli canopy development. At any rate, the Kc measured values do not fit well the linear or even the curvilinear model, as there are significant fluctuations above and below the fitted lines (Figure 3).

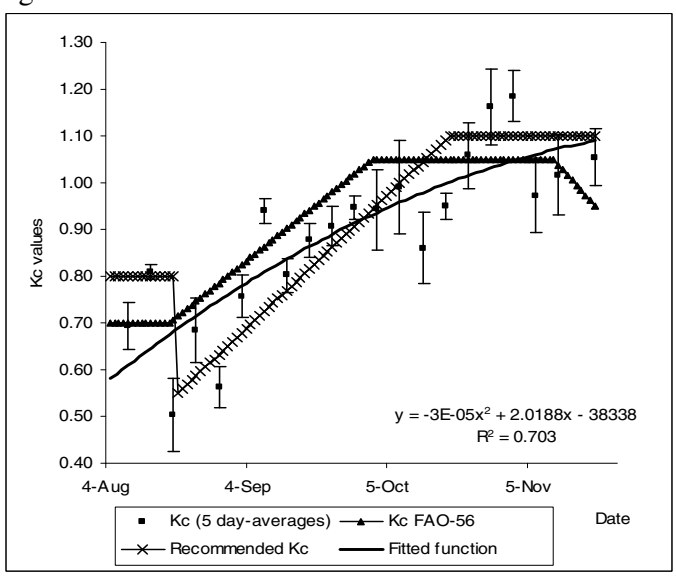

Figure 3. Crop coefficient curves: a) Recommended in Allen et al., (1998; triangles), b) recommended for fall plantings based on the data measured in the lysimeter (x). Squares indicate 5-day averages of measured values with the curve fitted. Bars indicate the standard error.

Evapotranspiration and crop coefficient of grapevine

The temporal variation in grapevine water use (ETc) during 2008 is shown in Figure 4. The observed values of daily ETc were similar to those measured by other authors (Lascano et al., 1992; Trambouze and Voltz, 2001). In 2008 maximum ETc occurred in August with 3.65 mm day^{-1} (Table 2).

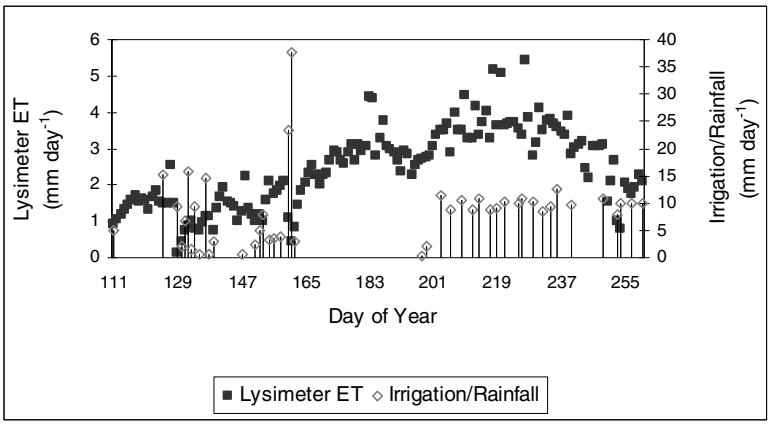

Figure 4. Daily evapotranspiration values measured in the vineyard lysimeter . Irrigation and rainfall during the experimental period is also indicated with vertical bars.

Monthly Kc values are shown in Table 2. The Kc values observed here are smaller than those found for Vitis vinifera cv. Thompson Seedless (Williams et al., 2003a, 2003b) but very similar to those reported for Vitis vinifera cv. Sultana (Yunusa et al., 2004).

Table 2. Irrigation, rainfall, reference evapotranspiration (ET_o), grapevine water use (ETc), and crop coefficient (Kc) in 2008.

2008

Total	369		800		352	

CONCLUSIONS

In a semiarid climate such as in this work area, the hourly FAO-56 and ASCE PM equations showed very good performance when compared to lysimetric measurements. In cold, semiarid environments, it is possible to take advantage of the late summer season and early fall for the production of vegetables, for which there is often a niche market. Our results for Central Spain showed that lysimeter ET for fall-grown broccoli amounted to 360 mm. The seasonal water use of the grapevines was 44% of ET_o in 2008, when the vines were nine years old. The experimental work

carried out during the period from 1999 to 2008 at the lysimeter station improve the accuracy in the estimation of crop water requirements.

ABSTRACT

The SIRMOD surface irrigation simulation, evaluation, and design software developed at Utah State University was applied to evaluate potential increases to irrigation performance from improved irrigation management within the Imperial Irrigation District of Southern California (IID). This study was conducted as part of a planning effort to develop strategies to satisfy the Colorado River Quantification Settlement Agreement and Related Agreements (QSA), which call for IID to generate more than 300,000 acre-feet annually through a combination of District and voluntary on-farm efficiency conservation savings.

Potential irrigation management performance increases were evaluated by calibrating the SIRMOD model for 34 selected border and furrow irrigation events for which delivery and tailwater hydrographs were measured. These events occurred at fields distributed throughout the Valley representing a range of crops, soils, run lengths, and tailwater production (surface runoff). For each event, simulations were conducted to identify potential reductions in tailwater resulting from different combinations of inflow rate and cutoff time. Simulations were constrained to minimize reductions in irrigation adequacy. Simulation results were detuned to represent practical, attainable performance based on an estimate of uncertainty in the soil moisture deficit prior to irrigation on the planning of an irrigation delivery.

BACKGROUND AND INTRODUCTION

The Imperial Irrigation District of Southern California (IID) is the nation's largest irrigation district, encompassing approximately 475,000 acres (190,000 ha) of irrigated agriculture.

Approximately 3.1 million acre-feet (3,800 MCM) of water is diverted annually for irrigation by IID from the Colorado River; the Colorado is IID's sole source of water for irrigation. Primary crops grown in IID include alfalfa, Bermuda hay, Sudan, sugar beets, wheat, carrots, onions, and lettuce. Soils range from heavy, cracking clay to sand with more than 80% of the service area consisting of cracking and heavy non-cracking clay soils. Primary irrigation methods employed by IID growers are graded border and graded furrow. Due to infiltration being relatively insensitive to intake opportunity time on many soils, high distribution uniformity and application efficiency are possible, with the primary on-farm loss being tailwater (surface runoff).

In 2003, IID entered the Quantification Settlement Agreement and Related Agreements (QSA), agreeing to the transfer of approximately 300,000 acre-feet (370 MCM) annually to other Southern California Colorado River water users through a combination of system and on-farm conservation projects aimed at increasing on-farm irrigation and distribution system efficiency. As a condition of the agreements, at least 130,000 acre-feet (160 MCM) must be generated through the implementation of on-farm conservation measures (CMs).

In 2007, IID completed its Efficiency Conservation Definite Plan (Plan), which identifies the most probable mix of on-farm and system improvements needed to satisfy transfer obligations while keeping costs below available transfer revenues. On-farm participants in the transfer program will be provided incentives to implement CMs to achieve conservation goals. The Plan identified numerous CMs that growers are likely to consider. Among those CMs growers expressed interest in implementing were management-based CMs aimed at increasing irrigation efficiency through decreased tailwater production. In particular, interest was expressed in improving surface irrigation methods through irrigation scheduling and event management.

Scientific Irrigation Scheduling (SIS), as evaluated under the Plan, includes decisions made prior to placing irrigation orders for individual fields including the timing, duration, and amount of water aimed at minimizing tailwater production while satisfying crop water requirements. Scientific Event Management (SEM), as evaluated under the Plan, includes decisions made after the start of an irrigation event based on observed advance, infiltration, and runoff aimed at minimizing tailwater production while providing adequate infiltration to meet crop water needs.

METHODOLOGY

Potential improvements in application efficiency from reduced tailwater production were estimated for individual irrigation events to gain insights into potential increases in irrigation efficiency through implementation of management-based CMs. Tailwater reduction potential was evaluated using the SIRMOD surface irrigation simulation, evaluation, and design software developed at Utah State University. First, the model was calibrated to determine infiltration characteristics for historical irrigation events. Next, parametric model runs varying inflow rate and set duration were completed for each event to determine the maximum application efficiency that could be attained while maintaining irrigation adequacy. Then, model results were detuned to allow for uncertainties or other considerations limiting the ability to optimize all irrigation

events over the course of a crop season. These estimates were used to parameterize a model estimating increases in irrigation performance from irrigation scheduling and event management of border and furrow irrigated fields. The model was applied district-wide across a range of crops and soils to estimate the total potential increase in irrigation performance from irrigation scheduling and event management (IID, 2007).

SIRMOD. SIRMOD is a surface irrigation software package providing simulation, evaluation, and design capabilities for border, basin, and furrow irrigation (Walker and Skogerboe, 1987; Walker, 1989; and Walker, 2004). The simulation of the hydraulics of surface irrigation systems at the field level uses hydrodynamic, zero-inertia, or kinematic-wave algorithms which can be used to identify the combination of event parameters (both management and physical) that optimize application efficiency. The evaluation algorithms utilize the two-point solution of the inverse problem allowing the computation of infiltration parameters from the input of advance data. The design algorithms utilize a standard volume balance procedure.

SIRMOD Calibration. Procedures for calibrating SIRMOD were developed based on available data, including delivery and tailwater hydrographs measured by IID's Irrigation Management and Monitoring Unit (IMMU). The delivery hydrograph is measured at the head gate, and the tailwater hydrograph is measured at the tailwater box at the lower corner of the field. Initially, an attempt was made to calibrate the model based on delivery and tailwater hydrographs for individual irrigation sets; however, upon close inspection of the hydrographs, it was determined that (1) the delay between the arrival of flows at the end of the set and arrival at the tailwater box and (2) overlapping of tailwater hydrographs from multiple irrigation sets limited the ability to calibrate the model based on data from a single set for some fields. To overcome this limitation, an alternative approach for model calibration was developed relying on advance time, tailwater production as a percentage of deliveries, and infiltrated depth determined from the IMMU dataset. Other input parameters used to calibrate the model were estimated from available data. Input parameters used in the calibration process are described in Table 1.

The 34 irrigation events simulated were selected from over 1300 events monitored by IMMU. Events were selected to cover the range of field configurations, cropping, soils, and tailwater production in IID.

Table 1. Input Parameters for SIRMOD Calibration.

Input/Calibration Parameter	Source	Method
Run Length	GIS	Visual Inspection of Aerial Photography
Field Width	GIS	Visual Inspection of Aerial Photography
Main Slope	GIS	Computation from Digital Elevation Model
Irrigation Method	IMMU	IID Staff Observation
Crop	IMMU	IID Staff Observation
Number of Sets	IMMU	Inferred from Tailwater Hydrograph
Furrow Geometry	Grower Consultation and Field Observations	Typical Geometry for Crop and Irrigation Method Simulated
Manning's n	Literature Values and Expert Judgment	Expected Values for Crop and Irrigation Method Simulated, Adjusted as a Calibration Parameter
Irrigation Cutoff Time	IMMU	Inferred from tailwater hydrograph
Infiltrated Depth	IMMU	(Delivered Volume – Tailwater Volume)/ Field Size
Percent Tailwater	IMMU	Tailwater Volume/Delivered Volume
Advance Time	IMMU	Inferred from tailwater hydrograph

Simulation of Irrigation Scheduling and Event Management. Following calibration, parametric SIRMOD runs were completed by varying inflow rates and set times to determine minimum tailwater production while maintaining observed infiltration and while maintaining distribution uniformity as estimated from the model through the calibration process. Thus, "optimized" irrigation events maintained irrigation adequacy.

For SIS, set durations from the original irrigation event were maintained, and the inflow rate was decreased to evaluate potential increases in irrigation performance. For each calibrated event, the inflow rate was reduced until the flow resulting in maximum application efficiency while maintaining the historical observed infiltration was found.

For SEM, the constraint imposed IID's delivery schedule was relaxed. IID regulations allow for growers to end deliveries early, provided that at least 3 hours advance notice is provided for the water to be shut off and backed out of the system. In the future, it is anticipated that growers will utilize available flexibility in shutoff time more often to reduce tailwater production.

Following the parametric model runs, inflow rates and set durations resulting in the least tailwater while maintaining irrigation adequacy were summarized for comparison to the observed event characteristics.

Note that changes to the infiltrated depth were not allowed in the model runs. This constraint results from limited flexibility in when irrigation events occur due to relatively firm irrigation timing resulting from the need for cultural practices. A good example of such constraints is the timing of cutting, drying, and baling for hay crops. Additionally, relatively low infiltration soils,

coupled with relatively high soil and water salinity in IID necessitates adequate infiltration to meet leaching requirements over the course of a crop season, or over a series of years in the case of perennial hay crops.

