Table of Contents

11th Water Distribution Systems Analysis Symposium (WDSA 09)

Asset Management

Bursts Identification in Water Distribution Systems

I. Borovik, B. Ulanicki, and P. Skworcow

Damage Detection of Operating Transmission Mains with Measured Boundary Conditions

Aaron C. Zecchin, Martin F. Lambert, and Angus R. Simpson

Evaluating Risk of Multi-Segment Pipes for Prioritizing Pipe Rehabilitation

M. Poulton, I. Kropp, and A. Vanrenterghem-Raven

Water Distribution Systems Corrective Maintenance Supported by Real-Time Use of Hydraulic Models

Juan G. Saldarriaga, Susana Ochoa, César A. Niño, and Oscar J. Cortés

Water Price Forecasting Method Based on Marginal-Cost Theory: A Case Study in China

Cui-Mei Li and Sui-qing Liu

Field Work

Assessing the Impact of Climate Change on Drinking Water Treatment Plant Design and Operation

Zhiwei Li, Robert M. Clark, Steven G. Buchberger, and Y. Jeffrey Yang

Axial Dispersion Coefficients for Laminar Flows in Water Distribution Systems

P. Romero-Gomez, Z. Li, C. Y. Choi, and S. G. Buchberger

Case Study: Homeowner's Preference Trade-Offs toward Plumbing Systems in Pipe Failure Prone Area

Juneseok Lee, Darrell Bosch, Ewa Kleczyk, Eftila Tanellari, Andrea M. Dietrich, and Vinod K. Lohani

Field-Scale Assessment of a Multispecies Water Quality System: A Chloramination Study

Matthew T. Alexander, Dominic L. Boccelli, and Margaret J. Kupferle

Pressure vs. Flow Relationship for Pipe Leaks

Thomas Walski, Brian Whitman, Mary Baron, and Fred Gerloff

Seoul (Korea) Online Water Quality Monitoring of Drinking Water

P. S. Shin, Y. R. Song, Y. J. Choi, and Y. S. Park

Hydraulic Transients and Biofilms

Air/Vacuum Valve Breakage Caused by Pressure Surges – Analysis and Solution

Guohua Li, Christopher C. Baggett, and Roberto A. Rosario

The Impact of Biofilm Development on Pipe Roughness and Velocity Profile

Martin Francis Lambert, Ryan Wilson John Edwards, Sean James Howie, Benjamin Bernard De Gilio, and Shane Pearse Quinn

In-Line Partially Closed Valves: How to Detect by Transient Tests

S. Meniconi, B. Brunone, and M. Ferrante

Simple Model of Attachment and Detachment of Pathogens in Water Distribution System Biofilms

I. Schrottenbaum, J. Uber, N. Ashbolt, R. Murray, R. Janke, J. Szabo, and D. Boccelli

Network Modeling 1

Impact of Storage Tanks on Energy Consumption in Municipal Water Distribution Systems

Santosh R. Ghimire and Brian D. Barkdoll

Hydraulic Analysis of Water Distribution Network Using Harmony Search

Zong Woo Geem

Integrated Hydraulic Analysis and Data Management Tool for Water Supply Systems in Developing Countries

Philipp Klingel and Nicolai Guth

The Impacts of Demand Variability on Distribution System Hydraulics and Transport

Xueyao Yang and Dominic L. Boccelli

Network Modeling 2

Augmented Gradient Method for Head Dependent Modelling of Water Distribution Networks

Calvin Siew and Tiku T. Tanyimboh

Enhanced Global Gradient Algorithm: A General Formulation

L. Berardi, O. Giustolisi, and E. Todini

Enhanced WDN Analysis: Representation of Actual Pipe Connections

O. Giustolisi

Identification of the Hydraulic Model from Operational Measurements for Supervisory Pressure Control

Ping Li, Ian Postlethwaite, Emmanuel Prempain, Bogumil Ulanicki, and Ridwan Patel

Network Modeling 3

An Operative Approach to Water Distribution System Rehabilitation

L. Berardi, O. Giustolisi, and D. Savic

Calibration of Water Distribution Network Models as a Tool for Detecting Missing and Erroneous Cadastral and Hydraulic Information

Juan G. Saldarriaga, Susana Ochoa, Daniel Rodríguez, and César M. Jurado

Integrated Planning for Dual Distribution Systems

Nabin Khanal, Vanessa Speight, Venkatraman Radhakrishnan, Tim Francis, Laurel Passantino, and James Swanson

Reliability Analysis of Water Distribution Systems Using Graph Decomposition

Jochen Deuerlein, Andreas Wolters, Dietmar Roetsch, and Angus R. Simpson

Network Modeling 4

A Framework for Alternative Formulations of the Pipe Network Equations

Angus R. Simpson and Sylvan Elhay

Inexpensive Modeling of Intermittent Service Water Distribution Networks

J. A. Cabrera-Bejar and V. G. Tzatchkov

Operational Perspective of the Impact of Failures in Water Distribution Systems

J. Bicik, Z. Kapelan, and D. A. Savi•

Network Monitoring and Sampling

New Concepts for Meter Placement in Water Distribution Systems for Demand Estimation

Doo Sun Kang and Kevin Lansey

Online Hydraulic State Prediction for Water Distribution Systems

Ami Preis, Andrew Whittle, and Avi Ostfeld

Sampling of Residential Water Use for Leak Control via Water Budgets

C. Arena, A. Criminisi, A. Fortunato, and M. R. Mazzola

Smart Pipe—Nanosensors for Monitoring Water Quantity and Quality in Public Water Systems

Yu-Feng Lin, Chang Liu, and Jordan Whisler

Network Optimization 1

An Approach for Integrated Optimization of Wastewater, Recycled, and Potable Water Networks

Graeme Dandy, Alana Duncker, Joel Wilson, and Xavier Pedeux

Application of Optimization Technology to Water Distribution System Master Planning

C. K. Rogers, M. Randall-Smith, E. Keedwell, and R. Diduch

Industrial Distribution System Simulation for Optimal Water Resource Assignment Using Probabilistic Tabu Search

S. H. H. Nourzad and M. H. Afshar

Optimal Pump Scheduling by Linear Programming

M. F. K. Pasha and K. Lansey

Network Optimization 2

An Integrated Approach for Distribution System Hydraulic Criticality and Emergency Response

Laura Jacobsen, Sri Kamojjala, and Brian Bowler

Decision Making under Information Constraints

Jianhua Xu, Jeanne M. VanBriesen, Mitchell J. Small, and Paul S. Fischbeck

Optimal Distribution of Pressure Measurement Points in Water Distribution Networks

Hui Zhang and Tinglin Huang

Scalable Parallel Computing Framework for Pump Scheduling Optimization

Zheng Yi Wu and Qi Zhu

Network Security 1

A Multi-Objective Evolutionary Computation Approach to Hazards Mitigation Design for Water Distribution Systems

Lufthansa Kanta, Kelly Brumbelow, and Emily Zechman

Multi-Objective Sensor Placements with Improved Water Quality Models in a Network with Multiple Junctions

R. G. Austin, C. Y. Choi, A. Preis, A. Ostfeld, and K. Lansey

Robust Sensor Placement for Detecting Adversarial Contaminations in Water Distribution Systems

Andreas Krause and Carlos Guestrin

Sensor Network Design and Performance in Water Systems Dominated by Multi-Story Buildings

Robert Janke, Terra Baranowski Haxton, Walter Grayman, Rakesh Bahadur, Regan Murray, William Samuels, and Tom Taxon

Network Security 2

Comparative Evaluation of Two Algorithms for Locating Contaminant Ingress Points

Hailiang Shen, Edward McBean, and Mirnader Ghazali

Comparison of Pressures Simulated Using Transient Analysis with Field Data from a Full-Scale Distribution System

G. Ebacher, M.-C. Besner, J. Lavoie, B. S. Jung, B. W. Karney, and M. Prévost

Effects of Redesign of Water Systems for Security and Water Quality Factors

Walter M. Grayman, Regan Murray, and Dragan A. Savic

Propagation of Chlorine Demand Signals Induced by Microbial Contaminants in a Drinking Water Distribution System

D. E. Helbling and J. M. VanBriesen

Network Security 3

A Markov Chain Monte Carlo Implementation of Bayesian Contaminant Source Characterization in Water Distribution Systems under Stochastic Demands

Kenneth W. Harrison and Hui Wang

Conditioned Backward Probability Modeling to Identify Contamination Sources in a Water Distribution System

R. M. Neupauer and M. K. Records

Real-Time Implementation of Contamination Source Identification Method for Water Distribution Systems

Annamaria E. De Sanctis, Sam Hachett, James G. Uber, Dominic L. Boccelli, and Feng Shang

Threat Perceptions and Risk Management in Urban Water Supply Schemes

Mitthan Lal Kansal and Aditya Tyagi

Network Security 4

Getting More from Your Investment Using Water Security Monitoring Technology for Everyday Operations

Dan Kroll

Modeling a Hydraulic Response to a Contamination Event

Terranna Baranowski Haxton and Thomas M. Walski

Novel, Rapid Molecular-Based Technique for Detecting Contamination in Drinking Water Distribution Systems

Stacia L. Thompson and Jeanne M. VanBriesen

Trajectory Clustering Approach for Reducing Water Quality Event False Alarms

Eric Vugrin, Sean A. McKenna, and David Hart

Network Water Quality Analysis 1

Comparing Single- and Multi-Species Water Quality Modeling Approaches for Assessing Contamination Exposure in Drinking Water Distribution Systems

Stephen Klosterman, Sam Hatchett, Regan Murray, James Uber, and Dominic Boccelli

Real-Time Valve Operation for Water Quality Improvement in Water Distribution Systems

Doo Sun Kang and Kevin Lansey

Simulation of Particle Transport in Drinking Water Distribution Systems

Klaus Ripl and Wolfgang Uhl

WDS Water Quality Parameter Estimation and Uncertainty

M. F. K. Pasha and K. Lansey

Network Water Quality Analysis 2

A Hybrid Heuristic Search Approach for Contaminant Source Characterization

Li Liu, E. Downey Brill, G. (Kumar) Mahinthakumar, and S. Ranji Ranjithan

Analysis of Model Sensitivity and Uncertainty for Chlorine Transport and Decay in a Water

Distribution System

W. J. Dawsey, B. S. Minsker, and A. Ostfeld

Characterizing Reactive Contaminant Sources in a Water Distribution System

Jitendra Kumar, E. Downey Brill, G. Mahinthakumar, and Ranji Ranjithan

Low Pressure Propagation at Service Lines

Juneseok Lee, Vinod K. Lohani, Andrea M. Dietrich, and G. V. Loganathan

North American Drinking Water Infrastructure Assessment

Drinking Water Infrastructure Assessment: The National Research Council of Canada Perspective

Yehuda Kleiner, Balvant Rajani and Rehan Sadiq

National Mains Failure Database Project

Neil S. Grigg

Needs and Trends of the Nation's Water Infrastructure—The Utility Perspective

Steven Buchberger, Robert Clark, Walter Grayman, Zhiwei Li, Matthew McCutcheon and Jeff Yang

Water Usage

Combined Energy and Pressure Management in Water Distribution Systems

P. Skworcow, H. AbdelMeguid, B. Ulanicki, P. Bounds, and R. Patel

Design of Dual Water Supply Systems

R. Chee, D. S. Kang, K. Lansey, and C. Y. Choi

Modeling Domestic Water Demand on a Suburb Level

M. L. Griffioen, J. E. van Zyl, and A. S. le Roux

Preliminary Spatial-Temporal Statistical Analysis of Hourly Water Demand at Household Level

Ernesto Arandia-Perez, James G. Uber, Feng Shang, Dominic L. Boccelli, Robert Janke, David Hartman, and Yeongho Lee

6th Urban Watershed Management Symposium

10,000 Rain Gardens, One Green Region

Tom Jacobs

A Level Spreader—Vegetated Buffer System for Urban Stormwater Management

Ryan J. Winston and William F. Hunt

A New Methodology to Evaluate Pollutant Removal of Gross Solids Separation Devices

D. P. Smith

A Simplified Model of Combined Sewer Overflows to Estimate Event Driven Enteric Pathogen Concentrations in Drinking Water Sources

Rishab Mahajan, James Uber, and Joseph Eisenberg

Source Control: The Solution to Stormwater Pollution

Michael A. Ports

A Student-Led Effort to Assess the Effect of Urban Runoff on Potter Lake

England Porter, John Kenny, Edward Peltier, and C. Bryan Young

A Tool for the Performance Assessment of Hydrodynamic Separators

Omid Mohseni, Janna M. Kieffer, and Jennifer A. Koehler

Accurate Sampling of Suspended Solids

Gregory P. DeGroot, John S. Gulliver, and Omid Mohseni

An Evaluation of Stormwater Wetlands in Series

J. M. Hathaway and W. F. Hunt

An Innovative Approach for Modeling Large Urban Hydrologic Systems

J. P. Cantone and A. R. Schmidt

Analysis of Bioretention Media Specifications and Relationships to Overall Performance

Sean W. O'Neill and Allen P. Davis

Analyzing the Impacts of a Retrofit Detention Basin Flow Control Strategy on Biodiversity in an Urban Stream System

Natalie A. Postel, Christine A. Pomeroy, Tom A. Jacobs, and Elangovan Karuppasamy

Are Rational C Values Too Low?

C. B. Young, B. M. McEnroe, and A. C. Rome

Assessing Hydrodynamic Separators under High Water Flow Conditions

David Saddoris, Omid Mohseni, and John Gulliver

Assessment of Standard Sumps for Stormwater Treatment

Adam Howard, Omid Mohseni, John Gulliver, and Heinz Stefan

Bayesian Load Duration Curves for Bacterial Total Maximum Daily Loads: Urban Case Study

Mary Schoen, Mitchell Small, and Jeanne VanBriesen

Bioretention/Bioinfiltration Performance in the Mid-Atlantic

R. A. Brown, W. F. Hunt, A. P. Davis, R. G. Traver, and J. M. Olszewski

Breaking Down the Barriers to Low Impact Development in Colorado

Andrew Earles, Derek Rapp, Jane Clary, and Janice Lopitz

Challenges in Attaining Recreational Stream Standards for Bacteria: Setting Realistic Expectations for Management Policies and BMPs

Jane Clary, Jonathan Jones, and Ben Urbonas

Characterizing Water Inputs to Catchments in the Santa Monica Mountains with δ180 and δD

W. Hu, B. Hibbs, and R. Bugarin

Clark County Regional Flood Control District Arc Hydro (CCRFCD Arc Hydro): Toward Ongoing Stormwater Master Planning

Stephen Bourne, Kevin Eubanks, Harshal Desai, and Brian Rowley

Codorus Creek Restoration—A Case Study for the Chesapeake Bay

Matthew P. Hoch, Christina Y. S. Siu, Shirley E. Clark, and Katherine H. Baker

Combining GIS, BMP Performance, and Strategic Planning to Support Water Quality Implementation Planning

Ken Susilo, Marc Leisenring, and Eric Strecker

Considerations, Opportunities, and Strategies for Infiltration Stormwater BMPs

Ken Susilo, Neven Matasovic, and Ronald S. Johnson

Construction and Performance of Bioretention Cells

G. O. Brown, R. A. Chavez, D. E. Storm, and M. D. Smolen

Cost Estimating Tools for Low-Impact Development Best Management Practices

C. Dasch Houdeshel, Christine A. Pomeroy, Lisa Hair, and Robert Goo

Data Reporting Guidelines for Certification of Manufactured Stormwater BMPs: Part II

Robert M. Roseen, Ernie Carrasco, Yuan Cheng, Bill Hunt, Charlene Johnston, Jim Mailloux, Walt Stein, and Tim Williams

Design of Integrated Bioinfiltration-Detention Urban Retrofits with Continuous Simulation Methods

William C. Lucas

Design Optimization of Hydrodynamic Separators

James H. Lenhart, Joanna B. Ogintz, and Scott A. de Ridder

Developing a Water Budget for a Constructed Stormwater Wetland

Kristen Mogavero, Gerrad Jones, and Bridget Wadzuk

Effects of Media Depth on Bioretention Performance in the Upper Coastal Plain of North Carolina and Bioretention Construction Impacts Study

R. A. Brown and W. F. Hunt

Engineered Waste Materials as Amendments to Prevent Erosion and to Stabilize Contaminated Sites

S. P. Kakuturu, M. Xiao, and L. N. Reddi

Enhancing Rain Garden Design to Promote Nitrate Removal

Emilie K. Stander, Michael Borst, Thomas P. O'Connor, and Amy A. Rowe

EPA Aging Water Infrastructure Research Program: State of the Technology for the Condition

Assessment and Rehabilitation of Wastewater Collection Systems

Daniel J. Murray, Jr.

Evaluation and Optimization of Distributed Stormwater Controls in Spreadsheet

Joong Gwang Lee and Scott Struck

Evaluation of Atriplx Shrubs Growth in Semi Arid Area

Mehemed A. Razzaghi

Evolutionary Optimization of Combined Sewer Overflow Control

Andrea Zimmer, David Hill, Barbara Minsker, Avi Ostfeld, and Arthur Schmidt

Examination of Pervious Concrete and Porous Asphalt Pavements Performance for Stormwater Management in Northern Climates

Kristopher M. Houle, Robert M. Roseen, Thomas P. Ballestero, Joshua F. Briggs, and James J. Houle

Field Evaluation of Indicator Bacteria Removal by Stormwater BMPs in North Carolina

J. M. Hathaway, W. F. Hunt, J. D. Wright, and S. J. Jadlocki

Field Testing Guidelines for Certification of Manufactured Stormwater BMPs: Part II

John Sansalone, Jeff Benty, Ernie Carrasco, John Gulliver, Jon Hathaway, Bill Hunt, Masoud Kayhanian, Uday Khambhammettu, Robert M. Roseen, Betty Rushton, and Tim Williams

From Grey to Green: Strategies and Concepts for Implementing Green CSO and Wet Weather Solutions

James C. Schlaman, Bryce Lawrence, and Scott Schulte

Generalized Storage-Reliability-Yield Equations for Rainwater Harvesting Systems

Lars S. Hanson, Richard M. Vogel, Paul Kirshen, and Peter Shanahan

How the Heart of America is *Goin' Green* to Solve Water and Sewer Issues

Lynn Hinkle and Michael Ports

Graywater Irrigation as a Means to Meet Water Demands in Arid Regions

Sybil Sharvelle, Masoud N. Azar, Mary Stromberger, and Larry Roesner

HCFCD M3 System: Maximizing and Maintaining Local Investments in Floodplain Modeling

Karl McArthur, Stephen Bourne, Yu-Chun Su, and Jacob Spenn

Hydrologic Footprint Residence: A New Metric to Assess Hydrological Alterations Due to Urbanization

M. H. Giacomoni and E. M. Zechman

Hypothesis-Based Flow Monitoring for Green Solutions

Deb O'Bannon and Erich Schmitz

Impact of Wet-Weather Peak Flow Blending on Disinfection Performance

Mary K. Stinson, Richard Field, and R. Boris Rukovets

Improving Hydrologic Sustainability of Texas A&M University Campus

Prakash Khedun, Chandana Damodaram, Marcio Giacomoni, Andrea Ryan, Hillary Holmes, Ross Klein, William Saour, Michelle Hollingsworth, Troy Berthold, Meg Davis, Philip Bullock, Neetha Ravikumar, Emily Zechman, Georgianne Moore, Bryan Boulanger, and Radu Stoleru

An Investigation of Infiltration in a Constructed Stormwater Wetland and Implications for Groundwater Quality

Gerrad Jones, Kristen Mogavero, and Bridget M. Wadzuk

Integration of Low Impact Development Studies into the International Stormwater BMP Database

Jane Clary, Marcus Quigley, Andrew Earles, Marc Leisenring, Eric Strecker, and Jonathan Jones

Kansas City—Balancing Green Infrastructure with Traditional Approaches for CSO Control

Scott D. Struck, Tom Jacobs, Ginny Moore, Robert Pitt, Michael A. Ports, Deborah O'Bannon, Erich Schmitz, and Richard Field

Kansas City, Missouri Overflow Control Plan Summary

Terry Leeds and Scott Struck

Kansas City's Stream Setback Ordinance: A Case Study on the Benefits of Stream Buffers in Urban Areas

Laurie Brown, Scott Schulte, and Bryce Lawrence

KC-One: Comprehensive City-Wide Management Plan Creates Leading Stormwater Management Program

J. W. Henson and R. Gaskin

Laboratory Testing Guidelines for Certification of Manufactured Stormwater BMPs

Roger Bannerman, Hans de Bruijn, Shohreh Karimipour, Masoud Kayhanian, Jim Mailloux, Jon McDonald, Mark Miller, Omid Mohseni, Kwabena Osei, and Scott Perry

Land Use and Runoff Uncertainty

Celina Bochis and Robert E. Pitt

Linking Environmental Assessment and Solutions

L. Gosselink, C. Herrington, and R. H. Glick

Long-Term Effectiveness of a Bioretention System Treating Road Runoff in Northeastern Kansas

Edward Peltier, Xiaolu Chen, Kelly Kindscher, and C. Bryan Young

Looking Upstream and into the Watershed for the Big Picture of Stream Health

Christina Y. S. Siu, Shirley E. Clark, Ruth A. Sitler, and Katherine H. Baker

LID-SWM Practices as a Means of Resilience to Climate Change and Its Effects on Groundwater Recharge

Iulia A. Barbu, Thomas P. Ballestero, and Robert M. Roseen

Maintenance of Stormwater BMPs

Andrew J. Erickson, Joo-Hyon Kang, Peter T. Weiss, C. Bruce Wilson, and John S. Gulliver

Modeling Performances of Detention Basins with Uncertainty Analysis

Daeryong Park and Larry A. Roesner

Monitoring the Hydrologic Effects of an Extensive Green Roof

Nathaniel Hanna Holloway, Charles J. Werth, and Arthur R. Schmidt

Multiple Watershed Scales Approach for Placement of Best Management Practices in *SUSTAIN*

Fu-hsiung Lai, Jenny Zhen, John Riverson, Khalid Alvi, and Leslie Shoemaker

Nexus Projects in Kansas City's Suburban Watersheds

Brian Rast

Non-Point Source Nutrient Loading in an Urban Watershed

Eric Gurr and Fidelia (Ola) Nnadi

Pervious Pavement System Evaluation

Amy A. Rowe, Michael Borst, Thomas P. O'Connor, and Emilie K. Stander

Planning for Sustainable Growth and Water Resources in the Chesapeake Bay Watershed

Thomas E. Dumm

Pollutant Transport within the Vadose Zone: Interactions of Soil Horizon Chemistry on Water Quality

Daniel P. Treese, Shirley E. Clark, J. Bradley Mikula, and Katherine H. Baker

Potential Data Analysis Methodology to Evaluate the Performance of Manufactured BMPs

Masoud Kayhanian, Robert M. Roseen, James H. Lenhart, and Greg Williams

Proposed Scaling Relations for Manufactured Stormwater BMPs

John S. Gulliver, Qizhong Guo, John J. Sansalone, Gregory Williams, and J. S. Wu

Rainwater Harvesting for Non-Potable Use in Gardens: A Comparison of Runoff Water Quality from Green vs. Traditional Roofs

Natasha Nicholson, Shirley E. Clark, Brett V. Long, Julia Spicher, and Kelly A. Steele

Redesigning Constructed Stormwater Wetlands: An Integrated Modeling Approach to Optimize Form and Function

G. D. Jones, K. A. Mogavero, and B. M. Wadzuk

Research of Hydrologic and Water Quality Performance of Four Linear Wetlands in Eastern North Carolina

J. D. Wright and W. F. Hunt

Reservoir Sedimentation Estimation Using Genetic Programming Technique

Vaibhav Garg and V. Jothiprakash

Sediment Monitoring Bias by Autosampler in Comparison with Whole Volume Sampling for

Parking Lot Runoff

George D. Fowler, Robert M. Roseen, Thomas P. Ballestero, Qizhong Guo, and James Houle

Selecting Optimal Water Supply Options—A Regional Water Supply Case Study in the Upper Kissimmee Basin, FL

Aditya Tyagi, Mitchell Griffin, Richard Nevulis, and Chris Sweazy

Simplified Solution for Groundwater Mounding under Round Stormwater Infiltration Facilities

Kaveh Zomorodi

South Lake Park Bioretention Gardens

J. J. Dremsa and T. A. Hartsig

State of the Practice of Wet Weather Flow Analysis

Mitchell Heineman

The Application of Environmental Site Design Processes to Design a Residential Subdivision

Steven D. Trinkaus

Effect of Bioretention on Runoff Temperature in Trout Sensitive Regions

Matthew Jones and William F. Hunt

The Lawrence Technological University Greenroof Performance Evaluation Project

Donald D. Carpenter and Preethi Kaluvakolanu

The Road to LID Plan Approval in Coastal North Carolina: Development of a Spreadsheet Modeling Tool for LID Based Designs

Hunter Freeman

The Runoff Reduction Method

Kelly A. Collins, Dave Hirschman, Greg Hoffmann, and Tom Schueler

Unit Process Modeling of Stormwater Flow and Pollutant Sorption in a Bioretention Cell

Zhuangxiang He and Allen P. Davis

Use of the Basin Development Factor to Evaluate Urban Watershed Response

Shiva Sunder, Theodore G. Cleveland, and David B. Thompson

Water Quality and Hydraulic Properties of the Permeable Friction Course

Michael Barrett, Brandon Klenzendorf, Brad Eck, and Randall Charbeneau

Water Quality Design Storms for Stormwater Hydrodynamic Separators

Victoria Julia Fernandez-Martinez and Qizhong Guo

Water Sustainability Index: Application of CWSI for Ahwaz County

J. Attari and S. A. Mojahedi

Development of Watershed Management Modeling System: The Los Angeles County Flood Control

District's Watershed Based Approach for Urban Runoff and Stormwater Quality

Youn Sim

7th Symposium on Groundwater, Hydrology, Quality, and Management

Aquifer Characterization and Protection

Implementing Source Water Protection Programs in Texas

Camille W. Sowells, Christina Petersen, Gordon McCurry, Alexandria Doody, and Sean Ables

Lithostratigraphy of Nigeria—An Overview

Kazeem Akorede Shitta

Specific Problems Related to Partially Penetrating Wells in Confined Aquifers

Ahmad Wagdy, Hany G. Radwan, and Sherif M. El-Didy

Tool for Estimation of Additional Drawdown Due to Partially Penetrating Wells in Confined and Semi-Confined Aquifers

Ahmad Wagdy, Hany G. Radwan, and Sherif M. El-Didy

Groundwater Characterization and Monitoring

A Novel Approach to Groundwater Model Development

Thomas D. Krom and Richard Lane

Groundwater Mixing Using Pulsed Dipole Injection/Extraction Wells

C. R. Radabaugh, D. C. Mays, and R. M. Neupauer

Groundwater Management and Its Uncertainty

A Critical Realization Identification Method Based on Pareto Dominance Analysis

J. Wang, J. Guan, and M. M. Aral

Combining Rule-Based Fuzzy Model with GIS to Predict Groundwater Vulnerability to Contamination

Dhundi R. Pathak, Akira Hiratsuka, Isao Awata, and Luonan Chen

Evaluation of Alternative Geospatial Models Using Image Ranking and Machine Learning: An Application in Shallow Groundwater Recharge and Discharge

Yu-Feng Lin, Peter Bajcsy, Alex Yahja, and Chulyun Kim

Implementation of the Sustainable Development Concept in the Field of Groundwater Management

C. Schöpfer

Projecting Future Groundwater Availability for Power Generation Plant Licensing

G. A. Day and C. Krambis, Jr.

Simulation of Subsurface Water Flow by Galerkin Finite Element Method in Dhaka City Aquifer

Shikha Rahman and Mohammad A. Bhuiyan

Groundwater Quality and Human Health

A Methodology to Reconstruct Groundwater Contamination History with Limited Field Data

Jiabao Guan, Morris L. Maslia, and Mustafa M. Aral

A Tale of Two Cities—Source Water Protection Case Studies for Systems in Rural Settings

Tina Petersen, Camille W. Sowells, Gordon McCurry, Alexandra Doody, Claudia Krug, and Sean Ables

Quantifying the Spread of Arsenic Contamination in Groundwater of the Brahmaputra Floodplains, Assam, India: A Threat to Public Health of the Region

C. Mahanta, N. Pathak, R. Choudhury, P. Borah, and W. Alam

Vadose Zone Transport of Nitrate in the Sierra Pelona Groundwater Basin, Agua Dulce, California

Claudia T. Krug and Zbigniew Kabala

Groundwater Quality Modeling—Solute Transport and Reactive Transport

Exploring the Potential of Nonlinear and Non-Equilibrium Alcohol Partitioning for Assessment of DNAPL Source Zone Architecture

Rhiannon E. Ervin and C. Andrew Ramsburg

Solute Flux Rate Uncertainty Evaluation at a Monitored Boundary

David E. Langseth

An Analytical Solute Transport Model for In Situ Estimation of Retardation

Gustavious Paul Williams and David Tomasko

Assessing Postulated Accidental Releases of Radioactive Liquid Effluents from Nuclear Power Plants

S. W. Taylor, G. A. Day, A. N. Findikakis, G. A. McLane, and L. E. Young

Modeling of Chlorinated VOCs Transport under Dual Bioreactions

Wonyong Jang and Mustafa M. Aral

Reaction Rates in a Transport System with Both Kinetic and Equilibrium Reactions

Gour-Tsyh (George) Yeh and Yilin Fang

Impacts of Urbanization on Groundwater Quality and Quantity

Comparative Study of Two Standard Septic Tank Drain Fields Using Different Sand with Recirculation for Nutrient Removal

Ni-Bin Chang, Marty Wanielista, Fahim Hossian, Zhemin Xuan, and Ammarin Daranpob

Environmental Impacts on Surface Water and Groundwater for Expanding Urban Water Supply Capacity Using Stone Quarries

Xing Fang, Ni-Bin Chang, Ming-Kuo Lee, and Lorraine Wolf

Groundwater Baseflow Sourced from Miocene Rocks and Residuals Carries Elevated Selenium into Southern California

Barry Hibbs, Mercedes Merino, Rachel Andrus, Wynee Hu, and Anna Doro-on

Investigating the Temperature Effects on Nutrient Removal in Green Sorption Media

Ni-Bin Chang, Marty Wanielista, Devan Henderson, and Ammarin Daranpob

Nutrient and Pathogen Removal with an Innovative Passive Underground Drainfield for On-Site Wastewater Treatment

Ni-Bin Chang, Marty Wanielista, Ammarin Daranpob, Fahim Hossian, and Zhemin Xuan

Selection and Prioritization of Best Management Practices for Potential Sources of Contamination in a Wellhead Protection Area

Tina Petersen, Camille W. Sowells, Gordon McCurry, Alexandria Doody, and Sean Ables

Interaction of Stream and Groundwater and Integrated Management

Controlling Saltwater Intrusion to Environmental Sensitive Areas Due to the Construction of the Rio Anton Ruiz Flood Control Project

David Weston and Rafael Velez

Estimating Groundwater Seepages to St. Lucie Estuary

Gour-Tsyh Yeh, Jae-Young Lee, Gordon Hu, and Detong Sun

Analytical-Numerical Solution for Seepage along an Earth Canal Disconnected from the Shallow Aquifer

Yi Liu and Zhuping Sheng

Hydrogeologic Investigation for New Water Supply for Water District No. 1 of Johnson County, Kansas

J. W. Henson, T. Schrempp, M. B. Horsley, and K. L. Hahn

Probabilistic Methods for Aquifer Parameter Estimation and Groundwater Modeling and Inverse Modeling

A Heuristic Algorithm for Optimal Alignment and Matching of Borehole Stratigraphy

Gustavious P. Williams, Norman Jones, and Jeffrey Handy

Composite Analysis of Test-Well and Observation-Well Data during Constant-Head Test

Yen-Ju Chen and Hund-Der Yeh

Wavelet Analysis of Characteristic Length Scales of Permeability in Stationary and Non-Stationary Porous Media

X. Qi and R. M. Neupauer

Education and Research

Framing the Design Process in an Undergraduate Environmental Engineering Class

Deb O'Bannon and Tom Kimes

Integrating Design Heuristics in an Environmental Engineering Course

Kathleen M. Leonard

Non-Traditional University Research Partners That Facilitate Service Learning and Graduate Research for Sustainable Development

M. A. Trotz, H. E. Muga, L. D. Phillips, D. Yeh, A. Stuart, and J. R. Mihelcic

Emerging and Innovative Technology

EIT Posters

A Decision Support System for Beneficial Use of National Dam Water Resources in Swaziland

J. I. Matondo and K. M. Msibi

Assessment of Combined Hydroseeding and Coconet Reinforcement to Control Soil Erosion

Mervin M. Cereno

Designing Effective Rainfall Harvesting Systems in Developing Areas of Sub-Saharan Africa

Emmanuel U. Nzewi

Innovative Design at Lake Lenexa

Scott R. Brand and Tom A. Jacobs

Production of Drinking Water from Lake Water Sources with a Nanofilter Membrane to Prevent the Formation of Disinfection Byproducts

Rajib Sinha, Anita Anderson, Craig Patterson, and David Pearson

Rainwater Harvesting Experiences in the Humid Southeast USA

Matthew Jones, William F. Hunt, and Jason Wright

Emerging and Innovative Technology in Wastewater Treatment

Deployable Decentralized Biofilm System to Degrade Organic Carbon, Nutrients and Benzene from Wastewater

Dong Chen, Che-Jen Lin, R. Gavin Jones, Sehul Patel, Rachelle Smith, Thomas G. Chasteen, Micheal Radi, Sabin Holland, Scott A. Waisner, and Jeffery L. Davis

Development of Slow-Release Chemical Oxidation Methods for Environmental Remediation

Stephanie Luster-Teasley and Patrick Onochie

Peracetic Acid as an Alternative Disinfection Technology for Wet Weather Sewer Overflows

E. Coyle and L. Ormsbee

Recycling of Multiple Waste Streams for Transportation Fuel Production via Algae Cultivation at Wastewater Treatment Plants

Patrick J. Dunlap and Andrew R. Shaw

Emerging and Innovative Technology in Water Treatment

Development of a Community Water Security Filtration System Using Composite Cartridges

Preface

The **2009 World Environmental & Water Resources Congress** held in Kansas City, Missouri, May 17-21, 2009, consisted of over 700 presentations, special sessions and workshops. The theme of the Congress was **Great Rivers** with about 190 sessions that ranged from asset management to low-impact development to watershed modeling to hazardous waste management to large river habitat to groundwater quality to green infrastructure to urban hydrology topics. This year's technical program focused the engineering challenges of balancing environmental and development issues while achieving a sustainable future. It is imperative that those working on the front lines – at the environmental/water engineering nexus – share insights from research and practical experience in the field to generate best solutions for the future on issues such as river system management, environmental challenges, watershed management and restoration, dam safety, hydraulic structures, and so much more.

I greatly enjoyed and appreciated all the help from the about 100 volunteers and staff members that poured a lot of energy into the 2009 EWRI Congress. Everyone was a critical component to the Congress being a success.

The 2009 World Environmental & Water Resources Congress Committee was:

General Congress Chair
William H. Espey, Ph.D., P.E., D.WRE, M.ASCE
Espey Consultants, Inc., Austin, TX
wespey@espeyconsultants.com

General Congress Co-Chair
Karen C. Kabbes, P.E., D.WRE, M.ASCE
Kabbes Engineering, Inc., Barrington, IL
KCKabbes@KabbesEngineering.com

Technical Program Chair
Steve Starrett, Ph.D., P.E., D.WRE, M.ASCE
Kansas State University, Manhattan, KS
stevestarrett@gmail.com

Technical Program Co-Chair
Roger W. Babcock Jr., Ph.D., P.E., M.ASCE
University of Hawaii at Manoa, Honolulu, HI
rbabcock@hawaii.edu

Local Arrangements Chair
Dave Renetzky, P.E., M.ASCE
HNTB Federal Services Corporation,
Kansas City, MO
drenetzky@hntb.com

Technical & Social Tour Chair
Sam Mryyan, Ph.D., REM
Adjutant General's Department, Topeka, KS
Sam.mryyan@us.army.mil

Partners, Exhibits & Sponsorship Chair
Donald W. Baker, P.E., M.ASCE
Water Resources Solutions, LLC
wrs@kc.surewest.net

Young Professionals & Student Activities Chair
Leon Staab, P.E., M.ASCE
Burns & McDonnell Engineering Company, Kansas City, MO
lstaab@burnsmcd.com

EWRI Director
Brian Parsons, P.E., M.ASCE
EWRI of ASCE, Reston, VA
bparsons@asce.org

Conference Manager
Stacey Ann P. Gardiner, CMP
301-934-8589 Phone
413-473-0324 Fax
stacey.gardiner@tggroup.com

The key 2009 Track Chairs follow, they certain had a lot of help from colleagues.

11th Water Distribution System Analysis Symposium - **Avi Osfeld**
Water Resources Planning and Management Track - **Eric Loucks**
Water, Wastewater & Stormwater Track, **Rob Traver, Richard Tsang**
6th Urban Watershed Management Symposium - **Scott Struck; Richard Field**
Emerging & Innovative Technologies – **Lily Anne Baldwin**
Engineering History & Heritage – **Jerry Rogers**
Education - **Cassie Klumpp**
Environmental Engineering & Public Health – **Alok Bhandari, Zhiqiang Hu**
7th Groundwater Hydrology, Quality, and Management Symposium - **Zhuping Sheng**
Hydraulics and waterways– **Jennifer Duan, Weiming Wu, George Constantinescu**
Watersheds – **Sharon Jean-Baptiste**
International Issues – **David Watkins**
Irrigation & Drainage – **Richard Allen**
Student Track – **Karen Kabbes**
Local Issues - **Sarah Fjell**

BURSTS IDENTIFICATION IN WATER DISTRIBUTION SYSTEMS

I. Borovik[1] , B. Ulanicki[2] and P. Skworcow[2]

[1]Bauman MSTU, 2-nd Baumanskaya, 5, 105005, Moscow, Russia; email: irencha11@rambler.ru

ABSTRACT

The leakage reduction problem as a whole is complex and requires co-ordinated actions in different areas of water network management, such as: direct detection and repair of existing bursts, general pipe rehabilitation programmes and operational pressure control. Water companies undertake a mixture of these complimentary actions. General pipe rehabilitation is the most costly and long term action, but is undertaken to improve a number of different factors including leakage and water quality. Operational pressure control is a cost-effective action for reducing leakage over whole sub-networks, and for reducing the risk of further leaks by smoothing pressure variations and is the subject of ongoing research. Detection and repair actions are targeted at sub-networks where bursts are present. Benefits of quick burst repair include reduced water losses, reduced disruption to traffic, reduced consequent losses (e.g. from flooding), and also reduced disruption to customers' supplies, which is an important water industry performance measure. The existing methods typically use passive identification approach whilst the presented approach is based on the active identification procedure.

The proposed burst location algorithm is based on comparing data by means of statistical analysis from a simple field experiment with results of water network simulation. An extended network hydraulic simulator is used to model pressure dependent leakage terms. The presence of a burst changes the flow pattern and also pressure at network nodes, which may be used to estimate the burst size and its location. The influence of such random factors as demand flows and background leakage on the process of burst detection is also considered. The field experiment is an extended fixed and variable orifice (e-FAVOR) test. During this test inlet pressure is being stepped up and down and the following variables are measured: inlet flow, inlet pressure (head) and pressure at a number of selected sensitive nodes. The method consists of three stages and uses two different models; one is inlet flow model (IFM) to represent the total inlet flow and another is the extended hydraulic model to simulate different burst locations. Initially the presence of a potential burst is investigated. If this is confirmed values of the demand, background leakage flow and burst flow in IFM are subsequently estimated. These are used to identify the burst site at the third stage of the method. The approach has been validated by solving a practical case study with correct diagnosis of the existing problems.

INTRODUCTION

The UK water industry is addressing the major challenge of reducing leakage in water distribution systems (WDS). Especially, unreported bursts are cause for concern with significant water losses and potential damage to urban infrastructure. Water distribution systems are complicated entities with thousands of interconnected pipes and other components. There is a need for developing efficient methods for identifying unreported bursts which remain invisible with the water draining away and never reaching the surface. Benefits of quick burst repair will also result in reduced disruption to customers, which is an important water industry performance measure.

Recently the UK water companies have heavily invested into restructuring water networks into smaller sub-networks known as District Metering Areas (DMAs). A DMA is a sub-network where the boundary flow is monitored in order to assess leakage. Its boundary is closed except for a low number of inputs and outputs with flow and pressure meters. This facilitates leakage management in terms of pressure control and bursts detection. When a new burst occurs it causes a noticeable increase in the minimum night flow (MNF) – and subsequently a burst location method can be applied. This research proposes such a method by exploiting different behaviour of background leakage and bursts under varying pressure (May 1994). John May proposed a pressure stepping experiment (FAVOR test) during which the inlet flow and inlet pressure were monitored. The authors of this paper observed that monitoring only the inlet variables is not sufficient even to estimate the size of the burst. Therefore, the test was extended to include additional measurements at a number of internal nodes in a DMA and is termed the extended FAVOR test (e-FAVOR test). The method comprises three steps: first performing the e-FAVOR test, subsequently estimating the size of the burst and finally identifying the burst location.

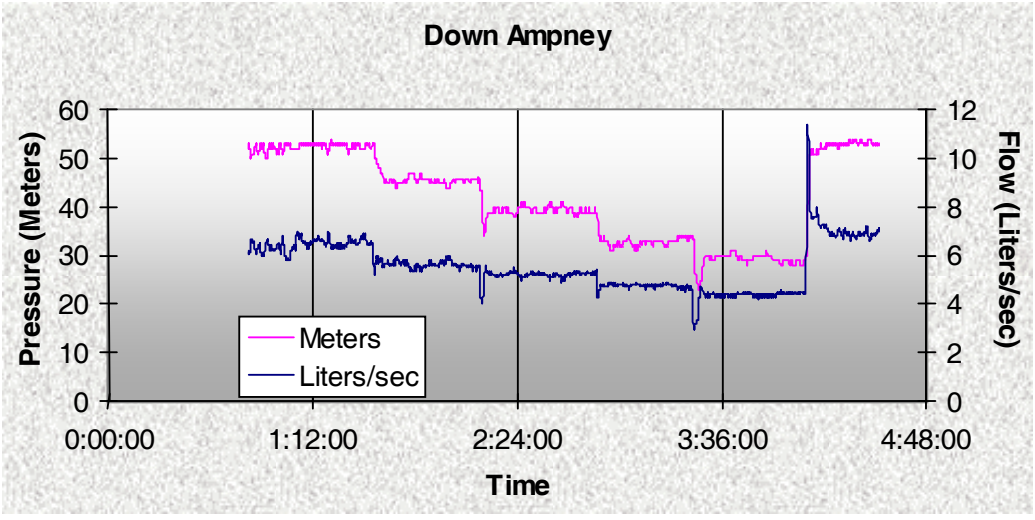

Figure 1. Typical results of the e-FAVOR Test – inlet flow and pressure

E-FAVOUR TEST

A typical e-FAVOR test is carried out during a night between 1 am and 5 am. The inlet pressure is changed stepwise over a typical range of values at 20-minute intervals during this period. Typical scenario of the inlet pressure and flow are depicted in Figure 1. It can be observed in Figure 1 that when the inlet pressure is changed stepwise, the flow changes in a similar manner. Note that only the steady-state data is considered and the data from the transient phase between steady states should be ignored.

It is not practical to measure internal pressure at all nodes in a DMA and therefore a small number of representative nodes (sensitive nodes) is selected for monitoring. The potential measurement points are hydrants and typically a water company is prepared to put 20 loggers for the experiment. The method of determining sensitive nodes has been developed by Prescott and Ulanicki (2006) and is related to that proposed by Bush and Uber (1998). The method uses the sensitivity matrix of the hydraulic model (Jacobian matrix) to determine how the pressure at each potential measurement node is affected by a burst at any node across the network. This matrix has dimension $m \times n$, where m is the number of potential pressure measurement points and n is the number of nodes in the network (possible burst location). The sensitivity matrix can be calculated from the network equations or extracted directly from a hydraulic simulator used in the method.

ESTIMATING THE BURST COEFFICIENT

The inlet flow can be represented by a three term inlet flow model (IFM):

$$q = d + c_1 p_i^{0.5} + c_2 p_{AZNP}^{1.5} \tag{1}$$

where d is an average total demand, p_i is pressure at a burst node, c_1 is the burst coefficient (related to the burst area), p_{AZNP} is average zonal night pressure and c_2 is the background leakage coefficient (related to the total area of the background leakage). The coefficients of the IMF can be estimated using least square method (LSM) from the available measurements for an assumed location of the burst.

It is assumed that the demand flow does not depend on pressure variations in a DMA and the average value of demand is constant over the considered period between 1 am – 5 am. The total background leakage flow represents the sum of all separate background leaks in a network and it is possible to use a single (common) coefficient of the background leakage c_2 and the Average Zonal Night Pressure p_{AZNP}.

The procedure is to assume the burst at a sensitive node and evaluate IFM model; this is carried out for each sensitive node using LSM. It is feasible because pressure p_i in model (1) is known from the e-FAVOR measurements. Note that number of obtained IFM models corresponds to number of sensitive nodes. Subsequently, the goodness of fit for each IFM model is tested using chi-square (χ^2) criterion and the best IMF model is selected to represent the burst flow and also the

demand and the background leakage flow. In order to verify the hypothesis, i.e. the compliance of the measured and calculated values of the inlet flow, the following measure is used:

$$\chi^2 = \sum_{k \in time_steps} \frac{\left(q'_k - q_k\right)^2}{q'_k} \tag{2}$$

where q'_k = model flow, q_k = measured flow.

The algorithm of burst size estimation in a DMA has been implemented in the MATLAB package and progresses through the following steps:

1. Read Excel files containing the experimental data.
2. Prepare the matrix of pressures at the sensitive nodes and calculate the values of the Average Zonal Night Pressure.
3. In a case of a network with many inlets, add all inlet flows together to form a total inlet flow.
4. Solve the least squares problem for each sensitive node $i \in S$ where S is a set of sensitive nodes.
5. Choose the solution which corresponds to the minimum value of the chi-squared criterion.

The outputs of the algorithm are values of the IFM coefficients and the resulting theoretical inlet flows and the vector of the χ^2 criterion values.

IDENTIFICATION OF BURST LOCATION

It was important to find a sensitive indicator of a burst location and the gradient of a pressure line was a very good candidate. A pressure line is a functional relationship between the inlet pressure and the pressure at a chosen node. In absence of leakage it is a straight line with gradient equal to 1. In the presence of a burst the gradient becomes smaller than 1 and the minimum value of the gradient is attained for the burst node. If a small background leakage is added the general rule does not change and the order in the gradient values is preserved with the smallest gradient for the burst node and the biggest gradient for the inlet node as depicted in Figure 2.

The gradients can be found by the least squares method to minimise deviations of the approximating straight line from the experimental data. The following information should be available for the burst location identification:

- inlet pressure which is stepped during the field experiment
- pressure measurements at the sensitive nodes
- gradients of the regression pressure lines for the sensitive nodes
- the IMF model estimated at the previous stage
- hydraulic model of the network

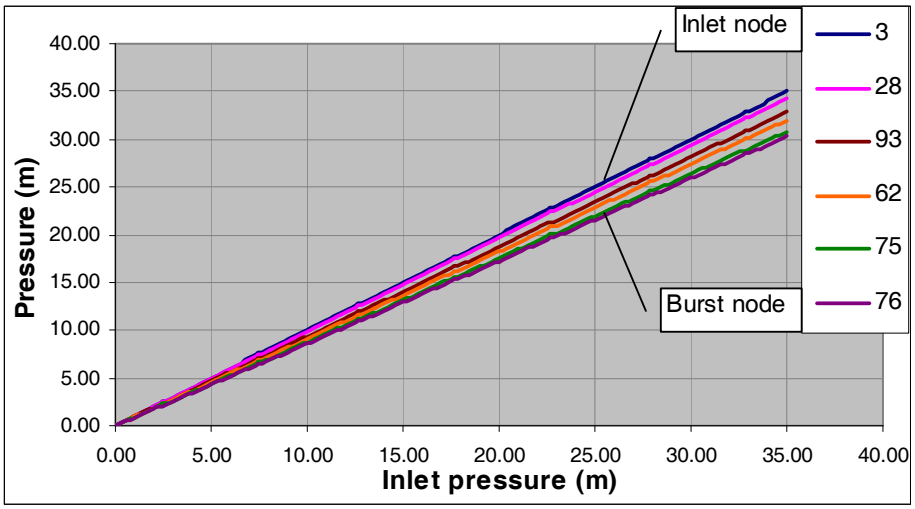

Figure 2. Pressure lines for a DMA nodes

The field measurements from the e-FAVOR test are used to estimate gradients of the measured pressure lines for sensitive nodes. A numerical experiments equivalent the e-FAVOR test is performed on the simulation model. The burst coefficient (calculated at the previous stage) is allocated to different nodes of the simulation model and the theoretical gradients of the pressure lines at the sensitive node are evaluated. For each burst location the value of the chi-squared criterion is calculated as:

$$\chi^2 = \sum_{i \in S} \frac{\left(b'_i - b_i\right)^2}{b'_i} \tag{3}$$

where b'_i = gradient estimated from measurements, b_i =gradient estimated from simulations. The allocation which gives the minimum value of the χ^2 criterion corresponds to the burst node.

SHENSTONE CASE STUDY

Shenstone DMA (illustrated in Figure 3) is fed through two PRV inlets and supplies 1008 consumers (917 domestic and 91 commercial). There are two 4 inch PRVs at inlet 1 and inlet 2, respectively, as shown in Figure 3. The recorded data from the e-FAVOR test are depicted in Figure 4.

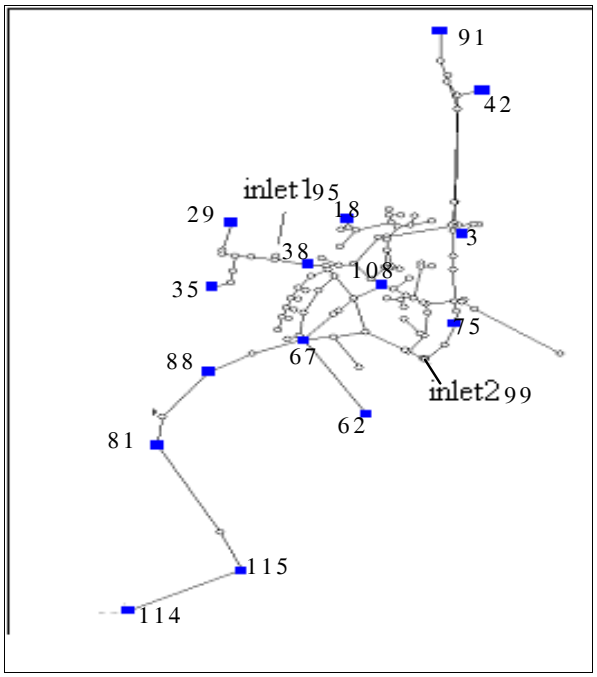

Figure 3. Shenstone DMA. Blue squares denote selected sensitive nodes.

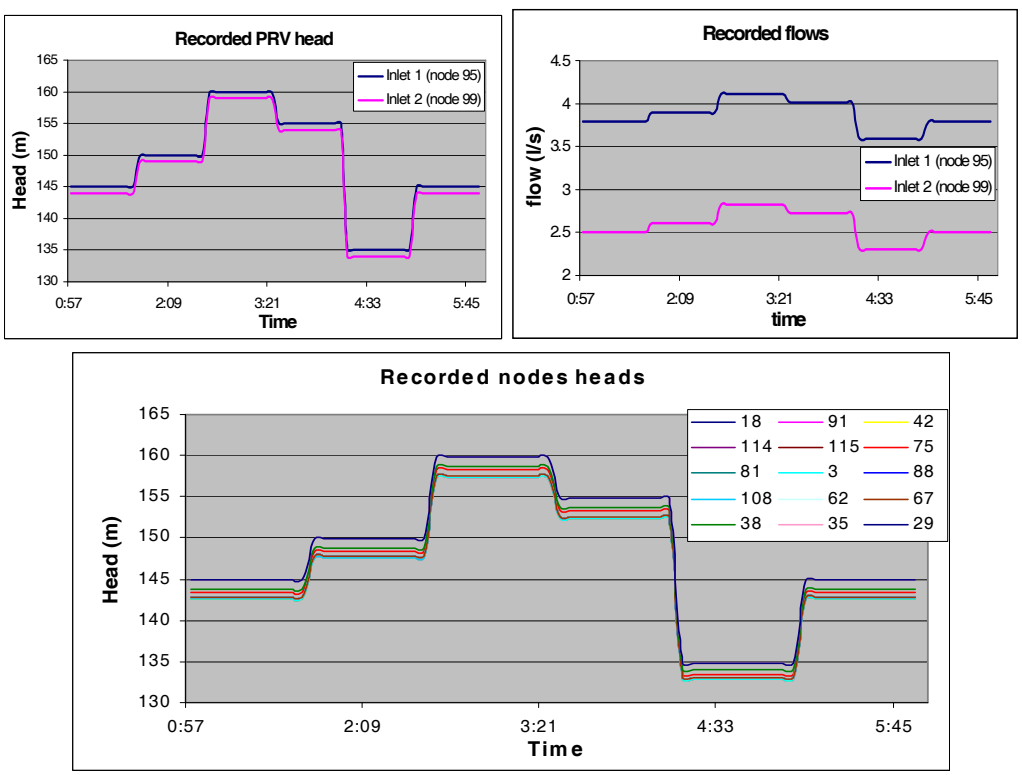

Figure 4. Recorded data

IFM models have been estimated by allocating a burst to different sensitive nodes. For each allocation a corresponding IFM model and the corresponding value of χ^2 have been calculated and are shown in Table 1. The IFM model corresponding to $\chi^2 = 9.31\times10^{-10}$ has been selected for estimating the size of the burst, therefore the coefficients of the model are $d = 4.0334$, $c_1 = 0.2429$ and $c_2 = 0.00227$.

62	3.922307	0.257142	0.002238	6.8E-08
67	3.950318	0.253477	0.002255	1.01E-08
38	3.803718	0.269449	0.002187	1.4E-07
75	3.972916	0.250807	0.002251	1.81E-08
35	3.766198	0.271833	0.002176	1.6E-08
29	3.735147	0.275068	0.002165	1.97E-08

The final stage was to find the burst location. The estimated burst coefficient $c_1 = 0.2429$ was allocated to each node of the hydraulic model one by one, simulated for each allocation and subsequently the model pressure regression lines were compared with the measured ones using χ^2 criterion. The best three allocation are shown in Table 2. The obtained results indicate a high degree of probability of the burst presence at node 80. The value of the total demand flow is 4 l/s, the value of the coefficient of the fixed area leakage (burst) is 0.2429. This finding was later confirmed by the water company following inspection of the area indicated by the proposed method.

69	1.44E-05
33	1.67E-05

CONCLUSIONS

The paper proposed a method for estimating burst flow and a burst location in a DMA. The method is based on an active identification procedure called e-FAVOR test which is carried out at night between 1 am and 5 am. The test requires deployment of pressure loggers to monitor pressure at sensitive nodes. The burst flow is estimated by comparing inlet measured flow and flow from the IFM model. The burst location is identified by comparing gradient of pressure lines from measurements and from hydraulic simulations. The method was formulated assuming presence of a single burst in a DMA, but can easily be generalised by application of genetic algorithms to search for the best flow and pressure line models. Findings were later confirmed by the water company following inspection of the area indicated by the proposed method. Another case study is currently under investigation.

ABSTRACT

Transmission mains are a pivotal component in water distribution systems. As such, regular testing of these mains, for the purpose of identifying regions of damage and deterioration, is an important aspect of responsible infrastructure management. Much research has been done on the use of hydraulic transient methods to aid in the assessment of pipelines. These methods typically require the isolation of the pipeline from the system to create the ideal conditions under which testing can be performed. In many cases, it is not practical to isolate the transmission mains and take them off line for testing. However, testing in an operating environment can serve to confuse existing transient assessment methods, as these methods require known boundary conditions, such as valves or reservoirs. This paper proposes a method that does not require knowledge of a pipelines boundary conditions, but uses a special arrangement of pressure sensors to facilitate the assessment of desired sections of the pipeline. The approach is based on the use of a frequency-domain model to analyze the pressure measurements and identify regions of damage and deterioration within the pipeline.

INTRODUCTION

Pipeline infrastructure represents some of the largest and most expensive infrastructure in the world. Fundamental to all industrial civilizations is the reliable transport of potable water through large transmission mains. These mains, typically a mild steel cement mortar lined composite, suffer deterioration with age whether it be internal spalling of the concrete, internal corrosion, development of blockages or leaks, or external weathering or damage (*Furness and Reet*, 1998). As such, regular testing of these mains, for the purpose of identifying regions of significant deterioration, is an important aspect of responsible infrastructure management.

Much research has been done on the use of hydraulic transient methods to aid in the assessment of pipelines, with a particular emphasis on leak detection (*Liggett and Chen*, 1994; *Vítkovský et al.*, 2000; *Wang et al.*, 2002; *Lee et al.*, 2005). The basic philosophy of hydraulic transient methods is that changes in the pipe condition will impact the nature of transient wave propagation within a pipeline, which is in turn observable from measurements of the fluid variables of the system (*Ferrante and Brunone*, 2003). Typically time-domain methods have been adopted (*e.g.* the inverse transient method (*Liggett and Chen*, 1994)), but there has been growing interest in

the use of frequency-domain methods (*Ferrante and Brunone*, 2003; *Lee et al.*, 2005; *Zecchin et al.*, 2005).

These methods require the isolation of the pipeline from the system to create the ideal conditions under which testing can be performed. In many cases, it is not practical to isolate the transmission mains and take them off line for testing. However, testing in an operating environment can serve to confuse existing transient assessment methods, as these methods require known boundary conditions, such as valves or reservoirs (*Wang et al.*, 2002; *Ferrante and Brunone*, 2003), known inputs (*Lee et al.*, 2005), or clean signals without any underlying transients (*Brunone*, 1999).

This paper proposes a method that does not require knowledge of a pipelines boundary conditions or measured inputs, but uses a special arrangement of pressure sensors to facilitate the assessment of desired sections of the pipeline. The approach is based on the use of a frequency-domain model to analyze the pressure measurements and identify regions of damage and deterioration within the pipeline. Advantages of the use of a frequency-domain model include (i) frequency-domain models are very efficient, (ii) the use of steady-oscillatory signals with frequency-domain identification makes the method robust to underlying transients, (iii) as frequency-domain models do not require discretization, spatial variables and wavespeeds can be easily estimated.

This paper is structured as follows. The next section presents the fundamental time- and Laplace-domain pipeline equations, where the admittance matrix expression for a pipeline with and without a damaged section is derived. This section is followed by an outline of the frequency-domain identification methodology where an expression for the system's feasible data space is used to derive a *goodness of fit* error function, the minimizer of which is the parameter estimate. After which a numerical example is presented, followed by the conclusions.

PIPELINE UNSTEADY FLOW EQUATIONS

Basic Partial Differential Equations

Unsteady pipe flow is governed by a system of two nonlinear hyperbolic partial differential equations. Under the standard assumptions (*Wylie and Streeter*, 1993), the equations governing the transient state variables of pressure and flow within a pipeline are the mass and momentum equations

$$\frac{\partial q}{\partial x} = -\frac{A_o^2}{\rho_o c_o^2}\left(\frac{\partial p}{\partial t} + \mathcal{C}\left[p\right]\right) \tag{1}$$

$$\frac{\partial p}{\partial x} = -\frac{\rho_o}{A_o^2}\left(\frac{\partial q}{\partial t} + \mathcal{R}\left[v\right]\right) \tag{2}$$

where $p = p(x,t)$, $q = q(x,t)$ are the state variables of pressure and flow continuous on the spatial and temporal coordinates x and t, A_o, ρ, and c_o the nominal cross-sectional area, density and wavespeed, respectively, and $\mathcal{C}$ and $\mathcal{R}$ are compliance and resistance operators, which are known to act on p and q respectively (*Zielke*, 1968; *Rieutord and Blanchard*, 1979). Intuitively, $\mathcal{C}$ describes how the cross-sectional inelastic storage

changes with pressure fluctuations, and $\mathcal{R}$ describes how the shear stresses within the fluid body change with the axial flow. An example of $\mathcal{C}$ is the Kelvin-Voigt viscoelastic model (*Rieutord and Blanchard*, 1979), and examples of $\mathcal{R}$ are the standard steady-state friction models (*Wylie and Streeter*, 1993), the laminar unsteady friction model (*Zielke*, 1968), and the unsteady turbulent friction model (*Vardy and Brown*, 2007).

Transform Representation of Fluid Equations

The Laplace transform is a useful tool in dealing with partial differential equations as it removes the time-dependency of the variables and yields a simpler ordinary differential equation (*Kreyszig*, 1999). Via the Laplace transform, the function $p(x,t)$ becomes the complex Laplace-domain function $P(x,s)$, where s is the complex Laplace variable. An important property of the Laplace transform is that the frequency-domain behavior of a function is given when the value of the Laplace-domain variable is restricted to the positive imaginary axis, that is $s = i\omega$ where i is the imaginary unit, and ω is the radial frequency (*Franklin et al.*, 2001).

The Laplace-domain representation of the pipeline equations (1)-(2) requires two simplifications, (i) the linearization of both equations, and (ii) homogeneous initial conditions. The standard approach to satisfy both these requirements is to linearize the system (1)-(2) about the initial conditions (*Wylie and Streeter*, 1993) and consider the transient fluctuations in p, q about these values. This is adequate for most applications as the initial conditions are typically the steady state conditions. The Laplace transformed solution to the linearized system (1)-(2) is

$$\begin{bmatrix} P(x,s) \\ Q(x,s) \end{bmatrix} = A(s)e^{-\tilde{\Gamma}(s)x} \begin{bmatrix} 1 \\ Z_c^{-1}(s) \end{bmatrix} + B(s)e^{\tilde{\Gamma}(s)x} \begin{bmatrix} 1 \\ -Z_c^{-1}(s) \end{bmatrix}, \tag{3}$$

where P and Q are the transformed pressure and flow, A and B are arbitrary functions dependent on the boundary conditions of the pipe, and $\tilde{\Gamma}$ and Z_c are the propagation operator and the characteristic impedance, respectively, and are given by

$$\tilde{\Gamma}(s) = \frac{1}{c_o}\sqrt{\left[s + \overline{\mathcal{R}}(s)\right]\left[s + \overline{\mathcal{C}}(s)\right]}, \quad Z_c(s) = \frac{c_o \rho_o}{A_o}\sqrt{\frac{s + \overline{\mathcal{R}}(s)}{s + \overline{\mathcal{C}}(s)}}$$

where $\overline{\mathcal{R}}(s)$ and $\overline{\mathcal{C}}(s)$ are the Laplace transforms of the linear approximations of the operators $\mathcal{R}$ and $\mathcal{C}$ respectively. Typically the only term requiring linearization is the steady-state quadratic term in $\mathcal{R}$, as for turbulent flow, $\mathcal{R}[q] = \overline{\mathcal{R}}[q] + O\left\{(q - q_o)^2\right\}$ where q_o is a reference flow rate (*Wylie and Streeter*, 1993; *Vardy and Brown*, 2007). However, the viscoelastic models (*Rieutord and Blanchard*, 1979) and unsteady friction models (*Zielke*, 1968; *Vardy and Brown*, 2007) are described by convolution operators, and hence are conveniently and exactly described by the Laplace transform.

A typical organization of (3) is the transfer matrix method (*Wylie and Streeter*, 1993). This method solves for A and B based on specifications of either pressure or flow at either end of a pipeline. Within this paper, the admittance form is of primary

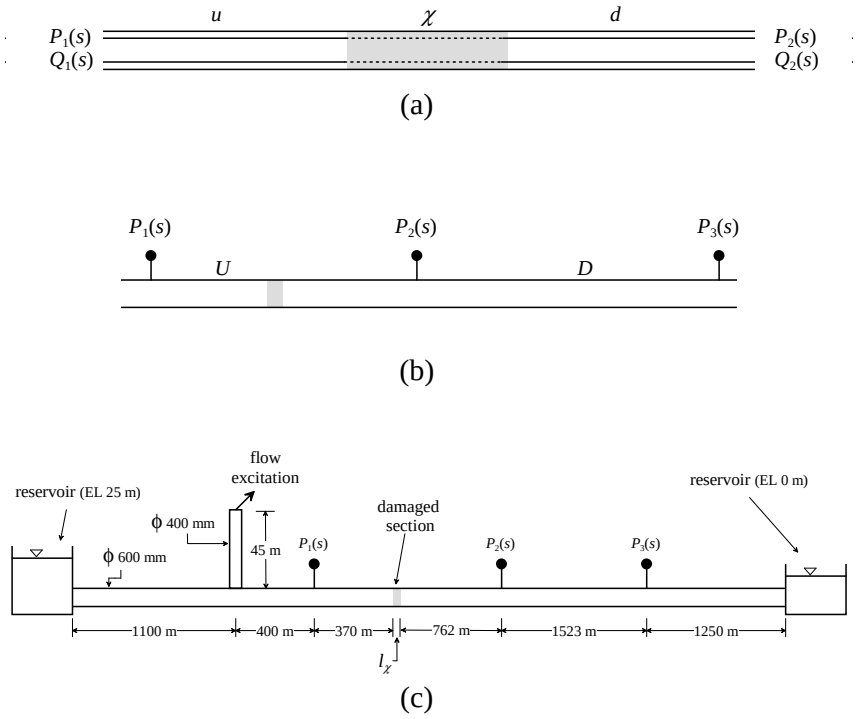

Figure 1: (a) Pipeline with damaged section χ. (b) Pipeline testing setup: a pipeline section bounded by two pressure sensors with a pressure sensor in between. (c) Network used in numerical examples (total length is 5405 + l_χ km).

interest, and, for a pipe of length l, is given as

$$Z_c^{-1}(s) \begin{bmatrix} \coth \Gamma(s) & -\operatorname{csch} \Gamma(s) \\ -\operatorname{csch} \Gamma(s) & \coth \Gamma(s) \end{bmatrix} \begin{bmatrix} P(0,s) \\ P(l,s) \end{bmatrix} = \begin{bmatrix} Q(0,s) \\ -Q(l,s) \end{bmatrix} \tag{4}$$

where $\Gamma(s) = l\tilde{\Gamma}(s)$. Equation (4) is termed an admittance map, as it describes the pipe end flows that are *admitted* from the pipe end pressures.

Admittance matrix of pipeline with damage

Consider the pipeline in Figure 1(a) consisting of undamaged sections u and d bracketing a damaged section χ. The admittance expression of this system takes the form

$$\boldsymbol{Y}_{u\chi d}(s) \begin{bmatrix} P_1(s) \\ P_2(s) \end{bmatrix} = \begin{bmatrix} Q_1(s) \\ -Q_2(s) \end{bmatrix} \tag{5}$$

where $\boldsymbol{Y}_{u\chi d}$ is the admittance transfer matrix for the system. By way of the transfer matrix rules in *Wylie and Streeter* (1993), or using the equation (4) expression for the

dynamics in sections u and d, by equating the end to end pressures and flows of each of the three sections, the following expression for $\boldsymbol{Y}_{u\chi d}$ can be derived

$$\begin{aligned}\boldsymbol{Y}_{u\chi d}(s) =& \frac{1}{Z_c(s)}\begin{bmatrix}\coth\Gamma_u(s) & 0\\ 0 & \coth\Gamma_d(s)\end{bmatrix} \\ &- \frac{1}{Z_c^2(s)}\begin{bmatrix}\operatorname{csch}\Gamma_u(s) & 0\\ 0 & \operatorname{csch}\Gamma_d(s)\end{bmatrix}\boldsymbol{Y}_{\tilde{\chi}}(s)^{-1}\begin{bmatrix}\operatorname{csch}\Gamma_u(s) & 0\\ 0 & \operatorname{csch}\Gamma_d(s)\end{bmatrix}\end{aligned} \tag{6}$$

where Γ_u and Γ_d are the propagation operators for sections u and d, Z_c is the characteristic impedance for these sections, and

$$\boldsymbol{Y}_{\tilde{\chi}}(s) = \boldsymbol{Y}_{\chi}(s) + \frac{1}{Z_c(s)}\begin{bmatrix}\coth\Gamma_u(s) & 0\\ 0 & \coth\Gamma_d(s)\end{bmatrix} \tag{7}$$

where $\boldsymbol{Y}_{\chi}$ is the transfer matrix admittance expression for the damaged section χ. By way of comparison, within the given notation, the admittance matrix for the case where section χ is undamaged (the pipeline is uniform) is given by (4) with

$$\Gamma(s) = \Gamma_u(s) + l_\chi\widetilde{\Gamma}(s) + \Gamma_d(s)$$

where l_χ is the length of section χ.

PIPELINE DAMAGE IDENTIFICATION METHODOLOGY

The objective of this paper is to develop a detection and identification methodology for the condition assessment of a single pipeline bounded by measurement stations. The approach involves estimating the parameters of the pipeline sections by minimizing a measure of the *goodness of fit* of the model to the data. As there are no defined inputs to this system, standard prediction error approaches (*Ljung*, 1999) cannot be used. Instead, the measure of the *goodness of fit* must be derived from analytic relationships between the measured system states. Mathematically, the analytic relationships between the states of the model are used to define the vector space that the model state lie within (*i.e.* a feasible data space, that is dependent on the model parameters), and the *goodness of fit* is defined as some measure of the distance of the measurements from this feasible data space.

Using the pipeline admittance matrices presented in the previous section, an expression of the models feasible data space is determined, from which a *goodness of fit* error function is derived.

Data space for pipeline model

Consider the segment of pipeline depicted in Figure 1(b) bounded by measurement stations 1 and 3 with a third station (station 2) in between. For pipes reach U and D between the three measurement stations, there are the following admittance relationships for the model states

$$\boldsymbol{Y}_U(s)\begin{bmatrix}P_1(s)\\ P_2(s)\end{bmatrix} = \begin{bmatrix}Q_1(s)\\ -Q_2(s)\end{bmatrix}, \quad \boldsymbol{Y}_D(s)\begin{bmatrix}P_2(s)\\ P_3(s)\end{bmatrix} = \begin{bmatrix}Q_2(s)\\ -Q_3(s)\end{bmatrix}, \tag{8}$$

where the admittance matrices $\boldsymbol{Y}_U$ and $\boldsymbol{Y}_D$ are of the form of (4) or (6) depending on whether they were damaged or not. From these expressions between the variables the feasible data space for the states $\boldsymbol{P} = [P_1\, P_2\, P_3]^T$ can be determined. Combining the expressions in (8) yields

$$\begin{bmatrix} Y_{U11}(s) & Y_{U12}(s) & 0 \\ Y_{U21}(s) & Y_{U22}(s) + Y_{D11}(s) & Y_{D12}(s) \\ 0 & Y_{D21}(s) & Y_{D22}(s) \end{bmatrix} \begin{bmatrix} P_1(s) \\ P_2(s) \\ P_3(s) \end{bmatrix} = \begin{bmatrix} Q_1(s) \\ 0 \\ -Q_3(s) \end{bmatrix} \tag{9}$$

where the elements of $\boldsymbol{Y}_U$ and $\boldsymbol{Y}_D$ are expanded out as Y_{Uij} and Y_{Dij} respectively. As Q_1 and Q_3 are unknown, only the second row can be used to define the feasible data space. That is, the only information about $\boldsymbol{P}$ that can be determined from (9) is that $\boldsymbol{y}^H \boldsymbol{P} = 0$ on $s \in \mathbb{C}$ where $\mathbb{C}$ is the space of complex numbers and

$$\boldsymbol{y}(s) = \begin{bmatrix} Y_{U21}(s) & Y_{U22}(s) + Y_{D11}(s) & Y_{D12}(s) \end{bmatrix}^H$$

where H is the Hermitian (conjugate transpose) operator. Omitting formal technical considerations, this implies that, for a given model, a feasible state vector $\boldsymbol{P}$ must be an element of the vector function space

$$\left\{ \boldsymbol{P}(s) : \mathbb{C} \mapsto \mathbb{C}^3 | \boldsymbol{P}(s) \perp \boldsymbol{y}(s) \text{ for all } s \in \mathbb{C} \right\}. \tag{10}$$

Geometrically this has the interpretation that, at each point $s \in \mathbb{C}$, $\boldsymbol{P}$ lies in a 2-D complex plane that is orthogonal to $\boldsymbol{y}$.

Parameter identification methodology

The vector function $\boldsymbol{y} = \boldsymbol{y}(\boldsymbol{\theta}, s)$ is a function of the system parameters $\boldsymbol{\theta}$ (*i.e.* roughness, wavespeed, *etc.*) and hence, so is the space (10). Given (10), a natural measure of the distance of the measurements $\boldsymbol{P_m}$ of the states $\boldsymbol{P}$ from this space is

$$\boldsymbol{P_m}^H(s) \left[\boldsymbol{y}(\boldsymbol{\theta}, s) \boldsymbol{y}^H(\boldsymbol{\theta}, s) \right] \boldsymbol{P_m}(s) \tag{11}$$

which is clearly only zero when $\boldsymbol{P_m}$ is in the set (10) and is greater than zero otherwise. From a parameter identification perspective, if $\boldsymbol{P_m} = \boldsymbol{P}$ (*i.e.* it is a perfect measurement), then (11) will be zero when $\boldsymbol{\theta}$ is the true value of the model from which $\boldsymbol{P_m}$ was measured.

The frequency-domain data consists of measurements $\boldsymbol{P_m}$ at discrete frequencies (*i.e.* as would arises from the discrete Fourier transform). That is, the data consists of $\boldsymbol{P_m}_n = \boldsymbol{P_m}(i\omega_n), n = 1, \ldots, N$ where ω_n are the measured frequencies (or Fourier frequencies). Motivated by (11), the *goodness of fit* error function for the model is

$$E(\boldsymbol{\theta}) = \sum_{n=1}^{N} \boldsymbol{P_m}_n^H \left[\boldsymbol{y}^H(\boldsymbol{\theta}, i\omega_n) \boldsymbol{y}(\boldsymbol{\theta}, i\omega_n) \right] \boldsymbol{P_m}_n \tag{12}$$

and the associated optimal parameter estimate is

$$\widehat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta} \in \boldsymbol{\Theta}} E(\boldsymbol{\theta}). \tag{13}$$

where $\boldsymbol{\Theta}$ is the set of feasible values for $\boldsymbol{\theta}$.

EXAMPLES

Two numerical examples are presented below to demonstrate the utility of the proposed method. The example system is depicted in Figure 1(c), where the test section to be identified is between stations 1 and 3.

Preliminaries

The nominal pipeline properties for Figure 1(c) are: wavespeed c_o = 1000 m/s and relative roughness $(\epsilon/D)_o$ = 0.001. The damaged section, taken as a corroded section with a spalling of the internal m=cement mortar lining, was modeled as having a slightly increased diameter D_χ = 610 mm, a reduced wavespeed c_χ = 850 m/s and an increased relative roughness $(\epsilon/D)_\chi$ = 0.02. Two cases were considered, case 1 which involved a nominal size damage of length l_χ = 6.8 m, and case 2 which involved a small damage of length l_χ = 0.85 m.

All pipelines were modeled as unsteady turbulent pipes using the model of *Vardy and Brown* (2007). The transient generation was taken as the time varying flow excitation located as the end of the 45 m branch. This was modeled as a constant base demand superimposed with a time varying multisine outflow taking frequencies from 0 to 30 Hz (the resultant flow took values on the interval [0.198,0.202] m^3/s). The time-domain data was generated by a method of characteristics hydraulic solver, where a time step of 0.001 seconds was used and the computational grid was generated so as to ensure a Courant number of 1 in all reaches. The simulations were performed until the system was approximately in a steady-oscillatory state. To model the inaccuracies in the measurements, the time-domain data was contaminated by independent Gaussian $\mathcal{N}(0, 0.01)$ variates (in meters of head). The frequency-domain data used by the identification methodology was generated by a discrete Fourier transform of the contaminated time-domain data.

The variable set to be estimated was comprised of[1], the damaged section parameters (location x_χ, l_χ, c_χ, D_χ, relative roughness $(\epsilon/D)_\chi$, and the steady-state Reynolds number $\mathbb{R}_{e_\chi}$) and the nominal undamaged pipeline parameters (c_o, $(\epsilon/D)_o$, $\mathbb{R}_{e_o}$) This created a total of 9 parameters in $\boldsymbol{\theta}$. The estimate $\widehat{\boldsymbol{\theta}}$ in (13) was computed using an evolutionary approach by way of the particle swarm optimization (PSO) algorithm[2] (*M. Clerc*, 2002).

Results and discussion

Statistics for the parameter estimates $\widehat{\boldsymbol{\theta}}$, based on 10 trials (each with a different noise sequence), are given in Figure 2(a) for case 1 and Figure 2(b) for case 2. For case 1, the majority of the parameter estimates are highly accurate with very little error

[1]The Reynolds number required estimation as it is a parameter of the *Vardy and Brown* (2007) model. Note that $\log_{10} \epsilon/D$ and $\log_{10} \mathbb{R}_e$ were estimated as they yielded a better paramterization for the computation of (13).

[2]A toroidal grid neighborhood structure was used with 81 particles and a termination criteria of 1000 iterations.

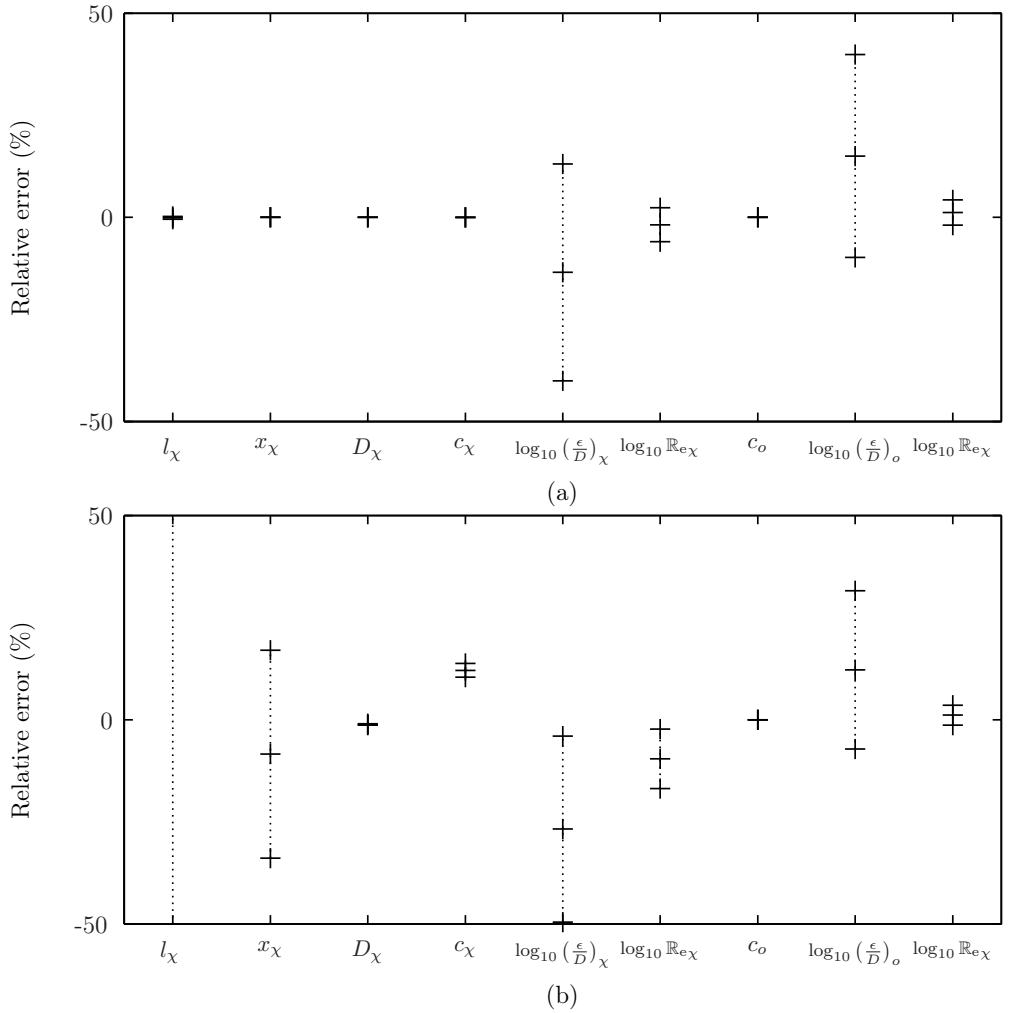

Figure 2: Relative errors of the parameter estimates for (a) case 1 with damaged section length l_χ = 6.8 m, and (b) case 2 with l_χ = 0.85 m. The relative errors are defined as $(\widehat{\theta} - \theta)/\theta\%$. The results are based on 10 trials (each with a different noise sequence) and are presented as the mean (centre bar) $\pm$ the standard deviation (upper and lower bars). The relative error statistics for l_χ in case 2 is 4.16$\pm$6.22.

and variance. This is particularly the case for the important parameters that locate the damage (x_χ), provide indications of its extent (l_χ) and degree of severity (D_χ and c_χ). The actual values for these estimates are given in Table 1, where the consistent high accuracy of the estimates is clear.

The $\mathbb{R}_e$, and to a greater extent, ϵ/D, parameters were not estimated with the accuracy of the other parameters. The $\mathbb{R}_e$ estimates were only slightly biased with a moderate variance, but the ϵ/D parameters were biased (with means 13% to 15% rela-

Table 1: Estimate statistics for important damage parameters. Statistics are based on 10 trials, each with a different noise sequence.

case	parameter	unit	actual value	estimate statistics	
				mean	standard deviation
1	l_χ	(m)	6.80	6.79	0.02
	x_χ	(m)	370.00	370.00	0.01
	D_χ	(mm)	610.00	609.94	$O\{10^{-5}\}$
	c_χ	(m/s)	850.00	849.74	0.42
2	l_χ	(m)	0.85	4.39	5.29
	x_χ	(m)	370.00	434.27	193.92
	D_χ	(mm)	610.00	602.79	$O\{10^{-3}\}$
	c_χ	(m/s)	850.00	952.69	14.32

tive error). Experience has shown that the error function (12) is typically less sensitive to these parameters. However, from a detection perspective, the accurate estimation of these parameters is secondary to the estimation of the damaged section parameters.

The performance of the nominal pipeline parameter estimates are similar for case 2 as with case 1, but the damage section parameter estimates are very different for l_χ, x_χ, and c_χ, as demonatrated in Figure 2(b) and Table 1. A positive error is seen in the estimates for wavespeed c_χ and, to a greater extent, the damage length[3] l_χ. Despite the large relative error for l_χ, the sample mean estimate was within a few meters of the actual damage length. The location estimate possesses an error of about -8 % (64.3 m), but the actual x_χ value is well within a standard deviation of the estimate, implying the promising result that, with a greater number of trials, the sample mean of estimates could yield a more accurate approximation of the true value.

The performance of any identification methodology is fundamentally dependent on the excitation of the system possessing a sufficiently broad spectrum. For pipeline systems, the impact of a damage is known to have a greater influence on the high frequency behavior of the system. Therefore, the lower performance of the small damage case 2 could be attributed to the fact that the system was only excited up to 30 Hz, meaning an excitation containing higher frequencies could yield an improved identification performance.

As a final comparison, the fit of the true damage location model was compared to the alternative models. The true model is the *damage in upstream section* model, and the two incorrect models are the *damage in downstream*, and the *no damage* models. Note that these models refer to the forms of the admittance matrices in (8). To undertake this comparison, the incorrect models were fitted to the perfect data to determine the smallest possible E value they could achieve. Table 2 presents the results of this

[3]These parameters are, to some extent, correlated in their influence on E as a larger damage length requires a higher wavespeed for the frequency response harmonics of the model to be more aligned with that of the measured system.

Table 2: Comparison of minimum error values for the three models . The upstream model values are the mean±standard deviation from 10 trials on noisy data, whereas the values for the other models are based on noise free data.

case	l_χ	damage model errors		
		upstream section	downstream section	no damage
1	6.80	0.0034 ± 0.0001	0.0610	0.0647
2	0.85	0.0041 ± 0.0021	0.0089	0.0098

comparison. For both cases, the true model fitted to the noisy data yielded a better fit than the incorrect models fitted to perfect data. This is a very promising result meaning that, even in the instance of inaccurate parameter estimates as with case 2, the true model can be detected as it yields a lower error value.

CONCLUSION

This paper has presented a frequency-domain methodology for the the identification of damage parameters within a section of pipeline bounded by pressure sensors. The methodology involved computing the minimizer of an error function derived from analytic relationships between the pressure sensors. Case studies involving a section of pipe over 2.6 km in length were presented where a damaged section 6.8 m long was identified with high accuracy, but a shorter damaged section (0.85 m) was not able to be identified as accurately (a explanation for this could be that the excitation was not sufficiently broad spectrum). This methodology shows great potential for future development and application.

ABSTRACT

The evaluation of risk at the individual pipe level can play an important role in the rehabilitation planning of water distribution systems. Yet pipe segments are generally arbitrarily defined in GIS or other databases and individual sections rarely make suitable rehabilitation entities on their own. In reality, groups of pipes need to be considered together for viable projects. The ability to group neighboring segments either prior to or subsequent to risk analysis has the potential to facilitate analysis and/or the actual practical rehabilitation. This paper looks briefly at the assessment of risk at pipe level before discussing how individual segments of pipe can be grouped into meaningful entities before or after such analysis. The objective is to maximize the benefit, in terms of risk avoidance, whilst minimizing the number of multi-segment pipes proposed for rehabilitation. Data from case studies are used to illustrate any advantages or shortcomings of the methods proposed.

INTRODUCTION

Rehabilitation of drinking water mains provides water companies with a great technical and strategic challenge, as well as a huge financial burden. For this reason, effective and pro-active asset management has taken on a very important role in recent years. During the last decade or so, tools and strategies have been developed to aid water companies, such as *CARE-W* (Saegrov) in Europe, *PARMS* in Australia and *WARP* in Canada. These have led to applications and implementations all over the world, including the USA. These tools and the models behind them continue to evolve. However, it is important to put them into context too, and ensure that they are optimized for practical use.

The key word that links these approaches is **risk**, defined as the probability of a failure multiplied by its impact (consequences). Risk can be considered at both the macro level (i.e. groups of pipes with similar characteristics) and the micro level (individual pipes). This distinction ultimately affects the final choice of

rehabilitation candidates. Working at the macro level allows an overall strategy to be realized, but the varying performance of pipes of a seemingly similar nature means that rehabilitation might not be fully optimized. On the other hand, considering each pipe in turn may not be conducive to effective practical rehabilitation. Of particular relevance here, is the spatial aspect – replacing a mile of connected pipes in one zone is likely to be more desirable than replacing the equivalent length, comprised of 6m sections, all over the city. The challenge is to combine the macro and micro approaches and define rehabilitation projects that are optimized in terms of both risk reduction and spatial proximity. In order to do this individual pipes have to be grouped with one or more neighboring pipes to form new multi-segment entities. Whether this should be done before or after risk analysis and evaluation is the subject of this paper.

DATA AND GIS

Data is crucial to rehabilitation planning and establishing a transparent and well-maintained database should be the first priority for any utility wishing to improve their asset management. Perhaps the biggest single aid to data management has been the introduction of Geographical Information Systems. GIS now forms the backbone of most utilities' data management systems. The ability to view spatial data has considerable advantages in rehabilitation planning. Knowing which pipes are physically connected or in close proximity carries far more significance than "anonymous" identification numbers in a conventional database. Although GIS is widely used for visual purposes, spatial attributes are not yet incorporated into many models, meaning that there is still untapped potential in this information.

There is though, a fundamental question which needs to be asked: "*What constitutes a pipe in a GIS or other form of rehabilitation database?*" Typically, this definition is left to the whim of the water company and the reason they created their database in the first place. While this may be adequate for day-to-day operation of the network, it is unlikely that the majority of pipes in the original database will be of a length suited to rehabilitation planning (i.e. neither too short, nor too long).

Another problem that rehabilitation planners face is the inherent dynamic nature of databases. Old pipes get removed, replaced or patched up; new pipes get added and so forth. So in time, the network can change significantly in appearance, yet break prediction models have to use consistent definitions for each pipe. There are though, some golden rules that help maintain clarity and form part of good database management practice:

- Never reuse ID numbers
- Always keep a track of all changes to pipes, in particular the date of these changes
- Make sure maintenance records always reference the pipe ID
- Never delete data for pipes no longer in service

RISK

There are several drivers of risk, most notably structural failure (breaks and leaks) but also hydraulic performance and water quality. Models such as *PHM* (Eisenbeis) and *Leyp* – Linear Extended Yule Process (Le Gat) use physical and environmental attribute data and previous break history to predict the future break rate of any pipe at any time. These failure prediction models also helps establish the relative impact of the different risk factors (such as diameter, material type, soil type or traffic loading). If structural integrity is the driving force behind the rehabilitation program, then such a model can help establish a priority list of candidates. However, a high break rate pipe in a low population-density area might be considered less of a risk than a pipe that is likely to break less often but is in the middle of downtown, for example. For this reason, sorting the pipes by predicted break number (or rate) might not tell the whole story. What it does do though, is provide a method for the validation of the model and also the theoretical evolution of the overall break rate.

Model Validation

Given adequate historic data (generally seven or more years of break and rehabilitation information), the model can be calibrated over a shorter period and actual breaks compared to predicted breaks during the remaining years. The following steps are taken:

- Sort pipes by descending **predicted break number** (favors longer pipes) or descending **predicted break rate** (favors shorter pipes)
- Calculate the cumulative length of pipe
- Calculate the cumulative number of breaks observed (this can be considered as the maximum number of breaks that could have been avoided if the current pipe and all those above it had been rehabilitated)
- Calculate the cumulative number of breaks predicted
- Calculate the relative cumulative length of pipe
- Calculate the relative cumulative number of breaks observed
- Calculate the relative cumulative number of breaks predicted

Figure 1 shows an example of a validation curve (also referred to as the benefit index). The bottom left hand corner is the most useful part as this relates to the pipes that would be replaced first if this ranked list was the sole method for choosing rehabilitation candidates. Replacing 0.5% of pipes in a year would require 200 years to replace the whole network. If pipes were replaced randomly, this would correspond to 0.5% of the breaks too. Several case studies have shown the ability of the *Leyp* model to provide good break rate estimations (hence the proximity of the actual and predicted graphs). However, it is the ranking ability that provides the most use – particularly for pipes that have no recorded breaks yet.

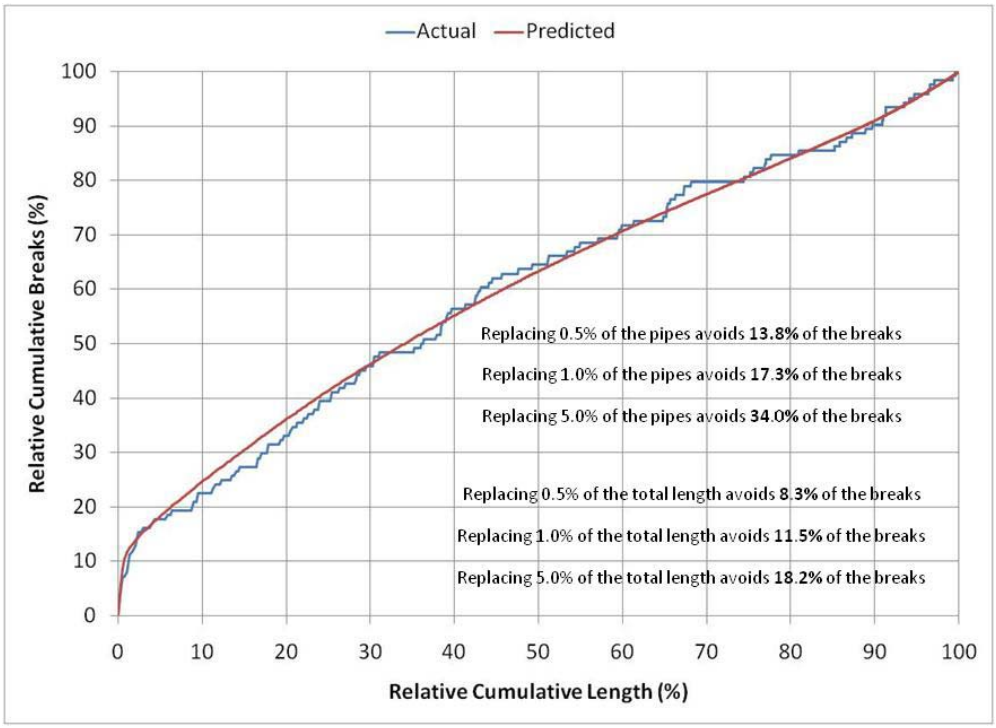

Figure 1: Validation curve based on results from the Leyp model and pipes ranked by decreasing predicted failure rate

Theoretical break rate evolution

By again making the assumption that pipes are replaced one-by-one according to their predicted break number/rate, it is possible to study the likely evolution of the break rate if different rehabilitation strategies (i.e. pipe mileages) are followed. In this case, the following steps are taken:

- Use *Leyp* to make break predictions for the next 20-25 years
- Sort pipes by descending predicted break number (favors longer pipes) or descending predicted break rate (favors shorter pipes) for the next year
- Calculate the cumulative length of pipe
- Sum the predicted breaks for each year
- By making the assumption that rehabilitated pipes inherit a negligible break rate for the rest of the study period (not necessarily the case), repeat the summation for each strategy but subtract the breaks corresponding to pipes that would be rehabilitated. For example, assuming rehabilitation of five km per year, in year one, the top five km will have zero predicted breaks and in year two, the top 10 km and so forth.

Figure 2 shows an example of such a break evolution.

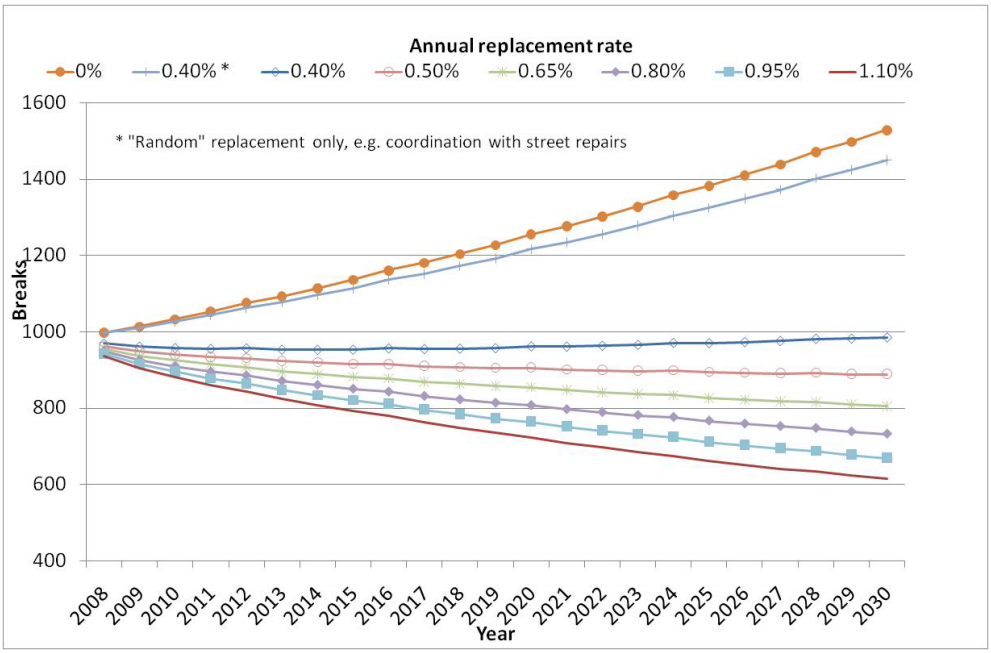

Figure 2: Example of break rate evolution according to different rehabilitation strategies

It is worth remembering that this is the maximum achievable benefit – inclusion of any lower ranked pipes as part of the rehabilitation total would lower the effectiveness. So, in effect this can be used as a benchmark for the maximum theoretical benefit. The reliability of predicted break rates so far in the future is less certain but in reality, break predictions can be updated on a yearly basis with new break data. It is certainly useful to establish the approximate rehabilitation rates that are required to stabilize or decrease the annual break rate.

GROUPING OF PIPES

In order to assess to what extent pipe definition affects break prediction results and to determine the optimal configuration, one must be able to manipulate the database, either by grouping or dividing pipes. This is best illustrated with a couple of examples:

In *figure 3(a)*, pipes A, B and C each have one recorded break. If the pipes are treated separately then the only two clues to the break frequency are:

1. The time between the start of break observations and the break
2. The time between the break and the end of the break observations.

In *figure 3(b)*, there is now a single pipe (D) with three breaks. Now there are four pieces of useful information:

1. The time between when break observations began and the first break
2. The time between the first and second breaks
3. The time between the second and third breaks
4. The time between the third break and the end of the break observations.

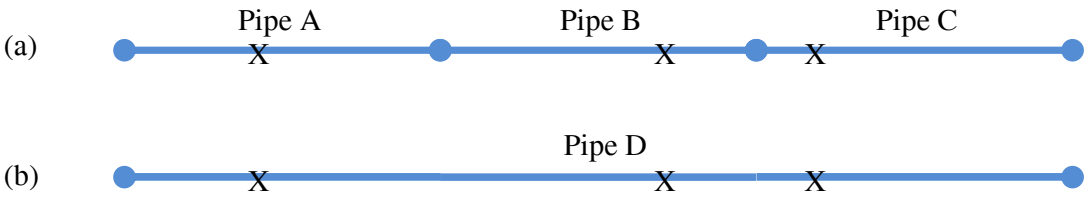

Figure 3: Grouping pipes

Although this paper focuses on pipe grouping, there are cases where the opposite is needed. In *figure 4(a)*, pipe E is very long and has three breaks in close proximity. Replacing the whole pipe may be expensive and unnecessary. Hence, it may be better to divide the pipe into two (F and G) as per *figure 4(b)*.

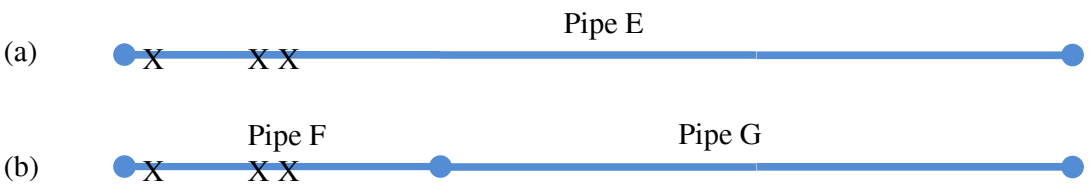

Figure 4: Dividing pipes

Having established that grouping pipes into multi-segments might be beneficial, the question remains at which point to carry out this aggregation. Pre-analysis grouping has the potential to facilitate analysis; post-analysis grouping has the potential to facilitate practical planning or rehabilitation projects.

Pre-analysis grouping

The grouping of pipes prior to any analysis means that the pipe attributes have to be considered. Obviously, grouping a 100 year old cast iron pipe with a brand new PVC one is pointless, as only one set of physical attributes could be used in any subsequent model. So it makes sense to create a list of rules for grouping pipes, for example:

- Pipes must be of the same material
- Pipes must be of the same diameter (or within a certain tolerance)
- Pipes must be of the same age (or within a certain tolerance)
- Total length of grouped pipes must be no longer than a predetermined threshold

Applying strict rules (i.e. no tolerances) has strong merits as pipes laid at the same time are likely to have the same "hidden attributes" (e.g. from the same batch from the same manufacturer). Often pipes from a particular period and sometimes a particular diameter show higher break tendencies than other pipes that would

otherwise appear to be fairly similar in characteristics. It is worth looking at the descriptive statistics of the data set (break rates for different attribute values) to establish if there are any trends that could influence the choice of grouping rules.

There are several methods for the actual grouping of pipes, ranging from advanced graph theory to simplified connectivity algorithms using common pipe nodes. Hydraulic modeling also relies on simplified versions of networks, so there are parallels to be made here. A reasonable degree of localized homogeneity is to be expected because of the way networks are originally designed. This could potentially lead to very long multi-segmented pipes, hence the reason for establishing a maximum length. For the purpose of this research, a single chain of grouped pipes was preferred to a group consisting of many "antennae". Two suggestions are made to achieve this:

1. Only consider grouping pipes that have a single neighboring pipe at each node
2. If a pipe has several neighboring pipes eligible for grouping, choose the longest

Additionally, many networks contain similar pipes separated by a short section of pipe that has been added after a break. These too can be grouped into a single pipe with the attributes of the longer segments being preserved. The following steps should therefore be implemented for pre-analysis grouping of pipes:

- Define the rules for grouping
- Eliminate sandwiched pipes as necessary
- Begin with any pipe (preferably with a single neighboring pipe) and test whether the two pipes can be grouped according to the rules
- Create two lists – one with the old (ungrouped IDs) and the new ID and one with the new IDs and all the IDs of the old pipes it regroups
- Continue, if appropriate with the next neighboring pipe or restart with another pipe
- Make sure that each pipe is only included in one new pipe group.

Post-analysis grouping: The grouping of pipes after any analysis means that the pipe attributes are less relevant (other than with respect to potential rehabilitation techniques maybe). This means that the 100 year old cast iron pipe **can** be grouped with the brand new PVC one if both are considered at risk. Nonetheless, rules can be used to limit the grouping options such as:

- Pipes must be of the same diameter
- Pipes must be in the same street

Grouping should be based on minimizing the overall risk. So far, only the break rate of grouped pipes has been used in this optimization. However, as previously stated, the ideal scenario is to use a score or categorization based on all the calculated risks and indeed opportunities (such as coordination with street repairs).

The following steps characterize a typical post-analysis grouping of pipes:

- Define a minimum threshold length for the grouped pipes e.g. 100m
- Define a maximum threshold length for the grouped pipes e.g. 500m
- Rank the pipes by the optimization parameter (e.g. predicted break rate for the following year)
- Start with the highest risk pipe and assuming it is less than the maximum threshold length find all its neighboring pipes
- Group with the neighboring pipe that together maximizes the optimization parameter
- Create two lists – one with the old (ungrouped IDs) and the new ID and one with the new IDs and all the IDs of the old pipes it regroups
- Stop if combined length now exceeds the maximum threshold length and begin with next pipe in the list that is not already part of a new group
- Continue regrouping if combined length is less than the minimum threshold length
- If the combined length is between the thresholds, only continue if adding another pipe increases the overall risk
- Make sure that each pipe is only included in one new pipe group.
- Rank the new multi-segment pipe groups

So at the end of the exercise, several viable rehabilitation projects have been created. Obviously these can be "fine tuned" using GIS to consider other pipes in the vicinity. As a useful indicator of efficiency, it is possible to refer back to the benefit index and see how replacing the new groups of pipes compares to spot replacement of individual pipes at risk.

CASE STUDY RESULTS AND DISCUSSION

Several pipe grouping studies have been carried out on European networks as part of larger break prediction and rehabilitation planning studies. Earlier research has concentrated on the grouping of pipes prior to running the *Leyp* model (Poulton). Interestingly, the study showed a slight decrease in performance using grouped pipes as opposed to the original configuration. Grouping not only results in fewer entities overall, but also fewer entities with one or more breaks. The apparent consequence of this was to decrease the effect of previous breaks and dampen the model's parameters, so as to weaken its ability to discriminate the break risk. It should be noted that only one dataset was used in the study and further studies are needed to confirm whether this is always the case.

From a practical perspective, pre-analysis grouping is very subjective because of the choice of rules and the chosen algorithm for regrouping. It is always recommended to first carry out the analysis with the original dataset. Should this produce satisfactory results (in reference to the model validation), then pre-grouping might be avoided altogether. In cases where the network is very fragmented though, it might be worth experimenting with grouping pipes.

Using the same original dataset, post-analysis grouping was proposed. Six separate simulations were performed with the following characteristics:

- Minimum "path" (i.e. chain of grouped pipes) length = approx. 150m
- Maximum path length = approx. 400m
- Pipes sorted by predicted break number (PBN) or predicted break rate (PBR)
- Paths restricted to same street? (yes or no)
- Diameter restrictions (all pipes can be grouped or only those <=300mm)
- Number of paths created
- Number of streets
- Number of pipes included in a path (total pipes = 216524)
- Total length of paths (total pipes = 8250km)

Table 1 summarizes the simulations and *table 2* summarizes the distribution of the number of pipes per path. Each simulation was able to create new multi-segment paths totaling more than half of the total network length, albeit that a large number of pipes already fell between the two threshold lengths and can already be considered as rehabilitation entities on their own. The remaining "orphaned" pipes were less than the minimum threshold length. Many of these could be added to rehabilitation projects during "fine tuning" if required, especially considering originally, 13% of the pipe segments had a length less than 5m and 38% less than 10m.

Table 1: Summary of grouping simulations

Sim. No.	Pipes sorted by	Same street	Diam	No. paths	No. streets	No. pipes	Length (km)
1	PBN 2008	Yes	All	24200	24200	76990	4980.0

To evaluate the benefit of post-analysis grouping, it is useful to make comparisons with results from individual pipe risk evaluations. Table 3 shows the following information:

- 4 rehabilitation strategies (15, 20, 25 and 30 km per year)
- For each simulation 1 to 6, paths are sorted by decreasing break rate
- PBN 2008 = original pipes sorted by descending predicted break number
- PBR 2008 = original pipes sorted by descending predicted break rate
- Number of paths, streets and pipes for the corresponding rehabilitation length
- Breaks 2008 = total breaks on groups of pipes comprising the corresponding rehabilitation length
- % PBR 2008 = percentage of maximum breaks (achieved by sorting by PBR)

Table 3: Comparison of break predictions for grouped pipes

The number of predicted breaks belonging to the paths selected for each rehabilitation strategy lies between the values obtained if sorting individual pipes by predicted break number (fewer pipes for any given rehabilitation length but also

fewer breaks "avoided") or predicted break rate (maximized "avoided" breaks but far more pipes). The grouping of pipes has a dramatic effect on the number of discrete rehabilitation projects that would be required and this is seen as a major benefit. The best way of grouping pipes, in terms of break avoidance potential, would appear to be using pipes with a high predicted break number (longer pipes) as starting points and building multi-segments from there irrespective of diameter or whether they lie on the same road.

CONCLUSIONS

The following conclusions can be drawn from this study:

- Spatial grouping of pipes has an impact on practical rehabilitation planning. The aim is to produce the most benefit in terms or risk prevention from the fewest separate physical interventions.
- Grouping prior to risk analysis is possible but the benefit remains inconclusive. In some cases this may improve or facilitate the analysis, while in others, the predictive capability of the risk model may be adversely affected.
- Grouping after risk analysis has clear advantages over treating each individual pipe as a separate rehabilitation project. In terms of likely break avoidance, this results in a slight decrease whilst dramatically reducing the number of rehabilitation entities.
- Further research should focus on optimizing all risk factors rather than just breaks.

Abstract

This article presents a new tool that supports real-time corrective maintenance of water distribution systems (WDS). This tool integrates Geographic Information Systems (GIS) with hydraulic modeling of WDS, providing a graphic interface in which, in the case of a failure, the operator can select the damaged pipe (usually a burst pipe), obtaining the following information from the support tool: (1) the exact valves that need to be closed to isolate and repair the burst pipe; (2) the amount and cost of water that is lost while the damage is not fixed; (3) the users that are left without service when closing the valves identified in (1); (4) the amount and cost of water required by users but not supplied to them because of the damage. In the developed tool, the identification of the valves that must be closed to isolate the burst pipe is carried out by means of a Recursive Iterative Algorithm (RIA). On the other hand, for the loading and display of information in the GIS, binary search and a fast ordering technique, known as Quick Sort, are used. The developed tool was applied to the WDS of Sector Estadio (250,000 inhabitants), which is a complex area of the city of Bucaramanga (Colombia); it proved to be a valuable operational tool which could also be useful for prioritizing damage repair.

1. Introduction

In water distribution networks (WDN), corrective maintenance consists of the actions taken by the WDN operator to fix bursts or other damages that can occur in pipes or other elements of the network, in order to restore the system to operational status. These damages are usually caused by material wear, extremely high pressures, changes on the operation of the system, construction works close to the pipes, soil displacement, among others, and its occurrence is usually reported to the WDN operator by neighbors and passers-by.

Unlike preventive maintenance, in corrective maintenance the repair works are undertaken only after the damage has occurred; therefore, the WDN operator must always have

personnel, vehicles and materials available to repair any damage and should do it as soon and efficiently as possible. Besides, given that a regular supply of potable water is a vital necessity for any community, when service disruption is unavoidable it should not take place without giving prior notice to the users and without previously making sure that the valves that are closed to carry out the maintenance work are those which affect the least amount of users as possible. Because of this, for corrective maintenance purposes it is necessary to have computational tools that can rapidly give precise answers and information to help the personnel at the office make timely, clear and efficient decisions regarding the repair works that must be carried out. Furthermore, complete topological information of the WDN, including the location and state of all closing valves and the position of the consumption node to which each subscriber is connected, is also required for corrective maintenance purposes.

Knowing the importance of having a tool capable of optimizing repair and maintenance works and supporting decision making in water supply companies, the University of los Andes suggested to the Metropolitan Aqueduct of Bucaramanga (company which is in charge of the operation of the WDN of the city of Bucaramanga, Colombia) to take advantage of the recent and available knowledge on WDN modeling and on geographic information systems (GIS). The idea was to create and implement an innovative software which allowed to determine, in real time, the valves that need to be closed in order to isolate the area where a damage (usually a burst) has occurred and to identify the exact users or subscribers that would be affected by this situation. As will be explained, the developed software not only carries out the mentioned tasks (i. e. identification of closing valves and affected users), but goes a step further, since it also provides essential information for the prioritization of damage repair, which is critical for the integral management of WDN.

It is worth mentioning that, as any other tool which serves as a support for corrective maintenance, the developed software incorporates as its functional core a hydraulic model of the WDN, since it allows running algorithms that seek to model and predict the behavior of the network when a change is made to its operational scheme. Thus, if the characteristics and state of each of the components of the system are not well known and if the hydraulic model is not calibrated (i. e. if it does not represent the performance of the real system), it is not possible to make appropriate decisions in order to optimize the operation and maintenance of the WDN and the support tool would be worthless. For corrective maintenance purposes, it is essential to know precisely the location, characteristics and state of each of the valves of the network, given that these elements have a great impact on the hydraulic behavior of any WDN and allow isolating the burst pipe which must be repaired. Moreover, the calibration of the model which will be used in the developed software must be complemented by a complete database of users' information, containing their geo-location and current water demand; with this information, it is not only possible to make a proper allocation of water consumption along the model, but also to determine the impact and the area affected by a burst.

2. Case study description

As is common for any WDN operator, the Metropolitan Aqueduct of Bucaramanga (AMB for its initials in Spanish) has to deal with unpredictable damages that occur along the network, which must be repaired by the company to fulfill the good quality and continuous service standard inherent to all water supply activities.

In the city of Bucaramanga (located in the northeast area of Colombia, with a population of 1.1 million), the process begins with the detection of the damage: once the water reaches the surface, it is reported by passersby, neighbors or, in some cases, by company employees. To report the damage, the person who saw it communicates with the company's Call Center, where an operator is in charge of identifying, through a series of simple questions, the location and extent of the damage. When the person who witnesses the damage is a company employee, he/she reports it directly to the unit responsible for repair works, which is known as Maintenance Section.

This report is stored in a SAP (*Systeme, Anwendungen und Produkte*) tool, which is used by the company to allow Maintenance Section to have access to this information, since they are located elsewhere in the city. Then, according to the location of the damage, each report is assigned to one of the subareas into which the city is divided; lastly, the order in which each damage will be repaired is determined subjectively (based on the description of the damage and on the knowledge and skills of each repair team).

Once the repair works have been assigned, maintenance teams are sent to each subarea with the materials and tools necessary to repair the majority of the damages. One of the first tasks they must complete after verifying the existence of the damage is to determine, based on their experiences, knowledge of the network, and some physical maps (which contain the network layout), how the burst pipe is connected to the rest of the system and which are the valves that should be closed in order to isolate it.

Since mistakes are inherent to most human activities, letting maintenance personnel decide which valves to close in order to carry out the repair works might involve some error. It is even possible that, when subjectively closing valves in the attempt of isolating a burst pipe, new nearby bursts are created by maintenance personnel. This is why it is crucial to take as much advantage as possible from the benefits that are provided by the new information technologies in terms of calculation, storage and display capacity, all of which could facilitate the identification of the valves that must be closed in order to isolate a certain pipe or area of the system. It is worth mentioning that hydraulic modeling must always be present in this process, since it indicates the possible paths through which water can reach the area of interest.