Estimated increases in irrigation performance represent idealized conditions in which the field is perfectly uniform. Additionally, it is unlikely that a grower could achieve optimum application efficiency across a series of event for a full crop season (or a full year in the case of hay crops). As a result, simulation results predicting a specific increase in application efficiency (translated to a percent decrease in tailwater production) for individual events were reduced based on an estimate of field nonuniformity and uncertainties faced by growers and irrigators in planning and conducting irrigation events.

RESULTS AND DISCUSSION

Selected Irrigation Events. As previously mentioned, a total of 34 irrigation events were selected for the SIRMOD analysis. Of these, 21 border irrigation events were selected and 13 furrow irrigation events were selected. Events were selected to represent a range of conditions affecting surface irrigation hydraulics. Characteristics of each event are summarized in Tables 1 and 2 for border and furrow irrigation, respectively.

Table 1. Border Event Characteristics Used in Calibration.

Field	Crop	Field Length (m)	Field Width (m)	Main Slope (%)	Border Inflow (L/s/m)	Cutoff Time (min)	Infiltrated Depth (cm)	Tailwater Percent	Advance Time (min)	Event Duration (hr)

Calibration Results. The calibration procedure resulted in the soil intake curves displayed in Figures 1 and 2 for furrow and border irrigation events, respectively. Intake was modeled using the modified Kostiakov-Lewis equation to include a term for infiltration due to cracking. Soils at each field were assigned to a general soils class (light, heavy, or heavy cracking) based on the NRCS soil survey as indicated in the legend of each figure.

Figures 1 and 2 indicate that the soils in IID tend to behave like the heavier NRCS soil intake curves. The results for light soils in IID appear to be relatively heavy with respect to intake characteristics when compared to the standard NRCS curves.

The cracking term was utilized in the intake equation when adjustment of the Manning's n value within reasonable limits failed to match the observed advance time. The cracking term is modeled as an instantaneous infiltration as seen in the y-intercepts of the soil intake curves. Cracking was introduced for a majority of the calibrations, which is consistent with field observations and with the relatively high shrink/swell characteristics of Imperial Valley soils.

The range of soil intake curves are highly variable and overlapping. Infiltrated depths for row irrigated events ranged from 2.0 to 5.6 inches (5.1 to 14.2 cm) with an intake opportunity time of 24 hours. Infiltrated depths for border irrigated events ranged from 1.6 to 7.8 inches (4.1 to 19.8 cm) with an intake opportunity time of 12 hours. The NRCS curves used in the calibration (and subsequently refined for each specific event) ranged from heavy clay to sandy loam with the majority falling between silty clay and sandy clay. The representative NRCS intake curves are consistent with the soil textures described in the soil survey of the Imperial Valley.

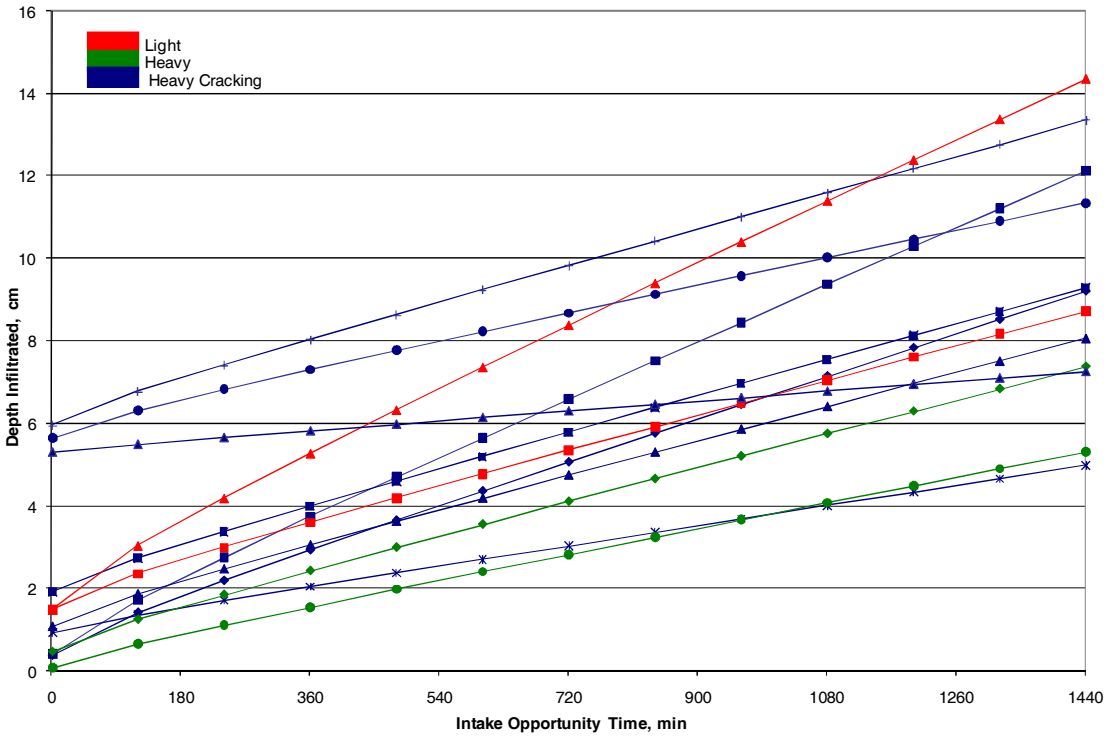

Figure 1. Calibrated Soil Intake Curves for Row Irrigated Events

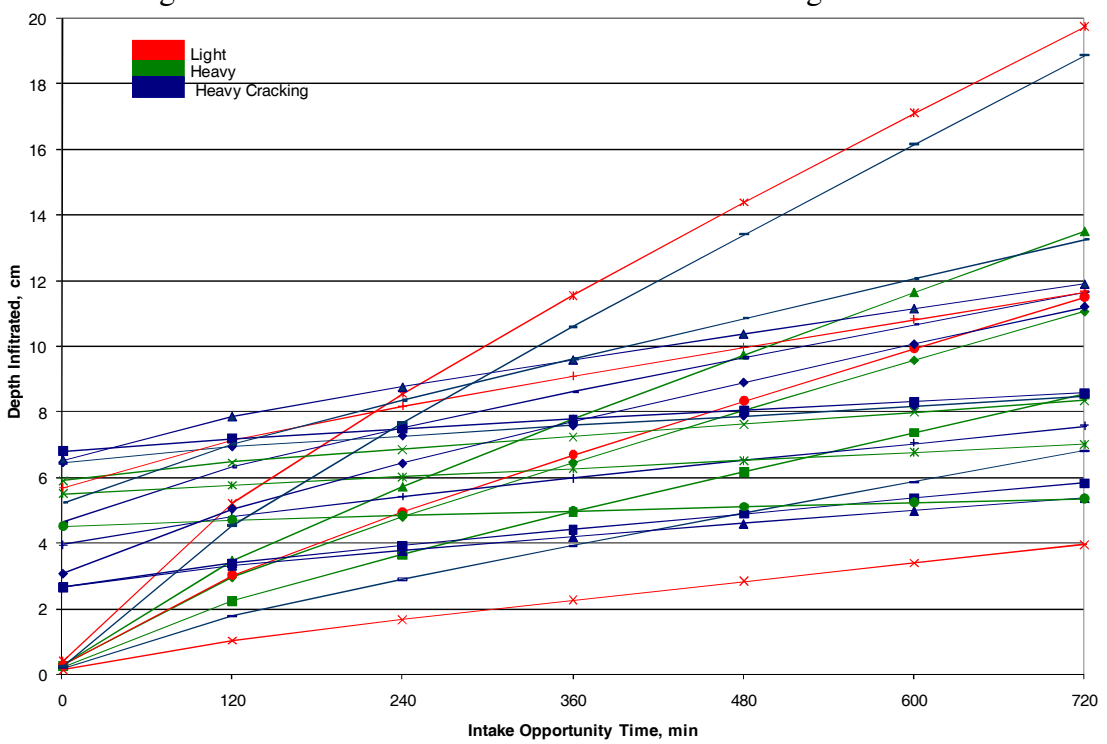

Figure 2. Calibrated Soil Intake Curves for Flat Irrigated Events

Simulation of Irrigation Scheduling and Event Management; Detuning of Model Results. As described previously, Scientific Irrigation Scheduling (SIS) and Scientific Event Management (SEM) are management-based conservation measures that were simulated by selecting flow, duration, and irrigation depth to optimize application efficiency. Optimum application efficiency (AE) was characterized as the maximum application efficiency attainable while meeting the desired total infiltrated depth (e.g., the estimated soil moisture deficit prior to irrigation).

Initially, a series of events was simulated representing SIS only. SIS was simulated by varying the ordered flow for each calibrated event to find the optimal AE while keeping the set duration fixed. Next, SEM was simulated by varying both the inflow and the set duration to find the optimal AE, thus removing the constraint that the delivery fit within the standard IID delivery cycle.

Optimal AE values were detuned to represent practical, attainable values of AE based on an approximation of the impact of uncertainty in soil moisture deficit prior to irrigation on the planning of an irrigation delivery. This uncertainty results from difficulty in quantifying the soil moisture depletion following the previous irrigation event, difficulty in quantifying crop ET since the last irrigation, and uncertainty of the availability of delivery on the requested day (carryovers). Additionally, within-field variability limits the ability to achieve uniformly high application efficiency for each irrigation set and over the course of multiple irrigation events. These uncertainties were represented by reducing the simulated soil moisture deficit by 5% and rerunning SIRMOD with the optimal flow (SIS and SEM) and duration (SEM only) to evaluate the impact on AE. The estimate of a 5% reduction in soil moisture deficit is representative of irrigating approximately one day earlier than the optimal date.

Detailed steps used to simulate optimal and detuned AE values for SIS and SEM are as follows:

1. Assign two soil deficits (z_{req}) that are less than the actual infiltrated depth for the furrow and the border irrigations. This assumes that the grower, on average, achieves more infiltration rather than less than the soil deficit. This assumption is supported by the fact that over time, adequate deep percolation must occur to maintain salt balance in the root zone and sustain production.

   Two depths were selected in order to bracket the estimated depletion prior to irrigation because the soil moisture depletion was not measured for the calibration events. The soil moisture deficits were selected to provide a representative range of application efficiencies for the calibration events. The soil moisture deficits were selected to be consistent with the observed range of estimated seasonal irrigation efficiencies developed as part of the Plan (IID, 2007).

2. Run SIRMOD using the inflow and duration from the calibration event at the two soil moisture deficits. Record the simulated AE, tailwater fraction, and tilewater fraction

(deep percolation as a fraction of delivered water) for each event and soil moisture deficit combination.

3. To simulate SIS, run SIRMOD again, decreasing the flow to maximize AE while limiting the deficit following the event to no more than 3% of the simulated deficit prior to the event. Record the simulated AE, tailwater fraction, and tilewater fraction for each event and soil moisture deficit combination. Thus, for each calibrated event, two optimal AE values under SIS are simulated.

4. To simulate SEM, rerun SIRMOD again, varying flow and duration to maximize AE while limiting the deficit following the event to no more than 3% of the simulated deficit prior to the event. Record the simulated AE, tailwater fraction, and tilewater fraction for each event and soil moisture deficit combination. Thus, for each calibrated event, two optimal AE values under SEM are simulated.

5. Decrease the soil moisture deficit by 5% for each optimized model run and rerun SIRMOD with the optimized flow (SIS and SEM) and duration (SEM only) to estimate the practical optimal application efficiency, tailwater fraction, and tilewater fraction.

Simulated application efficiencies are assumed to be representative of seasonal irrigation efficiency for purposes of evaluating the representative impact of SIS and SEM on on-farm water use. The cumulative distributions of application efficiency for the calibrated events, SIS, SEM, adjusted SIS, and adjusted SEM for furrow irrigated events are provided in Figure 3. Analagous distributions for border irrigated events are provided in Figure 4.

In Figures 3 and 4, application efficiencies for the calibration events ranged from 0.27 to 0.80 with an average of 0.62. For SIS, simulated application efficiencies ranged from approximately 0.48 to 0.89 with a mean of 0.74. Following adjustment, application efficiencies for SIS ranged from 0.53 to 0.85 with a mean of approximately 0.70. For SEM, simulated application efficiencies ranged from approximately 0.62 to 0.89 with a mean of 0.78. Following adjustment, application efficiencies for SEM ranged from 0.59 to 0.86 with a mean of approximately 0.75.

In general, for small soil deficits, and in some cases for soils with a large cracking term, large unit inflows with short set durations maximized application efficiency. The dynamics of these irrigations were such that the large flow was cut off before it reached the end of the field, and surface storage continued to drive advance to the end of the field, producing high uniformity and small quantities of tailwater. For large soil deficits, low flows with long durations maximized application efficiency.

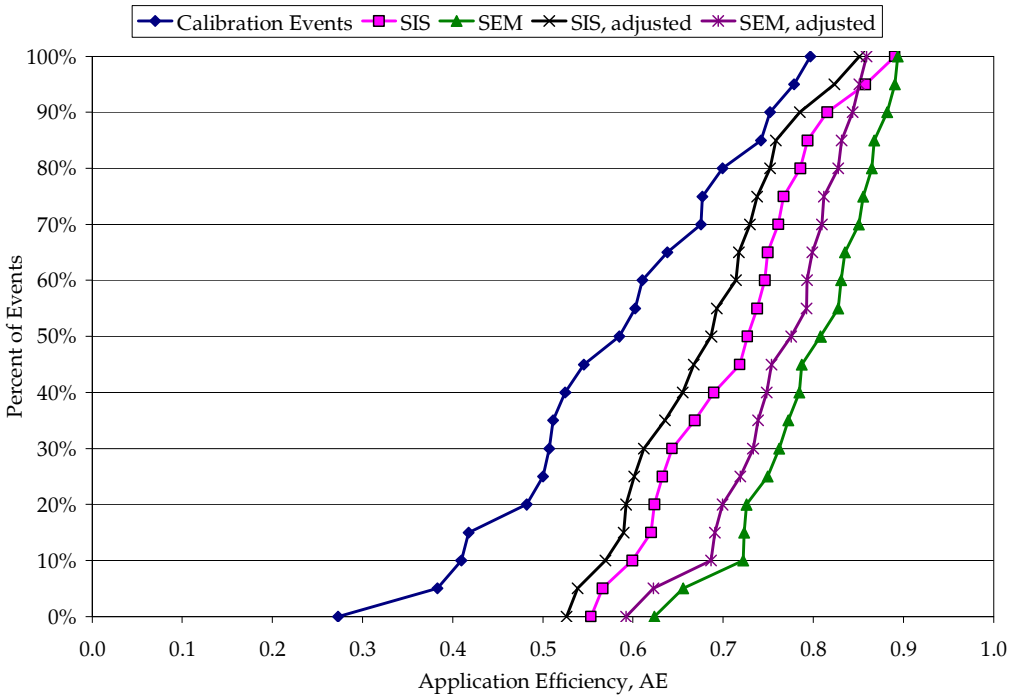

Figure 3. Cumulative Distributions of Application Efficiency for Calibrated Events, SIS, SEM, adjusted SIS, and adjusted SEM: Row Irrigated Events.

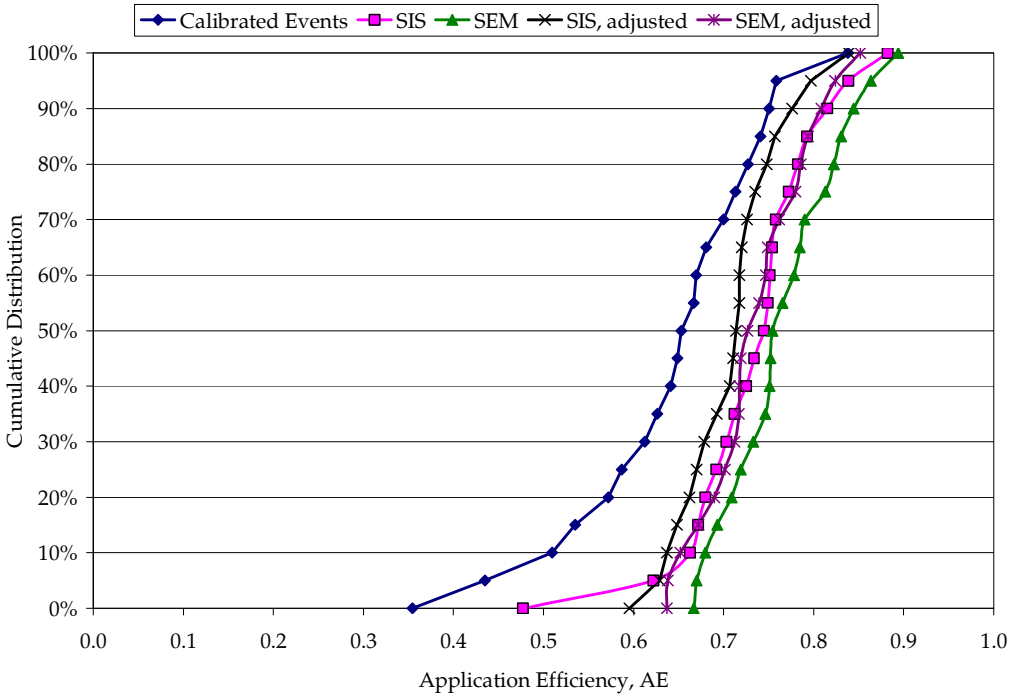

Figure 4. Cumulative Distributions of Application Efficiency for Calibrated Events, SIS, SEM, adjusted SIS, and adjusted SEM: Flat Irrigated Events

CONCLUSIONS

This study demonstrates that SIRMOD provides a useful tool for the evaluation of potential increases in irrigation performance from improved surface irrigation management. Additionally, SIRMOD evaluations of potential performance improvements can be completed with limited input data. Primary data requirements include delivery and tailwater amounts (from which infiltration depth is determined), general information describing field layout, slope, and surface roughness, advance rate, and set duration. SIRMOD could be applied as a management tool to provide near real-time feedback to growers regarding possible opportunities to reduce tailwater production while maintaining irrigation adequacy.

ABSTRACT

Magnetic flow meters are used to measure the flow rate of a liquid in a closed pipeline. This type of meter is becoming increasingly popular for measurement with agriculture applications. Electromagnetic meters were tested by the Irrigation Training and Research Center in pipelines located less than the 10 diameters upstream of disturbances with good results. Results show that location guidelines for placing a magnetic meter can be decreased even for turbulent conditions. This paper will discuss how a magnetic flow meter works, advantages and disadvantages of this type of meter, test results, and new guidelines for field applications.

INTRODUCTION

The accuracy and long-term success of any flow measurement program depends on many factors. Magnetic flow measurement is rapidly becoming the technique of choice in pipelines because of its simplicity and accuracy. However, the application of this technology has been limited in the past because of standard practice guidelines for magnetic flow meters, which have required installing the meters in a straight section of pipe at least 8-10 pipe diameters from any source of turbulence. In addition, standard practice recommends having at least two pipe diameters of straight unobstructed pipe downstream from the meter. However, in the case of many irrigation pumping plants, turnouts, and deliveries, these conditions can rarely be met without extensive and expensive modifications. Therefore, the Irrigation Training and Research Center (ITRC) at Cal Poly State University San Luis Obispo is currently investigating electromagnetic flow meters for potential applications under non-standard conditions.

Several current manufacturers claim that their magnetic meters can perform well even in locations where only two diameter lengths of straight pipe are available. Testing was done by the ITRC on several magnetic meters at the Cal Poly Water Resources Facility to evaluate comments by the manufacturers and to make recommendations to irrigation districts and growers interested in this new technology.

This research was conducted to determine:

- The accuracy of the magnetic meters in locations that are less than optimal
- The sensitivity of meters to increasing amounts of turbulence

Since this research was conducted, there have been numerous field installations of magnetic meters in various irrigation applications in California. The general consensus is that they are working well.

Magnetic Meters

According to Faraday's Law, a voltage will be induced proportional to the velocity of a conductor as it moves at right angles through a magnetic field. The water in the pipe is the conductor. By simply measuring the voltage, a magnetic meter is able to calculate the volume of the liquid passing through a controlled section.

Faraday's Formula: **E** is proportional to **V** x **B** x **D**

E = The voltage generated in a conductor
V = The velocity of the conductor
B = The magnetic field strength
D = The length of the conductor

This principle works for irrigation water passing through the magnetic field generated by the magnetic meter since the water acts as the conductor. The basic operating principle for magnetic meters is illustrated in **Figure 1**. Note that this discussion is limited to full-bore or in-line magnetic meters. There are several other types of meters on the market but this type is the one that was evaluated.

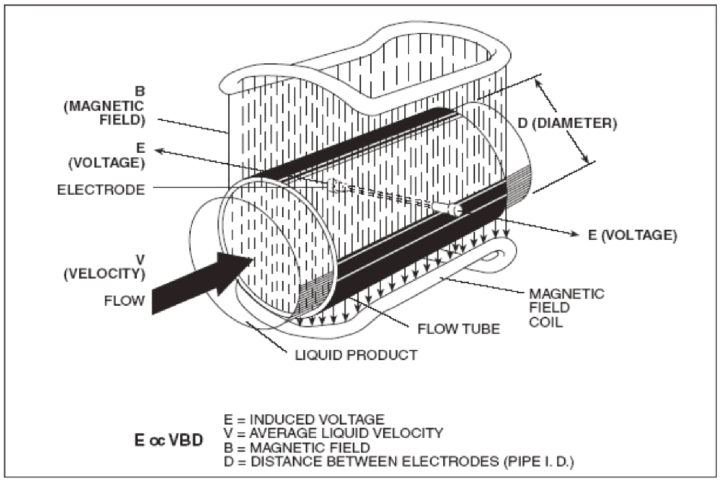

Figure 1. Operating principle for full-bore magnetic meter (Omega 2009)

As seen in **Figure 2**, there are two electrodes located inside the magnetic meter to measure the induced voltage. The flow rate/totalizer indicator is located on the top of the unit. These units can be placed at any angle. It is recommended that they be rotated so that one of the electrodes does not sit on the bottom of the pipe. This helps prevent problems from sediment covering the electrode. Note that on the unit in **Figure 2**, the magnetic field is generated by an insert unit into the pipeline. Some manufacturers install the coils to generate the magnetic field outside of the spool piece.

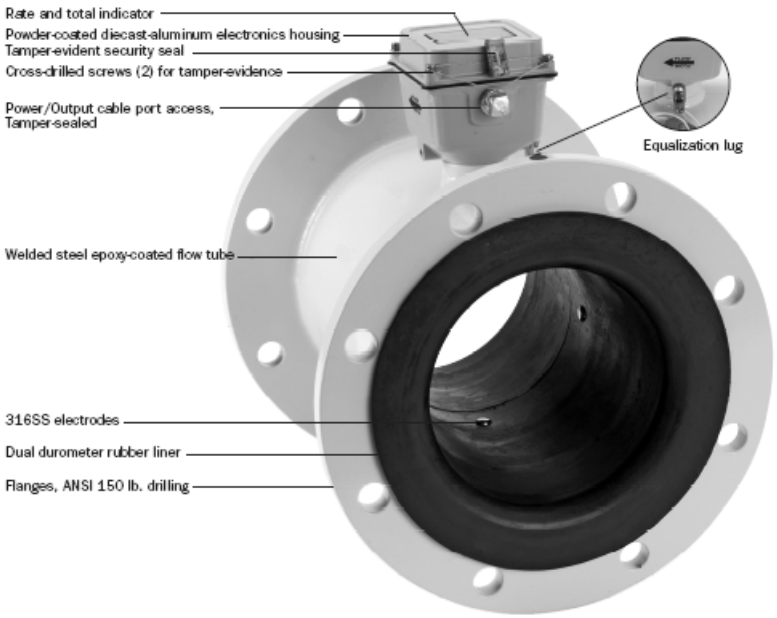

Figure 2. View of typical magnetic meter (SeaMetrics 2009)

Advantages of Magnetic Meters

- Highly accurate even with some flow disturbance.
- No headloss caused by meter.
- Is not impacted by trash, sediment, or sand.
- Can measure a wide range of velocity. This is a key criteria in areas that have seasonal high flows combined with very low flows.
- Has instantaneous and volumetric totalizing capability.
- Measurement accuracy is NOT affected by varying canal water levels.
- Minimal maintenance required.
- Temperature of the liquid has no effect on accuracy.

Disadvantages of Magnetic Meters

- Cost is a major constraint. Recently the cost has dropped dramatically, but this is still the most expensive option in some cases.
- Pipe must be full (as is the case in most agricultural applications).
- Installation into existing sites is often difficult and expensive.
- Sensitivity to turbulence.