The solution presented herein to the problems associated with corrective maintenance puts together computational tools, which carry out the hydraulic modeling of a WDN, with geographic information systems (GIS), which can store georeferenced information of each component of the system. The combination of these two tools allows for the implementation of algorithms that can give a solution to the problem stated above and that

can also display the answer in a graphic interface, making it easier to understand and analyze.

3. Algorithm

I0t is important to emphasize that without knowing the hydraulics of the WDN and the location, characteristics and state of each of its elements, it is not possible to determine how to operate it in order to solve the problems stated above regarding corrective maintenance. The performance of the hydraulic model of the WDN must match the behavior of the real system; this is why it is essential to have a calibrated hydraulic model before applying the algorithm that will be next described.

In order to identify the valves that need to be closed to isolate a burst pipe, it is first selected and the node through which the water is entering the pipe is identified. From this node, a Recursive Iterative Algorithm (RIA) is used to travel across the network in the upstream direction looking for the valves that close the pathways through which the water flows into the burst pipe. In general, it is not likely to have a closing valve just before the entrance node of the damaged pipe; the common situation is to have one or more pipes connected to the entrance node and to many other nodes upstream from them. Thus, the mentioned algorithm must "recall itself" as many times as necessary until all pathways through which the water is coming into the burst pipe are identified and closed; this is the main characteristic of a recursive algorithms.

This type of solution searching strategy is known as Backtracking: with this technique, a directed entity (in this case, the hydraulic network with a specific flow direction in each of its nodes) is traversed through in order to find a solution or set of solutions that satisfy the objective of the search. In the specific case that is being described in this paper, as a valve is found when looking through a certain pathway in the upstream direction, its state is changed to "closed" and the search in that specific pathway of the network finishes. Subsequently, the algorithm starts traveling back (i. e. in the downstream direction) through the same pathway that led to the valve that has been just closed; in its trajectory, it looks for nodes which are connected to pipes that have not been traversed through by the algorithm before. When a node like this is found, a new search process begins.

Any time a valve is closed, the hydraulics of the network must be calculated again to determine the new pathways through which the water is flowing into the burst pipe. This process is carried out iteratively until the damaged pipe is completely isolated and the initial group of valves that must be closed to achieve it is identified.

An exceptional situation found during the design of the algorithm was that, in some rare cases, even after traversing through the entire network it was not possible to isolate the burst pipe. When this happens, the algorithm throws an exception and informs the user about this situation.

Once the initial group of valves that must be closed to isolate the damaged pipe is identified, an additional algorithm which evaluates "valve redundancy" is executed. Valve

redundancy takes place when some valves of the initial group can stay open while the burst pipe still remains isolated. Therefore, it is required to identify which valves must be closed and which other valves can remain open; in this way, the least amount of valves is closed and no time and resources (both human and material) are wasted in closing unnecessary valves. The concept of valve redundancy is illustrated in the following figures.

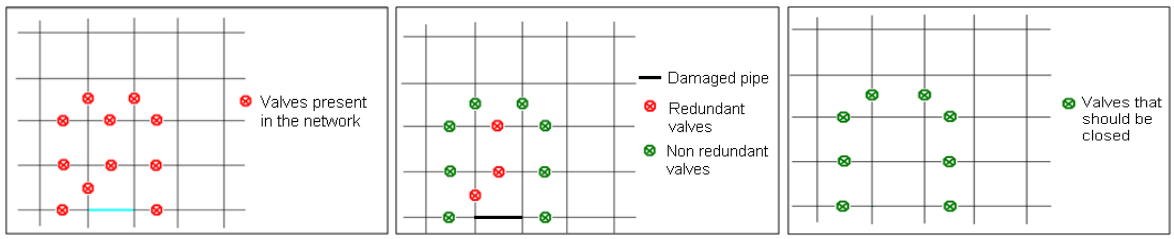

Figure 1. Valve redundancy: (a) initial group of valves of the system; (b) identification of redundant valves; (c) final group of valves which must be closed to isolate the burst pipe.

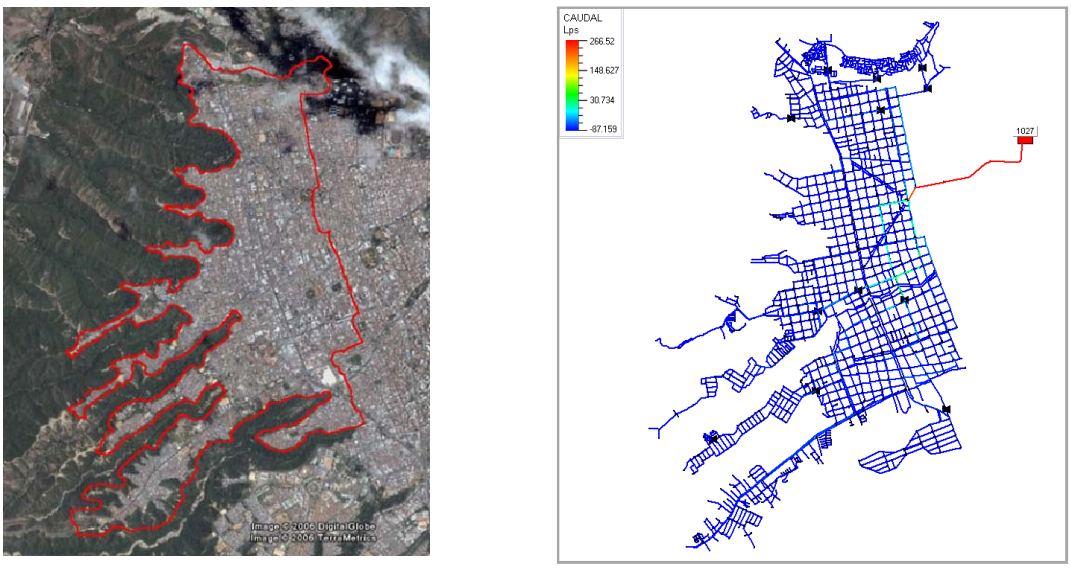

4. New software: CIERRES

CIERRES (which is the Spanish word for closure) is a computational tool implemented under the programming language *Visual Basic for Applications*, which was developed to be executed inside the program ArcGIS 9.1. Besides identifying the valves that must be closed to isolate a certain area of the WDN, *CIERRES* can also detect which users are affected by the service disruption and estimates the discharge that these users stop consuming while the damage is not fixed (i. e. the amount of water that is not sold during this time). Moreover, the program has a module which, based on the geometric characteristics and pressure regime of the system, can calculate the discharge that is lost because of the burst.

In order to obtain the required results, *CIERRES* is supported by a hydraulic modeling tool developed at the University of los Andes (i. e. hydraulic simulation software called REDES – see CIACUA, 2007b) which carries out the hydraulic calculations of the WDN and also runs the algorithm for the search and verification of the valves that must be closed to isolate the damaged pipe.

To test the program, a hydraulic model from a subarea of Bucaramanga's network was used. This subarea is known as "Distrito Estadio" and represents 25% of the city's network, supplying water for 27,000 house and commercial connections, with 5324 pipes (equivalent to a total pipe length of 1800 km) and 1772 valves.

Figure 2 shows an aerophotography of Distrito Estadio, as well as its hydraulic model.

(a) **(b)**

Figure 2. Distrito Estadio: (a) aerophotography; (b) hydraulic model.

Since *CIERRES* is connected to ArcGIS, all the geographic information is displayed graphically to facilitate its understanding and allow the georeferenced location of the users that are left unattended while repair works are carried out and of the valves that must be closed to isolate the burst pipe.

4.1. Design of CIERRES

In the design of any computational tool, it is necessary to define the architecture that it will use; it determines the functional and non-functional requirements and the constraints of the final program.

Through components and layers, the architecture seeks to define the tasks of each component, the interactions between them and their physical location. For example, in a *distributed system* its architecture is split up into components that run simultaneously on multiple computers; some of these components run from a central server and have specific security, persistence, processing and concurrence responsibilities, among others. On the other hand, in *standalone* applications the responsibilities are different; in this case, no communication is necessary between multiple computers, there are not concurrence problems, security is managed differently, among other aspects which make this type of architecture more appropriate for the requirements of the software that is being developed.

During the design of *CIERRES*, a three layer (i. e. Interface - Logic - Persistence) architecture was chosen. This structure allows for the clear division and definition of the tasks, in order to improve the understanding of the program during its implementation as well as in the case of maintenance or further improvements to the tool. Figure 3 shows the three layers that make up the new program. Within the first layer -GUI (Graphic User Interface)- are the classes related with the graphic interface, which are in charge of

interacting with the user, requesting and receiving information from him/her and transmitting it to the "Logic of the business" layer.

The "Logic of the business" is in charge of receiving the user's requests in order to represent each of the components of the network and communicate with *REDES* (a hydraulic simulation software) to calculate the hydraulics of the model, run the valve searching algorithm and extract from it the information that is required for the prioritization of corrective maintenance.

The last layer is "Persistence": it contains the classes that are in charge of extracting information from plain files and files related with the GIS used by *CIERRES*.

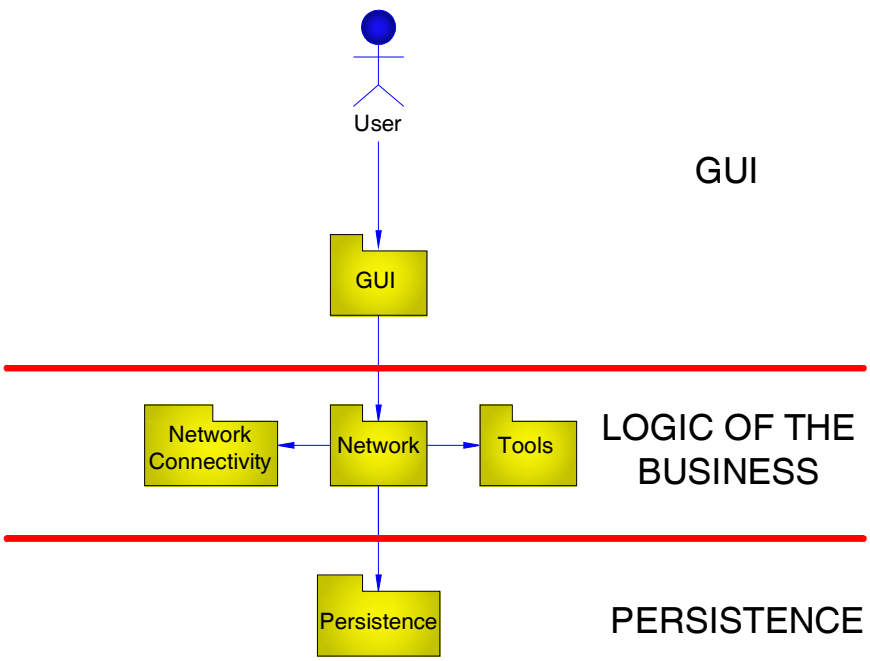

Figure 3. Three layer architecture of the program *CIERRES*.

With respect to the architecture of the program, it is important to highlight that the final application software is a *standalone* program, which means that all its components are installed and can be executed in only one computer, without requiring any connection with another computer.

4.2. Files used by CIERRES

The identification of the valves that must be closed to isolate a specific area of a WDN depends mainly on the hydraulics of the system, whose determination requires a hydraulic model of it. This model must have some special characteristics to allow *CIERRES* establishing the location of the valves that need to be closed to isolate a certain pipe.

The hydraulic models of the WDN that will be evaluated through *CIERRES* must be *.INP files, which corresponds to the type of file used in the hydraulic modeling of water distribution systems. Furthermore, when modeling WDN, there is usually not an element

exclusively aimed at simulating closing valves; thus, what is commonly done to model these elements is using short pipes whose state is changed from "open" to "closed" (as the closing valve open or closes).

For the program to identify the location and state of the closing valves, these must be represented by short pipes whose identifier starts with the letter "V". When the program detects a pipe with this characteristic (i. e. letter "V" at the beginning of its ID), it reads its state; if it is "closed", the program will know that it is a valve which is permanently closed, otherwise, it will know that it is an open valve which could be used to isolate a certain area.

Another important aspect related with the input information that must be given to the program is that associated to the spatial location of the users, its water consumption and consumption nodes to which they are connected. The information about water consumption must be provided through a plain file, which contains each user's identifier, geographic coordinates (X, Y, Z) and water consumption. The consumption node to which each subscriber is assigned is determined from the output file of the program *ASIGNA*. This program was also developed at the University of los Andes; it connects the water consumption of each subscriber to the closest node of the system.

4.3. Using CIERRES

The initial window of *CIERRES* (see Figure 4) is displayed inside the ArcMap environment of ArcGIS. In this window, the user must provide the location of the file with the calibrated hydraulic model; the location of *REDES*, which is executed underneath; and the location of the files that contain the users' geographic coordinates, demands and nodes to which they are assigned.

Figure 4. Initial window of CIERRES – options to generate shapefiles.

Figure 5 shows the graphical display of the shapefiles that were created; in this display, the yellow crosses represent the users, the nodes are shown by black dots, the blue lines

correspond to pipes, the closing valves whose state is “open” are shown by green lines, and the red lines show the valves that are permanently closed.

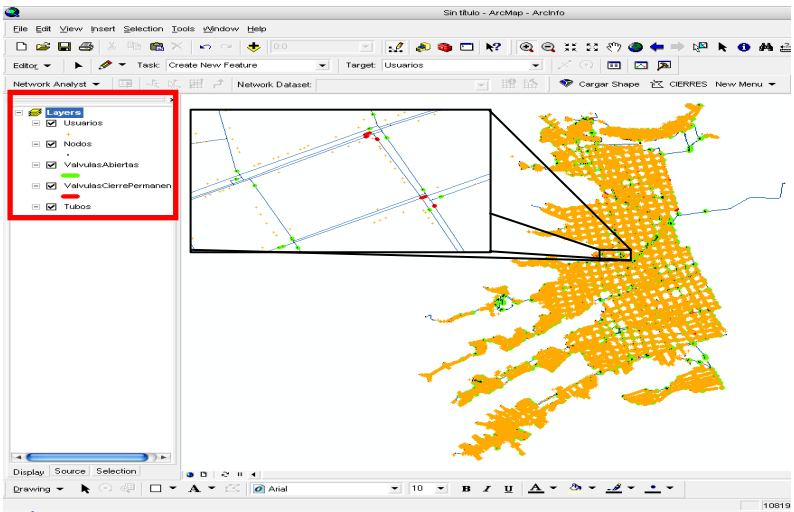

Figure 5. Graphical display of the shapefiles.

Once the input files have been processed and the shapefiles have been created, the next step is to indicate the burst pipe, so that the program can determine the area of the WDN which will be affected by the repair or maintenance works. To do this, the user must use the object selection button (see Figure 6) in order to point out the damaged pipe.

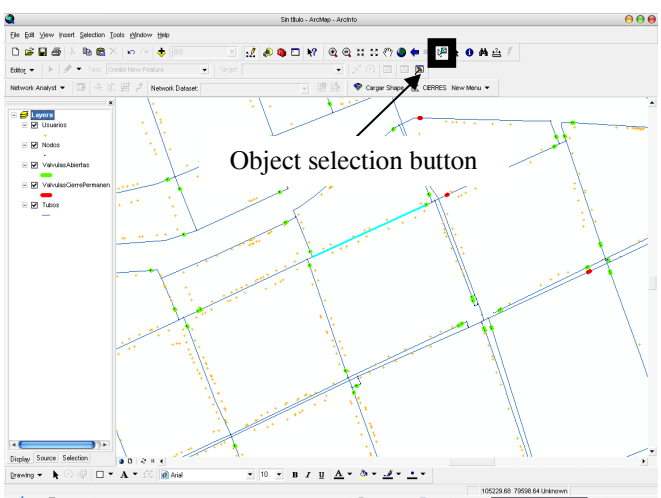

Figure 6. Selection of the burst pipe.

After the running *CIERRES*, the results are displayed in a window (see Figure 7) that shows the following items: the valves that must be closed to carry out the repair works, the users that are left unconnected (represented by black dots), and the pipe that will be repaired. In addition to this graphical display of the results, a plain file is generated which contains a report of the valves and users identifiers, as well as relevant information for the repair works.

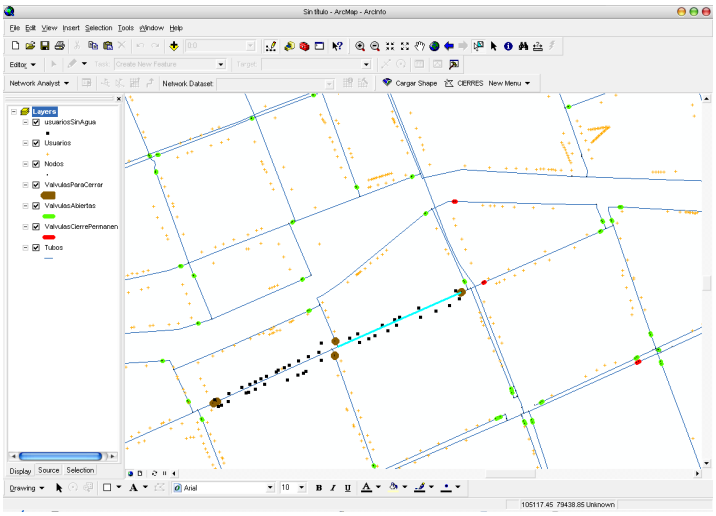

Figure 7. CIERRES response.

4.4. CIERRES as a Decision Support System (DSS)

The technologic and globalization level to which the modern world has come forces everyone to be more competitive, efficient and resourceful in order to generate good quality solution in as little time as possible. For this reason, it is important to have tools such as *CIERRES* which support the WDN operator in the decision making process, thus becoming a DSS (Decision Support System) tool.

The DSS are computational tools which help the people in charge during the decision making process, without substituting their expert knowledge. These systems use data and underlying models and are created based on the knowledge and rules provided by the experts; they facilitate the learning process of the user and put together the human knowledge with the processing capacity of the computers in order to improve the quality of the decisions and reduce the time that it takes to make them. Furthermore, the DSS are interactive, easy to use and user-friendly programs.

In the case of the Metropolitan Aqueduct of Bucaramanga, *CIERRES* was conceived as a system to support real-time decision making. Since it uses hydraulic modeling and GIS to tell the user which valves must be closed in order to isolate a certain pipe, *CIERRES* avoids letting the maintenance personnel decided it, which, as was stated before, might involve great errors and might also lead to an inefficient use of the available resources.

Furthermore, *CIERRES* allows for a continuous feedback between the model and the real distribution system; by identifying valves that are not working properly or areas whose isolation requires the closing of a great amount of valves, which leaves many users unconnected, the WDN operator can make decisions regarding the need for new valves or the need for a better division of the network into independent hydraulic sectors.

5. Conclusions

- Corrective maintenance should leave aside the empirical knowledge of maintenance crew members, which involves subjectivity and error, and should use computational tools in order to become an optimized process.

- In order to have adequate work tools that can aid WDN operators in the decision process, it is important to have a calibrated hydraulic model, which implies acquiring information of excellent quality, such as: topology, topography, users' census, registry of their historical demands, and flow and pressure measurements along the network, among others.

- Geographic information systems and advanced methodologies of programming must be combined with calibrated hydraulic models to develop support systems that enable companies to take actions on their networks, in order to improve the service, reduce the response time, and optimize repair maintenance works whenever a damage occurs.

- Reducing costs and improving service quality are issues that are generated by the use of such tools.

- When testing the developed software *CIERRES*, which combines geographic information systems with hydraulic modeling of water distribution networks, it proved to be a valuable operational tool that supports real-time corrective maintenance, making it more efficient and optimizing the use of resources required for repair works; besides, this software proved to be helpful for supporting decision making at the water supply company.

Abstract:

The purpose of this paper is to evaluate the pricing of China water utilities according to past twenty year's data. An econometric model describing both water supply and demand is specified and estimated on utilities located in the east area of China. Based on the estimated technology and demand parameters, a new method of forecasting water price is presented. It used the marginal-cost theory that is close to the historical data to establish the water price forecasting function, and according to the process of marginal-cost function to build the forecasting model. We derive the estimated parameters and discuss estimates of returns to scale and elasticity of water demand, analyzing the current pricing of water utilities by comparing marginal costs and marginal prices. In a case study of Shanghai, these estimates are then used to simulate first-best optimal pricing by solving a supply-demand system in prices and quantities. Finally, we find that the marginal cost price is the optimal pricing scheme, which is much better than fixed charge price and average cost price.

INTRODUCTION

Water is an important natural resource, and a basic necessity for human survival. Due to rapid industrial development and accelerating urbanization, the number of cities in China has increased dramatically, from 180 to 666, since the 1980s. As a result, the urban population and water demands have also increased rapidly, thus causing severe water shortages in urban areas. At the same time, the increasingly serious water pollution caused by urban development not only does great damage to human health but also intensifies the shortage of water resources.

Up to the end of 2004 in China, the total urban water supply production capability per day is about 247.5302 million m^3, compared with 142.203 million m^3 in 1990, it was increased 74%; service population is 30.33968 million persons, increased 94% contrast to 156.0010 million persons in 1990.

The capacity of public water supply increased fleetly, there are now about 3000 water treatment plants, of which the total production capacity is 167.9213 million m^3

per day. Increased 185% compared with 58.8590 million m^3 per day in 1990; service population is 266.1603 million people, compared with 112.0740 million persons in 1990, it increased about 137%; the urban public water supply capacity account for more than 68% of the total social water supply capacity, increased 27%; the ratio of urban water supply and demand increased 0.44, now reached 1.38.

In 2004 the total urban water supply is 49.03 billion m^3, in which industrial water consumption is 21.14 billion m^3 accounted for 43%; domestic consumption (included public service water consumption, housing water consumption, fire water consumption and etc.) reached 27.89 billion m^3 occupied 57%. Compared with 1990, the proportion of industrial water decreased 29%, whilst the proportion of domestic usage increased 29%.

Financial balance of water supply enterprises is very important for the safe supply of which guaranteed quality. Due to events in the past， the price of water in China is still too low to meet the operating and maintenance needs of basic water supply facilities. The price does not reflect the real usage value of water, thus resulting in over consumption. Hence, we must implement water price reform and establish a water price management system, and regulate the price through cost control. Only in that way can we recover investments, get a reasonable profit, and ensure normal operations and sustainable development.

In summary, price adjustment should be based on the following principles: cost compensation, reasonable profit, improved water saving, and equal contribution. Firstly, the price should be such that it would help to save water, and make the cost of water account for a specific portion of inhabitants' income and of industrial expenditure. At the same time, consumers' saving consciousness would be promoted, and they would stand to gain by saving water. Secondly, a reasonable charge should be levied for water resource and wastewater treatment, and a reasonable water price should be set. Thirdly, consumers' acceptance level should be considered. There should be a difference in water prices, and the price should be introduced step by step. A system of reward and punishment can be can be applied when necessary so as to save water and ensure that it is used reasonably. Finally, water should be publicized as a consumer good. A scientific water price measure and flexible price policy are also needed. The important point in price reform is to establish a proper price forming and operating system, to set up a price management system adapted to a market economy in order to let the price act in resource distribution, saving and efficient usage and, ultimately, to realize the sustainable development of water resources.

During last 10 years, water price in China have been average increased 2~10 times, especially in some well developed area. Figure 1 provides the average water consumption (liters /cap. d) and average Water Price (fen RMB/m^3) from 1980 to 2004 in China. Figure 2 depicts the water price of each province in 1999. By analyzing the water price variety with economic method, we can conclude appropriate water price. With water resources becoming more and more deficient,

how to save water usage has become an important problem in China. As one problem of water resources management, water price policy has economic lever effect and an effectively measure. Some previous studies evaluating water price efficiency have already been published, such as marginal-cost pricing(MCP)(FANG, 2004), average cost pricing(ACP)(SHI, 2003), shadow price(SP)(SHI, 2002), elastic water price(EWP)(DU, 2003). But to our knowledge, none of them use appropriate methods.

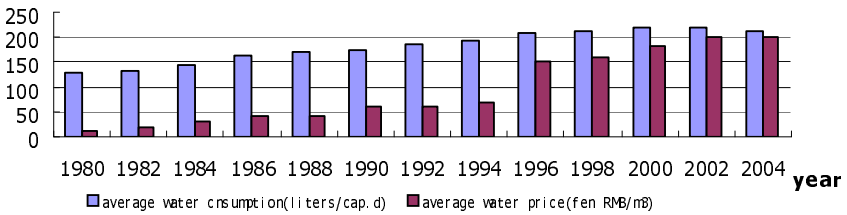

Figure. 1 water consumption and water price in China

The efficiency of water pricing is also an important concern in most developed countries. In England and Wales, the economic regulator (OFWAT) requires companies to publish their long run marginal costs. In Portugal, the 1994 Decree-Law also requires newly privatized water services to price water at a charge equivalent to the long run marginal cost. But if there is now a consensus on the importance of efficiency criteria in water pricing determination, it is surprising to note that only a few recent studies have evaluated the pricing of water utilities (WUies hereafter). See Kim(1995) and Renzetti(1999) for water pricing analysis in North America. See, for example, Mithchell(1978)for the telecommunication industry and Dimopoulos(1981) and Protti and McRae(1980) for the electric power industry.

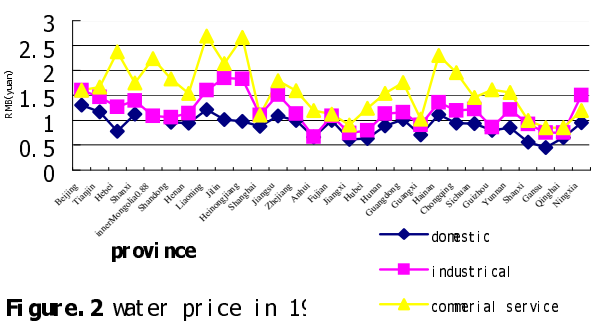

Figure. 2 water price in 19

It is also interesting to see that, while the economics literature is quite consistent in its criticisms of water pricing by WUies, only few studies have estimated the magnitude of the gains to be expected from moving to efficient prices. Moreover, estimates of welfare gains vary from one study to another. Swallow and Marin (1988) show that moving toward efficient prices will result in an increase of welfare within 2% of the

actual surplus. But Renzetti (1992) finds that a move to seasonally differentiated pricing raises the aggregated surplus by approximately 4%. This situation contrasts strongly with the exhaustive analysis of the potential welfare gains to be achieved from reforming the pricing practices of other types of public utilities.

Marginal-cost theory(MCP)

Marginal cost （MC）as a term, has been around for nearly 20 years, e. g. Mann (1982) with respect to water service and the provision of infrastructure. Marginal cost is the additional cost of producing or selling a single incremental unit, thus marginal cost of water service is the cost or saving incurred in providing more or less water service. Marginal cost has two components－short-run marginal cost, defined as the change in operating costs by changing the rate of utilization of existing capacity, and long-run marginal cost , defined as the cost of expanding capacity as well as the operating costs associated with increased capacity. In contrast to average cost, which uses embedded or historic accounting costs, marginal cost calculation involves projecting future operating and capacity costs for a specified time span by using cost changes that occur because of long-run incremental cost are concepts similar to marginal cost. Marginal cost refers to multi-unit changes. For practical purposes, incremental and marginal cost concepts are interchangeable.

Application of MCP to water price forecasting

Designing efficient water price is a crucial issue for water utilities and local communities. The first objective of a water utility pricing scheme is to generate revenues covering costs. But any pricing rate must also have two other functions: a pricing rate allocates costs between users and it has to provide incentives for efficient use and water conservation. Applying these criteria to determine the best rate structure is not an easy task. First, some of the criteria may directly conflict and require making tradeoffs among them. The balance between revenue stability and efficiency of price is an example of such tradeoff. Moreover, as water services involve high capital investments, a lot of expenses are fixed costs, which do not vary with the quantity of water consumed. This makes the allocation of costs among users more difficult to achieve.

The theoretical literature on public sector pricing prescribes the form of efficient prices for a variety of circumstances. In the simplest formulation, maximizing social welfare leads a public utility to use marginal-cost pricing (MCP). Maximizing aggregate net surplus leads to the well-known price equal to social marginal-cost rule:

$$P = \frac{\partial C(Q)}{\partial Q} + \lambda \qquad (1)$$

where Q is the volume produced by the water utility, C(Q), with $C' > 0$ and $C'' > 0$, its cost function, and λ is the marginal shadow price of water. This shadow price is positive when water is scarce or when water withdrawals have environmental impacts. If the price does not reflect the social marginal-cost, consumers do not receive an appropriate information about the societal cost of a marginal increase of demand.

Notice that the list of assumptions required for using this result is quite impressive. Among others, the demand for output must be stable, known with certainty and it must depend on no other price but its own. Furthermore, the public utility must be indifferent to the distributional consequences of its decisions and also to the possibility that its pricing may not be financially self-sustaining. MCP deserves a certain number of criticisms and gives rise to a certain number of practical difficulties. Firstly, the absence of a budget constraint may provide managers with inappropriate incentives for cost reduction. This is one of the reasons why average cost pricing (ACP) has been imposed on many regulated industries. Secondly, MCP does not reveal whether it is worth incurring the fixed costs, Coase (1946) Calviou et.al. (1993). MCP requires that the public authority decides for consumers whether they are ready or not to pay for covering total costs. Unfortunately, in many cases, the public authority may lack information to correctly implement this decision. Thirdly, MCP implies that the public utility runs a deficit if it operates under increasing returns to scale. One of the earliest criticisms of MCP is related to the distortion implied by this deficit. In the absence of lump-sum transfers, the benevolent authority must resort to distortionary taxes. Therefore, optimal pricing in the presence of a cost of public funds requires the price to diverge from the marginal-cost. An alternative solution is to use two-part tariffs with a marginal price corresponding to the marginal-cost and a fixed charge allowing to recover the deficit. Last, implementation of MCP can also generate considerable administrative costs which may counter-balance the efficiency gains. For example, MCP requires the installation of sophisticated meters capable of determining not only the total consumption level of each water user but also the time at which water consumption takes place.

Hunt & Shuttleworth (1993) discussed several advantages of a marginal costing approach, the main of which consists of encouraging investment and operation in the right direction from an efficiency point of view.

Case study in China

Shanghai is situated at 31'14' north latitude and 121'29' east longitude. Bordering on Jiangsu and Zhejiang Provinces on the west, Shanghai is washed by the East China Sea on the east and Hangzhou Bay on the south. North of the city, the Yangtze River pours into the East China Sea. Thanks to its advantageous geographic location, Shanghai has today become an excellent sea and river port, boasting easy accesses to a vast hinterland. With a pleasant northern subtropical maritime monsoon climate, Shanghai enjoys four distinct seasons, generous sunshine and abundant rainfall every year. Its spring and autumn are relatively short comparing with the summer and winter. In 2002, the average annual temperature was 17.8 degrees Celsius. The city had a total sunshine time of 1,686.5 hours in 2002 and received an annual rainfall of 1,427.9 millimeters. However, about 60% of the precipitation came during the May-September flood season, which is divided into three rainy periods, namely, the Spring Rain, the Plum Rain and the Autumn Rain.

The city had a total area of 6,340.5 square kilometers at the end of 2002, 0.06% of China's total territory. Shanghai extends about 120 kilometers in north and south and

nearly 100 kilometers in east and west. The city's 19 districts cover a total area of 5,299.29 square kilometers and its only county has an area of 1,041.21 square kilometers. The city has three islands -- Chongming, Changxing and Hengsha -- under its jurisdiction and Chongming Island is the third largest island in China, covering an area of 1,041.21 square kilometers. By the end of 2004, Shanghai's population of residents with permanent resident certificates had grown to 13.5239 million, representing 1% of China's total population. Since 1990 and particularly since the beginning of this century, Shanghai has been striving to build itself into an international economic, financial, trade and transportation center. Since 1992, the city has maintained a double- digit GDP growth rate for 13 consecutive years. In 2004, its GDP reached 745.027 billion yuan, 13.6% higher than the previous year in terms of comparable prices, representing the highest growth rate since 1996. The figure was 3.9 times that of 1990 and the average annual growth rate during the 1990-2004 period stood at 12%.

Residential affordability analysis in Shanghai

Since the beginning of reform and opening, Shanghai's economy has been developed rapidly. If dollars，Shanghai's per capita GDP was 4,172 U.S. $ to 4,515 U.S. $ from 2000 to 2001，then increased to 4,909 U.S. $ in 2002, and then to 5,642 U.S. $ per capita in 2003, Four years of aggregate growth is 35.23% per capita GDP, with a average annual growth rate of 10.59%.

Shanghai residents water consumption increased from the 682 million m^3 in 2000 to 743 million m^3 in 2003, while residents water consumption expanded 8.94%, total residents water consumption for the annual growth rate is 2.9%. Annual residents water consumption around 51.6~55.4 m^3 per capita. Per capita water consumption is between 141L/d~152L/d. During four years the residents water consumption elasticity coefficient is 2.9%÷10.59%=0.2738. Resident water consumption is about 0.27% growth each 1% growth of per capita GDP. Table 1 shows per capita GDP and per capita water consumption variety from 1990 to 2003 in Shanghai.

According to the “Shanghai Statistical Yearbook” (1990～2003), Average annual disposable income have increased from￥2,182 to￥14,867 from 1990 to 2003. Water expenditures accounted for less than 1% of per capita consumption expenditure, much lower proportion of the total disposable income, 2003 to 0.54%. The downward trend in the last three years, water expenditures is only ￥80 per capita. To further investigate the affordability of residents for water charges, the research group conducted a random sample survey, questionnaire that covers almost Shanghai. The survey shows: Shanghai residents have affordability to the adjustments of water price. The results of the survey are as following:

（1）64% of households drink barrel water that the residents have a higher water consumption；If water consumption can be directly, urban residents will account for 4% of the purchase barrels of water，88% will not buy，Improving water quality of drinking water for residents will cause a greatly cost reduced。

（2）According to questionnaire of the family’s attitude toward water expenditures monthly, it is not a burden for 30%; and only a small burden for 38%.

（3）If water quality agreed with the EU standards, water price would increase reasonable 80%.

（4）The families think that acceptable water expenditures account for less than 1% of the total household income is about for 37%; and the proportion of 1~2% is 30%; the proportion of 2~3% is 26%.

（5）The families accept three-part water price is 61%.

Enterprise affordability analysis

First, take water consumption and the proportion of the total cost as evaluation indicators. The bigger water consumption and bigger water costs proportion as major focus of investigation. Through comparing several cities industrial water price, we drew an conclusion that industrial water price in Shanghai is lower. With huge capital investments and water quality improved，water price increases are inevitable. In recent 20 years in Shanghai, water consumption per thousand yuan industrial value is decreased year after year, which indicates that water price effect is increased. Table 2 shows the tend of recent 20 years shanghai water consumption variety and industrial water consumption decreased per thousand yuan of industrial output.

Table 2 urban water construction variety in Shanghai unit: billion m^3, billion yuan

Shanghai Statistic Yearbook (2004)

Water price forecasting in Shanghai

By comparing water supply costs, evaluation residents affordability and assessing enterprise affordability, we can draw the conclusion that residents and enterprise are able to afford for the water price increase, and it will help to save water all over the society. Forecasting of Shanghai water price is based on the following principia:

First, green belt sprinkling, fire demand, street flushing demand and other municipal water must be paid. Second, cost control should be enhanced to restrain water price adjustment. Thirdly, it suggests that supply different water quality to different enterprise, to satisfy different industrial water requirement and to save industrial water cost. Last, there should be some special policy to protect the poor for water demand and

provide them basic water usage welfare. But the welfare is limitative, table 3 analyzes the basic per household water demand per month in shanghai. Base on the analysis we know that household basic water demand is about 15m^3 per month, two suggestions are given as follow. One is that under the 15m^3 per month, water price is an welfare and very low, a charge will be made whose water consumption exceed the specified limit. The current charge per excess cube meters is about ￥2.21(not include charge for wastewater discharge).

According to these principia, marginal cost theory and 20 years water demand and consumption data, we can forecast Shanghai water price in the future 5 years. The conclusion can be seen in table 4.

Table 3 Domestic water consumption investigation in Shanghai

Domestic average water consumption(m^3/ month)	2001		2002		2003	
	houses	Percentage	houses	Percentage	houses	Percentage
＜15	872651	58.56%	1012191	64.29%	1025952	60.80%
16～25	275094	18.46%	249947	15.88%	302809	17.94%
26～35	134271	9.01%	121270	7.70%	146499	8.68%
36～45	63151	4.24%	55874	3.55%	67223	3.98%
＞45	100955	6.77%	89884	5.71%	103153	6.11%
else	44080	2.96%	45138	2.87%	41842	2.48%
total	1490202	100.00%	1574304	100.00%	1687478	100.00%

Note: The consumer proportion from 2001 to 2003 monthly average water consumption below 10m^3 account for total is 47.82%, 46.17%.

Table 4 Three-part water price in shanghai (not include wastewater discharge cost) unit: RMB yuan

Water price (Yuan)	Water consumption(m^3/month)	2006	2007	2008	2009	2010
Basic water price	＜15	1.38	1.74	1.74	1.74	2.08
Second part water price	16~25	1.79	2.26	2.26	2.26	2.7
Third part water price	＞25	2.21	2.78	2.78	2.78	3.33

Conclusions

According to the Shanghai Statistic Yearbook (SSY)(1990~2003), household average water consumption is 13m^3 per month. For 58.56% of the households, the figure is below 15m^3 per month, while for other 18.46%, it is between 16-25m^3 per month. As the total of these two parts is 78%, this explains that carry out three-part water price is feasible and reasonable.

Artificially low water price in Shanghai leads to water over consumption and large quantity of wastewater discharge, which result in high pressure on the water environment. In order to develop and utilize water resources sustainable, justifying water pricing in Shanghai is necessary and pressing. It is proposed that water pricing could be justified in a marginal cost method and eventually towards the full cost

pricing. The assessment of impacts on water resources by raising water pricing shows that water pricing could be an effective tool for more sustainable water consumption.

ABSTRACT

This paper applied a water treatment plant (WTP) simulation model developed by the USEPA to evaluate effects of climate change on a WTP design and operation. The simulation model was validated using the Greater Cincinnati Water Works' Richard Miller WTP based on data collected for the Information Collection Rule (ICR) database. As part of the validation process, individual influent water quality parameters were "perturbed" and processed through the simulated Miller WTP to identify key influent water quality factors that significantly affect regulated contaminants in the treated water. TOC and ammonia were identified as key water quality parameters. After the validation process was completed, the simulation model for the Miller WTP was used to examine the impact on regulated contaminants of a set of influent water quality scenarios that might result from climate change. Results of the case study scenarios indicated that the existing Miller WTP operation might not be able to meet Safe Drinking Water Act MCL requirements. Therefore design and operational changes may be required to meet these climate change induced changes in source water quality.

BACKGROUND

Climate change may adversely affect water quality in streams and other raw water sources in the United States and therefore impact the design and operation of existing and future drinking water treatment. Climate change may affect both surface water and ground water quality. Increases in precipitation and resulting increases in flows can result in problematic turbidity levels, increased levels of organic matter, high levels of pathogens and increased levels of pesticides in lakes, rivers and streams. Although some areas may experience increases in run-off, some areas may experience droughts resulting in elevated levels of potentially toxic algae, and high concentrations of

organic matter, bacteria, etc (Interlandi *et al*. 2003, Jacobs *et al.*, 2001). Some of these changes may have an adverse impact on the ability of water treatment plants to meet Safe Drinking Water Act regulations. Climate change coupled with increasing population in urban areas will therefore impact existing and future drinking water treatment infrastructure. Water utilities are concerned about the effect of global climate changes on future water demands, influent water quality and the consequent quality of finished water. Therefore, it is important to assess how WTP effluents will respond to changes in influent water quality (pH, TOC, ammonia, UVA, turbidity, bromide, etc.) under possible future climate change conditions. This knowledge will help water utilities identify the water quality parameters that can affect regulated water quality parameters such as disinfectant residual, pH, and total trihalomethanes (TTHMs), and to seek effective treatment alternatives to control these key factors.

A tool that can assist in these efforts is the EPA Water Treatment Plant Model (EWTPM). The EWTPM primarily uses empirical correlations to predict central tendencies of natural organic matter removal, disinfection, and DBP formation in a treatment plant. The relationship between various water quality parameters, such as trihalomethane species, and the variables that influence their formation, such as pH, temperature, chlorine dosage, TOC and bromide can often be described using a nonlinear function. Changes in water quality parameters are caused by chemical addition and/or by unit treatment processes simulated in the EWTPM (USEPA, 2005). It can be useful to (1) assist utilities in identifying and screening new treatment technologies that can assist in meeting both the required levels of disinfection and DBPs regulated under USEPA's various microbial/DBP rules, (2) assist utilities in evaluating the possible effects of source water or treatment process operations on DBP formation, and (3) assist regulatory agencies in assessing the potential impact of new regulations on treatment requirements over a large group of plants. The EWTPM is utilized in this study to simulate the effect of climate induced influent water quality change on regulated parameters associated with the Safe Drinking Water Act.

An important step in applying the EWTPM is to validate the model based on known data inputs and outputs. Data from USEPA's Information Collection Rule (ICR) were utilized for this purpose, specifically data collected for the Greater Cincinnati Water Works' Richard Miller WTP. The ICR was designed to obtain water quality, water treatment, and occurrence information needed for development of Safe Drinking Water Act regulations (Obolensky and Singer, 2005; Obolensky et al, 2007). ICR data sources include detailed information about treatment, plant design and operations from all large public water systems in the United States serving populations of 100,000 or more for 18 monthly monitoring periods from July 1997 through December 1998.

This paper applies the EWTPM to evaluate the performance at the Miller WTP. First, the EWTPM is validated using the simulation of the Miller WTP to confirm that the EWTPM provides reasonable results. As part of the validation process, individual influent water quality parameters were "perturbed" and processed through the simulated Miller WTP to identify key influent water quality factors that significantly affect finished water quality. Next, the EWTPM is applied to a case study at the

Miller WTP to examine WTP performance under future assumed climate change scenarios. Finally, suggestions are made for the adaptation of current water treatment processes and associated infrastructure to meet the future needs.

VALIDATION OF THE EWTPM

Inputs to the EWTPM

Input requirements for the EWTPM, Miller plant simulation can be extracted from the ICR database including unit process design parameters, influent water quality, flow rate and chemical feed rates. The ICR database also provides water quality parameter values at various sampling locations along the treatment train and in the distribution system. These data can be compared against the output from the EWTPM. In this study, the data utilized for validating the Richard Miller WTP are based on sample period 10 (April 1998) in the ICR because of completeness of available data during this period. The unit process treatment train for the Miller WTP is shown in Figure 1.

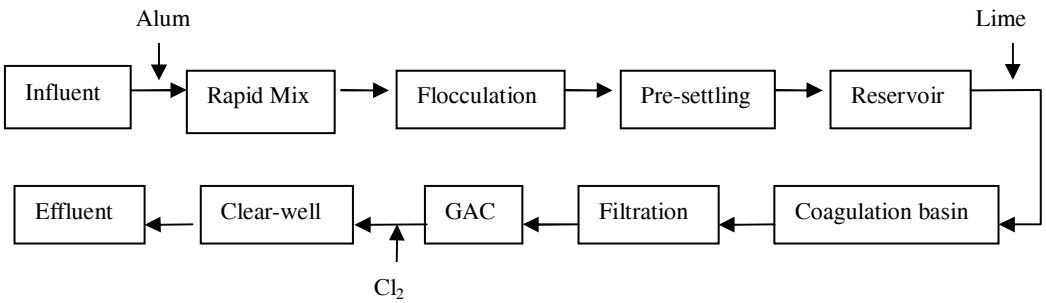

Figure 1 Unit Process Treatment Train for the Miller Plant

Design parameters are listed in Table 1. Chemical feed concentrations are: aluminum - 0.865 mg/L (before Rapid Mix); $Ca(OH)_2$ - 6.732 mg/L (before settling); Chlorine-3 mg/L (before clear well). During sample period 10, the influent flow rate was 4.41 m^3/s. The ICR water quality values at various sampling points are listed in Table 2.

Table 1 Miller WTP Unit Process Design Parameters

Unit Process	Volume, m^3	T10, min	T50, min

Validation of the EWTPM Using Miller WTP Data

Results from the EWTPM and the ICR database are compared in Table 3. They show reasonable agreement for pH, alkalinity (ALK), hardness, TOC, UVA_{254}, free chlorine residual and TTHMs. Simulated pH and alkalinity are slightly higher than sampled pH and alkalinity after lime is added. Sampled Calcium hardness and total hardness agree well with the corresponding simulated results. The sampled and modeled TOC results were in reasonable agreement in the finished water. The ICR data show that UVA_{254} is removed through coagulation and GAC in the Miller plant but most of the UVA_{254} is removed by GAC in the EWTPM. The simulated effluent UVA_{254} agrees well in the finished water. The simulated chlorine residuals are higher than the sampled results which imply that the initial simulated chlorine concentration in the model is probably higher than needed. For DBP TTHMs, good agreement was found between the simulated and the sampled results at the average tap (AVG1) and end of system (AVG3) points. It was concluded that the EWTPM adequately simulates the operations of the Miller Plant.

Effect of Perturbation of influent water quality

For the perturbation analysis, the operating conditions and most of the influent water quality levels in the Miller plant are assumed as constant, based on ICR sample period 10. One influent water quality parameter at a time is increased to 150% and then 200% of the existing value for subsequent runs of the EWTPM. Thus, the effect of perturbation on individual influent water quality were studied for the following water quality parameters: TOC (MCL 2mg/L), Chlorine residual (MCL 4mg/L), and TTHMs (MCL 80 µg/L). Table 4 summarizes the results at three observation points: effluent, average tap (1 day residence time) and end of system (3 days residence time). In Table 4, columns labeled with "100%" represent the results of the unperturbed influent. It can be seen that influent TOC has a significant effect on effluent TOC, chlorine residual and TTHMs at all three observation points. It can also be seen that increasing ammonia has no effect on effluent TOC levels but does decrease chlorine residuals and TTHMs. Bromide and alkalinity had no effect on effluent TOC and free chlorine residual but increases in bromide and alkalinity increased TTHMs slightly. UVA_{254}, hardness and turbidity had no effect on TOC, TTHMs or chlorine residual. Therefore, TOC and ammonia were identified as the key parameters affecting free chlorine residuals and TTHM formation.

Table 4 EWTPM response to a change of individual influent water quality parameter

Varied parameter	Input value	Regulated contaminant	Effluent			AVG1			AVG3		
			100%	150%	200%	100%	150%	200%	100%	150%	200%

IMPACT OF CLIMATE INDUCED WATER QUALITY CHANGES

In order to assess the impact of climate change, three specific scenarios were assumed. The performance of the Miller plant was evaluated and a determination made as to whether the current plant could meet the requirements associated with these scenarios and what modifications should be considered to account for these changes. These scenarios and assumptions are discussed in the following paragraphs.

Future scenarios at the Miller WTP

An average treated water flow during the 18 month ICR sampling period (July 1997-December 1998) at the Miller Plant, of 5.35 m^3/s. The raw water quality for the simulated plant is assumed to be the average of the influent water quality at the

following plants that use the Ohio River: Neville Island WTP in Pittsburgh of Pennsylvania, Richard Miller WTP in Cincinnati of Ohio, Evansville WTP in Indiana, Be Payne WTP in Louisville of Kentucky, Crescent Hill Filter WTP in Louisville of Kentucky and Fort Thomas WTP in Kentucky. These base-line data are shown in Table 5. Two future scenarios were assumed that increase the base-line average of the key water quality parameter TOC (2.56 mg/L) by 25% and 50%, which are 3.20 mg/L and 3.83 mg/L for scenario 1 and 2. It was assumed that the other water quality parameters remain constant.

Table 5 Base-line influent water quality parameters for the Miller WTP

Water quality parameter	pH --	ALK mg/L	TURB NTU	Ca_H mg/L	T_HARD mg/L	TOC mg/L	UV_{254} cm^{-1}	BROMIDE mg/L	NH3_N mg/L
Base-line value	7.76	71.8	26.6	77.4	141.0	2.56	0.096	0.069	0.21
Stan Deviation	0.20	23.3	41.5	32.9	34.0	0.54	0.049	0.040	0.19
Sample size	107	107	107	107	107	93	86	86	82

Performance of the Miller WTP subject to future changes

The performance of the Miller WTP is evaluated for TOC concentration and TTHM concentration in the finished water. The existing WTP processing train shown in Figure 1 and settings listed in Table 1 are assumed. Figure 2 and 3 shows the results of this analysis. It can be seen that TOC is stable after entering the distribution system but increases with increased influent TOC under scenarios 1 and 2. TOC meets the MCL (2.0mg/L) for the base-line condition but violates the MCL for scenarios 1 and 2. Figure 3 compares the formation of TTHMs for the three conditions. It can be seen that TTHMs increase with both the retention time in distribution system and the influent TOC concentration (represented by scenarios 1 and 2). TTHMs violate the MCL (80 ppb) at a retention time of 3 days for scenario 1 and at a retention time of 2 days for scenario 2.

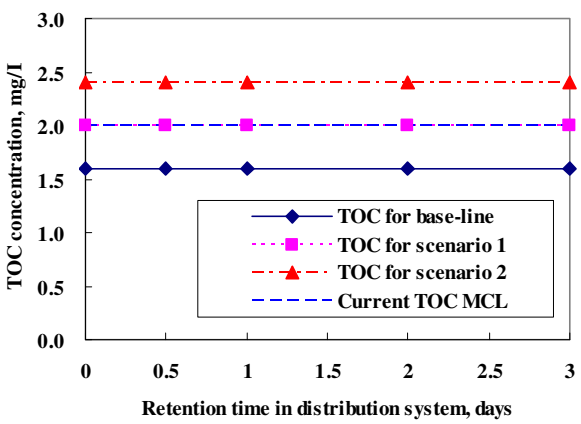

Figure 2 Remaining TOC in distribution system

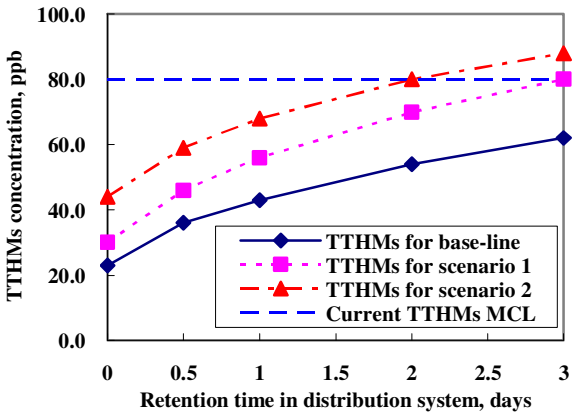

Figure 3 TTHMs formation in distribution system

Adaptation of the Miller WTP to future changes

Results in previous section shows the existing operation at the Miller WTP can not meet the MCL requirements for TOC and TTHMs under the assumed climate change scenarios. Therefore, the current design or operation needs to be modified to meet these requirements. Reducing the GAC reactivation period from 365 days can increase TOC removal.

It was found that the effluent TOC could be reduced to 1.8mg/L (lower than the MCL 2.0mg/L) when the GAC reactivation period is changed from 365 days to 180 days for scenario 1 and to 90 days for scenario 2. Figure 4 compares the formation of TTHMs for base-line conditions and for scenarios 1 and 2 against the change in reactivation rates. It is interesting to note that the TTHM formation curves are the same for both scenario 1 and 2 assuming the respective changes in reactivation rate. Clearly these adaptations to the existing operation in the Miller WTP, allow both TOC and TTHMs to meet their respective MCLs. However there is an increasing cost associated with each level of performance.

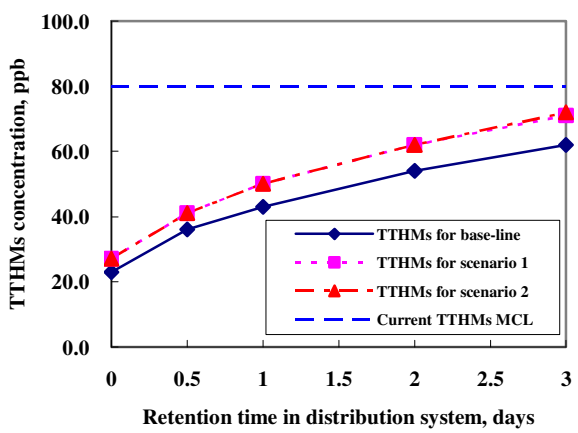

Figure 4 TTHMs formation after GAC reactivation period was changed

SUMMARY

The EWTPM was applied using the assumed conditions that currently prevail at the Richard Miller WTP to evaluate the effect of deteriorating water quality due to climate change. The results show that the EWTPM provides a reasonable replication of the existing WTP performance. A perturbation analysis using the EWTPM identified TOC and ammonia as key water quality parameters, which have significant effects on regulated contaminants.

The results of the analysis show that existing treatment operations can not meet the TOC and TTHM MCLs when influent TOC was increased by 25% (scenario 1) and 50% (scenario 2). Therefore, existing WTP operations were modified. When the GAC reactivation period is reduced to 180 days for scenario 1 and to 90 days for scenario 2, both MCL requirements can be met. The findings of this investigation will lead to identification of the key factors in water quality changes that can significantly affect the finished water quality, and provide an example to demonstrate how to adapt water infrastructure to future water resource changes.

ACKNOWLEDGMENT

This study is part of Water Resources Adaptation Program (WRAP)-Infrastructure supported by USEPA under project/contract EP-C-05-056 but has not been subject to review by USEPA.

Axial Dispersion Coefficients for Laminar Flows in Water Distribution Systems

P. Romero-Gomez[1], Z. Li[2], C.Y. Choi[1], and S.G. Buchberger[2]

A dispersive transport component has recently been incorporated into the constituent transport equation used for modeling water quality in pressurized distribution systems. Among the various issues that arose from this major development, dispersion coefficients (E) relevant to water distribution systems still remain unknown. In order to quantify E values, researchers have considered the long-established Taylor's theory (E) and time-dependent functions. However, discrepancies between theoretical and experimental approaches still exist because the former does not consider the transient nature of dispersion whereas the latter derives from the analytical relations that overestimate dispersion rates. The present study quantifies dispersion coefficients in pressurized pipes under laminar conditions by using Computational Fluid Dynamics (CFD). Assumptions made with CFD are few and mostly related to the velocity field in pipe flows. Consequently, the mass transports are obtained by solving the species equation over an axi-symmetric domain. Next, the resulting spatial-temporal constituent concentrations are used to estimate dispersion coefficient values determined by the method of moments (MOM) at equally-spaced locations along the length of the pipe. With the aim of building a quasi-analytical relation of* $E/E^* = \beta\, f_E = f(\mathrm{Re}, T, Sc)$*, transient simulations at a series of Reynolds numbers for laminar flows (Re < 2,100) were carried out in consideration of constituents with different molecular diffusivity in water. Among the various challenges that this study confronts, two are thoroughly described here: (i) the pre-analysis needed to obtain a solution that is independent of the numerical setup and (ii) the CFD benchmarking solution required under conditions when Taylor's theory applies (T > 0.30).*

1. INTRODUCTION

The dispersive transport of solutes has progressively been taken into consideration to better describe the water quality behavior of pressurized water systems. The fundamental aim is to expand the one-dimensional Advection-Reaction model (1D-AR) currently in use and turn it into a 1D-Advection-Dispersion-Reaction (1D-ADR) equation that predicts quality parameters with higher accuracy. The numerous research efforts in this field can be categorized into *(i)* those that seek a more efficient, accurate and applicable numerical solution to the expanded equation, and *(ii)* those that seek to determine the dispersion coefficients that better represent the solute transport. To the best of our knowledge, Sir Geoffrey Taylor (1953) was the first to quantify steady-state dispersion rates (*E**) via analytical solutions and corresponding experimental validations. Furthermore, he stated that "… the effect of molecular diffusion [D_{AB}] is negligible" before the steady-state conditions are reached, and that his formula for dispersion rates

only applies when the time of flow is greater than $\tau = a^2/(3.8^2 D_{AB})$. Such groundbreaking findings unfolded other investigations aimed at determining dispersion rates before τ is reached, a condition that most likely occurs in pipes of sizes and flows of a magnitude typically found in municipal water distribution systems.

Gill and Sankarasubramanian (G-S, 1970) derived a complex method for finding dispersion rates for an instantaneous injection of solute in a long pipe under steady laminar flows. They demonstrated that the dispersion rate increases with time as the solute travels downstream and asymptotically approaches the value calculated with Taylor's formula, E^*. However, the process of implementing the derived model into the 1D-ADR equation is complex and not feasible. In order to overcome this drawback, Lee (2004) provided simplified forms of G-S's equation (1970), versions that can actually be integrated into the 1D-ADR model. Romero-Gomez et al. (2008) used Computational Fluid Dynamics (CFD) to compute dispersion coefficients at various Reynolds numbers, thus covering the laminar, transitional and turbulent flow regimes. Because they found the CFD approach to be an expedient tool in quantifying dispersion rates in multiple flow and water quality scenarios, the objective of the present study is to thoroughly examine the effect of three parameters: *(i)* Reynolds number (Re) to account for flow characteristics, geometry dimensions, and solvent (water) properties, *(ii)* Schmidt number (Sc) to include the properties of dissolved substances, and *(ii)* dimensionless time (T) in order to define the extent to which the dispersion coefficient has elapsed before reaching steady-state conditions. These coefficients are defined as follows

$$Re = \frac{U_0 d}{\nu}; \qquad Sc = \frac{\nu}{D_{AB}}; \qquad T = \frac{4 D_{AB} t}{d^2}$$

2. COMPUTATIONAL FLUID DYNAMICS

Computational Fluid Dynamics (CFD) consists of discretizing a set of conservation equations and calculating their numerical solution under prescribed initial/boundary conditions. In order to perform CFD simulations of the species transport in a long pipe, three steps were carried out.

(i) The computational domain over which the conservation equations are solved was defined as a 2D axi-symetric rectangle with height (H) equal to the pipe radius and width (W) equal to the pipe length. A quadrilateral mesh was applied to all the simulated cases. In all instances, approximately 30% of the total number of cells (N) pertained to the boundary layer zone defined near the pipe walls. Characteristics of the mesh specific to each simulated geometry are provided in subsequent sections. The following boundary types were set at the domain edges: velocity inlet (left), outflow (right), wall (top), and axis (bottom).

(ii) All the simulations were two-dimensional, axi-symmetric, unsteady-state, and solved with a laminar viscous model. The mixture material was composed of water (ρ= 997 kg m^{-3}, *molecular weight* = 18.01) and the dissolved substance (sodium chloride, potassium permanganate or a theoretical material the properties of which were provided for each instance in the succeeding sections). The composite properties of this mixture were μ = 1.003 x 10^{-3} kg m^{-1} s^{-1} and D_{AB} of the solute. The hydrodynamic Boundary Condition (BC) at the inlet was the fully-developed velocity profile, whereas the species BC was the time-varying inlet concentration profile specific to the simulated scenario. The velocity field was assumed to be fully-

developed through the entire domain, thus reducing the numerical effort to solving only the uncoupled species transport equation with the following transient form

$$\frac{\partial}{\partial t}(\rho C_i) + \nabla \cdot \left(\rho \bar{u} C_i\right) = \nabla \cdot (\rho D_{AB}) \nabla C_i \tag{1}$$

(iii) The simulations provided the radial distribution of solute at the set time and space intervals by executing a prescribed command that saved the data into text files. Based on such data, the post-processing work involved the construction of either concentration vs. time curves, $C = C(t)$, at different locations, or concentration vs location curves, $C = C(x)$, at different times.

3. DISPERSION COEFFICIENTS

Lee (2004) provided a simple but accurate approximation for the exact but cumbersome expression developed by Gill and Sankarasubramanian (1970) describing the unsteady instantaneous rate of dispersion for a mass transported in a steady laminar flow through a pipe. The corresponding expression for the time-averaged rate of dispersion in a steady laminar flow during the period $[0, t]$ is given by

$$\overline{E(t)} = E^* \beta(T) \tag{2}$$

where, E^* is the steady-state dispersion rate by Taylor (1953), given by, $E^* = \frac{a^2 U_0^2}{48 D_{AB}}$ and $\beta(T)$ is a dimensionless factor defined by

$$\beta(T) = \left[1 - \left(\frac{1 - \exp(-16T)}{16T}\right)\right] \tag{3}.$$

Note that $\overline{E(t)}$ is a function of time, even in steady flow. Hence, in pipe network applications it is necessary to define a representative time in order to characterize the average rate of dispersion expected along a pipe link. Li (2006) found that this representative or "evolution" time of dispersion for a pipe link of length L is given by the nominal travel time, $t = L/U_0$. However, some recent preliminary studies suggest that time-averaged dispersion coefficients based on the nominal travel time in steady a laminar flow may be over-estimated (Romero-Gomez et al, 2008). Thus, Equation 2 may need correcting.

One way to correct Equation 2 is to apply a correction factor, f_E, to the right-hand-side,

$$\overline{E(t)} = E^* \beta(T) f_E \tag{2a}$$

f_E may be defined by,

$$f_E = \frac{\overline{E_m}}{E^* \beta(T)} = \frac{192\left(\overline{E_m}/\nu\right)}{Re^2\ Sc\ \beta(T)} \tag{4}$$

Herein, $\overline{E_m}$ is a time-averaged dispersion rate computed using the method of moments (MOM) based on a time history of the outflow concentration measured at end of a pipe.

According to Fischer *et al.* (1979), a numerical time-averaged axial dispersion rate during the period $[0, t]$ can be given by

$$\overline{E_m} = \frac{U_0^2\left(\sigma_t^2 - \sigma_0^2\right)}{2m(t)} \tag{5}$$

Where, σ_0^2 and σ_t^2 are the variance of tracer cloud at the upstream and downstream locations, given by, $\sigma_t^2 = m(t^2) - [m(t)]^2$; *m(t) and m(t²)* are the first-order and second-order concentration weighted moments for time *t*, given by, $m(t) = \frac{\sum_{i=1}^{n} t_i C_i \Delta t}{\sum_{i=1}^{n} C_i \Delta t}$ and $m(t^2) = \frac{\sum_{i=1}^{n} t_i^2 C_i \Delta t}{\sum_{i=1}^{n} C_i \Delta t}$; C_i is the solute or microbial concentration measured at t_i; Δt is the time interval between readings; and n is sample size.

4. CFD PRE-ANALYSIS

The aim of CFD pre-analysis is to determine the mesh size, discretization scheme and time step that have no effect on the CFD-simulated solution for axial dispersion. Conventionally, an increasing mesh size enhances the accuracy of results, though beyond a certain mesh refinement numerical errors begin to prevail and worsen the overall solution. The discretization scheme refers to how the continuous conservation equations are transformed into a discrete algebraic system of equations. In time-dependent modeling of phenomena, the time step setting determines the frequency with which a numerical solution is provided. The following mesh sizes (*N*) for the entire computational domain were tested: 1600, 3200, 4800, and 12000. Three discretization schemes were tested: 1st order upwind, 2nd order upwind and QUICK. Considering the typical time spans for the analyzed phenomenon, the following time steps (*Δt*, in seconds) were examined: 0.5, 0.1, 0.02, and 0.01.

The CFD-simulated conditions were as follows: d = 0.016 m, U_0 = 0.1128 m s^{-1}, (Re = 897), D_{AB} = 1.5 x 10^{-9} m^2 s^{-1}, (Sc = 670), ρ = 2,170 kg m^{-3}, MW = 58.45 kg $kgmol^{-1}$ (properties for NaCl), t = 100 s (T = 0.0023), H = 0.008 m, W = 1.6 m. The inlet concentration was a transient profile with background concentration equal to zero and a rectangular-shaped pulse of 10 s (starts at 5 s, ends at 15 s) with C_0 = 1 g L^{-1}. Such conditions result in a bell-shaped downstream concentration profile with respect to time.

The ratio of the downstream peak concentration (C_{MaxOut}) to C_0 is used for quantitatively assessing the effect of the settings on the solution. Figure 1a depicts the increase in C_{MaxOut}/C_0 that occurs with progressively increasing mesh sizes over the range of tested time steps, until a value of N = 4,800. A finer mesh (*N = 12,000*) overproduced numerical errors that consequently decreased the simulated downstream peak concentration. Thus, a mesh of *N = 4,800* was selected to further examine the discretization schemes, results of which are shown in Figure 1b. Whereas the 1st order upwind scheme largely lowers C_{MaxOut}/C_0 at all Δt's, the 2nd order upwind and QUICK schemes produce similar outcomes, although the latter slightly underestimates values as compared to the former. Because a simpler scheme was preferred for succeeding simulations, the 2nd order upwind was selected. In terms of the time step, Δt = 0.02 s produces values of C_{MaxOut}/C_0 that are slightly lower than Δt = 0.01 s; however, the latter significantly prolongs the computational time at the expense of less than 1% of improvement with respect to the former. Thus, Δt equal to 0.02 s was used in succeeding simulated scenarios.

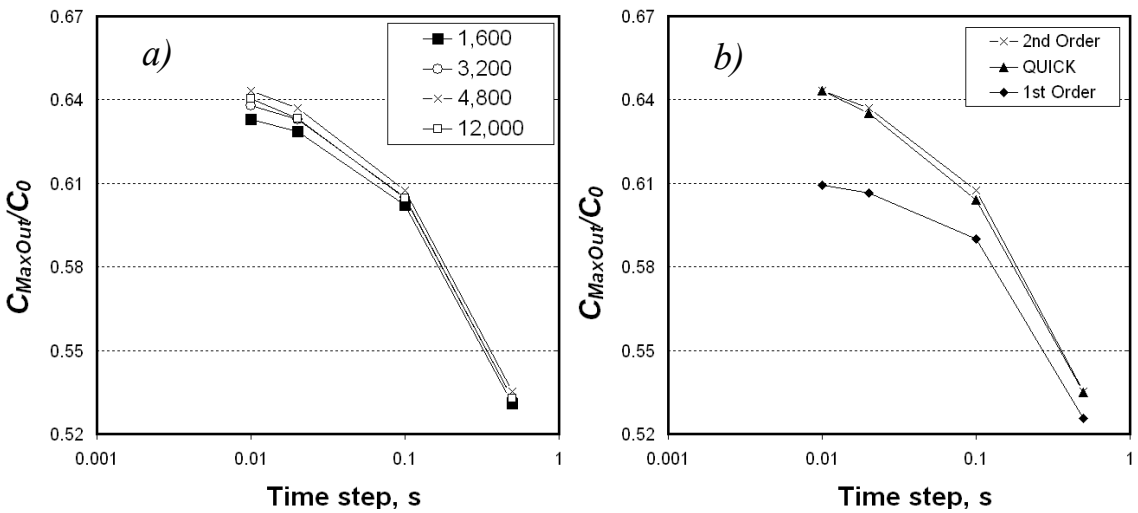

Figure 1. Maximum concentration related to inlet concentration at different CFD settings indicate that a mesh of size 24x200, 2nd order discretization scheme, and Δt = 0.02 s must be used to further carry out simulations

5. BENCHMARKING THE CFD SETUP

Although all CFD commercial programs or in-house codes are carefully tailored to fulfill the intended modeling purposes, benchmarking the CFD setup is advised in order to minimize the possibility of wrong settings or erroneous assumptions. In this work, the numerical setup and the simulated results were benchmarked against the experiments by Taylor (1953) in which a uniform concentration C_0 is allowed to enter the pipe at uniform rate at $x = 0$. Initially the pipe is filled with water, only ($C = 0$). Taylor (1953) called this configuration the special case B2, and thus demonstrated the applicability of his analytical solution to the problem of quantifying dispersion rates (E^*) when long times have elapsed, $t > \tau,\ \tau = a^2/(3.8^2 D_{AB})$. The CFD-simulated scenario was based on experimental conditions and results reported by Taylor (1953). Those results are as follows: d = 0.000504 m, U_0 = 0.00524 m s^{-1}, (Re = 2.627), D_{AB} = 6 x 10^{-10} m^2 s^{-1}, (Sc =

Table 1. Taylor's (1953) experimental results of type B2, for $t = 240\ s$, and continuous upstream injection of $Co = 10\ g\ L^{-1}$ (dissolved substance was potassium permanganate, $KMnO_4$, see Table 2 in Taylor, 1953 for more details).

0.804	0.01

1,675), ρ = 2,703 kg m^{-3}, MW = 158.04 kg $kgmol^{-1}$ (properties for $KMnO_4$), t = 240 s (T = 2.267), H = 0.000252 m, W = 1 m, N = 230,400, and C_0 = 10 g L^{-1}. The experimental results of the distribution of solute concentration as a function of distance from the pipe inlet are presented in Table 2. Note that the solute concentration is given with respect to the inlet concentration (C/C_0).

Figures 2a – 2f depict the concentration vs. distance curves at different times (and the corresponding T-value). Short simulation times (t ≤ 20 s, Figures 2a, 2b and 2c) show that the concentration drop from 1 to 0 in fact occurred within short distances (consider the x-axis range to be 0 - 0.12 m). Only Figure 2a (t = 5 s) corresponds to the case in which Taylor's theory assumes no effect of molecular diffusivity on the distribution of C/C_0, at $t < \tau$. At longer time spans (Figure 2d, 2e and 2f) the concentration drop took place within increasing distances, due to a stronger effect produced by axial dispersion. The experimental results in Table 2 and corresponding CFD-simulated concentrations are plotted in Figure 2f and show an excellent agreement between them; however, small overestimations of the modeling approach at $x < 0.55\ m$ are present. Taylor's analytical solution also overestimated the concentration values within this range of x-values, an outcome that suggests the possibility of slight experimental errors. Furthermore, the CFD-based dispersion rate (with Equation 5) is E = 1.48 x 10^{-5} m^2 s^{-1}, as compared to Taylor's coefficient E* = 1.52 x 10^{-5} m^2 s^{-1}. The error percentile of E with respect to E^*, $|E - E^*|/E^*$, is 2.7%, which confirms the suitability of using the CFD approach to further examine axial dispersion in other instances and scenarios.

Taylor's theory has been revisited and complemented in order to account for the transient phase of the dispersion rate before a steady-state condition is reached (at τ = 7.33 s, for this benchmarking case). The present research efforts aim to develop a coefficient that relates the transient dispersion rate to Taylor's dispersion coefficient (f_E, Eq. 4). At prescribed simulation times, transient coefficients can be calculated based on the concentration distribution along the pipe, $C(x)$, by using the MOM equation (Eq. 5). Therefore, an E-value exists for each considered dimensionless time T, for which the relation $E_i = E(T_i)$ can be plotted as shown in Figure 3. When the quasi-theoretical function indicated in Eq. 2 is also considered and plotted in Figure 3, an excellent agreement between both approaches is observed. However, there is evidence that such theoretical dispersion rates can be further generalized for applications to scenarios that most commonly occur in real water distribution systems (Tzatchkov *et al* 2002 and Li 2006). Therefore, the CFD tool could potentially be used for constructing a relation of dispersion rates (E) as a function of other relevant parameters that account for the solute properties (Sc) and flow/geometry characteristics (Re).

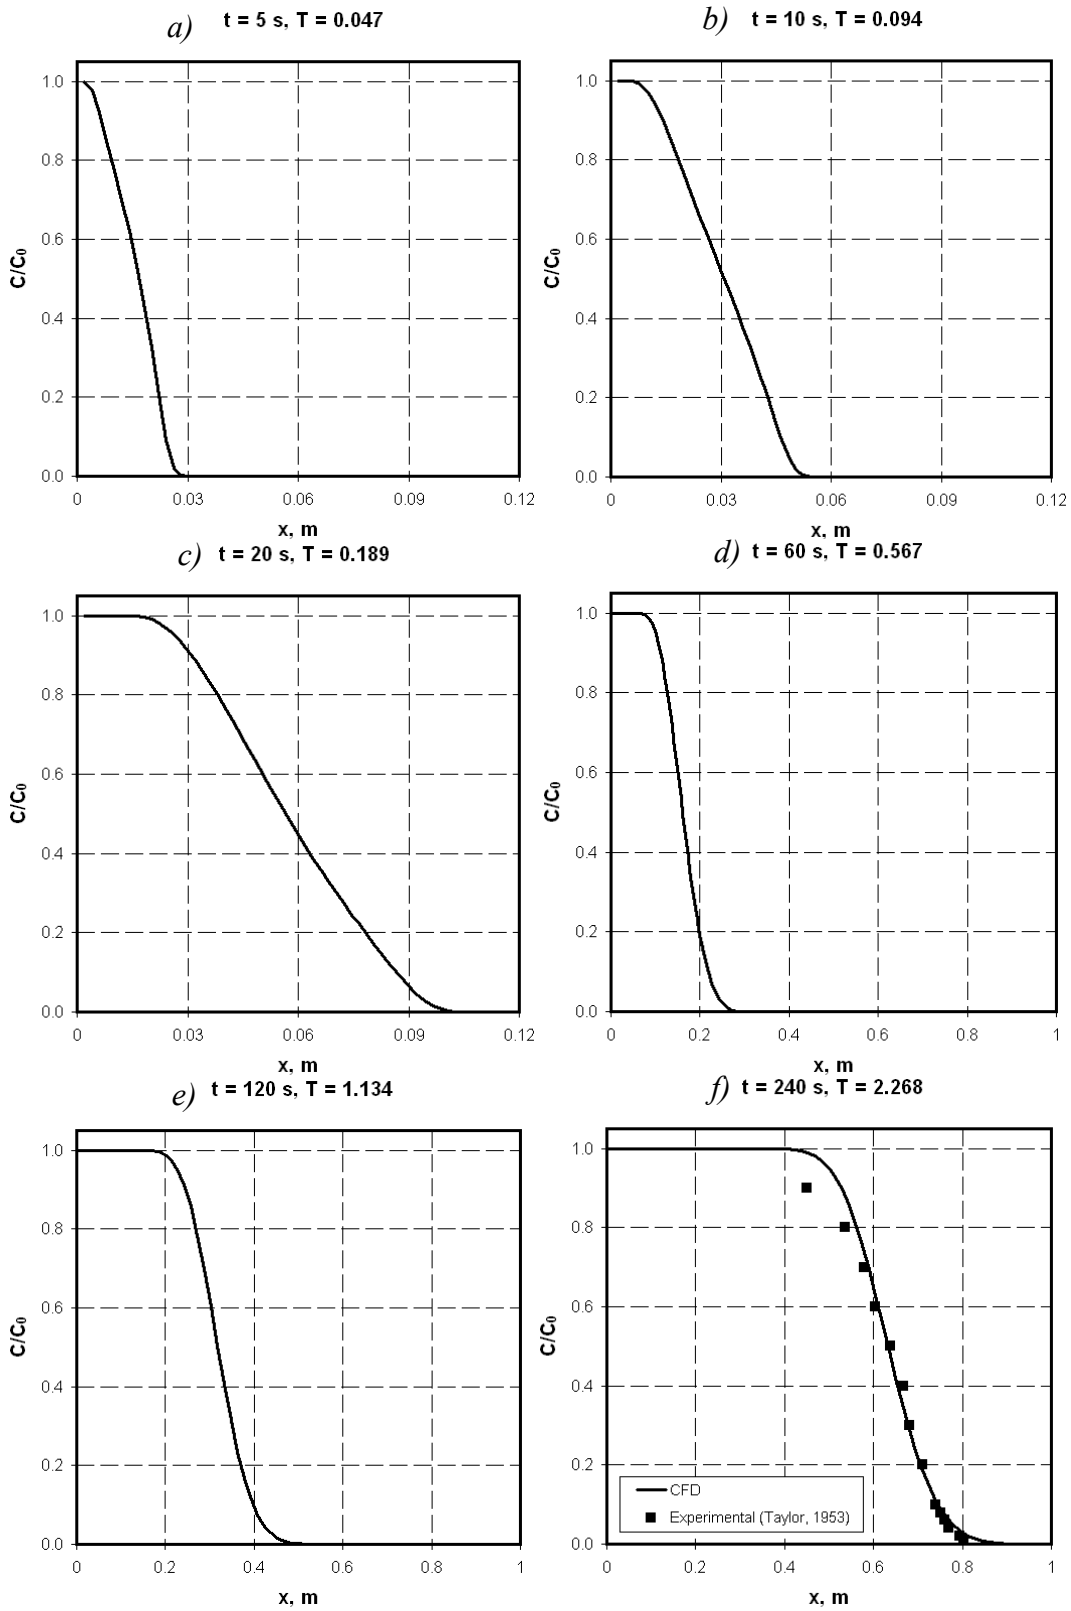

Figure 2. Concentration vs. distance at different simulation times. *x*-axis range is 0.00-0.12 m for (a), (b) and (c); x-axis range is 0-1 m for (d), (e), and (f).

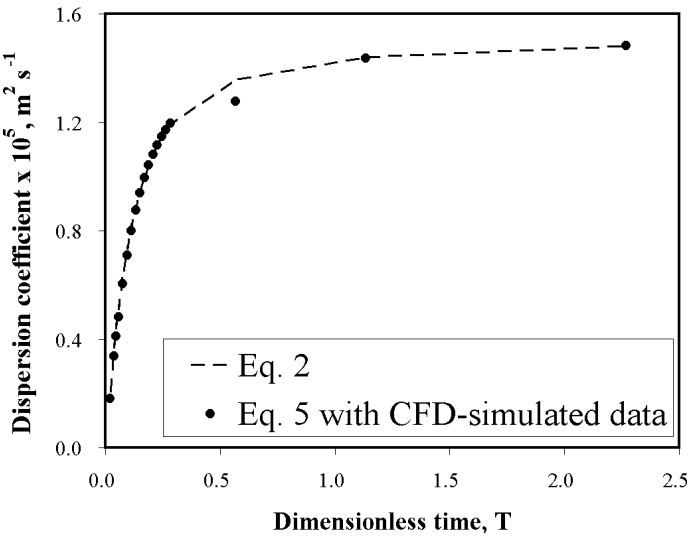

Figure 3. Comparison of unsteady-state dispersion coefficients between analytical and CFD-based MOM calculations.

6. PARAMETRIC STUDY (Re, Sc, T)

The parametric study consisted of examining the effect of Re, Sc and T on the unsteady-state dispersion rates. The characteristics of the numerical setup that remained the same for all the simulated scenarios were as follows: d = 0.016 m, H = 0.008 m, W changed as a function of the simulated scenario, N = 230,400, and C_0 = 1 g L^{-1} at a constant injection rate at the pipe inlet. The following values of mean flow velocities (U_0 in m s^{-1}) were examined: 0.0126, 0.0251, and 0.0503, which lead to Reynolds numbers of 200, 400 and 800, respectively.

The species molecular diffusion for material A was of the same order of magnitude as NaCl, D_{AB} = 1.5 x 10^{-9} m^2 s^{-1}, whereas material B was theoretical with a value of D_{AB} ten times as large as material A (1.5 x 10^{-8} m^2 s^{-1}). Such values led to Schmidt numbers equal to 670 and 67, respectively. The simulation times were calculated so that the resulting dimensionless time T had the following values: 25, 50, and 100 (all values multiplied by 10^{-4}).

The results shown in Table 2 as a function of multiple parameters demonstrate that the β-coefficient, as calculated with CFD-simulated data, is neither sensitive to the Reynolds number nor to the Schmidt number, but solely a function of the dimensionless time, T, as the analytical equation (Eq. 3) originally suggests. Nevertheless, there exists a consistent overestimation of analytical β (from Eq. 3) with respect to the CFD-based value for all the scenarios tested. Such overestimation may empirically be corrected by the coefficient f_E (Eq. 4) that ranged from 0.70 to 0.75 as a function of the parameter T. The trend of results in Table 2, as well as those presented in Figure 3, suggests that the value of f_E will continue to increase to a longer dimensionless time until it reaches an asymptotic value of 1. They can be quantified by performing simulations at other T-ranges and validated by means of experimental runs in short pipes at relatively small time spans. The conditions that produce small values of T give rise to large concentration gradients in the radial direction, which in turn may result in a lower accuracy for Eq. 5 to quantify the actual values of dispersion rates at different time spans. This claim, however, needs further studies.

7. CONCLUSIONS AND FURTHER RESEARCH

The present study provided an analysis of dispersion rates via Computational Fluid Dynamics (CFD) simulations as a function of the multiple parameters that characterize the flow, the fluid, the dissolved substance and the evolution of dispersion. First, the pre-analysis of the CFD setup determined the values of mesh size, time step and discretization scheme that have virtually no effect on the numerical solution. Next, the setup was benchmarked against the long-established experimental results obtained by Taylor (1953) for steady-state dispersion rates. The excellent agreement between both the experimental and CFD-simulated data proved the validity of the CFD approach to examining dispersive transport of solutes at multiple scenarios of flow and water quality. Thus, a parametric study with Reynolds number (Re) and Schmidt number (Sc) at small dimensionless times ($T \leq 0.01$) quantified the overestimation of the dispersion rates produced by the existing analytical equations. Such discrepancies may be corrected by means of either a correction factor or a redefinition of the dispersion coefficients (by using the method of moments), when short dimensionless times have elapsed. This investigation is relevant to water quality modeling in pressurized systems because solutes in drinking water travel along the pipes at relatively short T-values, too. In such conditions, large gradients of radial concentrations may well lead to an inadequate quantification of dispersion rates via the method of moments (MOM) that assumes uniform cross-sectional concentrations. This issue, as well as the experimental validation of CFD simulations, is the subject of ongoing research.

ABSTRACT

Pinhole leaks in copper plumbing pipes have become a nationwide concern because these leaks cause property damage, lower property values, and result in possibility of adversely affecting homeowners' insurance coverage. Multiple attributes of a plumbing system including cost, taste and odor impacts, potential for corrosion, health effects, warranty, convenience of installation, and proven performance in the market are considered when choosing an alternative plumbing material. Two phase surveys are conducted with selected homeowners in pinhole leak prone area in southeastern US community to observe their revealed and stated preferences. Health effects, taste and odor of water turned out to be the most important factors from the survey. In real life, however, homeowners were not well aware of these safety issues related with plumbing materials. It is recommended that water professionals should work on bridging the gap between public perception and research results.

INTRODUCTION

Recently, increased pinhole leaks in domestic copper plumbing pipes have been observed (Lee, 2006). When there is a leak incident in a house, the homeowners cover the repair/replacement cost of a home plumbing system as it is private property. The homeowners are typically faced with the following issues when a leak occurs: water damage and repair cost, service disruption, possible lowering of home value, and potential health consequences resulting from brown mold growth on the surface of walls, floors, and ceilings. Home plumbing decisions that may affect drinking water risks include choice of when to repair or replace as well as the type of material

to use in replacement. When informed about the attributes of each plumbing material alternative, consumers can decide on the alternative most preferable to them based on the preference tradeoffs among plumbing materials' attributes. The decision of choosing an appropriate plumbing material can be based on various attributes of materials such as cost (material cost plus labor and installation cost), health effects, corrosion susceptibility, strength, property real estate values, and behavior in the case of a fire, taste and odor of the water, longevity of the pipe system, warranty, proven performance in the market, and convenience of installation or replacement.

According to Marshutz' survey (2001), copper accounts for 90% of plumbing installed in new homes, followed by PEX (cross linked polyethylene) at 7%, and CPVC (chlorinated polyvinyl chloride) at 2%. A telephone survey (Lee, 2008) observed that the share of plastic pipe in plumbing industry is increasing due to ease in installation and lower material cost. Woodson (1999), an author with extensive plumbing experience, selected consumers' plumbing material alternatives as copper, CPVC, and PEX. It is noted that copper pipes generally performed well in plumbing except where there are major pinhole leak problems.

In this study, we developed a mail survey for selected homeowners in a southeastern community in USA which had experienced unusually high rate of pinhole leak incidents. Two phase survey approach was taken to systematically understand homeowner's attitudes and experiences regarding home plumbing system. Phase I focused on the revealed preferences; to gather information about the costs in addressing the problems and their experiences in dealing with the problems. Phase II is eliciting homeowner's preferences towards home drinking water plumbing attributes and materials (stated preferences) under the framework of Analytic Hierarchy Processes (Saaty, 1980).

HOMEOWNER SURVEY OF PINHOLE LEAK PRONE AREA

The southeastern community A was founded in 1980's and approximately 4,700 acres in size and is close to a river. There are about 3,300 homes including condos and apartments; and a total of 6,600 residents. Most of the residents are retired people. Water quality changes turned out to be the culprit for high rates of leaks. Even 6 year-old houses have suffered leaks. Ninety-five percent of the leaks were in cold water pipes and builders used copper pipes from the same suppliers.

In year 2006, there was a switch from Utility 1 to Utility 2. The switch caused problems mainly because of the differences in water qualities such as chlorine level, hardness, and pH. Contrary to affected home plumbing systems, utilities' major system did not have a leak problem because they are using different piping materials (mainly iron pipes). According to the recommendations from water quality experts from Virginia Tech, Utility 2 added corrosion inhibitor (phosphate) to water treating process (after April of 2006); and the number of newly reported leaks has decreased so far (Martin, 2007).

The affected homeowners in this community had three alternatives i) repairing the leak, ii) doing a complete replacement of existing plumbing system, and iii) coating the existing pipe system with epoxy. When they make a decision, they had to balance the risk of possible future leaks that might cause another damages to homes and personal belongings vs. the cost of a replumb or relining. So, their information sources were from other homeowners or plumbers who have had leaks recently and experienced repair, epoxy coating, or replumbed with other alternatives (PEX, CPVC). As mentioned, utilities took actions by adding corrosion inhibitors to reduce the leaks at home. If a certain period of warranty from replumbing or epoxy coating is guaranteed, their decision was based on the *cost* in addition to the repair of collateral damages to the home and furnishings due to replumb or relining operations.

Some community residents have been taking several additional actions such as i) *preventive replumbing*, which was even done by those who did not experience any leaks in their houses (after seeing what happened to their neighbors), ii) applied epoxy coating with or without leak experiences, iii) inline injection of phosphate (corrosion inhibitor) into home water systems, and iv) water softener or water conditioning systems.

Methodology and Survey Design

A two-phase survey approach was used to understand homeowner's concerns, attitudes, and experiences in pinhole leak prone area regarding drinking water and home plumbing system. In phase I, the survey instrument was designed to gather a wide variety of information about the nature of pinhole leaks, costs in addressing the problems, and their experiences in dealing with the problems. Socioeconomic data were included at the end of the survey. Specifically, 1st phase survey module includes items such as pipe materials, failed locations, whether they repair/replaced the systems, what alternatives they chose after a leak incident, and any preventive actions (if they had taken any). Time spent to deal with these issues, level of stress, level of concern for future possible leaks were also included in the module.

In phase II, AHP is adopted; a multiattribute preference elicitation tool that allows for examining tradeoffs among the available attributes. The decision making processes (replacing plumbing systems) of residents' coping with leak incidents (stated preferences from phase II) are compared with real decisions (revealed preferences) from Phase I survey. The surveys themselves could be administered in a mail format. In addition, this survey module was pre-tested with 135 Civil Engineering students in Virginia Tech, committee members of a property owner association in the affected community, and 3 faculty members from Civil Engineering in Virginia Tech who have extensive knowledge and experiences on these issues.

<u>Revealed Preference Survey (Phase I)</u>

A mail survey was implemented to the community residents in July 2007. Selected total sample size that we could contact by regular mail was 1,600. We followed the standard mail survey techniques (Dillman, 2000). The basic steps are; s*tep i)* questionnaire survey is included in the mail with postage-paid return envelope, s*tep ii)* send a reminder card, and *step iii)* for those who had not responded to the first

survey, send a second copy of the survey. We received total of 1,047 responses (65% response rate). Usual successful response rate in survey is known to be around 20-25% (Boyle, 2007). This unusually high response rate shows that community residents are interested and serious regarding these issues.

Stated Preference Survey (Phase II)

In the second phase of the survey, AHP was applied to those who were willing to be contacted again. From Phase I, we received 1,047 respondents and 400 respondents were willing to be contacted again for further questionnaire. Using the similar steps (Dillman, 2000), we sent 400 surveys and received 250 surveys back (63%). In this phase, we wanted to understand homeowner's decision making process in the choices of home drinking water plumbing systems and materials. After personal communications with the homeowner association committees and pinhole leak experts, we developed the most important and relevant criteria; corrosion, taste and odor of drinking water, health effects, convenience of installation, proven performance in the market, cost (labor + material), and manufacture warranty. Also we considered materials copper, PEX, and Epoxy Coating which corresponds to their existing real alternatives. For complete survey modules, refer to Lee (2008).

RESULTS

Revealed Preferences for Community Residents

In this section, important aspects of survey results relevant to the scope of this study are included. For complete survey results, refer to Bosch et al. (2008). Out of 1,047 respondents, 212 respondents (20%) reported incidents of pinhole leaks in their potable plumbing systems; 780 respondents (74%) reported no experience of leak incidents in their houses; and 32 respondents (3.2%) reported do not know. One hundred and twenty eight respondents (60%) of the respondents with leaks had experienced 1 or 2 leaks; 47 respondents (22%) had 3 or 4 leaks; and 33 respondents (15%) reported more than 5 leak incidents.

Seventy-seven respondents repaired the leak using a clamp (Table 1). It is likely that a clamp was used initially before leaking sections were replaced or replumbed for the whole house. One hundred thirty-three respondents repaired the leak by replacing the leaking pipe section. Copper was most often used. Fifty respondents repaired the leak by *replumbing the entire house*. PEX was most often used (32 respondents) for replumbing followed by Epoxy coating (9 respondents). Five respondents replumbed with copper (same or thicker pipes) and 4 respondents did replumb with CPVC.

Table 2 lists the cost of repairing pinhole leaks. Twenty-nine percent of respondents with leaks reported that the expense of repairing pinhole leaks was less than $100; while 30% reported expenses between $100 and $500; and 37% reported more than $500 in expenses for pinhole leak repairs. Seven respondents reported more than $10,000 in costs of repairs. This figure possibly includes replumbing the whole house. Property damage cost due to pinhole leaks are shown in Table 3. Ninety-two percent of respondents with leaks reported having to repair property damage caused by leaks in addition to the expense of repairing leaks. Forty percent of respondents with

damage reported less than $100 of damage while 49% had over $100 in damage. Twelve respondents had over $5,000 in property damage**.**

Stated Preferences for Community Residents

Among 250 surveys received, 133 respondents' data turned out to be reliable. Mean attribute results for 133 respondents show that health effect and taste/ odor are the two important factors in deciding on the plumbing materials. Corrosion resistance and proven performance in the market constitute the next set of important attributes. Cost and convenience of installation seems to be the least important factor. It is interesting to see that cost is not highly dominant factor for homeowners. This is partly due to the similar cost ranges listed in the given information. In real life, cost figure may become major factors if there is a large difference among alternatives.

To see the preference difference between those who have leak experiences and no experiences, 133 respondents' are broken down into two groups; with leaks (28 respondents) and without leak experiences (105 respondents). There is little difference in between each group and majority of respondents regarded health and taste of odor as their major decision factors.

Comparison between Revealed Preferences and Stated Preferences

To compare revealed and stated preferences, we link 133 respondents' AHP results with revealed preferences surveys. As mentioned, 28 households had experienced pinhole leak incidents. Hundred and five households had not experienced any leak incidents in their plumbing system. For 28 households who had experienced leak incidents, their original pipe materials were all copper before they had any leaks.

Among 28 homeowners, 7 households did replumb their whole plumbing systems and 21 households repaired the failed section. Table 4 shows the real actions and AHP results for those who replumbed after leak incidents. For example, respondent # 1,310 replumbed with Epoxy coating in real life; and AHP result (revealed preferences; 3rd column in Table 4) is Epoxy coating. Their real actions are corresponding to the AHP's decision results. Likewise, respondent1,301's real replumb choice was PEX and AHP decision result are matching. However, 1,322's AHP results are Epoxy; real actions were with thicker copper pipes.

Table 4 Preference of those who replumbed after leak incidents

Respondent Number	Revealed preferences (Real actions)	Stated preferences (AHP)
1,301*	PEX	PEX
1,310	Epoxy coating	Epoxy coating
1,314	Epoxy coating	Epoxy coating
1,322	Thicker copper	Epoxy coating
1,295	Copper	PEX
1,127	PEX	Epoxy coating
1,730	PEX	Epoxy coating

*highlighted part indicates indivdiduals who had the same revealed and stated preferences

CONCLUSIONS

Selecting alternative plumbing material is subjective to homeowners' perception and preferences. According to AHP results, health effects and taste and odor of water turned out to be the dominant factors for homeowners. Some homeowners showed preference for one material, but they chose another option in real life. It is highly likely that their decisions are influenced by the amount information they could access. For example, southeastern community A residents seem to think corrosion resistance as the only criteria when choosing an alternative plumbing material. Even though safety issues (health, taste and odor) turned out to be the most important in the stated preferences, homeowners were not well aware of these issues related with plumbing materials in real life. Due to limitations in the number of attributes in AHP, we could only include the most important 7 attributes in the survey. There should be other attributes that will affect consumer's decisions such as attractive marketing strategies, special discount offers or purchase incentives and advise from others (plumbers, consultants, architects, neighbors etc). In addition, higher number of sample size will show better comparison between revealed and stated preferences.

Through this research, homeowners will be able to make better informed decisions in selecting alternative plumbing materials. Water professionals, policy makers, water utilities should work on bridging the gap between public perception and research results. The results of these surveys can help fill the information gap about pinhole leaks among policy experts and water utilities who are dealing with this problem. This information will be helpful for advising policy experts and utility companies on ways to deal with pinhole leaks.

Abstract

Water distribution system network models are used to simulate both hydraulic and water quality characteristics in water distribution systems. These models primarily focus on modeling hydraulics and are unable to model more than one water quality parameter. EPANET-MSX (Multi-Species eXtension), a recently developed multi-species water quality version of EPANET, has the ability to model complex multi-species systems of water quality species. This study proposes to provide the first comprehensive evaluation of integrated models associated with chloramine dynamics, by-product formation, and nitrification through the use of field-scale measurements and distribution system network modeling. Hydraulic and multi-species water quality simulations will be performed using EPANET-MSX. This investigation will gauge the accuracy of EPANET-MSX through comparison with a comprehensive set of field-data. Successful implementation of such a model could change the way water distribution maintenance and operation is approached in the future.

1 Introduction

Water distribution systems are designed to transport a sufficient quantity of treated water from a treatment facility to consumers without compromising the water quality. In reality, this is not always achieved. At the time when many water distribution systems were designed, the primary objective was to provide adequate pressure throughout the system. As a result, networks were frequently over designed in anticipation of satisfying increasing demands. In such cases, the excessive hydraulic residence times make maintaining adequate disinfection residuals difficult. Providing too much disinfection encourages the formation of hazardous disinfection by-products, while providing too little disinfection encourages the formation of biological contaminants. Operating such a system can be challenging, especially when strict water quality regulations must be satisfied.

In recent years, water distribution system network models have generally been utilized to remedy quantity related issues. From a water quality perspective, these

models have generally been limited to representing a single water quality species, with first-order dynamics, derived from a single source. EPANET-MSX (Multi-Species eXtension), a recently developed multi-species water quality version of EPANET, allows for the simulation of more complex water quality behavior from multiple sources. However, little research has been performed to confirm the results of the integrated models that evaluate both hydraulics and a multi-species water quality model within an actual distribution system. Verification of such models could facilitate the use of modeling software in troubleshooting and maintaining water quality issues in the future.

This study intends to provide a comprehensive water quality analysis that integrates chloramine decay, by-product formation, and nitrification into a single model in conjunction with system-wide field-scale measurements. This model will also be the first field-verified evaluation of EPANET-MSX, which will focus only on chemical and biological components within the bulk phase, not the pipe surface. Additionally, this comprehensive analysis will assess the accuracy of EPANET-MSX and identify any disparities between advanced water quality simulations and actual distribution system performance. Successful verification of such a comprehensive model would demonstrate that water quality models can be used in the decision making processes related to water quality maintenance of distribution systems.

2 Materials and Methods

Hydraulic and water quality simulations will be performed using EPANET-MSX, a recently developed extension of EPANET that provides a general environment for performing multispecies water quality modeling. An existing hydraulic model was provided by our partner utility (*see Section 2.1*). Model hydraulics will be modified in anticipation of simulating observed conditions in the actual system (*see Section 2.2*). Existing kinetic models and nonlinear equilibrium relationships associated with chloramine dynamics, by-product formation, nitrification, and other chemical and biological species will be incorporated to approximate the interaction of various species within the bulk fluid (*see Section 2.3*). Bench-scale studies will be performed on water samples from the system to estimate the necessary parameters related to kinetic models (*see Section 2.4*). After kinetic parameters are estimated, a comprehensive field study will be performed to assess the performance of the model and to determine if any knowledge gaps exist (*see Section 2.5*).

2.1 *Network Characteristics*

This study is being conducted in collaboration with our partner utility and focuses on a portion of their distribution system. The system serves 19.2 MGD of water to predominately residential customers (*see Figure 1*). The system contains no storage tanks and is supplied by three different water sources (surface water,

ground water, and a combination of surface, ground and desalinated water). As seen in Figure 1, the system is divided into three regions, where each region is supplied by a different type of source water. Region 1 is supplied by ground water, Region 2 by surface water, and Region 3 by a combination of surface, ground, and desalinated water. The dashed lines in Figure 1 approximate the service boundaries of the three source waters. Blended source waters are expected in the areas near these regional boundaries.

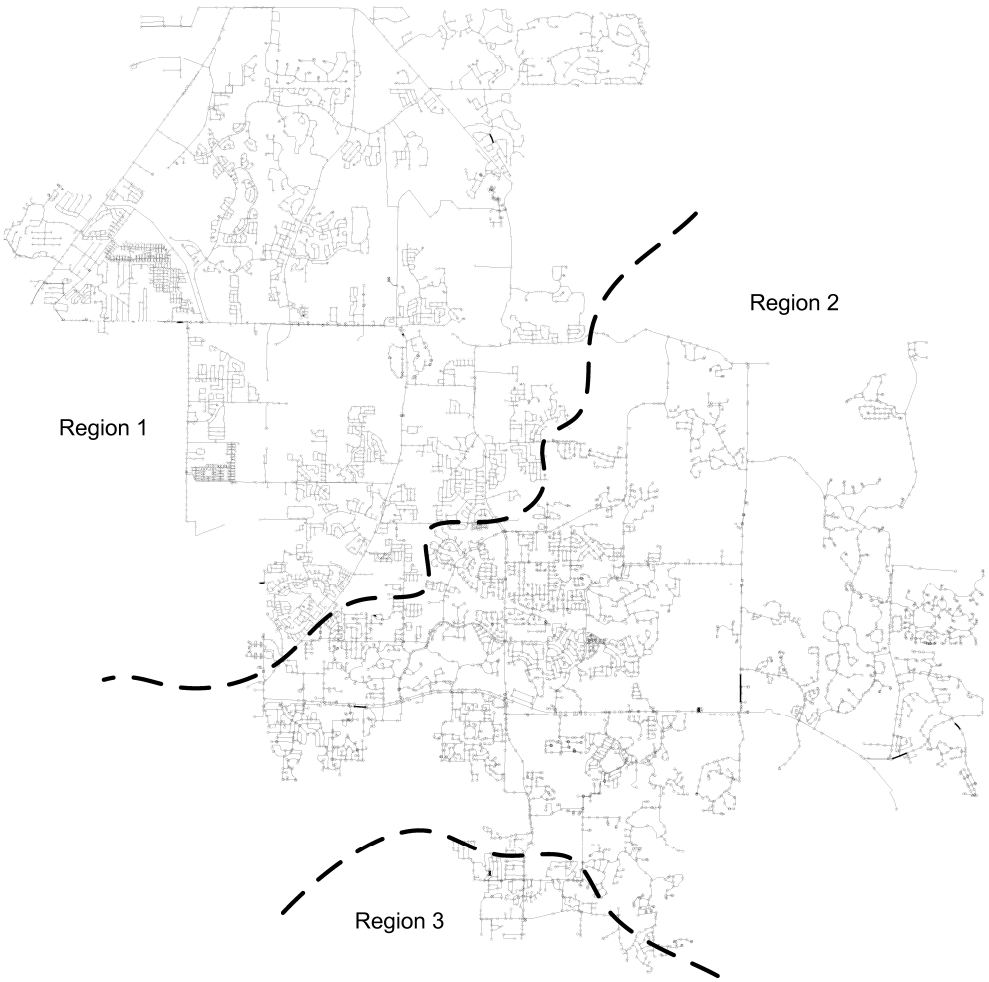

Figure 1: Partner Utility Network Model

2.2 *Hydraulic Simulations*

In order to achieve an accurate representation of water quality parameters, the hydraulics of the model network will likely need to be modified to characterize the conditions in the actual system. With the cooperation of our partner utility, pump operations and flow rates, in-line system flow rates and pressures, and other

significant data will be provided through their SCADA system. This data will be used to update the hydraulic model for representing the conditions observed during the field-study time period.

In such a system, with three different water sources, accurate representation of the hydraulics is important. Therefore, the demand pattern multiplier will be adjusted to ensure that the system is hydraulically balanced (i.e., the total volume of water entering the system will balance the water demanded by the system). In addition to adjusting the demand pattern, background levels of sulfate, each varying by approximately one order of magnitude, may be used to identify the water source throughout the system.

2.3 *Water Quality Simulations*

Chloramine System: Monochloramine (NH_2Cl) and dichloramine ($NHCl_2$) kinetics are modeled based on an existing auto-decomposition model developed by Vikesland et al. (2001) (*see Table 1*). This model incorporates hydrolysis reactions involving chlorine with ammonia or chloramines (*reactions 1 through 4*), disproportionation reactions of the chloramine species (*reactions 5 and 6*), redox reactions that occur at low levels of free chlorine (*reactions 7 through 10*), reaction pathways of monochloramine in the presence of natural organic matter (*reactions 11 and 12*), and acid/base equilibrium reactions of chlorine, ammonia, and carbonates (*reactions 13 through 16*) (Duirk et al., 2005; Vikesland et al., 2001). This model will require the estimation of the dissolved organic carbon (DOC) reactive site fractions, represented by DOC_1 and DOC_2 with monochloramine and free chlorine, respectively. Other parameters that will be measured include pH, temperature, dissolved organic carbon (DOC), alkalinity, free chlorine, ammonia, monochloramine, and dichloramine. These measurements will be used to determine the initial conditions of the multi-species model.

Disinfectant By-Product Formation: Two disinfectant by-products, N-nitrosodimethylamine (NDMA) and trihalomethanes (THM), are simulated using existing kinetic models (*see Table 2*). The NDMA model was developed by Chen and Valentine (2006), which provides a linear relationship between NDMA formation and reaction pathways of monochloramine and chlorine with natural organic matter (*reactions 13 and 14*). The THM model was developed by Boccelli et al. (2003), which presents a linear relationship between total trihalomethanes (TTHM) and total chlorine demand, or amount of natural organic matter that is oxidized. The rate of chloramine loss, and both linear parameters, θ and ϕ, will be estimated through bench-scale kinetic studies (*see Section 2.4*). These site-specific parameters will measured at various locations throughout the system.

Nitrification: Historically, nitrification has occurred in distribution systems with chloramine disinfection (Fleming et al., 2005; Liu et al., 2005). Ammonia loss within a distribution system may be attributed to assimilative growth and biochemical nitrification by ammonia oxidizing bacteria (AOB) and nitrite oxidizing

Table 1: Chloramine Loss – various pathways of decay (Duirk et al., 2005; Vikesland et al., 2001).

	Reaction Stoichiometry	Rate Coefficients & Equilibrium Constants
1	$HOCl + NH_3 \rightarrow NH_2Cl + H_2O$	$k_1 = 1.5 \times 10^{10}$
2	$NH_2Cl + H_2O \rightarrow HOCl + NH_3$	$k_2 = 7.6 \times 10^{-2}$
3	$HOCl + NH_2Cl \rightarrow NHCl_2 + H_2O$	$k_3 = 1.0 \times 10^{6}$
4	$NHCl_2 + H_2O \rightarrow HOCl + NH_2Cl$	$k_4 = 2.3 \times 10^{-3}$
5	$NH_2Cl + NH_2Cl \rightarrow NHCl_2 + NH_3$	$k_5 = 2.5 \times 10^{7}[H^+]$ $+4.0 \times 10^{4}[H_2CO_3]$ $+8.0 \times 10^{2}[HCO_3^-]$
6	$NHCl_2 + NH_3 \rightarrow NH_2Cl + NH_2Cl$	$k_6 = 2.2 \times 10^{8}$
7	$NHCl_2 + H_2O \rightarrow I$	$k_7 = 4.0 \times 10^{5}$
8	$I + NHCl_2 \rightarrow HOCl + Products$	$k_8 = 1.0 \times 10^{8}$
9	$I + NH_2Cl \rightarrow Products$	$k_9 = 3.0 \times 10^{7}$
10	$NH_2Cl + NHCl_2 \rightarrow Products$	$k_{10} = 55.0$
11	$NH_2Cl + DOC_1 \rightarrow Products$	$k_{11} = 3.0 \times 10^{4}$
12	$HOCl + DOC_2 \rightarrow Products$	$k_{12} = 6.5 \times 10^{5}$
13	$HOCl \rightarrow H^+ + OCl^-$	$pK_a = 7.5$
14	$NH_4^+ \rightarrow NH_3 + H^+$	$pK_a = 9.3$
15	$H_2CO_3 \rightarrow HCO_3^- + H^+$	$pK_a = 6.3$
16	$HCO_3^- \rightarrow CO_3^{2-} + H^+$	$pK_a = 10.3$

Rate coefficients and equilibrium constants are given at 25°C.

The term I is an unknown reactive intermediate.

[b]First-order chlorine decay coefficient
[c]Estimated unit of TTHM formation per unit of chlorine demand

bacteria (NOB) (*see Table 3*). The individual growth rates of AOB and NOB were modeled by Liu et al. (2005). This model utilizes Monod kinetics to express biomass concentration and considers the inhibition effect of monochloramine and the rate limiting effect of dissolved oxygen (Liu et al., 2005). This model can be found in *Table* 3 where $\mu_{1\ max}$ ($0.4\ day^{-1}$) is the maximum specific growth rate of AOB, $\mu_{2\ max}$ ($0.55\ day^{-1}$) is the maximum specific growth rate of NOB, K_1 ($2.0 \times 10^{-4}\ mg/cm^3$ as Cl_2) is the ammonia concentration yielding half of the AOB maximum rate, K_2 ($1.2 \times 10^{-3}\ mg/cm^3$ as N) is the nitrite concentration yielding half of the NOB maximum rate, K_3 ($4.0 \times 10^{-4}\ mg/cm^3$) is the estimated oxygen concentration giving half of the AOB and NOB maximum rate, and K_4 ($5.0 \times 10^{-4}\ mg/cm^3$ as Cl_2) is the inhibition concentration of monochloramine.

Microbial: Previous studies have suggested that chlorine to ammonia concentration ratios, or nitrification potential curves, may be used to indicate that conditions are favorable for nitrification to occur (Fleming et al., 2005). This theory is based on growth and inactivation kinetics of AOB in the presence of chlorine and ammonia. This strategy of predicting regions of greater nitrification potential, based on a straightforward ratio, will be implemented to assist in determining the water quality sampling locations. If nitrification occurs where measured ratios indicate, further validation would be provided that nitrification may be predicted by a simple chlorine to ammonia ratio.

Analysis of the biological species will take place only at 24 hour intervals. Collections of biomass, for the analysis of biological species, will be collected from the bulk water and concentrated. DNA will be extracted from the concentrated biomass with a commercially produced extraction kit. The *presence* of AOB and NOB will be determined by using polymerase chain reaction (PCR) of extracted nucleic acids using an available ABI real-time instrument (Hermansson and Lindgren, 2001; Rotthauwe et al., 1997; Schmid et al., 2003). Gel electrophoresis and Southern Blot hybridization will be used to validate the identity of each target

sequence. This procedure should be adequate in qualitatively predicting the *presence* or *absence* of AOB and/or NOB.

Table 3: Nitrification Modeling – various pathways of ammonia disappearance (Liu et al., 2005).

	Reaction Expression
15	$\mathrm{AOB}(t) = \left(\frac{\mu_{1\ max} * [\mathrm{NH_3}]}{\mathrm{K_1} + [\mathrm{NH_3}]}\right) \times \left(\frac{[\mathrm{DO}]}{\mathrm{K_3} + [\mathrm{DO}]}\right) \times \left(1 + \frac{[\mathrm{NH_2Cl}]}{\mathrm{K_4}}\right)^{-1}$
16	$\mathrm{NOB}(t) = \left(\frac{\mu_{2\ max} * [\mathrm{NO_2}]}{\mathrm{K_2} + [\mathrm{NO_2}]}\right) \times \left(\frac{[\mathrm{DO}]}{\mathrm{K_3} + [\mathrm{DO}]}\right) \times \left(1 + \frac{[\mathrm{NH_2Cl}]}{\mathrm{K_4}}\right)^{-1}$

For parameter definitions see Section 2.3

2.4 *Bench-Scale Assessment*

Parameter estimation studies will be performed prior to field-scale data collection. These studies will be performed to assess the kinetics associated with reactions of chloramine ($\mathrm{DOC_1}$) and chlorine ($\mathrm{DOC_2}$) with natural organic matter and the formation of NDMA (θ) and TTHM (ϕ). A sample of non-chloraminated treated water has been obtained from the utility for use in parameter estimation studies. Water quality species discussed in Section 2.3 will be measured prior to disinfection of the sample. These measurements will be used to provide initial background concentrations of the respective species in the model. The provided sample will be divided into smaller samples. One sample will be *chloraminated* at a standard 5:1 ratio of chlorine to ammonia-N. The other sample will be *chlorinated* at a low dosage to evaluate the kinetic behavior of reactions under such conditions (*see Table 1*)

After both samples have been treated with disinfectant, two groups of several disinfectant demand-free bottles will be filled (Summers et al., 1996). One group will be filled with the chlorinated sample and the other with the chloraminated sample. Both groups of samples will be stored in a dark temperature controlled environment. Sample bottles from both groups will be removed and necessary water quality parameters will be analyzed after 5 min, 15 min, 30 min, 1 hr, 2 hr, 4 hr, 8 hr, 24 hr, 48 hr, 72 hr, 96 hr, and 120 hr. Species concentration at various time intervals will be used to estimate kinetic parameters by using a Levenberg-Marquardt approach to minimize the sum-of-the-squared errors between observed and expected values.

In addition to parameter estimation studies, bench-scale measurements of nitrite ($\mathrm{NO_2^-}$) and nitrate ($\mathrm{NO_3^-}$) will be performed to gauge the accuracy of the nitrification model.

2.4.1 *Water Quality Measurements*

Chlorine and chloramines will be measured using *Hach Method 8167* (Hach Company, 2000), an adaptation of the DPD Colorimetric Method [4500-Cl G] (Eaton et al., 2005). This method uses *N,N*-diethyl-*p*-phenylenediamine (DPD) reagent packets as an indicator with a colorimeter to measure concentrations of free chlorine, monochloramine, and dichloramine (Eaton et al., 2005). A *Hach DR/850 Colorimeter* (Hach Company, 2000) will be used to make both bench-scale and field-scale measurements. Ammonia will be measured according to the Ammonia-Selective Electrode Method [4500-NH_3 D] (Eaton et al., 2005), which incorporates the use of an electrode to measure aqueous ammonia levels in acidified solutions, that converts NH_3 to NH_4^+.

Nitrate will be gauged by means of *Hach Method 8039* (Hach Company, 2000), an adaptation of the Cadmium Reduction Method [4500-$N0_3^-$ E] (Eaton et al., 2005). This is another colorimetric method, which uses cadmium treated with $CuSO_4$, to reduce nitrate to nitrite. The nitrite is then treated with an agent to form a red color, which is then measured with a colorimeter. Nitrite concentration will be quantified by *Hach Method 8507* (Hach Company, 2000), another adaptation of the Colorimetric Method [4500-$N0_2^-$ B] (Eaton et al., 2005), which is the same procedure as the Cadmium Reduction Method [4500-$N0_3^-$ E], excluding the reduction of nitrate to nitrite with cadmium. Nitrite and nitrate samples will be taken at time intervals no less than one hour, due to the time required to conduct their analysis.

Organic carbon measurements will be assessed using a *Shimadzu TOC analyzer*, which utilizes the combustion catalytic oxidation/NDIR to quantify a full array of organic compounds. The pH of various samples will be determined by using a glass membrane pH electrode, which is described in detail by the Electrometric Method [4500-H^+ B] (Eaton et al., 2005). Sulfate concentration will also be measured by *Hach Method 8051* (Hach Company, 2000), a colorimetric procedure adapted from the Turbidimetric Method [4500-SO_4^{2-} E] (Eaton et al., 2005) that utilizes a barium chloride ($BaCl_2$) reagent.