Turbulence and Magnetic Meters

Magnetic meters have been considered particularly tricky for pumping plants and turnouts, because of the meter's sensitivity to turbulence. For example, one of the main problems associated with turnouts is the turbulence that occurs just downstream of the gate. **Figure 3** shows a typical turnout application with a magnetic meter.

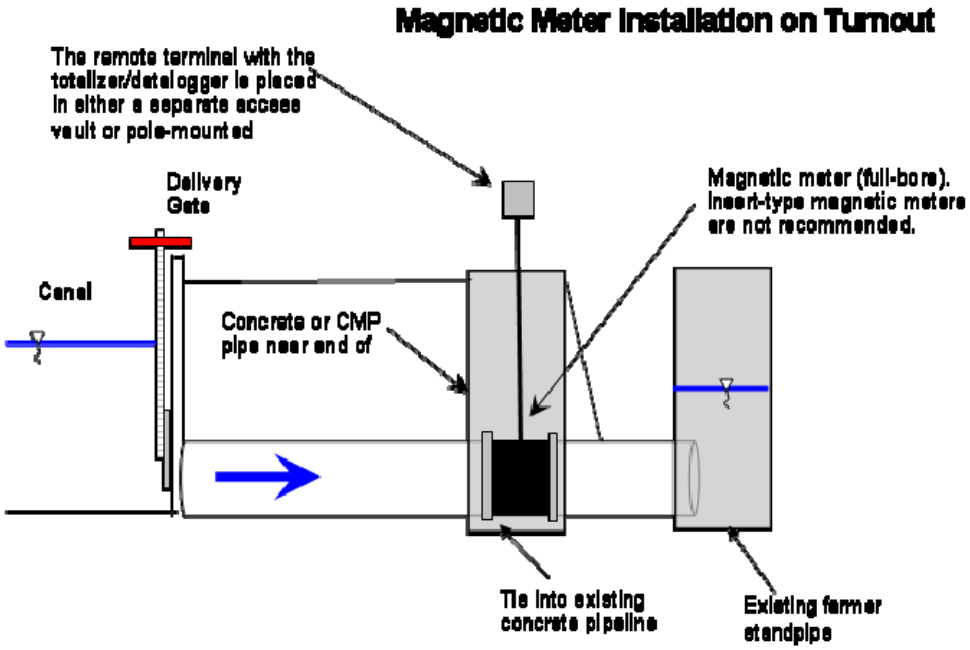

Figure 3. Conceptual sketch of magnetic meter installation for turnouts (not to scale)

In 1998, Hanson and Schwankl published results from non-optimal flow meter testing in their paper *Error Analysis of Flowmeter Measurements*. Pipeline measurements were taken with different types of flow meters to determine the effects on error resulting from different degrees of turbulence caused by elbows, check valves, and a partially opened check valve. Measurements were made at 2, 5, 10, and 15 pipe diameters downstream from the source of turbulence.

The results from Hanson and Schwankl (1998) indicated that for generally acceptable accuracy with propeller meters, pitot meters, and Doppler meters, measurements should be taken upstream of valves. The tests found that in some circumstances even with as little as 2 or 5 pipe diameters upstream of a flow meter, there were still large errors with all meters under conditions of severe turbulence.

Since most applications require the flow measurement downstream of a valve or turnout gate, manufacturers have recently claimed that their magnetic flow meter technology is now able to work effectively in situations where there is as little as two diameters of pipe length available. ITRC tested several magnetic meters at the Cal Poly Water Resources Facility to investigate these claims.

METHODOLOGY

Several manufacturers were tested in this study. The results are included here for one of the manufacturers[1]. Flow rates for the testing were measured with the SeaMetrics AG2000

[1] Reference to any specific product does not imply an endorsement or recommendation of use by the authors. The products names are included for completeness and clarifications in this paper.

Irrigation Magmeter in two different configurations at the Cal Poly Water Resources Facility. Two tests were conducted over a flow range of approximately 0.8 to 115 lps (12 to 1,800 gpm) using a second magnetic meter in optimal flow conditions as the control unit. **Figure 4** depicts the facilities used for testing.

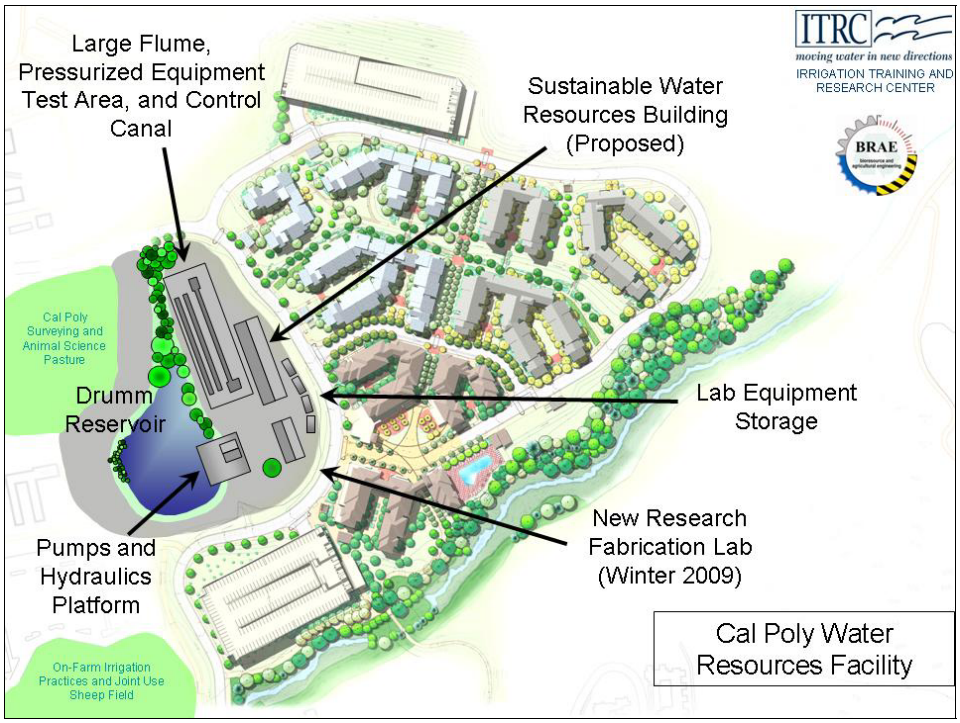

Figure 4. Cal Poly Water Resources Facility

The AG2000 flow meter readings were compared with the control unit to calculate the percent error in this paper as follows:

$$\% \text{ Error} = \frac{\text{AG2000 flow meter - Control unit}}{\text{Control unit}} \times 100$$

The AG2000 flow meter is an electromagnetic flow meter for use in 10 to 30 cm (4 to 12 inch) diameter pipelines. An optional 4-20 mA output module (AO55W) is available for remote monitoring applications with Supervisory Control and Data Acquisition Systems (SCADA) systems. The standard unit is battery powered and optional configurations are available for use with an external power source.

The control units used for the tests were a 10 cm (4 inch) and 30.5 cm (12 inch) McCrometer Ultra Mag flow meter, which had been calibrated using the weighing tank facility at the Water Resources Facility. ITRC did not attempt to verify the true accuracy of the AG2000 flow meter readings, only the percent error from the control units.

A magnetic flow meter was mounted on the Water Resources Facility Pump #2, downstream of a cast-iron concentric reducer, and immediately downstream of a butterfly valve (refer to **Figure 5**), designated as Test #1. The retail cost of this 25.4 cm (10 inch) magnetic meter is

$1,485, which is comparable to a standard propeller meter. This test configuration was designed to represent the "worst possible conditions imaginable" in an actual irrigation application.

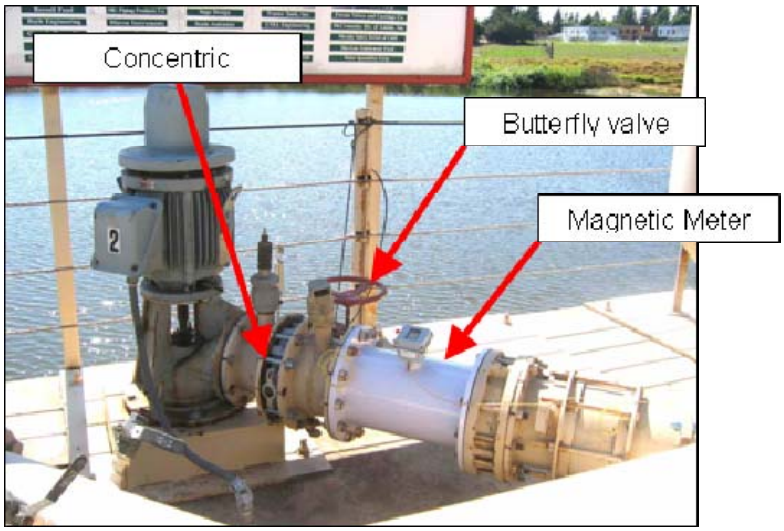

Figure 5. AG2000 test condition for Test #1 (10-inch)

A second AG2000 flow meter was mounted in a straight section of 10 cm (4 inch) pipeline only 20 centimeters (8 inches) downstream from a butterfly valve (equivalent to 2 pipe diameters), designated as Test #2 (see **Figure 6**). The retail cost of this 10 cm (4 inch) magnetic meter is $990, which is comparable to a standard propeller meter.

Once the initial flow rate was established, turbulence was introduced into the pipeline. The butterfly valves were adjusted during the tests from wide open to 75% and 90% closed in Tests #1 and #2, respectively. This testing would represent the worst possible case for irrigation applications.

Figure 6. AG 2000 test configuration for Test #2 (2 dia u/s & 0 dia d/s)

RESULTS

The error analysis of the AG2000 flow meter test results is summarized in **Table 1**. In Test #1, the percent error was less than **+2%** when the butterfly valve was partially closed up to 50%. The percent error was more than -10% when the butterfly valve was closed more than 75%. This increase in percent error may be attributed to the jetting effect of the cast-iron concentric reducer coupled immediately upstream of the butterfly valve.

Errors for this meter increased as the valve was closed and the flow rate was reduced. The AG2000 flow meter had a positive percent error (overestimating the flow rate) compared to the control unit when the butterfly valve was closed 50% or less. When the butterfly valve was closed more than 50% the AG2000 flow meter underestimated the flow rate by approximately 6-12%.

By comparison, the results reported by Hanson and Schwankl (1998) for partially closed butterfly valves with a propeller meter mounted two diameters downstream were ±14% at 42.7 lps (668 gpm), ±15% at 73.7 lps (1,153 gpm), and ±2% for flow rates of 139.9 lps (2,190 gpm). The valve was closed 10 degrees (out of 90 degrees) to provide the throttling effect. Based on the results of their study, it was recommended to always use a six vane straightening arrangement if measuring the flow rate downstream of a throttled butterfly valve.

The test results indicate that the AG2000 Irrigation Magmeter can be installed downstream of partially closed butterfly valves or other sources of turbulence without excessively degrading accuracy.

Table 1. AG2000 Test Results at Cal Poly ITRC Water Resources Facility

Test #	Valve Position	Ultra Mag Flow Rate (lps)	Ultra Mag Flow Rate (gpm)	AG2000 Flow Rate (lps)	AG2000 Flow Rate (gpm)	Error (%)
Test #1 25.4 cm (10") meter	Open	114.4	1,791	116.0	1,816	+1.4
	50% closed	102.1	1,597	102.4	1,603	+0.4
	60% closed	90.4	1,414	88.4	1,383	-2.2
	70% closed	81.2	1,271	72.8	1,140	-6.3
	75% closed	63.4	992	55.5	868	-12.5
Test #2 10 cm (4") meter	Open	25.6	401	25.6	401	0.0
	50% closed	21.6	338	21.6	338	0.0
	70% closed	7.9	124	7.9	123	-0.8
	80% closed	2.0	31	2.0	31	0.0
	≈ 90 % closed	0.8	12	0.8	12	0.0

In Test #2, the 10 cm (4 inch) AG2000 flow meter had a percent error of less than 1% even when the butterfly valve was 90% closed. Discrepancies were the same for conditions where the butterfly valve was wide open and when it was closed 80-90%. These results suggest that turbulence from a partially closed butterfly valve located two pipe diameters upstream had a negligible effect on the precision of the magnetic meter as compared to the control unit.

In summary, the test results indicated that under conditions of severe turbulence due to a partially closed butterfly valve, the 10 cm (4 inch) AG2000 flow meter readings were not adversely affected. For the 24.4 cm (10 inch) AG2000 flow meter, a partially closed butterfly valve coupled with a pump discharge caused errors of 1-2% up to 50% valve closure. The recorded percent error was generally reduced at the higher flow rates.

CONCLUSION

The test results indicate that the magnetic meter tested can be installed downstream of partially closed butterfly valves or other sources of turbulence without excessively degrading accuracy. Additionally, the magnetic meter is able to provide accurate readings to within ±2%, which is well within the limits expected for agricultural delivery. The costs of these units have also decreased to the point where they are competitive with traditional devices that cannot handle the turbulence associated with some irrigation applications.

ABSTRACT

A surface irrigation evaluation process in an irrigation project requires expensive field work. Models that reproduce irrigation events help to analyse the data obtained, and evaluate different scenarios of improvement. The use of combined models that reproduce the interaction between irrigation water and the conveyance and drainage network, agricultural production, and the environment can increase the productivity of the field work. Their results surpass the analyses based only on application efficiency, and provide a wide range of irrigation, hydrological and economic indicators. The application of one of these models (Ador-Simulation) in a study area of the Bear River irrigation project (UT) showed that an increase in irrigation efficiency from 56 to 77 % can be achieved optimizing current irrigation time. This results in a 27 % of water saving over the 2008 demand, and in a little increase in current low economic productivities.

INTRODUCTION

Irrigation is facing a time of changes. Some of the reasons behind these changes are the liberalization of trade in world agricultural commodity markets, the reductions in agricultural subsidies, the environmental restrictions, and the water scarcity in many areas of the world. Improving water management is a key factor for optimizing the use of this natural resource and achieving economic, social and environmental sustainability in the agricultural sector. Its application is user appreciated and cost effective, since its economic return (conserved water/investment) is often orders of magnitude larger than that obtained from improving the structures (Playán and Mateos, 2006).

Benchmarking is an important tool for improving water management in irrigation projects. It is a systematic process for securing continual improvement through comparison with relevant and achievable goals, norms, and standards (Malano and Burton, 2001). The rapid appraisal process (RAP) is a key part of benchmarking that allows for quickly determining key indicators of irrigation projects (Burt and Styles, 1999; Burt and Styles, 2004).

A more detailed diagnosis can be obtained through an irrigation evaluation process. This methodology combines field work and computer simulation. The data obtained in on-farm irrigation evaluations are used for applying simulation models. These models allow the assessment of the current irrigation performance, and identification of the main factor for improving water management. The models applied in this process have evolved from single on-farm irrigation simulation models (Playán et al., 2000; Dechmi et al., 2003; Lecina et al., 2005) to complex models that combine a number of integrated modules which permit us to simulate water flows in an irrigation district (Lecina and Playán, 2006a). This last kind of software has been designed to extend the insight on irrigation district performance gained through the process of irrigation evaluation.

In this paper we evaluate a surface irrigation area in the Bear River Basin (Utah) using the model Ador-Simulation. This model reproduces the interaction between irrigation water and the conveyance and drainage network, agricultural production, and the environment. It is composed of five simulation modules covering on-farm irrigation, crop growth, hydrosaline balance, water flow, and decision making in water allocation to farmers. Since the previous models and decision support systems do not include the simulation of the on-farm irrigation system (Merkley, 1994, Yamashita and Walker, 1994, Prajamwong et al. 1997, Mateos et al., 2002), Ador-Simulation presents the unique feature of analysing the interaction between on-farm and district irrigation management. A detailed description of this model can be found in Lecina and Playán (2006b).

The objective of this study is to show the capabilities of using such models, to improve water management by farmers and by Irrigation Districts/Companies water managers both on-farm and at irrigation project levels, and to support water resources decision making at basin level. This improvement takes into account the preference of the farmers of the study area to maintain current structures.

THE STUDY AREA

The study area is located close to the town of Tremonton, North Utah (Figure 1). The total irrigated area is 1,213 ha, all of them surface irrigated, and included in the Bear River irrigation project, that irrigates a total of 26.856 ha. This project was developed by a sugar beet company at the beginning of the twentieth century, and is currently managed by the Bear River Canal Co. (BRCC).

The climate is continental (the mean temperature is 10 ºC), with a large temperature difference between winter and summer. The mean annual precipitation is 441 mm (82 mm in summer).

According to the soil maps of the Natural Resources Conservation Service (NRCS), two main soil units can be distinguished in the study area, located in the terraces of the Malad river (Figure 1). The first unit correspond to Parleys soils (PdA). These

soils are deep, stone-free, and have a loam texture with no salinity problems. This unit occupies 530 ha in the study area. The second unit covers the remaining area and corresponds to Fielding soils (Fd), with similar characteristics, but with a silt-loam texture.

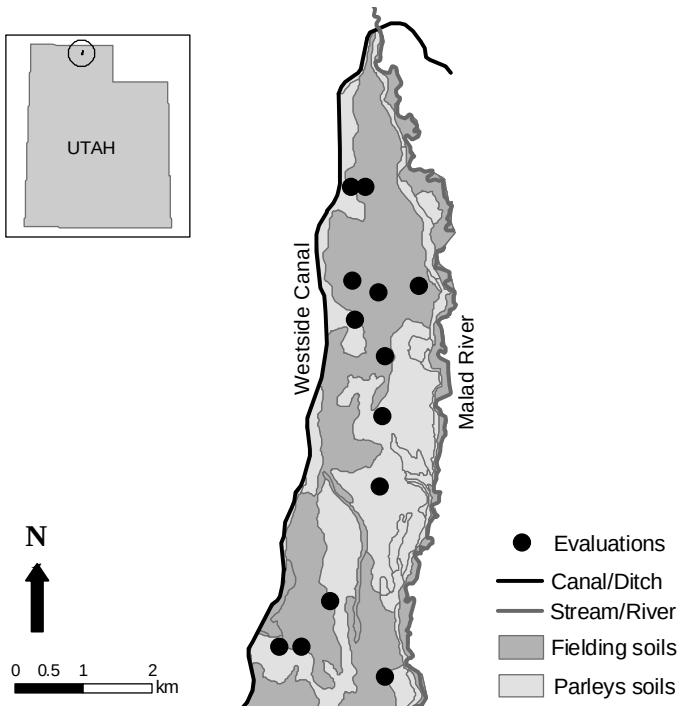

Figure 1. Location of the study area and irrigation evaluations. The background soil map has been adapted from NRCS.

A total of 79 land owners compose the study area, owning a total of 130 plots, according to the 2008 management database of the BRCC. The on-farm irrigation systems are, almost exclusively, blocked-end borders. Alfalfa (35 %) and corn (32 %) are predominant, and grass (11 %) and winter/spring grains (21 %) are also present in the cropping pattern of the area. Only 1 % of the irrigated is not cropped. The main destination of agricultural production is the livestock industry in the region.

Water conveyance structures consists of a network of unlined ditches which, starting at 24 headgates at the Westside canal, deliver water to the plots. Each headgate delivers the same discharge to all the plots within its irrigated command area. Irrigation return flows are collected and conveyed through buried drainage collectors that discharge into the Malad River, the natural drainage system of the area, and flow into the Great Salt Lake 25 km downstream.

Water deliveries is performed by the ditch riders of the BRCC. A rotation system is used applied with a daily irrigation period of 24 h. According to the classification system proposed by Clemmens (1987) for water delivery systems, the system is negotiated arranged, with fixed discharge. A fixed pricing structure (a specified fee per acre) is applied for water and services billing.

MATERIAL AND METHODS

On-farm irrigation evaluation

The purposes of the irrigation evaluations were to determine on-farm irrigation performance and to characterize soil infiltration. During 2008 a total of 13 irrigation evaluations were performed within the study area adopting the methodology proposed by Merriam and Keller (1978). Five of them were performed in the Parleys soils, and eigth evaluations were performed in the Fielding soils (Figure 1).

Borders were selected which were rectangular in shape. During the irrigation evaluation the farmer performed the normal irrigation practices. A measuring tape was used to determine the border dimensions. The slope and the standard deviation of soil surface elevation were determined from soil surface elevation measurements performed every 10-30 m along the border using a topographic level. Both parameters resulted from regression of elevation vs. distance along the border.

The inflow irrigation discharge was measured using a mini-propeller meter. The advance phase was determined from recordings of the advance time to reference points located along the border every 10-30 m. The flow depth at the upstream end of the border was measured shortly before cut off. A number of flow depth measurements were performed across the border, every 3-4 m. The average of all measurements was used to represent flow depth at this point and time.

Infiltration and roughness were determined from advance and flow depth using SIRMOD, a hydrodynamic one-dimensional surface irrigation model (Walker, 1993). Such a model was iteratively executed using tentative values of the coefficient k and the exponent a from the Kostiakov infiltration equation, and Manning n. The three parameters were adjusted until the model satisfactorily reproduced the experimental values of flow depth and irrigation advance for each evaluation.

The total available water (TAW, mm) (Allen et al, 1998) was determined by a soil survey carried out in the same field where the irrigation was evaluated. A soil sample was obtained in two holes in each plot for the top 0.15 m, and each subsequent 0.30 m until a depth of 1.20 m was reached. Field capacity, wilting point, and moisture content just before irrigation were determined (Soil Survey Division Staff, 1993). Bulk density was also determined at 0.20 m depth. The target irrigation depth (Zr) was determined as 50 % of TAW (Allen et al, 1998).

The next step was to determine the irrigation performance indices (Burt et al. 1997). These indices included the application efficiency (Ea) and the low-quarter distribution uniformity (DUlq). Ea expresses the percentage of irrigation water contributing to Zr. DUlq can be defined as the percentage of the average low-quarter infiltrated depth to the average infiltrated depth.

Model application

The basic data for the simulations were obtained from field work, the BRCC offices, and NRCS soil maps. Such data included on-farm irrigation water management, land tenure, morphology of the irrigation systems, water conveyance structures, crops and soil survey. Simulations were performed for the 2008 irrigation season on a daily basis (hourly for water delivery). The weather this growing season was slightly warmer and drier than the average.

In the Ador-Simulation model, the plot is the basic geographical unit. A typical irrigation unit (a border in this case) is characterized for each plot. Irrigation simulation is performed in the typical irrigation unit and extended to the whole plot area. In a large irrigation district it would be unmanageable to identify, characterize and simulate all borders in all cadastral plots. Therefore, a typical border was defined as characteristic of the irrigated area for each headgate (measured at the cartographical restitution of an aerial photograph, and taking into account the slopes determined in the on-farm evaluations). One of the two soil units of the study area was assigned to each plot according to the soil maps.

The initial soil water depletion at the onset of the simulation period was estimated from the meteorological conditions prevailing during the weeks preceding sowing. Depletion was established as a percent of TAW. The sowing date for each crop was statistically assigned, following the statistical distribution derived from farmers' interviews.

Each plot was related to a water conveyance network element (an irrigation ditch), and to the drainage network. In the case of the irrigation network, each element was characterized by a service and a conveyance discharge, which were obtained from the BRCC.

Crop growth and irrigation simulations were performed on the typical border of each plot. An irrigation was requested when 25 % of the border area was under water deficit (soil water depletion above allowable depletion). The duration of the phenological phases and the crop coefficients, the values of the thermal integral and the related temperature threshold, were derived from local experiences (Hill, 1994). The FAO methodology (Allen et al., 1998) was applied for computing the crop water requirements. The weather data was obtained from a weather station of the Utah State University Extension Service located in Tremonton. The Stewart coefficients for the determination of water stress sensitivity were obtained from the work by Doorembos and Kassam (1979). The common irrigation practices were gathered from farmers and BRCC manager interviews, and used to establish the relationship between agronomy and irrigation: pre-sowing irrigation, irrigation events following alfalfa and forage harvest. Yields, the economic value of crops, and costs were obtained from Government statistics.

The simulation of the current water performance was based on the cutoff time determined in the irrigation evaluations. In all evaluations, the cutoff time was longer than required to refill the soil water deficit. A simulation was performed in the typical border defined as characteristic of the irrigated area of each headgate to determine the optimum cutoff time. This optimum can be defined as the minimum cutoff time necessary in order to ensure that the average low-quarter infiltrated depth in the border attained at least Zr. The irrigation evaluations were equally optimized, and the ratio of real to optimum irrigation time was obtained for each soil type. This ratio was used to estimate the "real" irrigation time for each headgate under the current water management practices.

Two simulations of the water flows in the whole study area were carried out. The first simulated a representative **scenario of the current conditions** of on-farm irrigation practices in 2008. The second simulated the water flows for a **scenario of optimum irrigation time**. A number of irrigation quality, hydrological and

economic indicators were computed from the obtained results (Burt et al., 2007; Molden et al., 1998; Willardson et al., 1994).