Disinfectant by-products, NDMA and TTHM, will be evaluated by using a gas chromatography/mass spectrometer (GC/MS). *N*-nitrosodimethylamine will be gauged by isolating contaminants with solid-phase extraction (SPE) followed by analysis with a GC/MS with selective-ion monitoring (SIM) (Choi and Valentine, 2002). Total trihalomethanes will be measured according to the Purge and Trap Capillary-Column Gas Chromatographic Method [6200 C] (Eaton et al., 2005), which is a commonly used procedure to measure a variety of halocarbons and aromatic organic compounds.

2.5 *Field-Scale Assessment*

Field-scale activites will consist of both water quality and hydraulic data collection activities performed over a two week time period in the Winter/Spring of 2009. Due to temporal and spatial challenges the field-scale assessment will focus on only a portion of the system. Once all kinetic parameters are estimated and initial background concentrations of various species are quantified, the field-scale data collection may begin. These parameters and concentrations will be used to conduct a preliminary simulation. This simulation will be used to determine areas in the system where nitrification, or loss of disinfection residual, are expected to occur. This is expected to occur in areas where source waters are mixed (*see the dashed source boundary lines in Figure 1*). Sampling locations will be determined using a modified version of TEVA-SPOT (Boccelli and Hart, 2007; Hart et al., 2007), which assists in the placement of sampling locations. This will ensure that field-scale measurements accurately represent the entire system through adequate spatial coverage and a distribution of hydraulic residence times. In addition to the sampling locations determined by the software, samples will be collected at system sources and areas where source blending occurs.

Water quality samples will be taken from either fire hydrants or dedicated water quality sampling taps. Sampling sites will be visited two to four times daily, depending on spatial location and sampling time. All water quality measurements (*see Section 2.4.1*) will be performed in the field with the *Hach DR/850 Colorimeter* (Hach Company, 2000), excluding DBPs and biological species, which will be preserved and returned to the laboratory for analysis. Biological samples will be taken only once at each sampling location, unless nitrification conditions are suspected.

In addition to water quality sampling, hydraulic conditions will also be monitored throughout the system. As mentioned in Section 2.2, pump operations and flow rates, in-line system flow rates and pressures, and other significant data will be provided by our partner utility, through their SCADA system. This data will be used to update the distribution system demand estimates for the system model.

3 Preliminary Analysis

When selecting potential sampling locations, a few criteria must be considered. The locations must be spatially diverse and represent a broad range of hydraulic behavior (Boccelli and Hart, 2007). In this study, we would also like to capture areas with elevated nitrification potential (Fleming et al., 2005). This criteria may be satisfied by examining water age, chloramine residual, and/or Cl:NH_3 ratios. As mentioned in Section 2.5, the field-scale activities will be limited by temporal and spatial constraints. Therefore, sampling will likely be limited to a portion of a system that represents typical hydraulic and water quality conditions. This section illustrates the proposed approach of selecting sampling locations.

A provisional analysis of the partner utility network was performed to assist in identifying potential sampling locations. This preliminary model only considers chloramine decomposition to ammonia in the presence of natural organic matter (NOM), which is based on the model previously implemented by Shang et al. (Duirk et al., 2005; Shang et al., 2008a,b; Vikesland et al., 2001). An illustration of the spatial distribution in chloramine residual after a period of 72 hours may be seen in Figure 2. The initial conditions for this simulation were set at a pH of 7.55, 4.12 mg/L (80 μmole/L) of monochloramine, 200 mg/L of alkalinity (as $CaCO_3$), and 3.00 mg/L of TOC, with slow and fast reaction sites of 0.02 and 0.50, respectively. This figure depicts a small portion of the network model that borders a source water boundary (shown by a dashed line). In this system, the disinfection residuals were typically lower near extremities of the network and source water boundaries, where the age of the water is expected to be the greatest.

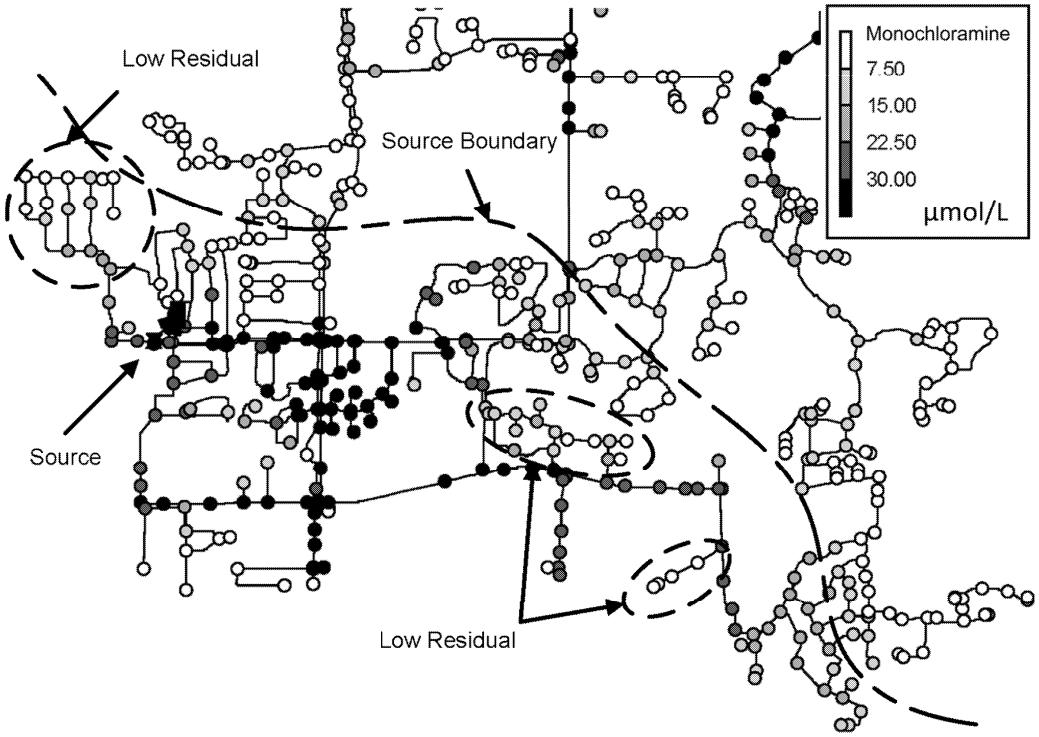

Figure 2: Preliminary Model of Monochloramine Residual in Portion of Network at 72 Hours

The preliminary simulations will be used to identify sampling locations that represent the overall distribution of water quality parameters to be measured. Figure 3 shows the empirical cumulative distribution function (cdf) of the monochloramine residual shown in Figure 2. The cdf represents the distribution system information that could be generated if sampling could occur at every location. In reality,

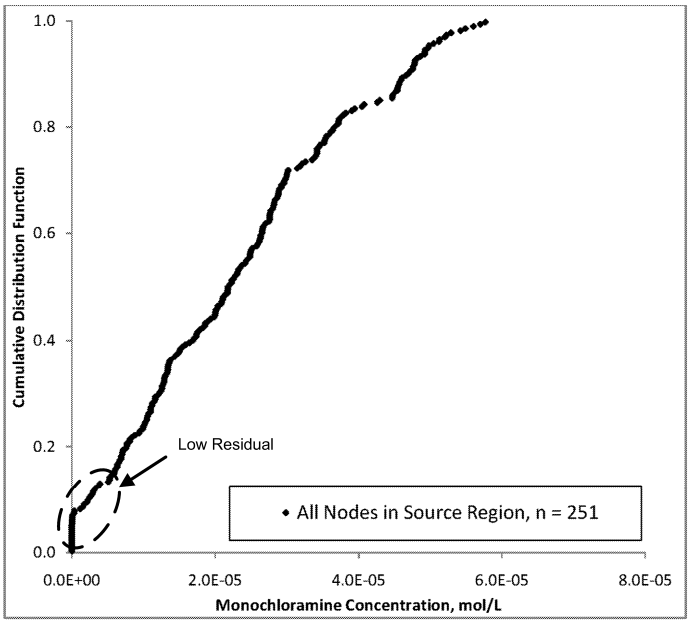

Figure 3: Illustration of the Distribution of Monochloramine Residual in Portion of Network at 72 Hours

only a subset of locations can be sampled. This subset of locations should be selected to represent the overall distribution to ensure adequate representation of all conditions within the distribution system. In addition to representing the overall distribution, the subset of sampling locations must also be spatially diverse. As an illustrative example, if the only interest were in representing the low monochloramine concentration range of the overall distribution, this objective could be satisfied by sampling entirely in the south east region of the system. However, the more preferable approach would be to more evenly distribute the sampling locations between the southeast and northwest area, both of which have low residuals. Such a design satisfies both the overall distribution and achieves spatial distribution of the measurements.

4 Summary/Future Work

This study intends to provide the first comprehensive evaluation of integrated water quality and hydraulic models, which places particular emphasis on the ability of EPANET-MSX to represent the multi-species water quality system. Successful verification of this comprehensive model could demonstrate that water quality models similar to this could be used in decision making processes related to water quality maintenance of distribution systems in the future.

The framework of this study has been established and parameter estimation studies will be completed over the next month with water supplied by the utility.

After the parameter values specific to the study water system are established, the model will be updated and actual sampling locations will determined. Once the sampling locations are determined, a two week field-scale assessment will follow. After data is collected and analyzed, the observed hydraulic and water quality data will be compared to the predicted model results, focusing on the ability of the model to represent both the hydraulics and water quality.

5 Acknowledgements

This research is based on funding by the Water Research Foundation, formerly known as the American Water Works Association Research Foundation. Their support is greatly appreciated. We would also like to thank Dr. Dan Oerther and his research assistant Mau-Yi Wu for their time and guidance particularly associated with the PCR analysis.

Pressure vs. Flow Relationship for Pipe Leaks

Thomas Walski, Bentley Systems
Brian Whitman, Wilkes University
Mary Baron, Wilkes University
Fred Gerloff, Wilkes University

Abstract

Leakage can be reduced by reducing pressure in a water distribution system. The magnitude of that reduction depends on the equation used to predict leakage. A common equation is to use a power function where the flow is estimated from the pressure terms raised to an exponent. There are a wide range of values reported in the literature for that exponent. Laboratory experiments were performed in which flow and pressure were measured for a wide range of leak shapes and sizes. The median value of the exponent was 0.54 which is lower than most reported but close to the theoretical value for an orifice. The high values in the literature can be explained in some cases as due to the method for estimating leak reduction. This is illustrated using a model of a small zone.

Background

Water loss through leakage has been identified as a problem in virtually all water distribution systems. Leakage is inevitable in all water systems. It is estimated that roughly 32 billion cubic meters of water is lost annually from water distribution systems by way of leakage (Kingdom, Limberger and Marin, 2006). Thornton (2002) estimated that the worldwide value of this lost was on the order of $81 billion per year.

Because the rate of leakage depends on the pressure within the pipe, one method of reducing leakage is pressure management. Reducing pressure has been shown to be effective in reducing leakage. Predicting the reduction in leakage due to pressure reduction is not exact. Most investigators agree that a power function of the form below should explain the pressure vs. leak relationship.

$$Q_f = Q_i\left(\frac{P_f}{P_i}\right)^n \qquad (1)$$

Where Q_f = final leak rate, Q_i = initial leak rate, P_f = final pressure, P_i = initial pressure, n = exponent

There have been a wide range of values reported to the exponent n (referred to as N1 in some papers). This paper will describe the literature regarding this problem, present the results of some experiments to determine n and discuss some issues with determining n in existing systems with an example using a water distribution model.

Theoretically, leaks should behave as orifices which implies that the value of n should be roughly 0.5. However, values reported in the literature show considerable range as summarized in Table 1.

Table 1. Reported Values of Leak Power

Reference	Values	Conditions
Ogura (1979)	1.39-1.72	Slits
Hikki (1981)	0.5	Drilled holes
May (1994)	0.5 fixed area 1.5 size = f(P) 2.5 long	Fixed area Size = f(Pressure) Longitudinal
Lambert (2001)	0.52-2.79	Literature
Farley and Throw (2003)	0.70-1.68 0.63-2.12 0.52-2.79	UK (1977) Japan (1979) Brazil (1999)
Thornton and Lambert (2005)	0.5-1.6	Function of ILI
Walski et al. (2006)	0.66-0.76	Drilled holes
Greyvenstein and VanZyl (2007)	0.52 1.38-1.85 0.79-1.04 0.41-0.53 0.67-2.3	Round Hole Longitudinal PVC Longitudinal AC Circumferential Corrosion steel
Noack and Ullanicki (2007)	0.5 – 1.0	f(soil permeability)

The prevailing hypothesis for the leak flow vs. pressure relationship is referred to as the FAVAD (Fixed and Variable Area Discharge) theory. It proposes that for circular leaks, the orifice equation adequately describes flow and an exponent of 0.5 is accurate. However, as the pressure increases, the pressure can actually expand the orifice size such that the apparent exponent is significantly greater than 1.

This has been further modified by correlating n with the ILI (Infrastructure Leakage Index) which is a ratio of current annual real losses divided by unavoidable annual real losses (Farley and Throw, 2003). A value of 1 would indicate a system that has only unavoidable losses while higher values indicate the presence of more losses that can be corrected. For plastic piping an n value of 1.5 is indicated while for metal pipes the values should range from 1.2 for an ILI of 1 to 0.5 for systems with a high ILI.

Walski et al. (2006), Noack and Ullanicki (2007) and Van Zyl and Clayton (2007) studied the effect of the surrounding soil on leak rate. In general, the nature and size of the orifice has a much greater effect on leakage rate that the porous media flow through the soil. Walski et al. (2006) described the conditions necessary for the soil to be limiting flow based on a dimensionless number and in general these conditions are not met for typical leaks. The remainder of this paper describes some experiments to determine n and how those values affect leakage estimates in large systems.

Test Apparatus Design

To effectively model leakage through various pipe materials and holes, an apparatus was constructed in a controlled laboratory environment where flow and pressure could be accurately controlled and measured. The test apparatus included one tank containing clean water, which housed the test sections of pipe. The water supply was directly connected to pressurized water pipe and was controlled via a pressure regulator. A calibrated pressure gauge was located after the regulator and placed at the same height as the water surface inside the tank (see Figure 1).

Figure 1. Picture of Experimental Apparatus

Each test section was secured within the tank using a union connector that easily allowed the removal and replacement of test sections. Schedule 40 PVC test sections ranged in size from 25 to 150 mm (1 – 6 inch) including either a circular, longitudinal (crack running parallel to direction of flow), or circumferential (crack running perpendicular to direction of flow) break.

The test sections with circular holes of varying size were used to verify previous research and confirm that the test apparatus was functioning properly. The circular holes were created using two drill bits which were sized at 2.7 mm and 5.6 mm (7/64 and 7/32 inches).

Longitudinal slits cut into the pipes to simulate a crack ranged from 25 to 50 mm (1 to 2 in) in length. These slits were constructed by using a heat gun and heated razor blade, similar to that of a small electric soldering tool. The desired area where the pipe was to be cut was gently heated with the heat gun as to not burn or seriously deform the pipe material. Upon sufficient heating, the hot razorblade was used to slowly cut the slit in the pipe to the desired length. Additional razor blades similar to that of the one doing the cutting (same thickness) were immediately inserted to the freshly cut slit to ensure that the PVC would not adhere back together while cooling. All razor blades were pulled out from the slit after cooling and examined for any areas or burs that might later obstruct flow. This slit construction method helped to assure some degree of consistency when simulating the same slit among different pipe test sections. Any large variation between two constructed slits, holes or circumferential breaks has the potential to adversely affect the measured discharge.

The half-circumferential breaks were constructed by use of a thin bladed band saw. The band saw was used to make cuts exactly half-way through the pipe, perpendicular to its length. The burs and other pipe shaving were then thoroughly removed from the area.

To compare different pipe materials, a 31 mm (1.25 inch) diameter copper pipe test section was tested. The 1 inch slit in the cooper pipe was created using a small cutting wheel (1.59mm (1/16) inch thick) attached to a pneumatic grinder. The two ends of the slit in the copper piping were cleaned using a small file of similar thickness.

The flow emitted though the break created in each test section will discharge though a hole in the side wall of the tank. The volume of water collected for a specific time interval was collected and measured to determine the system's flow rate. This method was used to measure all flows and was compared to the reading from the digital flow meter installed on the apparatus for quality assurance. Prior to any experimental tests, the flow meter was calibrated to ensure accurate readings and positioned between the pressure regulator and the bleeder valve. The bleeder valve is use to remove any of the air bubbles in the system that occur when changing system pressure. This calibrated pressure gauge served to monitor experimental pressures within the system.

Experimental Techniques and Methods

Values of both pressure and flow were measured for each of the experimental breaks constructed in the numerous test sections. The range of pressure readings selected was from 68.9 kPa (10 psi) to 483 kPa (70 psi) in increments of roughly 68.9 kPa (10 psi). There are three types of test sections used for the experiment, one for each type of break. Due to the cost of pipe materials, the tests sections were used to run multiple tests, starting with the smallest hole or slit.

The first set of tests consisted of the test sections with the circular hole. In the test section a circular 2.7 mm hole (7/64 inch) was first drilled into each of the test sections. The experiment first began starting at the lowest pressure. Once the flows through the orifice have been measured, the pressure increased incrementally to the maximum pressure; the

flow measurements were again calculated for each pressure. A minimum of six measurements were obtained over 15 second intervals for each pressure. When all of the readings were taken for the smallest hole, a bigger hole was then drilled overtop the existing hole and subjected to the exact testing procedure.

The experiments for the longitudinal slits and circumferential breaks were conducted using the same procedure. The longitudinal slits began with a slit 25 mm (1 in) long and were then increased to a 50 mm (2 in) slit. The half-circumferential breaks only needed to be cut once.

Data Analysis

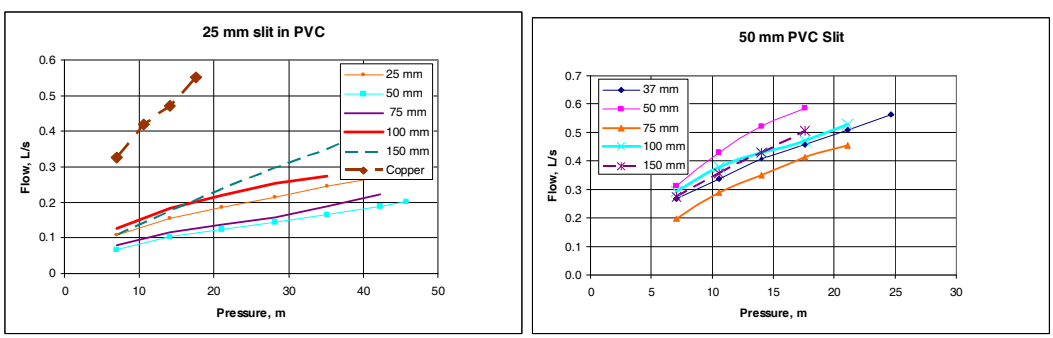
The data collected demonstrated the water loss through the breaks at variable pressures. The measured flow rates and pressures were used to determine values of the coefficients a and n in equation (2).

The plots of pressure vs. flow are shown in Figures 2 for each type of leak. All of the results were fit to a power function of the form

$$Q = aP^n \qquad (2)$$

Where Q = flow, L/s, P = pressure, m, a and n are coefficients.

The index of determination for virtually all the graphs was on the order of 0.99. The values plotted as straight lines on log – log graphs.



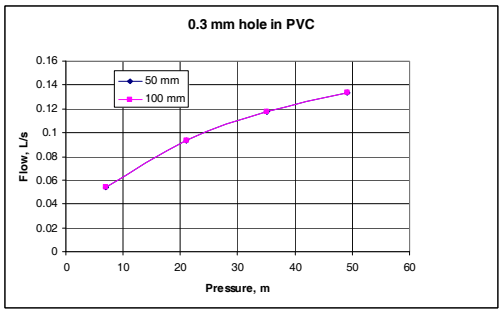


Figure 2a. Leak flow vs. Pressure for 25 mm slit in PVC Pipe (and one copper pipe)
Figure 2b. Leak flow vs. Pressure for 50 mm slit in PVC Pipe
(Values in the legend refer to the nominal pipe diameter)

Table 2 shows that the mean value of n is 0.58 and the median value is 0.54. It is difficult to reconcile these values with the values in excess of 1 as found in the literature. The following section provides an explanation for apparent n values larger than those found in this study.

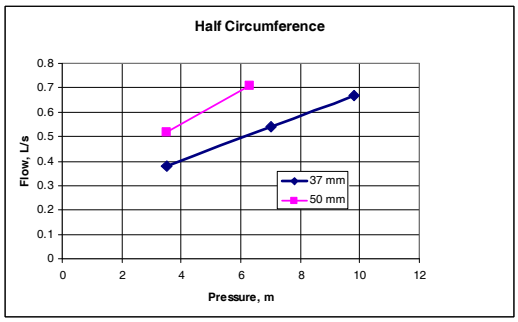

Figure 2c. Leak flow vs. Pressure for Circular Holes

Half Circ = half of a circumferential break

System Wide Exponent for Leak Reduction due to Pressure Control

The water produced at a source can be delivered to customers to meet fixed demands, pressure dependent demands or leaks.

$$Q_s = Q_f + Q_p + Q_L \qquad (3)$$

Where Q is flow and the subscripts on flow refer to supply (s), fixed (f), pressure dependent (p) and leakage (L), where leakage refers to leakage on the utility's side of the customer meters.

Both pressure dependent demand and leaks can be represented by an orifice equation of the general form:

$$Q = KP^n \qquad (4)$$

Where K is an orifice coefficient, P is pressure and n is an exponent which should be roughly 0.5. Substituting gives

$$Q_s = Q_f + K_p P^n + K_L P^n \qquad (5)$$

Where K_p and K_L are the orifice coefficients for pressure dependent demands and leaks.

The question becomes one of how to determine the exponent n to analyze the effect of pressure changes. Some investigators assume that pressure dependent demand is essentially zero such that given the water production before and after pressure reduction, the leakage after reduction can be determined as

$$Q_L(f) = Q_s(f) - Q_f(f) \qquad (6a)$$

or

$$Q_L(f) = Q_L(i) - [Q_s(i) - Q_s(f)] \qquad (6b)$$

Equation (6b) can overestimate the loss because it also includes reduction in pressure dependent demand. Ignoring the pressure dependent demand term and solving for n yields

$$n(apparent) = \frac{\log(Q_L(i)/Q_L(f))}{\log(P(i)/P(f))} \qquad (7)$$

Where i refers to initial (before pressure reduction) and f refers to final (after pressure reduction.

However, this equation tends to overestimate n (and the impact of pressure reduction) because it does not account for the fact that some of the reduction in source production is really due to reduction in metered water use (pressure dependent demand), not reduction in leakage.

This can best be illustrated by a numerical example. Given

Q_f = 20 ML/day (5.3 MGD)
P(i) = 400 kPa (59 psi)

$K_p = 0.4$
$K_L = 0.2$
$n = 0.5$

The initial flow into the area is given by

$$Q_s(i) = 20 + 0.4\ (400)^{0.5} + 0.2(400)^{0.5} = 20 + 8 + 4 = 32 \text{ ML/day (8.5 MGD)} \quad (8)$$

Next the pressure is reduced to 350 kPa (51.5 psi)

$$Q_s(f) = 20 + 0.4(350)^{05} + 0.2(350)^{0.5} = 20 + 7.48 + 3.74 = 31.2 \text{ ML/day (8.3 MD)} \quad (9)$$

The value of n should be calculated as

$$n(actual) = \frac{\log(4/3.74)}{\log(400/350)} = 0.5 \quad (10)$$

However, looking at source production numbers it is difficult to distinguish between pressure dependent demand and leakage so that the reduction in leakage (which should be 0.26) includes the reduction in pressure dependent demand (of 0.52). Hence n is calculated as

$$n(apparent) = \frac{\log(4/(4-0.78))}{\log(400/350)} = 1.67 \quad (11)$$

This results in overestimating leakage reduction due to pressure reduction. The value of n(actual) is the appropriate n for estimating the reduction in leakage, while the value of n(apparent) can be used to estimate the reduction in water source production as a result of pressure reduction.

System-wide Analysis of Leak Reduction by Pressure Control

As shown in the previous section, leak rates are dependent on pressure and the exponent for individual leaks is roughly 0.5. However, leaks are not the only pressure dependent demand on a water system and reducing pressure not only reduces leaks but also reduces other pressure dependent demands (PDD). In the following section, a model of a typical demand management area (DMA) is presented and the effects on a system are analyzed.

The area under consideration is a zone with 92 junction nodes and 120 pipes. Most pipes are nominal 150 mm (6 in.) although there are some 100 and 200 mm (4 and 8 in.) pipes. There is one source in the southwest corner through which the flow is metered and the pressure can be controlled. The average day demand is 37.8 L/s (600 gpm).

Leakage in the system is 20% of initial average day demand. The pressure head at the source is 90 m (295 ft) which results in average pressures of roughly 700 kPa (100 psi)

through the system depending on elevation. In this study, the pressure head is reduced in turn to 80, 70 and 60 m (262, 230 and 197 ft) and the leaks are assigned an orifice coefficient of 0.5.

As the pressure is reduced, the water use due to leakage and pressure dependent demand is also reduced. (The calculations were done with the WaterCAD program (Bentley Systems, 2008).) When all demand is considered to be fixed, there is no reduction in supply when the pressure is reduced. When only leakage is considered (and other demand is fixed), the use is reduced according to the orifice equation. When all PDD is considered (equation 6b), the apparent reduction in leakage is much larger.

When only leak flows are inserted into the formula for determining n (equation 10), then the values for n are 0.5 but when reduction in other PDD is included with leakage, higher values of n are found. This is shown in Table 3.

Table 3. Values of n calculated when pressure dependent uses are included and are not include in flow reduction determining n

Pressure reduction, m	Leak Only	Leak + PDD
10	0.5	1.4
20	0.5	1.5
30	0.5	1.7

Implications

The key implication of these calculations is that, if one is determining the expected reduction in leakage as a function of pressure, it is very important to understand what fraction of system demand is pressure dependent. Without knowing this it is not possible to accurately predict the reduction in leakage due to pressure reduction, especially if one is attempting to use a global n value to adjust demands in anticipation of pressure reduction.

Without knowing the fraction of demand that is pressure dependent, it is necessary to determine leak reduction by way of pressure control only by performing long term comparisons of source inflow vs. metered demand, not by using the drop in source production immediately upon reduction.

Conclusion

The results of the experiments reported in this paper indicate that the exponent (n) should not vary much from the orifice exponent of 0.5 for the set of leaks test in this study. Depending on the way in which reduction in leak flows are determined in calculating n, it is possible to calculate a value much higher than 0.5.

ABSTRACT

In the Metropolis of Seoul, Republic of Korea, more than 10.42million citizens are supplied with potable water by the waterworks Seoul metropolitan government. Seoul's waterworks now has a total of 6 treatment plants with a total daily production capacity of 5.10million m^3 (2007). An average daily production of 3.34million m^3 (2006) is guaranteed. This water is transmitted via a supply network consisting of more than 14,106Km of mains covering nearly 1.96 mil. taps. The distribution system includes 109 reservoirs (total storage volume: 2.35 million m^3) that provide emergency storage, balance water demands, and equalize pressure. The Seoul Metropolitan Government has various policies aimed at providing our citizens with safe and tasty tap water. We have a real time monitoring system to thoroughly manage the production and supply processes from the water supply sources to every household. The automatic water quality monitoring system was completed in July, 2006 according to a Seoul Water-Now Plan (Feb. 2001).

The water quality is monitored for 24 hours from the water source supply to the tap to secure safety of water, and the data is positively used to raw water monitoring, optimum water purification treatment and safe water distribution control. The real-time monitoring data is opened to the public through the homepage from 2008 March 21. Web site' address is http://water.seoul.go.kr/waternow/RealDataFullScale.php. 13 items are monitored including turbidity, residual chlorine, water temperature, etc. and 72 places consisting of 6 intakes, 6 water purifying plants and 60 supply places are monitored. It is planned to enlarge to 145 places to be monitored until 2010. As a result of running the system, The online monitoring system were contributed to maintain the safety of water quality from the source water to the tap water

Keywords: on-line**,** water quality monitoring, early warning system, SCADA

BACKGROUND

In the Metropolis of Seoul, Republic of Korea, more than 10.42million citizens are supplied with potable water by the waterworks Seoul metropolitan government.

Seoul's waterworks now has a total of 6 treatment plants with a total daily production capacity of 5.10million m^3 (2007). An average daily production of 3.34million m^3 (2006) is guaranteed. This water is transmitted via a supply network consisting of more than 14,106Km of mains covering nearly 1.96 mil. taps. The distribution system includes 109 reservoirs (total storage volume: 2.35 million m^3) that provide emergency storage, balance water demands, and equalize pressure.

There have been many changes along the 100-year history of Seoul's Waterworks. In the 1960's when the city's population was booming, the citizens had to suffer from lack of drinking water. After the 1990's, there is a growing demand for high-quality tap water among the citizens of Seoul. The Seoul Metropolitan Government has various policies aimed at providing our citizens with safe and tasty tap water. So, We have a real time monitoring system to thoroughly manage the production and supply processes from the water supply sources to every household. According to a Seoul Water-Now Plan (Feb. 2001), The automatic water quality monitoring system was completed in July, 2006.

PURPOSE OF ONLINE MONITORING

Seoul Water - Now system consist of early warning system, inner information system, opening to the public system. Each system has one's own purpose for system management.

The purpose of early warning system is as follow.

- The " source" monitoring purpose are oriented toward early warning systems that detect problems and signal the utility with a water intake on the source so they can take some action, such as shutting down the intake or changing the treatment to account for the unusual condition.
- The" treatment process" monitoring purpose are optimizing the amount of flocculants and disinfectants (free chlorine).
- The" distribution systems" monitoring purpose are supporting the operators and managers of small waterworks for early detection.

The purpose of opening to the public system is the increase of consumer confidence in drinking water quality

DESCRIPTION OF MONITORING EQUIPMENT

The water quality is monitored for 24 hours from the water source supply to the tap to secure safety of water, and the data is positively used to raw water monitoring, optimum water purification treatment and safe water distribution control.

Figure 1 shows the locations of the analyzers and sensors at Seoul Water Now (Korea) Several monitoring devices that measure different basic parameters are in place at the site. The chemical and physical, biological monitors were chosen on the basis of their reliability (see Table 1)

Site	Intake	Treatment Process					Distribution System		
	Pump station	Arrival bassin	Mixing & Flocculation	Sedimentation	Filtration	Clean water well	Pump Station	Reservoir	Household
Monitoring Items	Temp. pH Turbidity Ammonia TOC Cyanide phneols DaphnidTest Algae Flow	Temp. pH Turbidity R.C Alkalinity Flow	pH Turbidity R.C Alkalinity	pH Turbidity R.C Alkalinity	Turbidity	pH, temp., turb., R.C, Cond Flow	pH, temp., turb., R.C, Cond	pH, temp., turb., R.C, Cond	pH, temp., turb., R.C, Cond

Figure 1. Sensors and analyzers installed at Seoul Water Now (Korea)

Table 1. Measurement methods of online monitoring system at Seoul Water Now

Parameter	Measuring Method
Temperature	Thermo-resistive measurement technique
pH	Electrochemical
Conductivity	Probe equipped with two steel electrodes
Turbidity	Surface scattering using to detect the reflected luminance
Ammonia, Cyanide, Phenols	Ion-Selective Electrode
Residual chlorine	DPD method or electrodes
TOC	Chemical oxidation, catalyzed by UV radiation
Alkalinity	Titration- pH end point
VOCs	Purge-and-trap systems/ GC(ECD)
Toxicity	Daphnid Test
Algae	Fluorometry

As shown in Figure 2, 72 places consisting of 6 intakes, 6 water purifying plants and 60 supply places are monitored.

Namely, To block the infusion of hazardous pollutants and maintain the safety of the source water, automatic monitoring is in operation around the clock at 6 intake pumping stations involving 10 monitored items.(Phenols, Cyanide, turbidity, NH3-N, TOC, Temp, pH, Daphnid Test, Algae, etc.) To monitor the treatment process and provide safer and better-quality water, automatic monitoring is in operation around the clock at 6 water treatment plants involving 6 monitored items (Turbidity, Temp, pH, Alkalinity, Conductivity, R.C) To maintain the same water quality from at the time of departure from the purification plants to the time of arrival at the faucets, automatic monitoring is in operation around the clock at 65sites involving 5 monitored items. (pH, temp., turb., R.C, Cond.) It is planned to enlarge to 145 places to be monitored until 2010.

Each selected station employing remote water quality monitoring was equipped with sample taps, sample drains, controller. Except for turbidity measurements. All system require that suspended solids levels be reduced for proper performance. Therefore, a system for inline filtering of particles larger than 100um has been installed.

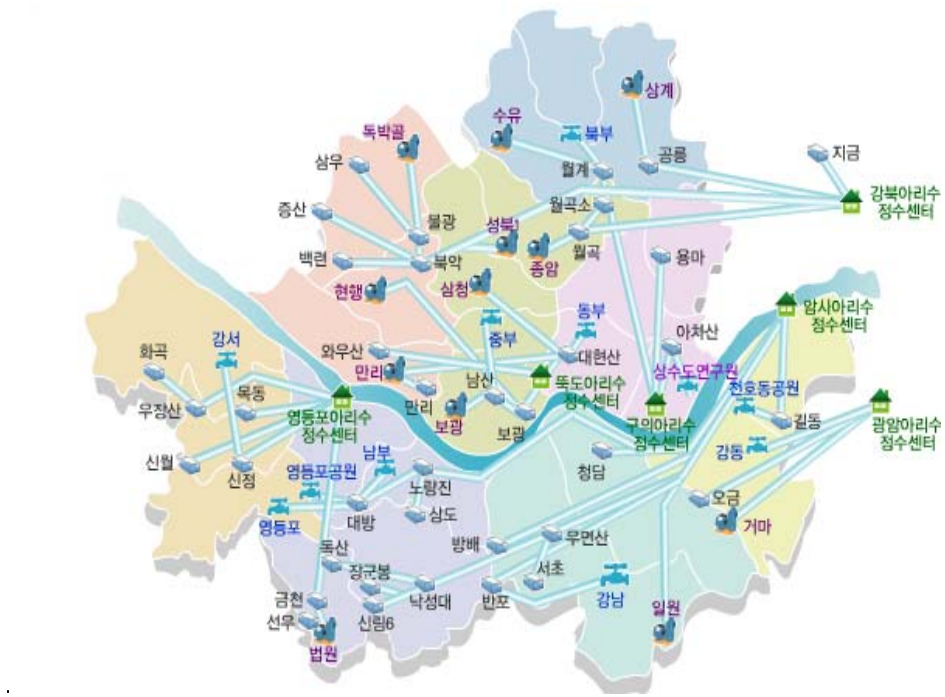

Figure 2. Locations of automatic online monitoring site in Seoul Water Now

DATA ACCESSIBILITY AND USE

As shown in the SWN system architecture scheme(see Figure 3), the acquired data are collected at the site, viewed through a user interface, and stored in a process database. Hourly data and daily average data, monthly average data, yearly average data are stored in a historical database.

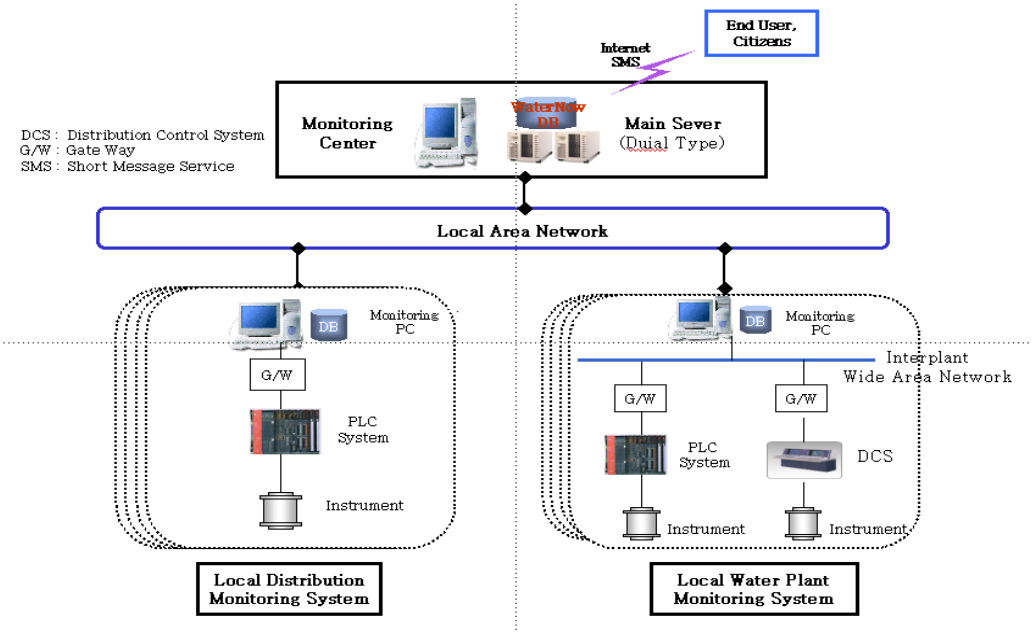

Figure 3. SWN system architecture scheme

The SWN system architecture is characterized by a client-server platform that includes RTUs, modems, LAN, and leased (point-to-point continuous link), and switched telephone lines.

Signals are collected by local RTUs, which are linked to the SWN system through a leased line. The same kind of link is used as a communication line between the facility site(14station) and master monitor station. End users view and data through a software interface developed in the framework of the SWN system. (Figure 4, 5, 6)

Data are used by treatment plant operators for process management , and control. Because the system is considered an integral part in water quality monitoring, the regional authority has electronic access to the data as well.

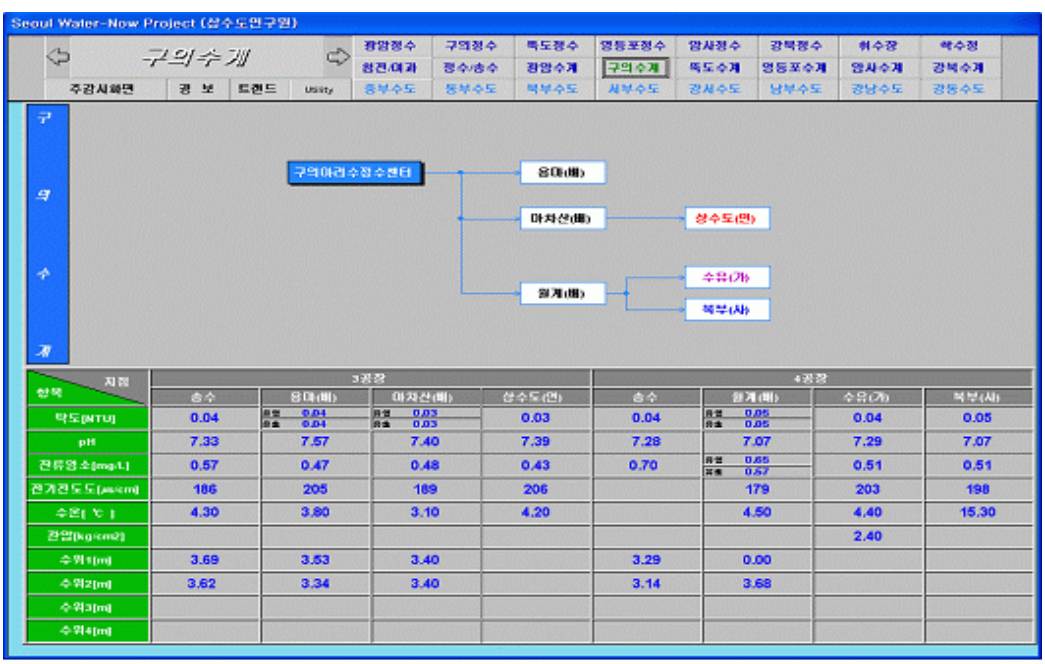

Figure 5. HMI system user interface of showing distribution water quality

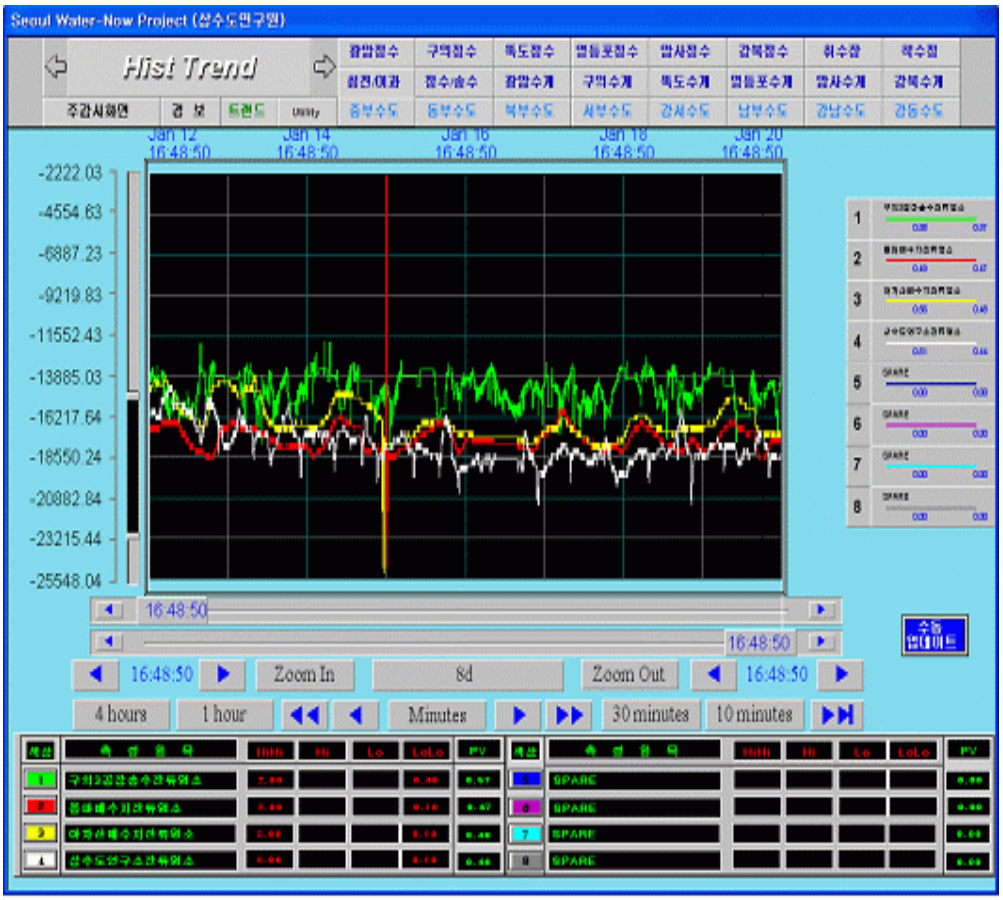

Figure 6. HMI system user interface of showing chlorine trends (distribution, weekly)

The SWN system provides for alarms and diagnosis of the analyzers functionality (e.g., alarms in terms of thresholds, low levels in process tanks, electrodes to be changed, etc.) Once abnormal water quality is monitored, the warning is informed through alarms & SMS to the operators and directors. Quickly, The operators conduct according to the accident treatment guidance

Seoul citizens can also obtain real time data by looking at a Web site, established by the Seoul waterworks Authority.

Web site' address is http://water.seoul.go.kr/waternow/RealDataFullScale.php

As shown in Figure 7, 3 items are opened including turbidity, residual chlorine, pH .

Opens to the public an hour average data and the calculation of an hour mean data is an mean value which excepts the max and min data in 5 minute data

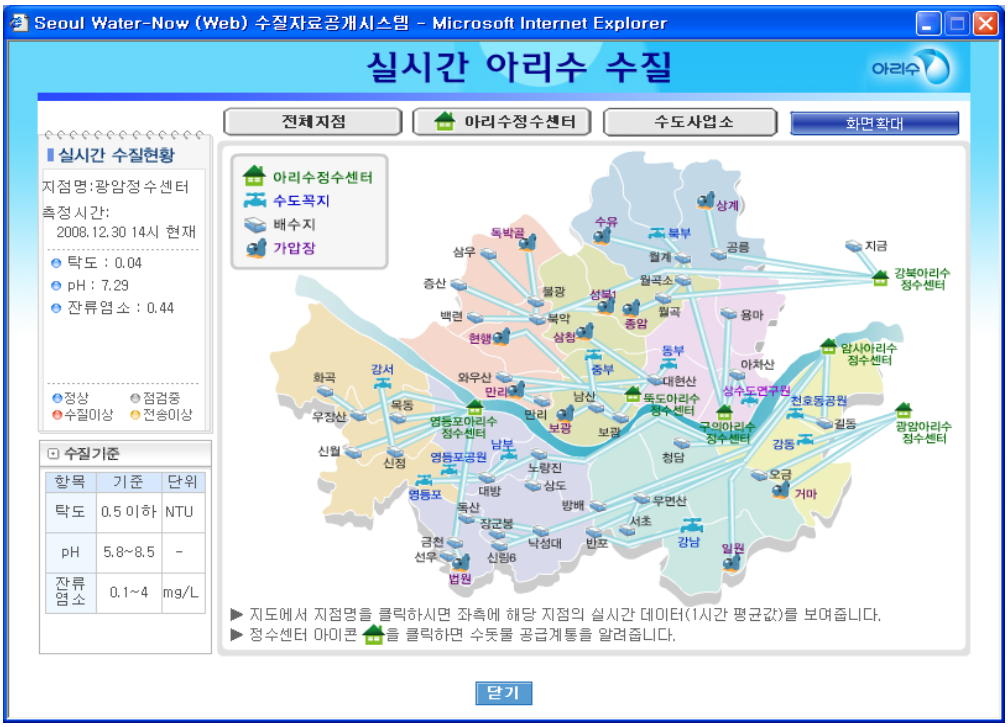

Figure 7. Web site user interface available through Seoul Water work Authority

QUALITY ASSURANCE

The online monitoring system is maintained by operators who have knowledge of the system processes as well as the sensors. Each week, a technician visits Sites to conduct maintenance, calibration, and verification of sensor reading. The on-line monitor results are checked by collecting grab samples and analyzing for free chlorine, pH, specific conductivity,

There have been occasions where faulty instrument readings were suspected and later verified by manual grab samples.

EVALUATION OF SUCCESSES

There have been several instances in which online monitoring result have alerted department staff of potentially harmful water quality situations in the treatment process and distribution system.

In one case, elevated turbidity values resulting from altering flow in the distribution system were tracked via online monitors, giving the operators a chance to address the

issue prior to any customer complaints. In another case, online monitoring allowed operators to respond quickly to a low chlorine residual front moving through the distribution system. Finally, recent online monitoring at locations previously monitored manually revealed that valve operation in part of the distribution system altered flow and created a temporal dead end.

CONCLUSION

The Seoul Water work is confirming to its customers that the drinking water it supplies is healthy, highly controlled, and of the best quality. According to a Seoul Water-Now Plan (Feb. 2001), The automatic water quality monitoring system was completed in July, 2006. SWN system were contributed to maintain the safety of water quality from the source water to the tap water. One of the most successful element of online system is unique display of information on the internet. Public accessibility to continuous water quality information has increased consumer confidence in drinking water quality as well as in water utility operations.

ABSTRACT

An improperly designed air/vacuum valve could generate excessive pressure surges in the valve caused by the instant valve closure and the rapid expulsion of air. This study characterized dynamics of the air valve and other air valves. Simulation results in a case study showed that large pressure spikes could be generated in the air valve. An air accumulator could reduce the surge pressures. Theoretical analysis demonstrated the feasibility of an air-throttling orifice and the mechanism of an anti-slam device in reducing pressure spike values. The study also illustrated that the excessive pressure surges generated in the valve tend to be damped out in the pipe main and the valve connections tend to experience higher pressure surges for potential breakages.

INTRODUCTION

An air/vacuum valve is usually installed in a water/wastewater pipeline system for vacuum prevention and surge suppression during hydraulic transients. Hydraulic transients could be introduced into the system through active changes such as pump shutdown/startup and reactive changes such as air valve opening/closing in response to the pump operations. Low-pressure waves caused by pump shutdown could result in air being drown in the air/vacuum valve and in the system. High-pressure waves due to operating pumps or pump startup tend to expel the air out of the valve. The rapid air release and the instant valve closure could lead to high pressure spikes at the valve. In some pipeline systems where hydraulic transients occur frequently, the repeated high pressure spikes might cause the air valve to break because of cyclic fatigue failure.

Li et al. (2009) described air valve breakages in a portion of Pinellas County's wastewater force main system due to significant and repeated pressure spikes. Field-recorded pressures at two air valves were even above 3.45 MPa. A transient model for the system has been developed to investigate the excessive pressure surges. Solutions have been proposed to dampen pressure surges and to prevent air valve breakages.

Lingireddy et al. (2004) described the pressure surges due to the rapid release of air through an air valve and stated that using smaller outflow orifices could decrease the pressure surges in the valve by two example applications.

AIR/VACUUM VALVE STRUCTURE

A typical air/vacuum valve is shown in Figure 1. The air/vacuum valve includes an inlet, an outlet, a chamber, a float, a valve disk, and a valve seat. The disk and the float are usually integrated as a single moving component. The valve seat often forms an orifice. The orifice might have dual-orifice sizes, a larger inflow orifice and a smaller outflow orifice. When the pressure inside the valve is lower than the atmospheric pressure, the float drops away from the orifice, and the valve will open and allow air to enter the valve and/or the pipe main. When the pressure inside the valve is larger than the atmospheric pressure, the air in the valve and in the pipeline system is exhausted from the valve and the system. Liquid will enter the valve and lift the float to close the valve.

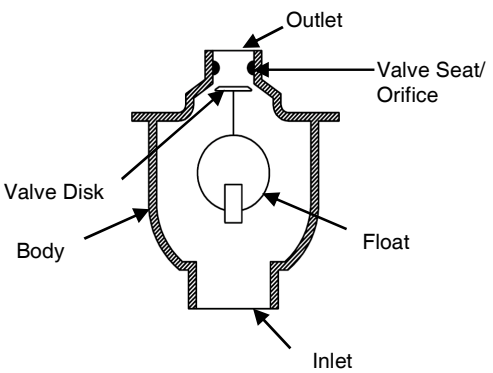

Figure 1. A Typical Air/Vacuum Valve Structure

Air/Vacuum Valve Modeling

The schematic of an installed air/vacuum valve is shown in Figure 2. The air/vacuum valve is connected with a water/wastewater pipe main through a connecting pipe and/or an isolation valve. The installed air valve could be characterized by using the following hydraulic components: the orifice, the air valve chamber, the connecting pipe, as well as the pipe main with a junction.

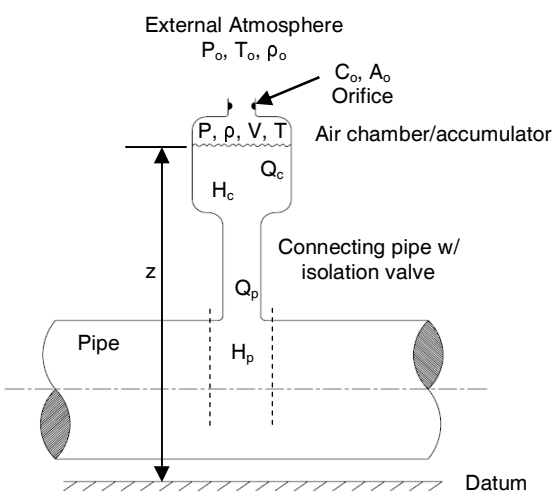

Figure 2. Schematic of an Installed Air/Vacuum Valve for

The orifice. The mass flows of air entering and exiting the valve are determined by the orifice. The mass

flow rates of air exiting the air valve under reversible polytropic flow conditions are given by (Lingireddy et al., 2004, Wylie and Streeter, 1993)

$$m = C_o A_o \sqrt{2p\rho\left(\frac{n}{n-1}\right)\left[\left(\frac{p_o}{p}\right)^{\frac{2}{n}} - \left(\frac{p_o}{p}\right)^{\frac{n-1}{n}}\right]} \qquad \text{for subsonic flow} \qquad (1)$$

$$m = C_o A_o \sqrt{p\rho n\left(\frac{2}{n+1}\right)^{\frac{n+1}{n-1}}} \qquad \text{for critical flow} \qquad (2)$$

$$\rho = \rho(p, T) \qquad (3)$$

In which m is outflow mass flow rate, C_o is coefficient of discharge for the outflow orifice, A_o is flow area for the outflow orifice, p is absolute pressure of air in the air valve, ρ is density of air in the valve, p_0 is atmospheric absolute pressure, T is absolute temperature of air in the air valve, and n is a polytropic index defining the thermodynamic process. A polytropic index of 1.0 implies an isothermal process for an ideal gas; 1.4 implies an isentropic process for small chambers with fast response times. Often an average value of 1.2 is used in design calculations.

The air valve chamber. The air inside the air valve chamber is assumed to follow the reversible polytropic relation

$$pV^n = C_A \qquad (4)$$

In which V is the volume of air in the valve chamber and C_A is a constant.

The pressure in the valve chamber is assumed to be the same throughout the volume at any instant. The compressibility of the liquid in the chamber is considered negligible compared with air compressibility. Inertia and friction are neglected. The integrated continuity equation is

$$\frac{dV}{dt} = -Q_c \qquad (5)$$

In which Q_c is volumetric liquid flow rate in the valve chamber.

Using the absolute liquid head in the valve chamber, the reversible polytropic equation is transformed into

$$\left(H_c' + H_o - z\right)\left[V - \Delta t\left(\frac{Q_c' + Q_c}{2}\right)\right]^n = C_A \qquad (6)$$

In which H_c' is the gauge liquid head in the valve chamber at the current time increment, H_o is barometric pressure head, z is liquid elevation head relative to the datum, V is the volume of air in the valve chamber at the previous time increment,

Δt is the time step, and $Q_c^{'}$ *and* Q_c are the volumetric liquid flow rates in the valve chamber at the current time increment and at the previous time increment.

The connecting pipe. For a short connecting pipe, the short connector may be considered to be inelastic and to contain an incompressible liquid. The equation of motion applied to the short connector is represented by (Wylie and Streeter, 1993)

$$H_p^{'} - H_c^{'} = C_1 + C_2 Q_p^{'} \tag{7}$$

In which $H_p^{'}$ is the gauge liquid head in the pipe main at the current time increment, $Q_p^{'}$ is the volumetric liquid flow rate in the connector at the current time increment, and C_1 and C_2 are constants that depend on length, diameter, and area of the connector as well as the head and flow rate at the previous time increment.

For a long connecting pipe, the compatibility equations could be used.

The pipe main with junction. The compatibility equations as well as a continuity equation at the junction are used.

Surge Pressures in Air/Vacuum Valve

Assume that at the instant the air is fully expelled, the air valve is instantaneously closed and liquid will be rapidly decelerated to zero from an initial velocity. The initial liquid velocity is approximately equal to the air velocity that is determined by the mass flow of air through an orifice. The rapid liquid deceleration produces a pressure surge which could be represented by the basic equation of water hammer:

$$\Delta H = -\frac{a\Delta V}{g} = -\frac{aV_o}{g} \tag{8}$$

In which ΔH is increment of pressure head change, a is wave speed, V_o is the initial air velocity through the orifice or the liquid flow velocity at the valve seat just before the valve closure, and g is acceleration of gravity.

The mass flow of air through the orifice could be expressed under standard atmospheric pressure and temperature conditions

$$m = \rho_o V_o A_o \tag{9}$$

$$\rho_o = \rho_o(p_o, T_o) \tag{10}$$

In which ρ_o is the density of atmospheric air and T_o is absolute temperature outside the air valve.

The initial air velocity through the orifice or the liquid flow velocity at the valve seat just before the valve closure could be expressed by

$$V_o = \frac{C_o}{\rho_o}\sqrt{2p\rho\left(\frac{n}{n-1}\right)\left[\left(\frac{p_o}{p}\right)^{\frac{2}{n}} - \left(\frac{p_o}{p}\right)^{\frac{n-1}{n}}\right]} \qquad \text{for subsonic flow} \qquad (11)$$

$$V_o = \frac{C_o}{\rho_o}\sqrt{p\rho n\left(\frac{2}{n+1}\right)^{\frac{n+1}{n-1}}} \qquad \text{for critical flow} \qquad (12)$$

From the above equations, the initial air velocity through the orifice just before the valve closure depends on the values of atmospheric absolute p_o and absolute temperature T_o outside the valve, as well as the absolute temperature T and pressure p in the air valve chamber. Since the air mass in the valve chamber is small and large areas of pipe and liquid surface provide heat capacity to the air mass, the air temperature in the valve chamber is close to the liquid temperature. The three parameters, the absolute atmospheric pressure, the absolute atmospheric temperature, and the air temperature in the valve chamber, are considered constant. Thus, the initial air velocity depends on the absolute pressure and the air density in the valve chamber. Under the same absolute pressure and the air density in the valve chamber, the initial air velocities are the same for different orifice sizes.

Surge Pressures in Pipe Main

The pressure surge generated at the valve disk/seat will propagate towards the valve chamber, the connector, and the pipe main. When a pressure pulse propagates from one pipe to another pipe or other pipes, the pressure pulse might be unchanged, increased, or decreased. To determine the fate of the pressure pulse, the characteristic impedance of each connected pipe must be considered. The characteristic impedance is $a/(gA)$, where A is the pipe area. The characteristic impedance of a pipe impacts the incident pressure waves. The higher a pipe's impedance, the more severe the pressure pulse is affected. When a pressure pulse propagates from a lower impedance pipe section to a higher impedance pipe section, the pressure pulse is increased. When the impedances of adjacent pipe sections are equivalent, the pressure pulse is unchanged. When a pressure pulse propagates from a higher impedance pipe section to a lower impedance pipe section, the pressure pulse is decreased.

Mathematically, an incident pressure pulse, H_w, by wave transmission, is related to the pressure pulse, H_n, at the nth step change of pipe section areas, A, by the following relationship (Wylie and Streeter, 1993):

$$\frac{H_n - H_0}{H_w - H_0} = \frac{\Delta H_n}{\Delta H_w} = 2^n \prod_{j=1}^{n} \frac{1}{1 + a_{j+1}A_j / a_j A_{j+1}} \qquad (13)$$

Since the pipe main has low impedance, the pressure surges generated in the valve tend to be dissipated in the pipe main**.** The air valve inlet and outlet tend to have high impedances because of small area and thick wall. The pressure surges generated in the valve might be amplified at the locations. Thus, the inlet and outlet

of the valve might experience higher pressure surges and the air valve tends to break here.

Reducing Surge Pressures in Air Valve

Using a smaller outlet orifice. Lingireddy et al. (2004) attempted to reduce pressure spikes caused by air valve closure by using smaller outlet orifices. As described above, the initial air velocity just before the valve closure has no direct link to the orifice size. The method could not be verified in this paper.

Using an air-throttling orifice. An air-throttling orifice could be installed at the air valve outlet to reduce the pressure spikes generated by the air valve closure. Usually, the air-throttling orifice is much smaller than the valve seat opening. The air flow through the air valve will be dominated by the air-throttling orifice.

Considering the short distance between the orifice and the valve seat, the air density in the valve outlet pipe could be assumed to be the same. The air flow velocity at the valve seat is given by

$$V = \frac{A_o V_o}{A} = \frac{D_o{}^2 V_o}{D^2} \tag{14}$$

In which D_o is the orifice diameter and D is the diameter of valve seat opening. The velocity of air flow at the valve seat is related to the air velocity through the orifice and the ratio of the orifice area over the valve seat opening. If the orifice diameter is a half of the valve seat opening diameter, the velocity of air flow at the valve seat is one quarter of the velocity through the orifice. Using an air-throttling orifice will decrease potential surge spikes generated by the valve closure.

Using an anti-slam valve. An anti-slam device is integrated with an air/vacuum valve to prevent valve slam shut. Figure 3 shows an example of such valves. Air passes unrestricted through the anti-slam device. When liquid rushes into the device, a disc closes and reduces the rate of liquid flow into the valve by throttling orifices.

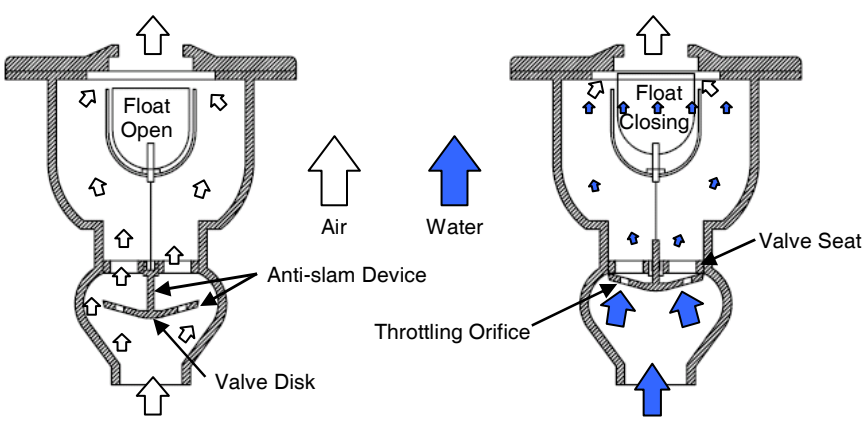

Figure 3. Schematic of an Anti-Slam Valve

Forming an air chamber/accumulator in the valve. At the instant the air valve is closed and air is not fully expelled out, an air pocket could be trapped in the air valve chamber. The air pocket functions as a surge-arresting device. The air pocket volume shall be large enough to absorb liquid momentum and to reduce the deceleration of the liquid in the air chamber/accumulator.

Structurally, an air/vacuum valve could form an air accumulator by having a longer body, a larger float, and a distance between the float and the valve disk/seat. Figure 4 shows the schematic of the air/vacuum valve.

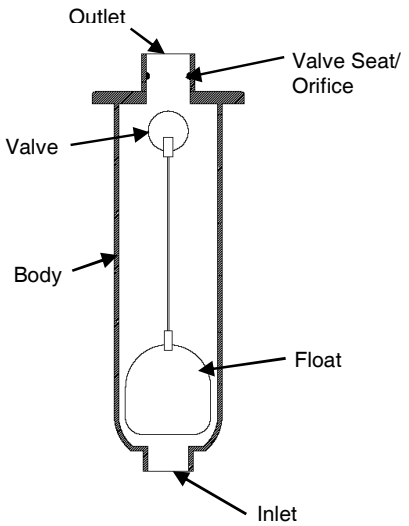

Figure 4. An Air/Vacuum Valve with an Air Accumulator

A Case Study

A portion of Pinellas County's wastewater force main system is shown in Figure 5.

The system includes Pump Station 95 (PS 95), Indian Rocks Beach Pump Station (IRB PS), McKay Booster Pump Station (McKay PS), and two associated force mains: Belleair Beach force main (Belleair Beach FM) between PS 95 and IRB PS and Indian Rocks Beach force main (IRB FM) between IRB PS and McKay PS.

PS 95 and IRB PS are lift stations with submersible pumps. McKay PS is an inline booster pump station with constant suction pressure control. Belleair Beach FM has a length of about 4150 meters with 0.254-meter PVC and 0.305-meter HDPE pipes. The IRB FM has a length of about 1370 meters and 0.406-meter HDPE pipe. Twelve .051-meter air/vacuum valves are installed in Belleair Beach FM and their locations and elevations are shown in the pipeline profile (Figure 6).

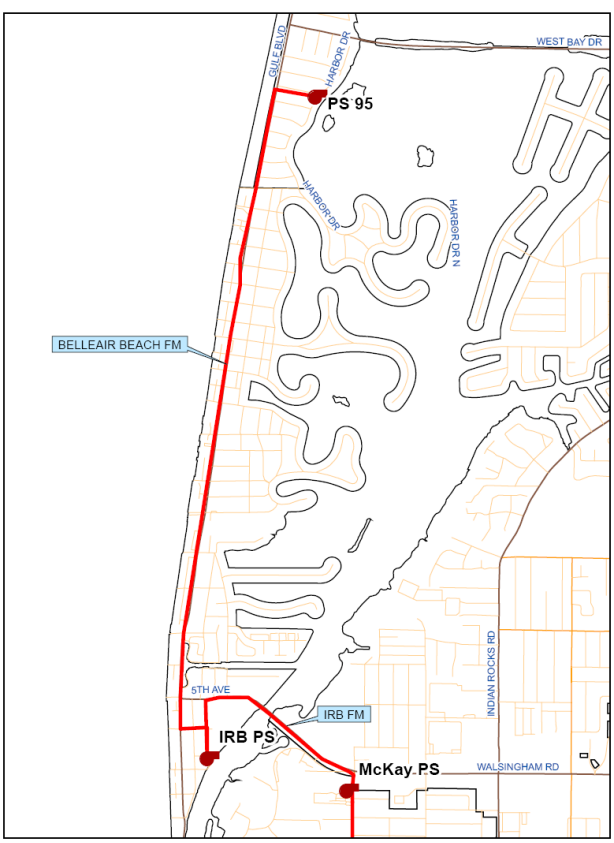

Figure 5. A Portion of Pinellas County's Wastewater Force Main System

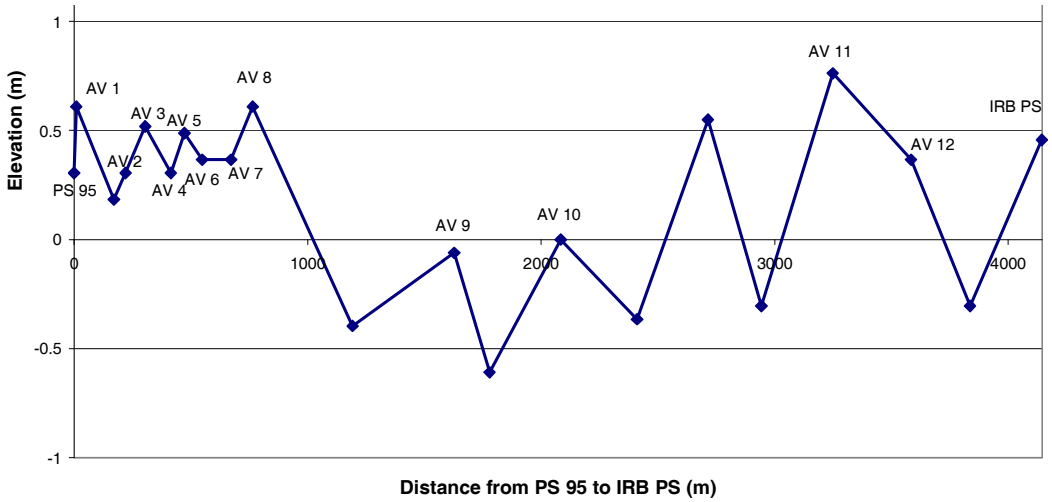

Figure 6. Pipeline Profile of Belleair Beach FM with Air/Vacuum Locations and Elevations

A transient model has been developed for the system using HAMMER V8 XM (Bentley Systems, Incorporated). The model has been described and calibrated in the paper (Li et al, 2009).

In the following simulations, IRB PS runs at full speed during the simulation period. PS 95 runs at the following time schedules. From 0~5 seconds, PS 95 runs at full speed; PS 95 shuts down at 5 seconds and its speed spins down to zero in 3 seconds; PS 95 starts up at 300 seconds and its speed ramps up to full speed in 5 seconds. The total simulation time is 400 seconds.

The air/vacuum valves have 0.038-meter diameters in their inlet orifices and outlet orifices. Three volumes (zero liter, 3.8 liter, and 7.6 liter) of the air chamber/accumulator have been simulated to investigate the effects of the air chamber sizes on the pressure surges in the valve. Figure 7 shows the simulated heads at Air Valve 1 under three accumulator volumes.

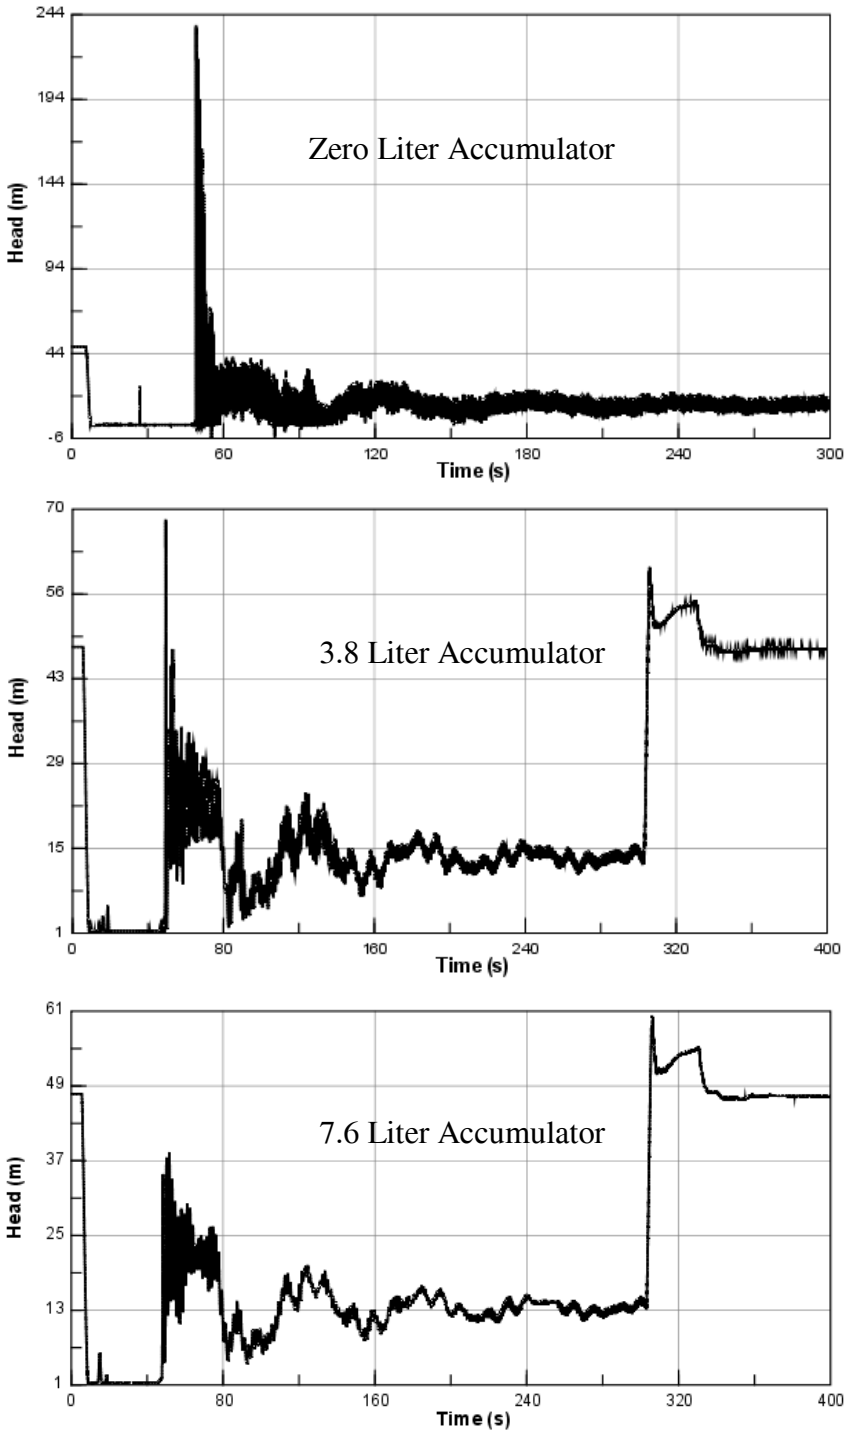

Figure 7. Simulated Heads with Three Accumulator Sizes at Air Valve 1

Simulation results show that the maximum pressures surge pressures are about 240 meters and 65 meters for accumulator sizes of zero and 3.8 liters. The pressure surges have been suppressed completely for accumulator size of 7.6 liter.

CONCLUSIONS

The rapid air release and the instant air/vacuum valve closure could result in detrimental pressure surges in the valve. The repeated high pressure spikes could cause the air valve breakage in its inlet and/or outlet connection. Fortunately, the pressure surges generated in the valve tend to be dissipated in the pipe main.

The pressure surges could be reduced by using an air/vacuum valve that forms an air chamber/accumulator. An air pocket formed in the valve just before the valve closure has significant impact to decrease the pressure spikes and even to suppress the pressure surges completely based on our case study in a portion of Pinellas County's wastewater force main system.

Installing an air-throttling orifice in the outlet of the valve could reduce the pressure surges in the valve. Using an anti-slam valve could prevent the valve slam and dampen the pressure surges.

ABSTRACT

The unpredictable impact of biofilms on friction in pipes causes difficulty in accurately designing for pipe roughness in biofouled pipes. The effects of biofilm growth on pipe roughness were experimentally investigated with the variation of growth conditions of velocity, diameter and water source. The results showed that differences in the growth velocity and source water altered the equivalent sand grain roughness of the biofouled pipes. The variation of the friction factor with Reynolds number in these biofouled pipes was not as expected for a rough surface and did not follow the traditional pipe friction equations. In addition, the change to the pipe velocity profile once biofilm had developed was analysed. One of the most important findings was that the Von Karman constant was significantly lower than normal in the biofouled pipes and that it varied with velocity. This enabled a modified version of the Colebrook-White equation to be created to describe the friction factor variation with Reynolds number in biofouled pipes. This research provides a basis for a method to predict the impact of biofilm development on pipe roughness.

INTRODUCTION

Water is the single most important resource for human civilisation and water pipelines are important in industrialised society for the transportation and distribution of water. For efficient pipeline design the energy lost within a pipe, which is mainly due to friction resistance at the pipe wall, must be accurately known. Recent studies have found that given the right conditions biological growth within pipelines can increase friction headloss dramatically Barton (2007), Picologlou et al. (1980) and (Sharp, 1954). This increase is not included in current design practice and as such results in a reduction in pipeline flow capacity, inefficient pump operation and ultimately greater cost. It has also been shown that these increases cannot be explained by the traditional equations such as the Colebrook-White equation (Eq.1).

$$\frac{1}{\sqrt{f}} = -0.86 \ln\left(\frac{\varepsilon}{3.7D} + \frac{2.51}{\mathrm{Re}\sqrt{f}}\right) \quad (1)$$

The most common form of biological growth within pipelines is biofilms. Biofilms are aggregations of microorganisms bound by a polymeric matrix which form on

surfaces in contact with water, shown in Fig. 1. Biofilms occur predominantly in systems which pump water containing a high amount of nutrients, in particular dissolved organic carbon (DOC). Most raw and recycled water is high in DOC and therefore biofilms present a problem for these pipelines, which are becoming more prevalent. Recycled water, in particular, is being used increasingly around the world.

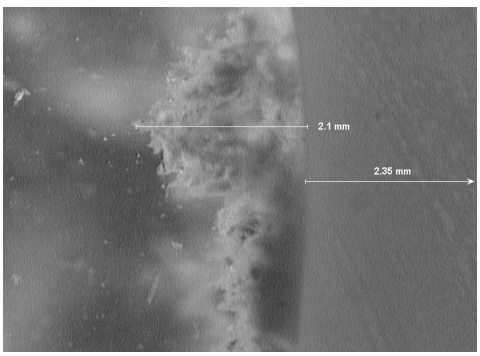

Figure 1. Biofilm inside a pipe

Several studies have found that biofilms have a significant impact on headloss in pipelines. Sharp (1954) found that friction had increased significantly in a 90km raw water rising main reducing its capacity by 22% in the eight years since its construction, increasing pumping costs by 13%. Upon inspection of the pipeline the source of the increased friction was found to be biofilm up to 9.4 mm thick coating the inside of the pipe. More recently, Barton (2007) found that biofouling had increased headloss by up to 25% in a Tasmanian hydroelectricity pipeline and decreased hydroelectric electricity output by 4%. Researchers have also consistently found that the headloss caused by biofilms is greater than their physical thickness would suggest and does not follow the conventional relations of pipe friction such as the Colebrook-White equation (Eq.1) and the Moody diagram. Picologlou et al. (1980) proposed the headloss due to biofilm development was mainly caused by two physical mechanisms; filaments that increase the roughness of biofilms and oscillate in the flow which increases drag, and the biofilm viscoelastic properties which allow them to deform and absorb energy.

A major issue preventing engineers from developing an allowance for friction caused by biofilms is the fact that their physical characteristics, and therefore the headloss they produce in pipes, are highly variable. Biofilm growth models have shown that the structure (and therefore surface roughness), density, growth rate, thickness and viscoelasticity of biofilms all vary depending upon the conditions in which they grow. These conditions include pipe velocity, nutrient availability and specific species of bacteria making up the biofilm (Picioreanu et al 2000).

The objectives of the study were to further understand the effect of biofilms on headloss in pipes. Two separate areas of investigation were pursued; the first was the variable physical characteristics and friction due to biofilms grown in varying velocity, diameter and initial inoculum conditions and second the effect of biofilms

on the velocity profile observed within of pipes. To achieve these aims, experimental work was required to grow biofilms under controlled conditions and measure their effects on the flow.

EXPERIMENTAL METHODS

To achieve the objectives of the study, two identical water recirculation systems were constructed in the Robin Hydraulics laboratory at the University of Adelaide to grow biofilms in both raw Myponga Reservoir water and River Murray water (collected from the Mannum-Adelaide pipeline at Millbrook Reservoir). The system was designed so that the desired growth variables could be compared and contrasted. Two systems were constructed to test biofilm grown in water from two different sources. Each system consisted of three pipes of the same diameter to identify the effect of velocity on the growth of the biofilm and a fourth pipe of a larger diameter was used to determine the influence of diameter on the growth of the biofilm and also enabled velocity profiles to be measured within it.

Experimental System

A diagram of the experimental setup can be seen in Fig. 2. The experiments involved a water recirculation system such that steady water flow could pass through four smooth plastic pipes, three 25 mm in diameter and one 50 mm diameter. Transparent pipes were used for the biofilm pipes so that biofilm growth within them could be observed with opaque plastic sheeting covered these pipes throughout the experiments so that biofilm growth was not affected by light. All other pipes including the delivery and overflow pipes were opaque uPVC material.

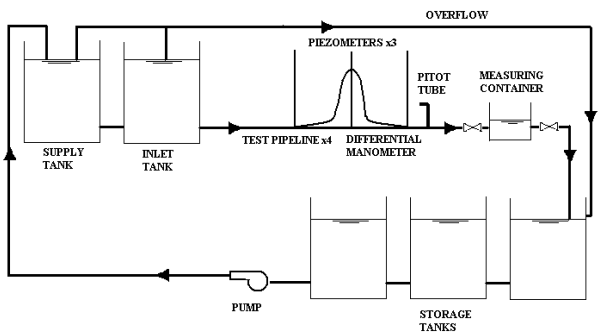

Figure 2. Experimental diagram

All eight pipelines over the two systems used valves to control the velocity. These were placed at the downstream end of the pipeline, after the test section. The overflow pipes for each system maintained a constant head level in the supply tanks to ensure constant velocity. To take headloss measurements differential manometers were attached to each test pipe to measure headloss over a 5 m length of the biofilm pipe. Piezometers were also included as a check to ensure accuracy. 50 litre measuring containers were used for volumetric flow measurements. A Pitot tube was

incorporated into the experimental design to measure the velocity profile within the 50 mm diameter biofilm pipe on the River Murray system.

Once constructed, initial testing was undertaken and confirmed that test pipes were hydraulically smooth. Smooth pipe velocity profiles were also measured. Following this, the biofilm was grown with the addition of the raw waters and excess nutrients in the form of dried River Red Gum leaves, *Eucalyptus camaldulensis*. Measurements were taken over the growth phase of the biofilm and final testing after 600 hours of growth.

At the conclusion of the experiments, microscopic photographs were taken of the biofouled pipe cross sections with the use of a dissecting microscope. This enabled biofilm thickness to be estimated. A viable count test was also conducted at the conclusion of the experiment on the biofilm grown in both the River Murray water and Myponga water. This was to provide a measure of the bacteria type and density in the biofilms grown from both source waters to determine if there was a difference.

The recorded volumetric flow rates and manometer headloss measurements were used to calculate friction factor by the use of the Darcy-Weisbach equation (Eq. 2) to find the friction factor of the biofouled pipe.

$$f = h_f \frac{D}{L}\frac{2g}{V^2} \tag{2}$$

where h_f = head loss (m), f = friction factor (dimensionless), L = length of pipe (m), D = pipe diameter (m), V = mean velocity (m/s) and g = 9.81 m/s^2.

The Swamee-Jain equation is equivalent to the Colebrook-White equation and can be rearranged to determine the equivalent sand grain roughness of a pipe (Eq.3). This represents the diameter of sand grains uniformly covering the inside of the pipe to produce the same friction factor.

$$\varepsilon = 3.7D\left[\exp^{-\left(\frac{1.325}{f}\right)^{0.5}} - \frac{5.74}{\mathrm{Re}^{0.9}}\right] \tag{3}$$

By the use of Eq. 1, 2, 3 and frequent regular measurements of headloss and flow rate, the friction factor and roughness of the pipes were recorded throughout the growth of the biofilm.

Experimental Approach

The two replicate water recirculation systems contained different source water and therefore different initial inoculums for biofilm growth. All other growth conditions were identical between the two systems so that initial inoculum was isolated as the only factor varying between the two systems. Biofilms were grown at three different velocities in each of the 25 mm diameter biofilm pipes in each replicate system. The selected velocities were 0.3 m/s, 0.7 m/s and 1.0 m/s so that the only growth factor varying between the pipes was velocity. The 50 mm diameter pipe was set at 0.3 m/s so a comparison could be made between different diameters with the same velocity. Following completion of the biofilm growth stage, the velocity (and therefore

Reynolds number) was varied through each pipe over the full range possible and the corresponding headloss was measured. This enabled a Moody-type diagram to be plotted relating Reynolds number to friction factor for each pipe. Velocity profile was measured for three different mean pipe velocities. It was measured prior to biofilm development and at the end of the experiment so that a comparison between smooth pipe conditions and biofouled conditions could be made.

EFFECT OF INOCULUM ON BIOFILM GROWTH AND FRICTION

The bacteriological tests of biofilms showed that the biofilms grown in each system were clearly composed of different types of bacteria and had different bacterial densities. The experimental results showed that this produced no clear trend to which initial inoculum produce rougher pipes. There were, however, clear growth patterns for each water source. The biofilm in the Myponga system grew at a relatively faster rate initially before reaching a plateau at 350 hours. The biofilm in the River Murray system on the other hand grew at a relatively constant rate throughout the experiment (Fig. 4). Initial inoculum is the only variable growth factor between the two systems and is therefore the cause of the different bacterial communities and growth patterns.

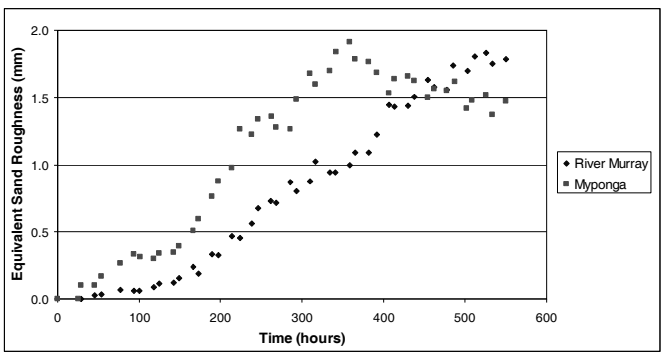

Figure 4. Equivalent roughness with time in the 25 mm diameter pipes at 0.3 m/s for both systems

The photographs of the biofouled pipes showed that there is great variation in biofilm thickness and structure both between different pipes and even in the same pipe. Despite this, the Myponga system biofilms were generally more clustered and the River Murray system more filamentous (Fig. 5). This is supported by observations of the biofilm pipes during the experiments in which the River Murray pipes appeared to have longer filaments vibrating in the flow than the Myponga pipes. These differences are due to the different bacterial communities present in each system.

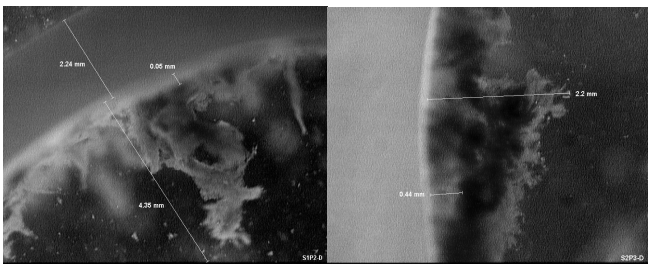

Figure 5. Biofilm in 25 mm diameter 0.3 m/s pipe in River Murray system (left) and Myponga (right)

EFFECT OF PIPE VELOCITY ON BIOFILM GROWTH AND FRICTION

It was discovered in both systems that biofilms grown under higher velocities were less rough than those grown under lower velocities. Fig. 6 shows the results from the 25 mm diameter pipes in the Myponga system.

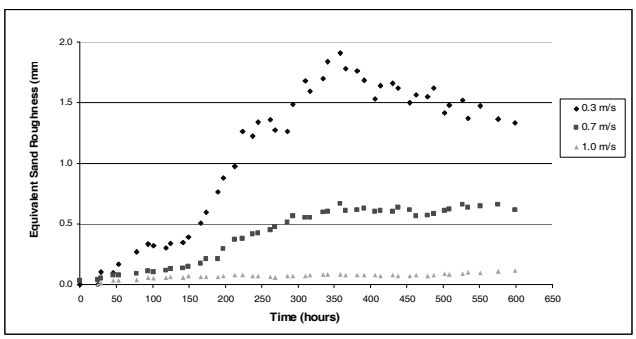

Figure 6. Equivalent roughness for 25 mm diameter pipes with varying velocity in Myponga system

When comparing the equivalent roughness of the 50 mm diameter pipes at 0.3 m/s and the 25 mm diameter pipes at 0.3 m/s in their respective systems, they produced very similar equivalent roughness values. This is shown for the River Murray system in Fig. 7. This implies biofilm growth is relatively independent of pipe diameter and highly dependent on pipe velocity. This may allow scale tests to be used to predict the biofilm roughness that will grow in any particular pipe.

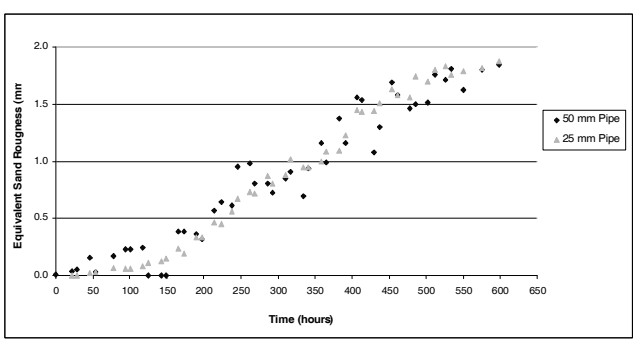

Figure 7. Equivalent roughness in Murray system with growth velocity of 0.3 m/s

VARIATION OF FRICTION FACTOR WITH REYNOLDS NUMBER

The results show that the biofouled pipes yield a different variation in friction factor with Reynolds number to that predicted for clean pipes by the Colebrook-White equation. Fig. 8 shows the observed trends for each different growth velocity in the Myponga system, with the predicted Colebrook-White curves for each pipe. With a lower growth velocity, friction factor was higher, supporting the previous results. The shapes of the observed curves also change with growth velocity, with the rate of increase of friction factor with Reynolds number increasing. It is clear that with more biofilm growth in a pipe, the more its variation with friction factor deviates from the predicted Colebrook-White curves. The curves for the River Murray system were similar shape for each growth velocity, indicating that velocity has a greater impact on friction variation than the initial inoculum.

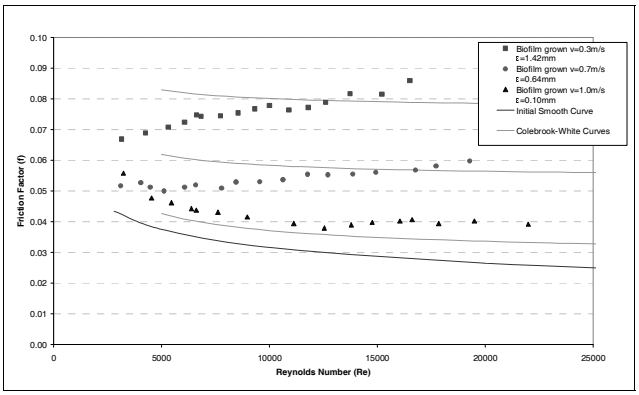

Figure 8. Friction factor variation for the Myponga system 25 mm diameter pipes

Another distinct observation was made in the 0.3 m/s growth velocity biofouled curves for the River Murray system (Fig.9) where a sudden and large drop in friction factor was observed at higher Reynolds numbers.

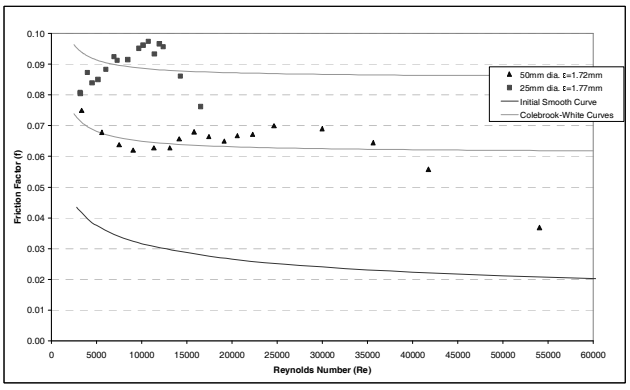

Figure 9. Friction factor variation for River Murray system 0.3 m/s pipes

The observed drop was due to the biofilm being sheared and washed from the pipe wall at these higher velocities. Only the biofilms grown at 0.3 m/s were sheared off at the range of velocities tested, suggesting these biofilms had lower strength than those grown at higher velocities. Although the biofilms sheared off at different velocities in the two 0.3 m/s growth velocity pipes, the pipe wall shear stresses at which this occurred were calculated to be nearly identical, at 3.0 N/m^2. This again shows that the physical and friction characteristics of biofilms are closely related to the growth velocity and independent of pipe diameter. Revisiting Fig. 8, it can be seen that the Myponga biofilms did not shear off at any pipe velocity. The Myponga biofilms were stronger, which can only be due to the different initial inoculum of each biofilm. Therefore, although it appears that the initial inoculum does not play a large role in determining the friction variation profile, it does determine biofilm strength and the shear stress at which it is sheared. This is an important finding for management of biofouled pipes.

EFFECT OF BIOFILM GROWTH ON PIPE VELOCITY PROFILE

Measured velocity profiles were compared with the theoretical velocity profiles for each bulk velocity. Theoretical profiles were determined using theory from Streeter and Wylie (1997). The velocity distribution within hydraulically smooth pipes is described by the following equation:

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln \frac{y u_*}{\nu} + A \qquad (4)$$

where u is the point velocity at a distance y from the pipe wall, ν is the kinematic viscosity of the water, κ is the Von Karman constant where κ = 0.40 as shown in Nikuradse's (1932) experiments and A = 5.5, also shown by Nikuradse. u_* is the friction or shear velocity as described in the following equations:

$$u_* = \sqrt{\frac{\tau_o}{\rho}} \qquad (5) \qquad\qquad \tau_o = \gamma h_f \frac{D}{4\delta L} \qquad (6)$$

where ρ is the density of water at a certain temperature and τ_o is the shear stress at the pipe wall where γ is the specific weight of water, h_f is the headloss, D is pipe diameter and δL is the length of pipe over which the headloss is measured.

The theoretical velocity profiles were calculated using Eq.4 and are shown in Fig.10 with the measured velocity profiles. The velocity profiles are shown as vertical slices through the centre of the pipe. The measured smooth velocity profiles match the theoretical profiles well. There is a small upward skew in the 0.89 m/s and 0.93 m/s profiles but this did not change the average velocity of the profiles.

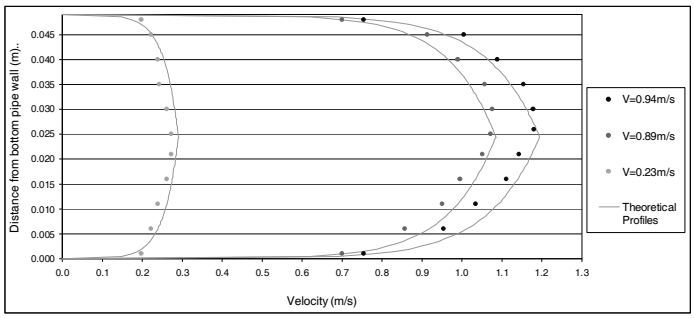

Figure 10. Observed and theoretical velocity profile in smooth pipe conditions

Velocity Profile in Biofouled Pipes

Given that biofouled pipes will not be hydraulically smooth, it was appropriate to model them as a fully rough velocity profile, described by the following equation from Streeter and Wylie (1997):

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln \frac{y}{\varepsilon} + B \tag{7}$$

where all terms are as in Eq. 4, ε is the equivalent sand grain roughness and B = 8.48, shown by Nikuradse (1932) for rough pipes.

At the time of testing, biofilm had been growing in the pipes for almost 600 hours. Equivalent sand roughness calculated by the Colebrook-White equation (Eq.1) was 1.725 mm. This estimate is flawed given that the Colebrook-White equation has been shown to be inadequate for biofilms. It was used, however, given the lack of a more accurate estimate. The theoretical rough profile did not match the observed velocity profiles in the biofouled pipe (Fig.11). Repeated attempts using different values of ε also failed to match the observed profiles. Therefore to fit each profile, a different value of ε was required for each bulk velocity. It is impractical, however, to vary roughness heights with velocity while designing for biofouled pipes.

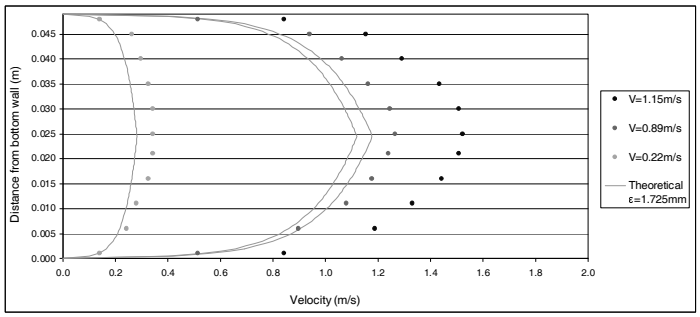

Figure 11. Theoretical rough profiles assuming ε = 1.725 mm

On closer inspection of the theoretical profiles it can be seen that the profile shapes do not match, with the theoretical velocities too low near the centre of the pipe and too high near the pipe walls. A sharper theoretical profile is required. To change the shape of the velocity profile the Von Karman constant, κ, must be altered. To determine the best fit for each of the observed profiles in the biofouled pipe, linear

regression was used to determine the κ and B values. The theoretical rough profile equation (Eq.7) was used in the following manner to achieve this:

$$\text{let} \qquad y = \frac{u}{u_*} \text{ and } x = \ln \frac{y}{\varepsilon}$$

$$\text{is in the form} \qquad y = mx + c$$

$$\text{where} \qquad m = \frac{1}{\kappa} \text{ and } c = B$$

Linear regression was used to determine the best fit slope (m) and y-intercept (c) for each profile. The values of κ and B found from each profile are shown in Table 1.

Table 1. Values of κ and B for observed velocity profiles of varying bulk velocity

Bulk Velocity of Profile (m/s)	κ	B
1.15	0.3569	12.25
0.89	0.3106	8.85
0.22	0.2821	9.60

These results show that Von Karman constant is significantly lower in the biofouled pipe than the 0.40 generally accepted for pipes. There is also a trend of decreasing κ with decreasing velocity. This is a significant result and suggests the equations used to calculate and predict headloss in pipes such as the Colebrook-White (Eq.1), which assume κ = 0.40, are not valid for biofouled pipes. Fig.12 shows the theoretical profiles found by linear regression which closely fit the observed velocity profiles.

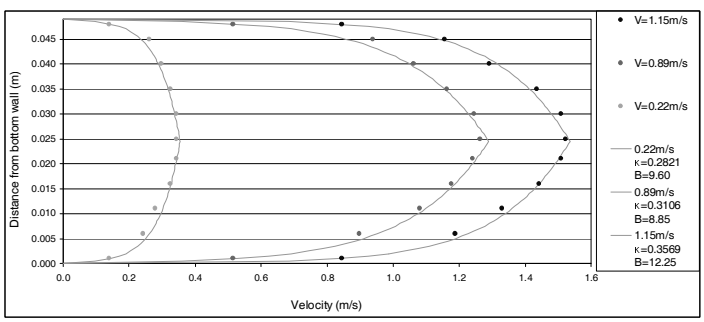

Figure 12. Observed and theoretical velocity profiles using κ, B found by linear regression

Given that the velocity profiles were experimentally derived there could be some error in the calculated values for κ and B. The same process of linear regression was performed on the observed smooth pipe profiles to determine κ. This found that κ was 0.4002 in the smooth pipe. This gives confidence in the values of κ calculated.

Modification of Colebrook-White Equation

The Colebrook-White equation (Eq. 1) was derived from the logarithmic velocity profile equation (Matthew, 1990). It assumes that κ = 0.40 in all pipes and this term was integrated in the –0.86 multiplier on the right hand side of the equation. By expressing the –0.86 multiplier in its true form, κ becomes a variable:

$$\frac{1}{\sqrt{f}} = -\frac{1}{\sqrt{8}\kappa}\ln\left(\frac{\varepsilon}{3.7D} + \frac{2.51}{\mathrm{Re}\sqrt{f}}\right) \tag{8}$$

This expression of the Colebrook-White equation may now be applied using a lower value of κ to test whether it better explains friction in biofouled pipes. A linear best fit equation for the calculated values of κ (Table 1) was used to express κ as a function of Reynolds number. It was found initially that although the equivalent roughness relationship for the biofouled pipes held in Eq.8, the absolute roughness values were predicted to be too high. Eq.8 was therefore modified further to correct this. This was achieved by changing the dimensionless constant multiplier for D in the equation to 0.85. The final modified Colebrook-White equation is consequently:

$$\frac{1}{\sqrt{f}} = -\frac{1}{\sqrt{8}\kappa}\ln\left(\frac{\varepsilon}{0.85D} + \frac{2.51}{\mathrm{Re}\sqrt{f}}\right) \tag{9}$$

The modified Colebrook-White curves are shown in Fig.13 with observed data from the River Murray 50 mm and also the 25 mm diameter pipe at 0.3 m/s. Both pipes were grown at the same velocity and should be expected to produce a similar trend in κ.

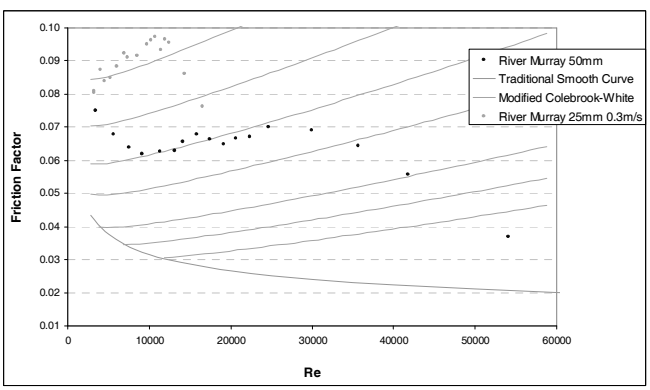

Figure 13. Modified Colebrook-White curves with observed data from River Murray system

The modified Colebrook-White equation goes someway to explaining the observed variation of friction factor with Reynolds number in the 0.3 m/s pipes from the River Murray system reasonably well. There is a departure from the predicted line at low Reynolds numbers for the 50 mm diameter pipe. There is also a departure at higher Reynolds number in both pipes due to the shearing and loss of biofilm. Both the relative roughness and equivalent roughness relationships are approximately that which should be expected, therefore Eq. 9 is a reasonably good description for the friction of the biofilms grown at 0.3 m/s in the River Murray system.

The observed data from the corresponding pipes in the Myponga system were plotted on the same modified Colebrook-White equation lines (Eq. 9) and shown in Fig.14. The Myponga pipes also match the modified Colebrook-White lines reasonably well.

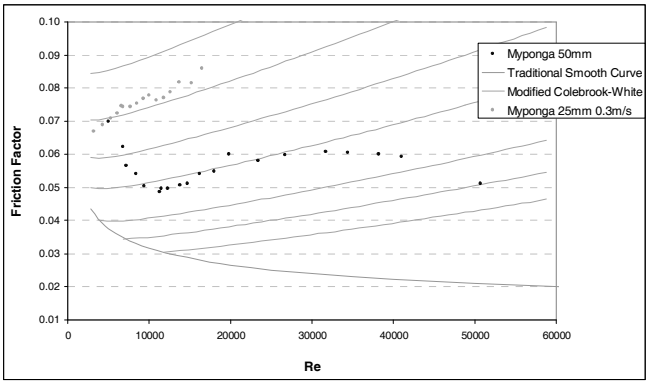

Figure 14. Modified Colebrook-White curves with observed data from Myponga system

On the limited evidence, Eq. 9 may be a start at understanding how biofilms grown under the same velocity behave when the flow conditions are varied. More research will be required to measure velocity profiles in biofouled pipes with various source waters, diameters, and velocities, to determine if a common trend in κ holds between them.

SUMMARY AND CONCLUSIONS

Investigation into the conditions that govern biofilm growth illustrated that biofilms grown from different initial inoculum had different growth patterns and different strengths. Velocity was shown to be the dominant factor in determining the roughness of biofilms and their resistance to fluid shear, however. Significantly, it was shown that Von Karman constant is much lower than the normal 0.40 in biofouled pipes and that it varies with velocity. A modified Colebrook-White equation accounting for this variation in κ was able to explain the variation in friction factor with Reynolds number in a biofouled pipe, which may provide a path to develop an accurate biofilm prediction equation.

In-line partially closed valves: how to detect by transient tests

S. Meniconi, B. Brunone and M. Ferrante

Dipartimento di Ingegneria Civile ed Ambientale, DICA, Università degli Studi di Perugia, via G. Duranti 93, 06125 Perugia, Italy; e-mail: silvia.meniconi@unipg.it

ABSTRACT

Reliable and quick techniques are needed to locate and estimate the asset of in-line partially closed valves in pressurised pipes. The methodology considered in this paper is based on the analysis of transient tests. As a matter of fact, singularities (e.g., junctions, partial blockages, partially closed in-line valves, leaks) give rise to reflected waves whose arrival time and amplitude – recorded in one or more sections of the pipe – allow their detection. Transients are generated by means of a total and fast closure of an end valve and the pressure time-history – referred to as pressure signal – is measured at a section immediately upstream the end valve. In the paper, first some numerical simulated signals show that this kind of analysis can be useful for locating the valve and determining its asset, also by means of two simplified numerical models. Then some results of an extensive laboratory campaign carried out at the Water Engineering Laboratory (*WEL*) of the University of Perugia, Italy, are reported.

INTRODUCTION

In recent years it was proposed to detect both blockage and partially closed in-line valves by means of transient tests. Such technique is convenient since the duration of tests is short and costs are noticeably lower than those of other methods (e.g., acoustic or steady-state tests), since it requests only the analysis of the time-history of the piezometric head (hereafter, the "pressure signal"). There are different approaches that follow this methodology and can be distinguished on the basis of the duration of the period of analysis. In the short period analysis approach (e.g., *Adewumi at al.*, 2000; *Misiunas et al.*, 2005; *Arbon et al.*, 2008), the analysis is limited to the first characteristic time of the pipe; whereas in the long period analysis approach it is studied the blockage-induced damping (*Wang et al.*, 2005) or the blockage-induced oscillations of the pressure response (*Mohapatra et al.* 2006a; 2006b; *Lee et al.*, 2008; *Sattar et al.*, 2008).

This paper follows the short period analysis approach, analysing the pressure signal during the first characteristic period of the pipe. In the first part, the results of numerical experiments are reported with regard to transients in a pipe with an in-line partially closed ball valve. By means of the numerical model proposed by *Wylie and Streeter* (1993) and *Contractor* (1965), it is pointed out that the asset of the device can be evaluated by means of the first pressure wave reflected back. Then the paper shows some results of an experimental campaign carried out at the Water Engineering Laboratory (WEL) of the University of Perugia, Italy.

NUMERICAL MODEL

In the numerical experiments, transients are generated in a single pipe system (i.e., supply reservoir, pipe, end valve) by the total instantaneous closure of an end valve. A numerical model based on the integration of the governing equations of transient flow by the classical Method of Characteristics (MOC) has been used for this purpose (*Wylie and Streeter*, 1993). The schematised pipe has a length of 164.93 m, an inner diameter, D, equal to 93.3 mm and a wave speed a = 371 ms^{-1}. The upstream reservoir has an invariable level, while the end valve discharges in the air. The presence of an in-line ball valve (Figure 1) has been considered at a distance L_{il} = 75.97 m from the end valve.
According to Figure 1, at the in-line valve, the following equations can be written:

$$\begin{cases} Q_{il} = Q_{1,n+1} = Q_{2,1} \\ h_{2,1} = C_N + B_N Q_{il} \\ h_{1,n+1} = C_P - B_P Q_{il} \\ \zeta = h_{1,n+1} - h_{2,1} = \chi \dfrac{Q_{il}\left|Q_{il}\right|}{2gA^2} \end{cases} \tag{1}$$

where $B_P = B+R_1|Q_{1,n}|$, $C_P = h_{1,n}+BQ_{1,n}$, $B_N = B+R_2|Q_{2,2}|$, $C_N = h_{2,2}-BQ_{2,2}$, B = characteristic impedance = a/gA, $R = f\Delta s/(2gDA^2)$, Q = discharge, h = piezometric head (= pressure signal), g = gravity acceleration, A = pipe area, f = friction factor, Δs = spatial-step size and χ = in-line valve head loss coefficient. In equations (1) the discharges and the piezometric heads are relative to time t, whereas B_P, C_P, B_N and C_N are calculated at t-Δt, with Δt = time-step size; moreover the first subscript refers to the pipe (1 = upstream the in-line valve; 2 = downstream), whereas the second one refers to the node (n + 1 = number of nodes of the pipe 1). The last equation of the system (1) gives the local head loss, ζ, across the in-line valve and it is assumed valid also in the unsteady-state. According to usual flow conditions in real pipe systems, numerical and experimental tests concern wholly turbulent flow. Subsequently the value of χ is constant for any given degree of throttling, δ.
To evaluate directly the pressure wave reflected by the in-line valve, $\Delta h_{R,WS}$, by neglecting friction losses, *Wylie and Streeter* (1993) proposed the following equation:

$$\Delta h_{R,WS} = \left(\frac{\chi g}{2a^2}\Delta h_I - \left(1+\frac{\zeta_0}{Q_0 B}\right) + \sqrt{\left(1+\frac{\zeta_0}{Q_0 B}\right)^2 - 2\frac{\chi g}{2a^2}\Delta h_I} \right) \Bigg/ \frac{\chi g}{2a^2} \tag{2}$$

where Δh_I = incident wave and the subscript "0" is relative to steady-state. When an instantaneous closure of the manoeuvre valve occurs, equation (2) reduces to the expression:

$$\Delta h_{R,WS} = \left(-1 + \sqrt{1 + \zeta_0 \frac{\chi g}{2a^2}} \right) \Big/ \frac{\chi g}{2a^2} \tag{3}$$

If the following condition is fulfilled:

$$\chi < \chi_{\lim} = 2aA/Q_0 \tag{4}$$

equation (3) can be written as (*Contractor*, 1965):

$$\Delta h_{R,C} = \zeta_0 / 2 \tag{5}$$

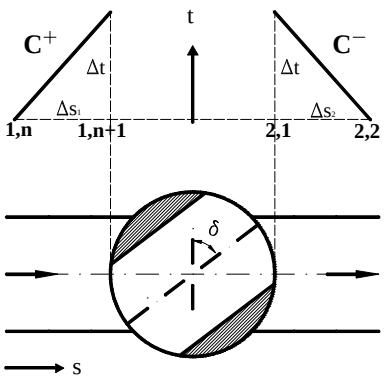

Figure 1. In-line valve numerical scheme.

NUMERICAL EXPERIMENTS

As an example, Figure 2 shows numerical pressure signals, h_M, at the measurement section immediately upstream the end valve, hereafter indicated as section M; h_M is calculated with respect to the value $h_{M,0}$ at the beginning of the transient. For a given steady-state discharge (Q_0 = 2.6 l/s), different values of χ (= 3118.3, 2000.0, 916.6, 399.2, 164.1, 109.4, 0.0) are considered. The total instantaneous closure of the end valve causes a sharp increase of the signal at t_v = 0.00 s. When the in-line valve is partially closed, it is also observed that the pressure rises at $t_{il,1}$ = 0.41 s and $t_{il,2}$ = 0.82 s, as a result of the arrival of the first and second pressure wave reflected by the in-line valve. At t_r = 0.89, the wave reflected by the upstream reservoir reaches the measurement section. It has to be noted that the larger the head loss coefficient – i.e. the smaller the degree of throttling – the larger the increase of the pressure signal, Δh_M, at $t_{il,1}$ (*Brunone et al.*, 2008), with Δh_M = 0 in the case of fully opened valve (χ = 0). Furthermore Δh_M is about the double with respect to the wave reflected back by the in-line valve that reaches the section M, $\Delta h_{R,M}$, because of the particular choice of the measurement section immediately upstream the manoeuvre valve.

In Figure 3 the reflection coefficient, C_R, i.e., the ratio between the in-line valve reflected wave and the incident wave, is plotted for different values of the relative roughness, ε/D (with ε = Colebrook-White roughness), and χ.

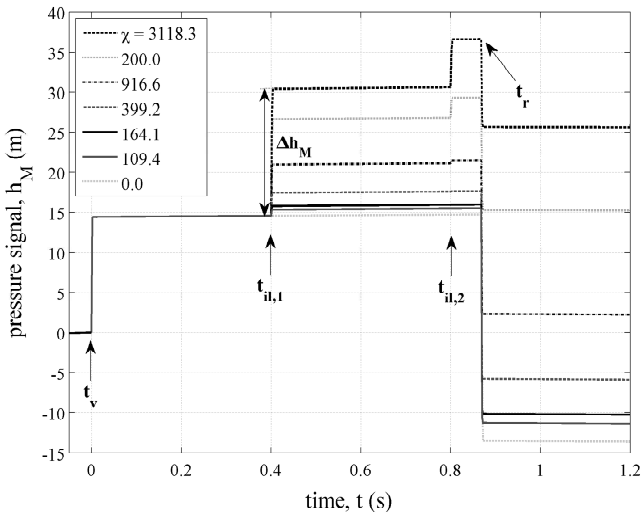

Figure 2. Numerical pressure signals (Q_0 = 2.6 l/s).

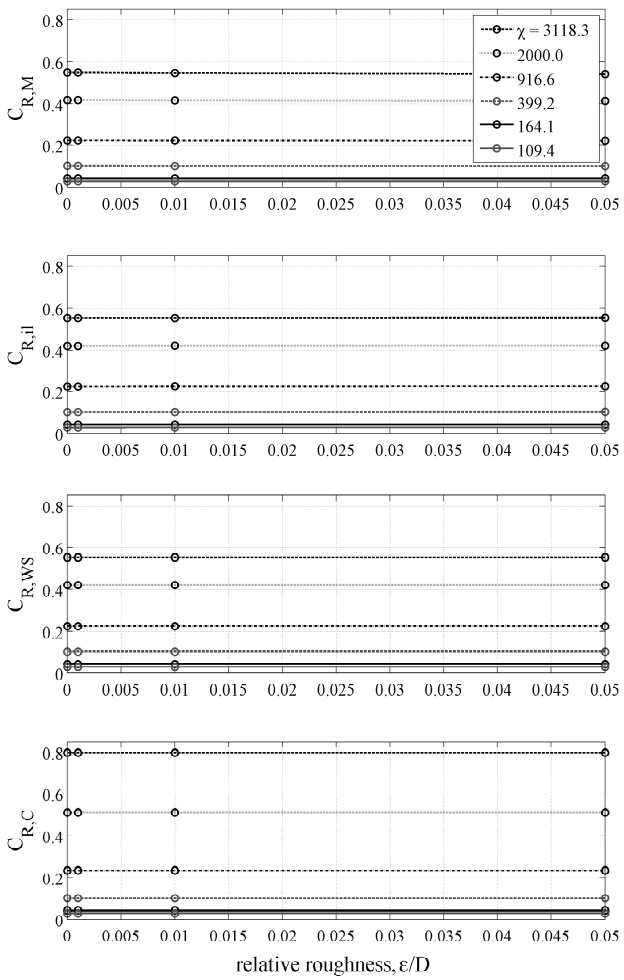

Figure 3. Numerical reflection coefficient by: a) MOC at section M, b) MOC at section 2, c) equation (3); d) equation (5).