RESULTS AND DISCUSSION

On-farm irrigation evaluation

Table 1 presents the aggregated results of the irrigation evaluations, distinguishing the two soil units. The evaluated crops were alfalfa and spring grains. The border size averaged about one and a half hectares, with a moderate variability. Borders are larger in Parleys soils than in Fielding soils. The field slope has a wide range of variation. On average, the slope was similar in both soil units (about 1.61 ‰). The standard deviation of soil surface elevation ranged between 10 and 22 mm, with an average value of 15 mm. These values indicate that laser levelling is often practiced in the study area.

Table 1. Results of the irrigation evaluations performed in the study area.

		Parleys soils	Fielding soils
Area (m^2)	Average	12,589	17,569
	CV (%)	47	21
Width (m)	Average	37	49
	CV (%)	17	20
Slope ($^0/_{00}$)	Average	1.89	1.48
	CV (%)	31	58
Standard deviation of soil	Average	13	16
surface elevation (mm)	CV (%)	38	22
Discharge (m3 s^{-1})	Average	0.091	0.091
	CV (%)	53	14
Irrigation time (h ha^{-1})	Average	5.70	7.18
	CV (%)	49	22
Irrigation depth (mm)	Average	144	230
	CV (%)	22	19
Manning *n*	Average	0.18	0.23
	CV (%)	20	13
Kostiakov *k* (m min^{-1})	Average	0.0145	0.0173
	CV (%)	15	18
Kostiakov *a*	Average	0.318	0.376
	CV (%)	4	5
Total Available Water (mm)	Average	204	228
	CV (%)	6	4
Application Efficiency (%)	Average	65	51
	CV (%)	18	18
Low Quarter Distribution	Average	66	74
Uniformity (%)	CV (%)	18	13

The irrigation discharges present a large variability –between 50 and 120 l s^{-1}- among irrigation ditches. Discharges were similar in both soil units, with an average of 91 l s^{-1}. The irrigation times, although largely variable as a function of the irrigation discharge, were long: about six hours per hectare in Parleys soils and seven hours per hectare in Fielding soils.

The irrigation application depth was generally high, with an average of 144 mm in Parleys soils, and 230 mm in Fielding soils. These irrigation depths were due to the available discharges, and to the irrigation scheduling influenced by soil physical characteristics and the presence of a water table. The TAW was high and uniform, with an average of 204 and 228 mm for Parleys and Fielding soils respectively. The seepage from the Westside canal resulted in the presence of a water table at a depth of about 1.30 and 1.50 m according to a piezometer network available in the area. The soil moisture of the vadose zone was used by crops for evapotranspiration, and constitutes a second source of water for this purpose. This effect was checked by the soil moisture determinations carried out just before the irrigation events. In an irrigation interval of about four weeks, the soil water depletion was about 55 % of the crop evapotranspiration.

Figure 2 presents the infiltration functions derived from the irrigation evaluations. The graphical representation has been grouped by soil unit. Based on these infiltration characteristics, two infiltration functions were derived and later applied to the simulation of irrigation in the study area. Infiltration in Fielding soils is larger than in Parleys soils. However, the geometry, slope, and discharge of the borders suggest that farmers have not taken soil infiltration rate differences into consideration. The main reason for that is the high spatial variability of the distribution of the soil units in the study area (Figure 1). Only in 9 of the 24 headgates contain a predominant soil unit occupying 85 % or more of the irrigated area.

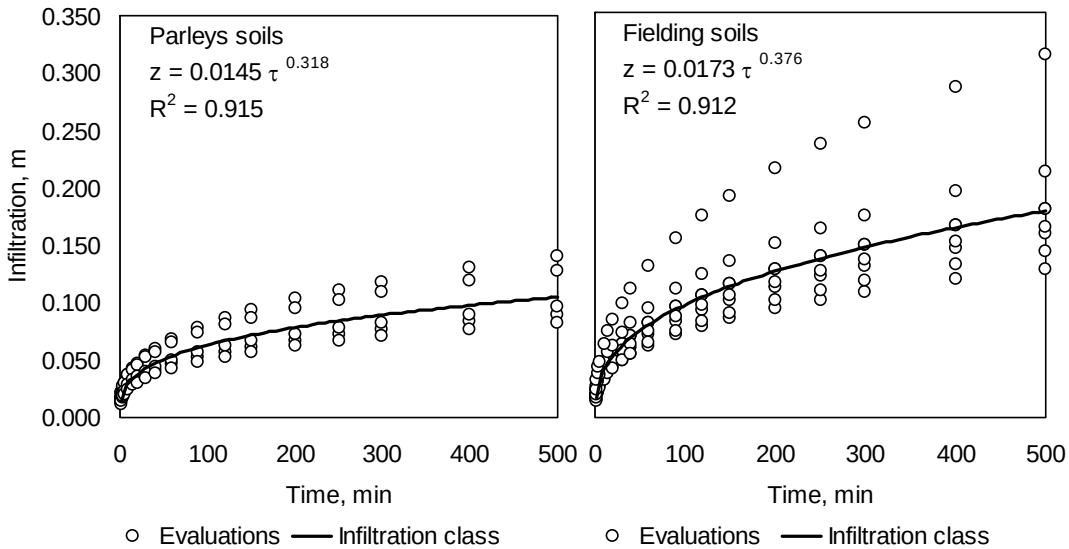

Figure 2. Infiltration functions corresponding to borders in Parleys and Fielding soils. The figures present results from the irrigation evaluations (symbols) and average infiltration curves (lines) and corresponding equations.

Application efficiency reached 65 % in Parleys soils, with uniform frequencies in a range of 54 to 87 %. In Fielding soils, the average application efficiency was 51 %, ranging from 35 to 63 %. These values of Ea can be classified as low, and the potential improvement for current irrigation pratices will be shown below.

The minimum DUlq was 55 %. In the Parleys soils the average uniformity was 66 %, while the average value for Fielding soils was 74 %. The accumulation of water at the end of the blocked-end borders is the main reason for these low values.

Model application

The first step was to optimize the cutoff time of the irrigation evaluations. The results showed that it is possible to reduce the irrigation time to an average of 5.2 h ha^{-1} ensuring that the average low-quarter infiltrated depth in the border attains at least Zr. This reduction allows for the increase of the application efficiencies to 72 % in Parleys soils, and 67 % in Fielding soils, with irrigation depths of 0.140 and 0.170 mm respectively.

The simulation of water flows in the whole study area for the **scenario of current conditions** of on-farm irrigation practices in 2008 considered the irrigation times determined in the evaluations. A number of parameters related to irrigation scheduling, conveyance network water losses, and evapotranspiration from the vadose zone were also considered in the simulation of the whole study area.

Irrigation scheduling parameters were the minimum interval between irrigations, and the maximum number of irrigations per crop. These parameters were provided by farmers and BRCC managers. Corn is irrigated between four and five times per season, with a minimum average interval of 14 days. Alfalfa and grass present the same number of irrigations but with an interval of about 28 days. Grains are irrigated three times per season in a minimum average interval of 21 days.

A previous study carried out by the BRCC determined that the average seepage and spills water losses in the conveyance network are about 10 % of the total water delivered from headgates.

A layer with constant moisture (field capacity) was considered in the model for reproducing the effect of the water table over the crop evapotranspiration. The depth of this layer was estimated at 0.70 m -over a root zone of 1.20 m- for obtaining similar water depletions just before irrigation to the depletions determined in the irrigation evaluations carried out during July and August.

Figure 3 shows the monthly water demand of the study area provided by the BRCC, and the demand simulated with the model. On a cumulative basis, the simulation results compare well with the BRCC data, with a seasonal difference of 3 %. On a monthly basis, during the peak of the season the differences vary between 2 and 10 %. In spring and autumn the differences are highly variable, reaching values between 8 and 35 %. These differences can be attributed to the agronomic practices of the farmers, which are difficult to establish and model. Additionally, soil infiltration during the first irrigation of the season is usually very large. Initial soil water content, temporal distribution of conveyance network water losses and water table depth oscillation are other factors which influence these monthly differences.

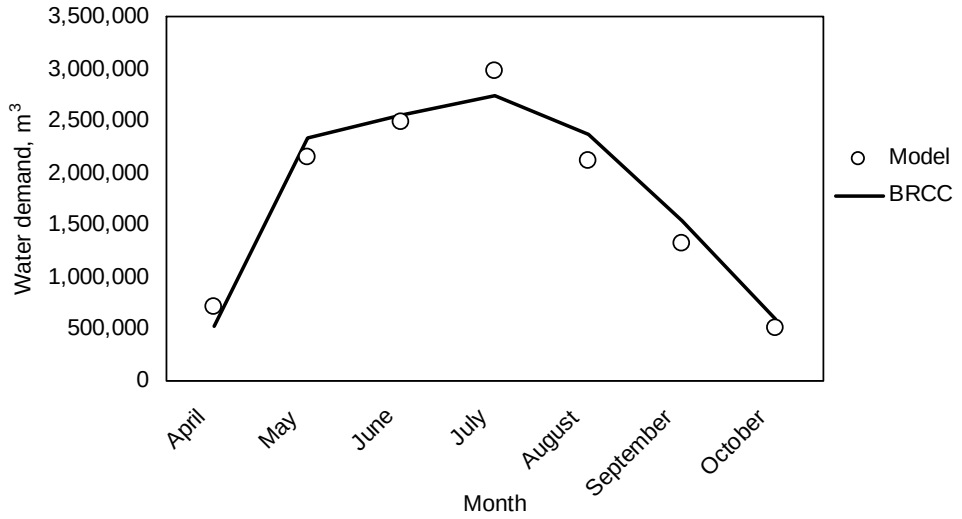

Figure 3. Water demands as registered by BRCC and simulated by Ador-Simulation in the study area.

The simulation of water flows in the whole study area for the **scenario of optimum irrigation practices** considered the optimized irrigation times determined for the evaluated irrigation events. The same values of irrigation intervals, percentage of conveyance network water losses and depth of the constant soil moisture layer were considered.

Table 2 shows the values of different indicators for the two simulated scenarios. The optimization of the cutoff time increase efficiencies about 20 %, to an average of 75 %, and DUlq from 62 to 75 %. The high TAW of the soils, the initial soil water content, and the vadose zone are the main factors that explain the reduced differences between application and irrigation efficiencies.

Improving on-farm irrigation practices would allow the reduction of water demand by 27 %, equivalent to a volume of 3,3 hm^3. The reduction could be higher if improvements in water delivery management are achieved, but this study did not have enough data for this estimation. This volume not only represents a water conservation, but also, a water saving due to the diminished irrigation returns flow to the nearby Great Salt Lake where this water can not be reused. For this reason, the consumptive fraction of the water demand is 100 %. The productive (crop evapotranspiration) consumptive fraction is increased from 60 to 77 % due to the reduction of return flows, and a minimal increase of the crop evapotransporation. The vadose zone contributes to this evapotranspiration with an estimated volume of 1,8 hm^3.

The difference between real and potential crop evapotranspiration is about 9 % in both scenarios, similar to other irrigation projects in the USA (Allen et al., 2005). This difference is mainly due to the effect of low DUlq, the optimization of cutoff time until the Zr is reached in the average low-quarter infiltrated depth in the borders, and the irrigation intervals applied. Although the capacity of the conveyance network allows for increasing the number of irrigation events with the irrigation times

adopted, the impact over crop evapotranspiration and yields are minimum, about 2 % (results not shown).

Table 2. Summary of simulation results obtained through the application of Ador-Simulation to the current scenario of the study area and an optimized scenario.

	Current Scenario	Optimized Scenario
IRRIGATION INDICATORS		
Irrigation time, h ha^{-1}	6.8	4.6
Average Application Efficiency, %	53	74
Average Irrigation Efficiency, %	56	77
Average LQ Distribution Uniformity, %	62	75
HIDROLOGICAL INDICATORS		
Canal Water Demand, hm^3	12.27	8.96
Precipitation, hm^3	1.25	1.25
Water Use from Vadose Zone	1.88	1.78
Crop Evapotranspiration, hm^3	9.55	9.59
Irrigation and Rain Return Flows, hm^3	6.25	2.90
Seasonal Soil Water Variation	-0.40	-0.51
Consumptive Fraction, %	100	100
Productive Consumptive Fraction, %	60	77
Crop Evapotranspiration Reduction, %	9	9
ECONOMIC INDICATORS		
Crop Yield Reduction, %	14	12
Crop Gross Value Reduction, %	12	10
Crop Gross Value, M$	1.488	1.516
Crop Net Value, M$	0.504	0.532
Gross Surface Productivity, $ ha^{-1}	1226	1249
Net Surface Productivity, $ ha^{-1}	416	439
Gross Consumptive Water Productivity, $ m^{-3}	0.092	0.117
Net Consumptive Water Productivity, $ m^{-3}	0.031	0.041

The crop evapotranspiration reductions imply a yield reduction of about 14 % in the current scenario, and 12 % in the optimized scenario, and consequently, a reduction in the gross crop production value of 12 and 10 % respectively. Due to these small differences between scenarios, and the low value of these field crops, the economic incentives for adopting a more careful control over irrigation time are negligible for the farmers. The net surface productivity is only increased by 23 $ ha^{-1}. Similar effects occur over low consumptive water productivities, whose value is lower than the average of US (Clemmens et al, 2008).