In particular, in Figure 3a and 3b $C_{R,M}$ and C_R, are calculated by MOC at section M and at the section immediately downstream the in-line valve, respectively. In Figure 3c and 3d reflection coefficients $C_{R,WS}$ and $C_{R,C}$ are obtained as the ratio between the reflected wave of equations (3) and (5), respectively, and the incident wave. It can be noted that, given χ, all the coefficients are about constant with ε/D: the increase of the friction losses has no effect on the first reflection by the in-line valve. This is also demonstrated by the fact that $C_{R,M}$, $C_{R,il}$ and $C_{R,WS}$ are approximately coincident, given ε/D. There is also a good agreement between $C_{R,WS}$ and $C_{R,C}$: the only two discrepancies, shown in such a figure, can be ascribed to the failure of condition (4).
In Figure 4 the dependence of the limit value of χ, χ_{lim}, on the steady-state discharge and the wave speed is reported. The smaller Q_0, the larger the value of χ_{lim}, given a; furthermore, the smaller the pipe stiffness (i.e. a), the smaller the value of χ_{lim}. In such a figure it is evident the value of χ_{lim} for signals of Figure 2: this value is 1940.61, and subsequently the values of $C_{R,C}$ for χ = 2000.0 and 3118.3 are incorrect (Figure 3d).

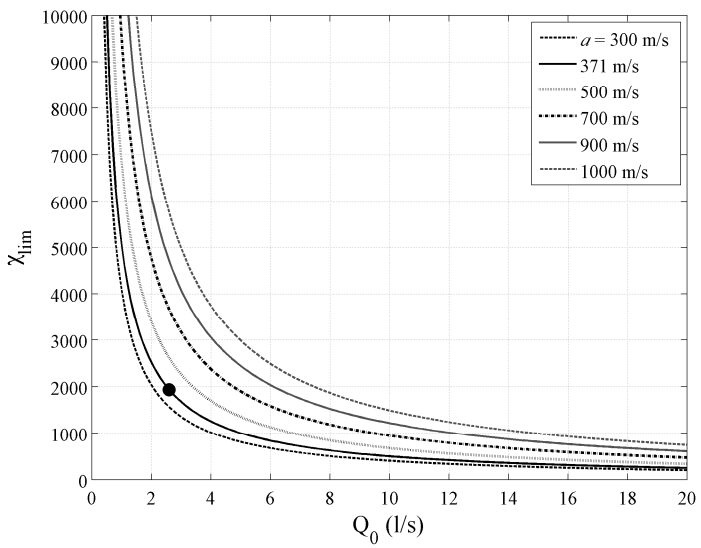

Figure 4. The value of χ_{lim} of equation (4) versus Q_0 for different values of a.

EXPERIMENTAL TESTS

Experimental tests were carried out at WEL in a high-density polyethylene pipe, with the same characteristics of that considered in the numerical simulation. The set-up is shown in Figure 5: the in-line valve is a ball valve with a nominal diameter DN90. All transient tests are generated by the fast and complete closure of the downstream end ball valve DN50.
In order to determine the hydraulic behaviour of the in-line valve, steady-state tests were carried out: the local head loss across the device, ζ_0, was measured by a variable reluctance differential pressure transducer, varying the discharge Q_0 and the degree of throttling, δ. In Table 1 the experimental mean values of χ and δ are reported.

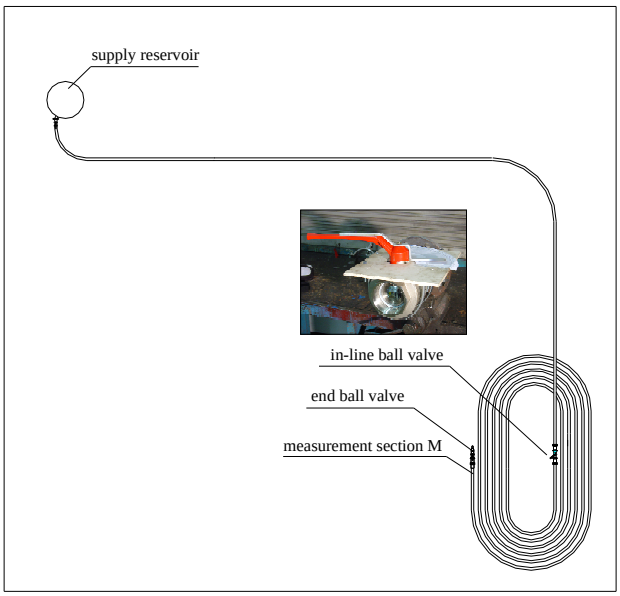

Figure 5. Experimental set up.

δ	90°	60°	50°	40°	35°	30°	25°	20°
χ	0	11.3	35.3	109.4	164.1	399.2	916.6	3118.3

Table 1. Experimental values of δ and χ for wholly turbolent flow.

As an example, Figure 6 shows the pressure signals, h_M, acquired with a frequency equal to 1024 Hz, with the same values of the steady-state discharge and χ of some signals reported in Figure 4; also in this case the occurrence χ = 0, corresponding to fully opened valve, is included as useful reference. The behaviour of experimental pressure signals is on the whole in good agreement with that given by MOC.
For all cases portrayed in Figures 4 and 6, the location of the in-line valve can be evaluated using the relationship:

$$L_{il} = \left(t_{il,1} - t_v\right) L / t_r \tag{6}$$

which connects the distances from the measurement section to the in-line valve, L_{il}, and the reservoir, L, to times t_v, $t_{il,1}$ and t_r. It is worthy noting that, according to equation (6), location of singularities coincides with the evaluation of the times at which pressure waves pass through the measurement section and then it is not necessary to estimating pressure wave speed.
Detection of these times can be properly and precisely done by means of wavelet analysis that is a powerful tool for edge detection that improves the precision of the procedure, with respect to time domain analysis (*Stoianov et al.*, 2001; *Al-Shidhani et al.*, 2003; *Ferrante and Brunone*, 2003b; *Ferrante et al.*, 2007). The wavelet transform of a discontinuous signal, sampled at constant frequency for a limited

number of time increments N ($s(i\Delta t)$, $i = 0 \ldots N\text{-}1$, with Δt = sampling period) can be defined as:

$$Ws(i\Delta t) = \frac{1}{2^j}\sum_{k=0}^{N-1} s(k\Delta t)\psi\left(\frac{(k-i)\Delta t}{2^j}\right) \quad j = 1,2,\mathrm{K}\ J \tag{7}$$

where 2^j is the scale parameter, with $J<\log_2 N$ and $\psi(t)$ is defined by the following expression:

$$\psi(t) = \begin{cases} 0 & 1 \le |t| \\ \psi(-t) & 0 \le t < 1 \\ -24t^2 - 16t & -0.5 \le t < 0 \\ 8(t+1)^2 & -1 < t < -0.5 \end{cases} \tag{8}$$

which is an approximation of the first derivative of the Gaussian function (*Mallat and Zhong*, 1992).

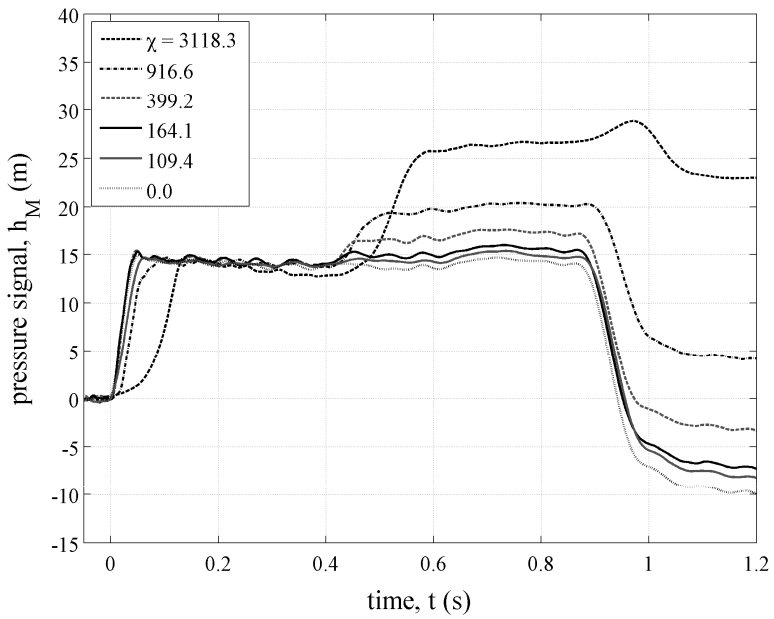

Figure 6. Experimental pressure signals (Q_0 = 2.6 l/s).

In correspondence to singularities, i.e. to the passage of waves through section M, the wavelet transform is marked by maximum local moduli that organize themselves into "chains", indicated by dotted lines in Figure 7, even in case of a modest fluctuation in pressure. An example of performance of wavelet analysis is given in Figure 7, where even if the time domain analysis (Figure 6) of the signal with χ = 109.4 does not reveal any evident singularities at $t_{il,1}$, the wavelet properly points out at $t_{il,1}$ = 0.41 s the presence of a very small step variation due to the passage of the

wave reflected back by the valve. Scrutiny of Figure 7 reveals of course also the singularities occurring at t_v = 0 s, and at t_r = 0.89 s. Then the distance L_{il} from equation (6) is equal to 75.73 m, with a relative error equal to 0.32%.

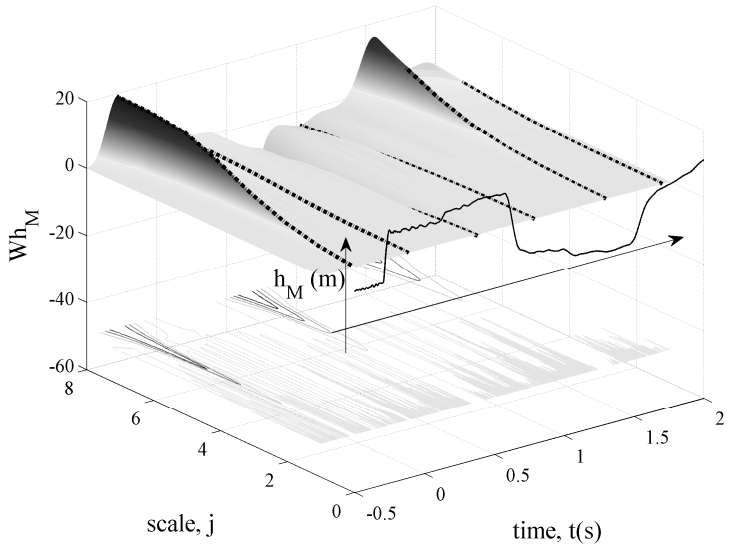

Figure 7. Wavelet transform, Wh_M, of the signal of Figure 6 with χ = 109.4.

Since the numerical simulation shows that friction losses have negligible effects on the first wave reflected by the in-line valve, in experimental tests the degree of throttling is estimated on the basis of the value of the first wave reflected by the in-line valve and registered at section M, Δh_M. Considering that such a value is approximately double with respect of $\Delta h_{R,M}$ and taking into account equation (3), the value of the head loss coefficient, χ_{WS}, may be derived. In Figure 8 the experimental value of the in-line valve head loss coefficient, χ, is compared with χ_{WS}: it can be noted that the error increases when the valve is very closed.

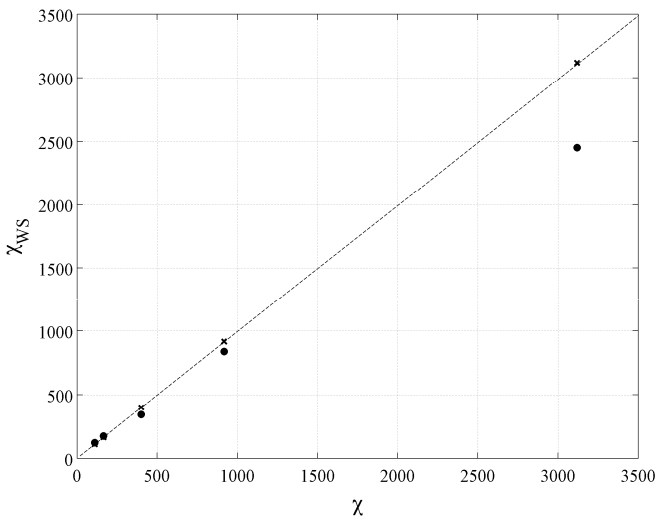

Figure 8. Comparison between of experimental head loss coefficient, χ, and χ_{WS}.

CONCLUSIONS

Numerical experiments carried out by MOC show that an in-line valve can be detected by analysing the pressure signal during the first characteristic time, i.e. within short period analysis approach. Moreover both the location of measurement section and friction losses have negligible effects on the value of the reflection coefficient of the in-line valve.
Laboratory tests carried out at WEL confirm on the whole the behaviour of numerical pressure signals. The good prediction of the in-line valve location by wavelet analysis – even for large degree of throttling – confirms the reliability of such a technique. A more extensive experimental campaign is needed to properly analyse the mechanism of interaction between in-line valves and incident pressure waves.

Abstract

The influence of wall biofilms on the transport of pathogens through a water pipe is mathematically described using an attachment - detachment model. The process coefficients of attachment and detachment are estimated from experimental data. A biofilm annular reactor model is presented and model predictions are compared to experimentally derived bulk phase and biofilm-sorbed pathogen data. The resulting pair of parameters, through minimizing the weighted root mean square error, are used in a single pipe model, and the results are discussed.

INTRODUCTION

Biofilms (BF) are ubiquitous and a common matrix for microbial growth and environmental persistence. While the majority of a biofilm is water, its other major constituents are microorganisms and various extracellular polymeric substances (carbohydrates, proteins, nucleic acids) interspersed with colloidal detritus (e.g. iron oxides) and water channels. Biofilms are beneficial in nature and in engineered systems where conversion of organic and inorganic substrates is desirable (i.e. wastewater treatment). However, in water distribution systems (WDS), microbial activity within the biofilm can deteriorate water quality in terms of aesthetics and public health (LeChevallier et al. (1987); Characklis and Marshall (1990)). Of particular concern for this paper is the potential role biofilm may play in modifying the temporal signature of human exposure to pathogens, and, as a result, potential disease risk. Pathogens introduced into the WDS may attach and accumulate in the biofilm matrix, then subsequently detach in higher densities either randomly or because of the changes in hydraulic conditions.

Early biofilm models were limited to linking substrate flux to the mechanisms of mass transport and substrate utilization (Rittmann and McCarrty (1980); LaMotta (1976)).

These models were further extended to multispecies models for 1-D biofilms by Rittmann (1992) and Wanner and Gujer (1986). Subsequent modeling attempts were expanded in two directions, a discrete versus a continuum approach. Examples of discrete descriptions of a heterogeneous multidimensional biofilm morphology are grid based Cellular Automata (CA) models (e.g. Noguera et al. (2004); Pizarro et al. (2001); Hermanowicz (2001)) and individual particle based models (IbM) (e.g. Kreft et al. (2001); Kreft and Wimpenny (2001); Piciorenau et al. (2004); Xavier et al. (2005)). Continuum models describe transport phenomena assuming that concentration is expressed by a density field that follows conservation laws, (i.e.conservation of mass and momentum), resulting in a system of differential equations. Newer continuum models describing multispecies interactions often are based on the model developed by Wanner and Gujer (1986), representing dissolved components in a diffusion reaction equation. Eberl et al. (2001), for example, describes a system of advection diffusion equations for the liquid phase and diffusion reaction equations for the biofilm, while others have focused on redistribution mechanisms using viscous fluid models (Dockery and Klapper (2001) and Cogan and Keener (2004)). Due to computational demands, models of biofilm processes appropriate for WDS scale would require a continuum approach. Early models by Dukan et al. (1996) and Servais and Prvost (1994) describing biofilm growth processes, were modified by Munavalli and Kumar (2004) and Zhang et al. (2004) to reduce complexity and allow application to hydraulic networks.

Whereas these and other WDS scale biofilm models have focused on biomass processes such as growth and accumulation on pipe surfaces, we are interested in the effect of established biofilm on pathogen transport in water distribution pipes. Experimental studies in biofilm reactors (e.g.Storey (2002)) and pilot scale systems (e.g.Quignon et al. (1997)) indicate that microorganisms transported in bulk flow can be incorporated into biofilm. Different surrogates have been investigated on different surfaces. Szabo (2006) for instance observed accumulation and persistence of *Klebsiella pneumoniae* (KP) on corroding biofilm coupons in annular reactors (AR).

In this paper we will present a modeling approach that includes the influence of the biofilm interactions on the transport of pathogens. Measurements of KP concentrations in the bulk and on the coupons in the dechlorinated AR system from Szabo (2006) will be used for the estimation of attachment and detachment model coefficients. First, pathogen pipe wall interaction (attachment - detachment) will be presented. Then, a comparable AR model will be established to support the estimation of the model parameters (attachment and detachment coefficient). Finally the model and estimated parameters will be applied to a simple WDS network of a single pipe.

MODEL DESCRIPTION

The modeling domain is divided into three compartments: the bulk phase, the concentration boundary layer, and the biofilm itself (see Figure.1). The pathogen concentration in the bulk (P_b), at the biofilm surface (P_s), in the biofilm (P_f) and in the detached

biofilm material (P_d) are predicted within their compartment. Note that the bulk phase concentrations are stated per volume, the biofilm concentration has units per area.

Model Assumptions

The one dimensional model describes the change in pathogen concentration over time. Advectional transport is solved with a Lagrangian scheme within the WDS network application used to interpret the temporal patterns of pathogen exposure. Biofilm is assumed to be a homogenous fixed layer at steady state, covering the inner pipe wall entirely. The nonmotile pathogenic matter attaches to the biofilm via transport to the biofilm and adsorption to the biofilm surface. It is assumed that there are unlimited sorption sites, and particulates, once attached, are assumed to be uniformly distributed within the biofilm. The pathogens colonizing the biofilm do not grow and natural mortality and inactivation are not included. This is also true for the bulk phase. It is assumed that the detached biofilm with incorporated pathogens does not reattach.

Attachment Process Description

Attachment processes are described as a combination of particle transport from the bulk liquid to the wall and the adsorption of those particles to the surface. Convectional transfer is due to superposition of diffusion and advection, and occurs between a fluid in motion and a surface. If the concentration at the surface (C_s) differs from that in the bulk (C_b) (cross sectional mean) a concentration gradient is developed by establishing an equilibrium between adjacent layers of the bulk phase. Figure 1 shows the concentration profile for turbulent flow as a dashed line. Although the transition is gradual, the flux over the concentration boundary layer, perpendicular to the surface, is approximately linear as illustrated in Figure 1 with a blue line. The change of pathogen concentration in the bulk due to transport of matter to the wall in order to achieve equilibrium, yields:

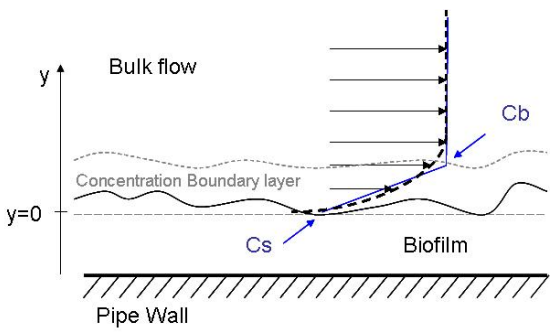

Figure 1: Concentration profile

$$V_b \frac{dP_b}{dt} = -h_m A(P_b - P_s) \tag{1}$$

where V_b is the bulk volume, A is the surface of the pipe and h_m is the mass transfer coefficient.

The boundary layer theory states that the transfer coefficient ($h_m = Sh\frac{D}{d}$) is proportional to the Sherwood number (Sh) and the diffusion coefficient (D) over the pipe diameter (d) derived after normalization of transfer equations. Chilton-Colburn's anal-

ogy, which is most accurate in the turbulent region, relates the Sherwood number to the D'Arcy Weisbach friction factor (f), the Reynolds number (Re) and the Schmidt number ($Sc = \frac{\nu}{D}$), thus providing a tool to estimate $Sh = \frac{f}{8} ReSc^{1/3}$, and the mass transfer coefficient.

Adsorption depends on particle surface properties and biofilm sorption sites. The rate of incorporation of particles that are situated close to the wall in the boundary layer into the biofilm is assumed to be first order. Therefore the change of wall pathogen concentration due to transport to the wall and adsorption to the biofilm is expressed as

$$V_b \frac{dP_s}{dt} = h_m A(P_b - P_s) - A_f k_a P_s \tag{2}$$

where A_f is the biofilm surface area and k_a is the attachment coefficient.

Detachment Process Description

The dominant detachment mechanism under the given hydrodynamic condition is assumed to be erosion, however, biofilm sloughing is the more important event. Continuous loss of biofilm particles will be a function of biofilm density and shear stress on the biofilm surface (τ). The detachment rate expression ($r_d = k_d A_f \tau P_f$) proposed in similar form by Bakke et al. (1990) depends on the concentration of pathogens within the biofilm. Thus, the pathogen concentration change in the biofilm, increasing with attachment of particles and decreasing due to detachment, can be written as:

$$A_f \frac{dP_f}{dt} = k_a A_f P_s - k_d A_f \tau P_f \tag{3}$$

where k_d is the detachment coefficient. The concentration of detached pathogens is tracked separately from the bulk matter in order to ensure no reattachment in the model. The change in detached concentration is expressed through the detachment rate.

$$V_b \frac{dP_d}{dt} = k_d \tau A_f P_f \tag{4}$$

Model Summary

Equations (1), (2), (3) and (4) simplify to the system of differential equations of first order:

$$\begin{aligned}
\frac{dP_b}{dt} &= -\frac{1}{r_h} h_m (P_b - P_s) \\
\frac{dP_s}{dt} &= \frac{1}{r_h} h_m (P_b - P_s) - \frac{A_f}{V_b} k_a P_s \\
\frac{dP_f}{dt} &= k_a P_s - k_d \tau P_f \\
\frac{dP_d}{dt} &= \frac{A_f}{V_b} k_d \tau P_f
\end{aligned}$$

where we introduce the hydraulic radius (r_h) as the cross sectional area of flow per wetted perimeter.

PARAMETER ESTIMATION

Pathogen persistence experiments conducted by Szabo (2006) simulated wall shear stress in a pipe with a diameter $d = 0.102\ m$ and a flow velocity of $v = 0.305\ m/s$, using an annular reactor (AR) with a motor speed of $100\ rpm$, a volume of one liter, and a residence time (θ) of two hours. Three iron foil coupons per slide were inserted in the AR and biofilm and corrosion were established through continuous contact with dechlorinated Cincinnati tap water for three to four weeks before KP was spiked into the system. Five different experiment with different initial KP concentrations and cultivating broth strength were performed in two reactor duplicates. Bulk and coupon concentrations were measured 30 minutes after inoculation and each day thereafter until KP was not detected in either phase.

Annular Reactor Model for Parameter Estimation

To allow estimation of detachment and attachment parameters, the pathogen transport model was adjusted to the geometry of an annular reactor. We assume that the shear stress at the AR wall imitates the shear stress at a pipe wall, and therefore that the velocity gradient over the boundary layer at the AR wall is equal to that at the pipe wall. Then the shear stress (τ) and the mass transfer coefficient (h_m) describing the transport of particles towards the biofilm surface are calculated for pipe flow, and used in the AR model to estimate the attachment and detachment coefficient k_a and k_d, respectively. The bulk concentration (P_b) in the AR case includes detached matter (P_d). Therefore the AR model is given as,

$$\begin{aligned}
\frac{dP_b}{dt} &= -\frac{1}{\theta}P_b - h_m\frac{A_{AR}}{V_{AR}}(P_b - P_s) + \frac{A_{AR}}{V_{AR}}k_d\tau P_f \\
\frac{dP_s}{dt} &= h_m\frac{A_{AR}}{V_{AR}}(P_b - P_s) - \frac{A_{AR}}{V_{AR}}k_a P_s \\
\frac{dP_f}{dt} &= k_a P_s - k_d\tau P_f
\end{aligned}$$

where V_{AR} is the AR volume, A_{AR} is the AR biofilm surface area and θ is the mean residence time. Note this is a linear system as θ, h_m, A_{fAR}, V_{AR}, k_d, k_a and τ are constant.

With the characteristic quantities $P_b^* = P_{b0}$, $P_s^* = P_{b0}$, $P_f^* = rP_{b0}$, $t^* = \theta$, where $1/r = A_{AR}/V_{AR}$, the AR biofilm model is nondimensionalized by substituting $P_b' = P_b/P_b^*$, $P_s' = P_s/P_s^*$, $P_f' = P_f/P_f^*$ and $t' = t/t^*$.

$$\begin{aligned}
\frac{dP'_b}{dt'} &= -P'_b - \alpha(P'_b - P'_s) + \beta P'_f \\
\frac{dP'_s}{dt'} &= \alpha(P'_b - P'_s) - \gamma P'_s \\
\frac{dP'_f}{dt'} &= \gamma P'_s - \beta P'_f
\end{aligned}$$

With the dimensionless parameter groups $\alpha = \frac{\theta h_m}{r}$, $\beta = k_d \tau \theta$, and $\gamma = \frac{k_a \theta}{r}$. α, β and γ can be regarded as the dimensionless mass transfer, detachment and attachment coefficients, respectively. By nondimensionalizing the AR experimental data in the same way we have previously, a consistent basis is created for combining field data to model predictions for estimation of β and γ (note that α is calculated). This nondimensionalization also imposes the natural scaling of the problem with benefits for numerical computation.

Estimation of Attachment and Detachment Coefficients

The AR measurements of bulk and biofilm KP concentrations by Szabo (2006) are used to estimate the attachment and detachment coefficients γ and β for the non-dimensional AR biofilm model. A grid search is implemented over a plausible parameter space (γ, β) and the minimum weighted root mean squared error is

$$J = \sqrt{\frac{1}{N}\left(\delta \times \sum(\widehat{P}_b - P'_b)^2 + (1-\delta) \times \sum(\widehat{P}_f - P'_f)^2\right)} \tag{5}$$

where $\delta = 0.4$ was selected using judgment, N is the number of measurements, P'_b and P'_f are the nondimensional concentrations predicted by the model and $\widehat{P}_b$ and $\widehat{P}_f$ are the nondimensionalized measured bulk and coupon biofilm concentrations of KP measures from the five experiments.

RESULTS AND CONCLUSION

Parameter Estimation

Calculated bulk and biofilm KP concentrations from the nondimensional AR model are compared to the measured data over the parameter space (γ, β). The response surface (J), defined by Eq. 5, is presented in Figure 2, using a 10×10 grid. The minimum of J occurs at the grid point $(\gamma, \beta) = (32080, 1.32)$ where $J = 0.86694$. The parameter pair at this minimum is assumed to best represent the experimental data. The results clearly show, however, that the estimate of γ is highly uncertain due to the experimental conditions and sampling intervals used, which were not designed for model parameter estimation.

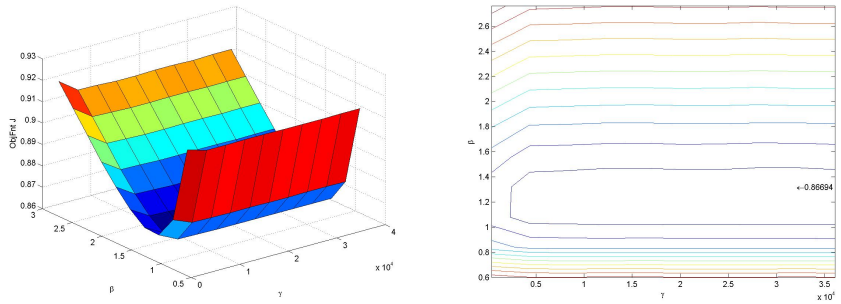

Figure 2: Response surface (left) and contours (right) of the weighted root mean squared error over the parameter space

The complete set of parameters for the AR model application is listed in Table 1. The nondimensional mass transfer coefficient used in the nondimesional AR model is determined to be $\alpha = 7.1715$. The estimated coefficients γ and β in dimensional form give, for the attachment coefficient $k_a = \frac{\gamma r}{\theta} = 0.022057$, and the detachment coefficient $k_d = \frac{\beta}{\tau\theta} = 6.6179 \times 10^{-7}$. The AR model with nondimensional model coefficients computes bulk and biofilm KP concentrations over time as presented in Figure 3 and Figure 4 respectively (black line). The two figures also show the nondimensional ex-

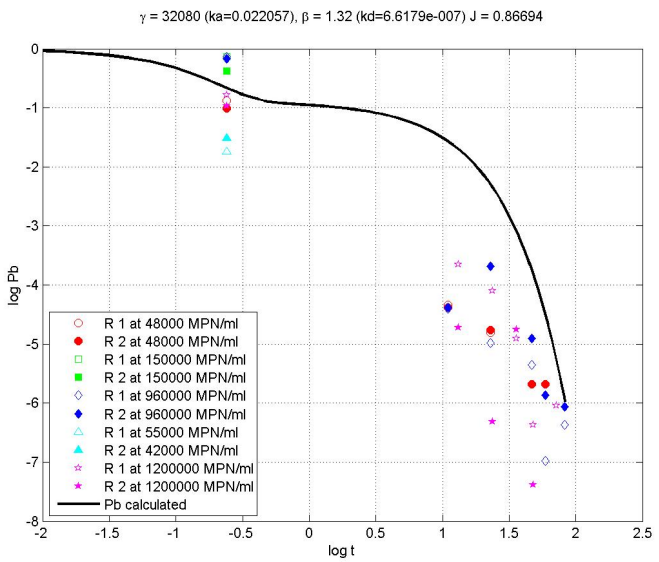

Figure 3: Dimensionless logarithmic KP concentration in the AR bulk phase versus dimensionless log time (where $(log(t) = log(\theta))$. The nondimensional experimental data are shown for duplicated reactors and five different experiments (the legend indicate the initial concentration of each experiment). Concentration over time estimated by the AR model is indicated by the solid black line.

perimental data for five different experiments (each conducted in duplicate (R1 and R2)) with varying initial KP concentration. The model prediction underestimates the experimental biofilm concentrations. This results from mass transfer limitations, as the

larger attachment coefficient γ does not decrease the error . This phenomena could be due to a variety of reasons. The calculated mass transfer coefficient could be too small, due to the friction factor (f) calculation using the Blasius formula for pipe flow. The mass transfer coefficient also depends on the diffusion coefficient (D), and the diffusion coefficient of KP could be too small (it is assumed equal to the value for *Escherichia coli* reported by Berg (1993)). Finally, the assumption of a similarity between the concentration gradient adjacent to the wall in pipe flow, and in an annular reactor could be inaccurate. Experiments, using smaller sampling steps, would be more suitable for attachment investigation and varying rotational AR speed, would help to understand the influence of the shear stress induced detachment.

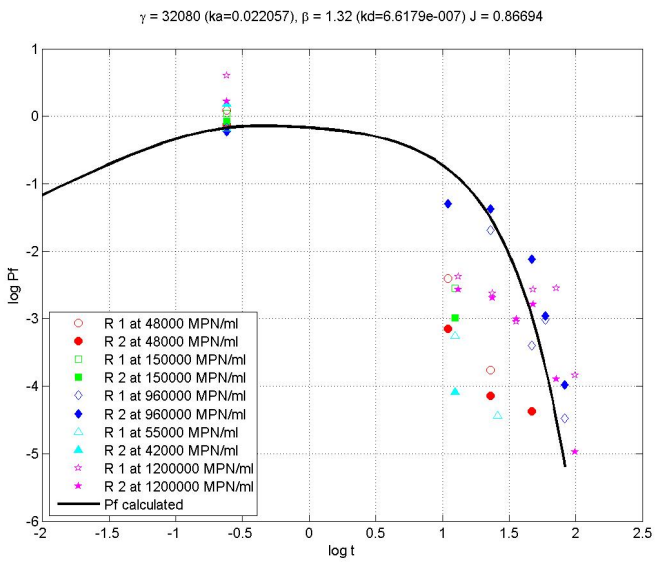

Figure 4: Dimensionless logarithmic KP concentration in the AR biofilm phase versus dimensionless log time (where $log(t) = log(\theta)$). The nondimensional experimental data are shown for duplicated reactors and five different experiments (the legend indicate the initial concentration of each experiment). Concentration over time estimated by the AR model is indicated by the solid black line.

WDS System Application of the Pathogen Transport Model

The set of parameters $(k_a, k_d) = (0.022057, 6.6179 \times 10^{-7})$ estimated by minimizing the weighted root mean squared error over an appropriate parameter space were applied to the attachment-detachment model for a pipe. The predictions are presented for a single pipe advection model application. A single pipe of 21km length with a residence time of 20 hours for given flow (v) and pipe diameter (d) describes the hydraulics for the model. The model was executed with a initial pathogen concentration ($P_{b0} = 4.8 \times 10^{10}\ MPN/m^3$) introduced in the system for the initial 20 hours, and run for a simulation time of 200 hours. The resulting pathogen concentration pattern for

bulk, surface, biofilm and detached material can be observed in Figure 5. The bulk concentration and the concentration of detached material at the end of the pipe are shown in Figure 6. The results predict a fast washout of the system, so the system is nearly cleaned out after twice the residence time. This behavior is likely a result of the discussed shortcoming of the parameter prediction. The model is under-predicting biofilm concentration in the AR, thus the washout rate would also be higher than expected.

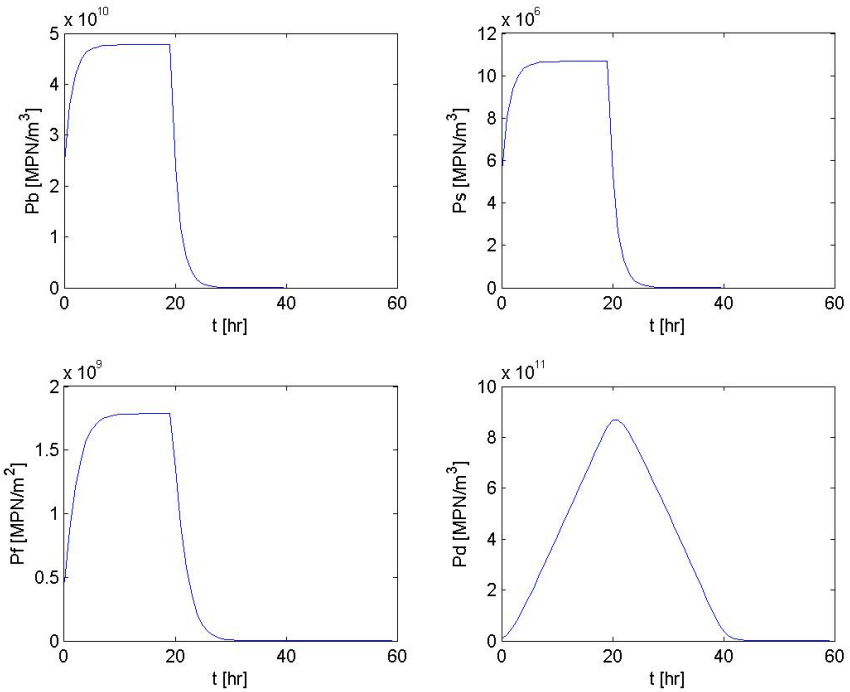

Figure 5: Average concentration for bulk (upper left), the surface (upper right), in the biofilm (lower left) and detached material (lower right) over time.

Conclusion

A simple linear pathogen attachment-detachment model was developed for applications to pipe flow, where advection would be incorporated by a Lagrangian scheme. The unknown coefficients of attachment and detachment are estimated with a least square search over the plausible parameter space using experimental data collected in annular reactors. The results suggest limitations from mass transfer assumptions, which require further investigation. Nevertheless, a first application of the transport model is presented, for a hydraulic pipe model with the set of fitted parameters. This results indicate that future work should be directed towards a more sound prediction of the unknown model parameters. The form of the mass transfer model should also be investigated. In addition to improvements in pathogen measurement frequency, investigation of the

influence of the AR mass transfer and the impact of the shear stress on detachment will improve the pathogen transport model predictions.

ABSTRACT: Municipal water distribution systems (MWDS) use a significant amount of electrical energy for the pumping of water from low elevations to higher ones. The use of electrical energy has an effect on pollution emissions and, therefore, potential global climate change as well. There are many aspects of MWDSs that affect energy usage. The properties of the storage tank(s), namely diameter and tank maximum water level, are singled out here for analysis. Various values of these tank parameters are modeled on seven MWDSs of various sizes using a system solver and the energy usage recorded. It was found that when averaged over all seven systems analyzed (1) a reduction of tank diameter of 20% results in approximately a 4% energy savings, and (2) the reduction of maximum tank water level by 20% results in approximately a 1% energy reduction.

INTRODUCTION

The use of electrical energy for pumping in municipal drinking water distribution systems (MDWS) has contributed to air pollution emissions and perhaps to global climate change. There is a need to incorporate water conservation, environmental impacts, energy consumption, and social aspects in addition to the system flows and pressures (Ellis 1978). There are several factors that influence energy consumption of pumping, such as scheduling (Brion and Mays 1991, Farmani et al. 2004, Pezeshk and Helweg 1996, Tarquin and Dowdy 1989) and pump configuration (Walski 2001). Storage tank capacity and minimum normal operational level have an affect on cost and the system hydraulics (Vamvakeridou-Lyroudia et al. 2007) but their affect on energy consumption is unclear.

The present paper presents an analysis of the effect of altering the tank diameter and maximum water level on energy consumption. The method is demonstrated in seven municipal water systems of varying size and complexity.

System Modeling

To examine the effect of varying storage tank parameters on MWDS energy consumption, seven systems were modeled using the system solver EPANET 2.0 (EPA 2000). Extended period simulations of ninety-six hours were modeled with a varying diurnal demand pattern based on data from Lineweaver 1963. This time period of simulation was chosen to ensure a long enough time for initial conditions to be insignificant.

SYSTEMS STUDIED

Seven MWDSs were used in the analysis (summarized in Table 1). It can be seen that there are a wide variety of system sizes, number of pumps, tanks and complexity, thereby providing a wide variety sample for the analysis. After simulations were performed on all seven systems, results were analyzed treating the systems together in a statistical approach.

ENERGY USAGE WITH VARYING TANK DIAMETER

Tank parameters that are somewhat under the MWDS utility's control are tank diameter and maximum water level. Each of these was systematically altered and the energy usage calculated.

Table 2.1 Summary of system characteristics (After Ghimire and Barkdoll, 2008)

System	Junctions (#)	Pipes (#)	Pumps (#)	Reservoirs (#)	Tanks (#)	Valves (#)	Δz_{max} (m)
S1	6	8	1	1	1	0	39.6
S2	44	62	1	1	1	0	33.7
S3	126	168	2	1	2	8	217
S4	126	144	6	2	2	4	93.0
S5	347	394	8	1	2	1	100.3
S6	873	958	3	1	1[#]	6	27.4
S7	12,525	14,824	6	2	4	5	73.7

Tank Diameter

Altering the tank diameter changed the hydraulics of the system for some cases and, therefore, it was necessary to alter the pump characteristics (head versus discharge) in order to ensure adequate pressure at all junctions at all times (Ghimire 2008). The normalized tank diameter, D' was defined as follows:

$$D' = \frac{D}{D_o} \tag{1}$$

where D is the diameter modeled, and D_o is the original tank diameter. Similarly, the normalized consumed energy, E' during the simulation period was as:

$$E^* = \frac{E}{E_o} \tag{2}$$

where E is the energy consumed by the system pumps with the modeled tank diameter and E_o is the energy consumed with tank(s) unaltered.

The results are plotted below in Figure 1. It can be seen that the energy utilization of 9 of the tanks is less sensitive to the variation of tank diameter than the remaining five tanks (S2, S3T1, S3T2, S4T1 and S4T2).

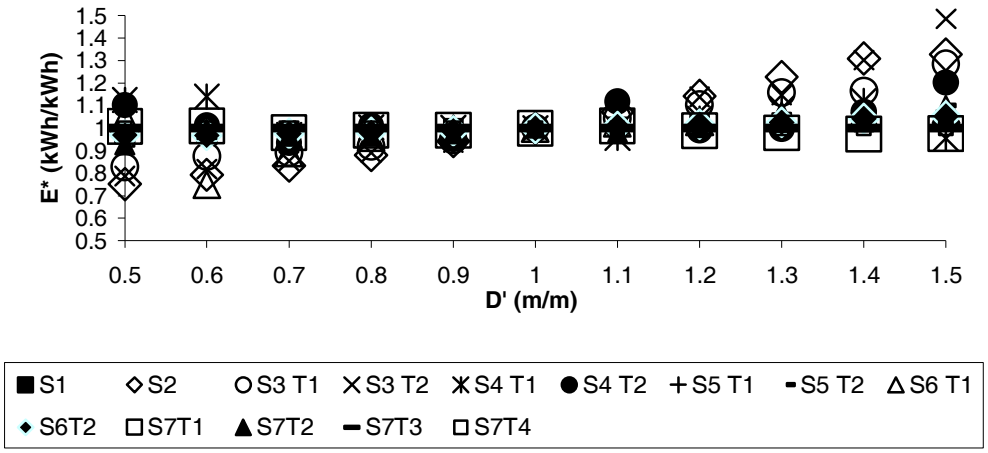

Figure 1. The sensitivity of energy consumption to the tank diameter of seven systems: 'S' represents 'System' and 'T' represents 'Tank'.

A closer-look at the diameter-sensitive tanks reveals that the high energy use was caused by an oversized pump(s) for those systems. Adjustment of pump curves was made to have the smallest pump that satisfied minimum pressures. After adjusting the pump curves thusly, the energy usage declined (Fig. 2). This agrees with the fact that pumps are more efficient at near-maximum discharge values. Figure 2 shows that the normalized energy can be altered by as much as 10% for a 50% change in normalized tank diameter, or have almost no effect, depending on the system and if the pumps are operating at peak efficiency.

Analyzing all seven systems en mass by taking the E* value averaged over D' reveals that (Fig. 3) an equation of energy utilization for the variation of diameter is given by an equation

$$E^* = 0.12D^* + 0.87 \quad (3)$$

with an R^2 value of 0.9480 and the error bars denoting ± 1 of standard deviation. The curve of the coefficient of variation (COV) exhibits wider variation between the system energy consumption values at values further away from D' = 1.0 and a maximum value of 0.087.

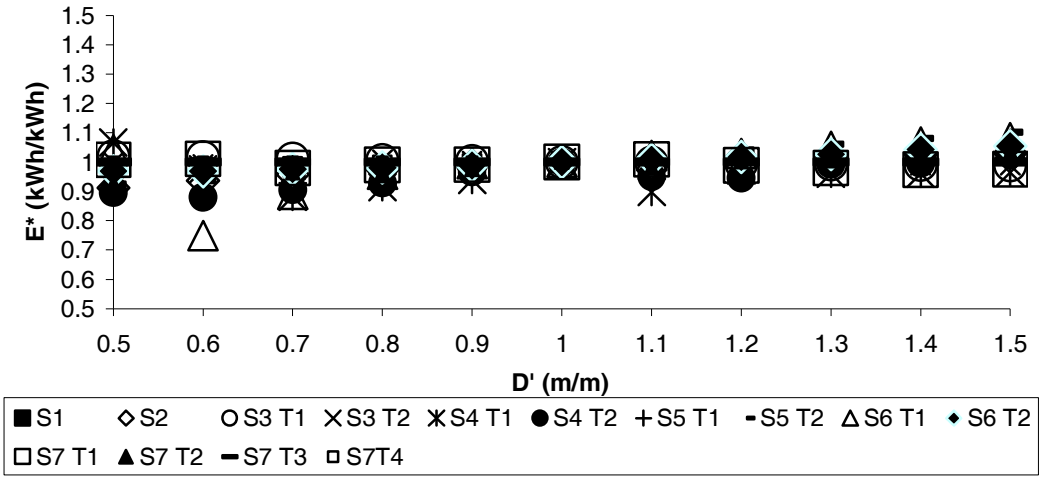

Figure 2. The sensitivity of energy consumption to the tank diameter of seven systems: After redesigning pumps of 3 systems S2, S3 and S4. 'S' represents 'System' and 'T' represents 'Tank'

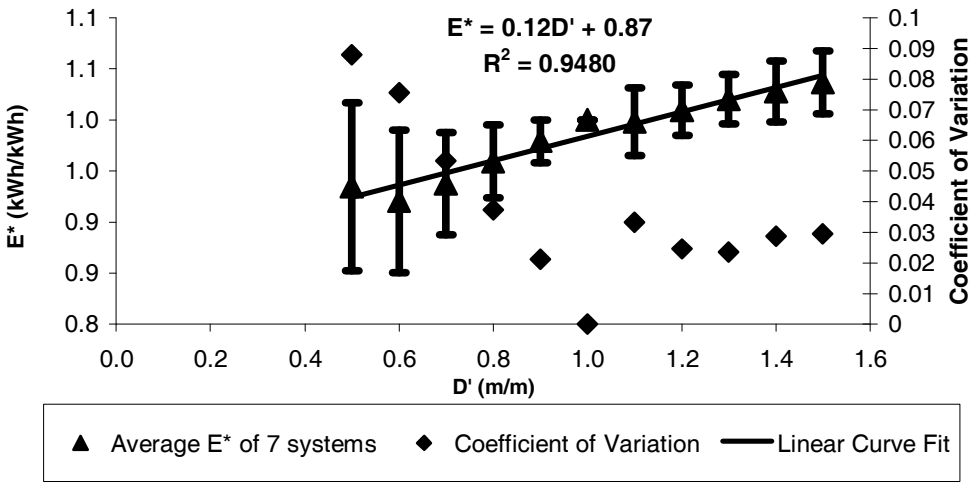

Figure 3: Average E* of seven systems for tank diameter variation for pumps sized correctly. Error bars denote ± 1 standard deviation (Ghimire 2008).

Energy Usage with Varying Maximum Tank Water Level

In addition to tank diameter, the maximum tank water level set point was varied in each tank one by one and the energy usage recorded. Each simulation was begun with the analyzed tank empty. The initial tank water level values of the remaining tanks were unaltered. During certain simulations, the pumps had to be altered to ensure adequate system pressures.

The maximum tank level was normalized (Eq. (3)).

$$H^* = \frac{H}{H_o} \tag{4}$$

where H^* is the normalized water height, H is the simulated maximum water height above the minimum value, and H_o is the original range in water levels between minimum and maximum water levels. The normalized energy is defined as above in Eq (2). For all values of H simulated see Ghimire (2008).

The results (Fig. 4) show that the energy usage is system specific, with some tanks exhibiting proportional, and others inversely proportional, behavior. The most sensitive tank resulted in a 30% reduction and/or increase in energy consumption and the least sensitive tank had a negligible change in energy use.

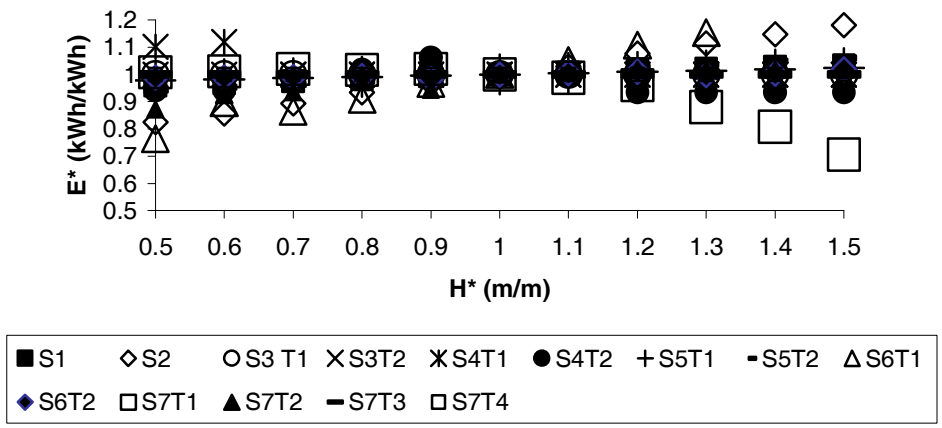

Figure 4: The sensitivity of energy consumption of seven systems to their tank maximum level before redesigning the pumps

The pump sizes were analyzed next to determine if pump over-sizing had an influence. It was found that the pumps were overly sized for systems exhibiting a high sensitivity to tank water level (S2 and S6T1) and non-monotonic behavior (S4T1, S4T2, and S7T1).

After redesigning the pump sizes, separate results were obtained and presented below in Figure 5. Eliminating pump over-sizing resulted in little energy sensitivity in all but S1, the simplest system.

When E* is averaged over all seven systems (Figure 6) it can be seen that the system-averaged E* values are linear (Eq. (5)) with an R^2 value of 0.9345 and a coefficient of variation ranging from 0 to 0.024.

$$E^* = 0.04H^* + 0.96 \tag{5}$$

CONCLUSIONS

From the results of current study, it is found that the variation of tank diameter has a greater impact in energy consumption than the tank water height, as evidenced by

the fact that a 20% reduction in tank diameter results in a 3.44% energy use reduction, while the same percentage reduction in maximum tank water level results in a mere 0.8% reduction, on average for the seven systems examined.

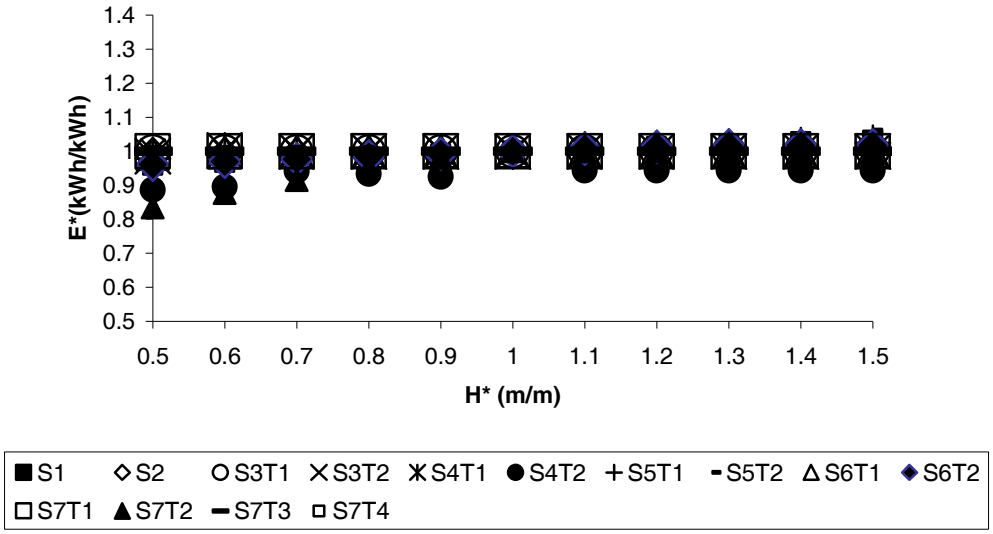

Figure 5: The sensitivity of seven systems and their tanks maximum level for energy consumption after redesigning the pumps

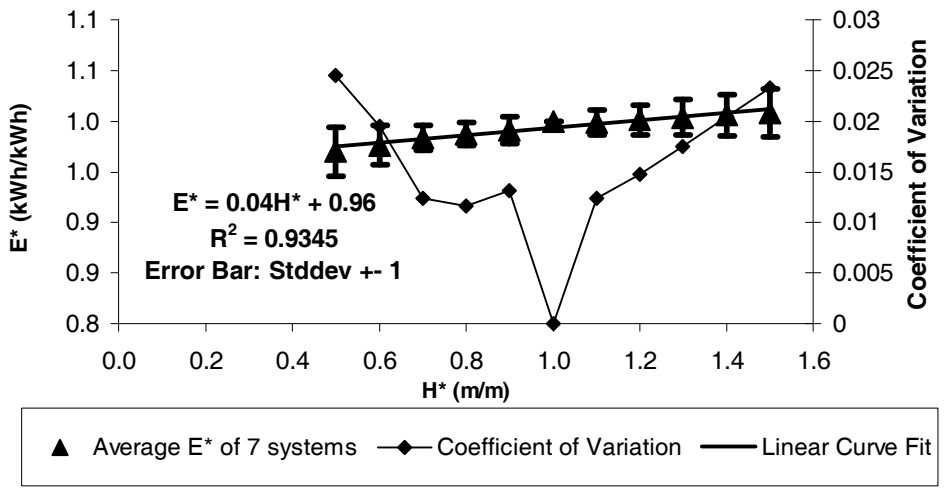

Figure 6: Average E* of seven systems for tank height variation after pump redesign. Error bars denote ± 1 standard deviation (Ghimire 2008).

Hydraulic Analysis of Water Distribution Network Using Harmony Search

Zong Woo Geem

Environmental Planning and Management Program, Johns Hopkins University, 11833 Skylark Road, Clarksburg, Maryland 20871; email: zwgeem@gmail.com

ABSTRACT

So far, water distribution networks have been hydraulically analyzed by using various techniques such as Hardy Cross method, Newton-Raphson method, linear theory, and Todini algorithm. This study proposes a novel technique for the analysis of water distribution networks using a phenomenon-mimicking optimization algorithm, harmony search (HS). The HS algorithm mimics the behaviors of musicians in improvisation process, where they play musical notes based upon randomness, experience, or variation of experience. In order to use the HS optimization algorithm, the network analysis is formulated as an optimization problem where energy conservation equation is incorporated in an objective function and mass conservation equations are incorporated in constraints. The proposed HS model is successfully applied to two example networks.

INTRODUCTION

Since 1936 when Hardy Cross first presented a systematic method from an idea in moment distribution method (Cross, 1936), various methods such as Newton-Raphson (Epp and Fowler, 1970), linear theory (Wood and Charles, 1972), and Todini algorithm (Todini and Pilati, 1987) have been proposed for water distribution network analysis.

The Hardy-Cross method initially estimates flows that satisfy the mass conservation at each node, and then updates flows in order to satisfy energy conservation in each loop. Because it updates a group of flows in each loop at a time, the convergence of the method is relatively slow. The Newton-Raphson method is a similar approach to Hardy-Cross method. However, it updates the flows by considering all loops simultaneously, which quickens the convergence. Linear theory initially estimates flows, and then iteratively updates the flows using a matrix of successively-linearized energy conservation equations. The Todini algorithm is a hybrid one between calculus-based optimization technique and Newton-Raphson method.

Meanwhile, there is still a chance to develop a new method for water distribution network analysis. The goal of this study is to provide a novel approach to hydraulic analysis of water distribution networks using a phenomenon-mimicking algorithm named harmony search (HS). The proposed HS algorithm (Geem et al., 2001), which mimics music improvisation, has been successfully applied to various

water engineering optimization problems such as pipe size design (Geem, 2006), ground water modeling (Ayvaz, 2007), multiple dam operation (Geem, 2007), and hydrologic parameter calibration (Kim et al., 2001). From the success demonstrated in previous applications, the HS algorithm is applied to the analysis of water distribution networks in this study.

EXISTING HYDRAULIC ANALYSIS TECHNIQUES

A steady-state flow of incompressible water through a pipe network is governed by two fundamental equations: a mass conservation equation and an energy conservation equation (Huddleston et al., 2004).

A mass conservation equation at each node can be expressed as

$$\sum Q_{in} - \sum Q_{out} = d_j \tag{1}$$

where Q_{in} denotes pipe flow into the node j; Q_{out} denotes pipe flow out of the node j; and d_j denotes nodal demand at the node j (positive sign of the nodal demand stands for outflow).

If there is no energy gain in any loop, the energy conservation equation at each loop can be expressed as

$$\sum_i h_f = 0, \quad i \in k \tag{2}$$

where h_f denotes head loss along the pipe i which forms loop k.

While mass conservation equations are linear as in Equation 1, energy conservation equations are nonlinear because the head loss equation has the following form:

$$h_f = K_i Q_i^n \tag{3}$$

where K_i denotes a friction coefficient for pipe i; Q_i denotes a flow through pipe i; and n denotes a flow exponent.

Normally, the following Hazen-Williams equation is used for head loss calculation in water distribution networks (Rossman, 2000):

$$h_f = 10.667 C_i^{-1.852} D_i^{-4.871} L_i \, Q_i^{1.852} \tag{4}$$

where C_i denotes the Hazen-Williams roughness coefficient; D_i denotes the pipe diameter (m); and L_i denotes the pipe length (m).

Another popular equation is Darcy's one (Mott, 2006) as follows:

$$h_f = f_i \times \frac{L_i}{D_i} \times \frac{v_i^2}{2g} = \frac{8 f_i L_i}{\pi^2 g D_i^5} Q_i^2 \tag{5}$$

where f_i denotes friction factor (dimensionless); v_i denotes average velocity of flow (m/s); g denotes the acceleration due to gravity (9.81 m/s^2); and π denotes the ratio of a circle's circumference to its diameter.

The Hardy-Cross method for analyzing the flow in water distribution networks follows the next procedure:

Step 1: Represent the head loss in each pipe in the form of $h_f = K_i Q_i^n$ as in Equation 3.

Step 2: Assign a flow rate for each pipe such that total flow into each node equals total flow out of the node plus nodal demand as in Equation 1.

Step 3: For each loop, the adjustment ΔQ is calculated as follows:

$$\Delta Q = \frac{-\sum h_f}{\sum \left| K_i \; n \; Q_i^{n-1} \right|} \tag{6}$$

where, if the flow is clockwise, the sign for Q_i (and h_f) is positive. Otherwise, the sign for Q_i (and h_f) is negative.

Step 4: Calculate a new estimate for Q_i by adding the adjustment ΔQ.

$$Q_i^{New} = Q_i^{Old} + \Delta Q \tag{7}$$

Step 5: Repeat Steps 3 and 4 until the adjustment ΔQ becomes negligibly small.

Other popular techniques in hydraulic network analysis, such as Newton-Raphson method, linear theory, and Todini algorithm use matrix operation in order to simultaneously analyze the network, but they also analyze it iteratively.

PROBLEM FORMULATION

For the hydraulic analysis, this study introduces the HS algorithm. Because the algorithm was originally developed for solving optimization problems, the hydraulic network analysis is transformed into an optimization problem. The energy conservation equation in Equation 2 can become an objective function in this optimization problem as follows:

$$\min \quad Z = \sum_k \left| \sum_i sd_i \; K_i \left| Q_i^{n-1} \right| Q_i \right|, \quad i \in k \tag{8}$$

where, in order to consider flow direction, the sign of flow direction sd (clock-wise is plus) and the expression $\left| Q^{n-1} \right| Q$ are used.

The approach shown in the above function intends to find a solution with a minimal sum of the error in each loop. Actually, Hardy-Cross method previously mentioned has the same objective of minimizing the error. But, while the latter minimizes it by adding the adjustment ΔQ to all pipe flows, the former minimizes it by selecting better flow rate Q_i for only certain pipes at each iteration.

Variables to be decided in this optimization are flows in all pipes. However, because some flows are dependent on other flows, the number of decision variables is actually reduced. For example in Figure 1, where there are four pipes and one loop, if we optimally update only one flow (say, Q_1 in pipe 1), we can deterministically

calculate the other three flows (Q_2 , Q_4 , and Q_3) using the mass conservation equation as in Equation 1.

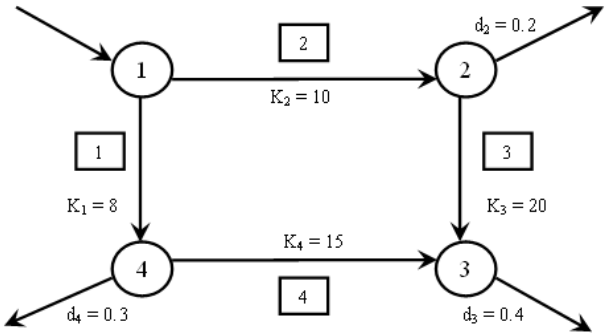

Figure 1. Schematic of One-Loop Network

The value range of the decision variable Q_1 in Figure 1 can be as follows:

$$0 \le Q_1 \le S \tag{9}$$

$$S = -d_1 = d_2 + d_3 + d_4 \tag{10}$$

The other flows in Figure 1 are specified as the following constraints:

$$Q_2 = S - Q_1 \tag{11}$$

$$Q_4 = Q_1 - d_4 \tag{12}$$

$$Q_3 = Q_2 - d_2 \tag{13}$$

In summary, the HS optimization model is to determine the values of certain independent decision variables (e.g., Q_1 in Figure 1) after incorporating energy conservation equations in the objective function and mass conservation equations in the constraints in order to minimize the error of energy loss.

HARMONY SEARCH OPTIMIZATION ALGORITHM

The proposed optimization model in the previous section is solved by using a phenomenon-mimicking optimization algorithm, harmony search (Geem et al., 2001). The HS algorithm uses an analogy between music improvisation and the optimization process. In music improvisation, musicians are playing musical pitches out of possible ranges of musical instruments in order to search for better harmonies. Likewise in the optimization process, algorithms are assigning variable values out of a possible range of decision variables in order to search for better solution vectors. Thus, a musical instrument corresponds to a decision variable; its pitch range corresponds to a value range; and harmony corresponds to a solution vector.

In the HS algorithm, a musician plays a pitch based upon one of three factors such as randomness, experience, or variation of experience. This mechanism becomes a novel stochastic derivative, rather than a calculus-based gradient derivative, for the optimization problem with discrete variables (Geem, 2008).

For the analysis of water distribution networks, the HS algorithm starts with an array named harmony memory (HM) which contains initial solution vectors randomly generated out of a possible value range:

$$\left[\begin{array}{cccc|c} Q_1^1 & Q_2^1 & \cdots & Q_n^1 & Z^1 \\ Q_1^2 & Q_2^2 & \cdots & Q_n^2 & Z^2 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ Q_1^{HMS} & Q_2^{HMS} & \cdots & Q_n^{HMS} & Z^{HMS} \end{array}\right] \tag{14}$$

where $(Q_1, Q_2, \ldots, Q_n)$ denotes a solution vector; Z denotes a corresponding objective function value; and HMS denotes the number of solution vectors stored in HM.

Based on the above-mentioned initial HM, a new solution vector $(Q_1^{New}, Q_2^{New}, \ldots, Q_n^{New})$ is generated. Variable Q_i^{New} can have one value as follows:

$$Q_i^{New} \leftarrow \begin{cases} Q_i & where \quad 0 \le Q_i \le S & w.p. \quad P_{Random} \\ Q_i & where \quad Q_i \in \{Q_i^1, Q_i^2, \ldots, Q_i^{HMS}\} & w.p. \quad P_{Memory} \\ Q_i + \Delta & where \quad Q_i \in \{Q_i^1, Q_i^2, \ldots, Q_i^{HMS}\} & w.p. \quad P_{Adjust} \end{cases} \tag{15}$$

where P_{Random} denotes a probability of random selection (randomness); P_{Memory} denotes a probability of memory consideration (experience); Δ denotes the amount of pitch adjustment; and P_{Adjust} denotes a probability of pitch adjustment (variant of experience). The amount of pitch adjustment, Δ, can have the following value:

$$\Delta = bw \times u(-1, 1) \times S \tag{16}$$

where bw denotes a bandwidth which is a tiny segment of total range; and $u(-1, 1)$ denotes a value generated by a uniform distribution between -1 and 1.

If a newly generated vector $(Q_1^{New}, Q_2^{New}, \ldots, Q_n^{New})$ is better than the worst vector stored in HM in terms of the objective function, those two vectors are swapped. Then, another new solution vector is generated using Equation 15 until a terminating criterion is satisfied.

EXAMPLE 1: ONE-LOOP NETWORK

The HS model was applied to a simple network, which has one loop, one supply node, three demand nodes and fours pipes, as shown in Figure 1 (Bhave and Gupta, 2006). Problem specifications are as follows: Type of Head Loss Function $h_f = K_i Q_i^2$; Friction Coefficients K_1 = 8, K_2 = 10, K_3 = 20, and K_4 = 15; Water Demands d_2 = 0.2 m^3/s, d_3 = 0.4 m^3/s, and d_4 = 0.3 m^3/s; Harmony Memory Size HMS = 10; Probability of Random Selection P_{Random} = 0.3; Probability of Memory Consideration P_{Memory} = 0.49; Probability of Pitch Adjustment P_{Adjust} = 0.21; Bandwidth bw = 0.1; and Tolerance (terminating criterion) $Z \le 0.01\,m$.

With the above values, HS found a solution vector (Q_1=0.4931, Q_2=0.4069, Q_3=0.2069, Q_4=0.1931) as shown in Figure 2. Table 1 shows the history of the best solution vectors HS found.

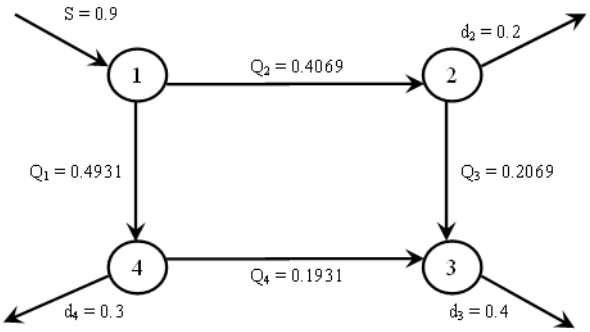

Figure 2. Final Solution for One-Loop Network

Table 1. History of Solution Vectors for One-Loop Network

Iterations	Z (m)	Q_1 (m^3/s)	Q_2 (m^3/s)	Q_3 (m^3/s)	Q_4 (m^3/s)
17	0.3446	0.5048	0.3952	0.1952	0.2048
26	0.2526	0.4850	0.4150	0.2150	0.1850
36	0.1116	0.4896	0.4104	0.2104	0.1896
53	0.0901	0.4904	0.4096	0.2096	0.1904
224	0.0309	0.4944	0.4056	0.2056	0.1944
380	0.0059	0.4931	0.4069	0.2069	0.1931

As previously mentioned, because the expression $\left|Q^{n-1}\right|Q$, instead of Q^n, was used, the HS model calculated flows correctly under the wrong assumption of flow direction. The flow Q_4 became -0.1931 m^3/s when the direction of Q_4 was assumed reversely (from node 3 to node 4; $sd_4 = +1$) and the constraint in Equation 12 was substituted with the following constraint:

$$Q_4 = Q_3 - d_3 \tag{17}$$

If Equation 12 was not substituted, a wrong solution vector (0.5639, 0.3361, 0.1361, 0.2639) was obtained as shown in Figure 3.

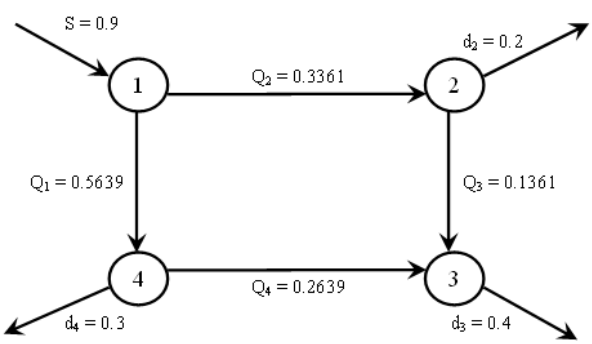

Figure 3. Wrong Direction Solution for One-Loop Network

Although the solution satisfies the mass conservation constraint of Equation 12, and also the energy conservation objective of Equation 8 (Table 2), the actual value of the

objective function becomes 2.0884 because Q_4 is -0.2639 under the constraint of Equation 12 (Table 3). Meanwhile, if the sign of flow direction was not properly considered ($sd_4 = -1$) with Equation 17, similar wrong solution vector (0.5639, 0.3361, 0.1361, -0.2639) was obtained.

Table 2. Objective Function Calculation with Incorrect Flow Direction

Pipe	K	Sign	Flow Rate	Head Loss
1	8	-1	0.5639	-2.5439
2	10	1	0.3361	1.1296
3	20	1	0.1361	0.3705
4	15	1	0.2639	1.0446
∑				0.0009

Table 3. Objective Function Calculation with Corrected Flow Direction

Pipe	K	Sign	Flow Rate	Head Loss
1	8	-1	0.5639	-2.5439
2	10	1	0.3361	1.1296
3	20	1	0.1361	0.3705
4	15	1	-0.2639	-1.0446
∑				2.0884

EXAMPLE 2: TWO-LOOP NETWORK

The HS model was further applied to another network, which has two loops, one supply node, three demand nodes and seven pipes, as shown in Figure 4 (Bradley, 2005).

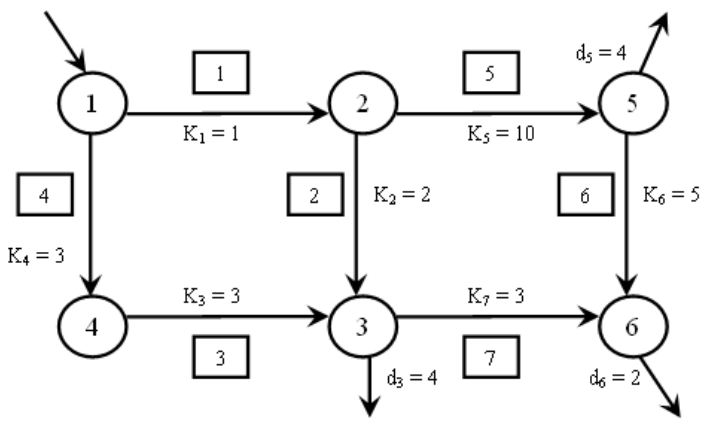

Figure 4. Schematic of Two-Loop Network

Problem specifications for two-loop network are as follows: Type of Head Loss Function $h_f = K_i Q_i^2$; Friction Coefficients K_1 = 1, K_2 = 2, K_3 = 3, K_4 = 3, K_5 = 10, K_6 = 5, and K_7 = 3; Water Demands $d_3 = 4$ m^3/s, $d_5 = 4$ m^3/s, and $d_6 = 2$ m^3/s; Harmony Memory Size HMS = 30; Probability of Random Selection P_{Random} =

0.3; Probability of Memory Consideration P_{Memory} = 0.49; Probability of Pitch Adjustment P_{Adjust} = 0.21; Bandwidth bw = 0.1; Tolerance (terminating criterion) $Z \le 0.5\,m$.

It should be noted that the number of decision variables for the two-loop network is only two such as Q_1 and Q_5. If Q_1 is assigned, Q_4 and Q_3 are successively determined, and if Q_5 is assigned, Q_2, Q_7, and Q_6 are successively determined. Thus, the number of decision variables in the HS model is equivalent to the number of loops in the problem network.

The mass conservation constraints for the two-loop network are as follows:

$$0 \le Q_1 \le \sum_{i=3,5,6} d_i \tag{18}$$

$$Q_4 = \sum_{i=3,5,6} d_i - Q_1 \tag{19}$$

$$Q_3 = Q_4 \tag{20}$$

$$0 \le Q_5 \le \sum_{i=3,5,6} d_i \tag{21}$$

$$Q_2 = Q_1 - Q_5 \tag{22}$$

$$Q_6 = Q_5 - d_5 \tag{23}$$

$$Q_7 = Q_2 + Q_3 - d_3 \tag{24}$$

After the HS model started with a solution vector (7.7160, 4.7343, 2.2840, 2.2840, 2.9817, -1.0183, 3.0183) with $Z = 84.62$, it reached a solution vector (6.5274, 3.8489, 3.4726, 3.4726, 2.6785, -1.3215, 3.3215) with $Z = 0.40$, as shown in Figure 5.

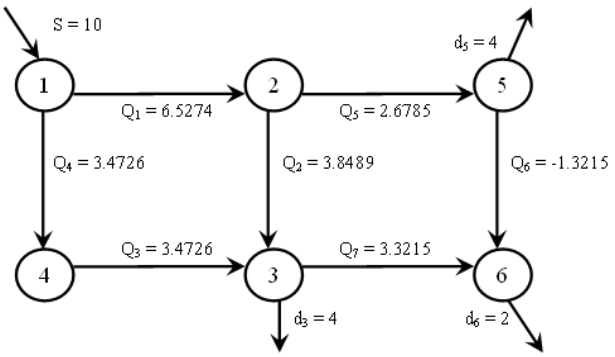

Figure 5. Final Solution for Two-Loop Network

CONCLUSIONS

This study proposed a new approach to the hydraulic analysis of water distribution networks using harmony search. The analysis was formulated as an optimization problem which has an objective function of energy conservation, constraints of mass conservation, and decision variables whose size is equal to the number of loops. The HS model successfully found pipe flows for two sample networks.

One advantage of the HS model is the fact that it does not require an initial solution vector which is sometimes critical to the convergence. Also, the HS model does not require any complicated mathematical expression and operation.

Based upon this fundamental study, further research should consider how to reduce the number of computing iterations and how to automatically generate energy conservation objective function and mass conservation constraints. Also, future research should cover more complex and realistic networks containing various hydraulic appurtenances such as pumps, valves, and multiple reservoirs.

ABSTRACT

In developing countries hydraulic models of water distribution systems are rarely used efficiently. The lack of appropriate know-how is one reason. Further, water distribution networks are dynamic technical systems changing rapidly due to maintenance works and network extensions. Therefore, the foundation for all technical tasks to assure a sustainable water supply is the deep going knowledge of the system. In developing countries the available system data is usually not up to date and of poor quality due to missing appropriate data management concepts. Integrating the data management and the hydraulic model as well as adapting the resulting tool to local constraints remedies the challenges resulting from the situation described above. Furthermore, linking the necessary work-flow of data collection to the tool eases the model implementation as well as the subsequent database update. In this paper a novel integrated data management and hydraulic analysis tool for water supply networks and linked work-flows specifically tailored towards its application in developing countries is presented. Based on a project of the German-Algerian technical cooperation in Béni Abbès the application of the tool is demonstrated.

1. INTRODUCTION

In developed countries hydraulic models and geo-information systems (GISs) are commonly applied to successfully analyze, design and operate centralized water distribution systems (Trifunović and Vairavamoorthy, 2008; Cornell and Dunphy, 2005). On the contrary, these sophisticated tools and models are rarely used efficiently in developing countries. Various reasons for the inefficient application or the absence of such tools and models exist. First, the benefits of hydraulic models and GISs are often simply not known or not seen. If those models and tools are known, the expectations regarding the possible results are usually high, while the necessary foundations to interpret the results achieved by model based calculations are often not present (Farley and Liemberger, 2005). Consequently, the lack of appropriate know-how is the second major reason for inefficient and inappropriate application and implementation of those tools. Third, the hydraulic model, the GIS and sometimes a digital or hardcopy network register are usually implemented, managed and updated separately consequently leading to redundancies and inaccuracies in the data bases and complex data transfer processes. Often a network

register does not even exist resulting in a poor and non-trustable data base quality and consequently in a poor model quality (Farley and Liemberger, 2005; Kumar, 1997, 1998). Integrating the network register, the GIS and the hydraulic model as well as adapting the resulting tool to local constraints remedies the challenges resulting from the situation described above. Furthermore, linking the necessary extended data collection process to the integrated tool eases the model implementation as well as the subsequent data base update.

This paper presents a hydraulic analysis and data management tool for water distribution systems specifically tailored towards its application in developing countries. The tool integrates the hydraulic model, the GIS and the network register and provides additional applications such as a graph decomposition module, automatic demand allocation and automatic topology generation. The system data as well as general spatial data are stored in a single central geo-database. All applications are integrated into the graphical user interface of the GIS as a toolbar. The common GIS functionalities together with the adapted network register tools allow data management and data analysis. Steady state and time extended simulation is supported. The graph decomposition module enables advanced topology analysis. The integrated tool is described in Section 2. Common work-flows, such as data collection, characterization of defects and model update are simplified by linking standardized processes with the novel user interface (see Section 3). Given a trained expert coordinates the overall process these simplified work flows can be delegated to non-experts. In Section 4, the advantages of the developed tool are demonstrated based on its application in the integrated water resources management (IWRM) project of the German-Algerian technical cooperation in the oasis Béni Abbès, Algeria (GTZ, 2008).

2. THE HYDRAULIC ANALYSIS AND DATA MANAGEMENT TOOL

Program architecture

In this subsection the components of the integrated tool and the interfaces of the components are presented. The functionalities and the realization of the integration of the components are described more detailed in the following subsections.

The tool consists of a geo-database, the hydraulic analysis and graph decomposition model KANET and the data management software package ArcGIS by ESRI. Further, an interface to an enhanced version of the hydraulic simulation program EPANET is implemented. The ArcGIS component ArcMap is used for visualization and spatial data analysis. For editing the system data of a water distribution network a toolbar is integrated into the graphical user interface (GUI) of ArcMap. Additionally, the toolbar consists of further tools for hydraulic modeling and analysis. The program codes of the components are integrated as Dynamically Linked Libraries (DLLs). All functions of the components are accessible through an ActiveX Dynamically Linked Library written in Visual Basic. Furthermore, it connects the KANET DLL on demand to perform simulation calculations or graph decomposition. If calculation is to be performed by EPANET, the data is transferred

through the KANET DLL to the EPANET DLL. The functions are implemented as commands and use the ArcGIS library ArcObjects to communicate with the host application. Therefore, ArcObjects acts as an interface between the database, ArcMap and the DLLs. Figure 1 gives an overview of the program architecture.

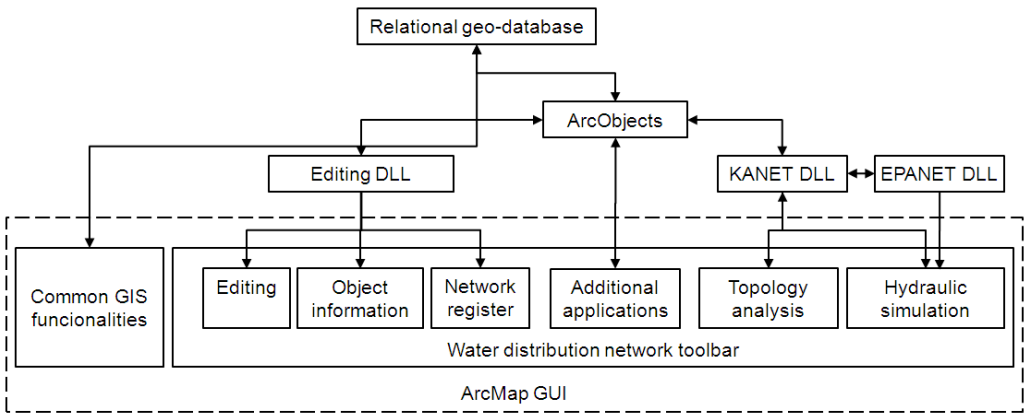

Figure 1: Components and program architecture of the integrated tool

The GIS model ESRI ArcGIS

ArcGIS is a software suite to manage and alter geo-spatial data and related attributes developed and distributed by the company ESRI (Ormsby et al., 2004). Geo-spatial data can be point features, line features or polygon features stored in feature classes. Attributes are data without a spatial reference stored in tables. Attributes are mostly related to a feature class. The data are stored in a relational geo-database or shape-files. ArcSDE offers the opportunity to connect ArcGIS to a centrally located Relational Database Management Systems (RDMS). The main components of ArcGIS are ArcMap and ArcCatalog. ArcMap allows all data analysis and modification regarded crucial for a GIS. Furthermore, ArcMap consists of applications and a GUI for user defined visualization of the geo-spatial data and the related attributes. ArcCatalog provides a GUI and functionalities to create data classes and manage data storage. ArcObjects is a Component Object Model (COM) library containing functions to develop GIS applications. ArcObjects allows the communication with the GUI of ArcGIS and the access to object data stored in feature classes and tables. Thereby the data access is independent from the physical representations of the data (for example shape-files, a personal geo-database or an ArcSDE connection). ArcObjects is applicable through the ArcGIS developer kit.

Database

The database contains all geo-spatial and object related data. The database may be a personal geo-database (for example MS Access) or an ArcSDE connection to a centrally located RDMS. The system data of water distribution networks are stored in a given database structure. A line feature class with the link information and a point

feature class with the node information of the network graph are the core of the structure. The feature classes consist of the geo-spatial shape information and additional attributes of the links and the nodes. Further necessary system data are stored in hierarchical organized tables. The data sets (objects) are connected through unique identifications (IDs). The shape information of the links and nodes allow geo-spatial visualization in the GUI of ArcMap. The interface of the hydraulic model KANET demands human readable data. Therefore the necessary data to build the network graph are saved as common object related attributes. Additional geo-spatial data can be freely organized in the same or other databases.

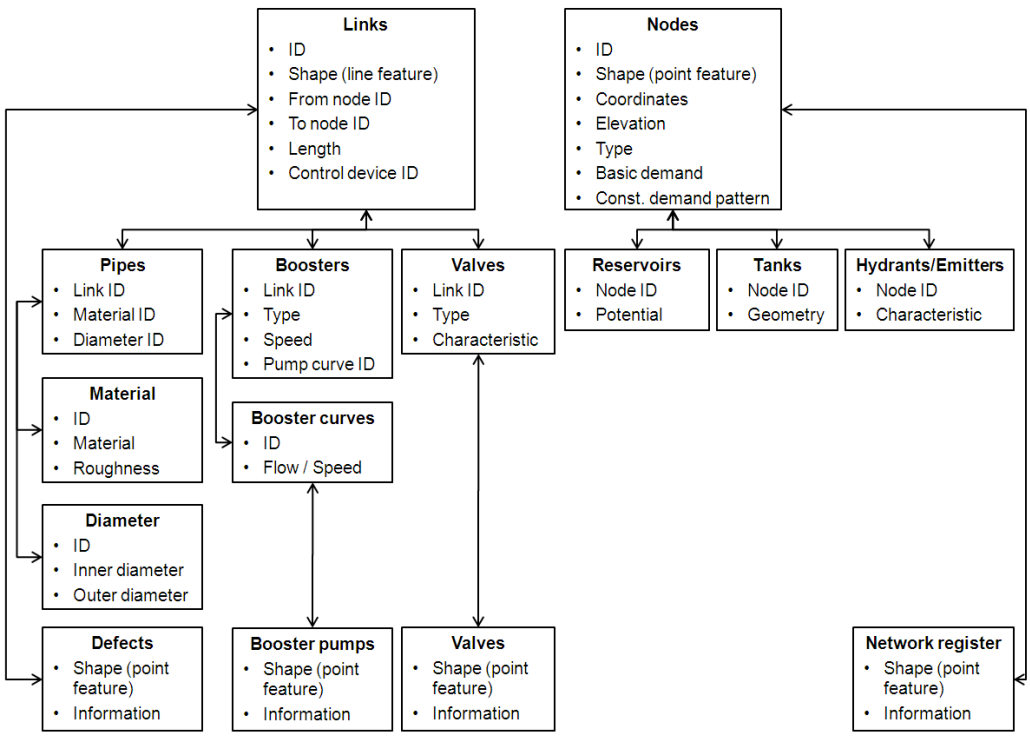

Figure 2: Schematic overview of the database structure for steady-state calculations

The link information is limited to the information needed to build the graph. The physical attributes of the pipes are organized in a separate pipe table. The KANET-algorithm for cost-optimal network design uses the link information as parameters and the pipe information as variables. For simulation calculations both the link and the pipe information are given parameters. Control devices like booster pumps and various types of control valves are related to links due to the modeling of their hydraulic behavior. In reality, control devices are elements with rather punctual then longish shape and location. For the visualization with real-world coordinates the true geo-spatial positions of control devices are additionally saved as point features. Accordingly, data concerning the network register are stored in a separate point feature class connected to the nodes point feature class. Defect data are stored in a

point feature class. The defect data is connected to the links line feature class to allow link related statistics.

Figure 2 gives a simplified schematic overview of the database structure for steady-state calculations. For time extended calculations patterns for control device settings, pump speeds, input node potentials and demands add to the structure. Further, the table with general parameters for the calculation algorithm is not shown.

The data management and network register tool

The data management and network register tool is a single library which contains all subsequent tools for manipulation and visualizing the water distribution system data. The functions are linked to the ArcObjects environment as a DLL (Editing DLL, Figure 1). The functionalities of the DLL are integrated into the GUI of ArcMap as part of the Water distribution network toolbar. The corresponding tools are described in the following.

Being exclusively responsible for editing and storing the data concerning the water distribution system the editing tool guarantees the consistency of the above described database structure. Tools for digitizing and modifying network elements and their attributes are implemented. Editing the network elements the accordant shape information of the link and node features are created and stored in the database. Additionally, the necessary attributes to build a network graph are generated automatically. References to relevant objects are made to check missing information. Dialogs to enter missing data are generated automatically. Further, the common attributes of the network elements can be edited. In addition to the shape information of the network graph the node coordinates are stored in the database as numbers. Therefore, the GUI of the stand-alone version of the hydraulic analysis model KANET can still be used. A database of the stand-alone version of KANET can be automatically converted to a geo-database compatible with ArcGIS. The spatial reference can be adjusted during the conversion process.

The information tool displays properties of the network elements. After a hydraulic simulation has been performed, the information dialog contains an additional diagram displaying the calculation results. Further, altering object related data and adding additional information of network elements in form of text or pictures is possible. Besides the visualization and manipulation of object related data the information tool allows the registration of defects. Thereby, the defects are characterized following given categories which can be adapted to the local constraints. Multiple defects can be related to one link. The real world location is stored in a separate point feature class (see accordant subsection further down). The relation of defects to links allows significant user defined reports and statistics.

Nodes of the network graph mark points of changes of the physical attributes of the system. Therefore, to achieve a complete information picture of the network the data at every node must be correct. According to this principle the later described work-flow to implement and update a consistent data base was developed. The network register tool supports the update of the network register with data collected in the field. In the GUI of the integrated tool surveyed nodes are labeled with a special symbol to get an overview of the progress. Further, an ID of the survey point

is generated automatically. The ID connects the node and the questionnaire for the data collection in the field. The completed questionnaire can be node related stored as an image. Therefore a scanner is connected to the integrated tool. The image is stored in a subfolder of the database´s path.

Additional data management and modeling applications

To support the conditioning of existing data (preprocessing) during the modeling process of the integrated tool several applications are implemented (Additional applications, Figure 1). The applications are written in Visual Basic and directly integrated into ArcGIS through the ArcObjects environment.

A tool provides functionalities to automatically and semi-automatically treat data without sufficient consistency to build a proper network graph. Not existing nodes at the ends of links are created. End points of links are adjusted to existing nodes if they are in distinct surroundings of the existing nodes. If a node is on a continuous link, the link is split. That can be either applied automatically or user controlled. The topology (the references of a link to its "start node" and "end node") of the modified elements is created automatically.

Further, functionalities for allocating a given population distribution to the demand nodes are implemented. The population expanses are divided into Thiessen polygons (Voronoi diagram) against the demand nodes. Thus, to each demand node a certain polygon with a related area and population density can be allocated.

The hydraulic analysis tool KANET

KANET is a hydraulic analysis tool developed by the Institute for Water and River Basin Management (IWG) of the University of Karlsruhe. The program consists of a graph model and algorithms for steady state and time extended hydraulic simulation and for graph decomposition. The hydraulic balance of a looped network with control devices is formulated as a set of optimization problems influencing one another. The problem can be solved by formulating it as a Nash Equilibrium with guaranteed convergence (Deuerlein et al., 2005). The components of the network graph can be identified according to their connectivity properties (Deuerlein, 2008). The application allows advanced topology analysis and data management. Supply areas, bottle necks, branched and looped network partitions are determined straightforward considering the state of the control devices. Accordingly, the graph decomposition can be used to calculate the hydraulic state of single components independently resulting in faster calculation times.

To enable data exchange with the Editing DLL and ArcMap a special DLL version of Kanet has been developed. KANET and the Editing DLL use the same data structure. Therefore, KANET only needs to gain access to the current database state. This is attained by handing over the ArcMap workspace of the database including all data needed. KANET uses ArcObjects to read the workspace data. Thus, it does not matter whether the data is stored in any kind of a local geo-database or a geo-database located on a server and connected via ArcSDE.

After KANET has knowledge of the data specific requests and functions can be performed. To proceed the requests and functions tools are integrated into the Water distribution network toolbar (see Figure 1). The results are returned either value by value or all values of a feature in a single request. The data exchange is performed by using the unique IDs of the features stored in the internal data structure of KANET. The results of calculation related functions are handled in three different ways. First, graph position information is stored into the respective feature class feature by feature. Second, calculated hydraulic analysis results are returned by the KANET DLL on demand as single values. Third, all calculated results are saved to a temporary Scratch Workspace provided by ArcObjects to allow the visualization of the hydraulic state of the network at each time-step. The time-step can be chosen in a drop down menu of the Water distribution network toolbar. Further, editing and simultaneously perform and display graph decomposition is possible. The KANET DLL is triggered to build the graph and perform the graph decomposition once an editing operation is executed. An editing operation may be the removal or modifying of a network element or the change of a valve state.

The hydraulic simulation tool EPANET

The hydraulic simulation software package EPANET is developed by the U.S. Environmental Protection Agency EPA (Rossmann, 2000). The software and the source code can be freely copied and distributed. EPANET allows steady state and time extended simulation calculations of the hydraulic state of a given looped pipe network including control devices. EPANET uses the Gradient Method by Todini and Pilati (1987) to solve the hydraulic state. The node-orientated approach treats control valves with certain heuristics.

In some circumstances such as less complex mainly branched networks the EPANET solver is faster than the KANET solver. Therefore, the main reason for integrating EPANET was the possibility of using its calculation algorithm. It is thought to combine the two algorithms in order to optimize calculation speed. EPANET could be used to solve the branched parts of the network while KANET solves the core of the network. Anyhow, as mentioned above, KANET guarantees the convergence, which EPANET in certain cases does not (Simpson, 1999; Deuerlein, Simpson and Gross, 2008). For connecting EPANET directly to the KANET DLL and ArcMap the DLL version of EPANET has been enhanced. The data for hydraulic calculations with EPANET is provided by the KANET DLL. The data is transferred by DLL-calls. Next, KANET triggers EPANET to calculate the hydraulic state of a time-step. After receiving the calculation results KANET triggers EPANET to calculate the next time-step. This procedure is continued until all time-steps of the simulation period have been calculated. Finally, KANET signals to the calling tool in ArcMap that the calculation is finished. The results can be displayed. Hence, there is no need for exporting and importing the data to a separate file. It is possible to load data into EPANET without creating an EPANET input file (*.inp). But the EPANET input file can be written by the enhanced EPANET DLL. Thus, EPANET itself is the export function to EPANET files.

User interface with integrated Water distribution network toolbar

ArcMap serves as the GUI of the integrated tool. The functionalities of all applications to edit, manage or analyze data concerning the modeled water distribution system are integrated into ArcMap as a toolbar (Water distribution toolbar, Figure 1). Geo-spatial data and the related attributes not concerning the distribution system can be edited, managed and analyzed using the common GIS-functionalities of ArcGIS. Figure 3 shows the GUI of ArcMAP and the integrated French version of the Water distribution network toolbar. Further, dialogs of the editing and information tools are shown.

An alternative for editing the water distribution system data and for hydraulic analysis calculations is the GUI of the stand-alone version of KANET. It accesses the same database as ArcMap and features read and write capability of ArcMap shape information. Therefore, import or export functions are not needed. The data is consistent and displayed equally in both user interfaces.

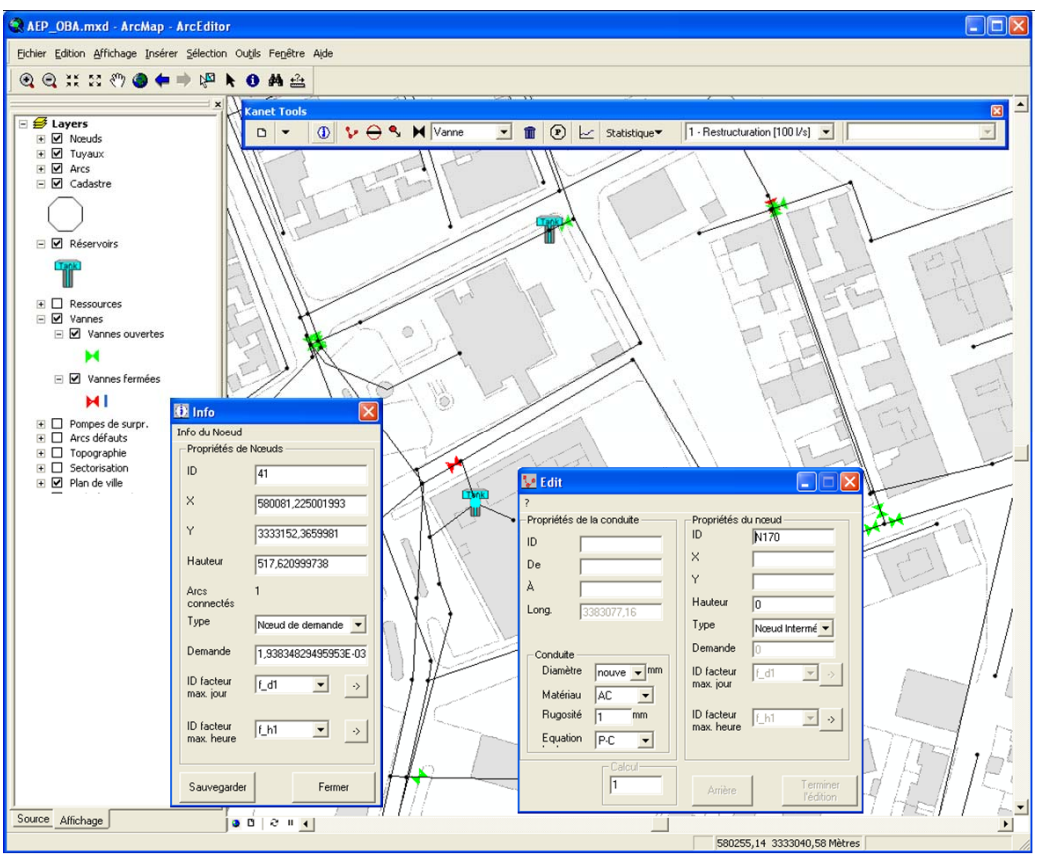

Figure 3: GUI of the integrated hydraulic analysis and data management tool

3. LINKED STANDARDIZED PROCESSES

Water distribution networks are dynamic technical systems changing rapidly due to maintenance works and network extensions (Roscher, 2006). Therefore, the foundation for all technical tasks to assure a sustainable water supply is the deep going knowledge of the system. This paper presents a novel integrated data management and hydraulic analysis tool for water supply networks and linked work-flows specially tailored towards its application in developing countries. The tool is described in Section 2. In this section, the standardization and linking of the work-flows to update the network register and to characterize defects are presented.

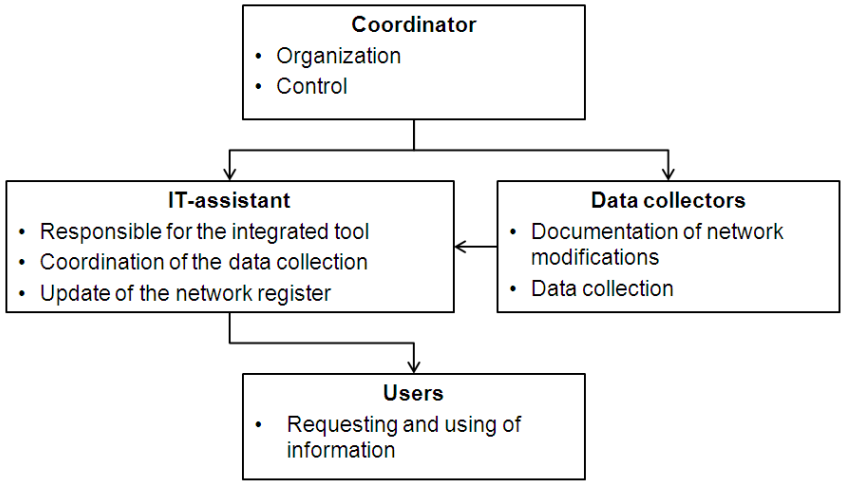

Figure 4: Organization of the data collection and network register update

To update the network register of the integrated tool a process with a questionnaire was developed (see Figure 4). A trained expert coordinates the overall process and controls the quality of the work. The IT-assistant exclusively works with the integrated tool. The assistant initializes a data collection at certain points in the network. Therefore, a questionnaire with a unique ID generated automatically in the network register is handed to the Data collectors. The Data collectors are favourably technicians of the maintenance sections of the water utility. The collectors document the physical attributes of the surveyed pipe section in the questionnaire following a given catalogue. Further, the location of the pipe section is documented referring to existing buildings etc. since the lack of knowledge is often a major problem. Hence, the pipe section can be detected even though the real-world coordinates of the section are still not known. The network register is updated by the assistant based on the documentation. The questionnaires are scanned and object based saved in the network register. The progress of the update and data collection can be visualized spatially. Additionally, the collectors document modifications of the network during their daily work. The corresponding questionnaires are handed over to the assistant to update the network register.

A second standardized process has the objective to characterize and document defects and its repairs. Therefore, a second questionnaire has been developed. In the questionnaire all necessary steps from the announcement, the survey of the defect to the repair of the defect are documented. The process is integrated into the organization of the process to update the network register (see Figure 4). The data is saved object based in the network register. Related reports and statistics are generated automatically.

4. APPLICATION IN BÉNI ABBÈS, ALGERIA

Initial situation and given data base

The oasis city Béni Abbès with approximately 13.500 inhabitants is located in the north-western part of the Algerian Sahara desert. The water supply is deficient in terms of water quality and water quantity distributed to the customers. The main deficiencies concerning the network are the complex topology with no pressure zones, the bad state of the infrastructure and the intermittent and intuitive operation. The lack of knowledge of the network results in unplanned network extensions, the impossibility of a proper maintenance and the intuitive system operation.

Within an integrated water resources management project of the German-Algerian technical cooperation the deficient water supply of the city will be rehabilitated (Klingel and Deuerlein, 2008). Amongst other topics, in the subproject *drinking water supply* a network register and a hydraulic model was set up. Therefore the IWG has developed and implemented the adapted integrated hydraulic analysis and data management tool.

Two public institutions are responsible for the water supply. In none of the two institutions exists a network register or some kind of data management. The only existing data of the infrastructure of the water distribution network are hardcopy plans made by an Algerian consultant. Verifications in the field have shown that the available data is unreliable to a high grade. Therefore the knowledge of the system is limited to the personal knowledge of a few employees. The risk of losing information or not having it available when needed is obvious.

Implementation of the network model

First, the available hardcopy plans of the system were digitized in order to implement a basic network register. A topographical survey delivered the necessary data to develop a digital land model. The elevations of the model nodes were generated automatically by merging the land model data and the nodes of the basic system graph. To clarify the most important topological aspects additional data were collected in the field. Accordingly, the existing data were verified in the field to plan the successive update of the network register.

By using the toolbar of the integrated tool the topology of the hydraulic model is generated automatically. This eased the modeling process resulting in immense time savings. Thus, together with the basic network register a basic hydraulic model

was set up. To complete the basic model further parameters had to be input. Consumption data was determined based on the population distribution. The demand data was allocated using the Thiessen-application of the integrated tool. The consumption behavior assuming a continuous supply was determined in a field study. Further, the tank geometries and pump characteristics were collected.

Process of data collection and model update

The data model of the integrated tool was implemented and updated by the IWG to an accuracy which allowed the planning of the restructuring of the network in order to introduce and establish a continuous water supply. The necessary further update of false information and the never ending process of updating the network register due to the dynamic nature of a distribution network were initialized by the IWG and will be carried out by the local staff of the water utilities. Therefore the above described (see Section 3) method for systematic update of the network register was developed. System elements are characterized and measured during data collection campaigns or maintenance works. The data is recorded in standardized questionnaires. Afterwards, the data is digitized in the network register. The employees are participating in ongoing trainings. The trainings are mostly on-the-job to consolidate the processes within the daily work. In near future the employees should be in the position to work and update the integrated tool independently.

Application of the tool for the planning of the restructuring

Based on a deficiency analysis, a concept for the rehabilitation and restructuring of the network was developed. The superior concept divides the network into pressure zones supplied by tanks by gravity. The pressure zones can be divided in subzones to allow water balances, leak detection and the successive introduction of continuous supply. The network restructuring with the necessary exchange, shut down and implementation of pipes was planned in an iterative process. The current topology was analyzed and the pressure zones were designed using the graph decomposition application. Simulation calculations were used within sensitivity studies to dimension the pipes and design the operation. During the planning, additional punctual surveys were made to update the network register successively. Two test periods in a pilot subzone were accomplished to proof the feasibility of a continuous supply and to sensitize the customers. The network data of the subzone will be updated completely within trainings of the local operators. The data collection campaigns have already started and will be finished before the final introduction of continuous supply. Klingel and Deuerlein (2008) detailed describe the network restructuring and the introduction of continuous water supply in Béni Abbès.

5. SUMMARY AND CONCLUSION

In developing countries the available system data of water distribution networks are often not up-to-date and of poor quality. The data are kept in hardcopy network

registers or single maps. Accordingly, hydraulic models are rarely applied successfully. One reason is the lack of adequate data. In this article a hydraulic analysis and data management tool for water distribution networks specially tailored towards its application in developing countries has been presented. By integrating the applications for data management, data preprocessing for hydraulic modeling and hydraulic analysis a data exchange between the applications is no longer necessary. Database consistency is achieved and the subsequent database update is simplified. Further, the work-flow for data collection is linked to the tool to ease the organization and to promote transparency. The application of the tool within the IWRM project in the oasis Béni Abbès was demonstrated. It is thought to transfer the developed IWRM concept to neighboring oases. The tool will be available for application along with manuals and concepts for the implementation.

Abstract

A stochastic water demand generator (PRPsym) and a well known distribution system network solver (EPANET) were linked together to analyze the impact of water demand variability on the underlying hydraulics and transport in a distribution system. The modified EPANET example 2 network model was used as a template and test network model for both hydraulic and water quality simulations at three different temporal aggregations (1-hour, 10-minute, and 1-minute). The mean, standard deviation and coefficient of variation at each hour for both hydraulic and water quality parameters were calculated for all nodes or links. Results showed that decreasing temporal aggregation of the water demands leads to increased flow rate variability. The increase in flow rate variability is related to the increased demand variability and the localized flow reversals that alter the travel path. The increase in flow rate variability was more evident in the links located at edges of the system rather than the main trunk lines. In addition to the hydraulics, water age simulations – used as a water quality surrogate – indicate that increased demand variability can significantly impact water quality simulations by altering residence times and travel paths. These preliminary results suggest that there are likely portions of a distribution system where typical modeling assumptions do not adequately represent localized water quality conditions.

1 Introduction and Objectives

Drinking water distribution systems are important and efficient devices for conveying water to consumers. However, operators face significant challenges in understanding and managing these systems since water quality in the distribution system deteriorates between the treatment plant and the consumers' tap. This issue has led to an increase in the modeling of transport and transformation of water quality constituents through drinking water distribution systems. In recent years, distribution system network models have become increasingly utilized for water quality analysis and advanced technical management, such as optimal sensor placement (Berry et al., 2006; Propato, 2006) and monitoring site selection for

the initial distribution system evaluation associated with the Stage 2 Disinfectants and Disinfection Byproduct Rule (USEPA, 2006). All of these require accurate representation of contaminant transport and water quality dynamics. Thus, accurate water demands – the factor primarily responsible for driving distribution system hydraulics and most influences the overall response of water distribution networks (Garcia et al., 2004) – are vital for adequately representing transport as well as performing network calibration, validation, and simulation.

Demands are inherently variable (e.g., daily and seasonal) and impact the underlying hydraulics and transport. Typical network modeling assumes deterministic demands (i.e., known and constant for short time periods) with temporal changes perfectly correlated in space. These deterministic assumptions generally focus on understanding the average hydraulic conditions without considering the impact that the intrinsic demand variability might impart on system dynamics. For a highly skeletonized system, these assumptions might be appropriate as the spatial aggregation of plentiful consumptive demands would likely reduce the overall impact of demand variability (due to averaging). However, as the industry moves towards "all-pipes" models, the loss of demand variability information through the use of deterministic demands may no longer adequately represent transport through the system. For example, when considering a residential area, the duration of any demand event is generally much shorter than a 1-hour time frame (Buchberger and Wells, 1996). The short demands can be quite variable during any 1-hour time frame and may include significant time fractions where the demands are zero. Therefore, the "smoothing" of the demands using typical network modeling approaches may not realistically represent the transport associated with these demands, which ultimately impacts the water quality description.

Overall, the objective of this study intends to investigate the potential impacts of demand variability over a range of spatial and temporal scales for representing transport through a distribution system. The current research is focused on analyzing the impacts of demand variability at three different levels of temporal demand aggregation (e.g., 1 hour, 10-minute, and 1-minute) on the underlying hydraulics and transport.

2 Methodology

Recognizing the natural randomness of network water demands, Buchberger and Wu (1995) proposed a non-homogeneous Poisson Rectangular Pulse (PRP) model to characterize the stochastic nature of residential water demands. The PRP model is the basis for PRPsym, a C-code developed for generating random water demands via Monte Carlo simulation. PRPsym assumes that the average network demands are known on an hourly basis and represents those hourly water demands through a sequence of rectangular pulses that represent individual water uses. The occurrence of each pulse is governed by a Poisson process; the intensity and duration of the demands are represented by log-normal distributions and

the resulting series of pulses are compiled by PRPsym into second-by-second demands for the simulation duration. Finally, the PRPsym produces time-averaged demands from the second-by-second data for any user defined time scale (Li and Buchberger, 2005). The ability of the PRPsym algorithm to generate demands at varying time aggregation allows the impacts of demand variability on distribution system hydraulics and transport dynamics to be evaluated.

3 Test Network and Simulation Experiments

3.1 Test Network

Figure 1 shows the test network – the modified EPANET Example 2 distribution system – including the node and pipe identification numbers. The system consists of 35 nodes, 40 pipes, 1 tank, and a pump station that operates based on the level of the tank. The pump station and the tank operate in a cyclical manner and alternatively serve as the supply source for the water demands in the system. When the pump is on, the tank is generally receiving water flowing up from the south along the main trunk line. When the pump is off, the tank acts as a source to transmit the water to both the south and the north. All of the nodes in the model are represented by the same, singular demand pattern.

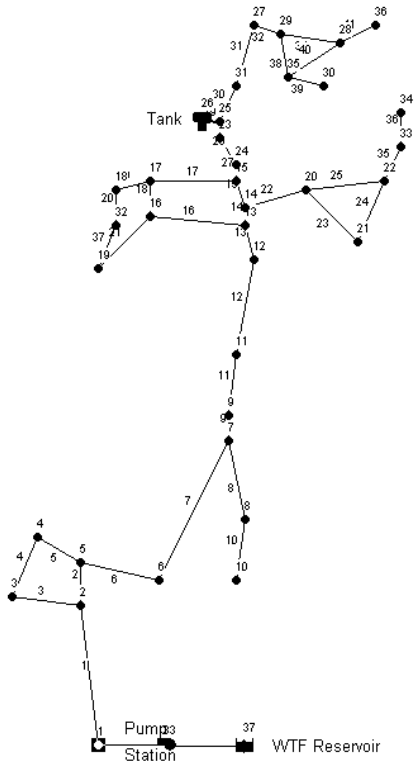

Figure 1: The modified EPANET Example 2 distribution system.

3.2 Simulation experiments

The EPANET toolkit (Rossman, 2000) was linked with PRPsym to perform the hydraulic and water quality simulation. PRPsym is used to generate a series of new EPANET input files with each node receiving its own unique 24 hour demand multiplier with respect to the three different time aggregation intervals (1 hour, 10-minute, 1-minute). From the simulations, parameters regarding both the hydraulics (demand, pressure, and flow rate) and water quality (water age as a surrogate) were collected at the three different levels of temporal aggregation (1-hour, 10-minute, 1-minute). The hydraulic simulations were performed with a 24 hour duration while the duration for water quality simulations was 720 hours. The lengthy water quality simulations were required to overcome the initial conditions in the network model, and allowed the system to achieve approximate stationarity. The 1-hour temporal aggregation was used as the benchmark deterministic case (equivalent to "typical" modeling approaches) and the deterministic results compared with the information from the other two temporal aggregations. Statistical measurements from the 10-minute and 1-minute temporal aggregations used in the comparison include the weighted average, standard deviation, and coefficient of variation (COV) calculated for both the 10-minute and 1-minute time aggregation intervals over each 1-hour time period. The coefficient of variation, defined as the ratio of the standard deviation to the mean, was used as a metric to show the relative variability on the metrics of interest for the temporal aggregation steps.

4 Results

The following sections present preliminary results associated with the impacts of temporal aggregation on consumptive demands with respect to pressure, flow rate, and water age (a rough surrogate for water quality). All of the results are based on a single realization of demands for a simple distribution system model. Additional effort will be placed on assessing the impacts from a more complete Monte Carlo ensemble as well as tested on a large, all-pipe network model.

4.1 Water demand variability

PRPsym provides the capability to maintain the same average hourly demands as the benchmark scenario (constant, 1-hour demands) for the 10-minute and 1-minute time aggregations. The functionality to maintain the same average demands for each temporal aggregation scenario ensures that the only difference between the cases is the demand variability at smaller time aggregations. In general, PRP theory indicates that demand variability will increase with decreasing time scale, and this relationship has been observed from measured demand data (Moughton et al., 2006).

Results from all 35 nodes illustrate this theory, and the demands from Node 10 have been selected as an example to represent the time series demands under the three different temporal aggregations. Figure 2 shows that as the temporal aggre-

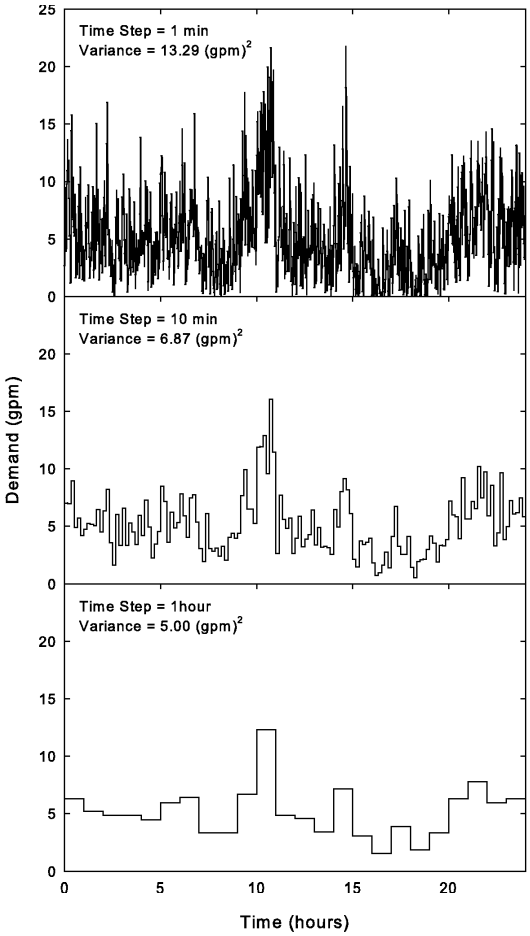

Figure 2: Time series of demands for node 10 for temporal aggregation scales at 1-minute, 10-minute and 1-hour.

gation increases, the average demands are "smoothed" with the demand variance decreasing from 13.25 $(\text{gpm})^2$ to 5 $(\text{gpm})^2$. The increasing temporal aggregation not only reduced the large peak demands, but also removed any instances of zero demands. While demand variability can be shown to increase with decreasing temporal aggregation, the remaining data needs to be evaluated to assess the impact that demand variability has on the underlying hydraulic and transport characteristics.

4.2 Pressure

Recognizing that demand variability will result in hydraulic and transport variability associated with the scale of temporal aggregation, pressure was selected as an initial parameter to evaluate the possible influence of demand variability on system hydraulics. Node 10 is selected as representative of the simulation results for all 35 nodes. Figure 3 shows that the mean and COV of the simulated pressure at node 10 at each hour for the 10-minute and 1-minute time aggregation simu-

lations. These results show there is little variability in the pressure data during the simulation period. Results from the other nodes are similar suggesting that demand variability has little influence on the pressure of this system.

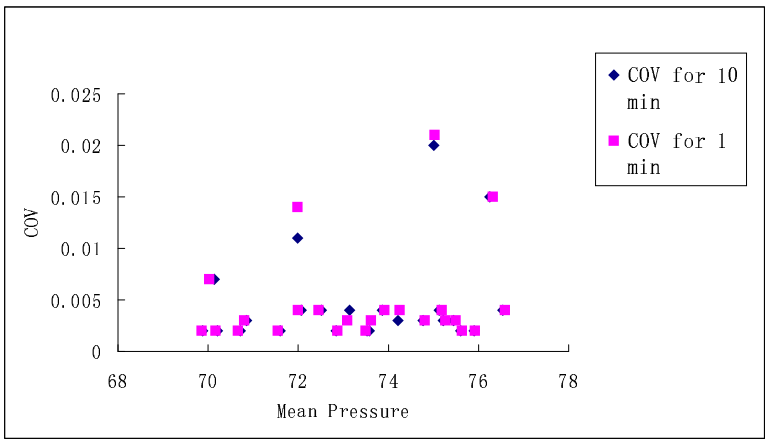

Figure 3: The COV value for pressure at node 10 for temporal aggregation of demands at 10-minute and 1-minute.

4.3 Flow rate

The influence of demand variability on flow rate provided an analysis challenge. As mentioned in section 3.1, the pump and tank alternate as sources to the system, which results in significant flow reversals throughout the system. Within EPANET, the directional component of flow rates are designated with a '+' or '-' coefficient. Therefore, during the 1-hour intervals where a flow reversal occurs, the estimated variance is much higher than at other times (due to the incorporation of both "positive" and "negative" flows). In order to eliminate the influence of the flow reversal conditions, and perform a better analysis of the flow rate variability by time aggregation, the simulations were separated into two scenarios: pump on and pump off. Results from one realization of the 10-minute and 1-minute aggregation scenarios showed that, for almost every link at all times, flow rates from the 1-minute temporal aggregation have higher COV values compared to those of the 10-minute temporal aggregation. There are only a few singular cases where the results were reversed, and were associated with flow reversals due to random changes in nodal demands, which will be further investigated at a later time.

To illustrate flow rate variability, a subset of pipes were selected to represent the spatial differences of variability in the system. These links include some in the main trunk line (link 2 and link 7), some associated with dead ends (link 10, 36, 39, 41), and others at branches (link 24). Figure 4 and Figure 5 compare the hourly flow rate COV values for the 10-minute time aggregation against the 1-minute time aggregation for "pump on" and "pump off" status, respectively. From

the two figures, two generalizations can be made associated with the temporally aggregated values for this system. First, all of the flow rate COV for the 1-minute aggregation step are greater than the 10-minute aggregation step (i.e., all data are above the "y=x" line, which is provided as the solid line in the figures). This data illustrates that the general concept of the PRP model (i.e., increased variability at smaller time aggregations) holds even for an interconnected distribution system. Second, the dead end and branch pipes have much greater COV values for both 10-minute and 1-minute time aggregation steps than the main trunk line pipes. The COV values for the main trunk lines are very small and appear to be located at the (0,0) point on both figures. As for the branch pipe (link 24), the COV is generally higher than the dead end pipes as a result of flow reversals that occur within the pipe (as before, the directional component needs to be accounted for in the analysis). This result confirms the (probable) intuitive insight that the stochastic nature of demands would have more of an observed impact at the edges of the distribution system than in the main trunk lines.

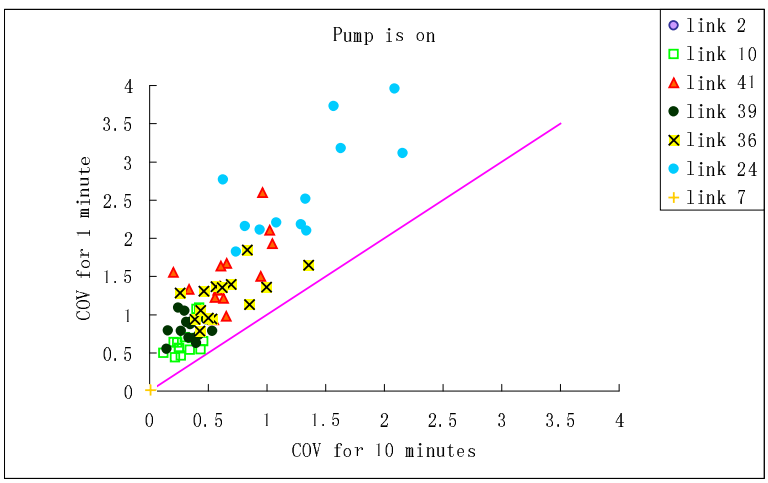

Figure 4: Flow rate COV comparison of the 10-minute and 1-minute temporal aggregations for selected links when the pump is on.

To further illustrate overall network response to time aggregation, the average COV for each pipe over the 24 hour simulation duration was computed for both the 10-minute and 1-minute cases and the differences between them calculated. These differences were projected onto the EPANET map to illustrate the spatial impacts of temporal aggregation on the flow rate variability over the entire network. Figure 6 shows the differences in flow rate COV due to the temporal aggregation (COV_{1-min} minus COV_{10-min}). This map illustrates that in the main trunk line, since the flow rate is relatively high, the COV value changes are relatively low between the two time aggregation steps, which is consistent with the data in Figures 4 and 5. At the edges of the system, where the links have

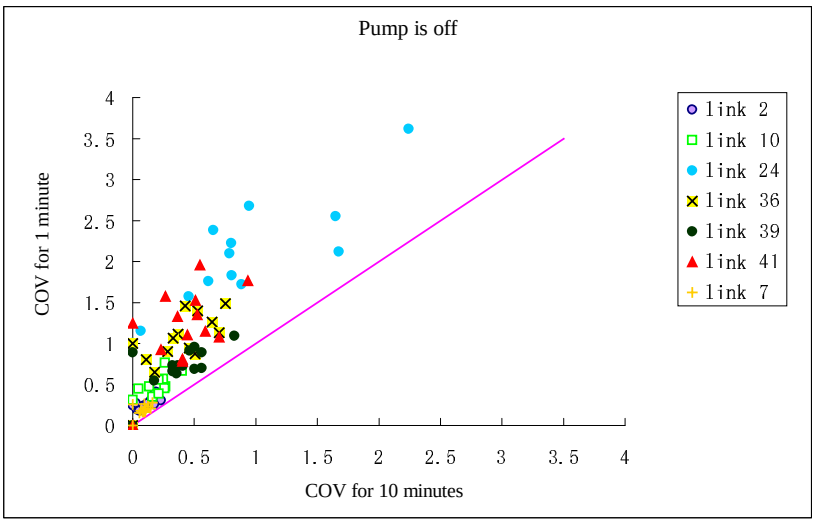

Figure 5: Flow rate COV comparison of the 10-minute and 1-minute temporal aggregations for selected links when the pump is off.

much smaller flow rates, the change in COV values is much greater. All of these results demonstrate the temporal aggregation of water demands leads to greater influence on flow rate variability at the system edge than in the main trunk line. However, while these results indicate that flow rate variability is impacted by the temporal aggregation (and ultimately transport), to truly understand the impacts associated with transport additional water quality simulations must be performed.

4.4 Water quality

Hydraulic residence time (water age) was used as a surrogate for water quality analysis for two reasons: 1) water quality, in general, is negatively impacted by longer residence times, and 2) significant differences in travel paths should result in observable differences in the simulated water age. Figure 7 shows the simulated water age data of node 29 from the last 24 hours of a 720-hour duration water quality simulation using the 1-minute, 10-minute, and 1-hour time aggregation steps. From Figure 7 there are two noticeable observations. First, there is a clear distinction regarding when the water is coming from the reservoir (water age $\leq$ 20 hours) or tank (water age $\geq$ 100 hours). Second, the short time aggregation steps indicate larger variability (although not very significant) in water age when the water is being fed from the reservoir. When the tank is feeding node 29 the increase in age continues to increase almost uniformly. However, by moving just a short distance downstream to node 30 the difference in water age results at the three time aggregations are significantly different. Figure 8 presents the simulated water age of node 30 from the last 24 hours of a 720-hour simulation. While the shapes of the water age data are generally the same for all three time aggregations, the shorter duration simulations show much greater variability than

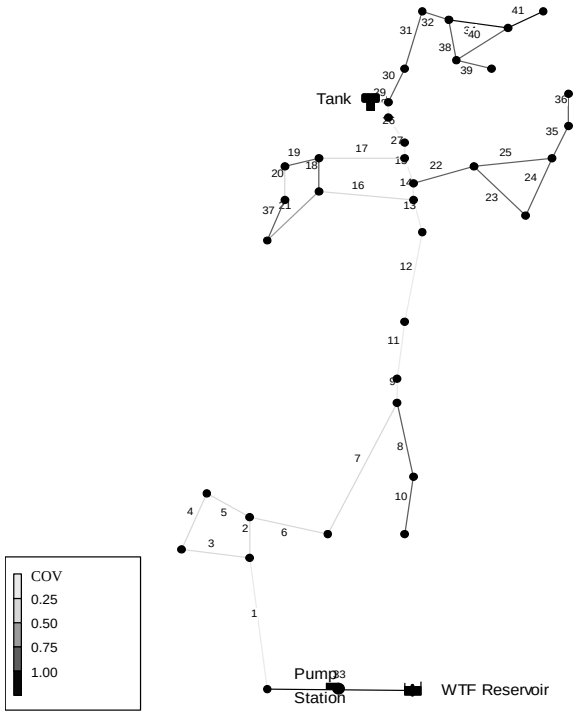

Figure 6: The overall network response to the change of time scale .

the 1-hour simulations. The increased variability results primarily from the flow reversals that occur between nodes 28 and 35. This indicates that a dynamic water quality parameter might exhibit significant variation at some points in the distribution system where the stochastic nature of the demands can impact travel paths. Ultimately, the influence of water demand variability on water quality may be much more complex and challenging than it appears to be for this simple network. Additional studies will be performed to further investigate the possible water quality implications for ubiquitous chemicals (e.g., disinfectant residuals) and for short-term contamination events

5 Summary and Future Work

In general, residential consumptive demands have been represented by a stochastic process model. As the drinking water industry moves towards more "all-pipe" network models and water quality applications where transport characteristics are more important, the role of stochastic demands may be significant in understanding and modeling distribution systems. The objective of this study was to perform a preliminary analysis by simulating the impacts of stochastic demands at multiple temporal aggregations on factors that impact hydraulics and transport characteristics.

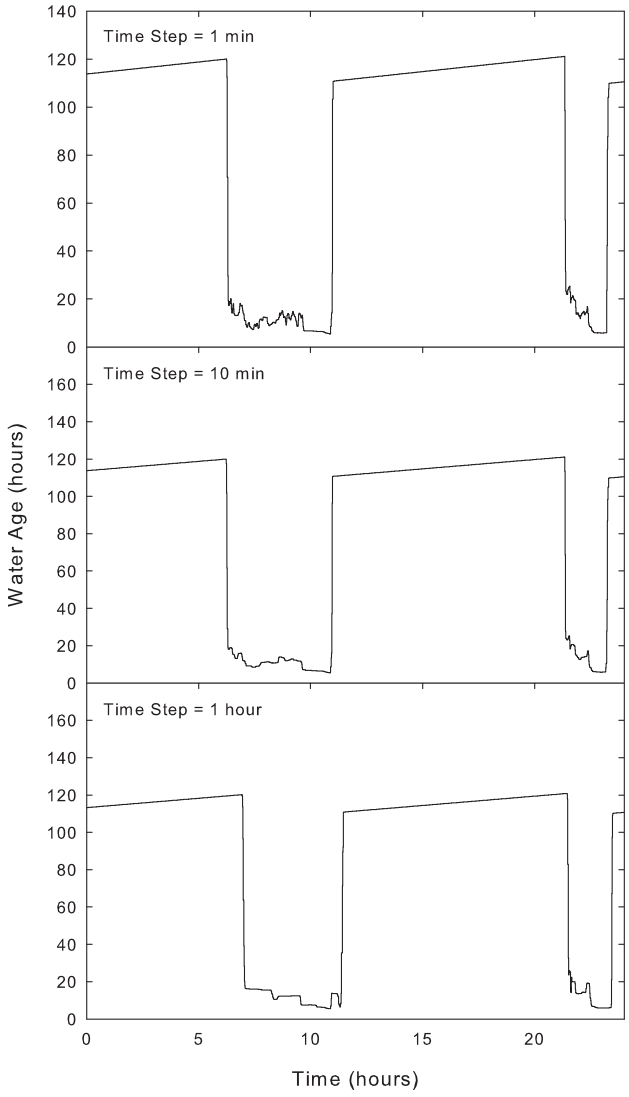

Figure 7: Time series of water age for node 29 for temporal aggregation scales at 1-minute, 10-minute and 1-hour.

From the preliminary analysis performed in this study, demand variability had an influence on this small network that varied with respect to the metric considered. From a hydraulic standpoint, the demand variability had very little impact on pressure, but did result in flow rate variability in parts of the system. For the main trunk lines, the demand variability had virtually no effect on the flow rates. However, as the branch and dead-end pipes were analyzed, there was an increase in flow rate variability that also correlated to decreasing temporal aggregation. As the industry moves towards more "all pipes" models, the impact of demand variability on flow rates may play a more important role. With respect to transport aspects, the water age analysis also illustrated that decreasing temporal aggregation increased variability, but a more significant impact on the water age

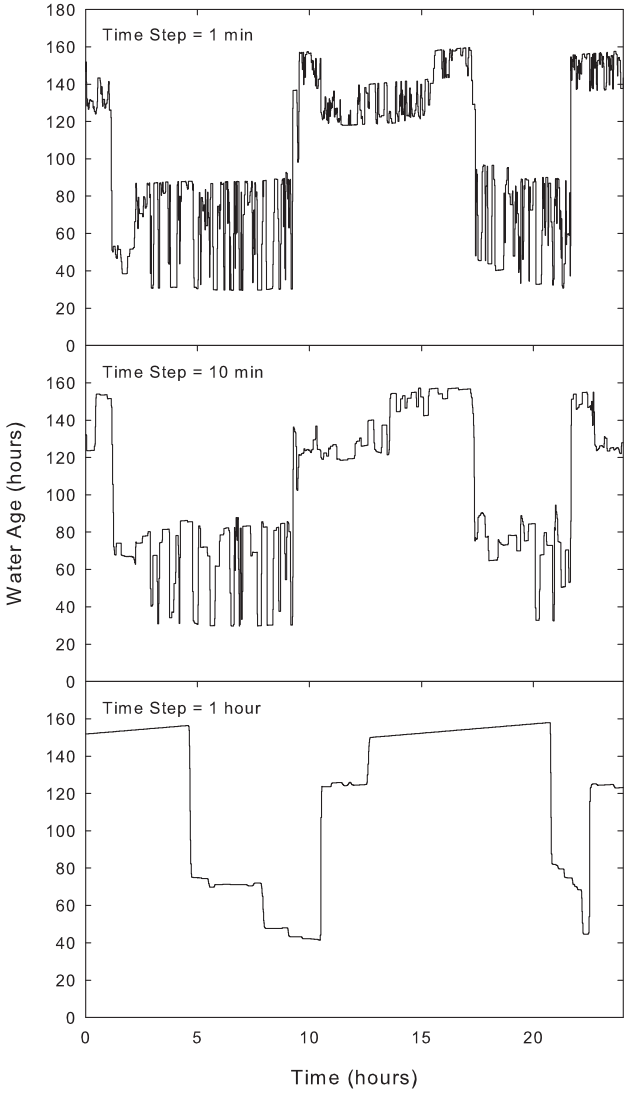

Figure 8: Time series of water age for node 30 for temporal aggregation scales at 1-minute, 10-minute and 1-hour.

variability was observed when the demand variability impacted the resulting flow path.

While the current study suggests that demand variability can have an impact on distribution system hydraulics and transport, these results are preliminary and performed with a single realization of demands on a relatively small network model. Future studies associated with temporal aggregation will consider: 1) a larger Monte Carlo ensemble of demand pattern realizations; 2) two additional water quality cases that consider a ubiquitous parameter (e.g., a disinfectant) and a short-duration event; and 3) extend the analysis to an "all-pipes" network model that consists of approximately 10,000 nodes. The objectives of these studies will

be to better understand the characteristics of distribution systems and problem types that are significantly impacted by demand variability.

Abstract

When analysing a pressure deficient network, it is crucial that the pressure dependent nature of nodal outflows be taken into account. The head dependent analysis (HDA) produces an accurate representation of the nodal outflows and network hydraulic performance. This is essential when modelling pipe leakages, network redundancy and reliability. These are vital aspects often considered in the optimization of a water distribution system (WDS). This paper describes an approach for head dependent analysis in which an embedded function for the head-outflow relationship is incorporated in the Gradient Method (GM). The procedure is capable of simulating both normal and deficient network operating conditions effectively. Results based on networks from the literature show that the proposed method is robust and converges smoothly and rapidly.

Keywords: demand-driven analysis, evolutionary computing, head-dependant modelling, head-outflow relationship, nodal outflow function, optimization, water distribution systems, augmented gradient method.

Introduction

Most of the available hydraulic simulation models for water distribution systems (WDSs) are based on demand-driven analysis (DDA). DDA assumes that all nodal demands are satisfied at all times, disregarding the fact that nodal outflows are pressure dependent. Hence, this method is only sufficient for analysing a network under normal operating conditions. The DDA becomes inadequate when considering pressure deficient scenarios such as major mechanical and hydraulic failures, fire-fighting flows etc, as it is prone to yield very low or even negative pressure values at some nodes. A solution to this problem is the head dependent analysis (HDA) method which considers the relationship between pressure and outflow. By applying this method, one would be able to identify the problematic nodes along with the exact magnitude of deficiency in terms of nodal pressure and outflow.

There are several head-outflow relationships, for instance Tanyimboh and Templeman (2004), Wagner et al. (1988), Fujiwara and Ganesharajah (1993), Germanopoulos (1985) are but a few. This paper introduces an algorithm which

incorporates the Tanyimboh and Templeman (2004) function within the Gradient Method (GM) (Todini and Pilati 1987). This proposed simulation model will be referred to as the head dependent GM (HDGM). Ultimately, the goal is to embed this pressure-outflow relationship within EPANET 2, converting it from a DDA to a HDA hydraulic network solver. This would be advantageous as HDA can then be explicitly applied to the extended period simulation and water quality analysis. After presenting a brief introduction of the Tanyimboh and Templeman (2004) function and GM, the HDGM is demonstrated. For reasons of simplicity, elements such as pumps, valves and other dissipation devices have not been included in the simulation model.

Head Outflow Relationship

Previous work shows that the Tanyimboh and Templeman (2004) function is computationally efficient. Compared to other head-outflow relationships, this function is unique in that it has no discontinuities in its function and/ or derivatives. This allows a smooth transition between zero and partial nodal outflow and between partial and full demand satisfaction, avoiding convergence difficulties in the computational solution of the system of constitutive equations. The Tanyimboh and Templeman (2004) function can be described as:

$$Qn_i(Hn_i) = Qn_i^{req} \frac{\exp(\alpha_i + \beta_i Hn_i)}{1 + \exp(\alpha_i + \beta_i Hn_i)} \tag{1}$$

where Qn_i and Hn_i are the outflow and head, respectively, at the demand node i. Qn_i^{req} is the required supply at node i. Both α_i and β_i are parameters to be calibrated with relevant field data. Figure 1 clearly depicts the basic form of the function. Further details of this function can be found in Tanyimboh and Templeman (2004).

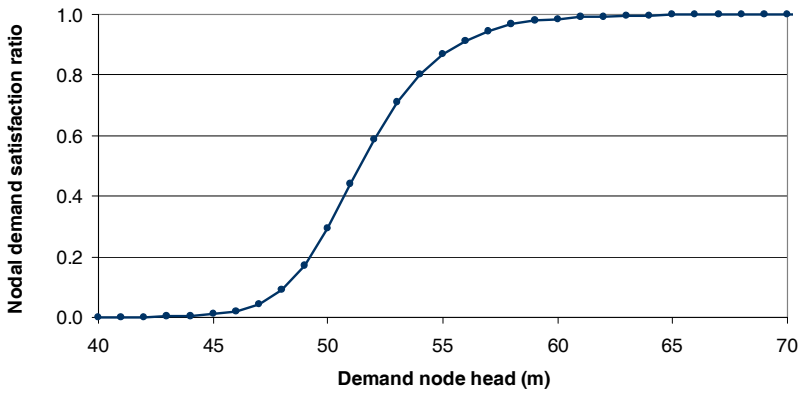

Figure 1. Tanyimboh and Templeman function (elevation= 45m, desired head= 60m)

Pressure Dependent Demand Simulation Model

A network hydraulics model is defined through a set of equations corresponding to two conservation laws, namely mass balance at nodes and energy conservation along hydraulic links. These equations can be solved simultaneously using a unified formulation such as the GM as described below:

$$\begin{bmatrix} A_{11} & \vdots & A_{12} \\ \cdots & \cdots & \cdots \\ A_{21} & \vdots & A_{22} \end{bmatrix} \begin{bmatrix} Qp \\ \cdots \\ Hn \end{bmatrix} = \begin{bmatrix} -A_{10}H_0 \\ \cdots \\ 0 \end{bmatrix} \tag{2}$$

where A_{11} represents the diagonal matrix whose elements are the $K_j(Qp_j)^{n-1}$. K_j and n are the pipe resistance coefficient and flow exponent in the head loss formula respectively. Qp_j is the flow rate in pipe j. The overall incidence matrix relating the pipes to nodes with unknown and known heads is represented by A_{12} and A_{10} respectively. A_{21} is the transpose of A_{12}. Qp denotes the column vector of unknown pipe flow rates. Hn and H_0 are column vectors for unknown and known nodal heads respectively. In the original GM where nodal demands are assumed to be fully satisfied, the elements of diagonal matrix A_{22} are Qn_i^{req} / Hn_i. To solve for pressure dependent demand, the elements of A_{22} are redefined as $Qn_i(Hn_i)/Hn_i$ where $Qn_i(Hn_i)$ represents the pressure dependent nodal outflow. Equations (2) are differentiated with respect to the pipe discharges and nodal heads to give:

$$\begin{bmatrix} D_{11} & \vdots & A_{12} \\ \cdots & \cdots & \cdots \\ A_{21} & \vdots & D_{22} \end{bmatrix} \begin{bmatrix} dQp \\ \cdots \\ dHn \end{bmatrix} = \begin{bmatrix} dE \\ \cdots \\ dq \end{bmatrix} \tag{3}$$

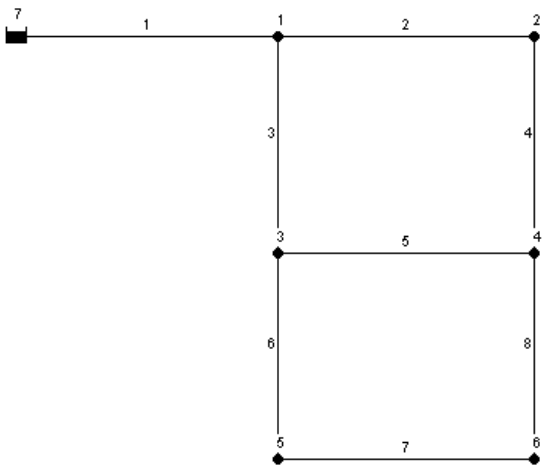
where D_{11} and D_{22} are derivatives of A_{11} and A_{22} respectively. dE and dq represent the pipe head loss and flow conservation at each node respectively and from Equations (2) can be rewritten as:

$$\begin{aligned} dE &= A_{11}Qp + A_{12}Hn + A_{10}H_0 \\ dq &= A_{21}Qp + A_{22}Hn \end{aligned} \tag{4}$$

By substituting equations (4) into equation (3), the iterative formulation of the HDGM can be described as:

$$Hn_i^{k+1} = (A_{21}D_{11}^{-1}A_{12} - A_{22})^{-1}\left[A_{21}Qp^k + Qn_i(Hn_i^k) - A_{22}Hn^k - A_{21}D_{11}^{-1}A_{11}Qp^k - A_{21}D_{11}^{-1}A_{10}H_0\right]$$

$$Qp_j^{k+1} = Qp_j^k - D_{11}^{-1}(A_{11}Qp^k + A_{12}Hn^{k+1} + A_{10}H_0) \quad (5)$$



where *k* represents the iteration number. Hence the algorithm first solves the equation for Hn_i before solving for Qp_j. More details regarding matrices A_{11}, A_{12}, A_{21} and A_{10} can be found in Rossman (2002) and Salgado et al. (1993).

Examples, Results and Discussion

The examples below are presented with the objective of demonstrating the effectiveness of the HDGM in the context of small and large networks. A FORTRAN 90 implementation of the above algorithm has been developed. To ensure convergence, a line search procedure has been incorporated into the program to facilitate the selection of a relaxation coefficient for each iterative solution. All the results herein were generated using the above-mentioned FORTRAN 90 HDGM program.

Example 1

The first example shown in Figure 2 is based on a simple network taken from the literature (Fujiwara and Ganesharajah 1993; and Tanyimboh and Templeman 2004). This single source network consists of 8 pipes of length 1000m and 6 demand nodes with the desired pressure heads of 60m. The HDGM was carried out with a variation of source heads from 40m to 80m. Performance of the network and each node are illustrated in Figure 3 and Figure 4 respectively.

Node	Elevation (m)	Demand (m^3/s)
1	50	0.0417
2	50	0.0417
3	45	0.0778
4	45	0.0417
5	55	0.0556
6	55	0.0889

Pipe	Diameter (mm)	HW roughness
1	500	140
2	400	140
3	400	140
4	400	140
5	250	140
6	250	140
7	250	140
8	250	140

Figure 2. Example 1

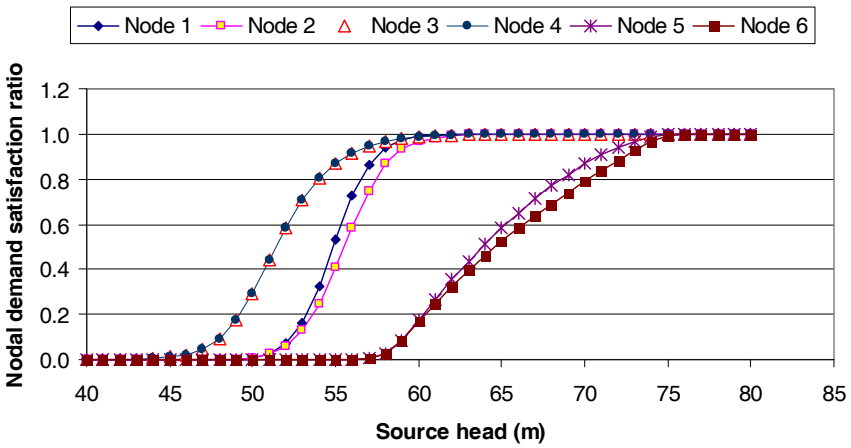


Figure 3. Nodal performance of Example 1

The demand nodes each have a unique head-outflow curve depending on their elevations, demands and relative distances from the source. The curves vividly show the magnitude of each nodal outflow at various source heads. For example, at source head 70m, the demand satisfaction ratio (DSR) of nodes 5 and 6 are 0.87 and 0.79 respectively whereas demands at nodes 1 to 4 are fully satisfied. In addition, the sequence of each node being fully satisfied (with the increment of source head) and the required source head for all demands to be satisfied can be easily deduced. In this case, node 3 and 4 are satisfied simultaneously followed by nodes 1, 2, 5 and 6. A source head above 76m is required for all demand nodes to be fully satisfied. It is worth noticing that the curves depict a smooth transition from no outflow at minimum head to a full outflow stage, exhibiting no discontinuities. The network performance is illustrated in Figure 4.

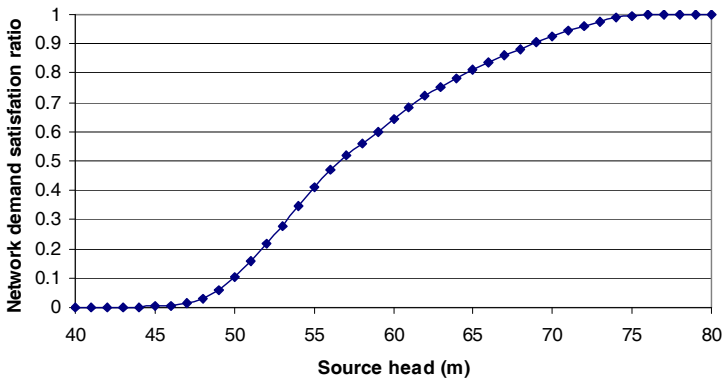

Figure 4. Network performance of Example 1

Result verification was carried out using the hydraulic feasibility test (Ackley et al. 2001) where the nodal outflows obtained from the HDGM are applied in EPANET 2 as nodal demands. Simulations for source heads ranging from 40m to 80m were performed. Nodal heads generated by EPANET 2 were then compared with those of

the proposed algorithm. Figure 5 shows a correlation of $R^2 = 0.9999995$ or $1 - R^2 = 5 \times 10^{-7}$ between the heads produced by both methods. This clearly confirms that the HDGM is producing results which are accurate and reliable.

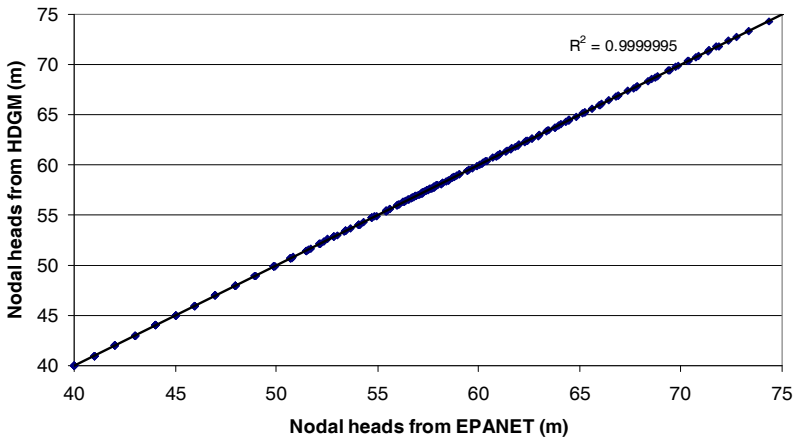

Figure 5. Hydraulic feasibility test for Example 1 for source heads between 40m and 80m

Example 2

The network in Example 2 consists of 48 nodes, 74 pipes and 2 reservoirs (Nodes 47 and 48) as shown in Figure 6. Data for the nodes and pipes can be found in Shan (2004). Both source heads were varied at the same rate within a range of 100m.

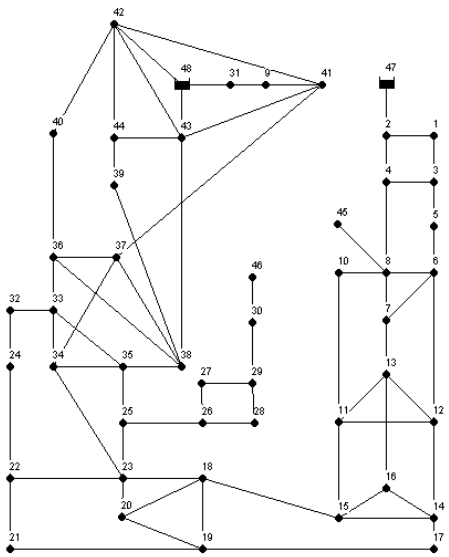

Figure 6. Example 2

Figure 7 shows the network performance of Example 2 for the full range of DSRs. The fact that results were obtained without convergence problems suggests the HDGM is robust. The network head outflow curve consists of two steps. All 13 demand nodes have elevation of 100m and desired head of 115m where demands are satisfied in full. The first step corresponds to the scenario where demand nodes 1, 14 and 17 have been fully satisfied with the head of source 47 and 48 rising above 115m and 65m respectively as shown in Figure 8. The remaining demand nodes only experienced a negligible increase in outflows. As soon as the head of sources 47 and 48 exceeded 150m and 100m respectively, outflows of demand nodes 9, 10, 21, 25, 30, 31, 32, 37, 45 and 46 began to increase significantly. This time, it is ten demand nodes achieving a DSR of 1.0 and hence the network experiences a leap in performance. This clearly explains why the latter step is steeper than the former.

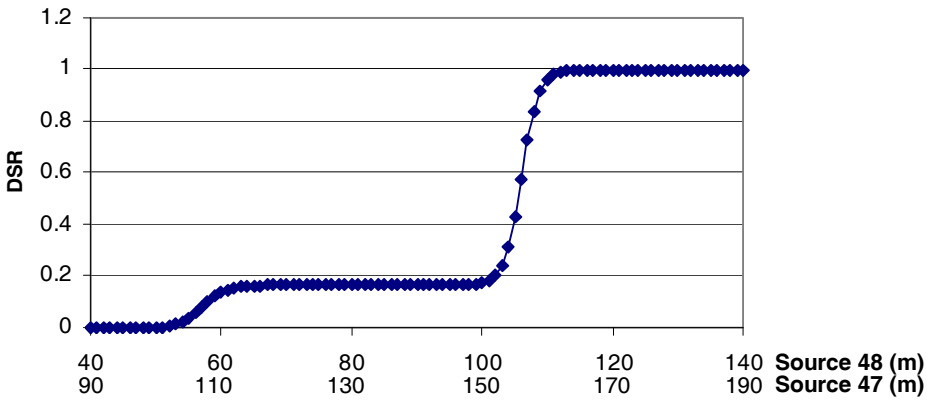

Figure 7. Network performance of Example 2

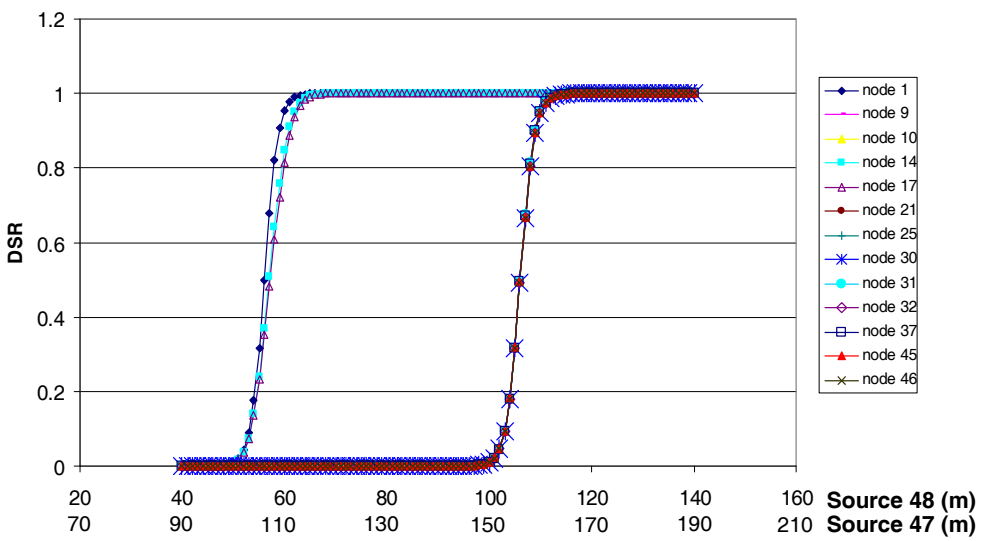

Figure 8. Nodal performance of Example 2

Figure 9 shows the number of iterations needed to achieve convergence. An average convergence rate of 8.68 iterations for this relatively large network suggests the HDGM converges rapidly and is efficient in simulating both normal and deficient operating conditions. A good method of ensuring that the algorithm does not converge falsely is to evaluate the norm of the right hand side of Equation 3. At solution, the norm should approach a value of 0 as an indication of the progress and accuracy of the algorithm. Figure 10 shows a consistent decrease of the norm value for several network operating conditions. The hydraulic feasibility test described above gave a correlation coefficient of $R^2 = 0.9997$ which confirms the accuracy of the HDGM. This verification was further strengthened by the identical results produced from the modelling of this network using PRAAWDS (Tanyimboh 2008).

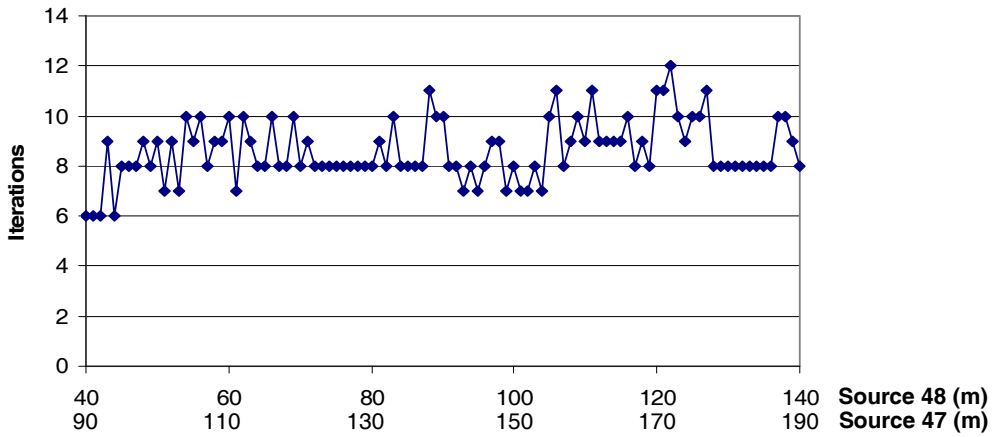

Figure 9. Iterations required to achieve convergence for Example 2

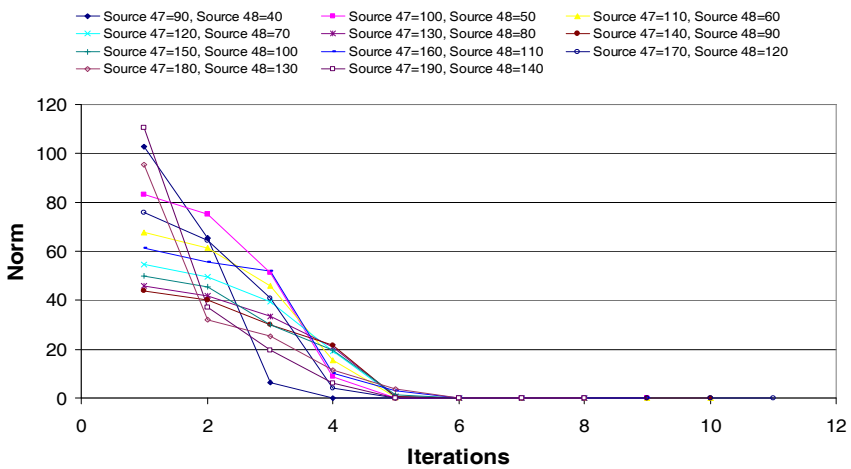

Figure 10. Value of norm at each iteration for Example 2

Conclusions

An augmented gradient method (HDGM) for the hydraulic analysis of water distribution networks has been presented. The proposed model is based on the Tanyimboh and Templeman (2004) head-outflow function and is shown to be capable of simulating both normal and pressure deficient conditions of a water distribution network. Result verification using the hydraulic feasibility test of Ackley et al. (2001) shows that the algorithm generates results that are reliable and accurate. Furthermore, the networks were also modelled using PRAAWDS which gave identical results. The algorithm is demonstrated to be efficient and robust as it converged rapidly and without problems for the analysis of a relatively large network over the full range of DSRs from 0 to 1.0. Hence, the goal of embedding this head-dependent demand model into EPANET 2 seems highly achievable.

The mentioned application would be the first phase of a project on long term optimal rehabilitation and upgrading of water distribution networks based on evolutionary computing (EC). DDA, which is liable to exaggerate the network deficiency, may produce unreliable results in terms of nodal outflows and heads and consequently mislead the EC search. Conversely, with the HDA, evaluation of candidate solutions will be precise, guiding the EC in a much enhanced way.

ABSTRACT

The behaviour of a looped water distribution network, operating under pressure in steady flow conditions, can be modelled by imposing mass and momentum conservation. When distributed demands along the pipes are present, they tend to be represented as lumped withdrawals at the pipes ending nodes. Although such simplification preserves mass balance, it might cause significant head loss errors which may lead to inconsistent results. Giustolisi and Todini (2008) recently proposed a correction scheme within a modified Global Gradient Algorithm (GGA) under the common assumptions of Darcy-Weisbach head loss formula and pipe friction factors independent from the flow regime.
This paper provides an extension of the mentioned approach to any generic monomial head loss formula, so it can be easily incorporated into existing commercial water distribution network simulators.

INTRODUCTION

The problem of identifying the hydraulic status of a looped pressurized water distribution network (WDN) consists in determining pipe discharges and nodal heads once network topology, pipe geometry, water demands and head value of at least one node are assigned. In steady flow condition, solution of such a problem should obey flow continuity (conservation of mass) at any point of the network and conservation of momentum along any path. Although mass conservation is represented by linear equations, usually referred to flow entering and exiting from each node, momentum conservation law depends on head loss along a given path (at least one link in the network) which is non-linear in flow.

On this premise, literature works on WDN hydraulic analysis follow two distinct approaches, namely the direct solution of the resulting non-linear system of equations or the use of optimization techniques. The first approach was introduced by H. Cross (1936) is based on iterative solution of linear approximations of the

original equations with respect to closed loops. This method was extended to simultaneously account for all the loops by using Newton-Raphson methods (Epp and Forley, 1970; Kesavan and Chandrashekar, 1972). The Newton-Raphson method was also used to calculate heads at nodes after non-linear transformation of pipe discharges (Martin and Peters (1963), Shamir and Howard (1968); Mignosa, 1987). Wood and Charles (1972) introduced the Linear Theory to provide the direct solution of the original equations by calculating pipe discharges, after a linear transformation of nodal heads. The second approach, based on optimization was introduced by Collins at al. (1978) and is centred on the minimization of the "content" and "co-content" models. Such a minimisation is performed by means of a network linear programming (NLP) code. Despite the NPL was tested to be less efficient than the GGA (Berghout and Kuczera, 1997), the optimization approach deserves attention as it is based on the convexity of the "content" functional which is fundamental to demonstrate the existence and uniqueness of the solution. Such a result is of crucial importance for successive development of gradient methods proposed by Todini (1979) and Todini and Pilati (1988). They used Collins et al. (1978) results to demonstrate that the solution of the system of non linear equations obtained from the minimization of a convex function (the Collins "content") under linear constraints is unique. On these grounds, they applied a Newton-Raphson gradient technique to solve, both in terms of pipe discharges and nodal heads, the system of non-linear equations, resulting from the minimization of the content. The resulting Global Gradient Algorithm (GGA) has been recognised to be the most robust and fast method for WDN analysis and it is considered to be a benchmark for any new WDN hydraulic solver. Moreover, GGA is embedded in several commercial software packages (e.g. EPANET2)

Irrespectively to the approach followed, a common assumption of all abovementioned methods is the representation of pipe distributed demand as equal lumped withdrawals at end nodes. It mainly descends from the poor knowledge of actual pipe connection but is useful to reduce problem unknowns by simultaneously preserving mass conservation at nodes. Recently, Giustolisi and Todini (2008) demonstrated that such a simplification results in significant errors in momentum balance which eventually impair correctness of the analyses performed for calibration, system design, real-time operations, rehabilitation strategies, optimal operation studies, reliability analyses, etc. They proved it considering the simple assumption of uniformly distributed demands along the pipes by means of a uniform function. In order to take advantage from the classical GGA they still assumed a symmetric partition of pipe distributed demand as nodal withdrawals and introduced a correction term of the hydraulic resistance coefficient. At the same time, they provided similar corrections for all matrices involved in the classical GGA. The mathematical development reported in that introductory work was based on Darcy-Weisbach formula and did not account for other monomial head loss formulas widely used by practitioners (e.g. Hazen-Williams).

This work is primarily aimed at filling in this gap by providing and extended formulation of the enhanced GGA, to be easily implemented into the existing algorithms or software packages.

HEAD LOSS CONSIDERING UNIFORMLY DISTRIBUTED DEMAND

When a liquid flows through a pipeline, shear stresses develop between the liquid and the pipe wall. This shear stress is a result of friction and its magnitude depends upon the properties of the fluid that is passing through the pipe, the speed at which it is moving, the pipe internal roughness, length and diameter. Under steady flow conditions, the head losses slope J due to fiction along a pipe is described by the Darcy-Weisbach formula (1) which is derived from the governing equations of the physical phenomenon at hand.

$$J = -\frac{dH}{dx} = \frac{8 f\left(\mathrm{Re}, \mathrm{Ke}\right)}{g\pi^2 D^5} Q|Q| = K\left(\mathrm{Re}, \mathrm{Ke}, D\right) Q|Q| \tag{1}$$

x is a linear coordinate whose origin is at the beginning of the pipe (see Figure 1), Q is the water discharge passing through the pipe with length L and diameter D, and f is the pipe friction factor which depends on equivalent roughness Ke and flow regime (i.e. Reynolds Number, Re); g is the gravitational acceleration constant and K is the pipe unit hydraulic resistance. In Eq.(1) the minus sign underlines the fact that the head always decreases in the direction of the flow (which can be either opposite or in agreement with the assumed positive direction of coordinate x).

The Darcy-Weisbach formula can be potentially used to find the head losses through pipe for any Newtonian fluid under any flow regime. However, in technical practice, there are other empirical formulations of the head losses in pressurized water pipeline that can be condensed into the generic monomial expression (2), where K_∞ usually does not depend on Re (i.e. fully turbulent flow is assumed)

$$J = -\frac{dH}{dx} = K_\infty\left(\mathrm{Ke}, D\right) Q|Q|^{n-1} \tag{2}$$

n=2 is predominant in Europe while n=1.852 it represents the Hazen-Williams expression, which nowadays is the most popular in the U.S. (Walski et al., 2001).
The empirical formulations have been developed from experimental data recorded under fully turbulent flow regime, which is assumed to be the most common in water distribution system. From a modelling point of view, the great advantage of using such expressions descends from computing pipe unit hydraulic resistance K_∞ only once during the simulation, by assuming that the only existing flow regime is fully turbulent irrespectively of the actual flow conditions.

Traditionally, actual demand is assumed to be uniformly distributed along the pipe. Such a simplification usually accounts for the inaccurate knowledge of actual connections.
In order to mathematically compute the head losses through a generic pipe connecting nodes i and j in the network a positive direction for the pipe discharge Q is assumed in the direction of coordinate x. Under the hypothesis of pressure independent demand (generally assumed in "demand-driven" simulation models as that originally discussed in Giustolisi and Todini (2008)) the functioning of such pipe is represented in Figure 1, where Q_i and Q_j represent the flow at nodes i and j respectively. Without loss of generality (considering the symmetry of the problem), in both cases the flow Q_i is assumed positive (in the same direction as abscissa x) and

the total uniformly distributed demand is designated as $P=qL$, with q, and consequently P, non-negative quantities. The first figure (top-left) entails the case of flow passing through the pipe in one direction (i.e. $Q_i \geq Q_j$), meaning that inlet flow entirely meet the distributed demand; the second drawing (top-right) refers to the opposite condition, where water flow is entering from both nodes and a flow inversion point (y) occurs within the pipe.

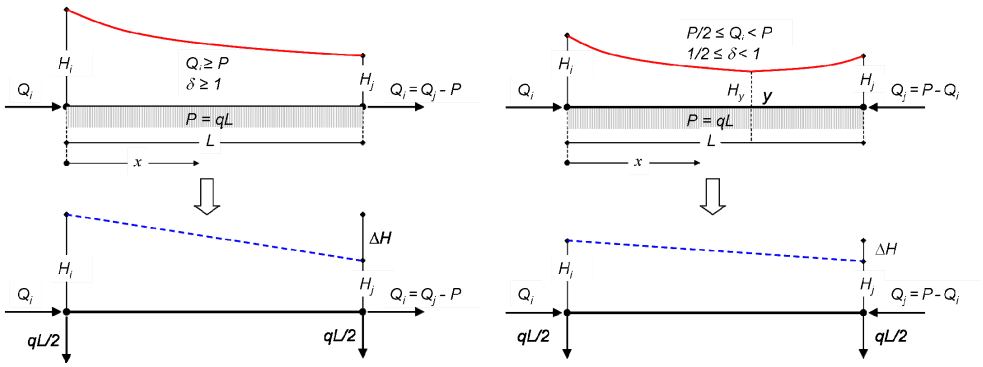

Figure 1. Uniformly distributed demand and its schematization in WDN model

It can be easily proved that the following equality holds irrespectively of the sign of actual flows Q_i and Q_j (with respect to the assumed positive sign)

$$Q_i - Q_j = P \tag{3}$$

Unfortunately, the existence of a uniformly distributed demand and variable discharge along the pipe prevent from using straightway the generic head loss formulation (2) unless it is referred to the head loss slope J_x occurring into each infinitesimal pipe element of length dx, carrying flow Q_x at distance x from the origin of the axis.

$$J_x = -\frac{dH}{dx} = K_\infty \left(\mathrm{Ke}, D\right) Q_x \left|Q_x\right|^{n-1} \tag{4}$$

Furthermore, the mass balance equation (3) written for section x (i.e. $Q_x = Q_i - qx$) allows deriving the linear variation Q_x with x (again independent on actual flow direction): $dQ_x/dx = -q$. Such a result is used to analytically compute the actual head loss through the pipe in the case of no flow inversion (Case (A) of Figure 1).

$$\begin{aligned} \left(H_i - H_j\right)_{actual} &= \int_0^L J_x dx = \int_0^L K_\infty Q_x \left|Q_x\right|^{n-1} dx = \int_0^L \frac{K_\infty}{-q} Q_x \left|Q_x\right|^{n-1} \frac{dQ_x}{dx} dx = \\ &= -\frac{K_\infty}{q} \int_{Q_i}^{Q_j} \left|Q_x\right|^n d\left|Q_x\right| = K_\infty \left[\frac{\left|Q_x\right|^{n+1}}{n+1}\right]_{Q_j}^{Q_i} \frac{L}{P} = K_\infty \frac{\left|Q_i\right|^{n+1} - \left|Q_j\right|^{n+1}}{n+1} \frac{L}{P} \end{aligned} \tag{5}$$

It can be easily demonstrated that Equation (5), obtained for one-direction flow, holds irrespectively on the sign of flows Q_i and Q_j as well as in the case of flow

inversion. In fact, the existence of inversion point *y* factually divides pipe into two sub-portions connecting nodes *i* and *j* to the fictitious node *y* (with $Q_y=0$) having the same positive direction assumed for pipe discharges. Head loss between nodes *i* and *j* can be computed by summing the head losses though the two sub-portions 0 – *y* and *y* – *L* (from 0 to *y* and from *y* to *L*) respectively by using Eq.(5).

In order to take advantage from the original formulation of the problem proposed by Giustolisi and Todini (2008), let's introduce the dimensionless quantity δ, which is the ratio between the inlet flow *Q* and the total distributed discharge *P*.

$$\delta = \frac{Q}{P}; \qquad Q_i = P + Q_j \Rightarrow \frac{Q_j}{P} = \delta - 1 \tag{6}$$

The head loss can be re-written accordingly.

$$\left(H_i - H_j\right)_{actual} = K_\infty \frac{\left|\delta\right|^{n+1} - \left|\delta - 1\right|^{n+1}}{n+1} P^n L \tag{7}$$

Thus, under fully turbulent flow and uniformly distributed demand Equation (7) represents the actual pipe head loss.

ENHANCED WDN SIMULATION MODEL

Usually, WDS simulation models represent distributed demands as two equal lumped demands at the terminal nodes. The two figures at the bottom of Figure 1 represent the effect of schematization in the two opposite cases considered, where the discharge through the modelled *k*-th pipe is constant ($Q_k=Q_i - P_k/2$) and head loss is computed by using Eq. (2).

$$\left(H_i - H_j\right)_{simulation\ model} = K_\infty \left(\delta - \frac{1}{2}\right)\left|\delta - \frac{1}{2}\right|^{n-1} P_k^{\,n} L \tag{8}$$

It is clearly different from the head loss in the original demand configuration (7). Giustolisi and Todini (2008) proposed to use a correction of hydraulic resistance *R* (=*KL*) to compensate the error of momentum balance due to schematisation, while preserving the symmetrical partition of distributed demand into the two end nodes.

In order to introduce such a correction into the existing algorithms, both Equations (7) and (8) are re-written in terms of the dimensionless parameter $\delta_k = Q_k/P_k = \delta - 1/2$ as follows.

$$\begin{aligned}\left(H_i - H_j\right)_{actual} &= K_{k,\infty} \frac{\left|\delta_k + \frac{1}{2}\right|^{n+1} - \left|\delta_k - \frac{1}{2}\right|^{n+1}}{n+1} P_k^{\,n} L \\ \left(H_i - H_j\right)_{simulation\ model} &= K_{k,\infty} \delta_k \left|\delta_k\right|^{n-1} P_k^{\,n} L\end{aligned} \tag{9}$$

Thus, the correction ε_k of pipe hydraulic resistance is obtained by equating the two head loss expressions in Equation (9)

$$K_{k,\infty}\left(1+\varepsilon_k\right)\delta_k\left|\delta_k\right|^{n-1}P_k{}^nL = K_{k,\infty}\frac{\left|\delta_k+\frac{1}{2}\right|^{n+1}-\left|\delta_k-\frac{1}{2}\right|^{n+1}}{n+1}P^nL \;\Rightarrow$$
$$\Rightarrow \qquad \varepsilon_k = \frac{\left|\delta_k+\frac{1}{2}\right|^{n+1}-\left|\delta_k-\frac{1}{2}\right|^{n+1}}{\left(n+1\right)\delta_k\left|\delta_k\right|^{n-1}}-1 \tag{10}$$

It is worth noting that Eq. (10) always returns a positive correction for both negative and positive δ_k as shown in Figure 2, which represents ε_k for three significant values of n. It is also noteworthy that the correction is null when the exponent n equals 1, as happens for laminar flow regime.

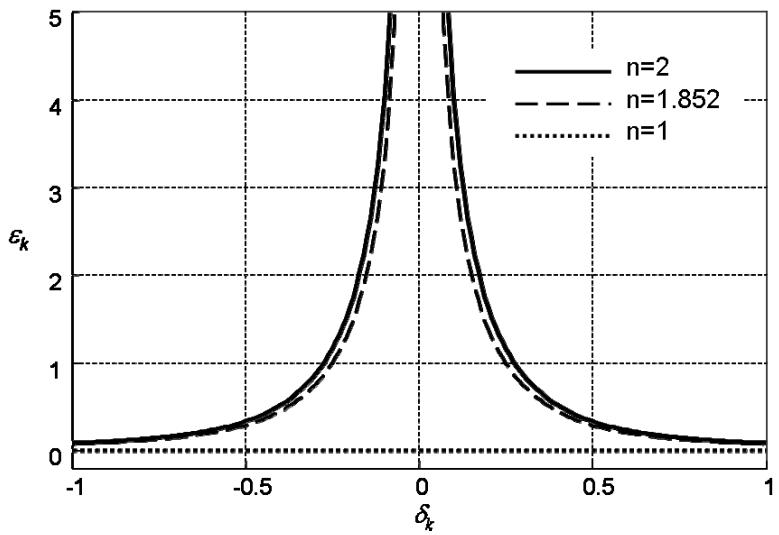

Figure 2. Representation of ε_k as a function of ratio δ_k for different values of n

The correct head loss term is the sum of the head loss resulting from the schematization plus the correction $E_k{}^{\varepsilon}$ introduced to take into account the "actual" uniformly distributed demand.

$$E_k^{\varepsilon} = \varepsilon_k R_{k,\infty}Q_k\left|Q_k\right|^{n-1} = \varepsilon_k R_{k,\infty}\delta_k\left|\delta_k\right|^{n-1}P_k^n = z_k R_{k,\infty}P_k^n$$
$$z_k = \varepsilon_k\delta_k\left|\delta_k\right|^{n-1} = \frac{\left|\delta_k+\frac{1}{2}\right|^{n+1}-\left|\delta_k-\frac{1}{2}\right|^{n+1}}{n+1}-\delta_k\left|\delta_k\right|^{n-1} \tag{11}$$

where $R_{k,\infty}$ (=$L_kK_{k,\infty}$) is k-th pipe hydraulic resistance. The dimensionless parameter z_k is instrumental to introduce the correction into the existing WDN simulation algorithms by using the same schematization of distributed demand as concentrated withdrawals at end nodes. Figure 3 plots the parameter z_k as a function of δ_k for different n values. As reported in the same figure, the head loss correction $E_k{}^{\varepsilon}$

numerically coincides with z_k under the hypothesis of P_k=1m^{3}s^{-1} and $R_{k,\infty}$ =1s^{n}m^{1-3n} (Giustolisi and Todini, 2008).

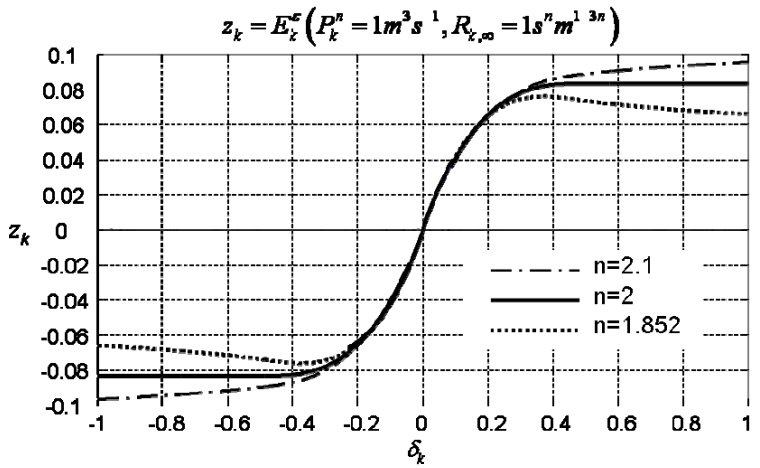

Figure 3. Representation of z_k for different values of exponent n.

In particular for exponent n=1 the correction is always null as the scenarios of both distributed and concentrated demands are equivalent in terms of head loss (due to the model linearity). In the case of n=2, the correction term increases up to the value 1/12 until pipe discharge is half of the distributed demand (δ_k = 0.5), from this point on it remains constant (Giustolisi and Todini, 2008). When other head loss monomial formulations are used, with n<2 (e.g. Hazen-Williams expression - n=1.852), the correction parameter z_k reaches a maximum value (lower than 1/12) for $\delta_k \leq 0.5$.

Finally, the z_k curves obtained for n>2 (i.e. n=2.1) shows that the error due to the schematization increases with δ_k towards infinity. This suggests that, apart from its physical meaning, the exponent n=2 leads to the maximum finite value of correction needed and should be considered as an upper bound of n to ensure the convergence of automatic algorithms.

GENERAL FORMULATION OF ENHANCED GGA

When the functioning of a WDN comprised of n_p unknown discharges (i.e. pipes), n_n unknown heads (i.e. internal nodes) and n_0 known heads (e.g. water tanks) is simulated following a demand-driven approach mass and momentum balance equations (12) must be simultaneously satisfied.

$$\begin{aligned} \mathbf{A}_{pp}\mathbf{Q} + \mathbf{A}_{pn}\mathbf{H} &= -\mathbf{A}_{p0}\mathbf{H}_0 \\ \mathbf{A}_{np}\mathbf{Q} &= \mathbf{d} \end{aligned} \tag{13}$$

Where matrix $\mathbf{A}_{pn}$=$\mathbf{A}^T_{np}$ and $\mathbf{A}_{p0}$ are the topological incidence sub-matrices of size [n_p, n_n] and [n_p, n_0], respectively, derived from the general topological matrix $\bar{\mathbf{A}}_{pn}$=[$\mathbf{A}_{pn}$ ¦ $\mathbf{A}_{p0}$] of size [n_p, n_n+ n_0], as defined in Todini and Pilati (1988); **d** is the column vector of pipe demands lumped at nodes; **Q** and **H** are the vectors of pipe discharges and nodal heads respectively.

The generic iteration (*iter*) of the Global Gradient Algorithm, as described in Giustolisi and Todini (2008), provides an approximated solution of the non-linear system of equations (12)

$$\begin{aligned}
&\mathbf{B}_{pp}^{iter} = \left(\mathbf{D}_{pp}^{iter}\right)^{-1}\mathbf{A}_{pp}^{iter}\\
&\mathbf{F}^{iter} = \mathbf{A}_{np}\left(\mathbf{Q}^{iter} - \mathbf{B}^{iter}\mathbf{Q}^{iter}\right) - \mathbf{d} - \mathbf{A}_{np}\left(\mathbf{D}_{pp}^{iter}\right)^{-1}\left(\mathbf{A}_{p0}\mathbf{H}_0\right)\\
&\mathbf{H}^{iter+1} = \left(\mathbf{A}_{np}\left(\mathbf{D}_{pp}^{iter}\right)^{-1}\mathbf{A}_{pn}\right)^{-1}\mathbf{F}^{iter}\\
&\mathbf{Q}^{iter+1} = \left(\mathbf{Q}^{iter} - \mathbf{B}^{iter}\mathbf{Q}^{iter}\right) - \left(\mathbf{D}_{pp}^{iter}\right)^{-1}\left(\mathbf{A}_{p0}\mathbf{H}_0 + \mathbf{A}_{pn}\mathbf{H}^{iter+1}\right)
\end{aligned} \tag{13}$$

To solve the system of equations (13) it is necessary to compute the diagonal matrices $\mathbf{D}_{pp}$ (containing the derivatives of the head losses with respect of the *k*-th pipe discharge Q_k) and $\mathbf{A}_{pp}$ together with their product $\mathbf{B}_{pp} = \mathbf{A}_{pp}(\mathbf{D}_{pp})^{-1}$.
Equation (14) reports the expression of the dimensionless parameter zD_k for any *n* and discharge condition (δ_k). zD_k is represented in Figure 6. In particular, the negative values zD_k are due to the existence of a maximum value of z_k for $n<2$.

$$\begin{aligned}
&D_{pp}(k,k) = \frac{d\left[R_{k,\infty}\left(Q_k\left|Q_k\right|^{n-1} + z_k P_k^n\right)\right]}{dQ_k} = R_{k,\infty}\left(n\left|Q_k\right|^{n-1} + \frac{dz_k}{d\delta_k}P_k^{n-1}\right) =\\
&= R_{k,\infty}\left(n\left|\delta_k\right|^{n-1} + zD_k\right)P_k^{n-1}\\
&zD_k = \frac{dz_k}{d\delta_k} = \left(\delta_k + \frac{1}{2}\right)\left|\delta_k + \frac{1}{2}\right|^{n-1} - \left(\delta_k - \frac{1}{2}\right)\left|\delta_k - \frac{1}{2}\right|^{n-1} - n\left|\delta_k\right|^{n-1}
\end{aligned} \tag{14}$$

From a numeric point of view, it is important to note that for δ_k approaching zero, $zD_k>0$. This fact assures robustness of the developed GGA.
Equation (15) reports the elements of the diagonal matrix $\mathbf{A}_{pp}$ which are the ratio between pipe head losses and relevant discharges; their expression is a function of the dimensionless parameter zA_k.

$$\begin{aligned}
&A_{pp}(k,k) = \frac{R_{k,\infty}\left(Q_k\left|Q_k\right|^{n-1} + z_k P_k^n\right)}{Q_k} = R_{k,\infty}\left(\left|Q_k\right|^{n-1} + \frac{z_k P_k^n}{Q_k}\right) =\\
&= R_{k,\infty}\left(\left|\delta_k\right|^{n-1} + \frac{z_k}{\delta_k}\right)P_k^{n-1} = R_{k,\infty}\left(\left|\delta_k\right|^{n-1} + zA_k\right)P_k^{n-1}\\
&zA_k = \frac{z_k}{\delta_k} = \frac{\left|\delta_k + \frac{1}{2}\right|^{n+1} - \left|\delta_k - \frac{1}{2}\right|^{n+1}}{(n+1)\delta_k} - \left|\delta_k\right|^{n-1}
\end{aligned} \tag{15}$$

Finally, the elements of the diagonal matrix representing the term $\mathbf{B}_{pp}$ are reported in Equation (16).

$$\frac{A_{pp}(k,k)}{D_{pp}(k,k)} = \frac{|\delta_k|^{n-1} + zA_k}{n|\delta_k|^{n-1} + zD_k} = zB_k \tag{16}$$

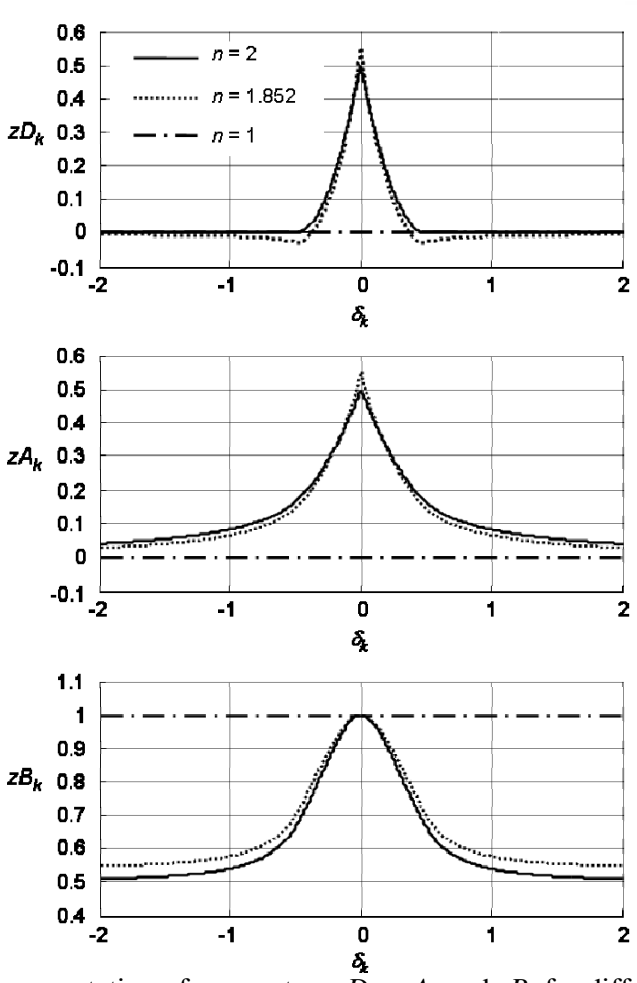

Figure 4: Representation of parameters zD_k , zA_k and zB_k for different exponents n

CONCLUSIONS

Giustolisi and Todini (2008) introduced an enhanced Global Gradient Algorithm which allows for correcting head loss error due to representation of uniformly distributed demands as nodal concentrated withdrawals. This paper provides an extension of the enhanced Global Gradient Algorithm aimed at using any empirical monomial formulation for describing pipe head loss. The resulting formulation represents a valuable basis for further investigations on WDN functioning by using the existing simulation algorithms.

ABSTRACT

The classical assumption of representing the total demand along a pipe as two lumped withdrawals at its terminal nodes is hitherto common. It is a simplification of the network topology which is useful in order to drastically reduce the number of nodes during network simulation. Conversely, this simplification does not preserve pipes' energy balance equation and, for this reason, it is a wrong approximation that could generate large head loss errors. This paper presents an extension of the Global Gradient Algorithm (GGA) which entails a modified GGA permitting the effective introduction of the lumped nodal demands, and without forfeiting a correct pipe head loss, by means of a pipe hydraulic resistance correction.

INTRODUCTION

The application of local linearization methods (Cross, 1936) and the global linearization techniques characterized by the simultaneous solution of all the equations of the network analysis problem (Collins et al., 1978) are the two main key moments of the search for the most efficient network simulation algorithm in terms of rapid convergence and robustness (reduced number of cases in which the search for the solution fails). The most comprehensive approach to global linearization techniques was set out by *Collins et al.* (1978) who defined the "content" and "co-content" models.

Different approaches to global linearization technique are treated in the literature: the Newton-Raphson Global Gradient Algorithm (Todini, 1979; Todini and Pilati, 1988); two similar approaches named Hybrid Method (Hamam and Brameller, 1971; Carpentier et al., 1985) and Newton Loop-Node Method (Osiadacz, 1987); the Linear Theory Algorithm (Wood and Charles, 1972; Isaacs and Mills, 1980; Wood and Rayes, 1981); the Newton-Raphson Loop Algorithm (an extension of the Cross method where all the loops are considered at the same time) (Epp and Fowler, 1970; Kesavan and Chandrashekar, 1972) and; the Newton-Raphson Head Algorithm (Martin and Peters, 1963; Shamir and Howard, 1968).

These algorithms share the common characteristic of requiring the solution of a system of linear equations several times in order to iteratively reach (i.e., by means

of successive approximations) the solution of the original system of partly linear and partly non-linear equations. However, the size of the linear system to be solved, and the information that has to be provided to formulate it or to identify a first-attempt solution required to initiate the iterative process, vary according to the method chosen.

The Global Gradient Algorithm (GGA) (Todini, 1979; Todini and Pilati, 1988) was used to develop EPANET2 (Rossman, 2000), which has probably become the de facto most widely used network simulation model in the world and which is also embedded in several commercial software packages.

Nevertheless, in all the previously discussed and available methods, water demands are uniquely represented as nodal withdrawals, although they are inevitably distributed along the pipes throughout connections to the properties. Such a simplification of the demand distribution was mainly due to the lack of detailed and reliable knowledge about the position and number of actual connections. However, information, data and maps needed to analyse the water distribution networks are today available and the use of information technology and geographical information system (GIS) is becoming common in water industry in order to map systems and support management. In particular, the improved description of both network topology (number and position of the connections to the properties along the mains of the water distribution networks) and its boundary conditions (demands) permit a more detailed system analysis for simulation purposes. The inclusion of such new information could be potentially achieved by adding one node for each connection point, but this would drastically increase the complexity of network analysis. Thus, the simplification of real demands as two lumped withdrawals at pipe end nodes is vital for maintaining acceptable computational times. Unfortunately, the assumption of two equal lumped withdrawals (each one half of the pipe demand) does not preserve pipes' energy balance equation. Thus, it could generate large head loss errors.

In fact, *Giustolisi and Todini* (2008) recently demonstrated that the assumption of uniformly distributed demands along the pipes, an expedient used when there is poor knowledge about the actual connections and demands, can generate large errors in energy balance when uniform demand is lumped into the two end nodes of a pipe in order to exclusively conserve mass balance. It is worth noting that the results obtained in this classical "average" assumption are conceptually valid also for different shapes of distributed demands along a pipe (Hamberg and Shamir, 1988), considering that in more general cases the error could be higher than that related to the uniform distribution assumption, as will be demonstrated later on in the paper. Furthermore, even when the actual pipe connections and demands are known, coarse simplifications focusing solely on mass balance conservation can produce significant errors in the energy balance, which cannot be assured without considering the actual network status (i.e., topological and mass balance considerations).

Thus, this paper will presents an extension of the GGA permitting the effective introduction of the lumped nodal demands, and without forfeiting a correct pipe head loss, by means of a pipe hydraulic resistance correction. It is worth noting that the standard hydraulic commercial software (e.g., a specific numerical minimisations of

the Content energy function (Carpentier et al., 1985; Piller 1995)), that relies on other algorithms can benefit from the improvement here presented as well.
Finally, the simplification here reported should not be confused with network skeletonization in the sense of model simplification (Anderson and Al-Jamal, 1995) through linearization around a given working point eliminating all redundant nodes by means of the Gauss-Jordan elimination technique (Ulanicki et al., 1996).
In fact, it is here reported a way to account for general shapes of demand distribution along pipes as reported in Hamberg and Shamir (1988) considering the adjustment of the network simulation model (GGA for example) in order to continue using the schematization of the demands as two concentrated water withdrawal at the end of pipes while preserving both energy and mass balance equations in the network model.

WDN SIMULATION MODEL AND HEAD LOSS FORMULATION

The demand-driven simulation of a network of n_p pipes with unknown discharges, n_n nodes with unknown heads (internal nodes) and n_0 nodes with known heads (tank levels, for example) can be described in matrix figure and formulated in the following non-linear system of equations based on energy and mass balance equations

$$\begin{aligned} \mathbf{A}_{pp}\mathbf{Q} + \mathbf{A}_{pn}\mathbf{H} &= -\mathbf{A}_{p0}\mathbf{H}_0 \\ \mathbf{A}_{np}\mathbf{Q} &= \mathbf{d} \end{aligned} \tag{1}$$

where $\mathbf{Q}$ is the $[n_p,1]$ column vector of unknown pipe flow rates, $\mathbf{H}$ is the $[n_n,1]$ column vector of unknown nodal heads, $\mathbf{H}_0$ is the $[n_0,1]$ column vector of known nodal heads, $\mathbf{d}$ is the $[n_n,1]$ column vector of demands lumped in the nodes driving the simulation, $\mathbf{A}_{pn}=\mathbf{A}^T_{np}$ and $\mathbf{A}_{p0}$ are topological incidence sub-matrices of size $[n_p,n_n]$ and $[n_p,n_0]$, respectively, derived from the general topological matrix $\bar{\mathbf{A}}_{pn}=[\mathbf{A}_{pn} \mid \mathbf{A}_{p0}]$ of size $[n_p,n_n+n_0]$, as defined in Todini and Pilati (1988). Furthermore, in the first equation of the system (1) $\mathbf{A}_{pp}\mathbf{Q}$ is the $[n_p,1]$ column vector of pipe head loss whose elements are:

$$E_k = \frac{8f\left(\mathrm{Re},\mathrm{Ke}\right)}{g\pi^2 D_k^5} Q_k \left|Q_k\right| L_k = R_k\left(\mathrm{Re},\mathrm{Ke},D,L\right) Q_k \left|Q_k\right| \tag{2}$$

where k = pipe index; f = Darcy-Weisbach friction factor dependent on the Re = Reynolds number and Ke = equivalent roughness; D_k = internal diameter, g = gravitational acceleration constant, Q_k = pipe flow rate and L_k = pipe length. Thus, R_k = pipe hydraulic resistance that is a function of Re (i.e. Q), Ke, D and L. Eq. (2) holds for laminar, rough turbulent and rough fully turbulent flow regimes.
In technical practice Eq. (2) is very often substituted by

$$E_k = R_k\left(\mathrm{Ke},D,L\right) Q_k \left|Q_k\right|^{n-1} = R_{k,\infty} Q_k \left|Q_k\right|^{n-1} \tag{3}$$

where $R_{k,\infty}$ is not dependent on flow regime (i.e. Q) and, therefore, constant during network simulations, while n is an exponent dependent on the head loss relationship used (1.852 for the Hazen-Williams and 2 for the Darcy-Weisbach rough fully

turbulent flow). The water demands are commonly lumped into the nodes, becoming the elements of the column vector **d**, although in reality they are distributed along the pipes converging at such nodes.

ERROR DUE TO INCORRECT DEMAND APPROXIMATION

Giustolisi and Todini (2008) have recently demonstrated that the above approximation is wrong because it generates head loss errors which may be significant when network analysis is performed for calibration, system design, real-time operations, rehabilitation strategies, optimal operation studies, reliability analyses, etc. They proved it considering the simple assumption of uniformly distributed demands along the pipes by means of a uniform function.
Therefore, Eq. (3) must be re-written to account for error in energy balance by means a correction ε_k in order to consider actual demand distribution in pipes,

$$\begin{aligned} E_k &= R_{k,\infty}\left(1+\varepsilon_k\right)Q_k\left|Q_k\right|^{n-1} = R_{k,\infty}\left(\left|Q_k\right|^{n-1}+\varepsilon_k\left|\delta_k\right|^{n-1}P_k^{n-1}\right)Q_k = \\ &= R_{k,\infty}\left(\left|Q_k\right|^{n-1}+\frac{z_k}{\delta_k}P_k^{n-1}\right)Q_k = R_{k,\infty}\left(\left|Q_k\right|^{n-1}+zA_kP_k^{n-1}\right)Q_k = A_{pp}\left(k,k\right)Q_k \end{aligned} \tag{5}$$

Hence,

$$\begin{aligned} &z_k = \varepsilon_k\delta_k\left|\delta_k\right|^{n-1}; \quad zA_k = \frac{z_k}{\delta_k} = \varepsilon_k\left|\delta_k\right|^{n-1} \\ &E_k^{\varepsilon} = R_{k,\infty}\varepsilon_k\delta_k\left|\delta_k\right|^{n-1}P_k^n = R_{k,\infty}z_kP_k^n \\ &A_{pp}\left(k,k\right) = R_{k,\infty}\left(\left|\delta_k\right|^{n-1}+zA_k\right)P_k^{n-1} = R_{k,\infty}\left(\left|Q_k\right|^{n-1}+zA_kP_k^{n-1}\right) \end{aligned} \tag{6}$$

where $A_{pp}(k,k)$ = elements of the new description of the diagonal matrix $\mathbf{A}_{pp}$ of Eq. (1), E_k^{ε}= head loss error due to incorrectness of demand representation, ε_k, z_k and zA_k = pipe dimensionless parameters useful in order to account for actual demand distribution along the pipes which are depend $\delta_k=Q_k/P_k$ = dimensionless parameter.
Furthermore, it is worth noting that the assumption $R_{k,\infty}$ (i.e. a constant pipe hydraulic resistance) in Eq. (5) implies that the correction ε_k accounts for the error due to the use of f(Ke) instead of f(Re,Ke) as will be demonstrated in the remainder of the text.
Assuming a uniformly distributed demand P_k and n=2 (corresponding to Darcy-Weisbach relationship for rough fully turbulent flow), *Giustolisi and Todini* (2008) have recently demonstrated that hydraulic resistances are underestimated in the model and, thus, overestimated during calibration in order to compensate this error.
This fact is particularly significant for pipes whose discharges (transferred water) are low with respect to the distributed demand outflow (δ_k tending to zero).
Considering now the well-known solution of the system (1) (Todini and Pilati, 1988):

$$\begin{aligned}
&\mathbf{B}_{pp}^{iter} = \left(\mathbf{D}_{pp}^{iter}\right)^{-1} \mathbf{A}_{pp}^{iter} \\
&\mathbf{F}^{iter} = \mathbf{A}_{np}\left(\mathbf{Q}^{iter} - \mathbf{B}^{iter}\mathbf{Q}^{iter}\right) - \mathbf{d} - \mathbf{A}_{np}\left(\mathbf{D}_{pp}^{iter}\right)^{-1}\left(\mathbf{A}_{p0}\mathbf{H}_0\right) \\
&\mathbf{H}^{iter+1} = \left(\mathbf{A}_{np}\left(\mathbf{D}_{pp}^{iter}\right)^{-1}\mathbf{A}_{pn}\right)^{-1}\mathbf{F}^{iter} \\
&\mathbf{Q}^{iter+1} = \left(\mathbf{Q}^{iter} - \mathbf{B}^{iter}\mathbf{Q}^{iter}\right) - \left(\mathbf{D}_{pp}^{iter}\right)^{-1}\left(\mathbf{A}_{p0}\mathbf{H}_0 + \mathbf{A}_{pn}\mathbf{H}^{iter+1}\right)
\end{aligned} \tag{7}$$

where *iter* = counter used during the iterative solution, it is necessary to achieve the diagonal elements of the matrix $\mathbf{D}_{pp}$ considering that they are the derivatives of the column vector $\mathbf{A}_{pp}\mathbf{Q}$ with respect to Q_k. Hence,

$$\begin{aligned}
&D_{pp}(k,k) = \frac{d\left(A_{pp}(k,k)Q_k\right)}{dQ_k} = \frac{d\left[R_{k,\infty}\left(Q_k\left|Q_k\right|^{n-1} + z_k P_k^n\right)\right]}{dQ_k} = \\
&= R_{k,\infty}\left(n\left|Q_k\right|^{n-1} + \frac{dz_k}{d\delta_k}P_k^{n-1}\right) = R_{k,\infty}\left(n\left|\delta_k\right|^{n-1} + zD_k\right)P_k^{n-1}
\end{aligned} \tag{8}$$

zD_k together with zA_k are useful in order to build the diagonal of $\mathbf{B}_{pp}$ in Eqs. (7),

$$\frac{A_{pp}(k,k)}{D_{pp}(k,k)} = \frac{\left|Q_k\right|^{n-1} + zA_k P_k^{n-1}}{n\left|Q_k\right|^{n-1} + zD_k P_k^{n-1}} = \frac{\left|\delta_k\right|^{n-1} + zA_k}{n\left|\delta_k\right|^{n-1} + zD_k} = zB_k \tag{9}$$

It is important to note that zD_k and zA_k tend to zero when δ_k tends to infinity (i.e. P_k is close or equal to zero) and the element zB_k of the diagonal matrix $\mathbf{B}_{pp}$ becomes equal to $1/n$ (i.e. 0.5 for n=2) and, consequently, GGA results unmodified for the k-th pipe. Furthermore, considering the case of P_k=0 (i.e. infinitesimal from a mathematical point of view), R_k(Re,Ke,D,L) and n=2 (i.e. the pipe head loss computed using the general Darcy-Weisbach formulation and without any distributed demand), the correction becomes

$$\varepsilon_k = \frac{R(\mathrm{Re},\mathrm{Ke},D,L)}{R_{k,\infty}} - 1 \Rightarrow E_k = R(\mathrm{Re},\mathrm{Ke},D,L)Q_k\left|Q_k\right| \tag{10}$$

Then, in this simple case, it is possible to obtain z_k, zA_k, zD_k and $\mathbf{D}_{pp}$,

$$\begin{aligned}
&z_k = \varepsilon_k\delta_k\left|\delta_k\right| = \frac{R_k}{R_{k,\infty}}\delta_k\left|\delta_k\right| - \delta_k\left|\delta_k\right| \Rightarrow E_k^{\varepsilon} = R_{k,\infty}\left(\frac{R_k}{R_{k,\infty}}\delta_k\left|\delta_k\right| - \delta_k\left|\delta_k\right|\right)P_k^2 = R_kQ_k\left|Q_k\right| - R_{k,\infty}Q_k\left|Q_k\right| \\
&zA_k = \frac{z_k}{\delta_k} = \frac{R_k}{R_{k,\infty}}\left|\delta_k\right| - \left|\delta_k\right| \Rightarrow A_{pp}(k,k) = R_{k,\infty}\left(\left|\delta_k\right| + \frac{R_k}{R_{k,\infty}}\left|\delta_k\right| - \left|\delta_k\right|\right)P_k = R_k\left|Q_k\right| \\
&zD_k = \frac{dz_k}{d\delta_k} = 2\left(\frac{R_k}{R_{k,\infty}}\left|\delta_k\right| - \left|\delta_k\right|\right) + \frac{P_k}{R_{k,\infty}}\frac{dR_k}{dQ_k}\delta_k\left|\delta_k\right| \Rightarrow \\
&\Rightarrow D_{pp}(k,k) = R_{k,\infty}\left(2\left|\delta_k\right| + 2\left(\frac{R_k}{R_{k,\infty}}\left|\delta_k\right| - \left|\delta_k\right|\right) + \frac{P_k}{R_{k,\infty}}\frac{dR_k}{dQ_k}\delta_k\left|\delta_k\right|\right)P_k = 2R_k\left|Q_k\right| + \frac{dR_k}{dQ_k}Q_k\left|Q_k\right|
\end{aligned} \tag{11}$$

ACTUAL DEMAND DISTRIBUTION IN WDN SIMULATION MODEL

The aim of this article is to improve the head loss error correction strategy by extending the results to the general case of *m* connections along the each *k*-th pipe delivering the demands $q_{k,j,}$ as reported in Figure 1.

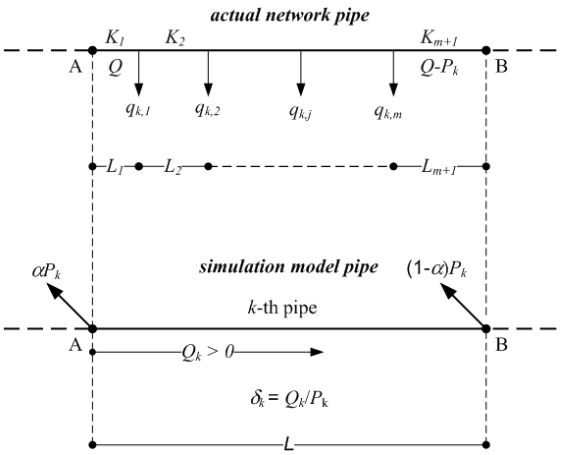

Figure 1. Actual pipe connections and schematic representation in WDN model

In fact, the improvement of the information technologies allows to describe better and better the network topology and the detail of the single connection are already available into the GIS systems. Thus, extending the demand-driven simulation model in order to consider this information without drastically increasing the number of nodes and pipes of the simulation model is an effective way to improve water network analysis avoiding course errors due to the wrong approximation of lumped demands into the nodes. Referring to Figure n.1, the general formulation for total pipe head loss considering *m* connections along the *k*-th pipe A-B is

$$\left(H_A - H_B\right)_{actual} = K_1 Q\left|Q\right|^{n-1} L_1 + \\ + \sum_{i=1}^{m-1} K_{i+1}\left(Q - \sum_{j=1}^{i} q_{k,j}\right)\left|Q - \sum_{j=1}^{i} q_{k,j}\right|^{n-1} L_{i+1} + K_{m+1}\left(Q - P_k\right)\left|Q - P_k\right|^{n-1} L_{m+1} \qquad (12)$$

$$K_1 = K_1\left(Q\right); \quad K_{i+1} = K_{i+1}\left(Q - \sum_{j=1}^{i} q_{k,j}\right); \quad K_{m+1} = K_{m+1}\left(Q - P_k\right)$$

where Q = flow rate entering or exiting from pipe depending on its sign, $q_{k,j}$ = demands of the *m* connections, L_i = *m*+1 lengths between two connections or one connection and ending nodes of the pipe and the related K_i = *m*+1 unitary hydraulic resistances which may depend on flow rates.
Assuming the dimensionless parameters,

$$\kappa_i = \frac{K_i}{K_{k,\infty}}; \quad \lambda_i = \frac{L_i}{L_k}; \quad \delta = \frac{Q}{P_k}; \quad \pi_i = \frac{\sum_{j=1}^{i} q_{k,j}}{P_k}; \tag{13}$$

where $K_{k,\infty}$ (=$R_{k,\infty}/L_k$) = unitary hydraulic resistance of the k-th pipe depending on the equivalent roughness only as in rough turbulent flow regime. Thus, Eq. (12) becomes

$$\begin{aligned}\left(H_A - H_B\right)_{actual} = &\left(\kappa_1 \delta \left|\delta\right|^{n-1} \lambda_1 + \right. \\ &\left. + \sum_{i=1}^{m-1} \kappa_{i+1} \left(\delta - \pi_i\right) \left|\delta - \pi_i\right|^{n-1} \lambda_{i+1} + \kappa_{m+1} \left(\delta - 1\right) \left|\delta - 1\right|^{n-1} \lambda_{m+1} \right) K_{k,\infty} P_k^n L_k\end{aligned} \tag{14}$$

It is important to note that the demand distribution along the k-th pipe is not symmetric with respect to flow direction and, therefore, Eq. (14) is written considering the positive flow direction (i.e. considering Q in A and the positive flow from A to B) and in particular π_i are related to the assumed positive flow versus.
Referring again to Figure 1, the pipe head loss in the simulation model (assuming the pipe resistance correction strategy) is given by,

$$\left(H_A - H_B\right)_{simulation\ model} = K_{k,\infty} \left(1 + \varepsilon_k\right) Q_k \left|Q_k\right|^{n-1} L_k = K_{k,\infty} \left(1 + \varepsilon_k\right) \delta_k \left|\delta_k\right|^{n-1} P_k^n L_k \tag{15}$$

where Q_k (=$Q - \alpha P_k$) = flow rate of the k-th pipe in the simulation model and $\delta_k = Q_k/P_k$, therefore $\delta_k = \delta - \alpha$. Thus, substituting $\delta = \delta_k + \alpha$ in Eq. (14) and equating ($H_A - H_B)_{actual}$ with ($H_A - H_B)_{simulation\ model}$ in order to achieve the conservation of energy balance, it is possible to obtain the correction,

$$\begin{aligned}\varepsilon_k = &\frac{\kappa_1 \left(\delta_k + \alpha\right) \left|\delta_k + \alpha\right|^{n-1} \lambda_1}{\delta_k \left|\delta_k\right|^{n-1}} + \\ &+ \frac{\sum_{i=1}^{m-1} \kappa_{i+1} \left(\delta_k + \alpha - \pi_i\right) \left|\delta_k + \alpha - \pi_i\right|^{n-1} \lambda_{i+1}}{\delta_k \left|\delta_k\right|^{n-1}} + \\ &+ \frac{\kappa_{m+1} \left(\delta_k + \alpha - 1\right) \left|\delta_k + \alpha - 1\right|^{n-1} \lambda_{m+1}}{\delta_k \left|\delta_k\right|^{n-1}} - 1\end{aligned} \tag{16}$$

It is worth noting that ε_k (i.e. z_k, zD_k and zA_k) is generally dependent on δ_k, as found in *Giustolisi and Todini* (2008) for the uniform function used as surrogate of the uniform distributed demand, but also on λ_i and π_i, which are parameters related to connection and demand distribution, κ_i and n, which are parameters related to flow regime, and α which is the parameter related to the way the total pipe demand is lumped into the two nodes A and B.
Furthermore, it is worth noting that for m=0, P_k=0, R_k(Re,Ke,D,L) and n=2 the corrections becomes equal to that of Eq. (10),

$$\varepsilon_k = \frac{\kappa_1 \left(\delta_k + \alpha\right) \left|\delta_k + \alpha\right|}{\delta_k \left|\delta_k\right|} - 1 = \frac{\kappa_1 \left(Q_k + \alpha P_k\right) \left|Q_k + \alpha P_k\right|}{Q_k \left|Q_k\right|} - 1 = \kappa_1 - 1 \tag{17}$$

CONCLUSIONS

An extension of the Global Gradient Algorithm (GGA) allowing the effective introduction of the lumped nodal demands without forfeiting the correct pipe head loss has been presented. A pipe hydraulic resistance correction (Giustolisi and Todini, 2008) has been used in order to modify the classical GGA.

The formulation of the pipe hydraulic resistance correction for any pipe demand pattern due to pipe connections has been achieved. Consequently, some dimensionless parameters have been gained in order to account for any pipe demand pattern in classical GGA.

The new formulation of the GGA can be easily implemented in all simulation packages based on GGA, such as for instance EPANET 2, and it can serve as a guide for other network simulation model strategies. Furthermore, it is envisaged that the new simulation model is essential for network model calibration purposes and also for other network analyses such as that of pressure-driven leakage and demand simulation model (Giustolisi et al., 2008).

Abstract

The operational pressure control is a cost-effective way to leakage reduction and many pressure control methods and algorithms have been developed. Whilst the pressure control algorithm is model-based, the hydraulic model of the considered distribution network is not always available. Therefore, this paper will focus on the development of an aggregated hydraulic model of the network considered, in particular, identification of a leakage enhanced model using the operational measurements or the available historical data. This will enable a pressure optimisation algorithm to calculate the optimal pressure schedules for the implementation of a pressure control scheme. The identification problem is formulated as a parameter estimation problem in this paper and a least-square based method is derived for estimating the parameters in the model. A case study provided by a UK water company is performed to illustrate the use of the method and the identification results from real operational data are presented.

Introduction

Leakage from water distribution networks is a source of major concern for water companies worldwide and leakage reduction is a key factor of water distribution network management. It is well known that water leakage in a distribution network is directly related to the system service pressure, hence pressure control is an effective way to reduce background leakage and various methods and algorithms have been developed for optimising the operational pressure so as to minimize background leakage and, at the same time, to satisfy pressure requirements at critical points (see e.g. Jowitt and Xu (1990), Ulanicki et al (2000, 2008) and references therein). Before implementing a pressure control scheme, it is necessary to perform planning studies to investigate the economical aspects of such a scheme. Such studies are usually based on the knowledge about the particular network considered and a convenient form of such knowledge

is a hydraulic model of the network. However, it is often the case that such a hydraulic model is not available from the water company and has to be obtained by some identification procedures using measurements or historical operational data.

This paper focuses on the development of an aggregated hydraulic model of the network considered, in particular, identification of a leakage enhanced model using the operational measurements or the available historical data for the implementation of supervisory pressure control. The rest of the paper is organized as follows. Next section gives the problem statement, which is followed by the derivation of a least-square based method for estimating the parameters in both pipe element model and leakage model of the network. A case study provided by a UK water company is then performed to illustrate the use of the method and the identification results from real operational data are presented. The conclusions are given in the last section.

Problem statement

To facilitate monitoring and control activities, it is common practice for water companies to split the water distribution network into district metered areas (DMAs) that are typically small areas and are isolated apart from designated inlets and outlets through which flows are monitored. Pressure reducing valves (PRVs) are used to maintain a specified pressure to the inlets of a DMA against the fluctuations in PRV inlet pressure and the changes of demand from the DMA. This structure also facilitates application of a pressure control scheme.

A prerequisite for pressure control design is an appropriate model of the network to be controlled, but such a model is not always available in practice, therefore some kind of identification procedure is needed so as to estimate an equivalence model from the available measurements or historical data. The equivalence hydraulic model will contain only boundary nodes, target (critical) nodes and fictitious pipes with which these nodes are connected (Ulanicki et al 2000). The data available for model identification are boundary heads and flows, target heads and flows, and the aim of the identification is to obtain a leakage enhanced network model for pressure control. More specifically, the parameters to be identified are the resistance/conductance of the fictitious pipes, the leakage coefficients and leakage exponent.

Hydraulic model identification

The aforementioned equivalence network structure can be conveniently represented by a node-branch incidence matrix $\mathbf{\Lambda}$ (see e.g. Ulanicki et al 2000). The matrix has a row for each node and a column for each branch. A row contains information about which branches are connected to a particular node. The elements of $\mathbf{\Lambda}$ take one of the three values -1, 0 and $+1$. The value -1 indicates that the flow of the branch is oriented towards the node, the value $+1$ indicates the flow of the branch is leaving the node and value 0 indicates that a branch is not connected to the node. Therefore, each column of $\mathbf{\Lambda}$ contains only two non-zero entries, $+1$ for the branch origin node and -1 for the branch destination node. Let N_{node} denote the total number of the (boundary and target) nodes in the equivalence network, in the most general case, the total number of branches (fictitious pipes) will be $N_{pipe} = \frac{1}{2}(N_{node} - 1)N_{node}$ and $\mathbf{\Lambda}$

will be a $N_{node} \times \frac{1}{2}(N_{node}-1)N_{node}$ matrix.

Pipe model parameter estimation

The main components in the aforementioned equivalence network are the (fictitious) pipes which can be described by many different formulae. In this paper, the head-flow relationship for the jth pipe element is expressed by Hazen-Williams formula (see e.g. Walski *et al* 2003):

$$\Delta h_j = h_{j,o} - h_{j,d} = R_j q_j |q_j|^{0.852} \tag{1}$$

where $h_{j,o}$ and $h_{j,d}$ are heads in [m] at origin and destination nodes of the jth pipe element respectively; R_j is the resistance of the jth pipe element; q_j is the flow in [l/s] through the element.

Let $\mathbf{\Lambda}_i$ denote the ith row of $\mathbf{\Lambda}$; $\mathbf{\Lambda}_j^T$ denote the jth column of $\mathbf{\Lambda}$; the heads at each node and the flows in each branch are collected in the nodal head vector $\mathbf{h}$ and the branch flow vector $\mathbf{q}$ respectively, i.e. $\mathbf{h} = [h_1, h_2, \cdots, h_{N_{node}}]^T$, $\mathbf{q} = [q_1, q_2, \cdots, q_{N_{pipe}}]^T$. The head-flow relationship for the pipe elements in the network can then be written as follows:

$$\mathbf{\Lambda}_j^T \mathbf{h} = R_j q_j |q_j|^{0.852} \quad j = 1, 2, \cdots, N_{pipe} \tag{2}$$

The mass balance equations at nodes can be written as:

$$\mathbf{\Lambda}_i \mathbf{q} = -q_{t,i} + q_{b,i} \quad i = 1, 2, \cdots, N_{node} \tag{3}$$

where $q_{t,i}$ is the total target flow (i.e. demand and leakage) for node i, $q_{b,i}$ is the boundary flow ($q_{b,i} = 0$ for non-boundary node) for node i. The above mass balance equations at nodes can be written in a compact form:

$$\mathbf{\Lambda q} = \underbrace{\begin{bmatrix} -q_{t,1} + q_{b,1} \\ -q_{t,2} + q_{b,2} \\ \vdots \\ -q_{t,N_{node}} + q_{b,N_{node}} \end{bmatrix}}_{\mathbf{q}_{t,b}} \tag{4}$$

To estimate the pipe resistance R_j, the pipe model (1) is rewritten in a reverse form:

$$q_j = G_j \Delta h_j |\Delta h_j|^{-0.46} \quad j = 1, 2, \cdots, N_{pipe} \tag{5}$$

where $G_j = 1/R_j^{0.54}$ is the conductance of the jth pipe in the network. The pipe equations (5) can be assembled in a vector form as follows:

$$\mathbf{q} = \begin{bmatrix} q_1 \\ q_2 \\ \vdots \\ q_{N_{pipe}} \end{bmatrix} = \underbrace{\begin{bmatrix} \Delta h_1 |\Delta h_1|^{-0.46} & 0 & \cdots & 0 \\ 0 & \Delta h_2 |\Delta h_2|^{-0.46} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \Delta h_{N_{pipe}} |\Delta h_{N_{pipe}}|^{-0.46} \end{bmatrix}}_{\mathbf{\Delta H}} \underbrace{\begin{bmatrix} G_1 \\ G_2 \\ \vdots \\ G_{N_{pipe}} \end{bmatrix}}_{\mathbf{G}} \tag{6}$$

Substituting (6) into (4), the following compact network model can be derived:

$$\mathbf{\Lambda \Delta H G} = \mathbf{q}_{t,b} \tag{7}$$

Since all heads, target flows and boundary flows are measured or available from historical data, the model equation (7) is linear with respect to the parameter vector $\mathbf{G}$ (from which the resistance $R_j, j = 1, 2, \cdots, N_{pipe}$ can be derived). Assume that a time history measurement data set of length K (i.e. $\{\Delta h_j(k), q_{t,i}(k), q_{b,i}(k)\}_{k=1}^{K}$ for $j = 1, 2, \cdots, N_{pipe}$ and $i = 1, 2, \cdots, N_{node}$) is selected, the parameter estimation can then be formulated as a least-square problem. For the model defined by (7), it is straightforward to write the explicit linear regression form in terms of the parameter vector $\mathbf{G}$ to be estimated:

$$\underbrace{\begin{bmatrix} \mathbf{q}_{t,b}(1) \\ \mathbf{q}_{t,b}(2) \\ \vdots \\ \mathbf{q}_{t,b}(K) \end{bmatrix}}_{\mathbf{Q}_{t,b}} = \underbrace{\begin{bmatrix} \mathbf{\Lambda}\Delta\mathbf{H}(1) \\ \mathbf{\Lambda}\Delta\mathbf{H}(2) \\ \vdots \\ \mathbf{\Lambda}\Delta\mathbf{H}(K) \end{bmatrix}}_{\mathbf{\Phi}} \mathbf{G} \tag{8}$$

where, for $k = 1, 2, \cdots, K$

$$\mathbf{q}_{t,b}(k) = \begin{bmatrix} -q_{t,1}(k) + q_{b,1}(k) \\ -q_{t,2}(k) + q_{b,2}(k) \\ \vdots \\ -q_{t,N_{node}}(k) + q_{b,N_{node}}(k) \end{bmatrix} \tag{9}$$

and

$$\Delta\mathbf{H}(k) = \begin{bmatrix} \Delta h_1(k)|\Delta h_1(k)|^{-0.46} & 0 & \cdots & 0 \\ 0 & \Delta h_2(k)|\Delta h_2(k)|^{-0.46} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \Delta h_{N_{pipe}}(k)|\Delta h_{N_{pipe}}(k)|^{-0.46} \end{bmatrix} \tag{10}$$

$\mathbf{G}$ can then be estimated by solving the above linear regression problem with the LS method as follows:

$$\hat{\mathbf{G}} = \mathbf{\Phi}^{+}\mathbf{Q}_{t,b} \tag{11}$$

where $\mathbf{\Phi}^{+}$ is the pseudo-inverse of $\mathbf{\Phi}$. From equations (8), (9) and (10), it is clear that the matrices $\mathbf{Q}_{t,b}$ and $\mathbf{\Phi}$ in equation (11) are formed entirely using the available measurement data $\{\Delta h_j(k), q_{t,i}(k), q_{b,i}(k)\}_{k=1}^{K}$ for $j = 1, 2, \cdots, N_{pipe}$ and $i = 1, 2, \cdots, N_{node}$.

Equations (8)$\sim$(11) provide a method for identifying an equivalence network model in the general case. If, however, the mass balance equation (4) can be solved, hence branch flows $q_j, j = 1, 2, \cdots, N_{pipe}$ are available; the identification algorithm can be greatly simplified. Since q_j is available, it is straightforward to write the explicit linear regression form in terms of the R_j from equation (1) for each pipe:

$$\underbrace{\begin{bmatrix} \Delta h_j(1) \\ \Delta h_j(2) \\ \vdots \\ \Delta h_j(K) \end{bmatrix}}_{\Delta\mathbf{H}_j} = \underbrace{\begin{bmatrix} q_j(1)|q_j(1)|^{0.852} \\ q_j(2)|q_j(2)|^{0.852} \\ \vdots \\ q_j(K)|q_j(K)|^{0.852} \end{bmatrix}}_{\mathbf{Q}_j} R_j \quad j = 1, 2, \cdots, N_{pipe} \tag{12}$$

Similar to (11), the resistance R_j can then be estimated as follows:

$$\hat{R}_j = \mathbf{Q}_j^{+} \Delta \mathbf{H}_j \quad j = 1, 2, \cdots, N_{pipe} \tag{13}$$

Assume that the measurement errors are independent, identically distributed (i.i.d.), the estimation error, i.e. the standard deviation of the estimate $\hat{R}_j$ can also be evaluated, this is given by:

$$\sigma(\hat{R}_j) = \sqrt{\frac{S}{K-1}(\mathbf{Q}_j^T \mathbf{Q}_j)^{-1}} \tag{14}$$

where S is the sum of squared residuals defined as follows:

$$S = \sum_{k=1}^{K} (\Delta h_j(k) - q_j(k)|q_j(k)|^{0.852} \hat{R}_j)^2 \tag{15}$$

Leakage model parameter estimation

The pressure management for leakage reduction requires an enhanced hydraulic model, which incorporate pressure dependent leakage terms. Several mathematical models relating the leakage and the operating pressure based on experimental results have been proposed. The leakage-pressure relationship as shown in equation (16) (Ulanicki *et al* 2008) is assumed in this paper:

$$l_i = k_i p_i^{\alpha_i} = k_i (h_i - H_i)^{\alpha_i} \tag{16}$$

where k_i is the leakage coefficient; α_i is the leakage exponent, h_i is the head of node i and H_i is the elevation of node i. The leakage exponent α_i ranges from 0.5 to 2.5 depending on many factors described in the literature. In this paper, the leakage exponent will be estimated along with the leakage coefficient k_i using the leakage measurement data $\{h_i(k), H_i, l_i(k)\}_{k=1}^{K}$. In practice, the leakage $l_i, i = 1, 2, \cdots, N_{node}$ may not be available, some kinds of estimation or approximation have to be used. The minimum night flow (MNF) will be used in the following case study to approximate the leakage.

The linear least-square method can not directly be used for estimating the parameters k_i and α_i in leakage model (16) as the model is not linear in terms of α_i. However, the problem can be resolved by taking logarithms of equation (16):

$$\ln l_i = \ln k_i + \alpha_i \ln p_i \tag{17}$$

For the given data set $\{h_i(k), H_i, l_i(k)\}_{k=1}^{K}$ of size K, the following standard linear regression form in terms of the transformed variables $\boldsymbol{\theta} = \begin{bmatrix} \ln k_i & \alpha_i \end{bmatrix}^T$ can readily be derived from equation (17):

$$\underbrace{\begin{bmatrix} \ln l_i(1) \\ \ln l_i(2) \\ \vdots \\ \ln l_i(K) \end{bmatrix}}_{\mathbf{L}} = \underbrace{\begin{bmatrix} 1 & \ln p_i(1) \\ 1 & \ln p_i(2) \\ \vdots & \vdots \\ 1 & \ln p_i(K) \end{bmatrix}}_{\mathbf{\Phi}} \boldsymbol{\theta} \tag{18}$$

The LS estimates of k_i and α_i is then given by:

$$\hat{\boldsymbol{\theta}} = \begin{bmatrix} \ln \hat{k}_i \\ \hat{\alpha}_i \end{bmatrix} = \boldsymbol{\Phi}^{+}\mathbf{L} \quad \text{and} \quad \hat{k}_i = e^{\ln \hat{k}_i} \tag{19}$$

The variance-covariance matrix of the estimate $\hat{\boldsymbol{\theta}}$ is given by:

$$\boldsymbol{\sigma}(\hat{\theta}) = \frac{S_T}{K-2}(\boldsymbol{\Phi}^T\boldsymbol{\Phi})^{-1} \tag{20}$$

where S_T is the sum of squared transformed residuals defined as follows:

$$S_T = \sum_{k=1}^{K}(\ln l_i(k) - \ln \hat{k}_i - \hat{\alpha}_i \ln(p_i(k)))^2 \tag{21}$$

The standard deviations of the model parameter estimates is then given by (see e.g. Bevington and Robinson 2003):

$$\sigma(\hat{k}_i) = \boldsymbol{\sigma}(\hat{\theta})_{11} / \frac{d(\ln \hat{k}_i)}{d\hat{k}_i} = \hat{k}_i \boldsymbol{\sigma}(\hat{\theta})_{11} \quad \text{and} \quad \sigma(\hat{\alpha}_i) = \boldsymbol{\sigma}(\hat{\theta})_{22} \tag{22}$$

where $\boldsymbol{\sigma}(\hat{\theta})_{ii}(i = 1, 2)$ is the main diagonal element of the matrix $\boldsymbol{\sigma}(\hat{\theta})$ defined by (20).

Case study

Pressure management in UK water industry has been an ongoing process for a period of time and an event-driven pressure management trial was recently carried out at a UK water company. As a part of the UK Engineering & Physical Science Research Council (EPSRC)-funded project NEPTUNE, a supervisory pressure control scheme covering wide areas and the associated implementation through the hardware used in the aforementioned trial are proposed for minimizing leakage and customer interruptions. However, the water company does not have a hydraulic model for the area considered. Without a model it is also difficult to estimate how much savings would result from the implementation of the proposed pressure control scheme.

In this section, an aggregated hydraulic model for the area considered will be developed using the available measurements for the implementation of the proposed supervisory pressure control scheme. The network extracted from the schematics of the considered area is shown in Figure 1. It has one boundary node (PRV in the figure) which is connected to six target (critical) nodes (DMAs in the figure). As there is no connections between target (DMA) nodes, the mass balance equation (4) can be solved and the branch flows $q_j, j = 1, 2, \cdots, 6$ will be available, which are equal to the measured target flows in this case. The PRV node is the common origin for all the pipe elements in the network, and the destination nodes are the associated DMAs. The total leakage for each target (DMA) node will be approximated by its MNF for estimation of parameters in leakage model (16).

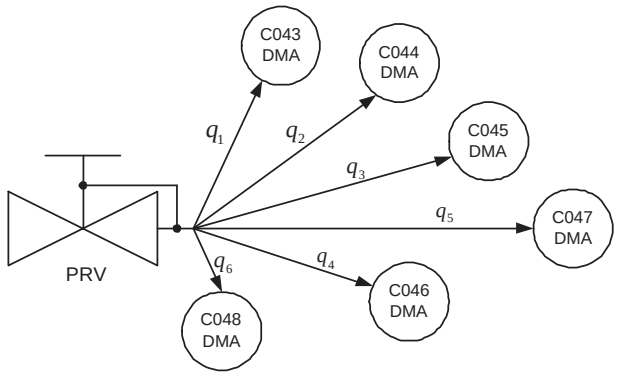

Figure 1: Schematic structure of the considered network

Historical data for parameter estimation

The available historical data files associated with the considered area are provided by a UK water company and they are summarized in Table 1. As can been seen, from this table, the data is not complete. Figure 2 shows the typical plots of the daily PRV outlet head and a DMA node flow over a week.

Table 1: Available data for identification

Nodes	DG2 pressure data	DG2 elevation	Flow data
C043	04/05/07∼04/08/08	130[m]	12/06/08 (Thur)
C044	01/04/07∼04/08/08	140[m]	01/04/07∼13/06/08
C045	01/04/07∼04/08/08	148.6[m]	01/04/07∼07/07/08
C046	01/04/04∼19/06/08	148.55[m]	01/04/07∼07/07/08
C047	01/04/07∼04/08/08	141.38[m]	01/04/07∼31/07/08
C048	09/07/08∼18/07/08	141.9[m]	09/07/08∼18/07/08
PRV	25/09/07∼12/02/08	149[m]	01/01/06∼10/10/07

It can be seen that the flow and head plots on weekdays approximately follow the same pattern which are obvious different from the plots on weekends. The minimum night flow occurs between 2:00am and 3:00am and there are two peaks in a daily flow plot. The first peak occurs around 6:45am in weekdays and two hours later on the weekends, the second peak occurs around 6:00pm.

The data collected between 11/01/2008 and 06/02/2008 are selected for modelling because this is the latest period of time over which the measurements for the PRV and most of the DMAs are available as shown in Table 1.

Identification results

Since there is no overlap between the PRV outlet head data and the C043, C048 head data as shown in Table 1, it would not be possible to estimate the resistances

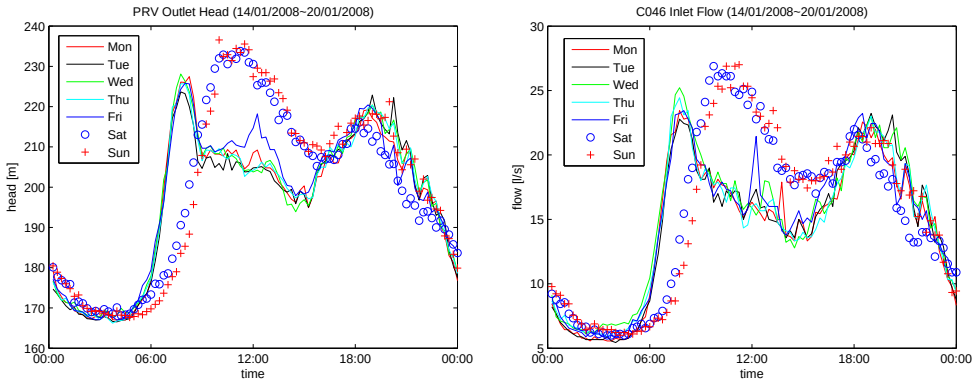

Figure 2: Daily PRV outlet head and DMA flow over a week

between PRV and C043, C048 DMAs. However, as shown in Figure 2, the PRV outlet heads on the weekdays approximately follow the same pattern, the PRV outlet heads taken in the different dates will be used as the replacement data for estimating the resistances between PRV and C043, C048 DMAs. Having removed all the outliers detected in the original data sets, model identification is performed and the results of parameter estimation are summarized in Table 2.

Table 2: Results of parameter estimation with the outliers being removed

DMA	R_j	$\sigma(R_j)$	k_j	$\sigma(k_j)$	α_j	$\sigma(\alpha_j)$
C043	0.7739	4.0945×10^{-2}	3.4763×10^{-2}		1.1	
C044	2.7862	1.8876×10^{-2}	9.6198×10^{-5}	1.0191×10^{-3}	2.5111	3.0285
C045	1.3865	1.4331×10^{-2}	2.2914×10^{-2}		1.1	
C046	0.1495	5.4148×10^{-4}	1.9783×10^{-1}	7.1931×10^{-1}	1.0091	1.0915
C047	0.4480	3.2228×10^{-3}	5.3411×10^{-2}	7.2589×10^{-1}	0.9741	3.8450
C048	0.3971	1.5554×10^{-2}	4.7983×10^{-2}		1.1	

The R_js in the table are estimated with equation (13) with the associated standard deviations $\sigma(R_j)$ being estimated with equation (14). Figure 3 shows the results of data fitting for C046 and C047 using their R_j estimates. The k_js and α_js of the leakage model in Table 2 are estimated by equation (19) with the associated standard deviations being evaluated with equations (20)$\sim$(22), where the leakage measurements are approximated by their MNFs.