Nevertheless, the water saving obtained from improving on-farm irrigation practices can increase the water availability in drought years, and this fact can constitute a true incentive for farmers. In order to achieve the results shown in the Table 3 for the scenario of optimum irrigation practices, the farmers should apply the findings obtained in this study about irrigation time. For this purpose, a number of graphics like the one shown in Figure 4 were developed. These figures indicate the irrigation

time that optimizes the application efficiency considering different unitary discharge and slopes, and a Zr equivalent to 50 % of TAW. As Burt and Styles (2000) pointed out, technical assistance to farmers and districts/companies is a key factor form improving water management.

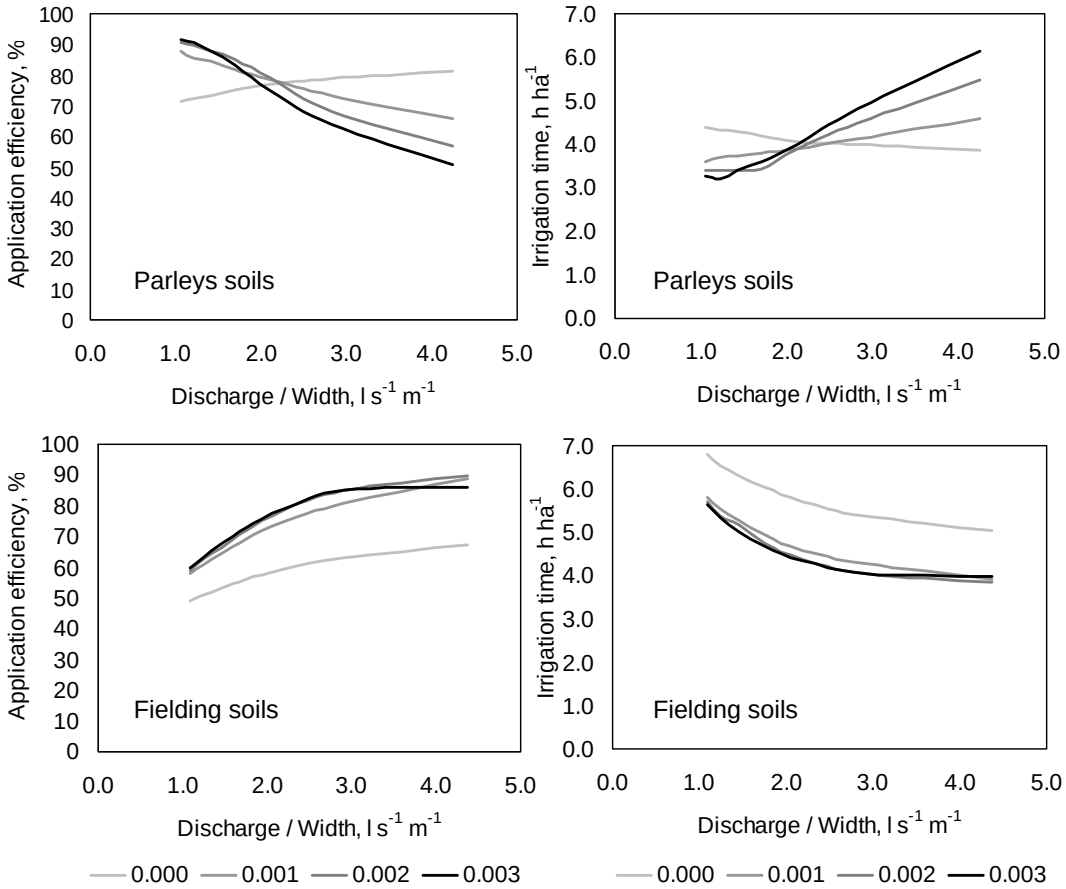

Figure 4. Application efficiencies for optimized irrigation times with a discharge of 85 l s^{-1} and different widths and slopes (m/m) in Parleys soils (with Zr of 102 mm) and Fielding soils (with Zr of 114 mm).

CONCLUSIONS

The productivity of irrigation evaluation field work processes can be notably increased by the use of combined models like Ador-Simulation. These models surpass the analyses based only on application efficiency, and provide a wide range of irrigation, hydrological and economic indicators.

The results can be useful for farmers and irrigation projects managers in order to improve on-farm irrigation practices, water delivery, and structures. River Basin Authorities managers can analyse potential water conservation and/or water saving in the agricultural water uses of the basin, and the economic and water security effects on farmers.

The application of this methodology to the study area in the Bear River irrigation project has shown that optimizing irrigation time can provide a potential of water

saving of about 27 % over the 2008 water demand. Although the effects of this improvement on the economic value of crop production and productivities are low, the water conserved could be important for reducing economic losses during drought years as the Bear River Canal Company could store some of that water in Bear Lake, upstream. The simulation can be easily applied to other years if managerial data are available, for example from RAPs, and using the data obtained from the field work performed in 2008.

ACKNOWLEDGEMENT

Thanks are due to the managers and farmers of the Bear River Canal Co., and technicians of the Utah State University Extension Service for their support. The postdoctoral contract of S. Lecina was funded by the Spanish Ministry of Science and Innovation and the Spanish Foundation for Science and Technology.

ABSTRACT

A channel through a neighborhood in Jefferson County, Kentucky was eroding and accumulating complaints of property damage and flooding. The channel, carrying an intermittent stream, had been filled by the developer of this neighborhood to be a grass channel flowing through the backyards. Development upstream increased the flows through this area and caused erosion of the grass channel. Efforts to armor the channel with gabion baskets and rip rap, and in some cases landscape timbers did not stem the tide of damage.

The length of channel being evaluated was approximately 1,800 feet. A solution for the entire length under review was desired. Armoring the banks with boulders was the preferred method to stabilize the stream banks. The SCS TR-55 program was utilized to calculate flows to size the proposed channel. The channel width was chosen to allow the channel to achieve bank full depth. The bank full depth was determined by field observation of sections of the entire length of the existing stream. The proposed channel alignment was arranged to closely resemble the existing and to minimize disruption to existing utilities as well as uses by the adjacent property owners.

Methodology of the hydraulic analysis and design of the stream bank armoring is discussed herein as a low tech solution for urban and suburban stream projects. Armoring the stream banks provided the protection needed while defining the stream and allowing movement of runoff through the project area without using a concrete channel. The use of boulders along the banks created a more "natural" channel appearance and satisfied the client (MSD) as well as the adjacent property owners.

BACKGROUND

In the late 1980's, the Saratoga Hills subdivision near Louisville Kentucky was developed. As a part of this development, a rock bottom intermittent stream was transformed into a grass swale. The grass swale made the backyards picture perfect for the new subdivision. In the years following this transformation, development upstream encouraged the retrenchment of the stream toward it original state. In 1997, a regional

flood event removed the remnants of the grass swale exposing the original rock bottom stream. What was a grass swale that neighbors could walk across turned into a stream spanning from inches to more than 20 feet in width. The transformation back to a natural system was causing soil erosion and property loss, including the exposure of several gravity sewer lines that were constructed parallel to the channel. The change was also threatening the adjacent homes with flooding along an 1,800 foot section of the stream. The problem impacted approximately 50 homes.

The local regulatory sewer and drainage authority, Louisville and Jefferson County Metropolitan Sewer District (MSD) started working with the Saratoga Hills Neighborhood Association in an effort to remediate the property loss and flooding concerns. In an effort to reduce or slow down erosion along the channel, remedial measures were installed. Rip rap, gabion baskets and property owner-installed landscape timbers slowed the inevitable erosion advance. Workshops were held to educate the neighborhood on green infrastructure solutions. Weekend native planting events were scheduled with material donated by MSD. These events continued the education of the neighborhood and get participation in reinforcing the stream banks using natural methods. The goal was to change the philosophy of the golf course, manicured lawn mindset; to develop a no-mow zone with plantings along the channel. However, most of the group that had purchased new homes with a nice grass swale in their backyards did not buy-in to the "no-mow" philosophy.

Improvements were needed to resolve soil erosion and potential property flood damage along the rear drainage system in the neighborhood. The subject channel is approximately 1,800 feet in length and runs between a 48-inch culvert at Saratoga Club Road and an existing storm water detention basin that eventually drains into Chenoweth Run Creek. Project goals were outlined as 1) stabilize the channel banks; 2) define the channel width the entire length; 3) provide a solution that will eventually blend with the neighborhood; 4) provide a "natural" look that will not look like an urban channelization project and 5) get the support of the neighborhood.

Boulder armoring was identified as the preferred method of remediation; providing a more natural appearance than poured concrete. It was anticipated that the channel would develop natural channel characteristics over time within the proposed defined channel. This method of protection would also allow the no-mow zones for the owners that chose to participate. Planting and native grass zones would be developed behind the boulder improvements. And for the owners not wanting to participate in the no-mow area, the boulders would give them erosion protection while allowing their 'golf course' mowing practices. The boulder protection would also provide the armoring needed for the storm velocities to which the channel is exposed.

There are multiple types of cross sections that exist within the project area due to variations of the existing terrain. Within the first few hundred feet, the stream is flat and covered with rip rap that has been placed to slow flows. The side slopes are slight and the channel width measures from 15 feet to just a few inches within this section. Within the

next several hundred feet the original rock bottom is evident and there are areas that have rock ledges that form cascades. The side slopes begin to increase and there are multiple methods of bank reinforcement in-place throughout this section. These range from gabion baskets to landscape timbers to large rip rap. The existing width increases to up to 20 feet in some areas. In the last section – several hundred feet leading into the existing drainage basin, the channel has eroded significantly and sediment has been deposited within the banks of the stream. In this area the channel width has gone beyond 20 feet in some areas but narrows down to just a few feet as it passes through the detention basin and outlets through an existing pipe and headwall.

DRAINAGE AREA AND DISCHARGE CALCULATION

The drainage area, depicted in Figure 1, above the culvert in Saratoga Club Road is approximately 82.6 acres and is made up of mostly residential lots with some undeveloped pasture land. The drainage area contributing directly to the channel identified for improvements is 74.0 acres, fully developed as residential lots. The total drainage area to the project is 156.6 acres. The MSD Design Manual recommends the Soil Conservation Service (SCS) method for runoff calculations is to be used when the drainage area exceeds 50 acres in size or is in need of a detention basin. The drainage area contributing to the subject channel meets this criterion.

In order to move forward with the design of the project, assumptions were made within the SCS – TR55 runoff model.

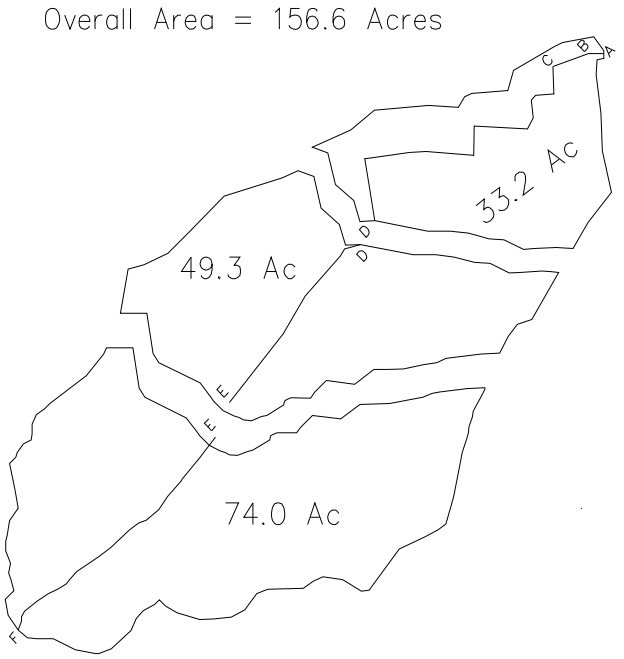

Figure 1. Drainage Area and Flow Path

To calculate the discharge for the upper portion of the water shed, the time of concentration had to be estimated. The time of concentration is the time it takes a drop of water to travel from the furthest point in the water shed to the outlet and is generally identified by T_c. The T_c is made up of the sum of three distinct components, summarized in table 1: 1) Overland (sheet) flow; 2) shallow concentrating flow; and 3) channel flow.