However, the estimate of leakage exponent for C045 takes negative value ($\hat{\alpha}_j = -3.4095 \times 10^{-1}$). To investigate the problem, the results of leakage data fitting for C045 DMA with the outlier being removed is plotted in Figure 4 and it shows, in overall, a slightly negative correlation between the MNF and pressure. This may indicate that the MNF is not a good estimate of the leakage for C045 DMA. As a remedy, the minimum MNF over the dates between 11/01/2008 and 06/02/2008 (excluding the outlier) is used as the estimate of leakage for C045 DMA and α_j takes the value of 1.1. k_j is then

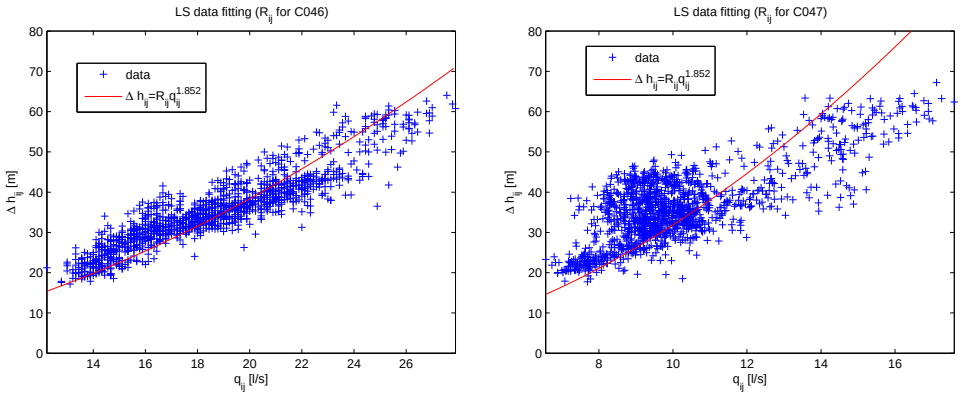

Figure 3: Results of R_j data fitting for C046 and C047 with outliers being removed

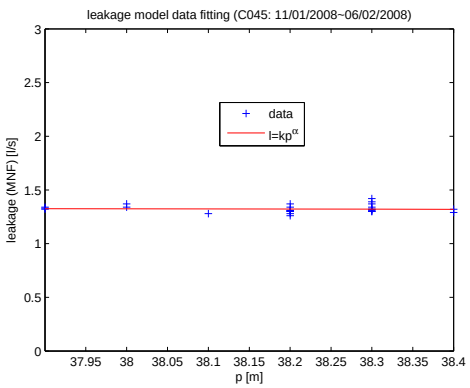

Figure 4: C045 MNF-pressure plot with outlier being removed

obtained as:

$$k_j = \frac{\text{minimum MNF}}{p_{minMNF}^{1.1}} \tag{23}$$

and this result is shown in Table 2.

The α_js for C043 and C048 are also assumed to be 1.1 as shown in Table 2 and the corresponding k_js are estimated with equation (23). This is because: (i) only one-day flow data (i.e. only one MNF) is available for C043 DMA; (ii) there are many missing data in flow and DG2 files for C048, therefore the averages of MNFs and the associated pressures over 09/07/2008-18/07/2008 are used for estimating k_j for C048 DMA with equation (23).

It needs to be pointed out that the estimation errors (standard deviations) of leakage model parameters k_j and α_j evaluated with equations (20)$\sim$(22) are quite large in comparison with the values of the corresponding parameter estimates as shown in Table 2. This is because the matrix $\mathbf{\Phi}^T\mathbf{\Phi}$ in (20) is ill-conditioned. This occurs when the measurements have only a marginal effect on the estimated parameters. In our case study, this is because we do not have the leakage measurements over a sufficient range

of pressure points. The MNFs have to be used in this study to approximate the leakage measurements for parameter estimation and the corresponding pressure range is very small (the pressure variations are not more than 1m at the most). This results in a nearly rank-deficient $\mathbf{\Phi}$ matrix defined in (18) which implies that the measurements are not "informative" enough and the identified leakage model will not be reliable when the pressure is outside the range of the measured pressure data used for identification.

Conclusions

A method for identifying a steady-state leakage enhanced hydraulic model of a water distribution network from measurements or historical operational data is presented in this paper. Only the head and flow data of the considered nodes are required by the method for identification. The method has been applied for a case study where a model of a real water distribution network provided by a UK water company has been identified from the available historical operational data. The case study also shows that the MNF alone is not "informative" enough for identifying a reliable leakage model and, sometimes, it is even not a good approximate to the leakage.

Further work is being carried out to validate and refine the identified model and to use the identified model for supervisory pressure control. The research is also being performed to develop the appropriate method for pre-processing the raw data, for example, to detect outliers and to deal with missing data etc, so as to facilitate the practical application of the method.

ABSTRACT

The selection of the most effective course of action for pipe rehabilitation is crucial to avoid the uncontrolled deterioration of water distribution systems (WDS). Moreover, it provides a rare opportunity to modify some elements of the existing infrastructure in order to meet the present service requirements. For instance, a rehabilitation plan could be aimed at simultaneously improving system reliability, pressure levels and/or leakage reduction. In this work WDS rehabilitation is formulated as a multi-objective optimization problem where decision variables for each pipe are "do-nothing" or "replace" by selecting from a set of commercial pipe diameters. It is shown that the solutions returned by a multi-objective genetic algorithm (MOGA) in such a complex decision scenario although good, could not be easily used to support decision making. A prioritization strategy is developed and presented which is based on MOGA solutions and provides an effective tool for both analysts and decision makers.

INTRODUCTION

There are several factors which make planning rehabilitation of municipal water distribution systems (WDS) a complex task. Some of these are the shortage of funds available, the large size of real networks, the choice of the right rehabilitation options among all available alternatives and the appealing opportunity of improving network performances by renewing infrastructure elements. The development of fast and robust tools for water distribution network analyses as well as computationally effective search and optimization methodologies has provided technicians and researchers with a wide range of tools aimed at constructing effective decision support systems (DSS). Decision makers are now asked to choose the most appropriate solution from the technically optimal alternatives returned by the DSS according to their own management criteria.

The review of literature dealing with the development of DSS for WDS rehabilitation clearly shows how the formulation of the problem moved from a single-objective to a multi-objective approach. In particular, the earliest works by Shamir and Howard, (1979), Walski and Pelliccia (1982) and Male et al. (1990) provided general guidelines for evaluating whether a pipe should be replaced/rehabilitated during a given planning horizon according to mainly economic criteria. Later on other criteria have been considered such as those aimed at reducing pressure deficiencies (Walski, 1985), improving water quality and system flexibility (Halhal et al., 1997) and reducing pumping costs (Kim and Mays, 1994).

Another crucial rationale included in some work, is the maximization of network reliability (Quimpo and Shamsi, 1991; Todini, 2000; Dandy and Engelhardt, 2006), although the common definition of WDS "reliability" has not been agreed upon. In a recent paper, Berardi et al. (2008) also demonstrated the effectiveness of accounting for leakage reduction and actual valve deployment while selecting pipes to be replaced.

The problem of selecting the most effective rehabilitation intervention is discrete, because of the limited commercial rehabilitation alternatives, and combinatorial, as it is aimed at pointing out a subset of pipes within the network. In recent years, the problem of selecting optimal rehabilitation action has been solved by using multi objective genetic algorithms (MOGA) (Goldberg, 1989; Savic 2002). They represent heuristic search-and-optimization techniques particularly suited for discrete and combinatorial problems. MOGA are usually able to return good approximations of the so-called theoretical "Pareto optimal set", which consists of the best set of trade-offs between all (conflicting) objectives. The interest of the scientific community in the use of MOGA in such a context is documented in many papers (e.g. Halhal et al., 1997; Cheung et al., 2003, Dandy and Engelhardt, 2006). Nonetheless, most literature only focuses on refining some objective functions or comparing the performance of different GAs. It is quite unusual to look at the decision process; this is usually left to decision makers without considering how complex this process could be for them starting from MOGA solutions. In fact, the number of technically optimal alternatives increases with the amount of objective functions and rehabilitation options involved in the optimization. Moreover, solutions which are economically comparable involve the selection of different interventions for the same pipes (i.e. solutions are not *contiguous*) (Giustolisi et al., 2006). Such evidence could potentially leave the decision maker in a quandary over the selection from MOGA solutions.

Recently, Berardi et al. (2008) demonstrated the effectiveness of assigning priority to each pipe when the problem is to select pipes for replacement (without changing their diameter) on a real WDS and optimizing 5 objective functions. That procedure was used to create a new set of *contiguous* interventions by adding pipes according to their priority up to the monetary budget available. Such a procedure differs from other existing "priority" models (for example Quimpo and Shamsi, 1991) as it explicitly accounts for the expected behaviour of the rehabilitated system as a whole.

This work enlarges the discussion reported in Berardi et al., (2008) by considering a wider range of rehabilitation alternatives rather than a binary decision

variable. Without loss of generality, the decision variables reported here refer to the options of "do-nothing" or "replace by selecting pipe diameter". For each pipe to be replaced the new diameter is selected from a set of commercial sizes. In spite of the fact that other rehabilitation options (i.e. different from replacement) are still not explicitly considered here, it can be argued that changing a pipe's diameter means to change its carrying capacity which produces a similar effect to that expected from other techniques (i.e. relining). On the other hand, it allows a simpler cost analysis to be included in this work and the implicit assumption of improving pipe structural condition. Furthermore, the main aim of the paper is not to show how specific rehabilitation technologies could be introduced for developing a DSS, but rather to discuss the use of the prioritization strategy (Giustolisi et al., 2006a, Berardi et al., 2008) in a more complex decision scenario.

MULTI-OBJECTIVE WDS REHABILITATION PROBLEM

The brief literature review reported above clearly shows that the selection of the best course of action for WDS rehabilitation is a multi-objective problem where each criterion should be represented by a specific objective function. The main advantages of adopting a multi-objective (MO) approach instead of a single-objective (SO) approach are: (1) defining the objective functions independently from each other and with simple mathematical formulations, (2) searching for several optimal solutions instead of just one "best" solution (as in SO optimization), (3) obtaining a set of "optimal" solutions which represent the final decision support (Savic, 2002). The evaluation of solutions in a MO optimization context is based on the so-called Pareto domination concept (Pareto, 1896-7). Each solution of the "Pareto optimal set" is *not dominated* by any other solution, i.e. in going from one solution to another, it is not possible to improve on one objective (e.g. reduce the risk of future failure) without making at least one of the other objectives worse (e.g. increase cost). Unlike in SO approaches (Halhal et al., 1997), the Pareto domination criterion allows immeasurable objectives to be considered without merging them into a weighted function.

In this work six objective functions are considered in order to emphasize the MO nature of a realistic decision context. They are listed below.

f_1: minimization of the investment required;
f_2: minimization of the expected cost of pipe breaks in one year time horizon;
f_3: fulfilment of preferential selection of some pipes;
f_4: maximization of system reliability;
f_5: optimal work allocation based on existing deployment of isolation valves;
f_6: maximization of expected leakage reduction.

The next sub-sections briefly report the mathematical formulation of each objective function; for further details the reader is referred to Berardi et al. (2008).

The possible decisions for each pipe are to "do-nothing" or "replace with a new diameter". It is evident that such an optimization problem differs conceptually from the previous one as the selection of a new diameter for replaced pipes affects the performance of the whole existing network. This means that two equally advisable solutions (i.e. similar objective function values) could refer to completely

different rehabilitation decision (i.e. different deployments of diameters) and network expected performance.

Investment (f_1). It represents the sum of all direct costs of pipe replacement and its formulation is reported in Eq. (1)

$$f_1 = \underset{R}{Min}\left(\sum_{p \in R} C_{repl} \cdot L_p \right) \tag{1}$$

C_{repl} represents the cost of replacement per unit length and is presumed to change according to pipe diameter; L_p is pipe length and R stands for the set of pipes selected for replacement.

Expected cost of pipe breaks (f_2). This objective function is based on a pipe failure prediction model. In literature several models have been proposed to predict pipe failures ranging from physically based to statistical approaches (Kleiner and Rajani, 2001), the latter being best suited for studying small distribution pipes. Irrespective of the model adopted, the objective function f_2 is reported in Eq. (2)

$$f_2 = \underset{R}{Min}\left(\frac{\sum_{p \in NR} D_p \cdot C_{repair} \cdot BR_p}{\sum_{p \in Net} D_p \cdot C_{repair} \cdot BR_p} \right) \tag{2}$$

where BR_p is the number of pipe breaks predicted in a one year time horizon; D_p is a "damage and other cost multiplier" which accounts for both direct and indirect costs of pipe breaks (Walski and Pelliccia, 1982; Dandy and Engelhardt, 2006); *NR* is the set of pipes not replaced; *Net* designates the whole set of pipes in the network. The choice of an annual time horizon allows urgent short-term intervention to be determined, avoiding the hypothesis of a discount rate and minimizing the uncertainties on future demand and pipe deterioration (Berardi et al., 2008). Eq.(3) returns values between 0 and 1 representing complete network replacement and do-nothing scenarios, respectively.

Preferential pipe selection (f_3). This objective allows preferences on the selection of certain pipes to be introduced into the MO decision context for WDS rehabilitation. For instance, such a selection criterion could be linked to company-specific needs for warehouse management or to policies aimed at removing/leaving undisturbed some materials (e.g. avoid removing asbestos cement pipes). Preferences on pipe selection are introduced in terms of weights w_p ranging between 0 and 1 and relevant objective function is reported in Eq.(3).

$$f_3 = \underset{R}{Min}\left(\frac{\sum_{p \in NR} w_p}{|NR|} \right) \tag{3}$$

$|NR|$ is the number of non-replaced pipes. Objective function f_3 should be minimized in order to push towards an earlier replacement of pipes with the highest preference.

System reliability (f_4). In literature there are many different definitions of water distribution system reliability (Walski and Gessler, 1999; Todini, 2000; Prasad and Park, 2004). In this work reliability analysis is based on network topology modifications resulting from the isolation of a failed pipe. In fact, when a pipe breaks, the emergency intervention requires the closure of the entire segment of the pipe concerned by shutting down the existing isolation valves. Due to the fact that real isolation valves are usually fewer than pipes, this operation could either result in unintentionally isolating other portions of the network or severe pressure drops, which could be below acceptable values. The measure of reliability adopted herein is similar to that proposed by Dandy and Engelhardt (2006) and is formulated in Eq.(4)

$$f_4 = \frac{\sum_{p \in NR} \left[\left(D \cdot Pr \right)_i + \left(D \cdot Pr \right)_d \right]_p \cdot BR_p}{\sum_{p \in Net} \left[\left(D \cdot Pr \right)_i + \left(D \cdot Pr \right)_d \right]_p \cdot BR_p} \tag{4}$$

Subscripts i and d denote the properties *isolated* (i.e. intentionally and unintentionally forced out of service) and *deficiently* supplied due to isolation of the segment containing the (failed) pipe p, respectively. Pr is the number of properties affected by segment closure; without loss of generality D is the same cost multiplier as in f_2; BR_p is the number of pipe breaks predicted over the planning time horizon. Computing f_4 requires the topological analysis of the network resulting from the isolation of each pipe segment (i.e. dependent on actual valve deployment) and the "pressure-driven" hydraulic simulation under the peak-hour demand scenario, which is the most critical in terms of pressure drops. Eq. (4) encompasses the realistic case of multiple emergency interventions within the same pipe segment and returns values between 0 and 1.

Optimal work allocation (f_5). An optimal rehabilitation plan should both minimize emergency service interruptions and avoid multiple planned works within the same area. In this paper such a selection criterion is based on the reasonable assumption that each pipe segment coincides with a service area. Hence, minimising the number of pipe segments affected by planned interventions would result in minimizing multiple service interruption for the same customers.

$$f_5 = \frac{|S_R|}{|S_{Net}|} \tag{5}$$

$|S_R|$ is the number of isolated segments and $|S_{Net}|$ is the number of all segments in the network.

Expected leakage reduction (f_6). Irrespective of the rehabilitation options included among decision variables, the selection of a pipe for intervention is assumed to coincide with (at least) its inspection and repair of possible detected leakages from joints and fittings. Accordingly, there is an opportunity of gaining the quickest

leakage reduction by means of rehabilitation interventions. Eq. (6) is assumed here to describe leakage reduction objectives. It slightly differs from that used in Berardi et al. (2008) because in the present decision problem, pipe diameters resulting from complete network replacements are still unknown. This fact prevents an upper bound of leakage reduction from being defined, thus f_6 is not scaled in [0, 1].

$$f_6 = Q_R^L \tag{6}$$

$Q_R{}^L$ is the total leak flow through pipes during the minimum demand hour, which is the most critical from a leakage perspective because pressure tends to be at a maximum. Such an objective requires network simulation for each rehabilitation solution evaluated during the optimization run.

All the hydraulic simulations in this work have been consistently performed by using the "pressure-driven" hydraulic simulator proposed by Giustolisi et al. (2008a, 2008b) It incorporates the pressure-leakage relationship of Germanopoulos and Jowitt (1989) where the k-th pipe leakage flow is $q_k=\beta_k L_k P_k{}^{\alpha}$, with L_k pipe length and P_k pipe average pressure. The effects of the k-th pipe rehabilitation are modelled by assuming a new leakage coefficient β_N (less than the present value β_0) and a reduced internal roughness in pipes. The automatic detection of network topological changes is performed here by using a recently developed algorithm (Giustolisi and Savic, 2008c) which shares the same matrix representation of network topology as that adopted into the hydraulic simulator, thus making their integration easier.

CASE STUDY

The network analyzed in this work is named "Apulian_1" and has been presented in several previous studies (for example Giustolisi et al., 2008b). Its layout is reported in Figure 1 where the existing valves are also depicted in order to visualize the pipe segments to be isolated when an intervention (either planned or emergency) is required. The main network data are reported in Table 1. Due to the lack of both recorded failures and age information, values of BR_p are obtained by assuming that all pipes are 30 years old and that 27 pipe breaks have been recorded in 14 years of monitoring. The failure prediction model used herein is reported in Eq. (7) (Giustolisi and Berardi (2007) and is based on the Evolutionary polynomial regression (Giustolisi and Savic, 2006) technique.

$$BR = a \cdot \frac{Ae^{1.5} Lt}{De} \tag{7}$$

It has been proved to be reasonably accurate for describing the total number of pipe bursts expected for homogeneous pipe classes with the same age (Ae) and diameter (De) for 48 different WDS. Lt stands for the total length of pipes in the class while a is a regression parameter which depends on the particular system analyzed (a= $1.24 \cdot 10^{-3}$ in this case). Without additional information on individual pipe history, the number of individual pipe failures BR_p is assumed to be proportional to its length. It

is worth noting that values of BR_p<1 should be interpreted as a propensity to future pipe breaks.

Table 1. Node and pipe data of "Apulian_1"

Node	Demand q_{design} [l/s]	Elevation [m]	Minimum pressure [m]	Pipe	Length [m]	Diameter [mm]	*Pr*	BR_p

				34	158.2	368	0	0.0078

In Figure 1 pipes 8, 25, 27 and 30 are put into a box because they are assumed to be *preferred* for selection. Note that their choice does not follow any specific strategy, but rather provides an example of including any type of preference into the DSS. The preferences are deliberately set w_p=0.5 for these pipes and w_p=0 for the others.
Figure 2 depicts the demand fluctuation assumed for "Apulian_1" with respect to the peak hour demand, as described in the second column of Table 1. It is evident that the two extreme demand scenarios are 8.00 a.m. (peak demand) and 1.00 a.m. (lowest demand and peak average system pressure). The former scenario is used for assessing system reliability (f_4) and the latter for estimating the leakage level (f_6).

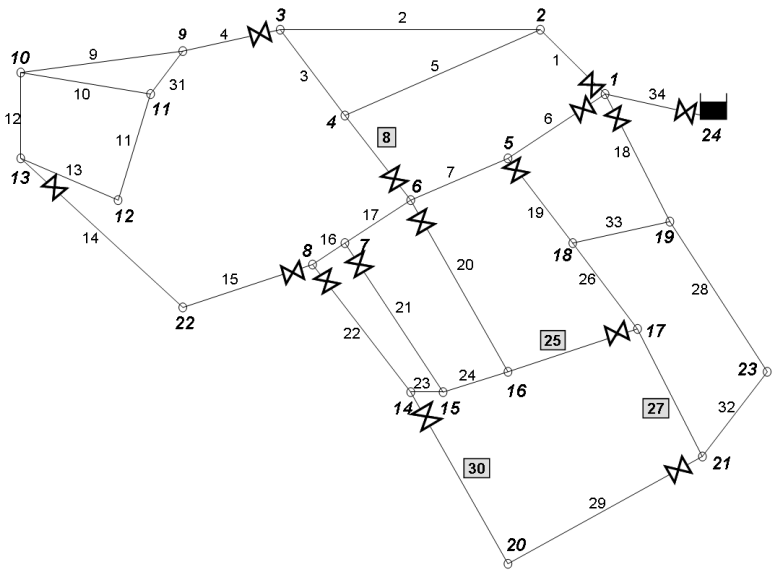

Figure 1. Layout of the network "Apulian_1"

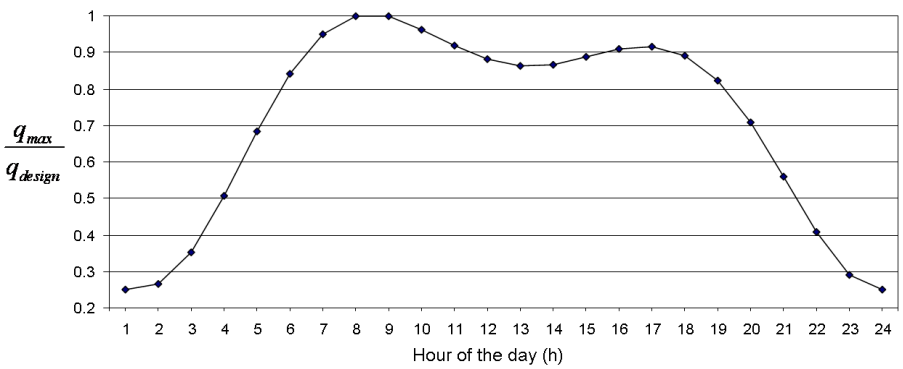

Figure 2. Daily demand pattern

Table 2. Repair and replacement cost

Index	Diameter [mm]	Repair cost [$/break]	Replacement costs [$/m]
1	100	572.00	62.00
2	164	637.42	73.20
3	184	654.56	80.71
4	204	671.96	88.21
5	229	694.10	97.21
6	258	726.07	107.41
7	290	782.49	118.23
8	327	886.58	125.70
9	368	977.47	137.89

Repair and replacement costs are reported in Table 2; the cost multiplier Dp = 1.5 for all pipes means that all properties are assumed to be domestic (Berardi et al., 2008).

A leakage coefficient $\beta_0 = 2.35 \cdot 10^{-7}$ is assumed for all pipes in the network due to the assumption that present water loss equals 25% of the peak hour demand; the leakage coefficient for replaced pipes is $\beta_N = 2.71 \cdot 10^{-8}$ as estimated from the realistic assumption of a residual water loss of 5% in the peak hour. $\alpha = 1.2$ in both cases. Furthermore, new pipes are assumed to have a Bazin's roughness coefficient $\gamma_N = 0.10 m^{1/2}$, lower than $\gamma_N = 0.20 m^{1/2}$ of old pipes.

FROM MOGA SOLUTIONS TO OPERATIONAL DSS

The MO problem is solved by using a Multi-Objective Genetic Algorithm called OPTIMOGA (Giustolisi et al., 2004). Each solution (individual) is comprised of 34 genes (i.e. decision variables) whose values (alleles) range between 0 and 9: 0 signify leaving the pipe undisturbed, while values 1-9 indicate the new diameter of the replaced pipe according to Table 2. The size of the resulting search space is 10^{34}. Although the search space could be significantly resized by reducing the range of diameters allowed for each pipe (e.g. according to technical expertise on WDS design), the present analysis aims to perform a global exploration of the search space without including additional information.

One single OPTIMOGA run (500 generations) returned about 5,000 solutions. As in other literature case studies, there are considerable differences between the rehabilitation options of equally expensive solutions. This makes it difficult to outline the best course of action without any additional selection strategy.
The prioritization strategy proposed here exploits MOGA solutions to retrieve information about the most advisable interventions. Pipes are initially sorted according to their frequency of selection for replacement (i.e. alleles values from 1 to 9) among MOGA optimal solutions. This first ranking helps point out the most critical pipes in the network (i.e. whose replacement could effectively improve system performance). Based on this additional information, analysts could proceed with a new optimization targeted at those pipes only. This "step-by-step" procedure would allow for a smaller search space to be investigated in the next optimization run and a less complex set of solutions to be provided to decision maker.
Alternatively, a second further sorting could be applied. This would be based on the distribution of diameters selected for each pipe and is aimed at getting the most advisable course of action starting from the original MOGA solutions. This strategy requires that each pipe is replaced by using the most frequently selected diameter. The set of interventions to be planned is then obtained by progressively adding replacement solutions up to the complete renewal of the network. The histograms in Figure 3 refer to the pipes of "Apulian_1" sorted according to their priority for replacement (pipe indices are in brackets). The "do-nothing" option is designated with "N" while diameter indices are 1-9. It shows that 3 out of 4 preferred pipes are selected for replacement within the first 9 interventions (i.e. pipes 8, 25, 27). Moreover, pipe 34 connecting the water tank to the rest of the network is one of the less important for replacement (it is the 29th most advisable intervention). This is consistent with the complete system isolation needed for its planned replacement. Nonetheless, the risk of its future failures and emergency system isolation make it preferable over pipes 16, 31, 17, 15 and 22.

Each sub-plot reports in black and white the diameter of the present network configuration (as reported in Table 1), and in solid black the percentages of selection among all MOGA solutions. For some pipes (e.g. #8, #5 and #28) there is only one predominant diameter which coincides with the original one. For other pipes (e.g. #1, #6 and #27) the most frequently selected diameter is very different from the original one, and it is usually smaller than the existing one.

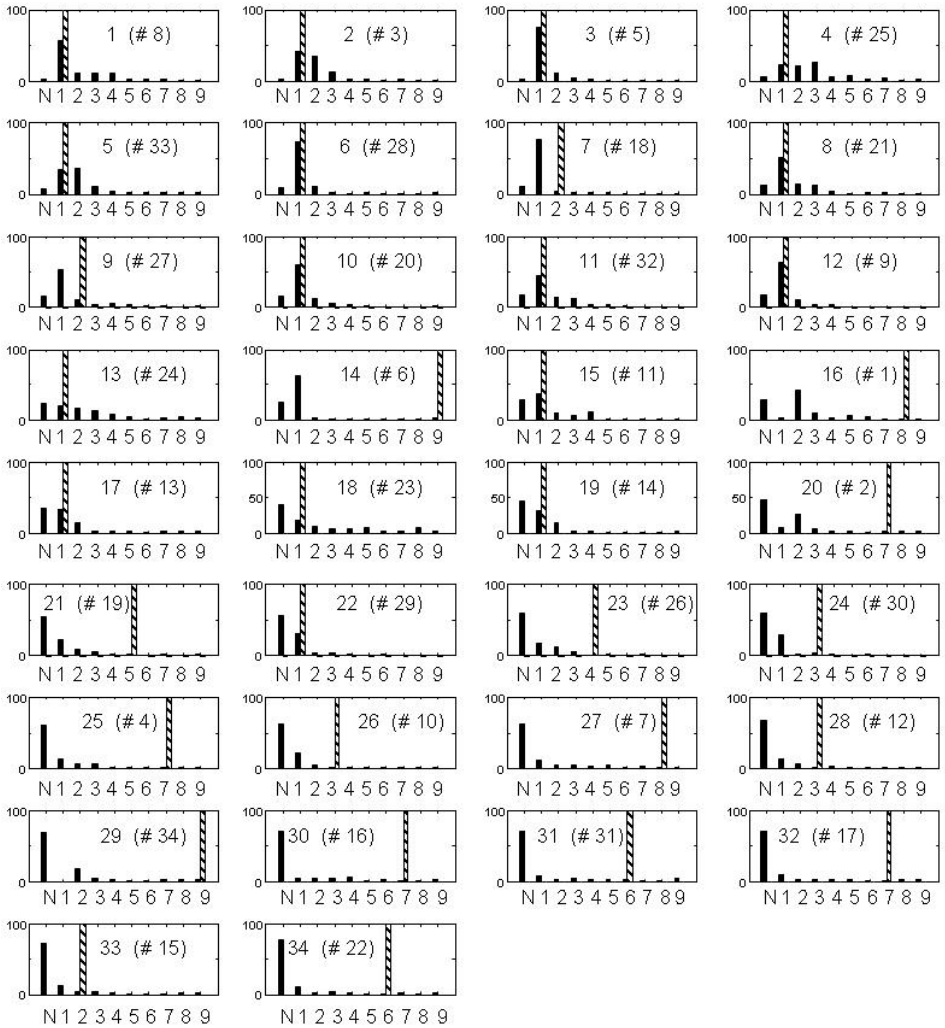

Figure 3. Statistics of pipe diameters in MOGA solutions

An operational DSS for planning interventions is obtained here by selecting pipes according to the priority shown in Figure 3. Relevant diameters are the most frequently selected. A set of 34 hypothetical new solutions is obtained by progressively adding such replacement works. However, differently from previous results (Berardi et al., 2008), not every solution is acceptable. In fact, after replacing the 27th pipe (i.e. #7 in Figure 1) with diameter 100mm instead of 327mm, the resulting network configuration no longer meets the minimum pressure required

during the peak demand hour (i.e. 10m). Nonetheless, the first 26 interventions (more than 76% of the complete network replacement) are still Pareto optimal if compared with MOGA solutions and with each of the other new solutions. The following Table 3 reports the incremental variation of each objective function achievable by replacing any individual pipe, up to the 26th intervention. Δf_1 is pipe replacement cost; Δf_2 is the reduction of breakage risk; Δf_3 is the fulfillment of preferential selection (it decreases for preferential pipes only); Δf_4 is the reduction of system unreliability; Δf_5 is 1 when a new pipe segment is isolated; Δf_6 is the percent reduction of leakage flow with respect of the do-nothing option at the peak-pressure hour (i.e. 1.00 a.m.).

Table 3. Incremental variations of objective function values.

CONCLUSIONS

In this paper the planning of WDS rehabilitation works is formulated as a multi objective problem with six objective functions and multiple intervention alternatives. The solution returned by applying a multi-objective genetic algorithm is analysed from a decision maker's perspective. The adoption of a prioritization strategy is discussed in order to overcome the ambiguities stemming from MOGA solutions and to plan effective courses of action. In this case study the rehabilitation

strategy obtained is Pareto optimal up to the replacement of the 76% of the network. Although different "off-line" prioritization strategies could be adopted, future works should investigate the effects of including a prioritization strategy during the MOGA run ("on-line" prioritization) in order to obtain contiguous and Pareto-optimal solutions to be easily analysed by decision makers.

Abstract

In the first place, this paper presents an examination of the effects of missing cadastral information on the modeling and calibration of water distribution networks (WDN). For this purpose, cadastral errors were artificially introduced to the hydraulic models of the WDN of three cities of the province of Valle del Cauca (Colombia), with population in the range of 15,000-30,000 inhabitants. The cadastral errors were introduced by eliminating some pipes from the unaltered models using the resilience index as selection criterion. From this examination, typical responses observed during the calibration process were associated to specific topological and hydraulic errors and it was also noted that there is a direct relation between the resilience index and the effect of the removal of a certain pipe on the hydraulic performance of the model. In the second place, after identifying the effects of missing and erroneous cadastral and hydraulic information on the calibration of WDN models, the inverse procedure was carried out: the calibration process was used as a tool for detecting missing and erroneous cadastral and hydraulic information. This methodology was successfully applied to the WDN of Sector Estadio (250,000 inhabitants), which is a complex area of the city of Bucaramanga (Colombia); through the calibration of this WDN, errors such as failing water meters, pipes and valves that existed in the real system but were not in the model, significant errors in pipe diameters in the model, among others, were identified.

1. Introduction

In order to optimize the operation of water distribution networks (WDN) and make effective decisions regarding their maintenance, rehabilitation, and enlargement, among other issues, good-quality calibrated models are necessary. The calibration of a WDN model consists of adjusting the model input parameters in such a way that model performance matches the measured system performance over a wide range of operating conditions (Walski et al, 2001).

To carry out the calibration of a WDN, complete cadastral information, as well as measurements of discharge at the entrance of the system, of water consumption and pressure at demand nodes are required. These measurements must cover a rather long time period, so that the system performance over a representative range of operating conditions is known. During the calibration process, several scenarios in which different values are given to each input parameter are created and, for each scenario, extended period hydraulic simulations are carried out; the calibration process finishes when a scenario whose performance reasonably agrees with measured system performance is found.

Although it may sound like a simple procedure, in many cases, especially in developing countries, the cadastral information is incomplete or erroneous, making the calibration process complicated and impeding the achievement of a good-quality hydraulic model. This is the reason why it is necessary to have a tool, within the calibration process, with which cadastral misinformation can be detected. In view of this necessity, this paper presents an analysis of the effects of missing and erroneous cadastral information on the hydraulic simulation and calibration of WDN models. Furthermore, from the results obtained in this analysis, a methodology is proposed which uses the calibration of WDN as a tool for detecting missing and erroneous cadastral and hydraulic information.

2. Theoretical background

2.1. Calibration methodology (Jurado and Saldarriaga, 2007)

As mentioned before, the calibration of a WDN model consists in adjusting the parameters that rule its hydraulic behavior. The calibration parameters taken into account by the methodology developed by the authors (Water Distribution and Sewer Systems Research Center – CIACUA) can be divided into hydraulic and topological ones. Among the hydraulic parameters are the unknown demands and node's emitters (i. e. emitters' coefficients and exponents), whereas among the topological ones are the pipes' internal diameters, absolute roughness, and minor losses. The calibration methodology is summarized in Figure 1.

In Figure 1, *Initial Model* corresponds to the first hydraulic-digital model which is obtained after processing and digitalizing all the topological and consumption information provided by the WDN operator. It contains nominal diameters, theoretical roughness coefficients, and does not take into account minor losses and Non-Revenue Water (NRW) records; thus, the hydraulic simulations carried out with this *Initial Model* do not match the pressure and discharge field measurements.

Base Line 1 is obtained by assigning the real internal diameters (according to the manufacturer's catalogues) to all pipes and also by assigning minor losses per meter of pipeline to each pipe of the model (for this purpose, typical values of minor losses per meter that have been found in previous calibrations are used). The minor losses To carry out the next steps of the methodology, the WDN must be first divided into groups or sectors with similar hydraulic, topologic and socioeconomic characteristics.

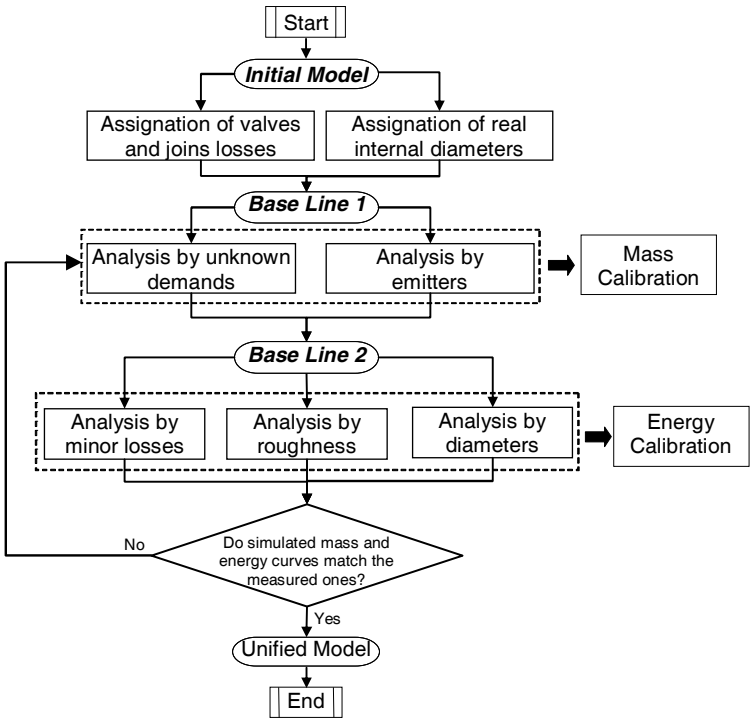

Figure 1. Calibration algorithm (CIACUA)

The *Analysis by unknown demands* is performed by creating several scenarios in which different multiplying factors are applied to the base demand of each group of nodes; this is done with the purpose of calibrating the system's mass (i. e. to balance the mass that goes into the system and the mass that goes out of it). With this analysis, it is possible to detect areas with high commercial losses (unaccounted demands, unknown demands, and/or illegal connections). In the *Analysis by emitters*, scenarios are created in which different values of the emitter's coefficient are assigned to the nodes of each group or sector; this analysis intends to simulate the technical losses that take place in the real system and to adjust the discharges and pressures of the WDN model to the measured ones. *Base Line 2* is obtained after compiling the results achieved from the two previous independent analyses (i. e. *Analysis by unknown demands* and *Analysis by emitters*). In *Base Line 2* the mass curves of the model must coincide with the measured ones and a good approximation to the measured pressure or energy curves must be achieved. Afterwards, a sensibility analysis of the hydraulic variables (i. e. pipe's internal diameters, absolute roughness, and minor losses coefficients) is carried out: scenarios in which different values of these variables are assigned to the pipes of each group or sector are created. The *Analysis by minor losses* evaluates the effect of fittings and other accessories, which generate minor energy losses, on the hydraulic behavior of the system. In the *Analysis by roughness* and in the *Analysis by diameters*, slight variations of the pipes' absolute roughness and internal diameter are carried out taking into account the pipes' material and medium flow velocity; the effects of such variations on the hydraulic behavior of the system are analyzed. Lastly, the *Unified Model* is created by compiling and iteratively adjusting the results obtained from the previous analyses: given that the adjustments made in the analyses by minor losses, roughness and diameters may

affect the mass curves that had been previously calibrated through the analyses by unknown demands and emitters, an iterative process in which small adjustments are made to all these variables (i. e. unknown demands, emitter's coefficients, minor losses per meter, absolute roughness, and pipes' internal diameters) must be carried out until the simulated curves of discharge and pressure coincide with the measured ones. Thus, the *Unified Model* corresponds to the calibrated model.

2.2. Resilience index (I_r)

The concept of network *resilience* was introduced by Ezio Todini in 2000; he defined it as "… the capability in the system to allow to overcome local failures and to guarantee the distribution of water to users…". The resilience index (I_r) is an indicator of the network *resilience*; it is a measurement of the system vulnerability of letting some nodes without service in the occurrence of a failure (Saldarriaga et al., 2007). In order to describe the concept of network *resilience*, Tondini introduced the concept of power: the total power of a WDN (P_{tot}) is defined as the sum of the power that is supplied by reservoirs and the power that is supplied by pumps:

$$P_{tot} = \gamma \sum_{i=1}^{n_r} Q_i H_i^* + \sum_{i=1}^{n_p} P_{pi}$$

where Q_i and H_i^* correspond to the flow and piezometric pressure of each of the n_r entrance reservoirs and P_{pi} is the power supplied by each of the n_p pumps. The total power of the system can also be expressed as the sum of the power that is dissipated by means of friction and because of the existence of leaks (P_{dis}), plus the power that is delivered at demand nodes (P_{out}), as shown in the following equation:

$$P_{tot} = P_{dis} + P_{out} \tag{1}$$

The power that is delivered at consumption nodes (P_{out}) can be classified in two ways: as the objective delivered power (P_{out}^{obj}), which is generated when all consumption nodes have the minimum service pressure; and as the real delivered power (P_{out}^{real}), which takes place under real service pressure conditions. P_{out}^{obj} and P_{out}^{real} are estimated as shown:

$$P_{out}^{obj} = \gamma \sum_{i=1}^{n_n} q_i h_{i,\min}^* \qquad\qquad P_{out}^{real} = \gamma \sum_{i=1}^{n_n} q_i h_i^*$$

where q_i, h_i^* and $h_{i,\min}^*$ correspond to the flow, real piezometric pressure, and minimum required piezometric pressure in each of the n_n consumption nodes of the system. From equation 1: $P_{dis} = P_{tot} - P_{out}$. From this equation and given P_{out}^{obj} and P_{out}^{real}, it is possible to define mathematical expressions to estimate the optimum and real dissipated power:

$$P_{dis}^{obj} = P_{tot} - P_{out}^{obj} \qquad P_{dis}^{real} = P_{tot} - P_{out}^{real}$$

The I_r of a WDN is defined as a function of the relationship between the objective dissipated power (P_{dis}^{obj}) and the real dissipated power (P_{dis}^{real}):

$$I_r = 1 - \frac{P_{dis}^{real}}{P_{dis}^{obj}}$$

When substituting in this equation the terms previously described, a general equation for the I_r is obtained:

$$I_r = \frac{\sum_{i=1}^{n_n} q_i \left(h_i^* - h_{i,\min}^* \right)}{\left[\sum_{i=1}^{n_r} Q_i H_i^* + \sum_{i=1}^{n_p} P_{pi} \right] - \sum_{i=1}^{n_n} q_i h_{i,\min}^*}$$

3. *Resilience Index vs. impact of the removal of a certain pipe on the hydraulic behavior of the WDN model*

As mentioned above, with the aim of evaluating the effects of missing cadastral information on the modeling and calibration of WDN, cadastral errors were artificially introduced to the hydraulic models of the WDN of three cities of the province of Valle del Cauca (Colombia). The cadastral errors were introduced by eliminating some pipes from the unaltered models using the resilience index (I_r) as selection criterion. In order to use the I_r as indicator or selection criterion, an analysis was first conducted to determine the relationship between the effect of the removal of a certain pipe on the I_r and on the hydraulic behavior of the system. The first step of this analysis was to calculate the hydraulics of the system without cadastral errors, to estimate its I_r, and to identify the pipes that could be removed without letting any consumption node disconnected. From now on, these pipes will be referred to as "removable pipes". Subsequently, one at a time, each of the removable pipes was removed from the unaltered model; for each of the models without a certain removable pipe, the system hydraulics and the I_r were calculated. With this information, the difference between the I_r of the unaltered model and the I_r of the model without one removable pipe was calculated; this difference will be referred to as ΔI_r. Besides, the pressure curves of the models without one removable pipe were estimated and compared against those of the unaltered model or prototype. Thus, it was possible to analyze the relationship between the change on the resilience index (ΔI_r) and the capacity of the model without one removable pipe to adequately reproduce the hydraulics of the prototype. This analysis was carried out for the WDN of three cities of the province of Valle del Cauca (Colombia): La Cumbre, Andalucía and Candelaria, which have varied topography and a population in the range of 15,000-30,000 inhabitants. For the three case studies, similar results were obtained. Next, the results found for the WDN of Andalucía are presented. In this network, 190

of the total of 360 pipes were identified as removable ones. Thus, 190 models were created in which one single pipe was removed. For each of these models, the pressure time series (i. e. values of pressure at different times of the day) at each of its nodes were compared to those of the nodes of the prototype; for every value of pressure at a certain node and time, a relative error was estimated as follows:

$$Relative\ Error\ in\ Pressure_{ij} = \frac{\left|P_{ij\ unaltered} - P_{ij\ mod\ ified}\right|}{P_{ij\ unaltered}} * 100\%$$

where *i* corresponds to the time of the day and *j* to the node of the system for which the relative error in pressure is calculated; the subindex "*unaltered"* refers to the pressure in the prototype or complete model and the subindex "*modified"* refers to the model without one removable pipe. In this case, the pressure at each node was calculated every 15 minutes. After estimating the relative error for each node at each time of the day, the average relative error was calculated. Figure 2 illustrates the relationship between the ΔI_r caused by the removal of a certain pipe and the average relative error in pressure observed in the model without that pipe.

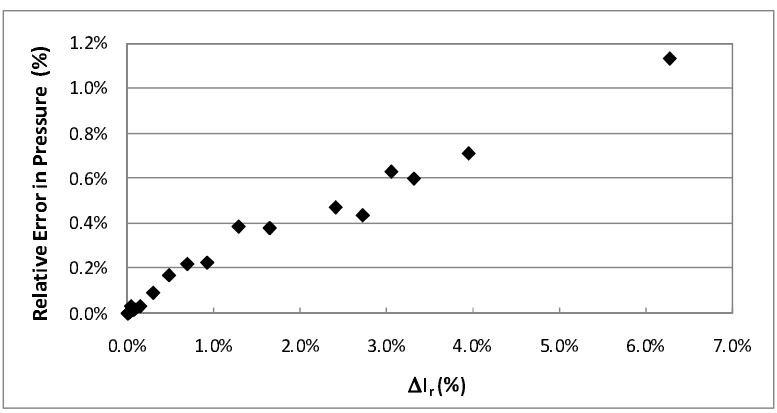

Figure 2. Change on the resilience index (ΔI_r) vs. relative error in pressure caused by the removal of a certain pipe from the model.

It can be noted that, in general, as the ΔI_r increases, the relative error in pressure also increases; it means that, when the removal of a pipe generates a great change on the resilience index of the network, the model without that pipe cannot accurately reproduce the hydraulic behavior of the prototype. Likewise, if a pipe that has a little impact on the resilience index of the network is removed, it does not affect in a significant manner its hydraulic behavior and the reduced model can adequately reproduce the hydraulics of the prototype.

4. Effects of cadastral misinformation on the calibration of WDN models

Normally, in the application of the calibration methodology described above (see Figure 1), a complete knowledge of the WDN topology is assumed. Therefore, the range of variation of the pipes' internal diameters during the calibration process is very narrow: in this process, the magnitude of the internal diameters is slightly varied

with the purpose of accounting only for pipe wall erosion or for biofilm growth. Nonetheless, as will be next explained, the only way in which a model with major cadastral errors can be calibrated is by significantly increasing the diameters of the pipes which are close to the missing element or cadastral error; this increase in the diameters gets to compensate the greater energy losses caused by the higher velocities that take place in adjacent pipes when the cadastral error is introduced. For this reason, the calibration algorithm was modified in such a way that greater variations in pipes' internal diameters were allowed during the calibration process.

Case Study: La Cumbre's WDN model (CIACUA, 2006)

To illustrate the effects of cadastral misinformation on the calibration of WDN models, the results obtained for the calibration of a hydraulic model of La Cumbre's WDN in which an important cadastral error was introduced are presented. In this model, the pipe with the highest impact on the system's I_r was removed (the ΔI_r caused by its removal is 13.09%), causing the greatest effect on the hydraulic behavior of the WDN model. It is worth mentioning that similar results were obtained for the calibration of Candelaria's and Andalucía's WDN models.

Initial Model and Base Line 1: These models were set up by digitalizing the existing topological and consumption information and by assigning real internal diameters and minor losses coefficients according to the manufacturer's catalogues and existing statistical information; these actions correspond to the first Scenario of Table 1. Moreover, in this phase, the mentioned cadastral error was artificially introduced and the network was divided into 6 groups according to the hydraulic, topologic and socioeconomic characteristics of each area of the WDN.

Base Line 2: In order to obtain the *Base Line 2* model, 13 scenarios were analyzed in which different multiplying factors were applied to the base demands of each group of nodes and different values of the emitter's coefficient were assigned. By doing this, it was possible to evaluate the sensibility of the WDN to the presence of leaks and unknown demands. The 13 scenarios that were analyzed and the first scenario, in which real internal diameters and minor losses were assigned, are shown in Table 1. From the creation and analysis of these scenarios, a model was achieved in which the discharge or mass curves coincide almost perfectly with the measured curves. Besides, the obtained model (*Base Line 2*) can reproduce, with an acceptable degree of accuracy, the pressure or energy curves at one of the pressure measuring points (Element 20); in the other measuring points (e. g. Element 204), the cadastral error (i. e. the removed pipe) has a sever effect on their energetic behavior and the simulated curve is below the measured one. These results are illustrated in Figure 3.

Subsequently, in order to calibrate the energy of the WDN and adjust the simulated pressure curves to the measured ones, the *Analysis by diameters* is performed.

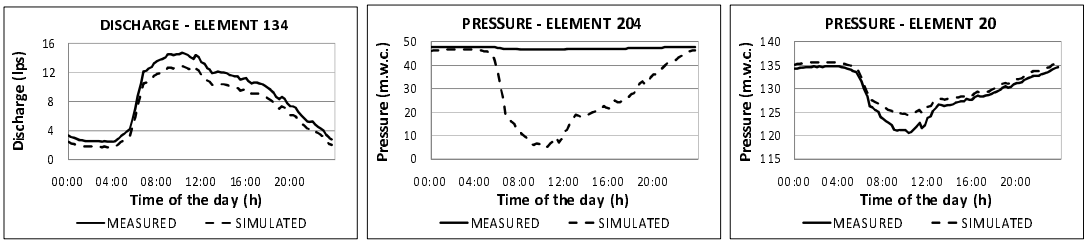

Figure 3. Discharge and pressure curves - Scenarios 1-14, *Base Line 2*, La Cumbre

Table 1. Scenarios 1-14. *Base Line 2*, La Cumbre

Scenario	Actions or variations
Scenario 1	PVC Pipes - k_m of 0.04 per meter
	AC Pipes - k_m of 0.05 per meter
	Real Internal Diameter PVC and Steel
	Assignation of k_m to known valves
	Assignation of k_m of 0.2 to each valve
Scenario 2	Nodes SEL 1 - Demand*1.2
	Nodes Group 1 - Demand *0.8
	Nodes Group 2 - Demand *3.6
	Nodes Group 3 - Demand *1.1
	Nodes Group 4 - Demand *1.2
Scenario 3	Nodes Group 3 SEL 1 -- Demand *2.3
	Nodes Group 6 SEL 1 - Demand *0.7
Scenario 4	High Pressure - Emitter Coefficient = 0.0002
	Medium Pressure - Emitter Coefficient = 0.0001
	Low Pressure - Emitter Coefficient = 0.000001
Scenario 5	SEL 1 - Emitter Coefficient *1.25
	Steel Pipes - Emitter Coefficient *1.25
	Very high pressure - Emitter Coefficient *5
Scenario 6	Nodes Group 1 - Demand *0.5
Scenario 7	Nodes Group 2 - Demand *1
Scenario 8	Nodes Group 3 - Demand *0.8
Scenario 9	Nodes Group 4 - Demand *0.8
Scenario 10	Nodes Group 4 - Demand *1
Scenario 11	Nodes Group 4 - Demand *1.1
Scenario 12	Nodes Group 4 - Demand *1.05
Scenario 13	Nodes Group 3 - Demand *1.3
Scenario 14	Nodes Group 3 - Demand *1.35

SEL = Socioeconomic Level

Analysis by diameters: In this analysis, 5 scenarios were created in which different multiplying factors were applied to the internal diameters of the pipes of each group; these scenarios are shown in Table 2. Such variations in the internal diameters were performed with the purpose of calibrating the pressure curves, without modifying the behavior of the discharge curve, which was already calibrated in *Base Line 2*. This analysis showed that the increase of the internal diameters of the pipes of groups 2 and 5, which are the closest ones to the error, was the only action capable of raising the simulated pressure curves and bringing them close to the measured ones. Besides, it was found that the simulated discharge curves would remain close to the measured ones after applying the mentioned multiplying factors to the internal diameters.

Table 2. Scenarios 15-19. *Analysis by diameters*, La Cumbre.

Scenarios	Actions or variations
Scenario 15	Group 1 - Diameters*2
Scenario 16	Group 2 - Diameters *2
Scenario 17	Group 3 - Diameters *2
Scenario 18	Group 4 - Diameters *2
Scenario 19	Group 5 - Diameters *2

Unified model: After determining that the simulated pressure curves were sensitive to the increase of the internal diameters in groups 2 and 5, more scenarios in which different multiplying factors were applied to the internal diameters of the pipes of these two groups were created in order to complete the calibration process. These scenarios are shown in Table 3.

Table 3. Scenario 20-25, Unified model. La Cumbre.

Scenario	Actions or Variation
Scenario 20	Group 5 - Diameters*2.2
Scenario 21	Group 5 - Diameters *2.4
Scenario 22	Group 5 - Diameters *2.7
Scenario 23	Group 2 - Diameters *0.9 Group 5 - Diameters *2.7
Scenario 24	Group 2 - Diameters *0.95 Group 5 - Diameters *2.7
Scenario 25	Group 2 - Diameters *0.933 Group 5 - Diameters *2.7

It was found that the 25th scenario, in which the diameters of group 2 were multiplied by 0.933 and the diameters of group 5 (where the error was located) were multiplied by 2.7, generated a model that represents in a very precise way the hydraulic behavior (i. e. mass and energy curves) of the unaltered system. These results are shown in Figure 4.

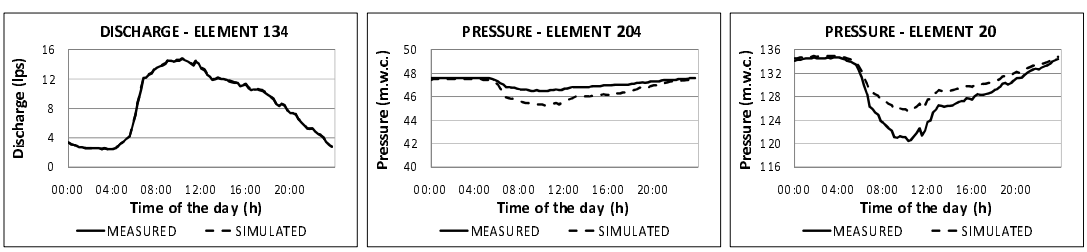

Figure 4. Discharge and pressure curves - Scenarios 20-25, *Unified Model*, La Cumbre.

It can be seen that with these adjustments, it was possible to generate a calibrated model with the presence of a significant cadastral error. Besides, it can be noted that the calibration methodology assigns greater diameters in the area where the error is located. This can be explained by the fact that, when there is an important cadastral error, such as a missing relevant pipe, the water has to flow greater distances to supply the demands throughout the network, which generates greater energy losses; the higher energy losses caused by larger distances of flow are compensated by assigning greater diameters to the pipes around the cadastral error, which reduces the

friction losses and makes it possible to calibrate the energy in the WDN model. Knowing that greater diameters are assigned to the pipes that are close to the error, it is possible to identify the areas with significant cadastral errors through the calibration process.

5. Calibration as a tool for detecting missing and erroneous cadastral and hydraulic information

5.1. Case study: Sector Estadio (CIACUA, 2007)

Sector Estadio is a hydraulic zone of the city of Bucaramanga (Colombia); it has 250,000 inhabitants and 27,000 subscribers from different socioeconomic levels. The WDN of Sector Estadio is made up of 190 km of pipeline with diameters ranging from 25 mm (1") to 600 mm (24") and pipes made of different materials, like PVC, steel, galvanized iron, among others. For this WDN, 4 discharge meters were used in order to monitor the system's hydraulic behavior and obtain the discharge curves that are required for the calibration process. One of the discharge meters was located at the entrance of the WDN, right after the supply tank; two other ones were placed each at one end of the hydraulic sector, at points where water is supplied to two other sectors of the city (sectors Bienestar and Regadero); and the other one was located at a strategic point of the network called Glorieta de San Francisco. The location of the discharge measuring stations is shown in Figure 5. On the other hand, pressure was measured at 21 measuring stations spread all over the hydraulic sector. Besides, water consumption of each subscriber was also monitored.

5.2. Division of the hydraulic model into groups

Before carrying out the calibration process, Sector Estadio's WDN model was divided into 23 groups according to the hydraulic, topologic and socioeconomic characteristics of each area of the WDN. This division is shown in Figure 6.

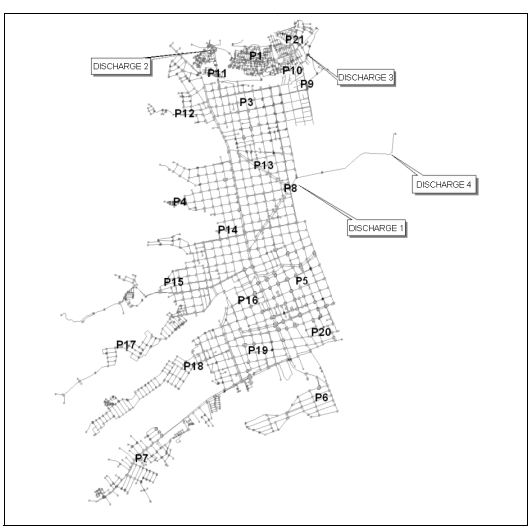

Figure 5. Location of discharge measuring stations, Sector Estadio.

Figure 6. Division of Sector Estadio's WDN model into groups.

5.3. Calibration Results

During the calibration process, several scenarios were analyzed. Table 4 shows the multiplying factors and values that were applied to the base demands, emitter coefficients and minor losses coefficients of each of the groups into which the network had been previously divided in order to obtain a calibrated model.

Table 4. Multiplying factors and values of base demands, emitter coefficients and minor losses coefficients.

Multiplying Factors of Base Demands		Emitter Coefficients		Minor Losses Coefficients	
Sector	Value	Sector	Value	Sector	Value
Group 11 (G11)	1.5	Group 7 (G7)	0.017	Group 1 (G1)	2
Group 11 (G11)	1.5	Group 1 (G1)	0.009	Group 4 (G4)	15
Group 12 (G12)	3	Bienestar	0.1	Group 5 (G5)	1
Group 15 (G15)	1.6	Regadero	0.1	Group 6 (G6)	40
Group 15 (G15)	2			Group 7 (G7)	20
Group 17 (G17)	2.5			Group 9 (G9)	10
Group 20 (G20)	1.5			Group 12 (G12)	15
Group 10 (G10)	7			Group 14 (G14)	1
Group 4 (G4)	1.5			Group 15 (G15)	1
Bienestar	1.2			Group 16 (G16)	1
Regadero	1.2			Group 17 (G17)	5
				Group 18 (G18)	1
				Group 19 (G19)	1

During the analysis by diameters, different multiplying factors were applied to each internal diameter depending on the pipe material and flow velocity. However, the multiplying factors with which a calibrated model was obtained were very small, which indicated that there were no important pipes missing in the model and that there were not significant errors in pipes' diameters either.

The calibration of this WDN model was conducted with data corresponding to high pressure regime; after the model had been calibrated, its performance was validated against data collected during medium and low pressure regimes. The performance of the calibrated model under the three pressure regimes is shown in Figure 7.

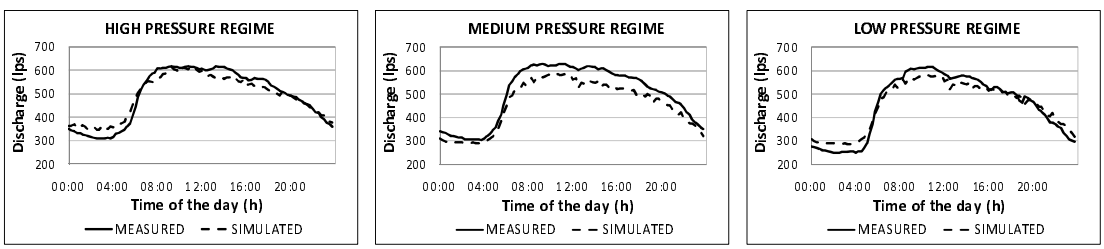

Figure 7. Performance of the Sector Estadio's calibrated model under high, medium and low pressure regimes.

5.4. Cadastral and hydraulic errors detected through the calibration process

Through the calibration process of Sector Estadio's WDN model, two important errors were found: an uncalibrated discharge meter at the entrance of the system and the existence of an unknown connection between two neighborhoods. Next, the way in which these errors were detected is described.

Uncalibrated discharge meter at the entrance of the system

During the calibration of the hydraulic model, it was found that the only way in which it was possible to adjust the simulated discharge curves (i. e. mass curves) to the measured ones was by applying an extremely high multiplying factor to the base demands of the nodes of Group 10: the multiplying factor with which the mass curves could be calibrated was 7.0 (see Table 4), which is a value outside of the normal range of variation of these multiplying factors. This abnormality suggested that there was an error close to Group 10; knowing this, an exhaustive search (both in the field and in the mathematical model) was conducted. From the field inspections, it was found that the cause of the problem was that the discharge meter located at the entrance of the system (at the exit of the supplying tank) was uncalibrated; this measuring device was overestimating the water discharges in approximately 45 l/s. The way in which the calibration process managed to balance the mass even with this error in discharge measurements, which caused an excess of water to enter the system, was by taking the water surplus out of the network in the area which was closest to the entrance (i. e. Group 10). After calibrating the discharge meter and producing new measured discharge curves, it was possible to eliminate the enormous multiplying factor that had been previously assigned to the base demands of the nodes of Group 10.

Existence of an unknown connection between two neighborhoods: Bosque Norte Alto and Villa Mercedes

When the calibrated model was being validated using data from the medium pressure regime, it was found that the model performance did not agree with the measured system performance. As shown in Figure 8, pressure measurements taken at measuring station F23, only match the simulated pressure between 6 a.m. and 6 p.m. After a detailed analysis, it was found that the only fact that could explain the measured behavior of the pressure at measuring station F23 was the existence of an unreported connection between the networks of Villa Mercedes and Bosque Norte neighborhood. In order to prove this hypothesis, the WDN operator conducted a campaign to look for the unreported connection in the field, finding the connection shown in Figure 9.

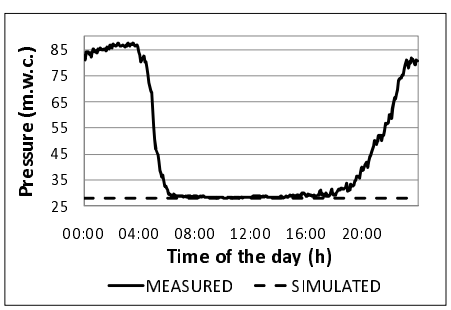

Figure 8. Simulated vs. Measured pressure at measuring station F23.

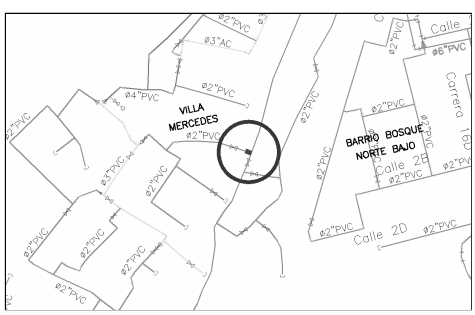

Figure 9. Unreported connection between Villa Mercedes and Bosque Bajo neighborhoods.

6. Conclusions

- The change generated by the removal of a certain pipe on the resilience index of a WDN (ΔI_r) has an inverse relationship with the capability of the reduced model (i. e. model without that pipe) to accurately simulate the hydraulic behavior of the unaltered system.
- The calibration methodology proposed herein allows to obtain a calibrated model even when there is a significant cadastral or hydraulic error in it and also makes it possible to identify the area where the error is located.
- When a relevant pipe is missing on the hydraulic model of a WDN, the calibration methodology gets to compensate the greater energy losses generated by the absence of the pipe by assigning greater diameters to the pipes that are close to the missing one; knowing this, it is possible to use the calibration methodology as a tool for detecting significant cadastral errors as like this one.
- In the same way, when there is an uncalibrated or failing discharge measuring device, the calibration methodology compensates this error in the mass of the system by applying extremely high multiplying factors to the base demands of the nodes which are close to the failing device. Thus, the calibration methodology constitutes a tool for detecting this kind of hydraulic errors.
- After identifying the effects of missing and erroneous cadastral and hydraulic information on the calibration of WDN models, the inverse procedure could be carried out: the calibration methodology proved to be an effective tool for detecting missing and erroneous cadastral and hydraulic information in WDN models.

Abstract

The southwest region of the US is facing problems with limited water resources and population growth. Some water utilities in the region are taking a proactive approach to planning that incorporates acquiring water resources in the future. Reusing treated wastewater effluent (reclaimed water) is one of the most viable solutions to expand water resources under conditions of fresh water scarcity.

Reclaimed water can be used primarily to fulfill the outdoor demands such as landscape irrigation and other non-potable water use. The possibility of treating the reclaimed water to the standards of potable water and using the same distribution system to supply the water is generally not considered to be a viable option. However, cities are studying options to provide dual distribution systems, with separate potable water and reclaimed water systems.

Traditional water master plans analyze potable water distribution systems, however with the limitations in water resources, new master plans have started to include consideration of reclaimed water infrastructure. This integrated approach to master planning will help utilities to understand the dynamics of their water sources and utilize the resources effectively. Medium-sized utilities such as the City of Surprise in Arizona have taken the initiative to implement such integrated water master planning to evaluate the feasibility of dual distribution systems.

The City of Surprise, AZ, with a planning area of nearly 300 square miles, is projected to grow from a current population of 100,000 to over 700,000 at build-out. The City is developing an Integrated Water Master Plan to provide guidance for the orderly improvement and growth of the City's water supply portfolio. The integrated

master plan consists of five components: water resources, groundwater recharge, drinking water infrastructure, wastewater infrastructure, and reclaimed water infrastructure. The three infrastructure components were studied using hydraulic models to evaluate the functionality and applicability of a dual distribution system for the growing city. The reclaimed water system was primarily evaluated to fulfill the landscape demand.

This paper summarizes the preliminary results of an integrated master planning for the City of Surprise, AZ with focus on benefits of simultaneous infrastructure master planning.

Introduction

Communities in arid areas of the country are facing problems with limited water resources. Reusing treated wastewater effluent (reclaimed water) is one of the most viable solutions to expand water resources under conditions of fresh water scarcity. The use of reclaimed water for landscaping and non-potable water uses can significantly reduce the burden on the potable water system.

Dual Distribution Systems

Dual distribution systems use separate pipe networks and facilities to supply potable and non-potable water. Rather than providing a single distribution system that provides potable water to serve all water demands, separate reclaimed water distribution systems can provide water for landscape irrigation and non-potable water uses. A reclaimed water system can be designed as a system totally separate from the potable water system or planned as a part of dual distribution system that provides reclaimed and potable water to the service area (Asano et al., 2007).

Most of the dual distribution systems in operation today consist of reclaimed water mains installed along with existing potable water pipes. Since reclaimed water can be used for non-potable water uses, smaller quantities of water would need to be treated to high potable water standards, resulting in cost saving at the treatment plant. However, a separate system necessitates the additional cost of facilities and operations. New communities, where no facilities currently exist, are in a position to optimize their systems because both reclaimed and potable systems could be built simultaneously (NRC, 2007). The cost savings realized from the reduction in potable water treatment could offset the costs of constructing two systems to some extent. Cities can adopt integrated water master plans for new developments that incorporate dual distribution systems to minimize their costs.

Sizing of most potable water systems is driven by fire flow requirements, resulting in large facilities. If non-potable water demand and fire flow could be served by a reclaimed water system, then sizing of the potable water system facilities could be reduced. The cities with current dual distribution systems are adopting partial dual distribution system where reclaimed water is used for landscape and non-potable water use and in some cases fire protection is provided from both the potable and reclaimed water lines (NRC, 2007). Utilities using partial dual distribution systems

include Irvine Ranch Water District, CA, City of Tucson, AZ, St. Petersburg, FL, and Colorado Springs, CO.

Some southwest water utilities are taking a proactive approach to planning that incorporates acquiring water resources in the future and studying options to provide dual distribution systems, with separate potable water and reclaimed water systems. The integrated approach to master planning will help utilities to understand the dynamics of their water sources and proper planning for their future infrastructure.

This paper summarizes the preliminary results of an integrated master planning approach for the City of Surprise, Arizona. Three infrastructure components (potable water, reclaimed water, and wastewater) were simultaneously studied using hydraulic models to plan and evaluate the functionality and applicability of optimized infrastructure for the growing city.

Integrated Master Planning for City of Surprise

Traditional water master plans analyze potable water distribution systems; however, with the limitations in water resources, new master plans have started to include consideration of reclaimed water infrastructure. Integrated planning, design, and construction of dual systems offer advantages in both water resource management and cost savings (Asano et al., 2007). The City of Surprise integrated master plan has five major components: water resources, groundwater recharge, drinking water infrastructure, wastewater infrastructure, and reclaimed water infrastructure.

The City of Surprise, AZ has undertaken a project to develop and implement an integrated water master plan. The integrated water master plan will provide guidance to the City for the orderly improvement and growth of the City's water supply portfolio and drinking water, wastewater, reclaimed water, and groundwater recharge infrastructure. The master plan was divided in two components: Water Resources and Water Infrastructure.

The Water Resources component of the integrated water master plan identified the projected water demands as the City continues to grow and develop, along with a water supply and reuse strategy that will meet the demands in a cost-effective and sustainable manner. The Water Infrastructure component of the integrated master plan developed comprehensive plans and infrastructure improvements that will allow the City to meet its growing demand in a cost-effective and sustainable manner.

Located in the greater Phoenix area, the City's 300 square-mile planning area is currently less than 20 percent developed. There is a great deal of uncertainty as to how and when the planning area will develop. The City is expecting to grow from a 2007 population of 104,895 to over 400,000 by 2030, and ultimately to 700,000 by build-out. The City would like to plan for new development by evaluating how investment in reclaimed water infrastructure can decrease the need for large-scale drinking water infrastructure. A key feature of this study was the desire to co-locate potable water and reclaimed water facilities to reduce the land requirements. The

tradeoffs between serving the new demands from fewer central facilities versus many distributed facilities were also examined.

Study Area

The study area for this project, shown in Figure 1, includes all of the City's Municipal Planning Area (MPA). The MPA has been divided into six Special Planning Areas (SPA) to maintain consistency with the City's previous master plan efforts and for convenience of wastewater and reclaimed water planning; i.e., the SPAs comprise logical drainage areas for existing, planned, and potential water reclamation facilities.

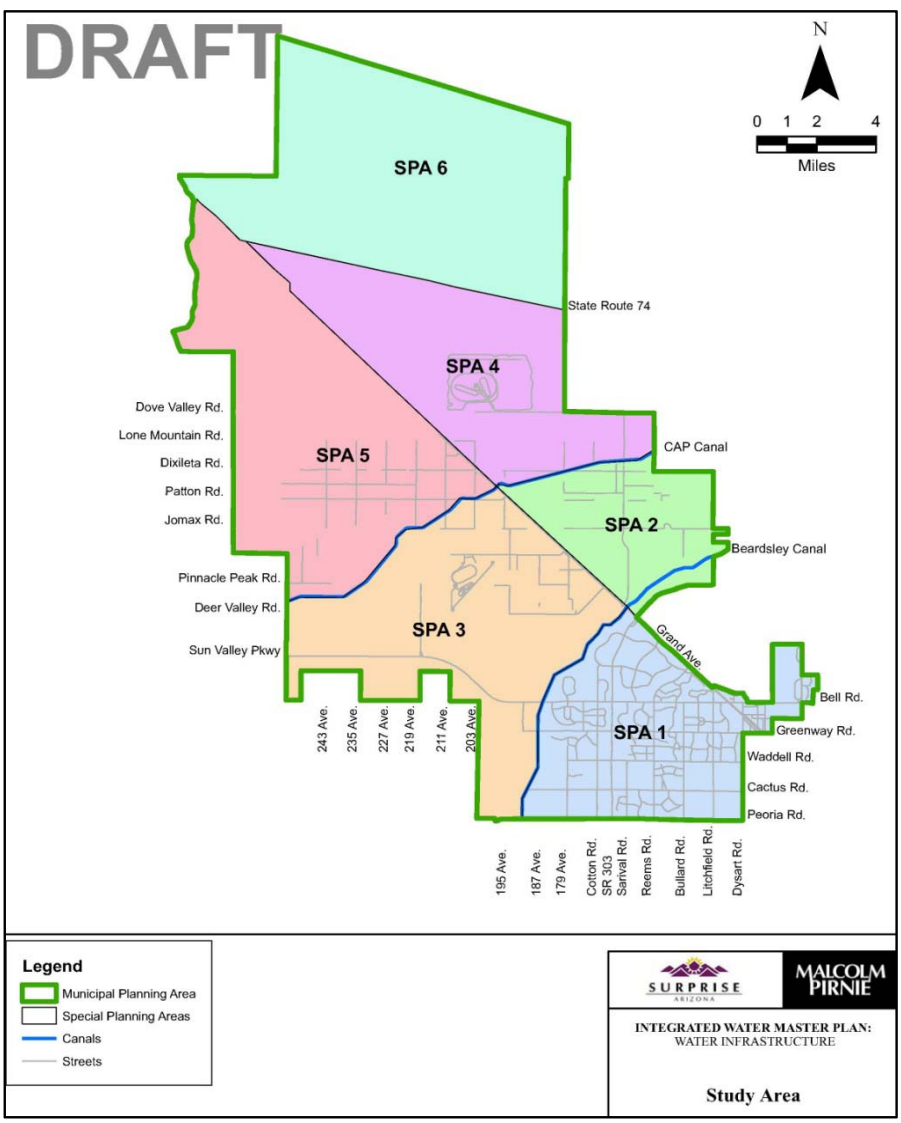

Figure 1: City of Surprise Study Area

Methodology

The City's drinking and reclaimed water distribution system was modeled under steady-state conditions using Bentley WaterCAD® V8 XM edition. Different infrastructure alternatives for potable water, wastewater, and reclaimed water were evaluated against system performance criteria and City's design guidelines.

A Demand Module tool was created as a part of the Water Resources component of the master plan to dynamically simulate water resource needs from GIS-based land use data, residential densities, and demand and flow factors. The tool combined the GIS data with indoor, outdoor, and landscape demand factors for the City and was used to allocate demand in the drinking water and reclaimed water hydraulic models. The drinking water system model was evaluated to supply indoor and outdoor demand while the reclaimed water system was evaluated to fulfill landscape demand, which represents the largest reclaimed water customers.

All infrastructure alternatives were developed using a common set of guidelines and assumptions relating to water demands, the reclaimed water management strategy, and system layouts and configurations:

- Piping networks followed the road alignments in the City's transportation element of the General Plan. No pipes were located in areas that were known to be undevelopable, such as mountainous regions.
- The piping networks for the future system were skeletonized models of the drinking water and reclaimed water transmission systems to an approximate one square-mile grid.
- Drinking water and reclaimed water pressure zones were delineated with 120-foot intervals of ground elevation in the planning area (12 pressure zones total).
- The Water Service Facilities (WSFs) i.e. storage tanks and pump stations for the drinking water system were centrally located within future service areas to minimize pumping requirements. Reclaimed water WSFs (storage tanks and pump stations) were co-located with the drinking water WSFs.
- The reclaimed water system was divided into distribution and transmission components. The distribution system supplied water from the reclaimed WSFs to customer locations while the transmission system supplied water from Water Reclamation Facilities (WRFs) to reclaimed WSFs.
- Reclaimed water distribution system pipes were laid alongside but not connected with the drinking water distribution pipes to minimize construction costs.
- Excess reclaimed water beyond the landscape irrigation demands was diverted to recharge facilities. These recharge facilities were located in areas where the depth to groundwater was high and away from potential interferences such as the landfill, the airport, and other regional recharge projects.

Summary of Results

Because of the close interrelation between wastewater, reclaimed water, and recharge infrastructure, the three systems were evaluated simultaneously to identify the most cost effective solution for the City. Alternatives for wastewater treatment, and corresponding generation of reclaimed water, were developed to serve the 6 SPAs using one of the following layouts:

- *Construct and Operate 6 WRFs* - Under this alternative, the City will design and construct a WRF in each SPA. Reclaimed water will be pumped from the WRF to storage and booster facilities that are co-located with WSFs. All surplus reclaimed water will be recharged.
- *Construct and Operate 4 WRFs* - Under this alternative, the City will design and construct four WRFs: one each in SPAs 1, 2, 3, and 5. The SPA 1, 2, and 3 WRFs will receive flows from their respective SPA. The SPA 5 WRF will receive wastewater flows from SPAs 4, 5, and 6. Reclaimed water storage, distribution, and recharge will be similar to the first alternative; however, reclaimed transmission mains and booster pumping will change slightly.
- *Construct and Operate 3 WRFs* - Under this alternative, the City will design and construct 3 WRFs: one each in SPAs 1, 2, and 3. Collection system flows from SPA 5 will be routed to the WRF in SPA 3. Flows from SPAs 4 and 6 will flow into the WRF in SPA 2. Reclaimed water storage, distribution, and recharge will be similar to the first two alternatives, but reclaimed water transmission and booster pumping will change.

Using the different locations for WRF sites, the wastewater collection system was laid out and sized to evaluate the tradeoffs between treatment costs and conveyance infrastructure costs. All three alternatives shared the same WSF setup used for the water distribution system. There were total 16 WSFs each serving particular service area in the drinking water system. Since the potable WSF and the reclaimed WSF were co-located for each service area in a pressure zone, cost for alternatives were affected by the choice of sites for WRFs. The location of the WRFs affected the total cost for all infrastructures through the need to pump reclaimed water produced at the WRF to the reclaimed WSFs, thus requiring different pump and transmission mains capacities for different alternatives.

The total 20-year present worth costs for the three alternatives were essentially the same at this level of planning with less than 1.5 percent difference between the highest and lowest total present worth costs. The cost savings from building fewer WRFs was offset by the larger collection system piping needed to convey wastewater from the northern areas to the WRFs and by the additional pumping of reclaimed water back to the northern areas. The 6 WRFs alternative had the lowest capital costs, but the highest annual O&M (primarily due to operating 6 WRFs). The 3 WRFs alternative had higher capital costs but the lowest annual O&M costs (due to lower WRF O&M and lift station pumping costs). The 3 WRFs alternative did have a slight 20-year present worth cost advantage over the other alternatives. However, the main disadvantage of 3 WRFs was the need for larger reclaimed water transmission

piping and pumping to return reclaimed water to the northern areas; this disadvantage was exacerbated by the fact that there were substantial elevation differences that would have to be overcome by pumping. The large wastewater and reclaimed water piping could also be less accommodating to developments that occur at remote locations early on as they would have to build the larger and longer piping to receive wastewater and reclaimed water service. This could again be mitigated to some extent by installing smaller, parallel piping, but at additional cost.

The analysis indicated that there were no appreciable differences in the long-term costs of all alternatives evaluated, but the alternative with 6 WRFs provided the following benefits:

- By placing the WRFs closer to the WSFs, this alternative reduced the need for larger conveyance and transmission piping and also reduced pumping requirements for the reclaimed water.
- This alternative with a larger number of WRFs could be more accommodating to development as it provides more flexibility in phasing the WRFs and infrastructure as development occurs within each WRF service area.

Performing simultaneous master planning allowed for the evaluation of a tradeoff between treatment costs & infrastructure costs (as well as for a tradeoff between costs for water, wastewater and reclaimed water) to arrive at an optimal solution. Refinements were made to further optimize the selected alternative. Figure 2 illustrates the reclaimed water distribution and transmission system at build-out. A cost comparison between a single potable water system and a dual potable-reclaimed water system was not made as part of this project because reclaimed water is an integral part of the City's water supply portfolio in the future. The results presented in this paper are preliminary, subject to approval by the City of Surprise and full adoption of the integrated master plan.

Abstract

Water supply utilities are increasingly being confronted with growing maintenance requirements in order to provide a reliable and cost efficient operation of the water distribution system in order to deliver high standard drinking water. One specific challenge is to find a satisfactory compromise between the contradictory objectives of saving investment cost and meeting the increasing expectations of customers. A valuable tool for the planner is reliability analysis of the system that for instance provides information about the importance of each particular pipe in determining the total reliability of the system. This information can be used to decide which pipes should be replaced next or potentially duplicated to reduce the risk of system isolation. Since structural (topological) reliability only considers the connectivity of the network a new approach for the calculation of structural hydraulic reliability is presented in this paper. The algorithmic implementation is based on a decomposition method of the network graph that greatly enhances both the calculation of pure structural reliability as well as structural hydraulic reliability.

INTRODUCTION

The calculation or estimation of the reliability of a system is a very important issue in all fields of engineering. Reliability and associated key performance parameters are becoming more and more the driving forces for decision making in water distribution network planning and management. There exist different concepts for the definition and calculation of water supply network reliability (Ostfeld, 2004). Xu and Goulter (1998, 1999) use a probabilistic hydraulic simulation model where the nodal demands, tank levels and pipe roughness values are stochastic parameters. The reliability of the system is defined as its capability of satisfying the customer's demands with sufficient pressure availability. Tolson et. al. (2001) distinguished between mechanical and hydraulic failures as well as reliability. Mechanical failures are caused by the components of the system such as pipes and pumps whereas hydraulic failures are the consequence of insufficient pressure conditions.

In this paper the mechanical reliability is called component reliability. It is defined as the probability that a particular component will satisfactorily perform a required function under predefined conditions for a specified period of time. In water supply systems analysis the reliability of the pipelines, pumping stations, control devices such as regulating valves and water treatment plants is of special interest. The reliability of pipes having similar age, material and diameters can be derived for example from defect statistics of such a pipe group. Different stochastic approaches are

used for transferring the statistical data into a probability of failure. For a more detailed explanation of the calculation of component reliability the reader is referred to literature (e.g. Mays and Ozger, 2004).

In contrast to the component reliability that is a particular characteristic of a component in the water distribution system, the structural network reliability is a property of the topological composition of the entire distribution system and the reliability of its components. Theoretical network reliability models may be used for the estimation of the probability that the total system performs well under given conditions for a certain period of time. Basically, three types of structural reliability may be distinguished: The *k-out-of-n-reliability* and their special cases for $k = n$ and $k = 2$. The *2-out-of-n-reliability* is also known as source – sink reliability and if $k = n$ the *n-out-of-n-reliability* is called all terminal reliability. Different methods exist for both the exact calculation of the structural (topological) reliability as well as simulation methods. Exact methods include for example full enumeration, minimum-path and minimum-cut-methods, inclusion – exclusion and factorization. A few of these methods will be outlined in this paper. A good overview of different methods can be found in Lucet and Manouvrier (1997) and Kuo (2002).

In the analysis of a hydraulic system like a water distribution network, the structural reliability is applicable only to a limited extent because the connectivity of a system does not guarantee that all customers can be supplied with sufficient pressure. On the other hand hydraulic reliability (sufficient pressures under different load cases) does not consider the topology of the system sufficiently. Consequently in this paper a new concept of structural hydraulic reliability is introduced that is based on the hydraulic supply reliability of the demand nodes. The computationally expensive calculations of structural reliability are simplified by use of decomposition of the network graph. In a general water supply network serial and parallel subsystems can be distinguished from so called complex subsystems. Subsystems are identified by application of a graph decomposition approach that subdivides the total system graph into 1-connected (trees and bridges) components and 2-connected (blocks) components. The structural property of the system describing the interconnectivity of its serial and parallel components is modelled by the so called block graph tree (Deuerlein 2008). Since real water distribution systems usually consist of different components such as main transmission lines (often bridge components), supply and pressure zones (often blocks) and secondary distribution pipes including house connections the calculation time can be dramatically reduced by application of the graph decomposition method.

First, the calculation of structural network reliability is explained using a simple example and the application of graph decomposition is also presented. So far hydraulic issues have not been considered in the analysis. This is done in the second part of the paper where the hydraulic reliability analysis is presented. The nodal supply reliability is introduced followed by an explanation of the so called (*m-0*)-analysis and (*m-1*)-analysis. In the former, the reliability is calculated assuming that all pipes are available. With the latter the so called importance of each pipe of the network can be calculated as the difference between the reliability of the configuration including the particular link and the reliability without that link. In contrast to the definition of

hydraulic reliability based on random demands using Monte-Carlo Simulation techniques, the structural hydraulic reliability is calculated for one particular load case.

THEORETICAL FORMULATION OF NETWORK RELIABILITY

General Concepts

The term reliability denotes the probability that a system performs a certain operation at a certain time under predefined conditions. A system usually is composed of several components. Consequently, the reliability of the system is a function of the reliability of its components. There are different kinds of physical systems that can be distinguished by the configuration of their components. There exist parallel and serial systems as well as so called complex systems. The configuration of the components highly affects the complexity of the calculation of system reliability.

Water distribution networks are an example for such complex systems. In terms of reliability modeling the water distribution system is represented by a so called stochastic graph. In a particular state the configuration of the graph depends on the current state of its components. Let us assume that the components have exactly two functioning states and thus failure may be expressed by the Boolean variable x_i with $x_i = 1$, if component i is functioning and $x_i = 0$ if it is not functioning. Let us further assume that only the links of the graph representing connecting components of the network such as pumps, pipes and valves are subject to failure and that the nodes are perfect. Then each state k of the stochastic network graph can be expressed by the vector $\mathbf{x}_k$ of its entire link set. Furthermore let p_j be the probability that a link j is functioning and $q_j = 1 - p_j$ the probability that it is not. The probability of a state k of the graph G can then be calculated (Lucet and Manouvrier, 1997) by

$$\Pr(G_k) = \prod_{j=1}^{m} \left[[\mathbf{x}_k]_j \, p_j + \left(1 - [\mathbf{x}_k]_j\right) q_j \right] \tag{1}$$

The reliability of the system is the probability that it fulfills a certain expectation. In general three kinds of network reliability are distinguished: The *2-out-of-n-reliability*, the *k-out-of-n-reliability* and the *n-out-of-n-reliability*. The *2-out-of-n-reliability* is also known as source-sink-problem and for the calculation of the all terminal reliability, the system is classified as functioning if there exists at least one spanning tree of the network graph. The different reliabilities can be calculated as the sum of the probabilities of system states where the network graph meets its specific requirements (J: set of all those states):

$$R(G) = \sum_{k \in J} \Pr\left(G_k\right) \tag{2}$$

Theoretically, the exact calculation of network reliability could be carried out by full enumeration of all possible states of the system. However, in reality, full enumeration is impractical for real existing systems with hundreds of thousands of links due to the extremely large number of combinations that would need to be enumerated. The total number of possible states of the system is 2^m. For only 100 network links this number is 1.2677e+30. The network reliability problem belongs to the class of NP-hard problems (see for example Ramesh et. al. 1987).

Serial Systems

Since a serial system functions only if all its components are functioning, its reliability depends heavily on the reliability of its weakest component. Consequently, a serial system in total is always only as good as its weakest component. The calculation of the reliability of the serial system *S* can be derived from Eq. (1) and Eq. (2) and results in the simple expression:

$$R(S) = \prod_{j=1}^{m} p_j \tag{3}$$

Parallel Systems

In contrast to serial systems, a parallel system is intact if at least one of its components works properly. In other words, a parallel system only fails if all its components fail. The reliability of a parallel system *P* is 1 minus the probability that the system fails. Using again equations (1) and (2) the formula for the calculation of the reliability of the parallel system is:

$$R(P) = 1 - \prod_{j=1}^{m} q_j = 1 - \prod_{i=j}^{m} \left(1 - p_j\right) \tag{4}$$

Complex Systems

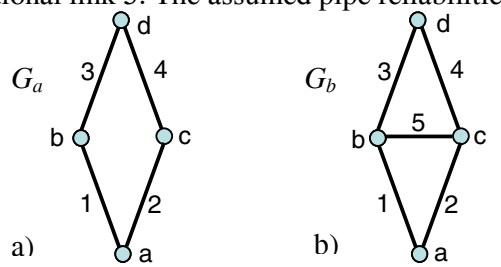
Systems that do not fall under the category of serial or parallel systems are denoted as complex systems. As mentioned above the reliability of those systems theoretically can be calculated by a full enumeration as the sum of probabilities of all feasible states (see Eq. (1) and Eq. (2)). Due to the great amount of calculation time required by this method the reliability of complex networks is usually determined by other approaches. Methods include path enumeration where all possible paths between the terminals are investigated and the cut enumeration where all minimal cuts leading to an infeasible system state are considered.

Theoretical Concepts of Component Importance

The importance of a network component is a measure for the change in structural reliability of a general system (graph *G*) if the component either is removed or fails. There exist qualitative and quantitative methods. One example is the so called reliability or Birnbaum importance $I_{B,j}$ (B-importance) which is defined by the equation

$$I_{B,j} = \frac{\partial R(G)}{\partial p_j} \tag{5}$$

The B-Importance is a measure for the change of system reliability as a result of a change of reliability of component *j* (Kuo, 2002). In general the analytical solution of Eq. (5) is very difficult for large systems. Another method of estimating the component importance is derived from the so called (*m*-1)-analysis. The reliability calculation as described above is called (*m*-0)-reliability since all network links are considered. Accordingly, the (*m*-1)-reliability is the reliability of the reduced system where one link is removed. The (*m*-1)-reliability of the reduced system can be calculated for each link with the same methods. Using the results of the (*m*-0)- and (*m*-1)-analysis the reliability importance $I_{B,j}$ of the network link *j* of graph *G* can be simp-



ly approximated by the difference of the two reliabilities for the system with and without component *j*:

$$I_{B,j} = R(G)_{(m-0)} - R(G)_{(m-1)_j} \tag{6}$$

A complete (*m*-1)-reliability analysis requires the calculation of *m* system configurations and is very time consuming. After the example in the following section the application of the decomposition of a general network graph as described in Appendix I to a more efficient calculation of structural network reliability will be outlined.

Example

Figure 1 shows the graphs of two simple networks. Network a) consists of four links, four nodes and one loop. In network b) the nodes *b* and *c* are connected by an additional link 5. The assumed pipe reliabilities range from 0.6 for link 4 to 0.9 for link 1.

Link	p
1	0.9
2	0.8
3	0.7
4	0.6
5	0.85

Figure 1: Example networks: a) rhombus, b) bridge system

The two-terminal reliability of the network is to be calculated. Node *a* is the source node and node *d* is the sink node. From the section above it follows that in case a) the network can be divided into serial and parallel components. The paths a-1-b-3-d and a-2-c-4-d are alternative paths from node *a* (source) to node *d* (sink). The two paths consist each of a serial system of two links. Consequently, the two-terminal-reliability of the system can be calculated using Eq. (3) and Eq. (4):

$$R(G_a) = 1 - (1 - p_1 p_3)(1 - p_2 p_4) = 1 - (1 - 0.63)(1 - 0.48) = 0.8076$$

The same result is obtained by use of the general formulations of Eq. (1) and Eq. (2).

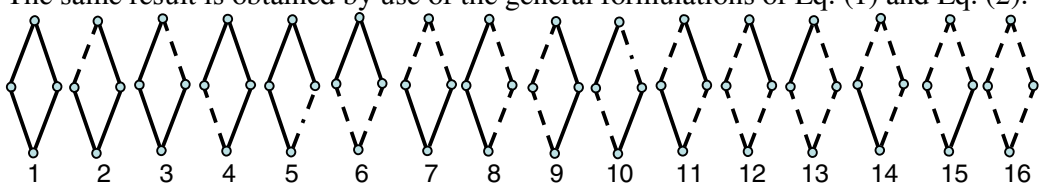


Figure 2: Full enumeration of possible system states of network G_a

A full enumeration of feasible states of the system (see Figure 2) shows that only the states 1, 2, 3, 4, 5, 8, 9 are feasible since in all other cases node *a* and node *d* are disconnected. Let $J=\{1, 2, 3, 4, 5, 8, 9\}$ be the set of feasible states. The reliability calculation using Eq. (1) and Eq. (2) can then be written as

$$R(G_a) = \sum_{i \in J} \prod_{j=1}^{m} \left[[\mathbf{x}_i]_j \, p_j + \left(1 - [\mathbf{x}_i]_j\right) q_j \right] = p_1 p_2 p_3 p_4 + p_1 p_2 q_3 p_4 + p_1 p_2 p_3 q_4 +$$

$$q_1 p_2 p_3 p_4 + p_1 q_2 p_3 p_4 + p_1 q_2 p_3 q_4 + q_1 p_2 q_3 p_4 = 0.8076,$$

which agrees with the value computed previously. Now let us consider system b) with the additional link 5. In this case the system can not be broken down into serial and parallel components. The number of possible system states is $2^5 = 32$, twice the number as in case a. Its two-terminal-reliability can be calculated for example by a full enumeration (result: $R(G_b) = 0.85418$).

Calculation of structural reliability using graph decomposition

It has been shown before that the calculation of structural reliability of serial and parallel systems is straight forward in contrast to that of complex systems. A serial representation of a complex system is its block graph tree (see Appendix I). From the right system in Figure 4 in Appendix I it is clear that if the reliabilities of the virtual block links or the connection nodes were known then the supply reliabilities of the block graph tree nodes could be calculated easily. For example if we know the reliability of the root node of tree 1 the supply reliability of the tree can be calculated as the product of the root node reliability and all tree link reliabilities. However, in general the blocks are complex systems that can not be reduced to combinations of serial and parallel systems and other methods need to be used.

Block reduction

The advantages of the application of the graph decomposition can be demonstrated by the comparison of the number of system states that have to be considered using a full enumeration of possible states of the system in Figure 4. Without application of the graph decomposition the total number of possible states is: 2^{19}= 524,288. Using the knowledge of the block graph tree structure the calculation of the reliability by full enumeration is only required for the complex systems of block 1 and block 2. Following the example of Figure 1b) the number of system states to be calculated is 32+32=64. However for real networks the number of pipes within a block often prevents the application of a full enumeration even for separate blocks.

Path element reduction

For the simplification of the block reliability calculation the nodes of the block are distinguished according to their nodal degree (number of connected links). A node with degree two is called an inner path node, a node with degree greater or equal three is denoted as path node. The link sequences without bifurcation between two path nodes are called path elements. Figure 3 shows a looped block subgraph and its path representation. The reliability calculation of a path element can be performed using the formula for serial systems. In the original system the full enumeration of the remaining complex system consists of 2^{17}=131,072 different states whereas in the reduced system only 2^{11}= 2048 states have to be calculated.

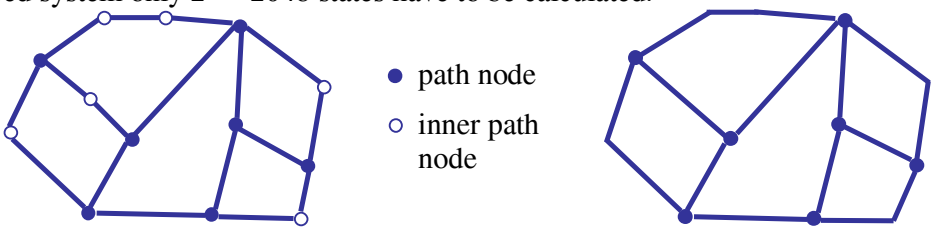

Figure 3: Path reduction of a looped block.

RELIABILITY CALCULATION OF WATER SUPPLY NETWORKS

General assumptions

The structural reliability calculation as explained above is suitable only to a limited extent for hydraulic systems analysis. In order to supply the customers with a sufficient amount of water it is not only sufficient that all nodes of the system are connected to a water source (topological criterion). In addition, the pressure heads at all demand nodes must be above a certain minimum allowable pressure. A full enumeration approach of hydraulic systems reliability would include the consideration of all 2^m possible states of the network similar to the structural reliability calculation above followed by hydraulic steady-state calculations or even extended period simulations of topologically feasible system states for different loading conditions. Since an exact calculation that considers all the different aspects is not possible for real existing water distribution systems assumptions and simplifications of the problem are needed.

In this paper a new concept for the supply reliability of a water distribution system is introduced that combines a hydraulic steady-state calculation with structural reliability analysis. In order to get an idea about the importance of each pipe of the system a so called (m-1)-analysis is carried out. Each (m-1) case includes the calculation of the hydraulic steady-state of the system followed by a topological (or structural) analysis of the system based on the particular flow distribution (as a result of the (m-1)-topology and the particular load case). In particular the (m-1)-calculations require the consideration of pressure dependency of nodal demands.

The calculation of the reliability of water supply networks in this paper is based on the following assumptions.

1.) For the definition of the stochastic network graph only the pipe states are subject to uncertainty. The nodes are assumed to be perfect and also pipe failures are assumed to be stochastically independent.
2.) The probability of failure of water treatment plants and storage tanks is considered as the reliability of the virtual links.
3.) It is assumed that both structural as well as hydraulic reliability of the virtual ground nodes is 1.

In the following measures for the reliability of the system and the supply reliability of a network node are introduced.

Nodal supply reliability

A very important piece of information in hydraulic systems analysis is the probability that a certain node is supplied with adequate amount of water under sufficient pressure conditions. This probability is denoted as nodal supply reliability $NSR_i \in [0;1]$. Its corresponding value is the probability of insufficient supply $NFP_i = 1 - NSR_i$. It can be visualized as the time fraction for which the node is not sufficiently supplied (e. g. a value of 0.00228311 means 20 hours/year). The nodal supply reliability $NSR_{i,(m-0)}$ of node i of the full system is distinguished from $NSR_{i,(m-1)}$ of the reduced system which is called (m-1)-nodal supply reliability (with $R_{s,i}$: structural 2-out-of-n-reliability, D_i, (Q_i): demand, (withdrawal) of node i):

$$a) \quad NSR_{i,(m-0)} = R_{s,i}\frac{Q_i}{D_i} \qquad b) \quad NSR_{i,(m-1)} = \frac{1}{m}\sum_{j=1}^{m} R_{s,i,(m-1)_j}\frac{Q_{i,j}}{D_i} \tag{7}$$

Network reliability definition

The definition of network reliability in this paper is a combination of both hydraulic as well as structural reliability (Index HS) based on nodal supply reliabilities. The reliability of the system is defined as the mean value of all nodal supply reliabilities.

$$a) \quad R_{HS,(m-0)}(G) = \frac{1}{n}\sum_{i=1}^{n} NSR_{i,(m-0)} \quad and \quad b) \quad R_{HS,(m-1)}(G) = \frac{1}{n}\sum_{I=1}^{n} NSR_{i,(m-1)} \tag{8}$$

The information that can be gained from this reliability formulation is more significant to hydraulic systems analysis than the pure structural reliability since it takes also into account the hydraulic properties of the system. An additional benefit is that the nodal supply reliabilities can be weighted, for example, by the demand and further scale factors for important customers like hospitals, etc.

Hydraulic pipe importance

The definition of the hydraulic importance of a network pipe is based on the (*m*-1)-hydraulic steady-state calculation with pressure dependent demands.

$$I_{H,j} = 1 - \frac{\mathrm{Q}_{total}(n-1)_j}{\mathrm{Q}_{\mathrm{total}}(n-0)} \tag{9}$$

$\mathrm{Q}_{total}(n-0)$ denotes the total withdrawal of the system in the (*m*-0) case and $\mathrm{Q}_{total}(n-1)_j$ is the maximal withdrawal with respect to the pressure dependency of the nodal demands for the network without pipe *j*. The hydraulic importance of a pipe can take values between 0 and 1. If as a result of the (*m*-1)-calculation all nodes of the system can be supplied with sufficient pressure then the value for the hydraulic importance of the corresponding pipe is zero. In contrary, if all the nodes of the system are disconnected by a pipe break, for example of a transmission line, then the hydraulic importance of this pipe is one. The hydraulic simulation algorithm used for the hydraulic importance calculations must be capable of simulating the pressure dependent behavior of the nodal demands realistically.

Algorithmic calculation of nodal supply reliability

As explained before the (*m*-1)-analysis consists of the calculation of structural reliability for a particular load case with one link removed from the network graph. A full (*m*-1)-reliability calculation including the calculation of the hydraulic importance of all pipes of the network requires the number of pipes independent steady-state calculations. Since nowadays the usage of 1:1 network models has become more and more common practice in hydraulic system analysis the number of network pipes can often exceed 100,000. Even with respect to the increasing speed of modern computers a full (*m*-1)-analysis would result in unacceptable calculation time. Therefore it is very important to use as much topological information as possible for simplifications of the water distribution system. In particular the (*m*-1)-calculations can take advantage of the knowledge of the different network components and their interconnectivity.

For the sake of simplicity it is assumed in the following description that under normal (m-0) - conditions all demands at the network nodes can be satisfied with sufficient pressure.

Algorithmic steps:

1.) (m-0)-calculation of hydraulic steady-state and nodal supply reliabilities of the total system using graph decomposition as described above and in Deuerlein (2008). Calculation of system reliability by Equation (8 a).

2.) (m-j)-calculations of hydraulic steady-state and nodal supply reliabilities for all pipes $j = 1,\ldots,m$ by using the following subdivision of cases:
Case 1: Pipe j is part of the 1-connected subgraph (Serial systems bridges and trees):
The network graph is subdivided into two separate components $C_{1,j}$ and $C_{2,j}$. The component $C_{2,j}$ that is not connected to the source node is disconnected from any supply node. In this case the hydraulic importance (see Eq. (9)) of the corresponding pipe can be stated simply as the ratio of the sum of demands of the disconnected components to the total network demand, without the need for a hydraulic steady-state calculation. In this case the nodal supply reliabilities of the disconnected nodes are zero as well as the topological all terminal reliability. The decrease of the total system demand has no effect on the reliabilities of the nodes of the supplied component since it was assumed that in the (m-0) case all nodes are fully supplied and the decrease in demand results in higher pressures in component $C_{i,j}$.
Case 2: Pipe j is part of the 2-connected subgraph (complex system block):
The (m-1)-calculation is carried out only for the block that pipe j belongs to. After the calculation it is checked if all the demand nodes of the block and all subsequent components (other blocks, bridges or tress) are above the minimum allowable pressure. If not, a pressure driven calculation of these components is carried out. The preliminary blocks are not negatively affected (only a rise of pressure is possible there). The topological reliabilities of the preliminary blocks are not affected at all; the ones of subsequent blocks can be easily updated by multiplication with the new cut node reliabilities. The reliability calculation within the block takes advantage of the path elimination (Figure 3). The algorithm processes only path elements and path nodes. The path reliabilities can be easily calculated from the pipe reliabilities by using the formula for serial systems. However, for real existing distribution networks with a large number of pipes and nodes this process may be still a very time consuming task.

3.) Calculation of the (m-1)-nodal supply reliabilities and (m-1)-system reliability: After all the $(m\text{-}1)_j$-cases are calculated the (m-1)-nodal supply reliability and the (m-1)-reliability of the total system follow from Eq. (7b) and Eq. (8b), respectively.

SUMMARY AND CONCLUSION

A new approach for the estimation of the water distribution system reliability has been presented in this paper. The main difference in comparison to other methods is

that it is based upon both structural reliability as well as network hydraulics. The consideration of pressure dependent demands requires a hydraulic solver that is capable of performing correct pressure driven analysis in hydraulic steady-state calculations. Although the graph decomposition approach is a promising tool for simplification of the analysis the structural reliability calculations are still a very time consuming task for large distribution networks having multiple redundancies. The graph decomposition supports the enhancement of the algorithm, yet more research needs to be done for the development of more sophisticated methods for a simplified and approximate calculation of the block reliability.

APPENDIX I: Graph Decomposition

In Deuerlein (2008) the decomposition of a general water supply network graph is described. An example is given in Figure 4. Firstly, a virtual ground node (node "r" in Figure 4) is introduced that is connected with all input nodes such as reservoirs and tanks (nodes "m", "n") by so called virtual links (links "16", "17"). The first step of the graph decomposition consists of the identification of connected components that are further subdivided into 1-connected and 2-connected components. The 2-connected subgraph includes the looped blocks of the network graph. The 1-connected subgraph can be further subdivided into bridge components (link "4") and the forest that is composed of several trees. Whereas the link sets of the graph components are distinct, the nodal sets are overlapping in the so called connection nodes.

Three different types of connection nodes are distinguished: The root nodes connecting a tree with a block (nodes "k", "e") or a bridge, the bridge terminal nodes that a bridge and the 2-connected blocks have in common (nodes "c", "d") and the articulation nodes that directly connect two looped blocks (node "l"). A very useful simplification of the network graph is the block graph tree where all looped blocks are substituted by a single block node that is connected with all cut nodes of the block. The application of the decomposition of the network graph and the block graph tree representation will be used for a more efficient calculation of network reliability of water supply networks. Figure 4 shows the decomposition of a simple network with three blocks B_1, B_2, B_3, one bridge and two Trees T_1 and T_2.

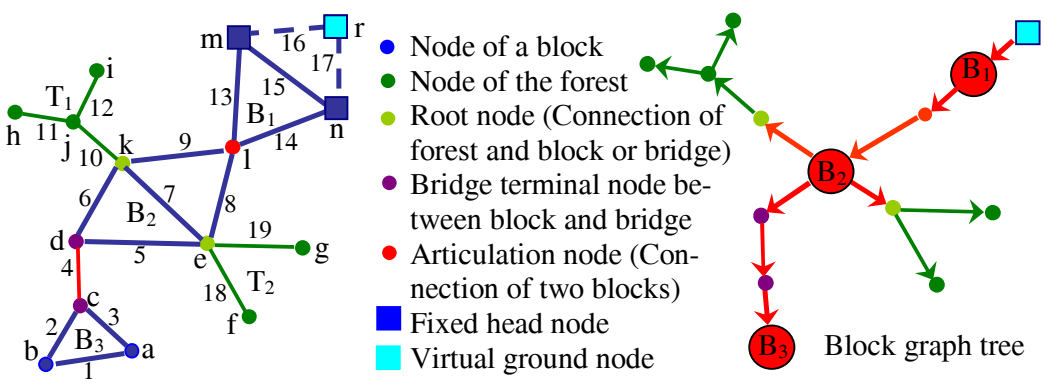

Figure 4: Graph Decomposition of an example network and its block graph tree

APPENDIX II: Notation and Abbreviations

n:	Number of nodes
m:	Number of pipes
D_i:	Demand at node i
Q_i:	Calculated outflow at node i
$NSR_{i,(m-0)}$ (or NSR_i):	(m-0)-reliability of node i (total system including all pipes)
$NSR_{i,(m-1)}$:	(m-j)-reliability of node i for the system without pipe j
$NSR_{i,(m-1)_j}$:	(m-1)-reliability of node i: mean value of all $NSR_{i,(m-j)}$
$R(G)_{(m-k)}$	(m-k)-structural reliability of G (k=0, 1)
$R_{HS}(G)_{(m-k)}$	(m-k)-$h$ydraulic supply reliability *of* G (k=0, 1)
$I_{B,j}$:	Reliability (Birnbaum) importance of pipe j
$I_{H,j}$:	Hydraulic importance of pipe j

Abstract

Since the late 1960s and early 1970s numerous papers have been written on the formulations and methods for solving the governing equations for flows and heads in water distribution systems. Many different names have been given to the various formulations and methods for solution used including the linear theory method, Newton's method, the Todini and Pilati method etc. The underlying equations are the flow continuity equations at nodes in the network, the head loss-flow relationships for individual pipes and finally the head losses around closed loops or for paths between fixed head nodes in the network. The set of equations is nonlinear and hence requires an iterative solution process.

The aim of this paper is to revisit the formulations of the equations for flows and heads in water distribution systems and provide clarity for a logical presentation of a framework for the different formulations. Five formulations are described including 1) flow equations where the equations are formulated only in terms of the unknown flows in a network 2) head equations 3) loop flow equations 4) flow and head equations and 5) the Todini and Pilati flow and head formulation. Graph theory is used to show how many unknowns are required to be solved for in each of the five formulations. A Newton solution method is derived for the flow formulation and the Todini and Pilati formulation.

INTRODUCTION

Pipes, pumps, tanks and valves are connected to form a water distribution system, often in a complex manner. A network for a city, small town or new subdivision is an example. Many or several loops or circuits are usually present in the network. There are usually entry points to the network (for example–tanks, storages and reservoirs) and also many withdrawal points (for example–homes, industries, parks and gardens, commercial buildings, etc.).

Nodes are defined as the end points of links in the network (pipes, pumps or valves) and are identified as either junction nodes with a variable head or fixed head nodes (for example–reservoirs). Flow may enter or leave the network at junction nodes.

There are a number of alternative formulations of the equations describing a water distribution system (Wood and Rayes (1981)–for the first three formulations; Todini and Pilati (1988) for the fifth formulation). Five formulations that are presented in detail in the paper include:

1. flow equations or *Q–equations* formulation in terms of unknown flows (*Q*s) in each link
2. head equations or *H–equations* formulation in terms of unknown heads or HGLs (*H*s) at each node
3. loop flow equations formulation or *LF–equations* in terms of unknown loop flows (*LF*s)
4. flow and head equations or *Q–H equations* formulation in terms of both the unknown flows and unknown heads

5. *Todini and Pilati Q–H equations* formulation in terms of unknown flows and unknown heads (Todini and Pilati 1988)

The objective of this paper is to provide clarity in the presentation of the five different possible formulations of the equations governing flow and head in a water distribution system network. The structure of the paper is as follows. Graph theory is briefly introduced to define the number of variables to be solved for in each formulation. The vectors and matrices required are then defined. Finally, details of the five formulations are given.

GRAPH THEORY FOR NETWORKS

Consider a network in the most general terms (based on the nomenclature of both Wood and Rayes 1981 and Boulos and Altman 1991). From graph theory it is shown that the above variables are related as follows (Boulos and Altman 1991)

$$NP = NJ + NL + (NF - NC) \quad (1)$$

where

- NP = number of links (including pipes, pumps and valves) in the network
- NJ = number of nodes in the network (excluding reservoirs or fixed head nodes))
- NL = number of closed simple loops in the network (loops that have no interior crossing links—also called non–overlapping or natural or primary loops)
- NF = number of reservoirs or fixed head nodes in the network
- NC = number of separate disconnected subnetworks. Usually $NC = 1$ but if a link closes in a network that results in separated parts it is possible to have $NC > 1$.

For networks containing two or more reservoirs (or other form of fixed head source), it is necessary to consider NF-NC required independent paths between nodes of fixed head in the analysis of a network. A path is defined as a non–intersecting series of links between any two fixed head nodes (e.g. reservoirs) that does not contain a closed simple loop. Consider an example network that is fully connected such that NC=1. For two reservoirs (NF=2) there is only one path between the two reservoirs (thus NF-NC= 2-1=1). For three reservoirs (NF=3) there are three possible paths between the reservoirs, however, there are only two independent paths required (NF-NC=3-1=2). It does not matter which of the two paths between the reservoirs are selected in the three reservoir case, as one path between two of the reservoirs is redundant and is not required.

Based on Eq. 1, it generally holds that there are more links NP in the network than nodes NJ such that

$$NP > NJ.$$

In addition there are usually more links NP or nodes NJ than closed simple loops NL plus required independent paths in the network (NF-NC) such that

$$NP > NL + (NF\text{-}NC).$$

Finally, for networks with at least one closed simple loop the number of nodes (NJ) exceeds the number of closed simple loops plus required independent paths

$$NJ > NL + (NF\text{-}NC).$$

As a result, the ordering from the minimum number of variables to the maximum to be solved for is shown in Table 1. A ten pipe example network is shown in Figure 1.

Table 1. Number of variables to be solved for each formulation

FORMULATION	NUMBER OF VARIABLES	NUMBER FOR TEN-PIPE NETWORK
Loop flows	$NL + (NF - NC)$	3
Heads	NJ	7
Flows	NP	10
Todini Q+H	$NP + NJ^*$	17/10
Flows+Heads	$NP + NJ$	17

*however, only a matrix solution of size NJ is required to solve for the heads (see later on in the paper)

Thus in summary, for networks that contain loops, the number of unknown loop flows (*LF*s) is always less than or equal to the number of unknown heads (*H*s) that in turn is always less than the number of unknown link flows (*Q*s).

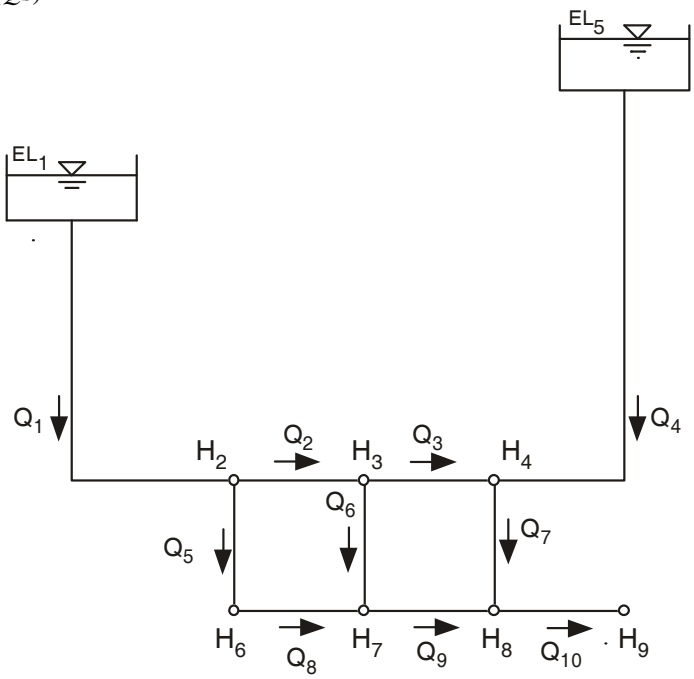

Figure 1. The unknown flows and heads in a ten-pipe network

VECTORS OF UNKNOWNS AND KNOWNS

Consider a water distribution network of pipes and junctions or nodes in which the system has *NP* pipes, *NJ* variable-head nodes, *NF* fixed-head nodes and *NL* closed loops. The number of required independent paths is (*NF-NC*). Assume the network is completely connected (thus *NC*=1). The general column vector of flows for *NP* pipes or links (expressed as the transpose of a row vector) for a water distribution system is

$$\mathbf{q} = [Q_1, Q_2, \ldots, Q_{NP}]^{\mathbf{T}}$$

The general column vector of heads for *NJ* nodes is

$$\mathbf{h} = [H_1, H_2, \ldots, H_{NJ}]^{\mathbf{T}}$$

The ten pipe network shown in Figure 1 has 10-unknown flows and 7-unknown heads.

The known column vector of demands for *NJ* nodes in a general network is

$$\mathbf{dm} = [DM_1, DM_2, \ldots, DM_{NJ}]^{\mathbf{T}}$$

In the third formulation of the equations for a water distribution system unknown loop flows will be solved for. A vector of unknowns is defined as

$$\mathbf{u} = [LF_1, LF_2, \ldots, LF_{NTL}]^{\mathbf{T}}$$

where the number of closed loops and required independent paths is $NTL = NL + (NF - NC)$.

TOPOLOGY MATRICES FOR NETWORKS

Two matrices are useful for describing the topology of a network (Todini and Pilati 1988) including:

- The unknown head node matrix = **A1** (the size of the matrix is *NP* x *NJ*). If a link (in row *j* of **A1**) enters the node *i* in the designated flow direction (in column *i* of the **A1** matrix) then the a_{ji} element is -1. If it leaves the node it is +1. If the node and link are not connected it is 0 (zero).
- The fixed head node matrix = **A2** (the size of matrix is *NP* x *NF*). If a link (in row *j* of matrix **A2**) enters the fixed head node *f* in the designated flow direction (in column *f* of matrix **A2**) then the a_{jf} element is -1. If it leaves the fixed head node it is +1. If the fixed head node and link are not connected it is 0 (zero).

THE BASIC NODE AND PIPE GOVERNING EQUATIONS

There are two types of governing equations for flow and head (HGL or pressure) in a network of pipes. These include

- continuity of flow at each node
- head loss–flow relationship for each individual pipe

The continuity equation at each of the variable-head nodes in the network is given by:

$$\sum_{j=1}^{NP} \langle a_{ij} Q_j \rangle + DM_i = 0 \ldots\ldots\ldots \text{for } i = 1, 2, \ldots, NJ \qquad (2)$$

where the a_{ij} elements (a zero, -1 or +1 value) are from the $\mathbf{A1}^{\mathbf{T}}$ matrix. Typically only 2 to 4 a_{ij} elements of a row of the $\mathbf{A1}^{\mathbf{T}}$ matrix will be non-zero. Thus only non-zero values of a_{ij} will contribute to the continuity equation for the pipes attached to node *i*. Note that flows out of the node will be positive while flows into the node will be negative.

The head loss equation (or energy equation) for the pipe p_j in the network connecting node *i* and node *k* is given by:

$$H_i - H_k = r_j Q_j |Q_j| \ldots\ldots\ldots \text{ for } j = 1, 2, \ldots, NP \qquad (3)$$

where r_j = resistance factor assuming say the Darcy Weisbach head loss equation based on the Darcy-Weisbach friction factor *f* is used (that is dependent on the Reynolds number and the relative roughness for the pipe). The modulus sign in Eq. 3 ensures that the sign of the flow matches the sign of the head difference on the left hand side of the equation. The resistance factor is given by:

$$r_j = \frac{8 f_j L_j}{\pi^2 g D_j^5} \text{ …… for } j = 1, 2, \ldots, NP \quad (4)$$

where L_j = pipe length, g = gravitational acceleration, D_j = pipe internal diameter. The friction factor may be estimated by the Swamee and Jain (1976) equation as:

$$f_j = \frac{1.325}{\left[\ln\left(\frac{\varepsilon_j}{3.7 D_j} + \frac{5.74}{\mathbf{Re}^{0.9}}\right)\right]^2} \text{ …… for } j = 1, 2, \ldots, NP \quad (5)$$

where ε_j = roughness height, **Re** = Reynolds number for the flow in the pipe. A Hazen-Williams head loss equation could easily be also used to replace Eq. 4. The vector of pipe resistance factors is $\mathbf{r} = (r_1, r_2, \ldots, r_{NP})^T$.

FORMULATION 1: FLOW EQUATIONS OR THE Q–EQUATIONS FOR A NETWORK

The unknown flows Q_js are labeled on Figure 1 for the ten-pipe network. The direction of flow in each pipe has been selected based on an expected flow pattern in the network. The direction may have been selected incorrectly in some pipes but this does not matter. In the final solution, if a pipe flow turns out to be negative, then that flow was assumed to be in the wrong direction initially.

The flow equations are formed from both the continuity equations at each of the nodes (a total of *NJ* equations) and the energy equations for simple closed loops and required independent paths in the network (a total of *NL+NF-NC* equations). To implement this formulation the loops need to be defined via the loop matrix (Todini and Pilati 1988). In addition, required independent paths between nodes of fixed head also have to be defined.

For the Q-equations formulation, the set of continuity equations are given by Eq. 2.

Now consider the energy equations around closed simple loops or between fixed head nodes along required independent paths in a network. These equations are nonlinear. A direction (usually positive for clockwise) for each of the loops must be assumed. Upon traversing a closed simple loop in the network the sum of head loss around the loop must be zero. This is expressed as

$$\sum_{j \in S_k} r_j Q_j \left| Q_j \right| = 0 \text{ ……for } k = 1, \ldots, NL \quad (6)$$

for each closed simple loop in the network where S_k = {indices of the pipes in loop k}.

In addition to closed simple loop energy equations, (*NF-NC*) required independent paths between reservoirs or fixed head nodes in the network must also be considered. Consider a series of pipes between two reservoirs designated as reservoir m and reservoir q. The head loss in the pipes between two reservoirs must be equal to the difference in elevation or HGL between the 2 reservoirs (EL_m and EL_q). Each path should be traversed in the same direction as the loop flow direction (usually clockwise). This may be expressed as

$$\sum_{j \in S_k} r_j Q_j \left| Q_j \right| - (EL_m - EL_q) = 0 \ldots\ldots\ldots \text{for } k = 1,..., NF\text{-}NC \qquad (7)$$

where S_k = {indices of the pipes in path k}. Note that application of Eq. 7 may be a little tricky. It is best to traverse the loop in the direction of the loop flow arrow between the reservoirs–then make the right–hand side equal to the head loss difference between the reservoirs or fixed head nodes. Finally, move the right–hand side term to the left–hand side of the equation so that the function is then equal to zero. The same sign convention regarding the sign of the assumed head loss and the assumed flow direction in the pipe is assumed for required independent path energy equations as for closed simple loop energy equations. It is clear that the equations in Eq. 2 are linear while Eqs. 6 and 7 are non-linear.

Solving this set of non-linear equations for the flow equations formulation can be carried out by using a Newton iterative solution which requires computation of the Jacobian matrix. This approach provides a linearizing approximation that is amenable to an iterative solution process (details of the Newton solution process are given in Formulation 5). Newton's method is equally applicable to all formulations presented here. The characteristics of the Jacobian (for example- symmetry, positive definiteness, Stieltjes type) and the use of sparse solution methods, where applicable, will significantly affect the computational cost and hence the speed of the Newton solution technique for each of the formulations. The formulation with the minimum number of variables to be solved for does not necessarily lead to the most effective method in terms of speed of convergence. A detailed comparison of the numerical and convergence properties of the various formulations is beyond the scope of this paper.

FORMULATION 2: HEAD EQUATIONS OR THE H–EQUATIONS

The unknown heads H_is are labeled on Figure 1 for the ten-pipe network. The head equations are formed from the continuity equations (Eq. 2) and the link flow equations (Eq. 3) by eliminating the flow terms in Eq. 2 between both sets of equations. Solving for the flow from Eq. 3 gives for pipe p_j linking nodes i and k:

$$Q_j = \frac{(H_i - H_k)\left|H_i - H_k\right|^{(1/n)-1}}{r_j^{1/n}} \ldots\ldots\ldots \text{for } j = 1,2,\ldots, NP \qquad (8)$$

The H-equations formulation thus becomes by substituting Eq. 8 into Eq. 2.

$$\sum_{i=1}^{NP} a_{ij} \frac{(H_i - H_k)\left|H_i - H_k\right|^{(1/n)-1}}{r_j^{1/n}} + DM_i = 0 \ldots\ldots\ldots \text{for } i = 1,2,\ldots, NJ \qquad (9)$$

where the a_{ij} elements (a zero, -1 or +1 value) are from the $\mathbf{A1}^{\mathbf{T}}$ matrix. If the node connected to node i for a particular pipe is a fixed head node then the H_k value is replaced by EL_m. Note that all equations in Eq. 9 are non-linear in contrast to the Q-equations formulation where the continuity equations (Eq. 2) are linear equations. The H-equations formulation is easy to implement in a computer code. It is not necessary to define the loops for this formulation (in contrast to the Q-equations formulation) and this is a huge advantage of the technique. Only the link connectivity information is needed including the node numbers at the end of each link, the length, diameter and roughness of each pipe and the properties of each node (elevation and demand) (Todini and Pilati 1988).

FORMULATION 3: LOOP FLOW OR LF–EQUATIONS

The loop flow or LF–equations are obtained by writing the energy equations (similar to Eq. 6 and 7) for the closed simple loops and all required independent paths in the network by incorporating appropriate loop flows or *LF* values. The LF values for the ten-pipe network are shown in Figure 2. As each closed simple loop is traversed the head loss along each link is added (or subtracted) according to the sign convention used. Flow directions must be assumed for each pipe. A direction (usually positive for clockwise) for each of the loop flow *LF*s must also be assumed.

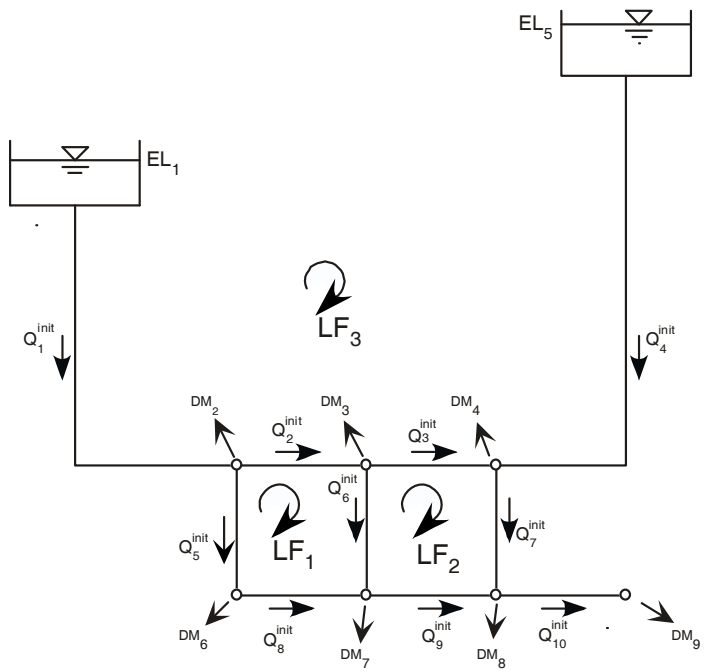

Figure 2. Unknown loop flows for the LF-equations formulation

A column vector of initial flows in the network must be chosen such that they satisfy continuity at each node as follows

$$\mathbf{q} = [Q_1^{init}, Q_2^{init}, ..., Q_{NP}^{init}]^{\mathbf{T}}. \tag{10}$$

Thus as shown in Figure 2, flow directions in each pipe must be chosen for each Q_j^{init} in each pipe. In Eq. 10, the Q_j^{init} values that satisfy continuity at each node in the network remain unchanged for all iterations. Note that this is quite different from the loop flow corrections formulation for the manual Hardy Cross method (1936) where the initially selected flows are updated in the loop immediately after the computation of each loop flow correction.

From Eq. 6, the energy equations in the LF-equations formulation for each of the *NL* closed loops in the network are

$$\sum_{j \in S_k} \left\langle r_j \left[Q_j^{init} + \sum_{s \in L_j} LF_s \right] \middle| Q_j^{init} + \sum_{s \in L_j} LF_s \middle| \right\rangle = 0 \ldots \text{for } k = 1, ..., NL \tag{11}$$

where S_k = {indices of the pipes in closed loop s} and L_j = {indices of the loops associated with pipe j}.

From Eq. 7, the energy equations in the LF-equations formulation for each of the (*NF-NC*) required independent paths in the network are

$$\sum_{j \in S_k} \left\langle r_j \left[Q_j^{init} + \sum_{s \in L_j} LF_s \right] \left| Q_j^{init} + \sum_{s \in L_j} LF_s \right| \right\rangle - (EL_m - EL_q) = 0 \ldots \text{for } k = 1,..., (NF\text{-}NC) \quad (12)$$

where S_k = {indices of the pipes in closed loop k} and L_j = {indices of the loops associated with pipe j}. If the direction of the loop flow *LF* is in the same direction as the assumed link flow, the *LF* value is added to the initial flow assumed for the pipe or link. To the contrary, if the *LF* direction for the closed simple loop being considered is opposite to the assumed flow direction in the link, the *LF* value is subtracted from the pipe flow. The initial link flow is adjusted by the final converged value of *LF*s computed for each closed simple loop s of which the link is a member.

As seen in Table 1, the minimum number of equations results for the LF–equations formulation where the *NL* closed simple loop equations and the (*NF-NC*) required independent path equations are formulated in terms of a loop flows in each simple loop and path. All of the equations in the LF–equations formulation are nonlinear. In the LF-equations formulation, as for the Q–equations formulation, all loops and required independent paths need to be identified.

The continuity equations do not form part of the set of the LF–equations as long as the initial flow in each link satisfies the continuity at each node in the network.

The LF–equations in terms of the unknown loop flows in the network have in the past been recommended as the preferred formulation of the equations for a network due to the smaller size of the number of variables to be solved for in the equation formulation (Epp and Fowler 1970, Wood and Rayes 1981, Nielsen 1989). Ellis and Simpson (1998) indicated that the process for determining the preferred formulation is not straightforward. It not only depends on the number of equations but also the initial set up time prior to the equations being iteratively solved for (e.g. in determining a set of link flows that satisfy continuity) and also is quite dependent on the starting vector for the set of unknowns that is selected to commence the iterative solution process.

FORMULATION 4: THE Q-H EQUATIONS FORMULATION

The flow and head equations are formed from both the continuity equations (from Eq. 2) at each of the nodes and the head loss equations for each pipe expressed in terms of nodal heads at each end of the pipe (from Eq. 3). Thus there are a total of $NP + NJ$ unknowns to be solved for in the Q-H equation formulation.

The column vector of unknown flows and heads in the network is

$$\mathbf{m} = [Q_1, Q_2, \ldots Q_{NP}, H_1, H_2, \ldots H_{NJ}]^{\mathrm{T}}.$$

Thus the Q-H equation formulation is made up of the continuity equations from Eq. 2 as:

$$\sum_{j=1}^{NP} \langle a_{ij} Q_j \rangle + DM_i = 0 \ldots\ldots \text{ for } i = 1, 2,\ldots, NJ \quad (13)$$

where the a_{ij} elements (a zero, -1 or +1 value) are from the $\mathbf{A1^T}$ matrix and the pipe head loss equations from Eq. 3 which are

$$H_i - H_k - r_j Q_j \left|Q_j\right| = 0 \qquad \text{for } j = 1,2,\ldots, NP \tag{14}$$

where the *i* and *k* indices refer to the node numbers at the end of each pipe *j*.

The number of equations in this formulation is clearly larger than the number of equations for the Q-equations formulation or the H-equations formulation. Thus the size of the matrices that need to be dealt with in the iterative solution process will consequently be larger. However, the form of the governing equations is simpler and computation of the Jacobian elements is considerably easier. In addition, it is not necessary to determine the loops in the network as for the Q-equation formulation.

FORMULATION 5: THE TODINI AND PILATI Q-H EQUATIONS FORMULATION

The Todini and Pilati (1988) formulation is effectively a type of Q–H equation formulation. The description below is based on material from Simpson and Elhay (2008). The formulation is based on two sets of equations solving for all unknown heads and flows simultaneously in a sequential iterative manner. The method has an extremely efficient approach to the inversion of the Jacobian matrix by partitioning the governing equations in a smart way. The advantage of the Todini and Pilati formulation is that the Jacobian matrices are symmetric. The Todini and Pilati (1988) formulation is used in EPANET (Rossman 1994) and a number of other commercially available hydraulic software packages for the simulation of water distribution systems.

Based on Eq. 2 the continuity equations for all the pipes in the network and the topology matrices introduced earlier in the paper, the following matrix form can be written:

$$\mathbf{A}\,1^{\mathbf{T}}\,\mathbf{q} + \mathbf{dm} = 0 = \mathbf{f}_2(\mathbf{q}, \mathbf{h}) \tag{15}$$

where the left-hand-side of Eq. 15 is denoted by the function $\mathbf{f}_2(\mathbf{q}, \mathbf{h})$. Now for the head loss equations for each pipe p_j connecting nodes *i* and *k* then Eq. 3 can be re-written as:

$$r_j Q_j \left|Q_j\right| - \left(H_i - H_k\right) = 0\,. \tag{16}$$

This can also be written in matrix form, but first a diagonal matrix **G** of size *NP* x *NP* is introduced where:

$$\mathbf{G} = \begin{pmatrix} r_1\left|Q_1\right| & 1 & \ldots & \ldots & 0 & 0 \\ 0 & r_2\left|Q_2\right| & \ldots & \ldots & 0 & 0 \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & \ldots & \ldots & r_{NP-1}\left|Q_{NP-1}\right| & 0 \\ 0 & 0 & \ldots & \ldots & 0 & r_{NP}\left|Q_{NP}\right| \end{pmatrix} \tag{17}$$

The non-linearity in the system arises because the matrix **G** depends on the unknown flows in **q**. The matrix form of Eq. 16 can be written as follows (taking into account that some nodes are fixed head nodes):

$$\mathbf{Gq} - \mathbf{A}1\mathbf{h} - \mathbf{A}2[\mathbf{el}] = 0 = \mathbf{f}_1(\mathbf{q}, \mathbf{h}) \tag{18}$$

where **[el]** is a vector of the reservoir or fixed node heads. Note that Eq. 18 is denoted by the vector function $\mathbf{f}_1(\mathbf{q}, \mathbf{h})$. The two sets of matrix equations in Eq. 15 and Eq. 18 may be written in the following block matrix form as:

$$\mathbf{f}(\mathbf{q}, \mathbf{h}) = \begin{pmatrix} \mathbf{G} & | & -\mathbf{A}1 \\ -- & - & -- \\ -\mathbf{A}1^{\mathbf{T}} & | & 0 \end{pmatrix} \begin{pmatrix} \mathbf{q} \\ -- \\ \mathbf{h} \end{pmatrix} - \begin{pmatrix} \mathbf{A}2[\mathbf{el}] \\ -- \\ \mathbf{dm} \end{pmatrix} = 0 \tag{19}$$

This system is really the set of equations for Formulation 4 – the Q-H equations, however, the partitioning in Eq. 19 will be exploited below to develop a much more efficient solution scheme. The first matrix on the left hand side of Eq. 19 shows the partitioning of a (*NP* + *NJ*)–square matrix into 2 block rows and 2 block columns. Note that the first block matrix on the left had hand side of Eq. 19 has a special structure that may be exploited because it is symmetric. In addition the only non-constant values in this matrix are the diagonal elements of **G**. A Newton iterative solution to the set of non-linear equations in Eq. 19 can be formulated in terms of Taylor's series expansion and linearization as:

$$\mathbf{J}(\mathbf{q}^{(k)}, \mathbf{h}^{(k)}) \begin{pmatrix} \delta\mathbf{q}^{(k+1)} \\ -- \\ \delta\mathbf{h}^{(k+1)} \end{pmatrix} = \begin{pmatrix} -\mathbf{f}_1^{(k)} \\ -- \\ -\mathbf{f}_2^{(k)} \end{pmatrix} \tag{20}$$

for the k+1st iteration where k = 0, 1, 2, etc. Decomposition methods that avoid the need for solving for the inverse of the Jacobian are applied to solve Eq. 20. An initial set of guesses of initial flows (Eq. 10) are required. A value corresponding to a velocity of 1.0 fps is often selected.

The Todini and Pilati (1988) method solves the equations describing the flows and nodal heads in a water distribution network by a reformulation of Eq. 19 which exploits the diagonal nature of **G** and which uses an explicit block-form of the inverse as shown below. This leads to a simplification and hence a significant improvement in the speed of the solution algorithm.

Now consider the derivative of the first matrix on the left side hand multiplied by the vector $(\mathbf{q}^{\mathbf{T}}, \mathbf{h}^{\mathbf{T}})^{\mathbf{T}}$ of Eq. 19 so that we can form the Jacobian as shown in Eq. 20. The diagonal nature of **G** can be exploited with only the diagonal elements of the **Gq** matrix changing upon differentiation so computation of the Jacobian is very straightforward. Rewrite Eq. 19 as:

$$\mathbf{f}(\mathbf{q}, \mathbf{h}) = \begin{pmatrix} \mathbf{Gq} & | & -\mathbf{A}1\mathbf{h} \\ -- & - & -- \\ -\mathbf{A}1^{\mathbf{T}}\mathbf{q} & | & 0 \end{pmatrix} - \begin{pmatrix} \mathbf{A}2[\mathbf{el}] \\ -- \\ \mathbf{dm} \end{pmatrix} = 0 \,. \tag{21}$$

The derivatives of the diagonal elements of **Gq** assuming that *r* is constant (despite the fact that friction factors *f* actually depend on flow: the friction factors may be updated at the end of each iteration) are:

$$\frac{d}{dQ_j}\left(r_j Q_j \left|Q_j\right|^{n-1} \right) = r_j n \left|Q_j\right|^{n-1} \qquad \text{for } Q_j \neq 0 . \tag{22}$$

The terms in the second matrix (with **A2** etc.) on the left hand side of Eq. 21 do not depend on **q** and **h**. The Jacobian matrix for the system of equations in Eq. 22 becomes:

$$\mathbf{J} = \begin{pmatrix} n\mathbf{G} & | & -\mathbf{A}1 \\ -- & - & -- \\ -\mathbf{A}1^{\mathbf{T}} & | & 0 \end{pmatrix} \tag{23}$$

This matrix has some very nice properties of symmetry and sparseness. Todini and Pilati (1988) show an analytic expression for the block-form of the inverse of **J** where we denote the inverse of **G** to be **D** temporarily. This inverse is easy to compute for a diagonal matrix and is tractable as long as all flows Q_j are not zero. It has terms $1/(nr_j|Q_j|)$ at each location along the diagonal. Assume that the head loss exponent *n* is the same for each pipe. The Jacobian becomes:

$$\mathbf{J}^{-1} = \begin{pmatrix} \frac{1}{n}\mathbf{D} - \frac{1}{n}\mathbf{DA}1(\mathbf{A}1^{\mathbf{T}}\mathbf{DA}1)^{-1}\mathbf{A}1^{\mathbf{T}}\mathbf{D} & | & -\mathbf{DA}1(\mathbf{A}1^{\mathbf{T}}\mathbf{DA}1)^{-1} \\ ---------- & - & ---------- \\ -(\mathbf{A}1^{\mathbf{T}}\mathbf{DA}1)^{-1}\mathbf{A}1^{\mathbf{T}}\mathbf{D} & | & -n(\mathbf{A}1^{\mathbf{T}}\mathbf{DA}1)^{-1} \end{pmatrix} \tag{24}$$

The reformulation allows the solution process for each iteration to be done in two stages: one for the flows and another for the heads. Substituting Eq. 24, Eq. 15 and Eq. 18 into Eq. 20 and simplifying gives the two-step Todini and Pilati algorithm for solving successively at each iteration for the heads and discharges as follows:

$$\mathbf{h}^{(k+1)} = (\mathbf{A}1^{\mathbf{T}}\mathbf{G}^{-1}\mathbf{A}1)^{-1}\left[\mathbf{A}1^{\mathbf{T}}\left\langle (1-n)\,\mathbf{q}^{(k)} - \mathbf{G}^{-1}\mathbf{A}2[\mathbf{el}]\right\rangle - n\,\mathbf{dm}\right] \tag{25}$$

and

$$\mathbf{q}^{(k+1)} = (1-\frac{1}{n})\,\mathbf{q}^{(k)} + \frac{1}{n}\mathbf{G}^{-1}(\mathbf{A}1\mathbf{h}^{(k+1)} + \mathbf{A}2[\mathbf{el}]) \tag{26}$$

where $n = 2.0$ for the Darcy Weisbach head loss formula or $n = 1.852$ for the Hazen-Williams head loss equation. Note that in the pair of equations above the only matrix inverse that is not trivial to compute occurs in Eq. 25 and involves the *Schur Complement* term of $\mathbf{A}1^{\mathbf{T}}\mathbf{G}^{-1}\mathbf{A}1$ which is the size of *NJ* by *NJ* (the number of nodes in the network). Thus although we are dealing with a total of (*NP* + *NJ*) unknowns the use of an analytical inverse of the Jacobian has reduced the matrix to be solved down to the size of *NJ*.

CONCLUSIONS

The objective of this paper has been to provide clarity in the presentation of the five different possible formulations of the equations governing flow and head is a water distribution system network. A set of

non-linear equations arises for each of the formulations. These include: 1) flow equations 2) head equations 3) loop flow equations 4) flow and head equations and 5) the Todini and Pilati flow and head equations formulation. Details of each of these formulations have been presented in this paper. Graph theory has been used to show the relationship between the numbers of variables in each formulation.

The order of size of problem ranked from minimum to maximum number of variables for the five different formulations is: 1) loop flows 2) heads 3) Todini and Pilati Q-Hs 4) flows 5) flows and heads. The size of the problem does not necessarily determine which is the most effective formulation. Currently the Todini and Pilati Q-H equations formulation is commonly used in many commercial and Government hydraulic simulation packages. The main part of the iterative solution process in the Todini and Pilati algorithm has been reduced to same size of problem as the head equations formulation. This has been achieved by a smart reorganisation of the governing equations using an analytic expression for the inverse of the Jacobian using partitioning of the matrix. Further work is required to evaluate if the loop flow equations formulation can be competitive with the Todini and Pilati method is terms of computational speed.

ABSTRACT

Intermittent supply is prevalent among developing countries. Inequitable water distribution, possible water contamination, wasting water, coping costs of consumers and water providers, meter malfunctioning and inconvenience to consumers are some of its consequences. There are two major views on how this problem should be considered. The first view looks at a transfer to the 24-hour supply by reducing water loss and adding new supply sources, while the other accepts intermittent supply as a reality and looks for appropriate design and operation methods that can minimize its negative impacts. Important differences between intermittent and continuous service water distribution networks operation should be considered in the second case, such as initial network charging, pressure-dependent water demand, and design pressure. In this paper, the use of known free public domain network models, such as SWMM for modeling initial pipe network charging and EPANET for modeling the network intermittent operation, is proposed and exemplified.

INTRODUCTION

Intermittent supply is prevalent among developing countries in Latin America, Asia and Africa (Totsuka et al. 2004; Lee and Schwab, 2005). Inequitable water distribution, possible water contamination, wasting water, coping costs of consumers and water providers, meter malfunctioning and inconvenience to consumers are some of its consequences (Totsuka et al. 2004; Lee and Schwab, 2005). Quite frequently tap water is not pure enough for drinking or water with no good flavor. For these reasons users have to buy expensive purified water. To overcome the inconveniences of being with no tap water, users are encouraged to have a water tank on the house roof, cistern, or other permanent deposit at home. This house addition provides families a water reservoir in case of supply breaks. Its need varies considerably from one neighborhood to another and from one city to another. Figure 1-(a) and 1-(b) show the roof tank arrangements used in Mexico. The first of them, shown in Figure 1-(a), comprises a larger tank (cistern) at ground level and a pump to fill the roof

tank, and is employed when more water storage is needed or when water pressure in the supplying network main during service hours is very low. The second one, shown in Figure 1-(b) is used when water pressure is not so low so that that the roof tank can be filled directly from the network main.

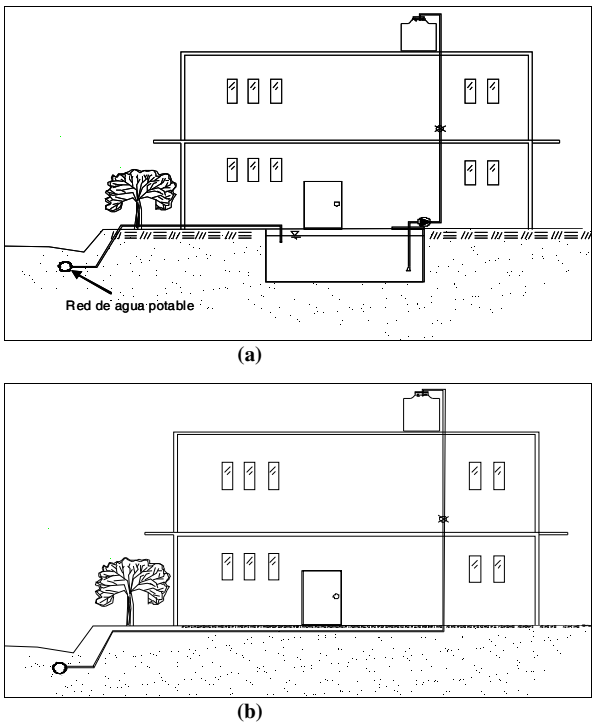

Figure 1 Roof tank arrangements used in Mexico: (a) Ground level cistern, water pump and roof tank, (b) Roof tank alone

A study carried out by the Mexican Institute of Water Technology during 2005-2006 defined country specific water utility performance indicators (Bourguett-Ortiz and Tzatchkov 2007). The appropriateness for Mexico of existing performance indicator systems was assessed first, e.g. the IWA Manual for Performance Indicators (Alegre et al., 2000), the World Bank (Yepes and Dianderas, 1996) and the Asian Development Bank indicator directives (McIntosh and Yniguez, 1997). Most of them turn out not to be practical for the conditions of Mexico, mainly because of the long lists of indicators they manage and the related large amount of data needed, some of which are difficult to obtain. Then, instead of adopting one of those systems, the following 12 specific indicators were defined: per capita water produced, updating of water user database, source water metering, customer water metering, updating of infrastructure asset information, service connections with continuous water service, water production cost, urban wastewater treated, customer complaints, customers that pay on time for the water service, number of water utility employees per every 1,000 service connections, and number of water utility employees dedicated to leak reduction and control.

A free access Internet Web site (http://www.pigoo.gob.mx/) was created in order to make the described performance indicator information transparent and easily accessible for different institutions in the country and for the public in general. The

Internet Web site is in Spanish and displays the evolution of the indicators for the participating water utilities. The information can be consulted by city or grouped by states, administrative regions according to the Mexican National Water Commission, or city size. Sixty three Mexican cities with more than 50,000 inhabitants participate providing information to this study. These cities cover all the Mexican states and the different climatic zones existing in the country, that vary from dry desert and semi desert regions in Northern Mexico to humid subtropical regions in South Mexico. Figure 2 shows the evolution of the indicator Service connections with continuous 24 hours a day drinking water service, expressed by the relation of the number of service connections with continuous service to the total number of service connections in the city.

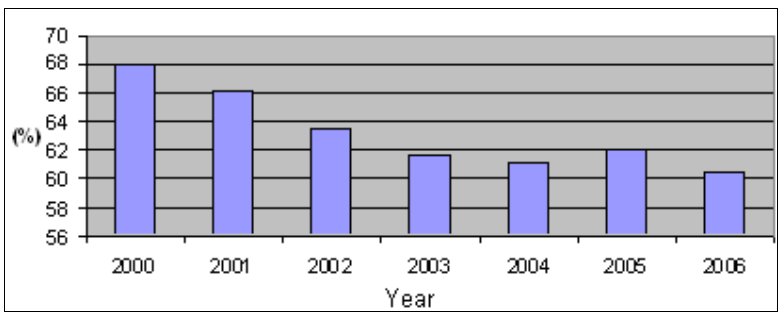

Figure 2. Evolution of the indicator Service connections with continuous 24-hours a day drinking water service (http://www.pigoo.gob.mx/)

This indicator shows a low percentage of continuous 24 hours a day supply, that decreased from 68% of connected households in 2000 to about 60% in 2006.

There are two major views on how intermittent water supply problems should be considered (Totsuka et al. 2004). The first one looks at a transfer to the 24-hour supply by reducing water loss and/or adding new supply sources, while the other accepts intermittent supply as a reality and therefore advocates the necessity of providing appropriate design and operation methods that can minimize its negative impacts. Water distribution network models can be very useful tools in developing such methods. Important differences between modeling and design of intermittent and continuous service water distribution networks should be considered in the models, however, such as pressure-water demand relation, hourly demand variation, peak demand factors, minimum design pressure and initial pipe network charging (Batish 2003, Tzatchkov and Cabrera-Bejar 2008).

Up to the knowledge of the authors of this paper, K. Vairavamoorthy and coworkers (Vairavamoorthy and Lumbers 1994; Vairavamoorthy and Elango 2002; Vairavamoorthy et al. 2000; Vairavamoorthy 2001) are the only authors that have developed models specific for intermittent supply distribution networks. Although in some of their papers they say their models would be available, at present they are not. Besides that, from the brief explanation given in the papers, their models seem to be more academic than practical. Ease of use and low cost (or no cost) of a model are fundamental for models to be used in developing countries where economic resources are generally limited. Fortunately, free public domain computer sewer and water

network models, such as SWMM and EPANET, can be used to model intermittent supply distribution networks, as proposed in this paper.

MODELING INTERMITTENT SERVICE WATER DISTRIBUTION NETWORKS

Water distribution network models originated from developed countries where water service is continuous and the water demand is satisfied all the time. When a user needs water, he or she opens the tap and receives the water he or she needs. Because of that such models are normally "demand-driven models", i.e., water demand is fixed and the model obtains the pressure in the network for the given demand. Most known water distribution network models, such as Epanet (Rossman, 2002), Infoworks WS, and others, are of that kind. On the contrary, intermittent service water distribution networks operate for a limited time, only when supplied with water, the amount of water each user is able to collect depends on the available pressure at his connection and the duration of the service, and not always the user demand is fully satisfied, i.e., these networks are "supply-driven" and "pressure-driven" or "pressure-dependent demand", and should be modeled this way. A common error is to model a pressure-driven network as a demand-driven. Hydraulic behavior obtained from a supply-driven and pressure-dependent demand network model is very different from that of a demand-driven model, however (Batish 2003, Tzatchkov and Cabrera-Bejar 2008).

On the other hand, continuous service distribution networks are always full with water, and intermittent services ones are filled with water every time service is resumed. Initial water charging of the networks obviously cannot be modeled with known demand-driven network models, so that special models have to be developed. Such a model would give the time a network needs to start the service, the volume of water that is needed to fill it, which of the users would receive the service first, and which last; and which would have deficient service.

MODELING INITIAL NETWORK CHARGING WITH SWMM

The Storm Water Management Model (SWMM) is a dynamic rainfall-runoff simulation model used for runoff quantity and quality that transports this runoff through a system of pipes, channels, storage/treatment devices, pumps, and regulators. Produced by the Water Supply and Water Resources Division of the U.S. Environmental Protection Agency's National Risk Management Research Laboratory, it can be freely downloaded from the following Internet site: http://www.epa.gov/ednnrmrl/models/swmm/index.htm. Being capable of modeling the transition from free surface to pressurized flow in the network pipes, it could be used to model, to some extent, the initial water distribution network charging. The following process can be used (explained in SWMM terms):

1. No subcatchment areas are introduced
2. The water source or tank is represented by a storage with the real dimensions of the tank and an inflow pattern corresponding to the given supply schedule is introduced into it.

3. A large value (say 100 m) is assigned to the Surcharge depth at each network junction. This way surface flooding at the node is avoided and pressure flow in the pipes can be modeled.
4. Every roof tank (or group of roof tanks) is represented as a Storage with its dimensions.
5. The water demand, taken from the roof tanks, is represented as an Inflow curve with negative values applied to each Storage.
6. "Dynamic wave" routing method is activated in the SWMM simulation options.
7. Under dynamic wave routing SWMM requires there must be at least one outfall node in the network. Since there are no such nodes in water distribution networks, a fictitious node is added somewhere and connected with a fictitious pipe to the nearest real network junction. The diameter of this fictitious pipe is assigned with a very small value, say 0.001 m, so that it does not influence the simulation results.
8. SWMM is run obtaining the evolution of the flow in the network pipes, the evolution of roof tanks filling, and so on.

Figure 3 shows a small size water distribution network located in the city of Guadalajara, Mexico modeled in SWMM for a period of 3 days with intermittent water supply, 5 hours of water supply daily. The corresponding supply itinerary, applied at the water source, is shown in Figure 4. The model comprises 3 cycles of network charging, five hours of water service, and network emptying. The service area has 462 parcels and 2310 inhabitants, corresponding to a maximum hourly design flow of 17.40 L/s according to the Mexican design standards. The total length of the pipes in the network is 4,090 m, with diameters for 50 to 150 mm. The supply source is a tank. Figure 5 shows the instantaneous water surface profile during network charging, obtained by SWMM for a series of three 10 cm diameter pipes from this network. Figure 5 shows the water level evolution in one of the roof tanks (the closest to the supply source) obtained by SWMM for a period of 3 days. The rising reaches correspond to water service hours, and the falling ones to water demand during non-service hours.

A slightly different approach would be to model with SWMM only the initial network charging, and after that to model the charged network operation with EPANET, as explained in the next section, in order to make use of more modeling options included in EPANET, that are specific for water distribution networks.

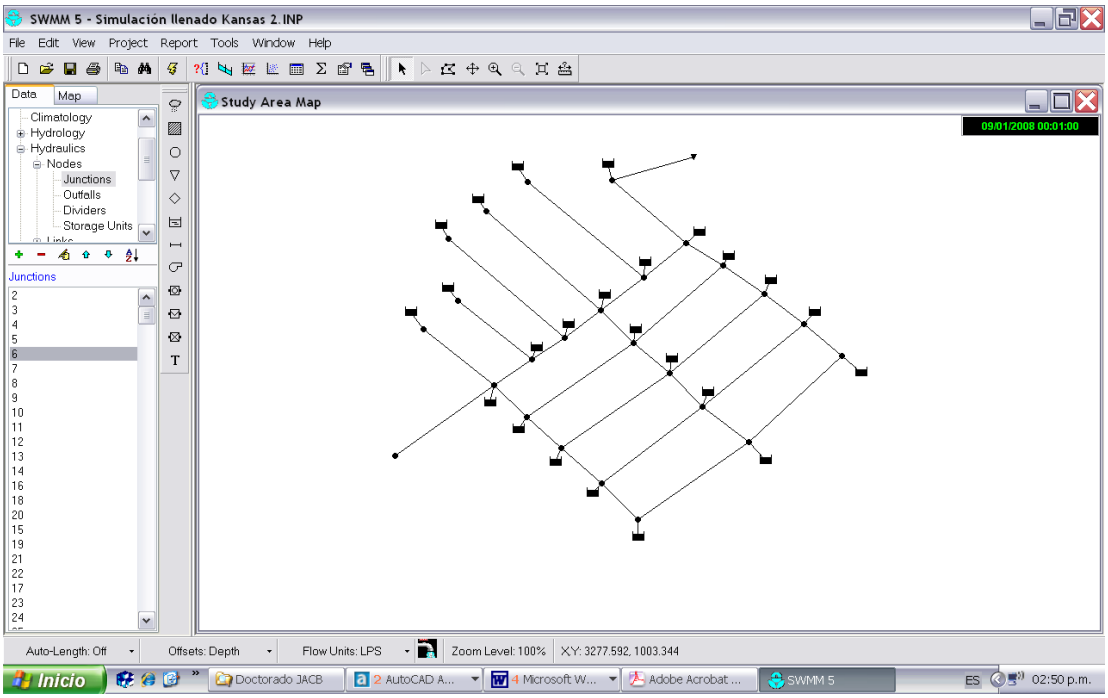

Figure 3. A small water distribution network modeled for initial charging in SWMM

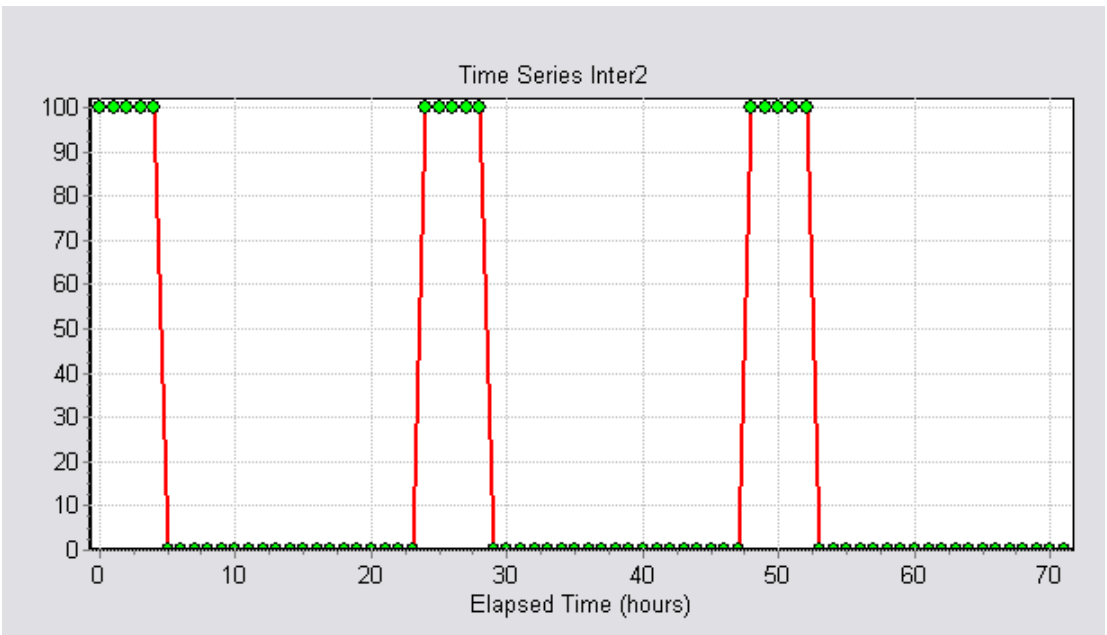

Figure 4. Water supply itinerary applied at the source tank of the network shown in Figure 3.

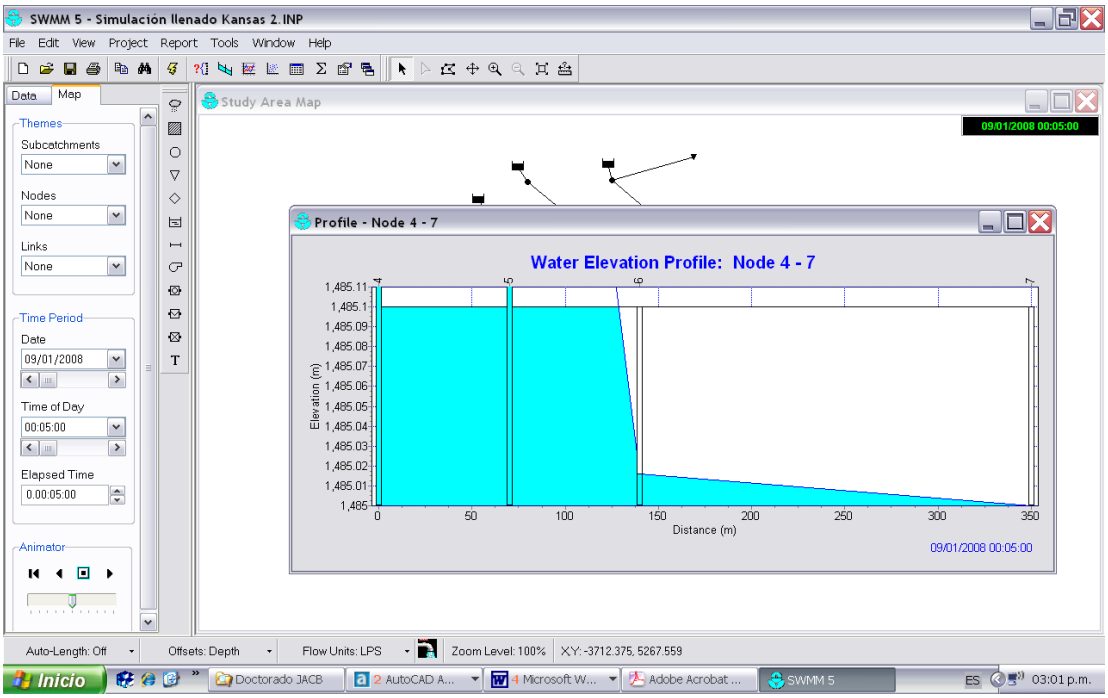

Figure 5. Instantaneous water surface profile during network charging, obtained by SWMM for a series of three 10 cm diameter pipes from the network shown in Figure 3.

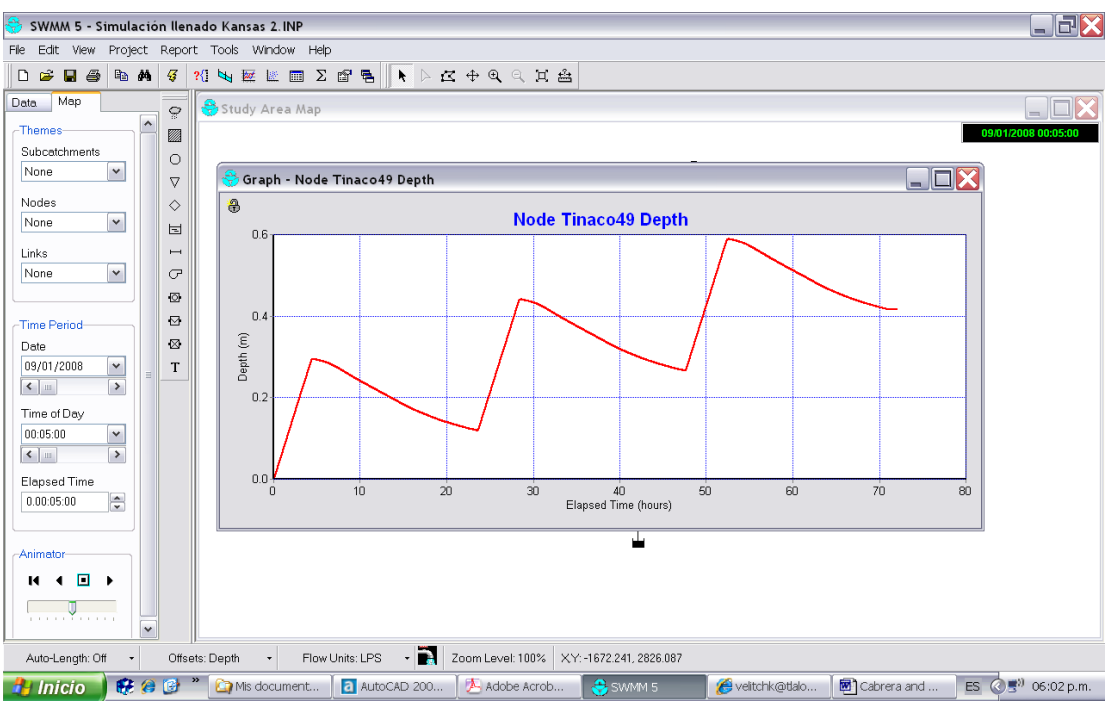

Figure 6. Water level evolution in one of the roof tanks of the network shown in Figure 3, modeled by SWMM

MODELING WATER DISTRIBUTION NETWORKS WITH ROOF TANKS WITH EPANET

Developed by of the U.S. Environmental Protection Agency's Water Supply and Water Resources Division, EPANET is software that models water distribution piping systems. It can be freely downloaded from the following Internet site: http://www.epa.gov/nrmrl/wswrd/dw/epanet.html. Although it is based mainly on a demand-driven model, it has a node component named *emitter* that can be used to represent pressure-dependant demand. EPANET can be used to model intermittent water service, after the initial water charging, in one of the following two ways:

1. In principle, every roof tank could be modeled in EPANET as a tank connected to the network. Given the extremely large number of service connections in a water distribution network, this approach obviously is impractical, but could be used with equivalent tanks, each of them representing a group of roof tanks, the same way as water demand for a group of service connections is concentrated in network nodes in conventional water distribution network models. Figure 7 shows the network from Figure 3 modeled in EPANET by this approach. Figure 8 is a zoom to one of the equivalent tank. The pipe leaving the tank is used to represent water use inside the houses.
2. Representing each demand node as emitter. This approach is simpler and may be more appropriate for large networks.

More details and examples are presented by Tzatchkov and Cabrera-Bejar (2008).

CONCLUSIONS

Intermittent water service is undesirable, but present in many cities in developing countries. A transfer to continuous 24-hours is possible by non-revenue water reduction and other technical means, provided sufficient water is available at sources, but it may take many years to be accomplished. Meanwhile, intermittent water service specific models could be used to better understand the hydraulic behavior of intermittent service water distribution networks and improve their design and operation. Most known water distribution network models are demand-driven and not appropriate for intermittent water service networks that are supply and pressure driven. Inexpensive software models, such as SWMM and EPANET can be used to model initial network charging and roof tanks, typical for intermittent service water distribution networks.

ABSTRACT

Failures in water distribution systems (WDS) occur on daily basis, requiring the fast response from WDS operators. This paper presents an impact model which investigates the adverse effects of failures from an operational rather than strategic perspective in order to provide a better insight into their development over a given impact horizon. The performance indicators (PI) currently in place have been found inadequate and a set of new operational PI considering the magnitude, duration and sensitivity of customers has been introduced. The proposed operational impact model has been applied on a case study where a pressure-driven hydraulic model has been coupled with a geographic information system (GIS) and a discolouration model in order to provide a comprehensive overview of the failure to allow WDS operators to make more informed decisions.

INTRODUCTION

Failures in water distribution systems (WDS) occur on daily basis, primarily due to ageing infrastructure or equipment failure, but often also due to damage caused by third parties. The magnitude and scale of the impact typically depends on a number of factors among which the geographic location and topology of the WDS play an important role. Generally, three types of failures in WDS can be recognised: mechanic, hydraulic and water quality failures (Filion et al., 2007). Many researchers over the years have tried to estimate the impact of failures in WDS on its stakeholders. However, this is a complex problem, in particular because of its social aspects. The work done so far has focused primarily on impacts from pipe bursts, as part of strategic management and long term asset management plans (e.g. Skipworth et al., 2002). In the UK the high standard of the delivery of potable water is monitored by the Water Services Regulation Authority (OFWAT) using several performance indicators (PI), which amongst other focus on long term pressure adequacy (e.g. Pressure of water mains - DG2) and continuity of water supply (e.g. Supply interruptions - DG3) (OFWAT, 2008). It is believed that these indicators do not sufficiently reflect the impact of a failure on customers since the measures used ignore their type and vulnerability to service disruptions. Most of the research dealing with failures in WDS uses the fraction of delivered demand (FDD) and its similar forms as a PI to assess the level of service (e.g. Gupta and Bhave, 1994; Ostfeld et al., 2002; Kapelan et al., 2006). Although being an effective measure on a large scale, FDD does not consider the sensitivity of individual customers to a reduced level of service. Mansoor et al. (2005) defined several performance measures including

"adequacy" which was again based on the amount of delivered demand, but furthermore distinguished the importance of customers by applying different severity weightings.

Modelling of failures in WDS is prone to many errors and uncertainties due to the stochastic nature of water consumption and also because the hydraulic models typically available are not calibrated for simulating such conditions. Bhave (1981) was probably the first to stress the importance of using a pressure driven analysis when modelling WDS under failure conditions in order to capture the dependence of nodal outflows on available pressure. Since then various pressure-driven models were developed and are being used more frequently. In this work, a pressure driven modification of EPANET (Rossman, 2000), based on the method proposed by Ang and Jowitt (2006), was used in order to model the behaviour of WDS under failure conditions.

With the current improvements in monitoring technologies and wider availability of near real-time data, there is a need to investigate the impacts of various failures from an operational of view, in order to better prioritize work of WDS operators and field technicians. Giustolisi et al. (2008) have already proposed several operational PIs based on the amount of unsupplied demand over 24 hours, however, the sensitivity of customers has not been taken into account. This might be seen as a disadvantage for current customer-oriented water utilities. It is argued that the currently available PIs are not fully suitable to support these new requirements and a comprehensive impact model needs to be established to enable quantification of operational impacts of failures and their effect on various stakeholders (e.g. the customers and the water utility). This paper provides a brief overview of such an impact model, tailored specifically to assessment of failures from operational perspective.

METHODOLOGY

As suggested earlier by Bicik et al. (2008), it is important to consider different stakeholders (e.g. water utility, its customers, etc.) when assessing the impact of failures in WDS. The approach, initially based on a value tree (Michaud and Apostolakis, 2006) has been revised because different impact factors affect multiple stakeholders (e.g. low pressure, supply interruption, etc.), however in a different way. Hence, it is proposed to represent the effects of the impacts in a tabular rather than a tree like structure. The main impact factors caused by a failure (e.g. pipe burst, pump failure, etc.) currently envisaged and their different effects on the interested parties are listed in Table 1. The various effects included in Table 1 have been further classified into three categories: economic, environmental and social, denoted as [EC], [EN] and [S] respectively.

Table 1. Impact factors and their economic, environmental and social effects on stakeholders

Impact Factor	Effect	
	Water Utility	Customer
Lost Water	Cost of lost water [EC] Carbon Footprint of extraction and treatment [EN]	Lost Revenue [EC]

Low Pressure	Regulatory penalties [EC] Customer Complaints [EC] Undelivered water - revenue loss [EC] Water quality problems [EC]	Contaminant intrusion [S] Inconvenience & danger [S] Lost Revenue [EC]
Interruption to Supply	Regulatory penalties [EC] Customer Complaints [EC] Undelivered water - revenue loss [EC] Water quality problems [EC] Regulatory penalties [EC]	Contaminant intrusion [S] Inconvenience & danger [S] Lost Revenue [EC]
Discolouration	Customer Complaints [EC] Interventions (flushing) [EC] Water quality problems DWI [EC]	Discolouration [S]
Damage to third parties	Compensations [EC]	Flooding [S] Transport disruption [S]
Energy Losses	Cost of energy [EC] Energy required to clean & pump water [EN]	

From the table above, it can be seen that failures generally have greater economic impacts on water utilities whereas customers are more concerned about the social aspects. Since social impacts are difficult to quantify (Rahman et al., (2005) several surrogate measures are proposed here. These measures are based on the amount of undelivered water as well as the failure duration and increase in discolouration potential. Due to the complexity and the fact that there are no existing models for some of the effects in Table 1 (e.g. contaminant intrusion, flooding of properties, transport disruption, etc.) only a subset of those mentioned above has been incorporated into the overall impact model. The following sections will provide details about selected PIs used to capture the impacts caused by low pressure, interruption and discolouration. These impacts are seen as the most important as well as the most practical ones.

Low Pressure Problems

Low pressure problems cause a wide range of direct and indirect adverse effects affecting both the water utility and its customers. In the UK, OFWAT requires low pressure incidents (i.e. drops of pressure below 15m of head at water main) to be reported (i.e. as part of the DG2 PI) by every water utility. Although, short term failures such as those caused by pipe bursts can be excluded from the DG2 register (i.e. list of properties receiving substandard pressure) and thus this PI does not immediately affect the water utilities in the short term operational perspective considered here. Low pressure, although not being as severe as a complete interruption to water supply, causes inconvenience to customers and affects pressure sensitive water consumption. This in turn reduces the revenue of a water utility in case of metered customers (in the UK, approximately 67% of properties are not metered, depending on a particular water utility). Furthermore, inadequate pressure problems occurring in the case of fire might even lead to loss of lives and properties (Filion et al., 2007).

The proposed approach uses the number of affected customers (see Equation 1), the undelivered demand due to low pressure (see Equation 2) and the average low pressure impact duration (see Equation 3) as surrogate measures reflecting the social aspects of low pressure impacts. Furthermore, each of the above indicators should be evaluated for a given type of customer (i.e. residential, commercial, industrial and critical) in order to reflect their importance.

$$LP_{type} = \sum_{i=1}^{N_N} Cust_{i,type} \times \begin{cases} 0 & if \quad P_i(t) \geq \mathrm{P}_{req} \quad for \quad \forall t \in <1,T> \\ 1 & otherwise \end{cases} \tag{1}$$

$$UWLP_{type}[m^3] = \frac{3600}{1000} \times \sum_{t=1}^{T} \sum_{i=1}^{N_N} \begin{cases} \dfrac{\left(D_{i,req}(t) - D_i(t)\right) \times Cust_{i,type}}{Cust_{i,count}} & if \; 0 < P_i(t) < \mathrm{P}_{req} \\ 0 & otherwise \end{cases} \tag{2}$$

$$AVGLPD_{type}[h] = \frac{1}{Cust_{total,type}} \sum_{t=1}^{T} \sum_{i=1}^{N_N} \begin{Bmatrix} Cust_{i,type} & if \; 0 < P_i(t) < \mathrm{P}_{req} \\ 0 & otherwise \end{Bmatrix} \tag{3}$$

where:

- N_N is the number of demand nodes in the system
- t is the simulation time (with assumed time step of 1 hour)
- T is the impact horizon in number of time steps (hours)
- $P_i(t)$ is the pressure at demand node i and time t (m of head)
- P_{req} is the minimum required pressure in m of head to deliver the full requested demand at node i (in this case 15m)
- $D_{i,req}(t)$ is the requested demand at node i and time t in *l/s*
- $D_i(t)$ is the delivered demand at node i and time t in *l/s*
- $Cust_{i,type}$ is the number of customers of particular type supplied from node i
- $Cust_{i,count}$ is the number of customers supplied from demand node i
- $Cust_{total,type}$ is the total number of customers of a particular type affected by the failure at least during one time step over given impact horizon T

In order to represent economic losses of a UK water utility caused by low pressure it is vital to distinguish between metered and unmetered consumption since the water consumption of a large percentage of customers is not metered. Hence it is proposed to use following performance indicator to measure the lost revenue due to undelivered water because of low pressure.

$$UWLR[m^3] = \frac{3600}{1000} \times \sum_{t=1}^{T} \sum_{i=1}^{N_N} \begin{cases} \dfrac{\left(D_{i,req}(t) - D_i(t)\right) \times Cust_{i,M}}{Cust_{i,M} + Cust_{i,UM}} & if \; 0 < P_i(t) < \mathrm{P}_{req} \\ 0 & otherwise \end{cases} \tag{4}$$

where:

- $Cust_{i,M}$ the number of metered customers supplied from node i
- $Cust_{i,UM}$ the number of unmetered customers supplied from node i

Water Supply Interruption

Interruption to water supply is defined here as a drop of pressure at water main to 0 m of head or below this threshold. It is acknowledged that this is a simplified assumption and that in reality an interruption occurs even at less significant pressure drops (e.g. due to the elevation of individual properties and head losses through internal plumbing). Interruption is the most severe failure with the highest impact on customers and as shown by Sadiq et al. (2006) it can also lead to intrusion of contaminants into the WDS and cause health related problems.

The performance indicators used to evaluate the interruption of water supply are similar to those described in previous section by Equations (1), (2), (3) and (4). However, the duration of an interruption is calculated as the number of hours from the beginning of the failure until the supply is fully restored, which is different from the low pressure impact where the duration is calculated as a sum of the number of hours when inadequate pressure is received by the customers. In order to provide a measure which is well understood by the operators in the UK, the interruption duration is categorised in a similar way as suggested by OFWAT (2008). The following classes are introduced: 0-3h, 4-6h, 7-12h, 13-24h and more than 24h. However, even in this case the interruption duration is calculated per customer type (e.g., 4 residential properties affected for 4-6h and 1 industrial customer affected for 0-3h).

Discolouration

Apart from taking into account the effects of failures related to reduced level of service in terms of low pressure or inadequate flow, it is also important to consider water quality related issues. Discolouration caused by disturbance of normal flow regime usually plays a key role for water quality considerations (at least in the UK). A discolouration model based on risk trees developed by a panel of experts (Dewis and Randall-Smith, 2005) has been applied to estimate the increase in discolouration potential of all pipes in the WDS after a failure has occurred. As pointed out by Vreeburg and Boxall (2007) using a discolouration model based on shear stress would be more appropriate, however, no such model was available to the authors. The discolouration impact is expressed as the number and length of pipes experiencing increased discolouration potential due to a failure and also as the total discolouration score increase defined as follows:

$$TotalDiscInc = \sum_{j=1}^{N_P} \begin{cases} Disc_{j,failure} - Disc_{j,norm} & if\ Disc_{j,failure} > Disc_{j,norm} \\ 0 & otherwise \end{cases} \quad (5)$$

where:

- N_P is the number of pipes in the system
- $Disc_{i,norm}$ is discolouration index of a pipe i under normal conditions
- $Disc_{i,failure}$ is discolouration index of pipe i under failure conditions

Nowadays WDS are typically divided into district metered areas (DMA) where inflows and outflows into/from such areas are monitored in order to minimize leakage. Modelling particular types of failures at DMA level might be sufficient in most cases as failures usually have a localised impact. However, it is vital to use an all-pipe model of the whole

WDS in order to model major failures such as pump outages, large pipe bursts and isolations of segments of pipes. Such failures are likely to have impacts on other parts of the WDS that might not be immediately obvious due to WDS in urban areas being looped. Furthermore, when discolouration is considered, the disturbances caused by a failure might spread far upstream and downstream from the actual location of a failure and stretch well beyond the boundaries of a single DMA.

CASE STUDY

The above proposed impact model has been applied to a large WDS (see Figure 1) comprising of about 9,000 pipes and supplying over 25,000 properties (69% of the properties are not metered).

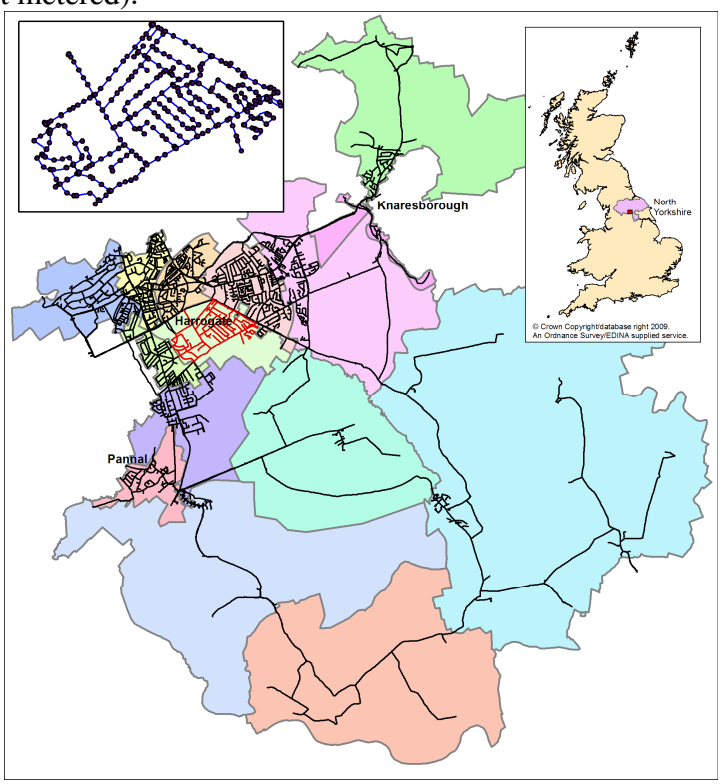

Figure 1. Case Study Area

The model covers an area of 16 DMAs of various types, stemming from fully tree-like networks located mostly in rural areas to highly looped networks in urban areas. A pipe burst of a constant outflow of 10 l/s starting from midnight and lasting for 24 hours has been simulated in the highlighted DMA in Figure 1. The affected DMA provides water to almost 1,600 properties and is located in an urban area. An extended period simulation model has been run using a modified version of EPANET in order to obtain the pressures at demand nodes and the reduced demands delivered due to insufficient pressure.

RESULTS AND DISCUSSION

Although, the magnitude of the burst flow is high (i.e. 10 l/s), which makes it a major event, no interruption to water supply has occurred during the impact horizon of 24 hours

since the pressures have never dropped to 0m of head or below that level. In real life a part of the system would be isolated in order to carry out the repair of the burst, this however has not been considered. Therefore, the performance indicators related to interruptions are not going to be reported here. Figure 2 reports the impact model results for different lengths of the impact horizon and shows the amount of cumulative undelivered demand caused by low pressure. The total undelivered metered demand is also shown as it relates to the loss in revenue for the utility.

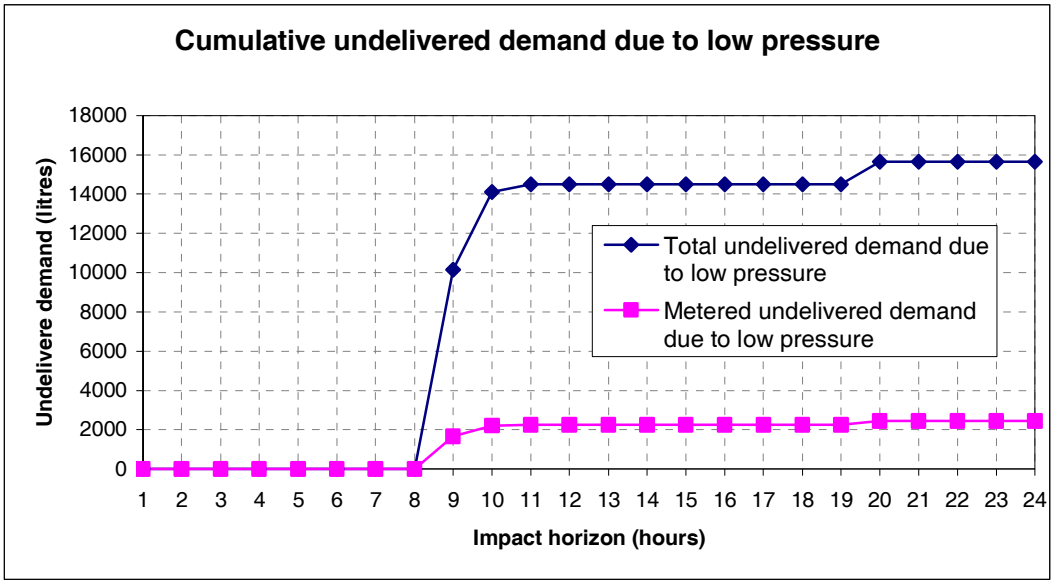

Figure 2. Cumulative undelivered demand in the analysed system due to low pressures

Due to the size of the considered WDS and the localized impact in this case, the fraction of the undelivered demand does not exceed 0.1% of the overall demand for the whole system. The major increases in the undelivered demand occur at peak times (i.e. 8:00AM, 9:00AM, 10:00AM, 7:00PM and 8:00PM) and outside of these critical hours the system remains unaffected (apart from potential discolouration problems). As can be further noticed, the amount of undelivered metered demand is relatively low and does not represent a significant economic loss to the water utility when compared to the amount of water lost due to the burst (i.e. 864,000 litres). In this case the environmental impact can be related indirectly to the amount of water which has escaped from the system by considering the carbon emissions produced during the extraction, treatment and delivery of the leaked water.

Figure 3 is a snapshot, showing the impact at the peak time (i.e. 8:00AM) rather than the cumulative results. The spatial distribution of the affected properties as well as the pipes which are likely to experience an increase in discolouration potential due to the failure are visualised using GIS. It can be seen that the areas of increased discolouration risk can be geographically distant from the location of the failure. In total there were 337 pipes having the length of 12.5km whose discolouration potential increased.

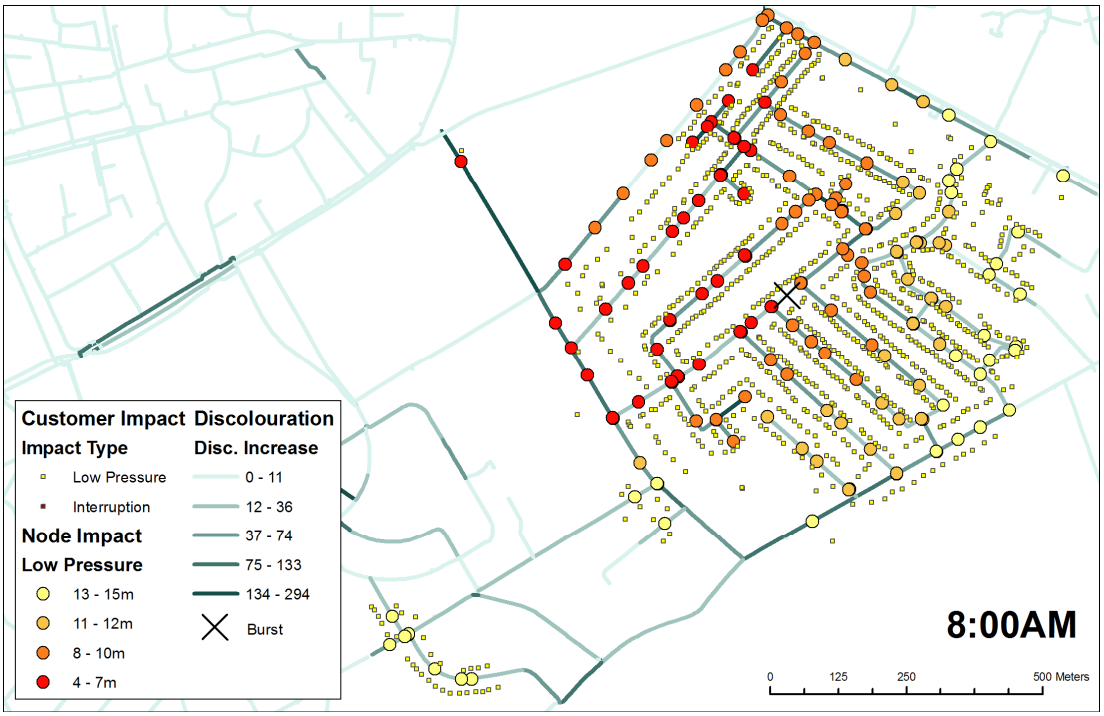

Figure 3. The estimated impact of a pipe burst at peak demand time

CONCLUSIONS

The impact model presented in this paper aims to provide WDS operators with a better insight into the adverse effects of failures and their development in time. That will help them make more informed decisions and prioritise the actions of repair teams. It is argued that in order to meet the high levels of standard of delivery of potable water, the indicators currently used to assess the impact are inadequate and need to be extended. A set of new performance indicators that specifically distinguishes between types of affected customers and incorporates both the duration and magnitude of a failure has been formulated. A pressure-driven hydraulic model based on modified version of EPANET has been coupled with a GIS, in order to consider the sensitivity of the customers. The hydraulic model is also integrated with a model that relates disturbances in normal flow regime to discolouration potential.

The increasing importance of impact evaluation can also be seen in recent attempts to move from traditional and well established WDS reliability studies towards risk-based approaches (e.g. Kapelan et al., 2006; Beuken et al., 2008). These studies take into account not only the likelihood of occurrence of adverse events but also consider their impact. The impact model presented here, forms only one component of a risk-based methodology (Bicik et al., 2008) for the operation of WDS under failure conditions, which is being developed as part of an ongoing EPSRC funded Neptune project (Savic et al., 2008).

This paper has described in detail only a few out of almost 50 performance indicators that form the output of the implemented overall impact model. Although, the number of reported PIs is relatively high, it is believed that the WDS operators will choose the most

representative set of PIs to use themselves according to their experience. As part of future work it is envisaged to focus on finding suitable methods to visualise such a broad range of performance measures using GIS and ways to speed up the computational time required to apply the impact model on large scale WDS.

ACKNOWLEDGEMENTS

The work on the NEPTUNE project was supported by the U.K. Science and Engineering Research Council, grant EP/E003192/1, and Industrial Collaborators. The authors also thank Lewis A. Rossman for providing the pressure-driven modification of EPANET. The kind assistance of Mr Ridwan Patel from Yorkshire Water Services and Dr Mark S. Morley is greatly appreciated.

New Concepts for Meter Placement in Water Distribution Systems for Demand Estimation

Doo Sun Kang[1] and Kevin Lansey[2]

ABSTRACT

Kang and Lansey (2008a) have shown that water distribution system (WDS) nodal demands can be estimated in real-time using pipe velocity measurements from a supervisory control and data acquisition (SCADA) system. The field measurements are key elements for the real-time state estimation. However, the limited number of metering locations has been a significant obstacle for the real-time studies and identifying locations to best gain information is critical. Previous studies for the data sampling mainly focused on minimizing either parameter or prediction uncertainties. However, reducing uncertainty does not guarantee a good fit for the model predictions in terms of the mean estimate. Therefore, robust objective criteria, that guarantee precise and accurate state estimates, must be applied. Here, an optimal meter placement (OMP) problem is formulated as a multi-objective optimization model. Three distinctive objectives are posed: (1) minimization of nodal demand estimation uncertainty; (2) minimization of nodal pressure prediction uncertainty; and (3) minimization of absolute error between demand estimates and their expected values. Objectives (1) and (2) represent model precision while objective (3) describes model accuracy. The OMP problem is solved using a multi-objective genetic algorithm (MOGA) based on Pareto-optimal solutions. The trade-off between model precision and accuracy is clearly observed from a simple network study and it is strongly recommended to use both criteria as objectives.

INTRODUCTION

Generally, state estimates (SE) improve with more field measurements. However, due to budget limitations, only a few selected key locations are monitored. Given the type and number of measurements, the topological distribution of meters in networks strongly influences the SE quality. If portions of a system are insufficiently measured, the state variables in those regions can not be accurately estimated and will contain a high degree of uncertainty.

Optimal sampling design (SD) for WDS model calibration (parameter estimation, i.e., roughness coefficient) is an important issue and has been completed by a number of researchers. Meier and Barkdoll (2000) used genetic algorithm to find an optimal combination of calibration test locations to maximize a total length of pipes having non-negligible flow velocities (≥ 0.3 m/s). Lansey et al. (2001) proposed a sensitive-based heuristic method for design of data collection using model prediction uncertainty. They used first-order second moment (FOSM) analysis for model prediction uncertainty quantification. Kapelan et al. (2003, 2005) formulated the SD problem as a two objective optimization problem. The objectives were to minimize the relevant uncertainties and to minimize a total SD cost (i.e., number of measurements). The optimal SD problem was solved using genetic algorithms. They used FOSM analysis to estimate parameter and prediction uncertainties. The aforementioned SD problems are usually solved considering multiple demands under steady-state hydraulic conditions to take into account various demand loads.

Yu and Powell (1994) presented optimal meter placement (OMP) algorithm for system-wide pressure estimation. The optimization is based on a systematic extension of a given measurement system, starting from purely pseudo-measurements (nodal demand guesses) and at every stage one metered measurement (nodal pressure head) is added based on maximum covariance of state variables.

The aforementioned SD/OMP studies only considered model precision by minimizing the uncertainties (either parameter or model prediction) as their objective function. However, reducing uncertainty does not guarantee a good fit for the model predictions. In this study, we address a new criterion, accuracy, as one of multiple objective functions. Here, "precision" refers to the uncertainty of state estimates and "accuracy" denotes the unbiased tracking of the target value. Therefore, a meter placement design presented in this study comprises finding the set of meter locations that optimally improve the accuracy and the precision of state estimates. The state condition of concern is the nodal demand.

METHODOLOGY

The OMP problem requires demand estimation and uncertainty analysis. The methods applied are taken from Kang and Lansey (2008b) and described in steps 1-3. The OMP location is determined using a genetic algorithm (step 4).

1. Demand aggregation and field data generation. To reduce the number of unknowns and subsequently the number of measurements for demand estimation, nodal demands are grouped (i.e., aggregated) based on the relative locations and user characteristics, such as industrial, commercial, and residential. Once group total demands are estimated, they are allocated to individual nodes proportionally to the consumption ratio of each node as estimated from population densities or customer

billing records. Field measurement data sets (here, pipe flow rates) are synthetically generated using simulation model by adding Gaussian random errors for actual values.

2. Uncertainty quantification. The uncertainties caused by measurement errors are transferred through the demand estimation process and result in inaccurate demand estimates and subsequently propagated to the predicted output variables. Here, the first-order second moment (FOSM) approximate method is applied in a two step process:
First, the variances of nodal demands caused by measurement errors are estimated by

$$Cov(\mathbf{x}) = E[(\mathbf{x} - \hat{\mathbf{x}})(\mathbf{x} - \hat{\mathbf{x}})^T] \cong (\mathbf{J}^T \mathbf{R}_\mathbf{z}^{-1} \mathbf{J})^{-1}$$

where E is expectation operator, $\hat{\mathbf{x}}$ and $\mathbf{x}$ is the actual and estimated demand, respectively, and $\mathbf{R_z}$ is the covariance matrix of the measurement (pipe flow rates) error. $\mathbf{J}$ is the Jacobian (or sensitivity) matrix of pipe flow rates with respect to the nodal demands evaluated at the base demands. Note the diagonal elements of the covariance matrix, $Cov(\mathbf{x})$, are the variances of the individual nodal demand estimates. Second, the covariance matrix of nodal pressure predictions are estimated using $Cov(\mathbf{x})$ from first step and

$$Cov(\mathbf{y}) = \left[\left(\frac{\partial \mathbf{y}}{\partial \mathbf{x}} \right) Cov(\mathbf{x}) \left(\frac{\partial \mathbf{y}}{\partial \mathbf{x}} \right)^T \right]$$

where $\mathbf{y}$ denotes nodal pressure and $\partial\mathbf{y}/\partial\mathbf{x}$ represents the sensitivities of the nodal pressures with respect to the nodal demands. The diagonal terms of the covariance matrix, $Cov(\mathbf{y})$, are the variances of individual nodal pressure predictions. This FOSM has been successfully applied for uncertainty analysis of hydraulic variables by Xu and Goulter (1998), Lansey et al. (2001), and Kang et al. (2007, 2008).

3. Demand estimation. For demand estimation, a recursive state estimator based on the weighted least squares (WLS) method is applied (Kang and Lansey, 2008a and b). The WLS method has been widely used for parameter estimation (Datta and Sridharan 1994; Reddy et al. 1996) and state estimation (Powell et al. 1988) in WDS.

Consider the non-linear measurement model:

$$\mathbf{z} = \mathbf{h}(\mathbf{x}) + \mathbf{e}$$

where $\mathbf{z}$ is the measurement (pipe flow) vector, $\mathbf{x}$ is the true state vector of nodal demands and $\mathbf{h}(.)$ is a non-linear vector function relating measurements to states. $\mathbf{e}$ is the measurement error vector. The elements of $\mathbf{e}$ are assumed to have zero mean and the corresponding measurement covariance matrix is denoted by $\mathbf{R_z}$. Here, $\mathbf{h}(.)$ are linear/nonlinear equations describing the conservation of mass at each node and the conservation of energy across a pipe. These equations are solved using the hydraulic simulation model as a sequence of steady state conditions.

The demand estimation problem is formulated as a minimization of the squares of the errors or:

$$E(\mathbf{x}) = \frac{1}{2} (\mathbf{z} - \mathbf{h}(\mathbf{x}))^{\mathrm{T}} \mathbf{R}_\mathbf{z}^{-1} (\mathbf{z} - \mathbf{h}(\mathbf{x}))$$

A Taylor series expansion provides an approximation of the non-linear vector function **h(x)**:

$$\mathbf{h}(\mathbf{x}+\Delta\mathbf{x}) \approx \mathbf{h}(\mathbf{x}) + \mathbf{J}(\mathbf{x})\Delta\mathbf{x}$$

The minimization problem is rewritten as:

$$E(\mathbf{x}+\Delta\mathbf{x}) = (\Delta\mathbf{z} - \mathbf{J}(\mathbf{x})\Delta\mathbf{x})^{\mathrm{T}}\, \mathbf{R}_{\mathbf{z}}^{-1}\, (\Delta\mathbf{z} - \mathbf{J}(\mathbf{x})\Delta\mathbf{x})$$

where $\Delta\mathbf{z} = \mathbf{z} - \mathbf{h}(\mathbf{x})$.

The first-order optimality condition for this problem is:

$$\frac{\partial E(\mathbf{x}+\Delta\mathbf{x})}{\partial \Delta\mathbf{x}} = -\mathbf{J}^T(\mathbf{x})\,\mathbf{R}_{\mathbf{z}}^{-1}\,(\Delta\mathbf{z} - \mathbf{J}(\mathbf{x})\Delta\mathbf{x}) = 0$$

Hence, the linear least-squares solution can be expressed as:

$$\Delta\mathbf{x} = (\mathbf{J}^T(\mathbf{x})\,\mathbf{R}_{\mathbf{z}}^{-1}\,\mathbf{J}(\mathbf{x}))^{-1}\mathbf{J}^T(\mathbf{x})\,\mathbf{R}_{\mathbf{z}}^{-1}\,\Delta\mathbf{z}$$

Using the previous time step (*t*-1) solution as the initial estimate for current time *t*, the recursive equation for the multi-scan demand estimation is rewritten as:

$$\mathbf{x}(t_i) = \mathbf{x}(t_{i-1}) + (\mathbf{J}^T(\overline{\mathbf{x}})\,\mathbf{R}_{\mathbf{z}}^{-1}(t_i)\,\mathbf{J}(\overline{\mathbf{x}}))^{-1}\,\mathbf{J}^T(\overline{\mathbf{x}})\,\mathbf{R}_{\mathbf{z}}^{-1}(t_i)\,(\mathbf{z}(t_i) - \mathbf{h}(\mathbf{x}(t_{i-1})))$$

Note that the Jacobian matrix **J** is calculated only once using the base demands, $\overline{\mathbf{x}}$, prior to the multi-scan estimation to reduce the computational time. For a complete description of the demand estimation approach, see Kang and Lansey (2008a and b).

4. Multi-objective genetic algorithm. Genetic algorithms (GAs) are stochastic search techniques based on the evolutionary mechanisms inspired by biological evolution processes such as selection, crossover, and mutation (Goldberg 1989). The GA starts from a population of randomly generated individuals and evolves toward better solutions through many generations. Many design problems involve multiple objective optimizations and, if more than one objective is considered in an optimization problem, there may not exist only one best solution with respect to all objectives. Instead, there exists a set of solutions called Pareto-optimal solutions. All solutions on the Pareto-front are equally optimal but by moving from one Pareto solution to another the improvement in one function value causes deterioration in at least one other function value. Therefore, engineer's experienced judgment is still required to provide a practical solution depending on the application.

Three objectives are formulated: (1) minimize demand estimate uncertainty (Eq. 1a); (2) minimize pressure prediction uncertainty (Eq. 1b); and (3) minimize the RMSE between estimated demands and expected true values (Eq. 1c).

$$F_1 = \sum_{i=1}^{nnode} \sum_{t=1}^{ntime} sqrt(diag(Cov(x_{i,t}))) \tag{1a}$$

$$F_2 = \sum_{i=1}^{nnode} \sum_{t=1}^{ntime} sqrt(diag(Cov(y_{i,t}))) \tag{1b}$$

$$F_3 = \sum_{i=1}^{nnode} sqrt\left\{ \sum_{t=1}^{ntime} (x_{i,t} - \hat{x}_{i,t})^2 / ntime \right\} \tag{1c}$$

where *nnode* and *ntime* are the number of nodes and the simulation time, respectively, and *diag*(.) denotes diagonal elements of covariance matrix. For better comparison, The three objective functions (Eq. 1) are scaled by their corresponding values when

all locations are measured, $F_{i,full}$. The scaled dimensionless objective functions are:

$$Minimize \ \ f_1 = \frac{F_1}{F_{1,full}}$$

$$Minimize \ \ f_2 = \frac{F_2}{F_{2,full}}$$

$$Minimize \ \ f_3 = \frac{F_3}{F_{3,full}}$$

Note that the scaled objective functions are limited below at a value of 1.

RESULTS

The study network and network data are shown in Figure 1. To reduce the unknowns, nodes with similar consumer types are grouped i.e., industrial for node 3 itself, commercial for nodes 2, 4, and 6, and residential area for nodes 7, 8, and 9. Only those seven nodes have demands. Pipe flows are assumed to be measured on an hourly time step. The task here is to find the two best locations among the twelve pipes where the pipe flow rates will be monitored (assuming the flow from the source, i.e., pipe 13 is always measured). Flow transducers are assumed to have 10% measurement error, that is introduced by adding the Gaussian noise, $N(0,\sigma)$, where $\sigma = 0.1\mu/3.27$ to actual flows.

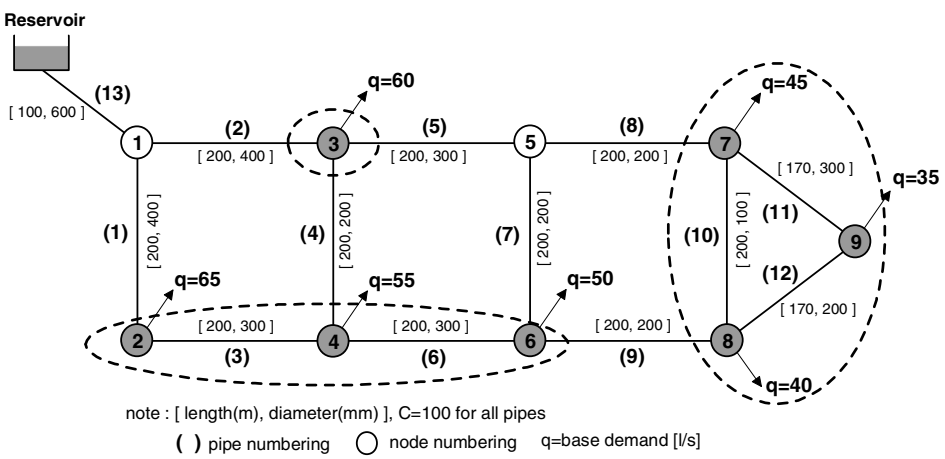

Figure 1. Study network schematic

Full enumerations are performed first by using the total 66 possible combinations (12 combinatorial 2, ${}_{12}C_2$). The problem is then solved using the MOGA. The solutions from the MOGA are compared to the solutions found by a full enumeration (Figure 2). As seen the Pareto solutions obtained from the full enumeration and the MOGA are identical. For the MOGA simulation, we defined 50 populations and 100 generations, i.e., 5,000 function evaluations. The stochastic search methods like GA repeat the same genes and relevant function evaluations. To prevent the costly repetitive

function evaluations, solutions (i.e., genes and relevant function values) obtained from previous generations are stored in the cache and used if the same genes are detected in the current generation. By doing so, GA could save computation time by 1/2 of the full enumeration although it has more function evaluations.

The trade-off between model precision and accuracy is clearly shown in Figures 2a and b. The Pareto-front between f_1 and f_2 (Figure 2c) appear to be correlated suggesting potential redundancy between the uncertainty objective functions.

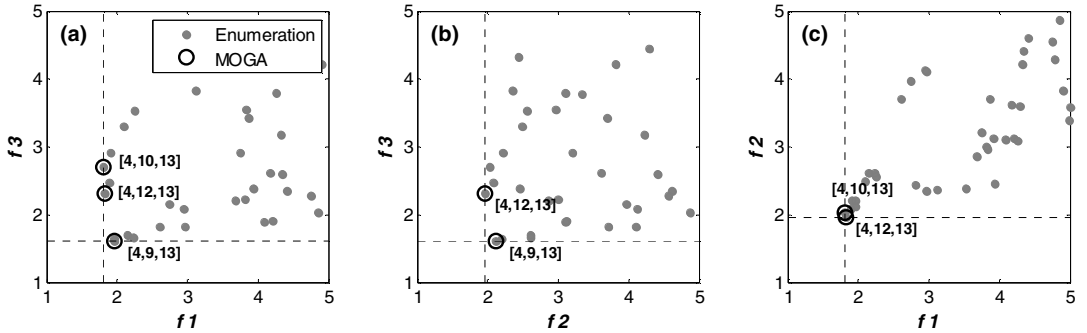

Figure 2. Pareto-front solutions from full enumeration and MOGA for three objective function pairs (OMP sets are in brackets)

To verify the suitability of the applied objective criteria for the OMP problem, the demand estimations are performed using the Pareto-front solutions. Three solution sets (set 1 – pipes 4, 10, 13 / set 2 – pipes 4, 12, 13 / set 3 – pipes 4, 9, 13) are selected. Note that measurement sets 1, 2, and 3 provide minimum values for function f_1, f_2, and f_3, respectively. Figures 3a, b, and c show the demand estimates and associated 95% confidence intervals for node 4 using measurement sets 1, 2, and 3, respectively. Figures 3a and b show precise but inaccurate state estimates. The demand estimates are poor and actual (true) values are frequently out of the estimated confidence bounds. On the other hand, Figure 3c shows relatively wider confidence intervals but more accurate estimates compared to Figures 3a and b. If only uncertainty measures are used as objective functions, sets 1 or 2 would be selected as solutions while set 3 is rejected. Therefore, for robust solutions, both model precision and accuracy should be considered as dual objectives in OMP problems.

Another important result observed from this study is that the OMP problem should be solved considering unsteady hydraulic conditions to take into account the temporal changes of nodal demands. In general, sampling design problems for parameter estimation are solved using multiple demand loads under steady state conditions. For example, demands at peak hour (8 am), average hour (2 pm), and minimum hour (3 am) are used to consider multiple system loading conditions. However, as seen in Figure 3, steady estimations at several points may not provide sufficient information for identifying accurate solutions. Instead, more robust solutions can be obtained by comparing the unsteady simulation results during a certain time period. Here, 24 hour

duration extended period simulation (EPS) has been performed based on an hourly time step.

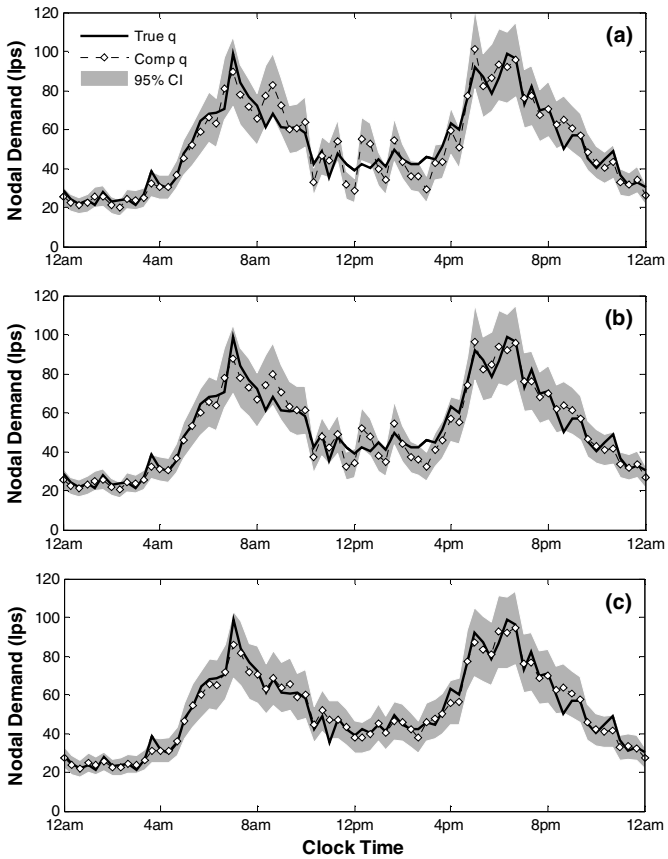

Figure 3. Demand estimates and 95% confidence intervals for node 4 using three Pareto-optimal sets: (a) Set 1 – pipes 4, 10, 13, (b) Set 2 – pipes 4, 12, 13, and (c) Set 3 – pipes 4, 9, 13

DISCUSSION

Optimal meter placement (OMP) for state estimation (SE) is formulated and solved in a multi-objective optimization model. Three objective functions, representing demand estimation uncertainty, pressure prediction uncertainty, and demand estimation accuracy, are defined. The optimization problems are solved using a multi-objective genetic algorithm (MOGA) based on Pareto-optimal solutions. The results from the example problem clearly demonstrate the trade-off between model accuracy and precision. It is seen that a precise state-estimation does not necessarily guarantee an accurate estimation and vice versa. Therefore, both measures should be included in an SE OMP problem as objectives. However, the Pareto-fronts between two uncertainty functions appear to be correlated each other indicating potential redundancy. Further study can be conducted for larger network to investigate the effect of different numbers of meters and solution layout.

Abstract

This paper describes and demonstrates a method for on-line hydraulic state prediction in urban water networks. The proposed method uses a Predictor-Corrector (PC) approach in which a statistical data-driven algorithm is applied to estimate future water demands, while near real-time field measurements are used to correct (i.e., calibrate) these predicted values on-line. The calibration problem is solved using a modified Least Squares (LS) fit method. The objective function is the minimization of the least-squares of the differences between predicted and measured hydraulic parameters (i.e., pressure and flow rates at several system locations), with the decision variables being the consumers' water demands. The a-priori estimation (i.e., prediction) of the values of the decision variables, which improves through experience, facilitates a better convergence of the calibration model and provides adequate information on the system's hydraulic state for real time optimization. The proposed methodology is demonstrated on a prototypical municipal water distribution system.

1. Introduction

The integration of near real-time hydraulic data with computer simulations for on-line operation and control of large-scale urban water distribution systems can be used in a variety of applications ranging from real-time optimization of pump and valve settings for efficient power management; to the detection and quantification of leaks. Such a system can also be used for the implementation of water security systems and for the prediction of system performance during emergency events (e.g., pollution events, main pipe rupture, or significant fire).

Over the last 10 years, computer simulation models of water networks have been widely used by water systems operators (Walski et al. 2003). In conventional practice, model calibration is carried out off-line (USEPA 2005) using a short-term (e.g., one week) sample of hydraulic data (e.g., based on a limited set of flow rate and pressure measurements within the network). Thereafter, uncertain system parameters (e.g., water demands and pipe roughness) are adjusted until an acceptable match is achieved between the model outputs and physical observations. Ormsbee (1989) and Lansey and Basnet (1991) were among the first to develop formal optimization methods for determining the uncertain system elements. Datta and Sridharan (1994), and Reddy et al. (1996) used the regression approach in which parameter uncertainties were estimated as part of the calibration process. Greco and Del Giudice (1999) used a "sensitivity matrix" to minimize the least squares differences between observed and predicted values, and Lingireddy and Ormsbee (1998) developed a calibration method using Artificial Neural Networks (ANN). More recently, Kapelan et al. (2007) used the shuffled complex evolution metropolis (SCEM-UA) global optimization algorithm to solve a least-squares-type calibration problem where both calibration parameter values and associated uncertainties were considered in a single optimization model run.

The current research uses a Genetic Algorithm approach following methods developed by Savic and Walters (1995); Wu and Simpson (2001); Kapelan et al. (2002); Wu et al. (2002); Walski et al. (2006); and Clark and Wu (2006).

Overall, the main limitation of all off-line calibration procedures is that they approximate the unknown parameters using a short-term sample of hydraulic data. The calibration results may represent the system hydraulics during the short period of the sampling procedure but they are not expected to accurately represent the system conditions for the full range of operational conditions that can occur. In the case of water demands this issue is even more critical, since water demands have dynamic/stochastic pattern variations which fluctuate with time-changing economic and demographic characteristics and may even show trends with local climatic conditions *(*Maidment and Miaou 1986; Kenward and Howard 1999; Zhou et al. 2000*).* In principle, much more realistic predictions can be achieved by updating the hydraulic state-

estimation using continuous on-line hydraulic measurements, provided by a sensor network installed on the distribution system.

There have been several recent studies that have assimilated on-line measurements into hydraulic state estimation models. Davidson and Bouchart (2006) propose proportional and target demand methods. These are two techniques for adjusting estimated demands in hydraulic models of water distribution networks to produce solutions that are consistent with available Supervisory Control and Data Acquisition (SCADA) data. The two techniques assume that pipe resistances and SCADA data are accurate and that the combination of SCADA data and demand estimates produce over-determined problems. Nodal demands are regarded as stochastic variables which fluctuate about an estimated mean value. The method of weighted least squares is used to obtain solutions that satisfy all of the constraints imposed by SCADA data with adjusted nodal demands that most closely resemble the estimates. The methods are intended for use in real-time modeling but are limited to quasi-steady state flow.

Shang et al. (2006) presented a predictor-corrector method, implemented in an extended Kalman filter to estimate water demands within distribution systems in real-time. A time-series ARIMA model is used to predict the water demands based on the estimated demands at previous steps. The predictions are corrected using measured nodal water heads or pipe flow rates. As noted by the authors, the proposed methodology is in a preliminary stage and aimed mainly to study the impact of spatial correlation between demand forecast errors on demand estimations. The methodology is demonstrated on EPANET example 3, having 59 demand nodes, through three simulation studies with 20 pressure, 20 flow rate, and 40 flow rate sensors. The main conclusion was that the model performances depend on sampling design, measurement uncertainty, demand forecast error and the spatial correlations among the demand forecast errors. Although only preliminary results were presented, the study provided a modeling framework and mathematical tools for further implementations on more complex case studies.

In this study, a Predictor-Corrector (PC) approach which integrates a limited number of continuous hydraulic observations with a computer simulation model is implemented to continually predict the hydraulic state of a real urban water supply comprised of 10550 demand

nodes. The *M5 Model-Trees algorithm* (Quinlan 1992) is used to forecast future water demands for a rolling planning horizon of 24 h ahead, and *Genetic Algorithms* (Holland 1975) are used to correct (i.e., calibrate) these predicted values in real-time. Thereafter, at each subsequent time step, the corrected outputs of previous iterations are used as inputs for the prediction model. This a-priori estimation of the calibration parameters values, which improves through experience, facilitates a better and quicker convergence of the calibration procedure towards the optimal solution of the problem and provides adequate information on the system's hydraulic state for real time operation and control.

2. Methodology

Model definitions and assumptions

1. Calibration Parameters: The calibration parameters used in this study are the variations in water demands (i.e., defined as demand multiplication factors; see next paragraph for a full description of this parameter). The demand multiplication factors (DMFs) are calibrated at each time step of the overall process. Other uncertain variables are less dynamic and their values are assumed to be constant for a certain period of time. It is assumed that valve and/or pump settings are known inputs, while pipe roughness coefficients are calibrated off-line using conventional procedures (with complete supplementary information on pipe diameter, material type, and age).

2. Demand Multiplication Factors (DMFs): The baseline demand (D_{base}) of each consumption node is a deterministic value that usually equals to the average daily demand (i.e., average daily demand is calculated from monthly or quarterly meter readings and billing records). The patterns in demand on a finer time scale are described by Demand Multiplication Factors (DMFs). For each short-term time step in the demand pattern, the relevant DMFs are multiplied with the baseline demands of the consumption nodes to obtain the actual water consumption (i.e., $D_t = D_{base} \times DMF_t$; where D_t is the actual nodal demand at time step t and DMF_t is the demand multiplication factor at the same time step). It is assumed that the min-max DMFs boundaries are 0 and 3, respectively; previous publications (Walski et al. 2003; Jonkergouw et al. 2008) have shown that these min-max boundaries provide acceptable estimates for hourly basis demand multiplication factors.

3. Calibration parameters grouping: There are thousands of unknown parameters in a typical urban water system and only a relatively small number of direct measurements available. This creates an ill-posed, underdetermined problem which leads to non-unique solutions. This can be overcome by grouping the unknown parameters. Grouping is based on the assumption that water customers in a given area of the system will have the same characteristics and will not need large adjustments to achieve calibration (Wu et al. 2002; Walski et al. 2006). The main advantage of 'grouping' is that the size of the problem is reduced - making it possible to find unique solutions to the optimization problem. In this study, the consumption nodes were grouped based on spatial analysis of the system and each group of consumption nodes is assigned its own set of demand multiplication factors.

4. Time step: the method developed in this study is general and can be adjusted to a wide range of time-step intervals so that even frequent continuous sensor measurements can be used in the model. The current analysis uses a fixed one hour time step in order to match the frequency of available hydraulic data.

5. Time cycle: The common approach (Shang et al. 2006, Alvisi et al. 2007, and Ghiassi et al. 2008) for the time-series forecasting of water demands relies on direct identification of patterns existing in the archived system data. It has been observed that water demand patterns usually follow a 24-h cycle. This cycle is called the Diurnal Demand Pattern (DDP) and is used by many urban water utilities to plan the system operation one day ahead (i.e., to schedule pump operation and plan tank storage). Weekend demand patterns often differ from weekday patterns and usually follow a 168-h (1 week) cycle. In this study, daily and weekly demand cycles were used, so that the DMFs at each time-step are predicted based on previously calibrated DMFs from past hours 24, 25, 168, and 169.

Predictor-Corrector Model

The predictor-corrector loop process starts at t=169 hr, after performing an off-line calibration procedure for the first 168 h (1 week) of the collected data; the aim of this off-line calculation is to generate initial values for the input data-set of the prediction model; no a-priori information on the first 168 h DMFs values is available except of the min-max boundaries which are 0 and 3,

respectively. At t=169 h the prediction-correction process (Fig. 1) is initiated. The following paragraphs describe the model steps:

1. DMF prediction: DMFs values of each group of demand nodes are predicted using the *M5 Model Trees algorithm*, with the inputs being the calibrated DMFs from past hours t-24, t-25, t-168, and t-169

2. EPANET simulation: the system hydraulics are simulated using the steady-state mode of EPANET, with the predicted DMFs as inputs; the hydraulic simulation outputs are nodal pressures and pipe flow rates

3. On-line hydraulic data integration: pressure and flow measurements (from a set of in-line sensors) are inserted to the model at the current time step

4. DMF correction/calibration: a calibration problem is formulated and solved using *Genetic Algorithms*. The objective function is the minimization of the differences between predicted and measured hydraulic parameters (i.e., pressure and flow rates at the measured locations), with the decision variables being the consumers' water demands (i.e., the Demand Multiplication Factors - DMFs). A modified Least Squares fit method (the Huber function) which takes into account noisy measurements is implemented to solve the optimization problem

5. DMF delay: the calibrated DMFs are being delayed for 24, 25, 168, and 169 h before being used as inputs in the prediction model

- Steps 1 to 5 are repeated at each subsequent time step

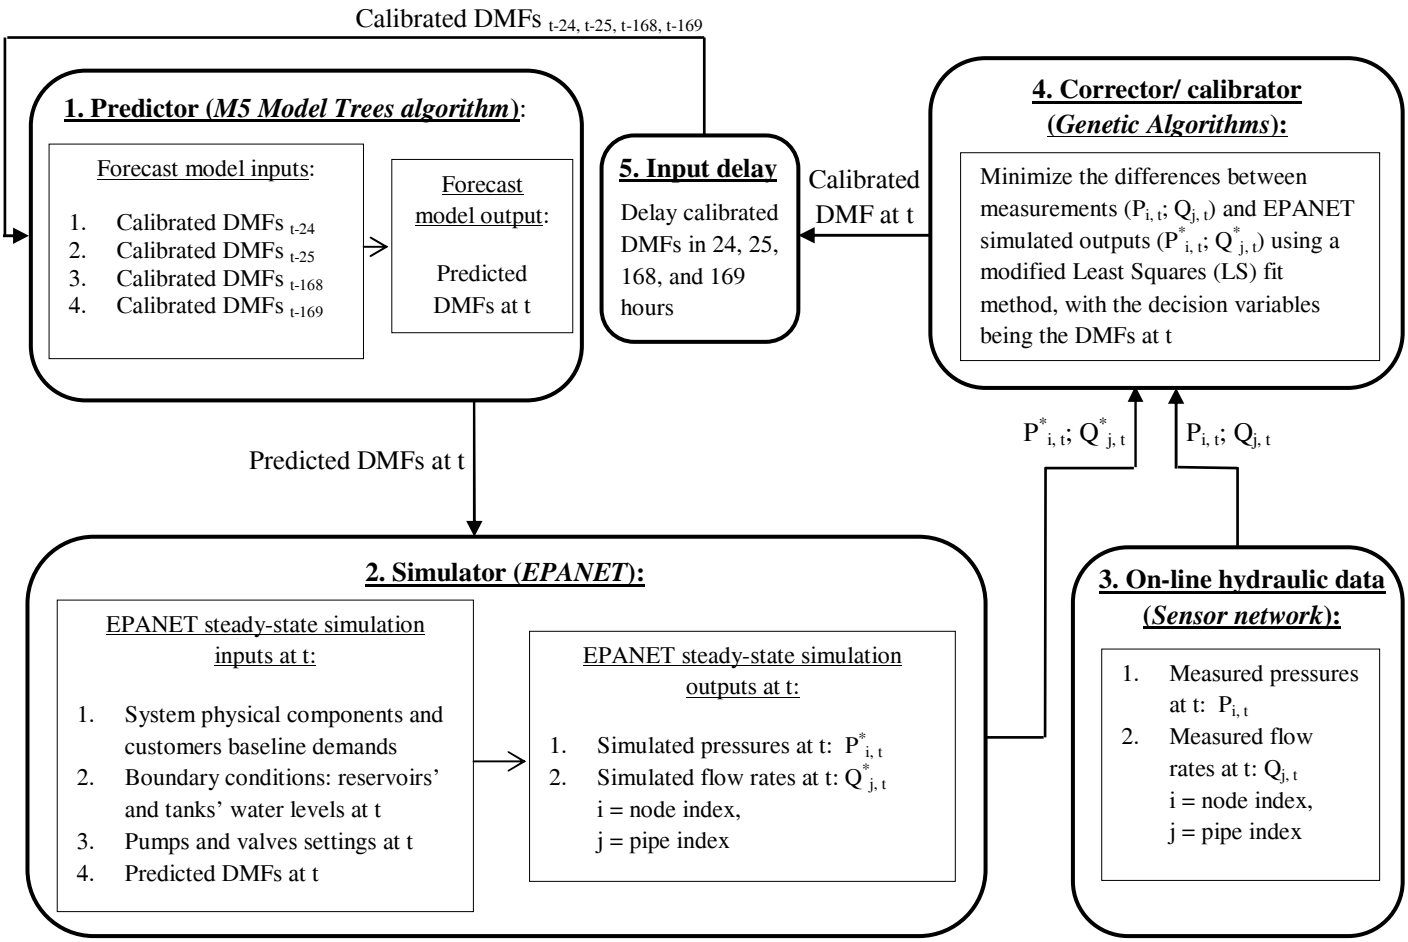

Fig. 1: predictor- corrector loop for Demand Multiplication Factors (DMFs) prediction at the t^{th} time step

The basic building blocks of the predictor-corrector model (e.g., *M5 Model Trees algorithm* and *Genetic Algorithms*) are described in the following paragraphs.

M5 Model Trees algorithm (Quinlan 1992)

The M5 model trees algorithm (Appendix A gives a more comprehensive description of the methodology) builds rule-based predictive models using a top-down induction approach. The tree is fitted to a training data set by recursively partitioning the data into homogeneous subsets based on its attributes. Thereafter, the tree is constructed with all training cases being predicted by the tree leaves (i.e., each leaf is a linear regression model that can explain the remaining variability of each homogeneous subset). In order to simplify the tree structure, and thus to improve its ability to classify new instances, the tree is then pruned from the bottom-up by quantifying the contribution of each attribute to the overall predicted value and removing those

attributes that add little to the model. At the last stage, a smoothing process is performed to compensate for the sharp discontinuities that will inevitably occur between adjacent linear models at the leaves of the pruned tree.

As observed in previous studies (Solomatine and Xue 2004, Bhattacharya et al. 2007, and Ould-Ahmed-Vall et al. 2007), Model Trees have several advantages compared to other data-driven techniques such as Artificial Neural Networks (ANN), Support Vector Machines (SVM), and Regression Trees: Their accuracy is similar to that of both ANN and SVM and much better than that of Regression Trees; they are interpretable to users (in contrast to 'black-box' ANN and SVM models) and hence can provide insights to prevent sources of inefficiencies; and they are much faster in training compared to all other methods.

Genetic Algorithms (GA) (Holland, 1975)

Genetic Algorithms are heuristic combinatorial search techniques that imitate the mechanics of natural selection and natural genetics of Darwin's principles of evolution. The basic idea is to simulate the natural evolution mechanisms of chromosomes (represented by string structures), involving: selection, crossover, and mutation. This is accomplished by creating a random search technique that combines survival of the fittest among string structures with a randomized information exchange. A typical form of a genetic algorithm involves three main stages: 1) Initial population generation: the genetic algorithm generates a bundle of strings (termed population, or generation), with each string (chromosome) being a set of values of the decision variables/optimization parameters. 2) Computation of string fitness: the genetic algorithm evaluates each string's fitness (i.e., the value of the objective function that corresponds to each string). 3) Construction of a new generation: the genetic algorithm establishes the next generation by performing selection, crossover, and mutation. The process of selection involves choosing strings (chromosomes) from the current population for reproduction according to their fitness values. Crossover involves the partial exchange of information between pairs of strings; and mutation is the random change in one of the string locations. The genetic algorithm parameters are the population size, the mating and mutation rates, and the number of generations.

Calibration Problem Objective Function

The objective of the calibration process is to match the computed and measured sensor node data (pressure and/or flow rates), taking into consideration possible noise in the measurements. In this application, calibration is achieved by minimizing a modified least-squares of differences function known as the Huber function (Huber 1973). The Huber function implementation to the hydraulic state estimation problem is described as follows:

1. The differences (i.e., residuals) between modeled and observed pressures and flow rates at each time step, at sensor node *i* - are defined as $R_{i,t}^{P}$ and $R_{i,t}^{Q}$ respectively
2. The Huber function of each residual R is defined as

$$f\left(R_{i,t}^{P\ or\ Q}\right) = \begin{cases} \frac{1}{2}\left(R_{i,t}^{P\ or\ Q}\right)^2, & \left|R_{i,t}^{P\ or\ Q}\right| \le h \\ h\left|R_{i,t}^{P\ or\ Q}\right| - \frac{1}{2}h^2, & \left|R_{i,t}^{P\ or\ Q}\right| > h \end{cases} \quad (1)$$

   where h is a predefined value that represent the tolerance to noise in measurements; for small residuals ($|R| \le h$) that represent low to zero values of noise in sensor measurements, the Huber function minimizes the usual least squares function (i.e., l_2 norm approximation), for large R ($|R| > h$) that represent high values of noise in sensor measurements, it minimizes a linear penalty function which is relatively insensitive to noise (i.e., l_1 norm approximation)
3. The overall calibration problem objective function to be minimized at each hydraulic time-step *t* is defined as

$$\sum_{i=1}^{N_P} f\left(R_{i,t}^{P}\right) + \sum_{i=1}^{N_Q} f\left(R_{i,t}^{Q}\right) \quad (2)$$

   where *i* is the sensor nodes index, N_p is the total number of pressure sensors, and N_Q is the total number of flow rate sensors

- In this application the value of *h* in each sensor node at each time-step is equal to the average of all previous time-steps sensor node residuals multiplied by a factor of 2.

3. Results

The predictor-corrector approach developed in this study was tested against the real input data of Network 2 (Fig. 2) of the "Battle of the Water Sensor Networks (BWSN): A Design Challenge for Engineers and Algorithms" (Ostfeld et al. 2008). The network corresponds to an anonymous but real water distribution system comprising 12,523 nodes, two constant head

sources, two tanks, 14,822 pipes, four pumps, five valves. The system was subject to highly variable demand patterns over a period of 934 hours (~39 days). Hydraulic simulations for this system are considered valid for this entire duration. The original EPANET input file was downloaded from the University of Exeter Centre for Water Systems (ECWS) web-site (http://www.exeter.ac.uk/cws/bwsn).

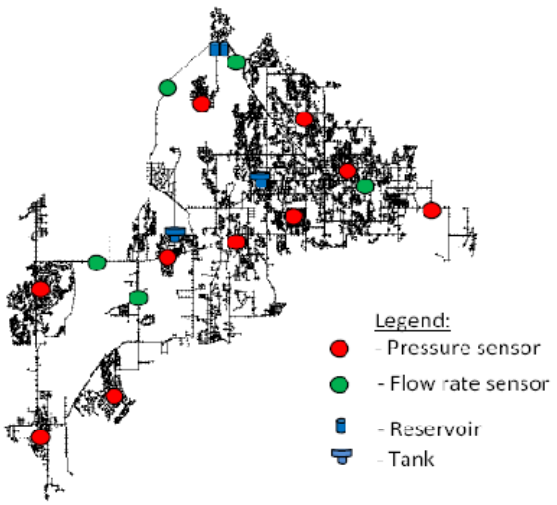

Fig. 2: Network 2 with the sensor nodes locations

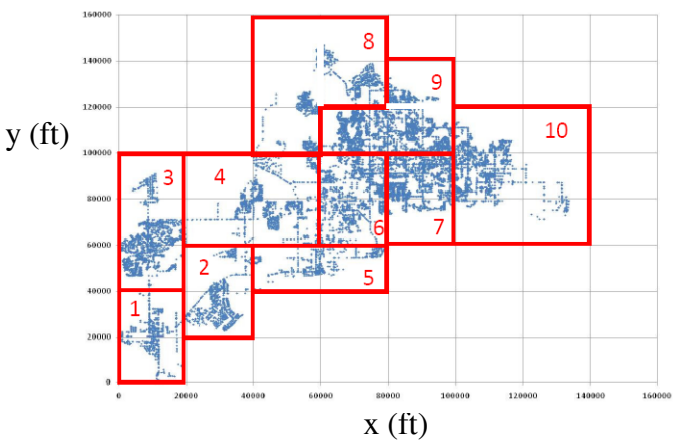

Fig. 3: demand nodes groups on a plane grid of the system

The current application assumes that continuous in-line data are available from 10 pressure and 5 flow rate sensors (Fig. 2). The nodal flow and pressure records from these locations were generated by the EPANET model using real input data for the system. The reservoirs and tank water levels were considered as known inputs. The analysis considers 10 demand zones (i.e., 10 groups of demand nodes; see Fig.3) based on a spatial analysis of the system. It is expected that the consumption nodes in each zone will follow the same demand pattern and each nodal base demand at each zone will be multiplied with the same DMF. Therefore, the number of decision variables to be calibrated/corrected at each time-step is equal to 10.