T_c = Tsheet+Tshallow+Tchannel

Table 1. Summary of Time of Concentration Calculation

Sub Area	Length (ft)	Slope (ft / ft)	Manning's n	Velocity (ft / sec)	Travel Time (hr)
Sheet	100	0.020	0.24		0.238
Shallow	239	0.029	0.05		0.024
Channel	2083	0.028	0.03	5.076	0.114
Channel	3004	0.026	0.04	7.320	0.114
				Total T_c	**0.49**

To design the channel improvements in this lower portion of the watershed, downstream of the culvert under Saratoga Club Road bank full flow was used. The bank full flow depth was observed in the field, and it varied within the different reaches with the deepest being approximately 1 foot. Bank full, or channel forming flow, can occur in the 0.8 to 2.0-year storm event. The channel width was chosen to allow space for the channel to achieve bank full depth. The flowrate was calculated using the SCS TR-55 model. Both the 2-year storm and the 10-year storm were analyzed with the existing upstream channel geometry.

The soil type and land use was evaluated for the drainage area to determine a curve number, which is similar to the rational formula's "C" factor. The land use for the area was observed to be a residential district (1/4 acre lots) with some undeveloped open space and pasture. The weighted curve number for the 156.6 drainage area was estimated to be 80.

- The peak flow calculated for a **2-Yr.** rainfall return period is **192.9 cfs**
- The peak flow calculated for a **10-Yr.** rainfall return period is **344.6 cfs**

The 100 year storm was not analyzed because there was no change in either the upstream conditions or the outlet conditions.

TOPOGRAPHIC SURVEY

A topographic survey of the project area was performed. This survey located existing topographic features as well as visible utilities in the area. The edges of the existing channel were located along with the existing planimetric and topographic information for the project area. Cross sections were taken at 50 foot intervals along the channel. This data was used to interpolate cross sections along the channel for use in the design.

PRELIMINARY DESIGN

Measurements were taken of the width of the existing channel in our project area as well as that of the section of channel directly upstream of the project area. These measurements, the bank full observations, along with the space restrictions that exist within the project boundary led to a proposed uniform channel width of 12 feet. This width was used in the drainage calculations when determining the flow into/through the project area.

The existing channel centerline was approximated based on the edge of channel determined by the land surveyor. A proposed channel alignment was laid out that attempted to follow the existing channel's path. Where existing natural features, (large trees, brushy banks, etc.), sanitary sewer features and other improvements such as fences and extensive landscaping were encountered, the channel alignment was adjusted to allow for protection of the feature. The proposed alignment was laid out to stay within the existing sanitary sewer and drainage easement, where possible.

Typical sections, as depicted in Figure 2, were developed to show the different scenarios for the rock boulder toe depending on the existing terrain. These typical sections were

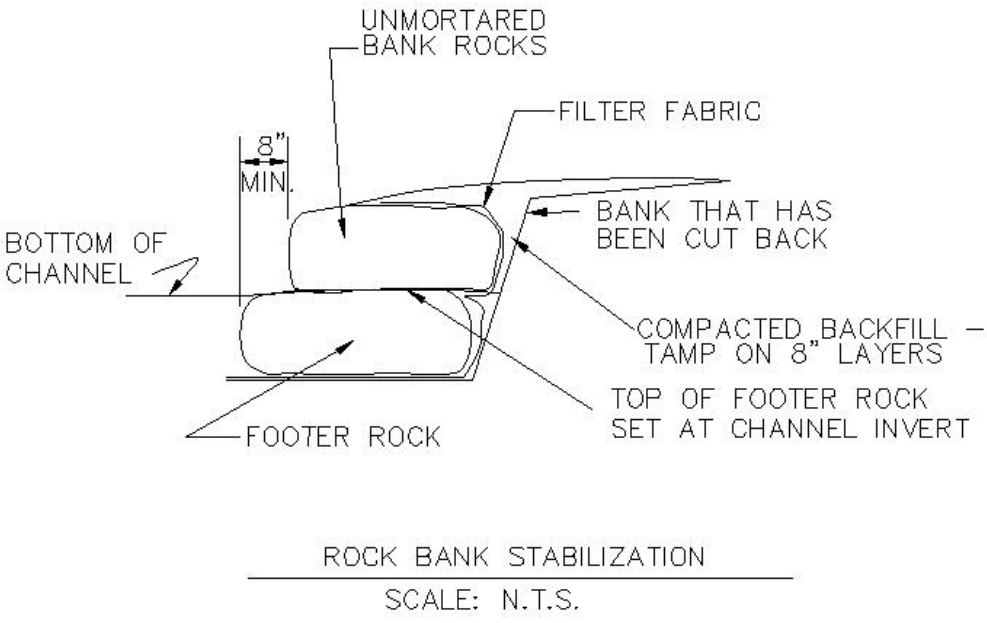

Figure 2. Typical Section Rock Stabilization

inserted into the cross sections to allow the designer to determine which section would fit best and how the rock boulder toe would transition from one section of channel to another. The cross sections were developed assuming a boulder height of one foot. The height the boulders would be stacked, or number of one foot courses, was determined from the existing terrain. The boulder "wall" course height was designed to have the soil behind the boulders at three to one grade or less. This would allow ease of maintenance for the property owners. A filter fabric was specified behind the boulders for prevention of soil loss.

A summary of the existing channel characteristics with velocities was presented in Table 1. The proposed channel geometry was evaluated for the 2 year and the 10 year storm events within the TR 55 software and the HYDRAIN software to get an idea of the proposed system performance. In the lower reaches of the channel velocities approached 7 feet per second (fps).

The maximum allowable velocity for a vegetative channel, with these characteristics, is approximately 2 fps. With the relatively steep slopes in the existing channel, grass lining could not withstand the shear stresses and would not be stable. Therefore, alternative methods were required.

The proposed channel could have been designed with larger rip rap. However, MSD's past experience with this type of installation suggested property owners would not be pleased with the irregular surface, vegetation (weeds) between the rock and the trash that sometimes get caught within the rock. The design needed to be able to withstand the high velocities and shear stresses that existed and appear more natural than man-made.

A standard channel width of 12 feet allows velocities to decrease to near 5 fps for a 2 year storm and also provides the capacity for sediment to be dropped during lower seasonal flows. The original channel's rock bottom that had been exposed provides a stable base for the higher velocities that sometimes occur. The boulders provide protection of the adjacent grass and soil during the typical bank-full flows and help maintain channel width definition as scouring velocities are reached.

PROPOSED PLANTINGS

After a site visit to the project area, the Biologist involved with this project suggested plantings that could be a part of the final restoration. Their suggestions included dividing the project area into two zones for plantings: Zone I is directly adjacent to the channel. Zone II is an area further back from the channel edge. In Zone I, fast growing trees and shrubs could be planted. Some of the possibilities in this area include: Flowering dogwood; Silky dogwood; Sycamore; Green Ash; Tulip Poplar and Persimmon. In Zone II some of the possibilities include: Northern Red Oak; White Oak; Black Oak and Black Walnut. Within areas that are determined to be a "no-mow" zone, a native seed mix could be planted that might consist of the following: Annual rye (if restoration occurs in the spring); winter wheat (if restoration occurs in the fall/winter); deer tongue panic grass; wild rye; switch grass; barnyard grass and creeping bentgrass.

CONSTRUCTION

PERMITTING

The channel is classified as an intermittent blue-line stream and required permits from two agencies associated with water and water quality.

Under the provision of Section 404 of the Clean Water Act, a Corp of Engineers permit was required. The project was judged to fall under the provisions of the Nationwide General Permit for Aquatic Habitat Restoration, Establishment and Enhancement Activities. Construction in the channel also required two permits from the Kentucky Department of Environmental Protection (KDEP). The first permit was a Stream Construction Permit – for restoration of a channel, the second a Water Quality Permit. There was more discussion than usual regarding the sediment control set up for the channel. Since the channel is classified as an intermittent Blue Line only one rock bag check dam was desired by the KDEP and that was an outlet protection measure. Originally, the design called for four rock bag check dams in the channel to catch sediment in the base flow. KDEP did not agree and the contractor was instructed to remove all but one rock bag check dam. Unusual treatment of the channel was thought to be justified since a detention basin existed at the channel outlet.

RELIANCE ON CONTRACTOR

The successful bidder was a contractor who had constructed other stream bank boulder revetments. Construction of the boulder toe walls is not much different than fitting together a child's building block set. Some pieces fit in one location better than they fit in another. Since fitting boulders of various sizes into a wall and providing positive drainage over or through the wall is a tedious process, having patience with this very hands-on approach can prove invaluable. When care is taken to think through the process the finished product will more than likely pass the test of time.

CONSTRUCTION

Construction began on the upstream end of the channel with transition stone laid from the existing 48-inch headwall to match the existing ground-line. Rip Rap was removed and boulders placed. The south side of the channel was higher than the north side and boulders were adjusted in the field to match existing ground line incorporating the proposed 50 foot cross sections detailed in the construction plans as closely as possible. Work proceeded downstream, first removing the rip rap or gabions, then placing the boulders and filter fabric and finally backfilling.

The Contractor provided a three man crew to perform the work. First, a mini-excavator operator removed rip rap and placed the boulders along the exposed banks. Second, a driver transported excavated rip rap and gabions to the staging area and carried selected boulders back to the work zone. The third member of the crew was a laborer who placed the filter fabric; fine tuned the backfill and trimmed the fabric once the backfilling was completed.

With work occurring in the actual channel, there was little that could be done to stop the transport of fine sediment. Efforts were made to keep rip rap in the stream and in other critical areas to help trap sediment during the low flows. The detention basin downstream was used as an erosion control measure allowing silt to be captured before discharge into the receiving stream.

Work was disrupted on a few occasions when sanitary sewer connections were encountered in a shallow trench, just under the excavated rip rap. These connections were much more shallow than anticipated and could be the result of the channel bed seeking its original level. Repair of a few connections were required after the equipment crushed the existing pipe.

ADJUSTMENTS

The channel was specified to be 12 feet in width. The Contractor and the MSD Inspector made the decision to adjust the alignments of the wall in certain locations to avoid removal of trees. The channel width was not compromised significantly and no ill effects are anticipated.

No geotechnical exploration was performed as part of the design. The Contractor chose to remove all of the rip rap / sediment from the original rock flow line. The restored channel is a rock bottom channel almost the entire length. Some pools exist and sediment is beginning to accumulate along the walls in portions of the channel creating a prototypical sand bar structure.

As the project progressed, additional thought was put into the restoration with native grasses, shrubs and trees. With the exception of the staging area that was located in the detention basin storage area, the disturbed foot print was quite small for the project. Occasionally, the disturbed limit was as close as 6-inches from the back of the installed boulder to as much as 10 feet. MSD reviewed the project site and recognized most of the properties abutting the project were maintained lawns. Experience on other projects led to the decision to restore in standard lawn grasses, rather than paying a premium for native seed. Although it would be more favorable to the stream to be surrounded by water favoring grasses and shrubs, there was a concern the property owners would see the native grasses and shrubs as “weeds”. When most moved into their homes it was a grass lined swale that they could walk across to visit their neighbors. Having the good intentions of a native restoration was not viewed as meeting the property owner’s perspective on the channel. A native restoration would likely be removed and reinstalled as lawn by the property owners. Three of the approximately 50 homeowners adjacent to the project have called MSD with concerns of not having the native restorations installed. MSD will work with these owners in the near future to establish a few native areas in the hope of providing an example of what these types of plantings could do for the rest of the neighbors. MSD is very interested in encouraging native restoration, where appropriate, throughout the entire Louisville Metro area.

LESSONS LEARNED

- Focus on the flow in the channel in order to match the channel to "normal" flow conditions
- Don't expect plans to be followed to the letter. Field conditions change. Materials used in construction vary which adds to the aesthetics of the project.
- Design should be flexible where possible. Communicate the areas that are not flexible.
- Understand as a designer, the boulders do not all come in the dimensions you called for. These are not toy blocks!
- Work with a Contractor, build a trust with them and make sure that they understand the intent of the project.
- Set expectations early for all involved, the local authority, the neighborhood, the Contractor and the Inspector.
- Make sure property owners understand intent, schedule and what they will be seeing.
- Match restoration as closely as possible to surrounding or get buy-in from the majority of property owners – don't throw your restoration money under the mower.
- Weather – understand how it will impact your construction and plan for it…. Because it will.