The total running time on a DELL PC (2.66 GHz, 3.0 GB of RAM) of the GA calibration process (i.e., with a GA population of 48 ‘chromosomes’ and 30 GA generations) is about 5 minutes and the total running time of the data driven prediction process is less than 10 seconds.

Base Run: Demand Multiplication Factors (DMFs) prediction accuracy

Following previous data-driven models implementations (e.g., Solomatine and Xue 2004 and Bhattacharya et al. 2007), about 33% of the data (from t = 680 to 934 hrs, corresponding to a total of 254 hrs) was used for cross validating the model predictions. The predictive ability of the model can be evaluated with several prediction metrics. In this application, the following commonly used metrics were applied to evaluate the fit between predicted (p) and actual (a) values:

1. Correlation Coefficient (CC): measures the degree of correlation between predicted and actual values; it ranges from -1 to 1, with 1 corresponding to an ideal correlation:

$$CC = \frac{Cov(p,a)}{\sigma_p \sigma_a} \quad (3)$$

where $Cov(p,a)$ is the covariance between p and a; and σ_p, σ_a are their standard deviations

2. Root Mean Squared Error (RMSE): RMSE is a frequently-used measure of the differences between values predicted by a model or an estimator and the values actually observed; it ranges from 0 to infinity, with 0 corresponding to ideal fit:

$$RMSE = \sqrt{\frac{\sum_{i=1}^{N}(p_i - a_i)^2}{N}} \quad (4)$$

where p_i and a_i are the predicted and actual values of case i; and N is the number of cases

3. Mean Absolute Error (MAE): MAE is similar to RMSE, except it uses absolute error values instead of the squared errors; it ranges from 0 to infinity, with 0 corresponding to ideal fit:

$$MAE = \frac{\sum_{i=1}^{N}|p_i - a_i|}{N} \quad (5)$$

where p_i and a_i are the predicted and actual values of case i; and N is the number of cases

4. Root Relative Squared Error (RRSE): RRSE value is relative to what it would have been if a naive predictor had been used. More specifically, this simple predictor is just the average of the actual values; it ranges from 0 to infinity, with 0 corresponding to ideal fit:

$$RRSE = \sqrt{\frac{\sum_{i=1}^{N}(p_i - a_i)^2}{\sum_{i=1}^{N}(a_i - a_{av})^2}} \quad (6)$$

where p_i and a_i are the predicted and actual values of case i; a_{av} is the mean of the observed data; and N is the number of cases

The accuracy of the 10 zones DMF predictions is summarized in Table 1:

Zone index	CC	RMSE	MAE	RRSE
1	0.87	0.05	0.06	0.16
2	0.89	0.06	0.06	0.18
3	0.92	0.04	0.05	0.18
4	0.85	0.06	0.06	0.18
5	0.85	0.06	0.06	0.18
6	0.86	0.06	0.07	0.17
7	0.91	0.07	0.06	0.16
8	0.92	0.05	0.06	0.16
9	0.87	0.04	0.05	0.15
10	0.92	0.04	0.05	0.15

Table 1: Predictive metrics for DMFs in 10 demand zones from base run

The results indicate that the predictor – corrector model has relatively good predictive accuracy for all 10 demand zones according to all four metrics. All of the DMFs were predicted with a correlation coefficient exceeding 0.85 with mean absolute error below 10%. Figures 4 to 6 show the improvement achieved in the predictor-corrector model predictions through experience, as demonstrated on one of the system demand nodes (e.g., Junction 7631). In this example, the correlation coefficient (CC) is used as the characteristic measure of predictive accuracy. The data set of results from t = 169 – 934 hrs was divided into 3 segments (Δt_1 =169 - 424 hrs; Δt_2 =425 - 679 hrs; and Δt_3 = 680 to t=934 hrs). Figure 4 shows a correlation coefficient, CC = 0.66 for time period Δt_1. This low value is explained by insufficient input data for the Model Trees predictor in forecasting future DMFs. For the second (Fig. 5) and third (Fig. 6) time periods, with the increase in training data, there is an improvement in the predictor-corrector performances that is refelected in higher correlation coefficients, CC = 0.85 and 0.92, for periods Δt_2 and Δt_3, respectively.

Comparison between on-line and off-line calibration model performance

Since the main hypothesis of this study is that on-line hydraulic-state prediction models are more accurate than off-line calibration models in representing the hydraulic state of the water system, the predictive accuracy of the proposed predictor-corrector analysis must be compared with reference results from off-line calibration. The off-line reference result are based on a calibration using the same pressure and flow records for a one-week period ($\Delta t_0 = 0 - 168$ hrs). The off-line calibration process was much more intensive then the on-line model (200 GA iterations instead of 30, with a GA population of 120 decision variables' strings instead of 48) and resulted in a relatively high fit for the DMF's during the calibration time period.

The predicted Demand Multiplication Factors (DMFs) for time period 3 (680 - 934 hrs) were used together with EPANET analyses to calculate unknown hydraulic outputs (e.g., flow rates; flow directions; and nodal pressures). Thereafter, these parameters, which represent the hydraulic state of the water system - were used to evaluate and compare the predictions accuracy of the on-line and off-line models.

1. Flow rate prediction

The statistical evaluation of the predicted flow rates includes 5 ranges of predictive accuracy (i.e., within 5, 10, 15, 20, and 25 % of the actual flow rates for two groups of pipes: 1) pipes with diameters less than 24'' which correspond to more than 80% of the network length and 2) medium and large pipes with diameter greater than 24" The statistics are computed for all the pipes in the system (e.g., 15000 pipes) throughout time period 3 (i.e., over a period of 254 hrs); such that the total number of flow rates considered is 3.76×10^6 (14822x254). The results for pipe groups 1 and 2 are shown in Figures 7 and 8, respectively. The proposed predictor-corrector model outperforms the off-line calibration process and provides significantly better estimates of flow rates for both sets of pipes. The predictions are generally much more accurate for the medium and large pipes (group 2, Figure 8) than for the small diameter pipes (group 1, Figure 7). For the medium and large diameter pipes, the predictor-corrector model is within 5% of the actual flow rates for 68% of the samples and within 25% for 95% of the sample population (Fig. 8). For the smaller pipes the 5% and 25% accuracy rates drop to 48% and 86% of the

population. In contrast, the off-line calibration is only within 5% of the actual flow for 22% of the small pipes and 43% of the medium to large pipe sample population.

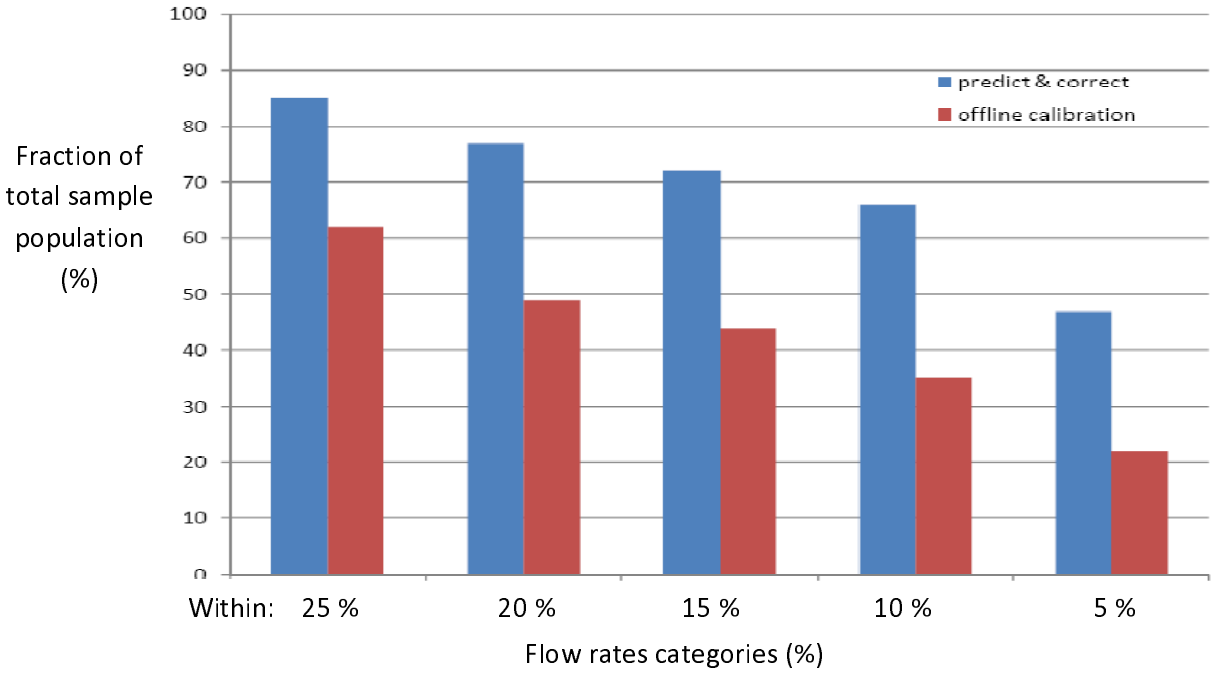

Fig. 7: Comparison of estimated and measured flow rates using the predictor-corrector and off-line calibration methods small pipes (with diameter less than 24")

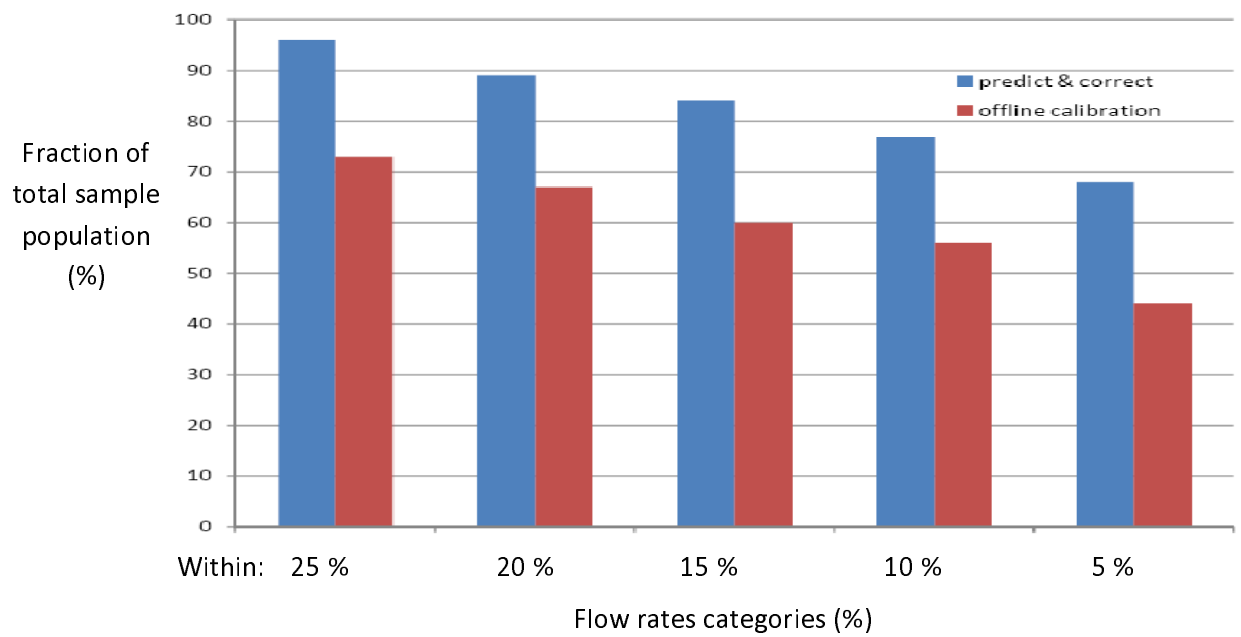

Fig. 8: Comparison of estimated and measured flow rates using the predictor-corrector and off-line calibration methods for medium and large pipes (diameter greater than 24")

The proposed predictor-corrector model correctly estimated the flow direction for 100 % of the sample population of 114822 pipes from t = 680 to 934 hrs while the off-line calibration was accurate for 97% of the actual flow directions in the system. The main conclusion from the above is that flow directions are less sensitive to variations in the DMFs (at least for this reference pipe network) as both the on-line and off-line models were able to provide very accurate estimations of this parameter.

2. Pressure prediction

The statistical evaluation of nodal pressures considers 7 ranges of predictive accuracy (i.e., ± 2, 4, 6, 8, 10, 12 and 14 psi of the actual pressures). The statistics are computed for all the nodes in the system (e.g., 12523 nodes) through time period 3 (t = 680 - 934 hrs); corresponding to a total sample population of 3.81×10^6. It can again be observed that the proposed predictor-corrector model provides significantly better estimations for the pressures than the off-line calibration process. In this case, 87% of the samples are estimated within 4psi using the predictor-corrector scheme compared to 42% using the off-line calibration.

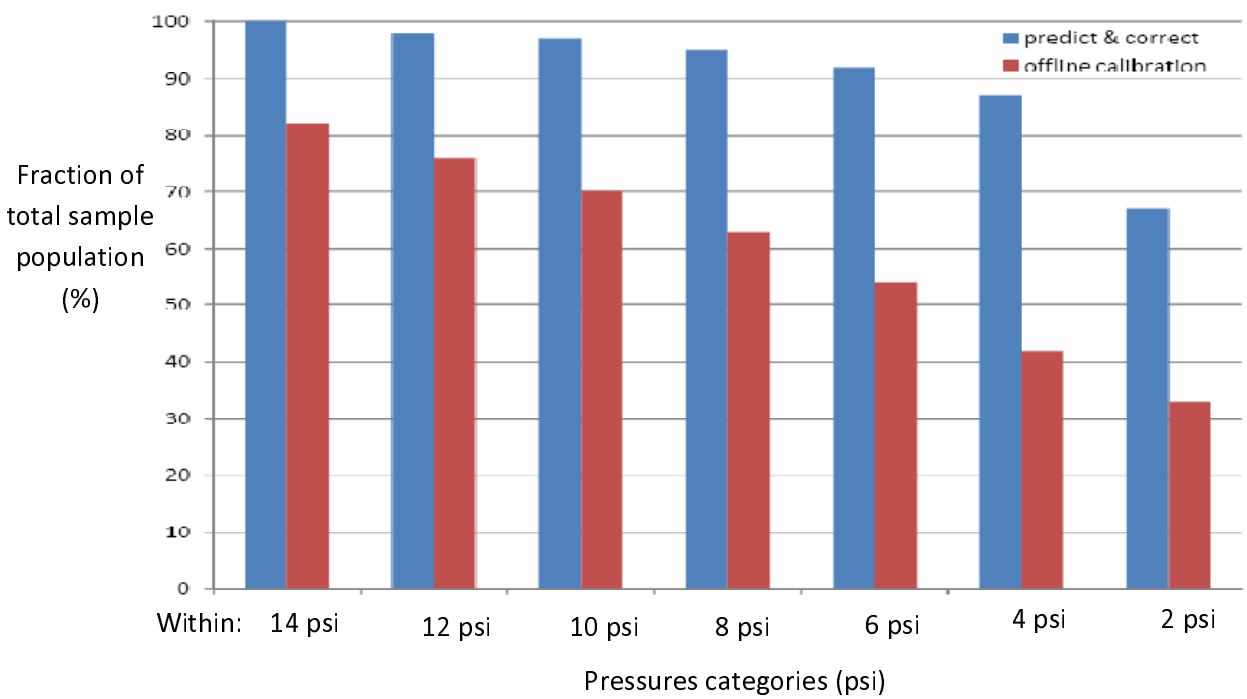

Figure 9: Comparison of predictive accuracy for nodal pressures using the proposed predictor-corrector scheme and an off-line calibration process

Effect of Demand Zone selection

The Authors have carried out a sensitivity analysis to evaluate how the partition of the system into demand zones can affect performance of the predictor-corrector model. Figure 10 shows a revised partition of the network into 20 demand zones. In order to keep the problem slightly over-determined, the number of the sensor locations was increased to 25. In order to comply with the increase in the number of decision variables in the calibration problem, the genetic algorithm parameters were altered to 60 iterations with a population of 96 decision variable strings (vs. 30 and 48, respectively, used in the base run).

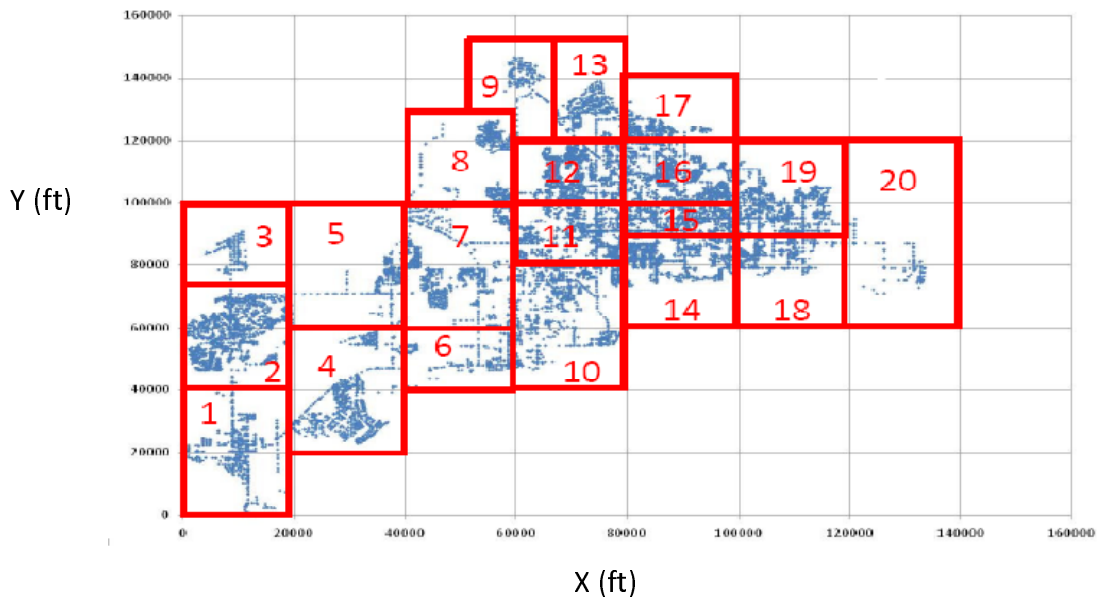

Fig. 10: Sensitivity analysis using 20 demand zones for the reference pipe network

The correlation coefficients for the DMF's in the 20 zones DMF are summarized in Table 2:

Zone index	CC	Zone index	CC
1	0.88	11	0.85
2	0.86	12	0.88
3	0.83	13	0.87
4	0.89	14	0.78
5	0.84	15	0.89
6	0.88	16	0.92
7	0.88	17	0.91
8	0.86	18	0.86
9	0.93	19	0.86
10	0.92	20	0.87

Table 2: Correlation coefficients of DMFs for the 20 zone model of the network

The average correlation coefficient for the entire system (CC = 0.87) is slightly lower than that obtained in the base run (average CC = 0.89) but requires much higher computational effort (e.g., about double the total running time of the base run) making it not worthwhile to change the demand zones selection used in the base run. Although, the revised partition of the network into 20 demand zones need not necessarily improves the predictive accuracy of the model (at least using CC values) this process of testing different system partitions is important as it may improve the model performances. As a conclusion of this sensitivity analysis, grouping demand nodes into demand zones requires high level of judgment based on good knowledge of the system structure. Therefore, if Geographical Information System (GIS) data of the municipality is available, then it is advisable to incorporate it in the demand zone selection procedure and to test the model performances with several system partitions.

4. Summary

This paper has presented and demonstrated a Predictor-Corrector (PC) model for on-line, hydraulic state prediction of urban water networks. The method uses a statistical data-driven algorithm (M5 Model Trees algorithm) to estimate future water demands, while near real-time field measurements are used to correct (i.e., calibrate) these predicted values on-line. The calibration problem is solved using Genetic Algorithms with a modified Least Squares (LS) fit method (Huber function) to account for noisy measurements. The a-priori estimation (i.e., prediction) of the decision variables values, which improves through experience facilitates a better convergence of the calibration model towards the optimal solution of the problem; and provides adequate information on the system's hydraulic state for real time optimization. Future research efforts will focus on the implementation of the developed methodology on large scale urban water system using physical data from an in-situ sensor network. Additional efforts will focus on the ability to detect anomalies such as leakage and burst events in real time. The integration of water networks aggregation methods to reduce the computational time required for the calibration process will also be explored.

Appendix A: *Model Trees* Construction using the *M5* Algorithm (Quinlan 1992)

Suppose we have a set of *T* training cases. Each case is specified by its value of a fixed set of attributes and has an associated target value. The aim is to construct a model that relates the target values of the training cases to their values described by the input attributes. The performance of the model will generally be measured by the accuracy with which it predicts the target values of unseen cases (cross-validation data set). Fig. A1 illustrates a set *T* which is described by two input attributes (x_1, x_2) and one target attribute (y):

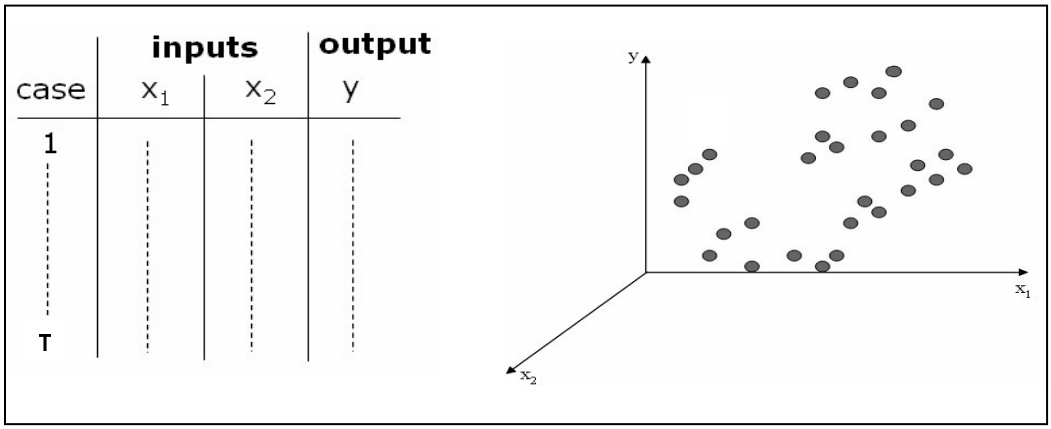

Fig. A1: Set T - described by 2 input attributes (x_1, x_2) and 1 target attribute (y)

In this tree based model, the set *T* is either associated with a leaf, or some test is chosen that splits *T* into subsets corresponding to the test outcomes. The same process is applied recursively to the subsets. This persistent division often produces over-elaborate structures that must be pruned back (i.e., this process is described by the following steps).

Step 1: Building the Initial Tree

The standard deviation of the target values of cases in *T* is computed. Unless *T* contains very few cases (e.g., three examples or less) or their values vary only slightly (e.g., 5% of the standard deviation of the class values of the original set of examples), *T* is split on the outcome of a test. Every potential test is evaluated by determining the subset of cases associated with each outcome; let T_i denote the subset of cases that have the *i-th* outcome of the potential test. If we treat the standard deviation $sd(T_i)$ of the target values of cases in T_i as a measure of error, the expected reduction in error (*SDR*) as a result of this test can be written as:

$$SDR = sd(T) - \frac{1}{|T|}\sum_i |T_i| \, sd(T_i) \qquad \text{(A1)}$$

After examining all possible tests, the model tree chooses one that maximizes this expected error reduction (*SDR*). At this step an initial model tree has been grown and a multivariate linear model is constructed for the cases at each node of the model tree using standard regression techniques. Fig. A2 illustrates this process on the data set *T* introduced in Fig. A1.

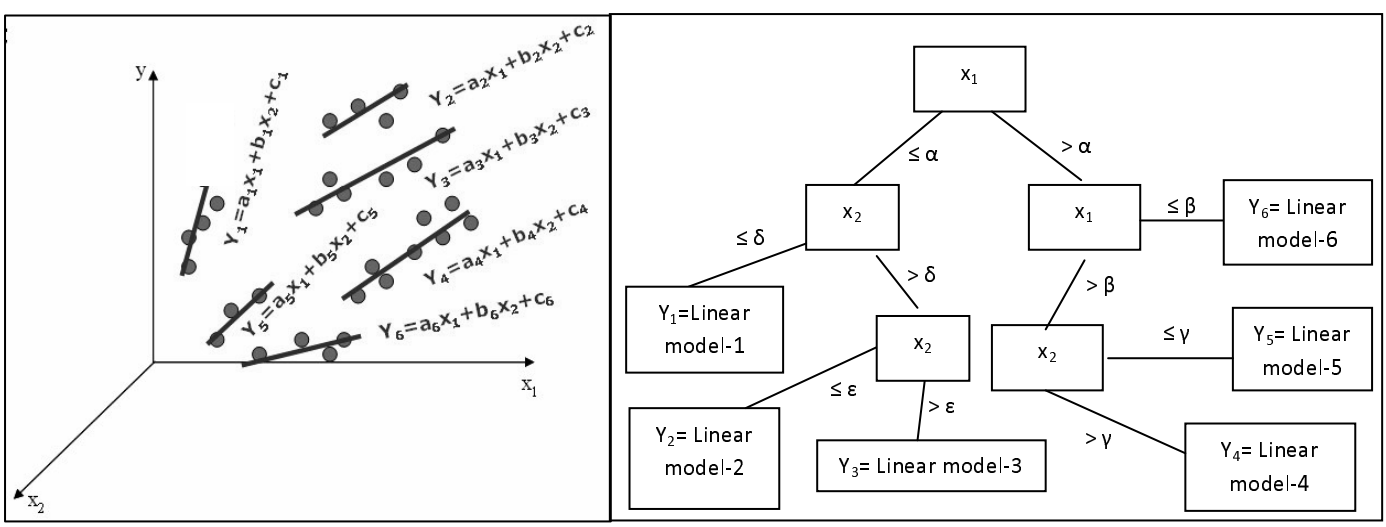

Fig. A2: model tree construction based on the data set - *T*

After that, the tree is transferred into a simple set of *If-Then* rules that simplify the tree structure and make the tree internal structure interpretable to users. Fig. A3 illustrates this process on the data set *T* introduced in Fig. A1.

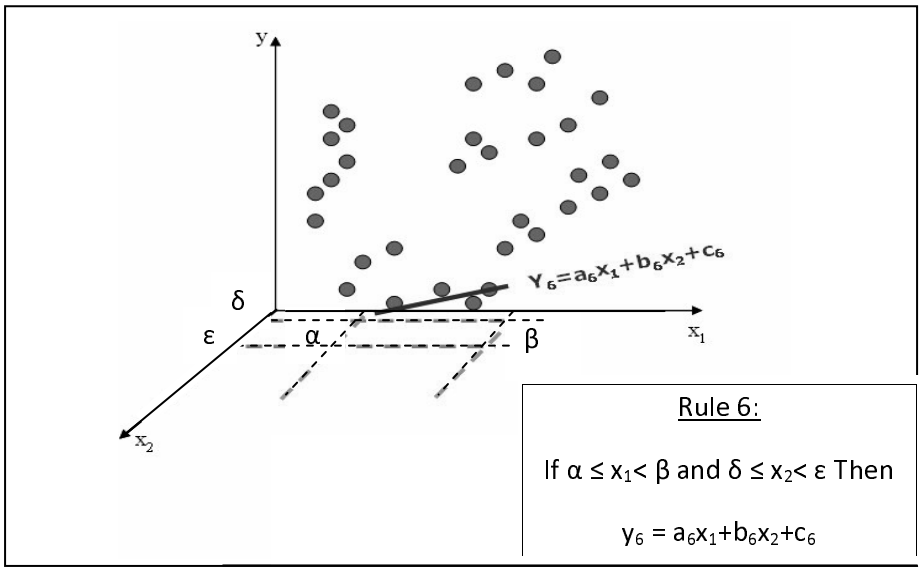

Fig. A3: model tree transformation into an *If-Then* set of rules demonstrated on sub-set Y_6

Step 2: Pruning the Tree

At the second step, the over-elaborated model tree structure is simplified, and pruned bottom-up - and thus its ability to classify new data sets (i.e. cross validation data) is improved. The simplification of the model tree is performed mainly by removing variables that contribute little to the model; in some cases the algorithm removes all variables, leaving only a constant.

Step 3: Smoothing

The smoothing process is performed to compensate for the sharp discontinuities that will inevitably occur between adjacent linear models at the leaves of the pruned tree, particularly for some models constructed from a smaller number of training examples. In smoothing, the adjacent linear equations are updated in such a way that the predicted outputs for the neighboring linear input equations are becoming close in value.

SAMPLING OF RESIDENTIAL WATER USE FOR LEAK CONTROL VIA WATER BUDGETS

ABSTRACT

The paper provides insights into the sampling techniques that may be employed to assess domestic water use for developing water budgets at district scale aimed at losses evaluation. The basic idea is to use only few meters to provide inference on the total use of a district metered area by standard statistical sampling procedures. Random and stratified sampling are compared with reference to the sampling fraction necessary to obtain estimates of the daily use totals (or means) with given precision and confidence level. An application with real data from a small, homogeneous group of connections in Palermo (Italy) shows how stratified sampling allows a considerable reduction of the sampling fraction. A sensitivity analysis on model parameters (group variance, precision, confidence levels) shows how stratified sampling is always a better option than random sampling and that results are mainly driven by precision, with a considerable increase of the required sample size when the desired precision shifts from 5% to 1%.

INTRODUCTION

Developing water budgets is a basic step to assess the level of water losses in district-metered water distribution networks and is hence preliminary to the selection of asset management options such as leak detection and removal, pipe rehabilitation or substitution. It requires knowledge of water use of individual customers. Albeit conceptually straightforward, the water budget methodology has its major drawback in the metering of water use, as the metering system can be (inhomogeneously) old (or even absent in some instances) or it can prove difficult to organise extensive and detailed surveys of consumption data, whose format and information attached are in most cases designed for accounting purposes, rather than for technical ones. In addition, the amount of time required to implement such procedures may be incompatible with the requirements of the asset planning (and subsequent decision-making) process and with a real-time strategy of monitoring losses. This is particularly true whenever heterogeneous types of domestic uses co-exist within the same administrative unit, as is the case for the Italian "Ambiti", groups of neighbouring municipalities where water service is operated by a single company and

therefore sharing the same water tariff and the same investment plan. For such reasons, water budgets are often given up in the diagnosis of water losses in a water distribution network in favour of bottom-up approaches such as continuos night flow measurement (Farley and Tow, 2003).

It can be hence of some interest to explore the option to provide only few districts, or customers, with a perfectly working and updated metering system and to extend the results obtained to similar districts or users. In this paper the focus will be on this latter option, i.e. working with microdata of residential water use to assess water use of the whole district. Evaluation of the feasibility of working at larger scale (i.e. determining the number of districts to meter in order to infer total water use of a larger number of districts) is left to future work.

Curiously enough, the idea has received little attention both from the research community and from water utilities: after the pioneer work by Hanke and Mehrez (1979) on microdata of peak hour water use, although the importance of sampling domestic water use has been recognised and illustrated (Mays, 2004), little research and field work has been produced on the subject: Arreguin Cortes and Ochon-Alejo (1997) apply stratified sampling procedures directly to losses measurements, while Speight et al. (2004) suggest stratified sampling methodology as a suitable procedure for water quality assessment in water distribution systems and propose stratification criteria that are then evaluated via a synthetic data set. To some degree, such reduced set of experiences is in contrast with the considerable development of studies and tools for modelling time series of domestic consumption (e.g. Buchberger and Wu, 1995, Magini et al., 2008). Both aspects, however, should be seen as complementary, as the possibility of extending the results of time series modelling of single or multiple users to an entire district-metered area is also related to the selection of an appropriate sample size.

The paper is organized as follows. After a brief review on the theoretical background of sampling, a case study is introduced and a sensitivity analysis on the variables involved in the methodology is carried out, in order to highlight the ones with the largest impact on the necessary sample size.

SOME RESULTS FROM SAMPLING THEORY

Statistical sampling allows to obtain information on a given characteristic η of a population Ω of size N (η may be the water use of N domestic users) through a subset of Ω, i.e. n sampling units, with $n<N$. Sampled values of the characteristic will be denoted with y, in order to distinguish them from population values η. Information is conveyed through a synthetic value $f(\eta)$, such as the mean of the characteristic or its total, whose estimator will be denoted with h(y). The problem is to assess the number of sampling units to be drawn such that the estimated synthetic value h(y) may be assumed with a certain degree of confidence α to approximate the "true" value with a given precision ε. In statistical terms this implies that $f(\eta)$ has a probability of $1-\alpha$ to fall within interval $[h(y) - \varepsilon, h(y) + \varepsilon]$.

Sampling techniques vary according to how sampling is performed, i.e. to how the n units are selected out of the population. Simple random sampling, for instance, refers to a method of selection of the n sampling units such that the distinct samples

have an equal chance of being drawn. In stratified sampling, the population is first divided into M nonoverlapping subpopulations Ω_k (called groups or *strata*) of size N_k with $1 \leq k \leq M$ and samples of size n_k are then drawn from each stratum. If each stratum is sampled randomly, then the sampling procedure is described as stratified random sampling. Some standard definition and results from sampling theory are reported in the following (Cocchi, 2006).
Let $m(\eta)$ be the population mean and $v^2(\eta)$ the population variance:

$$v^2(\eta) = v(\eta,\eta) = \frac{1}{N}\sum_{\lambda=1}^{N}(\eta_\lambda - m(\eta))^2 \tag{1}$$

An unbiased estimator of (1) is:

$$s^2(\eta) = s(\eta,\eta) = \frac{N}{N-1}v^2(\eta) \tag{2}$$

In stratified sampling, a group mean and a group variance can be defined:

$$m(\eta_k) = \frac{1}{N_k}\sum_{\lambda=1}^{N_k}\eta_{k\lambda} \tag{3}$$

$$v^2(\eta_k) = \frac{1}{N_k}\sum_{\lambda=1}^{N_k}(\eta_{k\lambda} - m(\eta_k))^2 \tag{4}$$

An unbiased estimator of (4) is the following:

$$s^2(\eta_k) = \frac{N_k}{N_k-1}v^2(\eta_k) \tag{5}$$

that is, the variance of the *k*-th subpopulation.
In addition, a within-stratum variance can be introduced...

$$v_e^2(\eta) = \frac{1}{N}\sum_{k=1}^{M}N_k v^2(\eta_k) \tag{6}$$

...and a variance between the strata:

$$v_t^2(\eta) = \frac{1}{N}\sum_{k=1}^{M}N_k\left[m(\eta_k) - m(\eta)\right]^2 \tag{7}$$

$v^2{}_e(\eta)$ is hence the weighted average of the group variances, group size being the weight, and $v^2{}_t(\eta)$ is a measure of the distance of the mean of each group from the mean of population Ω.
It can be shown that the following additive decomposition holds:

$$v^2(\eta) = v_e^2(\eta) + v_t^2(\eta) \tag{8}$$

that is, total population variance is the sum of a within-stratum variance and the between strata variance. The strategy of stratified sampling consists of maximizing the distance among different groups (the variance between strata) thus minimizing within-stratum variance. As sample size is driven by within-stratum variance,

reducing it through appropriate stratification will determine significant reductions of the overall sample size.
Incidentally, from (8) an expression for sample variance follows:

$$s^2 = \frac{1}{(N-1)}\left\{\sum_k N_k\left[m_k - m\right]^2 + \sum_k (N_k - 1)s^2{}_k\right\} \tag{9}$$

The above proposition on the possibility of reducing sample size through the selection of an appropriate stratification criterion can be understood by considering that, whatever the type of sampling procedure, the estimation error ε of a given population characteristic is proportional to the variance $V[h(y)]$ of its estimator:

$$\varepsilon = v_{\frac{\alpha}{2}}\sqrt{V\left[h(y)\right]} \tag{10}$$

where $v_{\alpha/2}$ is a given percentile of the (assumed gaussian) distribution W of standardized $h(y)$.

In random sampling, the number n_{random} of sampling units necessary to obtain an estimation of the population mean with precision ε at a confidence level α is given by:

$$n_{random} = \left(\frac{(\varepsilon/z_{\alpha/2})^2}{s^2(\eta)} + \frac{1}{N}\right)^{-1} \tag{11}$$

where $s^2(\eta)$ is the population variance that can be substituted by its unbiased sample estimator $s^2(y)$.
In stratified sampling, n_{strat} is given by:

$$n_{strat} = \left(\frac{N(\varepsilon/z_{\alpha/2})^2}{\sum N_k s^2(\eta_k)} + \frac{1}{N}\right)^{-1} \tag{12}$$

In n_{strat}, within-stratum variances appear instead of total variance (as in simple random sampling), hence n_{strat} will in general be less than n_{random}.

If sampling fractions f_k in each stratum are the same, i.e. if $f_k = n_k/N_k = n/N = f$ then stratified sampling is called proportional. Optimal stratified sampling consists instead of subdiving n_{strat} among the different strata in such a way that the n_k's minimize estimators' variance. The problem to solve is a constrained minimization. In the case of the mean, it may be stated as follows:

$$\text{Min } V\left[m_s(y)\right] \qquad \text{Subject to:} \qquad \sum_{k=1}^{M} n_k = n \tag{13}$$

The Lagrangian for such problem is:

$$\psi(n_1, n_2, ..., n_M; \theta) = V\left[m_s(y)\right] + \theta\left(\sum_{k=1}^{M} n_k - n\right) \tag{14}$$

in which $V[m_s(y)]$ is given by:

$$V\left[m_s(y)\right] = \frac{1}{N^2}\sum_{k=1}^{M} N_k(N_k - n_k)\frac{s^2(\eta_k)}{n_k} \tag{15}$$

By setting to zero the partial derivatives of ψ with respect to n_1, n_2 ... n_M and q one obtains:

$$n_k = n\frac{s(\eta_k)N_k}{\sum_{k^*=1}^{M} N_{k^*}s(\eta_{k^*})} \tag{16}$$

As expected, the sample size within each stratum is proportional to the subpopulation variance $s(\eta_k)$.

Remarks on the application of sampling procedures to domestic water use

Any sampling procedure assumes population variance to be known, implying that a suitable number of preliminary data should be already available in order to obtain estimates of population variance. In the case of stratified random sampling, such preliminary information should be larger than for random sampling, as the available data will be split into different groups. In addition, stratified sampling requires that appropriate stratification criteria be adopted. Such stratification criteria should be applied to the set of preliminary data to estimate group variances. In the case of domestic water use, reasonable stratification criteria may be household typology (e.g. with or without garden), number of users per connection and probably also income. Unfortunately, in most cases none of such pieces of information is available in the water utilities' databases on customers, which simply contain the contract holder's data, without any specification on household size, number of household occupants etc. This requires that some assumptions on the stratification variables be made, based on statistical information that in many instances is fortunately readily available (e.g. in Italy through ISTAT, the National Institute of Statistics), but may not have the desired spatial resolution (e.g. the distribution of household size may not be available for small municipalities, and data from larger cities should be used). This may induce errors in the sampling procedure, reducing the expected precision of results. In the authors' view, while the impact of the sample size available for sampling plan calibration may be evaluated via standard statistical tools, the assessment of the uncertainty related to the selection of the stratification variables and to the thereto related assumptions should be assessed via a simulation study.

However, one of the advantages of stratified sampling applied to the assessment of water consumption is that in many cases homogeneous districts (subnetworks) may be identified from the standpoint, for instance, of income, thus reducing the need for further stratification.

A CASE STUDY

The above ideas have been applied to a small group of homogeneous users (around 50 connections) located in a council house district in the Noce neighbourhood in

Palermo, Italy. Households share all the same typology (two-storey residential units, each with four flats, no garden, all flats have a surface of around 90 m^2) and inhabitants can be assumed to belong to the same socio-economic level. Albeit homogeneous, daily water use per connection in the district features a considerable variability (average daily water use per connection: 351 l, standard deviation of daily water use per connection: 225 l) to be ascribed to the different number of users in each connection. Thus, this seems to be the classical situation where a possible stratification has already taken place (for instance on income and household typology) and attention can be restricted only to the variability in water use related to the number of persons served by each conection. For large cities, data from 2001 national census include a classification of families according to their size (1 person, 2 person ... ≥5 persons) at neighbourhood scale. We could then assess the percentage of families in Noce neighbourhood belonging to each class. We ranged the available water use data (50 values) in descending order and attributed the water use data to the different family size classes according to the surveyed census percentages. Data belonging to a given stratum were used to estimate group variances. This can be done by assuming that *k*-th subpopulation variance is equal to the variance of the available sample. Admittedly, the uncertainty related to variance estimates can be large owing to the small number of available data in each stratum.

For illustrative purposes, these estimates have been applied to a hypothetical water distribution district, serving the entire population of the Noce neighbourhood (around 10,500 connections), with the same household characteristics as above, i.e. two-storey council houses with no garden and with flat surface of around 90 m^2. Table 1 reports the data for such hypothetical situation.

Table 1. Data for a hypothetical, homogeneous water distribution district – stratum mean and variances have been estimated using real microdata from a council house district in Palermo, Italy.

Number of users per connection	Connection number per stratum, N_j	Stratum water use standard deviation, $s(\eta_k)$ [l/conn.day]	Stratum water use variance, $s^2(\eta_k)$ [l^2/conn.^{2}day^2]	Stratum water use mean, m_k [l/conn.day]	Stratum water use variation coeff., CV_k
1	2,194	35.7	1,275.1	80.2	0.44
2	2,680	39.6	1,566.0	213.0	0.19
3	2,216	59.3	3,517.1	382.0	0.15
4	2,378	40.6	1,650.7	505.3	0.08
≥ 5	1,155	86.7	7,516.5	806.0	0.11
Population	N 10,623	$s(\eta)$ 224.9	$s^2(\eta)$ 50,571.3	$m(\eta)$ 351	CV 0.6412

With such data and assumptions on stratification, assuming one wishes to assess the average daily use per connection with a precision of ± 25 l/day (around 7% of the estimated daily consumption) and a confidence level of 95%, one obtains n_{strat} = 16

(around 0,15 % of connections) and n_{rand} = 303 (circa 2.85% of connections). Whereas this last figure is in good agreement with the application results reported in Mays (2004) (pages 1.5 - 1.6), it is clear how stratified sampling allows a considerable reduction of sample size. Optimal repartition of sampling units among strata, performed according to (16), yields the sample sizes reported in Table 2.

As stated above, however, it is difficult to draw definite conclusions on the effectiveness of the procedure only based on such few calibration data. For this reason, a sensitivity analysis was performed to assess, even roughly, the range of variability of the required sample size for different values of precision, confidence level and model parameters (group variances).

Sensitivity analysis was performed considering all the possible combinations of three different precisions (±1%, ±5% and ±10%), three different confidence levels (90%, 95% and 99%) and five different values of each group coefficient of variation (a "base case" value equal to the CV_k's of Table 1 and four departures from this value equal to 0.50, 0.75, 1.25 and 1.50 of CV_k). Estimated mean water use was not subject to sensitivity analysis as it does not affect sample size. Likewise, subpopulation size N_k was left unchanged. This resulted in 3,215 different combinations (scenarios) of precision, confidence levels and group variances. For each scenario, n_{random} and n_{strat} were computed through the following steps: 1) multiplication of a given combination of CV_k for the corresponding group means m_k provides an estimation of sample group variances s_k by (5); 2) eq. (9) can then be used to assess the overall "scenario" sample variance s^2. Leaving mean values unchanged, but varying s_k, s^2 will also vary. Thus, eq. (11) may be used to estimate n_{random}.

Table 2. Optimal sample sizes for the sampling problem from Table 1.

Stratum, k	Number of users per connection	Sample size, n_k
1	1	3
2	2	3
3	3	4
4	4	3
5	≥5	3
Total sample size		16

Results

Table 3 reports results of the analysis in terms of minimum and maximum sample units for each different precision and confidence level scenario, with both stratified and random sampling. Minimum and maximum sample sizes (n_{min} and n_{max}) are attained for group variances set all at their minimum and maximum value respectively. Overall, sample fractions show a considerable variability, ranging in the case of stratified sampling from 0.02% (precision = ±10%, confidence level 90%, all group variances at their minimum value) to 23% (precision = ±1%, confidence level 99%,all group variances set at their maximum value), and from 1.00% and 73.2% in

the case of random sampling. The advantage of using stratified sampling is clear considering ratio n_{strat}/n_{random} which ranges from 1.5% (±5% precision, 99% confidence level, all group variances at their minimum value) to, at most, 31.1% (precision = ±1%, confidence level 99%, all group variances set at their maximum value).

It is worthwhile observing how the range of variability of the sample coefficient of variation is quite little (min = 0.63, max = 0.68, base case 0.64), as a consequence of the little value of the ratio $v^2_e/v^2_t = 0.04$, meaning that the adopted stratification criterion is able to capture a considerable part of water use variability, leaving the rest to within-stratum variance. Hence, even considerable departures in the scenaios from the base-case within stratum variances do not produce considerable changes in the resulting sample variance. Nonetheless, table 3 shows that sample size seems to be quite sensitive to sample variance in the case of stratified sampling, and much less in the case of random sampling, as should be expected. An increase of around 5% in population standard deviation (equal to the corresponding shift in the coefficient of variation from 0.6288 to 0.6613 documented in Table 3) produces comparable increases in sample size in the case of random sampling, with ratios $(n_{max} - n_{min})/n_{min}$ not exceeding 16%. In the case of stratified sampling, instead, such ratios increase to around 700%. This indicates to what extent within-stratum variability affects sample size. The procedure is however even more sensitive to precision, and quite less to confidence levels.

Table 3. Sensitivity analysis results.

ε [%]	α [%]		CV	n_{strat}	n/N [%]	n_{rand}	n_{rand}/N [%]	n_{strat}/n_{rand} [%]
1%	90%	min	0.6288	140	1.32%	5,331	50.18%	2.60%
		max	0.6613	1,140	10.73%	5,598	52.70%	20.40%
	95%	min	0.6288	198	1.86%	6,252	58.85%	3.20%
		max	0.6613	1,548	14.57%	6,508	61.26%	23.80%
	99%	min	0.6288	337	3.17%	7,562	71.19%	4.50%
		max	0.6613	2,418	22.76%	7,776	73.20%	31.10%
5%	90%	min	0.6288	6	0.06%	412	3.88%	1.50%
		max	0.6613	51	0.48%	454	4.27%	11.20%
	95%	min	0.6288	9	0.08%	575	5.41%	1.60%
		max	0.6613	72	0.68%	632	5.95%	11.40%
	99%	min	0.6288	14	0.13%	955	8.99%	1.50%
		max	0.6613	124	1.17%	1,047	9.86%	11.80%
10%	90%	min	0.6288	2	0.02%	106	1.00%	1.90%
		max	0.6613	13	0.12%	118	1.11%	11.00%
	95%	min	0.6288	3	0.03%	150	1.41%	2.00%
		max	0.6613	19	0.18%	166	1.56%	11.40%
	99%	min	0.6288	4	0.04%	257	2.42%	1.60%
		max	0.6613	32	0.30%	283	2.66%	11.30%

For instance, a shift in precision from 5% to 1% at, say, a 95% confidence level produces an increase of the required sample size from 72 to 1,548 (i.e. samples twenty times bigger) in the case of stratified random sampling and a corresponding increase of around nine times (from 632 to 6,508) in the case of random sampling. Similar increases are also found in the case of minimum values of within stratum variances (samples 21 and 9 times bigger for stratified and random sampling respectively). Confidence level has a softer, albeit always relevant, impact on sample size. With a precision of ±1% and all group variances set at their highest value, for results to be accepted at a confidence level of 99% in the case of stratified sampling, a sample size twice as big as in the case of a confidence level of 90% is required (from 1,140 to 2,418 sampling units). In the case of random sampling sample size should be around 38% larger (from 5,598 to 7,776).

CONCLUSION

The paper has discussed the basic issues in designing a sampling plan for domestic water use, mainly aimed at conducting water balances at the scale of district meter area. After reviewing the main results of sampling theory for two popular types of methodologies, stratified and random sampling, a case study is introduced based on microdata (recorded water uses) from a small, homogeneous council house district in Palermo, Italy, in order to illustrate the methodology and to perform a sensitivity analysis on the relevant variables, namely precision and confidence levels of estimates, as well as group variances.

Results show that, overall, stratified sampling always allows great savings in data collection, compared to random sampling, with sampling fractions varying from less than 0.1% to 23% depending on group variances, precision and confidence level. With the random sampling methodology, sampling fractions vary between 1% and 73%. In stratified sampling, the variable with the strongest impact on sample size is precision, with requested sample sizes eighty times bigger for precision of ± 1% than for precision ± 10%. Sample size is also sensitive to group variances, with requested sample sizes around seven times bigger for twice bigger group variances. The paper also highlights the need for preliminary microdata of water use in order to estimate group variances and for simple stratification criteria, requiring readily available "exogenous" information on people served per connection, household size and typology etc. The impact of the reduced availability of such preliminary and exogenous information on the precision of water use estimates will be assessed via a simulation study.

Abstract

A 2005 study by the American Society of Civil Engineers showed that six billion gallons of clean, treated drinking water disappears every day, mostly due to old, leaky pipes and mains. The amount is enough to serve the population of California. The approximate dollar cost, given varied water rates in different U.S. regions, is $12.5 million - $92 million. Moreover, leaking systems have wasted not only dollars but also priceless natural and energy resources for future generations.

A current research project funded by the US Environmental Protection Agency – Midwest Technology Assistance Center is designed to improve water supply infrastructure via a highly-advanced, cost-efficient monitoring system. A research group led by the Illinois State Water Survey, in collaboration with the Department of Mechanical Engineering at Northwestern University, has been developing a “Smart Pipe” prototype: a multi-sensor array to monitor water flow and quality using state-of-the-art nanotechnology. Each sensor unit in the array will include sensors for pressure, flow velocity and temperature on a 2.5mm by 2.5 mm silicon skin. The Smart Pipe will be equipped with a wireless processor and antenna to transfer monitoring data via commercial wireless communication systems.

With several Smart Pipes installed in critical sections of a public water system, real-time monitoring will be able to automatically detect flow rate, pipe pressure, stagnant points, slow-flow sections, pipe leakage, backflow, and water quality without altering flow conditions in the pipe. Moreover, applying this technology at an affordable cost will help small and/or rural public water systems in rule implementation, capacity development, and water systems operations. Further study is intended to improve this prototype via real-life application that includes the study of the frequency of required maintenance, fouling investigation, measurement calibration, real-time data communication software, manufacturing cost efficiency, long term stability, and assessing the precision and accuracy under differing environmental conditions.

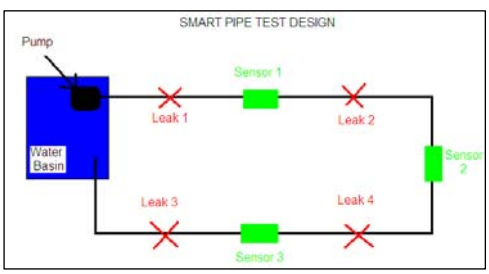

Figure 1

Extended Abstract

This extended abstract is to present the process and results of the development of Smart Pipe. A video of a live demonstration for proving the concept was performed in the Summer of 2008. The video is available at: http://www.youtube.com/watch?v=8xSlLCScIqw. The prototype development of the sensor chip to be packaged in the Smart-Pipe system was completed in the Fall of 2008.

Figure 2

THE PROOF OF CONCEPT

Hardware Design: The system for proving the concept involved the use of an existing commercial sensor instead of the prototype nanosensor since it was in the development stage at the time. The pipe system was constructed using 2-inch PVC pipes with three sensor sets. The dimensions of the test system

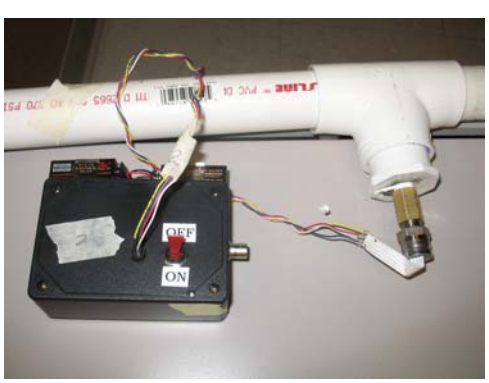

Figure 3

were approximately 4X2 meters as shown in Figure 1. The four controllable leaks were valves that could be opened or closed to simulate a leak, and the sensors were spaced equidistant from each another (Figure 2). Each sensor set used Honeywell pressure sensors (part number 19C100PG5K) that threaded into the pipe using a tee. Each sensor was wired to an amplifier (Figure 3) and was tested successfully using a voltmeter and an oscilloscope to measure the pressure. The nanosensors were packaged or tested at that proof-of-concept stage, but they can be quickly implemented in an existing water system by feeding the wires through a hole drilled into a rubber pipe connector (Figure 4).

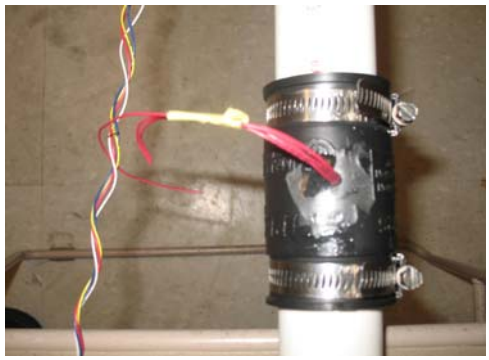

Figure 4

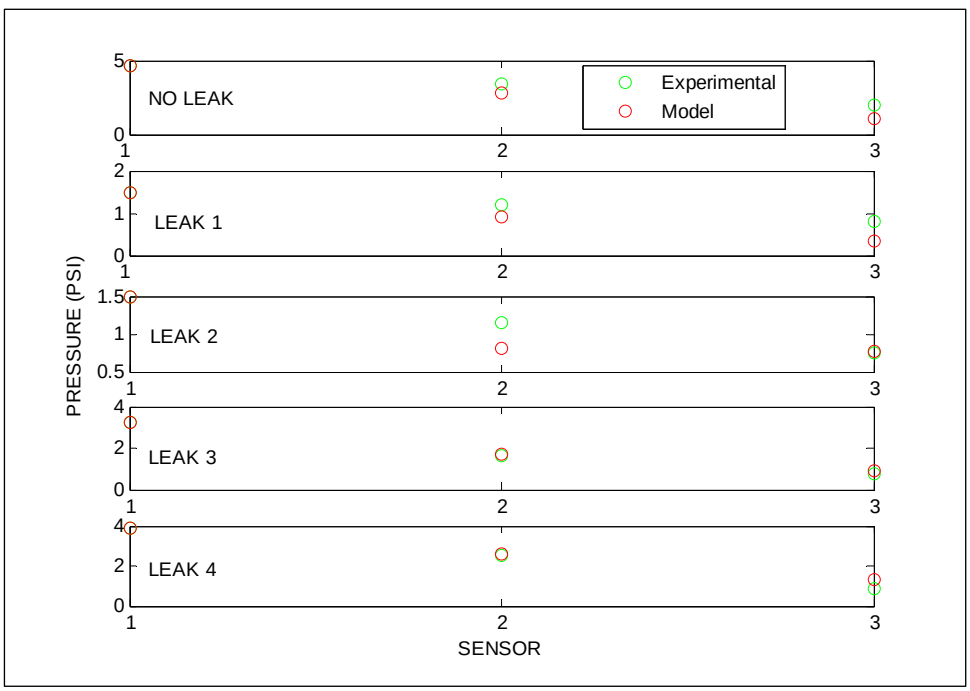

Figure 5. The comparison of experimental results and model results using various leaking scenarios.

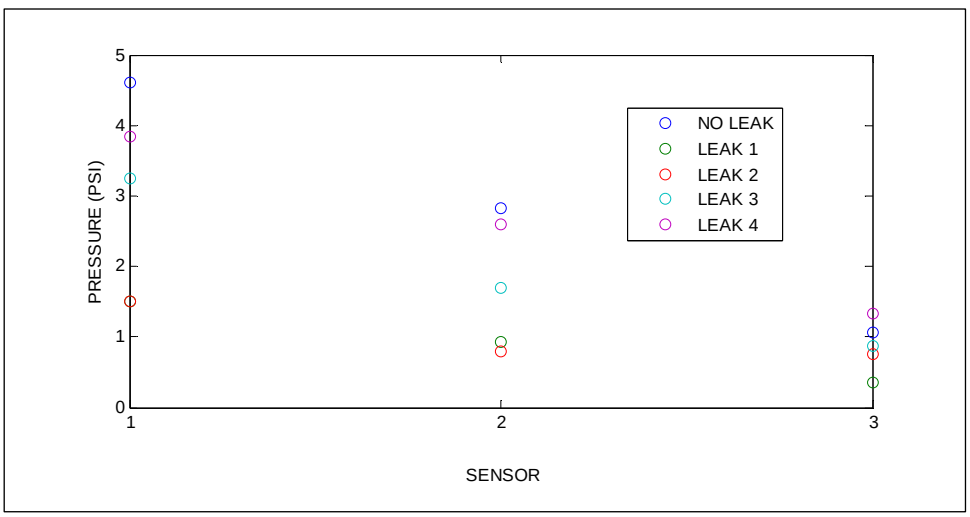
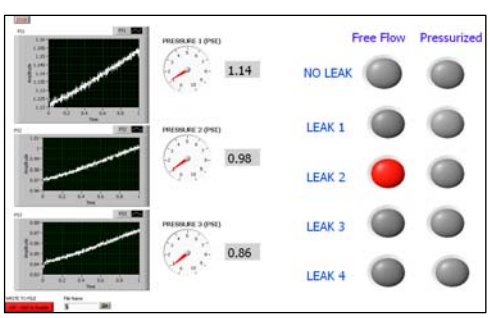
Numerical Simulation: A mathematical model was developed using MATLAB to compare the data recorded by sensor set 1 to predict the pressures of the other sensors for each of the possible leak scenarios (Figure 5). The model also showed variance

from the actual collected data, but some variance is to be expected due to the makeshift nature of the pipe system. Also, the experimental data Figure 6 show that the pressure sensors are capable of detecting a unique and distinct set of pressures for the various leak scenarios.





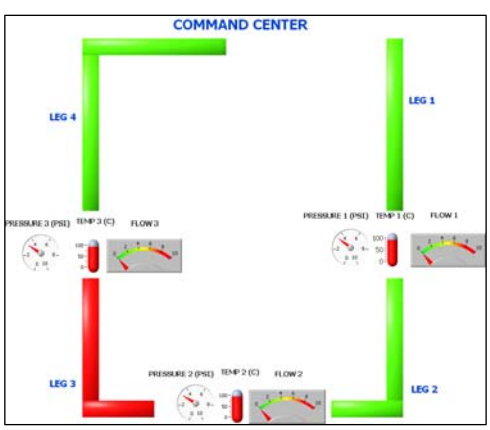


Figure 6. The comparison of experimental results from 5 leaking scenarios.

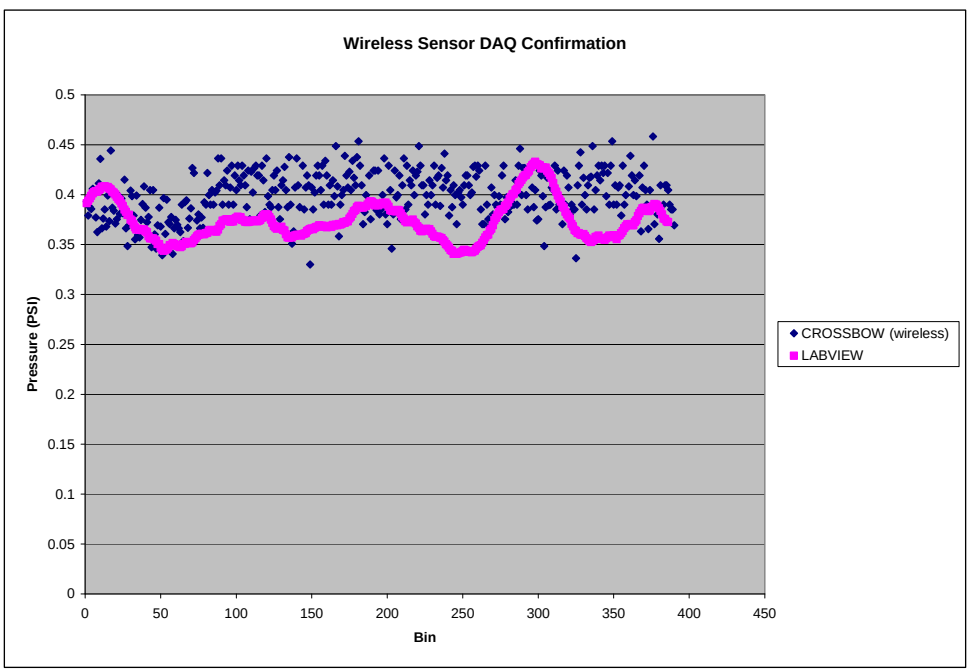
Real Time Data Acquisition and Detection: There were two versions of a Graphic User Interface (GUI), developed for data acquisition using LabView software. As shown in Figure 7, both versions of Command Center were tested successfully for acquiring test data from a hard-wired system, can continuously monitor the sensor outputs, and can notify the user when and where a leak occurs.

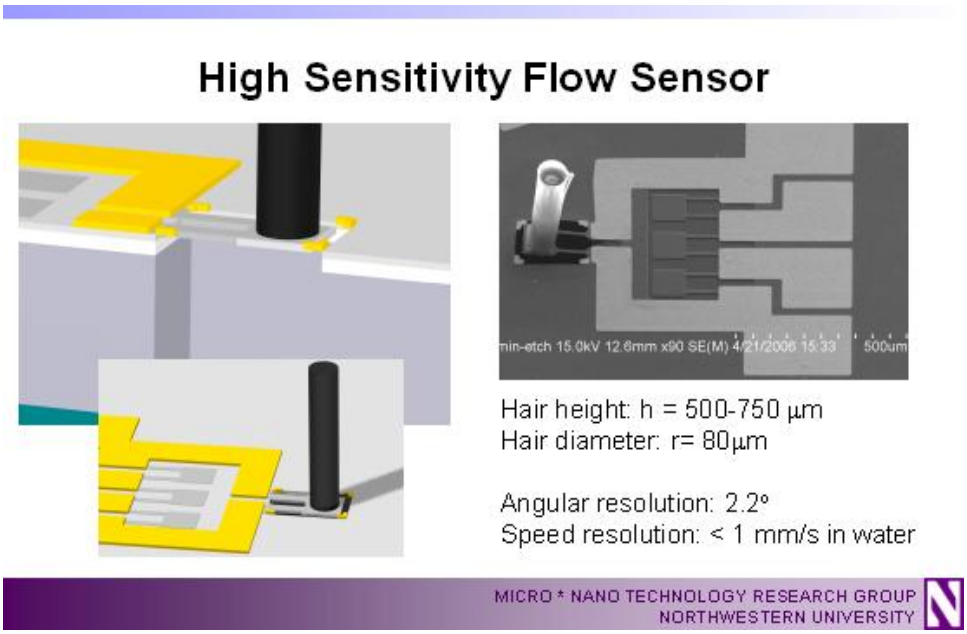
(a)

Figure 7 Command Center

(b)

The software of the wireless system Crossbow is compatible with the Command Center generated by using LabView. Figure 8 shows data taken from the same pressure sensor using both the LabView data acquisition card and the Crossbow wireless data acquisition transceivers. Currently, the signal-processing software is written in LabView code and the signals are acquired through cables connecting the sensors to the computer. The agreement of the two sets of data above shows that the Crossbow devices are capable of supplying the same data but without the need for the sensors to be connected to the computer.





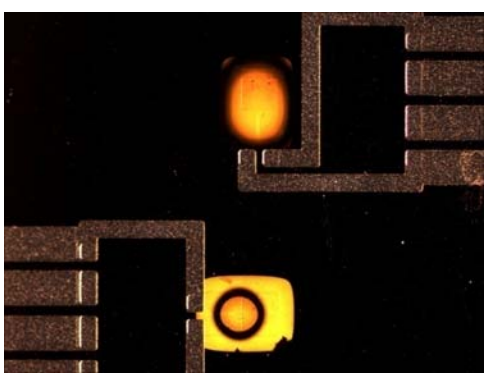


Figure 8. The comparison of data acquisition by wired device (LabView) and wireless device (Crossbow).

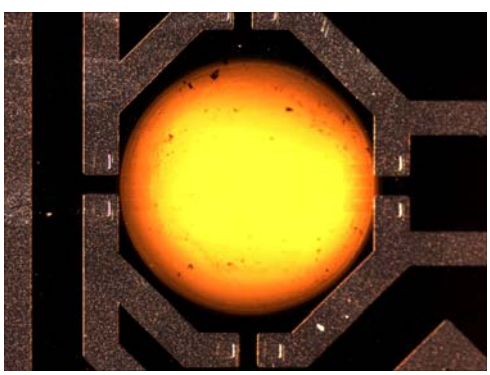
NEW GENERATION OF NANOSENSOR CHIP



The new generation of the nanosensor set, G4, has been recently completed. This nanosensor set includes one pressure sensor, one temperature sensor, and two flow sensors (X direction and Y direction) as shown in Figure 9. The flow sensors are the most challenging aspect of the development and testing because of their complex design. Figures 10 and 11 show the test data taken from the flow sensor placed in Smart Pipe sensor number 1 of our experimental setup (Figure 1).

(a) The design diagram and dimensions of the flow sensor

(b) Photos of the actual temperature sensor (above) and the flow sensor (below) taken by microscope

(c) Photo of the actual pressure sensor taken by microscope

Figure 9. The new generation of nanosensor set - G4.

In Figure 10, the first 13 seconds of data represents free flow throughout the entire pipe system. The flow sensor outputs a relatively constant voltage representing the steady state system. At 13 seconds, the valve at the end of the pipe system is shut off, blocking the flow and allowing pressure to build up in the pipes. Although the pressure sensors are unable to detect the motion of the water, the flow sensor data clearly detect that the water has stopped flowing past the sensor after 13 seconds (zero flow is calibrated to -3 Volts.)

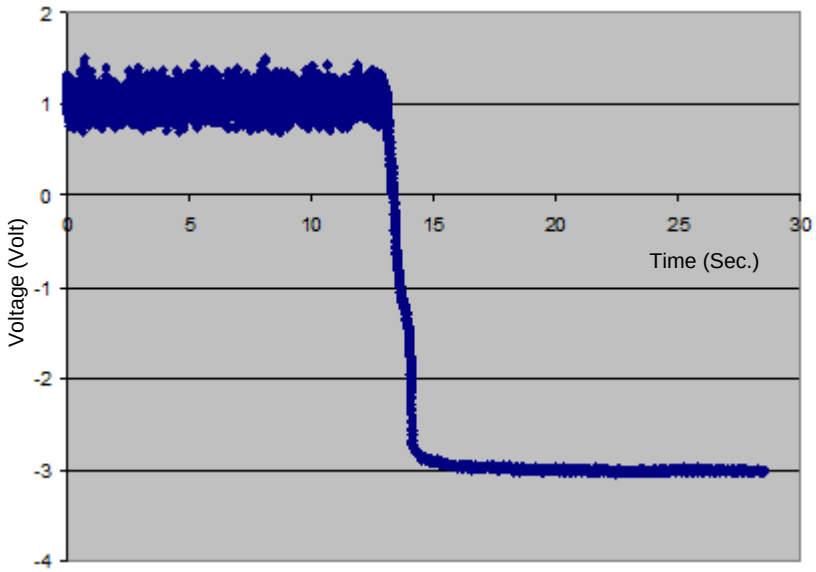


Figure 10. Flow detection by the nanosensor.

In order to test leak detection, we retained the pressurized state shown at the end of Figure 10 and opened the leak at valve 2 at approximately 40 seconds (Figure 11). A spike in the flow past sensor 1 was immediately detected until the valve was shut off again after several seconds before it fell back down to zero flow. Since the end valve remained closed throughout the process, even with the valve at leak 2 opened, no flow was allowed to pass through sensors 2 or 3. Thus, the successful

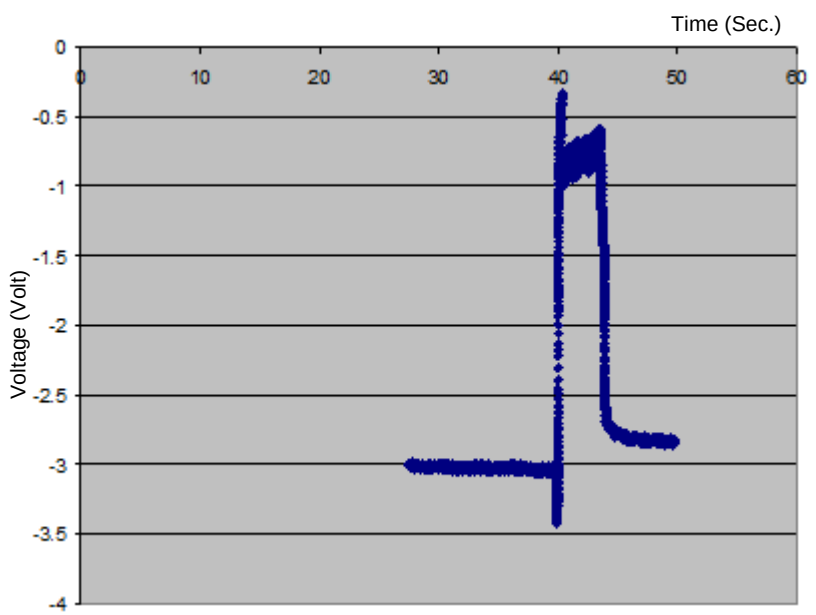

Figure 11. Leak detection by the nanosensors.

detection of flow past sensor 1 determines the existence of a leak between sensors 1 and 2.

SUMMARY

We have presented the proof of concept and the efficiency of nanosensors for the Smart Pipe system, which is still under development. The results from the proof of concept have demonstrated the efficiently of detecting pipe leakage using flow and pressure sensors as well as the feasibility of using a wireless infrastructure. The development of the prototype sensor chip for the Smart-Pipe system was completed in the Fall of 2008. The test results for multiple sensors have shown the feasibility and durability of the nanosensor set. The nanosensor set has greater potential in addition to pipe leakage detection. For example, a temperature sensor has been developed for future tests in water quality detection. The integration between this new generation of nanosensor sets with Smart Pipe is in progress and is dependent on future research funds.

Abstract

This paper outlines an approach to the integrated optimization of wastewater, recycled and potable water systems in an urban area. The approach will be demonstrated through consideration of a case study of the Hume corridor in Melbourne, Australia. A total of 44,000 new residential lots are planned in this area. These houses will have their garden and toilet connected to a Class A recycled water system. The recycled network will also incorporate some industrial demands.

As the recycled water system will receive its inputs from wastewater treatment plants, the three networks had to be considered in an integrated fashion. The case study considered the development of two optimisation models, one for the wastewater system and the other for the potable and recycled water systems. The interface between the two models occurred at the wastewater and recycled water treatment plants. Values were set for the capacities of these plants for each model and they were adjusted to ensure compatibility between the two models.

The recycled network was designed to the same level of service as the potable water network, e.g. 25 m minimum allowable pressure head at all demand nodes. As potable water top-up of the recycled system is to be considered, it was found that the potable water network needed to carry flows greater than potable peak hour demands.

The results obtained clearly indicated the value of using evolutionary algorithms in an integrated fashion to optimize potable and third pipe systems. Application of this approach to other areas is likely to make third pipe systems more attractive and to lead to significant savings in the use of limited water supplies.

Introduction

Diminishing water supplies and a desire for improved sustainability have highlighted the need for greater reuse of water in urban areas. The efficient use of recycled wastewater requires treatment to a suitable standard and a separate "third pipe" distribution system supplying the recycled water to urban, industrial and/or agricultural users. The distribution network for recycled water is often simpler than the distribution network for potable water as it usually has a smaller number of consumers and does not require the same level of redundancy as the potable network. However, the existence of alternative sources for recycled water and the possibility of topping up this source with potable water mean that the optimization of the recycled network is not a trivial exercise. In fact, there is a strong case for optimizing the potable and recycled networks together, given that the two networks are inter-connected and the demands on the two networks are inter-related. In many cases this integrated optimization should be extended to include the wastewater collection and treatment systems as well.

Considerable research has been carried out into the optimization of water distribution systems (Schaake and Lai, 1969; Alperovits and Shamir, 1977, Quindry Brill and Liebman, 1981; Gessler, 1982). The application of evolutionary algorithms (EAs) to this problem (Simpson et al, 1994, Dandy et al, 1996; Savic and Walters, 1997) has lead to the development of a practical tool that has been applied in master planning and design studies for a large number of cities in the USA, UK, Australia and elsewhere. EAs have the significant advantage that, being guided search procedures, they can be coupled with a detailed simulation model of the system that can include any non-linearities, discontinuities and/or logical variables. In fact, they do not require any simplifications to be made to the hydraulics of the system in the optimization process.

Similarly, the optimization of wastewater system design has received considerable attention in the research literature (Argaman et al, 1973, Mays et al, 1976; Galan and Grossmann, 1998; Swammee, 2001). More recently, evolutionary algorithms (EAs) have been applied to the problem of optimizing wastewater systems (Heaney et al, 1999; Diogo et al et al, 2000). Once again EAs provide a practical tool that can be applied to the optimum design of large scale wastewater networks for similar reasons to the optimization of water supply systems (Savic and Walters, 2001).

A number of water authorities are now developing third pipe systems that distribute recycled wastewater to industrial and domestic consumers. As these are pressured distribution systems, they can be designed and optimized in the same way as potable water distribution systems.

The next level of optimization is to optimize all three networks simultaneously. To the authors' knowledge this has not previously been attempted for a real system. The ideal approach would be to develop a single optimization model that includes all three networks. However, this approach is unlikely to be feasible at the current time because of the long computer run times that would be required. This paper presents an alternative approach that involves linking two separate optimizations models; one for the wastewater system and one for the recycled and potable water systems.

The paper outlines some of the issues involved in developing an integrated optimization model and how they can be addressed. This is described in the context of a case study of the Hume/Epping Corridor in the North of Melbourne, Australia. The water utility is Yarra Valley Water and they funded the study.

Issues in Integrated Optimization of Wastewater, Recycled and Potable Water Systems

It is widely recognised that an integrated approach to urban water management is required, particularly in areas with limited fresh water supplies. A number of urban water utilities are utilising recycled wastewater or stormwater for industrial water use, watering of public or private gardens, toilet flushing, top up of hotwater services or even potable supply. Such developments generally require a "third pipe" network to distribute the recycled water.

The design of the three networks (wastewater, potable water and recycled water) are clearly linked in the following ways:

(1) Recycled water is provided from wastewater treatment plants. The choice of where to locate new or upgraded wastewater treatment plants has significant impact on the location of the source(s) of recycled water and hence on the design of the recycled distribution system.
(2) The seasonal pattern of supply from treated wastewater is unlikely to match the pattern of demand on the recycled network, so significant storages may need to be provided at wastewater or recycled water treatment plants.
(3) It may be cost effective to design the potable supply network so that it can augment the recycled supply when required. This places additional demands on the potable water supply network.

These considerations will be demonstrated in the case study.

Case Study: The Hume/Epping Corridor, Melbourne, Australia

The Hume and Epping North corridors are developing areas serviced by Yarra Valley Water in the North of Melbourne. A total of 44,000 new residential lots are planned in this area

The wastewater collection system needs to be upgraded in response to the expected development of the area. New and upgraded infrastructure needs to be sized, as well as investigating the best strategy to treat, transfer or dispose of the wastewater. The layout of the wastewater system is shown in Figure 1.

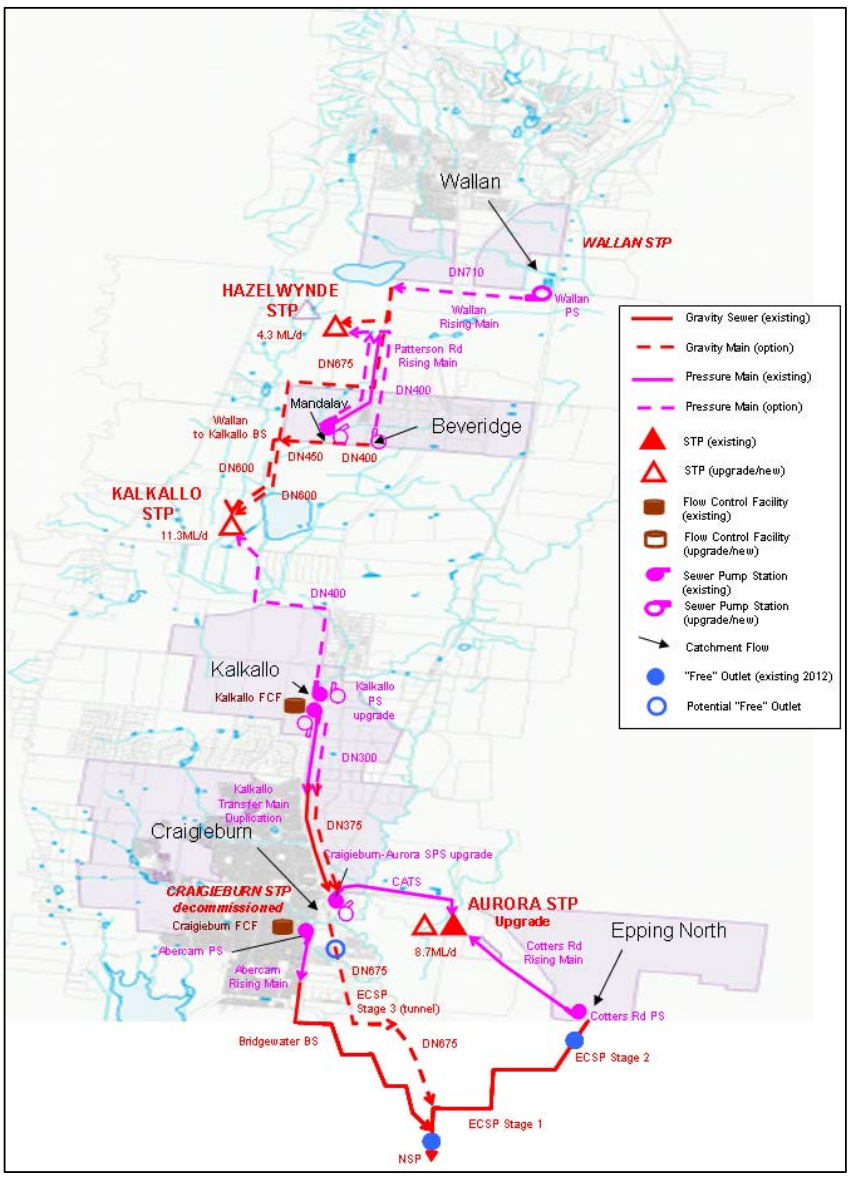

Figure 1: Layout of the Wastewater System

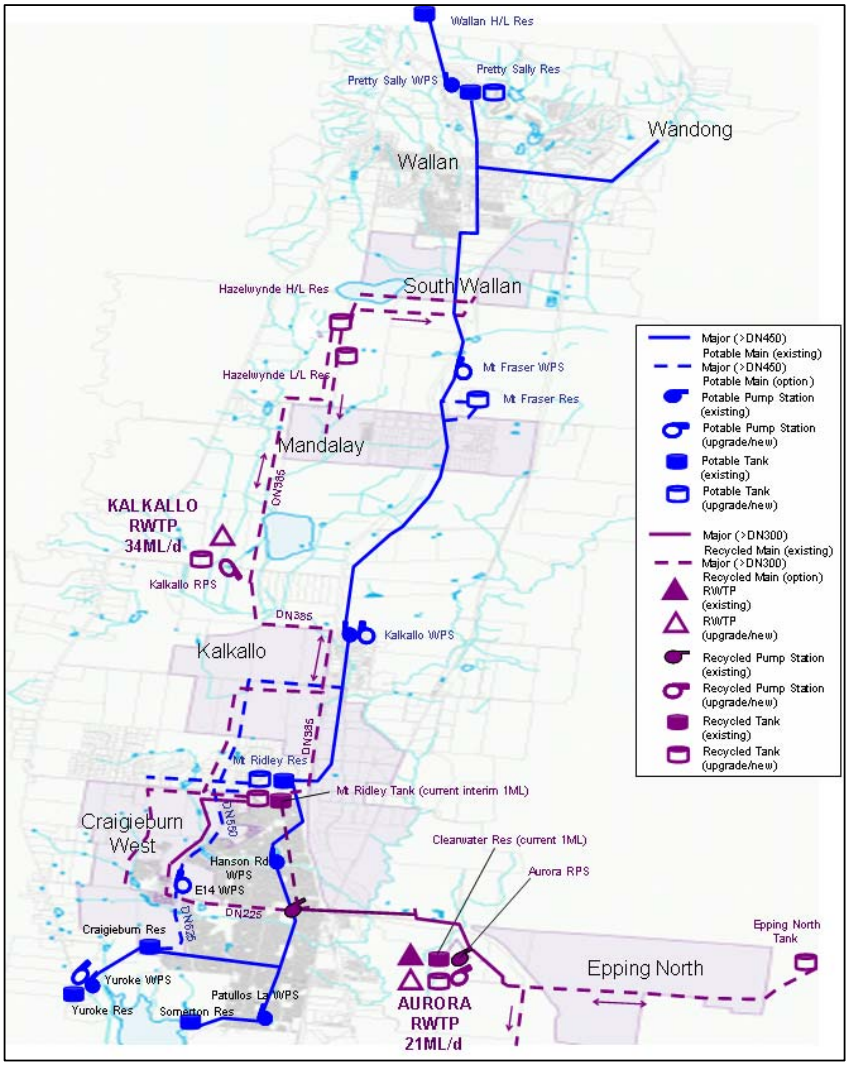

Figure 2: Layout of the Recycled and Potable Water Networks

The layout of the recycled and potable water networks is shown in Figure 2. As the recycled system will receive its inflows from the wastewater system, the wastewater strategy will directly influence the availability and locations of supply to the recycled system. Therefore the wastewater, recycled and potable systems were all investigated together in an integrated study to determine the best overall design and operating strategy.

Optimization of the Wastewater System

The optimization of the Northern Suburbs Sewerage Strategy was completed using Optimizer GA optimization software. The optimization was first completed in 2006 for the wastewater system. However, that initial study did not account for costs associated with the potable and recycled water systems.

The planning options for the wastewater system are characterised by conveyance options and treatment plant options. Ultimately, flow generated in the Northern Suburbs Sewerage Catchment can either be transferred south to the Melbourne Water system or treated locally and disposed or utilised as a recycled water source. The interconnectivity between the

wastewater system and the recycled water system is based on the location and capacity of local treatment plants.

The wastewater optimization study completed in 2006 did not account for the benefit to the potable water system of using local treatment plants. As such, the results from the wastewater only optimization study indicated that local treatment plants were not cost effective and all flow should be transferred south to the Melbourne Water System. The recommendations from the 2006 study suggested that further investigations be carried out to establish the benefit of local treatment plants to the potable water network and that the wastewater optimization be reviewed in light of the findings.

The integrated optimization study completed in early 2009 evaluated the wastewater system improvement and operational costs in conjunction with the recycled and potable systems. The methodology adopted for this study involved conducting individual GA optimization runs for the wastewater system and the potable/recycled water system for selected increments in local wastewater treatment plant capacities. The wastewater system optimization was then completed for each treatment plant capacity scenario and the optimized solution cost wastewater system was then combined with the optimized solution cost for the potable/recycled water system in the same scenario, thus producing a cost-effectiveness curve from which an overall optimal solution for the integrated system could be determined.

The planning alternatives for the Northern Suburbs Sewerage Strategy include upgrade of existing trunk sewers, new diversion sewers, upgrade of existing pumping stations, new pumping stations, new storage facilities and new treatment plants. All feasible combinations of sewer routing and system components are included as multiple pathways in the sewer network model and subsequently evaluated by GA optimization to select an optimal network configuration. Table 1 summarises the performance criteria used in the optimization.

Table 1. Summary of Wastewater Optimization Criteria

Facility Planning Design and Performance Criteria Category	Performance Criteria
Design Storm Event	1 in 5-year, 36-hour design storm
Maximum Surcharge in Gravity Sewers	No flooding or overflows allowed in design storm event
Minimum Velocity in Rising Mains	0.75 meters per second (m/s)
Maximum Velocity in Rising Mains	3.0 m/s for existing rising mains
Treatment Plant Capacity	Existing capacities for some treatment plants, range of treatment capacities for new and upgraded treatment plans depending on the scenario

Optimization of the Recycled and Potable Water Systems

Optimization of the potable and recycled water networks considered a number of different demand options (possible future developments) and also different strategies for the recycled water network (different levels of potable top-up to offset the size of recycled water infrastructure). The optimization was carried out for a 24-hour dry summer day demand (DSD) for ultimate build out (year 2030). The recycled network was designed to the same

levels of service as the potable water network, e,g. 25 m minimum allowable pressure head at all demand nodes

The preferred ultimate solution was subsequently staged in 5 year increments. Table 2 summarises the potable water and recycled water DSD demand for each staging period.

Table 2. Potable Water and Recycled Water Dry Summer Day Demands

Year	Potable Water DSD Demand (ML/d)	Recycled DSD Demand (ML/d)	Total DSD Demand (ML/d)
2010	39.1	6.3	45.4
2015	55.3	19.7	75.0
2020	70.6	33.0	103.6
2025	86.7	45.4	132.1
2030	95.5	54.0	149.5

The different source options for the recycled water network were also considered as separate scenarios so that a matching wastewater solution could be developed for each scenario. This allowed a range of total solutions (wastewater, potable and recycled water) to be developed and compared. The key source scenarios are shown in Figure 3.

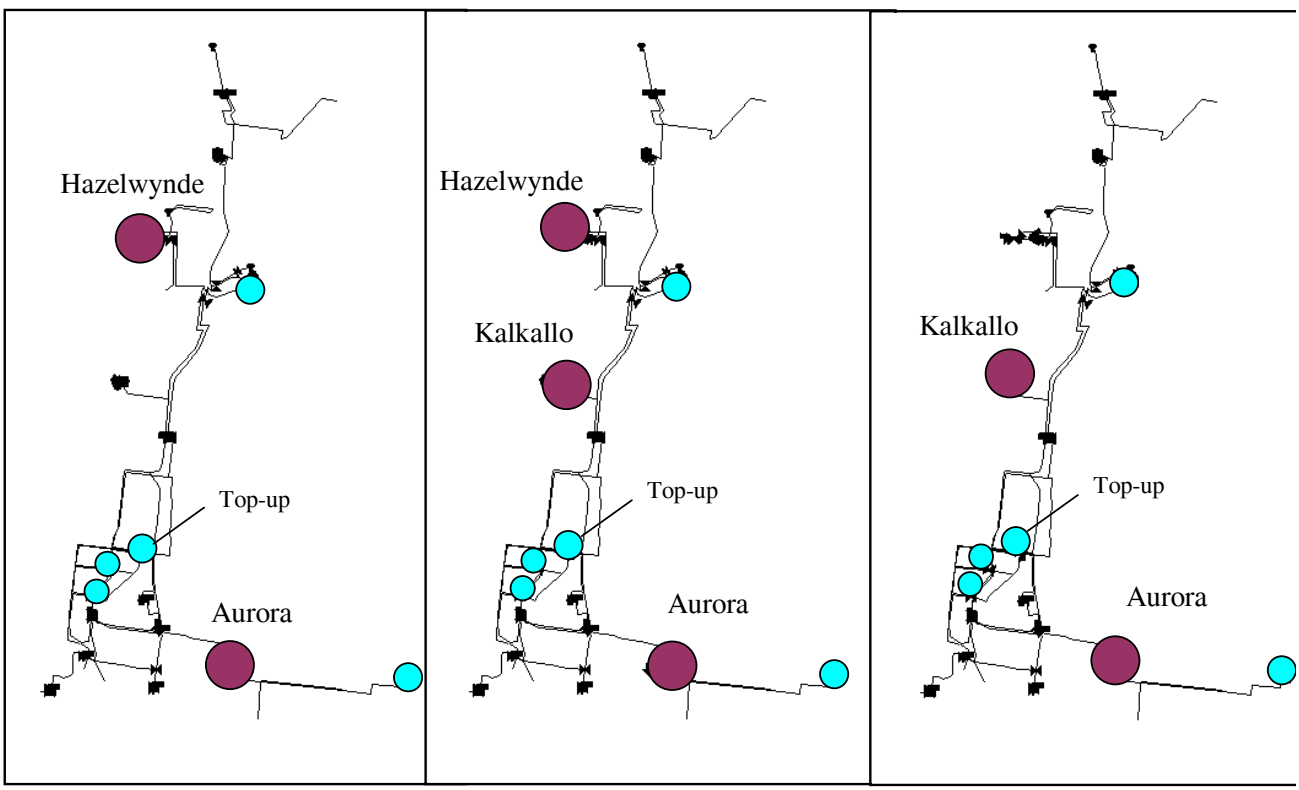

Figure 3: Recycled Water Source Scenarios

The optimization of the potable and recycled water networks involved new and duplicate pipeline options, new and expanded pump station options, new storage options, valve setting options, pump control options and potable top-up options. Flow rates from sources were also

considered as options, but the inclusion of a particular source (or not) was fixed by the scenario being considered.

The potable water top-up options included top-up at number of reservoir sites or emergency cross connections in the system (through pressure reducing valves). The top-up timing and flow rates were determined in the optimization through trigger level controls (either tank levels or downstream pressures) and valve settings (either flow control valves or pressure reducing valves).

Linking the Optimization of the Wastewater, Recycled and Potable Water Systems

Linking the wastewater solution with the potable/recycled water solutions involved pairing solutions from compatible source scenarios, as well as considering the interface between the wastewater treatment plant (WWTP) and the recycled water treatment plant (RWTP). Figure 4 shows a flow chart of the process between the wastewater collection system and the recycled water distribution system.

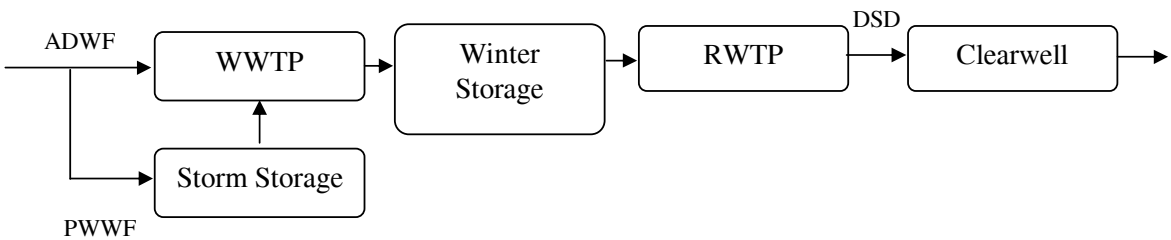

Figure 4: Linking the Wastewater and Recycled Water System

The recycled water treatment plant (RWTP) is sized to meet the dry summer day demands of the area it is supplying. In this optimization, the area supplied by each treatment plant could vary depending on the volume of water supplied from potable water top-up or other treatment plants in the solution. The recycled water clearwell was sized to ensure that any variation in demand over the 24-hour period could be served (this storage was required to refill over the 24-hour period). In this optimization the recycled water diurnal demand varied from 0.12 times to 2.8 times the average hourly flow on a dry summer day.

The wastewater treatment plant is typically sized to meet Average Dry Weather Flow (ADWF). During a storm event the treatment plant can treat up to 4 times ADWF, but any additional flow must be stored in a storm storage tank until it can be treated. The storm storage is sized to hold the peak wet weather flow (PWWF). As part of the optimization process this trade-off between storm storage size and WWTP size was considered.

The interface between the WWTP and the RWTP is the winter storage. This is a large storage designed to store the Class B water produced by the WWTP over the winter when recycled water demands are low, but wastewater continues to be treated. During summer when recycled water demands are high, the winter storage is required to supply the RWTP. If there is a mismatch between the recycled water demands and the wastewater inflow at a particular treatment plant site this can result in a very large winter storage to store excess flows (and then accumulated flows), or a large winter storage required for peak demands, but not enough inflow to fill it.

As part of the optimization, the source scenarios were setup to provide a good match between the wastewater and potable/recycled water solutions. However with some flexibility in each

solution as to how much was used or treated at each source, some solution refinements or re-optimization with fixed flow rates were required for some sources. This ensured that the total solution cost was minimized and the winter storage was sized adequately and used most effectively.

In optimizing the wastewater and potable/recycled water separately a number of different scenarios were required to adequately investigate all source options and determine the best overall solution. This approach also allowed the cost of each different source scenario to be determined and each optimization run was able to focus on a smaller problem and obtain a better solution in a shorter time.

Results

Table 3 summarises the estimated costs of the three key solutions developed. Note that A$1 = US$0.66 (approximately). A range of other solutions considering different rates of top-up and additional demands were also developed. Table 4 summarises the estimated costs of the three key scenarios with the addition of a potential new development area (an additional 100 ML/d demand on the potable/recycled water network and additional flows for the wastewater network).

Table 3. Total Solution Costs – Base Case Solutions (A$millions)

	Waste Water Total Cost	Melbourne Water	Class B Storage	Recycled Solution	Potable Solution	TOTAL
Scenario 1	$88.11	$33.70	$14.90	$176.50	$42.40	$355.60
Scenario 2	$98.59	$31.88	$8.25	$179.97	$43.23	$361.92
Scenario 3	$112.90	$33.15	$14.40	$203.80	$42.40	$406.66

Table 4. Total Solution Costs – Alternative Solutions (A$millions)

	Waste Water Total Cost	Melbourne Water	Class B Storage	Recycled Solution	Potable Solution	TOTAL
ALT 1	$194.78	$30.50	$27.88	$369.16	$75.89	$698.21
ALT 2	$155.00	$31.82	$24.30	$344.35	$75.61	$631.09
ALT 3	$168.39	$36.73	$31.64	$355.07	$75.68	$667.52

Although the Scenario 1 solution was the lowest cost total solution for the current planning assumptions, this scenario (Aurora RWTP + Hazelwynde RWTP) is the most expensive setup when the potential new 100 ML/d development is considered. The potential development outside the current planning boundary adds significant cost to the solution and Scenario 2 (Aurora + Hazelwynde + Kalkallo) becomes the most cost effective scenario.

The preferred solution selected by Yarra Valley Water for staging was the Scenario 2 Base Case solution. This solution was not the lowest cost base case solution, but selecting this solution will give the system flexibility (and save costs) if the potential 100 ML/d development goes ahead in the future.

By developing a range of solutions considering different source options and also different demand scenarios, the sensitivity of the design and the costs can be evaluated. The impact of different assumptions and boundary conditions to the wastewater solution, potable water and recycled water solution can also be measured and evaluated. This optimization analysis has

provided Yarra Valley Water with information that can be taken into account when developing the final service strategy for the corridor. It is expected that a highly cost-effective plan will result.

Summary and Conclusions

With increasing scarcity of water, recycled water systems are becoming more common. It is important to design the wastewater, potable and recycled water systems for an urban area in an integrated fashion. These combined systems can be very complicated as they have a large number of pipe, pump, storage and treatment options. Formal optimization procedures offer considerable potential to identify cost-effective designs for these combined systems.

This paper demonstrates the application of evolutionary algorithms to the optimization of an integrated wastewater, potable and recycled water system in the Hume/Epping Corridor in the North of Melbourne. The study was carried out for Yarra Valley Water (YVW).

Although it is desirable to be able to optimize all three systems simultaneously, in this case study the wastewater system was optimized using one model and the recycled and potable water systems were optimized using a separate model. The interface between the two models occurred at the wastewater and recycled water treatment plants (RWTP). Values were set for the capacities of these plants for each model and they were adjusted to ensure compatibility between the two models. Three different combinations of locations of the RWTPs were considered. Flexibility in terms of possible future demands were also considered in the scenarios modelled by allowing for the demands of a potential new development.

The results obtained provided useful information to YVW on the preferred scheme for development of all three collection and distribution networks. The study demonstrated the feasibility of an integrated approach to this planning problem.

ABSTRACT

This paper presents the application of optimization techniques to the development of a phased expansion plan for the City of Ottawa's water distribution system. The approach involved an iterative process where capacity-driven solutions generated by an optimization model were evaluated for reliability of supply during failure conditions and water quality characteristics in order to update constraints for subsequent re-optimization. An infrastructure solution and phasing plan is presented. It was found that the approach is sound, but the number and variety of alternatives must be limited to achieve reliable results from the optimization model.

INTRODUCTION

When the City of Ottawa, Canada, embarked on a master planning exercise for its water distribution system, staff wanted to take a more systematic and comprehensive approach to evaluating the very large number of potential system expansion alternatives, compared with the traditional methods of the past. This paper describes the development of the expansion strategy for the system using optimization technology that considers growth over a 25 year planning period. The infrastructure solution was optimized by minimizing life cycle costs over this period, considering a range of performance objectives including pressure limits, reliability of supply, and water quality. The development of the solution considered operation of the system under a wide range of conditions.

EVOLUTIONARY ALGORITHMS

Evolutionary algorithms are optimisation techniques based on the principles of evolution and the concept of 'survival of the fittest'. By using the principles of selection, reproduction and mutation, solutions to problems can be evolved rather than explicitly designed. Although the process of evolution itself is slow, the process of simulated evolution is an efficient method of searching spaces that cannot be fully searched by other means. For instance, in the well-known New York Tunnels water

distribution system (Alperovits and Shamir, 1977), with 20 pipes and 16 possible pipe diameters, there would be approximately 1.2×10^{24} unique solutions. Even with very fast computers, it would take hundreds of years to fully evaluate all of these solutions. Therefore a more efficient approach is required.

Evolutionary algorithms have previously been applied to a number of 'trial problem' water distribution systems (Savic & Walters, 1997) and also some industrial networks (Keedwell & Khu, 2003; Savic, Walters & Randall-Smith, 1998; Savic, Walters & Randall-Smith, 2000). In each case, the Genetic Algorithm (GA) has been found to significantly outperform competing techniques, but the examples cited tend to operate on relatively simplistic views of water distribution systems. For instance, Savic & Walters (1997) and Keedwell & Khu (2003) view the network from a pipe-sizing viewpoint only. In the study described in this paper, the objective was to optimise many aspects of the network including pipe sizing and routes, pump settings, pressure zone boundaries, storage and treatment capacity variables.

The GA term was originally coined by John Holland in 1975 (Holland, 1975). The algorithm works by generating a random population of solutions. These solutions are made up of the variable settings for the network (e.g. pipe diameters, pump settings, tank diameters, etc.) and are evaluated against performance criteria by a 'fitness' or 'objective' function. The algorithm takes the variables, applies them to the problem and the fitness function returns a measure of how well that particular solution solves the problem. Once the population has been created, each of the solutions is evaluated and some are selected for progression into the next generation, biased towards those that are best at solving the problem. These solutions are then changed by processes known as 'crossover' and 'mutation' to create new solutions which are then evaluated by the objective function and returned to the population. This process is repeated until it appears that the genetic algorithm has converged on a 'near optimal' solution.

The main tasks needed to apply a GA to a problem are to define a system representation and an objective function. To accomplish this, we must first look at the network which we are proposing to optimise.

EXISTING WATER DISTRIBUTION SYSTEM

Ottawa is a City of about 800,000. An abundant fresh water supply is available from the Ottawa River, which marks the northern boundary of the City. Two water purification plants (WPPs) are located along the river and feed the City's distribution system (Figure 1). The Britannia plant has a rated capacity of 350 million litres per day (MLD) and the Lemieux Island plant is currently rated at 290 MLD. A 110 MLD expansion of the Lemieux plant is currently underway. There are 7 open pressure zones and 4 relatively small closed zones. A Greenbelt separates the core urban area from three distinct urban communities to the east, west, and south. The majority of future urban growth will be taking place in these outlying communities.

There are single 1220mm diameter transmission feeds serving the East and West Urban Communities (EUC and WUC). The South Urban Community (SUC) is

bisected by the Rideau River. A 1220mm main feeds the west portion of the SUC, whereas a 762mm main feeds the relatively small urban area on the east side of the river. There is no link between these two portions of the SUC, which operate at slightly different pressures. With the exception of these single feeds through the Greenbelt, the distribution system is very well looped, providing a high level of redundancy for meeting normal and emergency water needs. However, even in the unlikely event of a critical transmission failure, reservoir storage in the external urban expansion areas will allow supply to be maintained at a restricted rate while emergency repairs are carried out. Major storage reservoirs are located in the core area (108ML) and EUC (82ML). Smaller reservoirs are also located in the WUC (34ML) and SUC (18ML). Some elevated storage is also available in these urban communities.

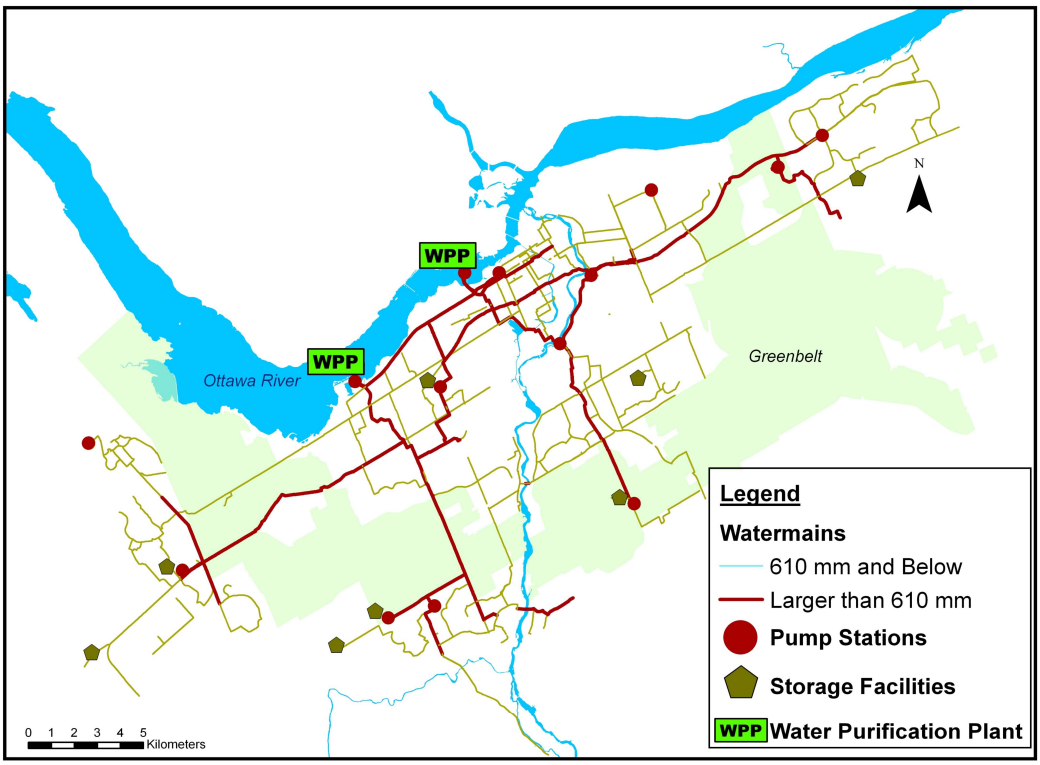

Figure 1. City of Ottawa Water Distribution System

DEMAND PROJECTIONS

At the time of the study, Ottawa's population was expected to increase by roughly 35%, from about 760,000 in 2004 to 1,070,000 by 2021, according to official projections. Although significant intensification is anticipated within the core urban area, the majority of growth will take place in the expansion areas outside the Greenbelt. The 25 year planning horizon selected for the study extends a full 10 years beyond the City's 2021 official planning horizon. The above projections were linearly extrapolated, resulting in an estimated 2031 population of 1,240,000. The current system-wide maximum day demand is in the order of 590 MLD whereas the 2031 maximum day demand would be 1060 MLD based on extrapolation of the

official projections. Basic demand is consistent throughout the year in Ottawa, with peak demands associated with outdoor use in the summer period. There is a downward trend in unit consumption rates, and for conservative results, these rates were assumed to be held constant into the future.

OPTIMIZATION APPROACH

The general approach to solving the optimization problem involved the application of GA technology to an iterative hydraulic system design process that considered a wide range of infrastructure alternatives and a comprehensive set of design criteria. An Optimization Model was developed and used to generate capacity-driven solutions. These solutions were evaluated and further optimization constraints identified to ensure that subsequent solutions would meet reliability and water quality (as indicated by water age) criteria. A number of iterations were required to arrive at a final optimal solution for the year 2031.

The Optimization Model was also used to develop 2011 and 2021 solutions based on an alternatives set corresponding to the 2031 solution. These solutions also involved an iterative design process considering shorter-term reliability objectives. Considerable judgment was involved in the phasing of reliability elements that were not required for interim capacity needs. Consideration was given to risk and affordability issues as part of the phasing plan development. Watermain diameters and elevated storage facilities were fixed based on the 2031 solution, but phasing of pumping station and reservoir expansion was considered as part of the optimization.

OPTIMIZATION MODEL DEVELOPMENT

The Optimization Model was developed based on the Mouchel GA*net* approach, developed jointly with the University of Exeter. The model comprises a GA application (GA*net*), a GIS, and the well-known EPANET hydraulic solver. The GA*net* software is responsible for the creation and evaluation of solutions that are simulated in EPANET. The relationships between the GA*net* software, input files, and EPANET software are illustrated in Figure 2. The GA*net* input file includes all the information needed to control the selection of alternatives including global GA parameters, infrastructure variables, and an objective function that is used to assess the overall 'fitness' of the solutions generated. The infrastructure alternatives are represented as 'dummy' elements in the EPANET model.

GA*net* conforms to the idea of object oriented design. Every element in the network which has some impact on the execution of the GA, is modelled as a separate object. The object types include pipes, tanks, pumps, and water purification plants (WPPs). Each of these object types belongs to one or more 'super-classes' which group the objects together according to the function that they perform in the GA. These groups are: Decision Variable Objects; Cost Objects; Constraint Objects; and Monitor Objects. Each object has capabilities that enable it to perform the function required of it. For instance:

- A decision variable object has the ability to take a value from the GA and make a change to the object in the EPANET Dynamic Link Library (DLL).

- A cost object has functions to calculate the cost associated with making a particular decision. Note that there are instances where objects can incur costs without being a decision variable. For example, where a WPP incurs cost based on the flow through it which is influenced by other decisions that the GA might make.
- A constraint object is able to calculate the violation of a constraint. For example, a network junction where a water demand is specified will be evaluated for minimum pressure against the design criteria.
- A monitor object monitors certain specific values over time. Every constraint object is also a monitor object, but the reverse is not true. For instance the WPPs needs to monitor their flow, but there is not necessarily a constraint on that flow.

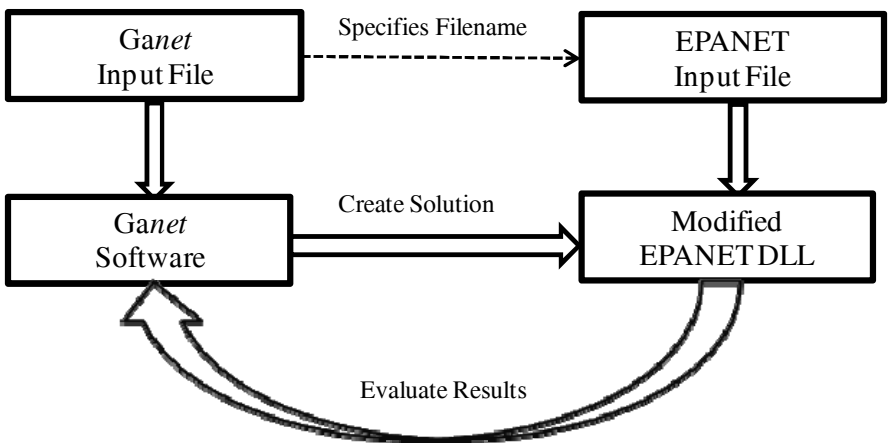

Figure 2: GA*net* / EPANET Relationships

As previously mentioned, each object can belong to one or more of these super-classes. For instance, a pipe is a decision variable (diameter), a cost object (based on the diameter), a constraint object (based on the velocity through the pipe) and a monitor object (to record the velocity). By organising the classes in this way, the software has the capability to model objects with complex behaviour.

There are some engineering alternatives that need to be considered as a single variable. For those alternatives, more than one modification must be made to the network as a result of one decision made by the GA. In this application we have coined the term Custom Decision Variable (CDV) which relates to the fact that any changes can be made to the network and the GA is only aware of the variable as another integer. For example, to adjust a pressure zone boundary, a specific set of pipe closures and openings may be required. These CDVs allow greater flexibility to the range of modifications that may be made to the network, without losing focus on feasible combinations of network modifications.

OBJECTIVE FUNCTION

The objective function is critical to the success of the optimization because it contains the only information that the GA has about the problem at hand. The objective function is used to evaluate the overall fitness of each solution. Those

solutions with a high fitness score have a greater chance of selection for further evolution. There are two primary components of the objective function: the infrastructure cost calculation, and the hydraulic penalty calculation. In essence, the objective function represents the trade-offs between cost and competing performance objectives. The GA can only accommodate the trade-offs by weighting each component of the objective function. In practice, this involves converting measures of non-compliance with performance objectives to costs that are added to the net present value (NPV) of a solution. The GA attempts to minimise the overall 'cost' of the network which is a combination of actual dollar costs and penalty costs.

The NPV cost calculations include capital costs, energy costs, and operations and maintenance costs. Modifications to the GA software were required to include online cost calculations within the software rather than provided as pre-calculated costs via an input file. This was needed to allow for calculations that depended on the hydraulics of the simulation such as flow through the WPPs. The cost models for pipes must also consider river, rail, and highway crossings. Each pipe object can have up to three cost models to account for these crossings.

In addition to the dollar cost, the GA must evaluate whether it is meeting the design criteria. While a number of engineering criteria apply to the problem as described in the following section, many are evaluated as part of post-optimization analyses carried out following each iteration of the design process. The fundamental hydraulic criterion that is evaluated as an integral part of the GA optimization is minimum pressure at each demand node in the system model. In addition to this criterion, the GA also evaluates the solution with respect to minimum and maximum storage facility levels and watermain velocities.

These constraints represent the performance criteria that the GA attempts to meet while minimising the cost of the infrastructure modifications required to deliver them. These constraints are conveyed to the algorithm through the use of penalty functions. These functions compute the violation of the constraint, multiply this value by some penalty factor and add it to the overall 'cost' of the solution. A key part of the model development process involved tuning of the penalty cost factors, so that an appropriate balance between costs and penalties could be achieved as part of the optimization. For example, for each demand node in the Optimization Model, the GA calculates the shortfall (in metres) of the simulated pressure in relation to the target pressure at each time step and multiplies this figure by $1,000,000. This means that some non-compliance with pressure targets can only be accommodated if there are major cost savings associated with the solution compared to other candidate solution. The selected factor was determined by evaluating the results of a number of test runs of the GA to ensure that non-compliance in the solutions was limited and reasonable.

ENGINEERING DESIGN CRITERIA

The optimization was subject to design criteria and constraints established in consultation with the City's Technical Advisory Committee (TAC) for the study. The majority of the criteria are based on well established industry standards. Preliminary reliability criteria were taken from previous City studies. Specific key decisions that

influenced the range of infrastructure alternatives that were ultimately considered included the following:

- Dual transmission is to be provided to the three urban growth areas outside the Greenbelt to provide a high level of supply reliability;
- Elevated storage can be available to provide balancing storage only, with emergency and fire supply provided by redundant watermains;
- Elevated storage must be provided when a minimum pressure of 105 kPa (15 psi) cannot be maintained as a result of the hydraulic grade line (HGL) in the upstream zone should the pump station fail, and when the pressure zone population is greater than 10,000;
- Water age throughout the future distribution system should remain below the desirable limit of 5 days where possible, but should not exceed current values at any existing location where this limit is exceeded.

INFRASTRUCTURE ALTERNATIVES

A broad range of future infrastructure alternatives that could form part of an overall 2031 solution was identified. These alternatives included watermains, new pump stations, pump station expansions, elevated storage facilities, reservoir expansions, control valves, and expansions at the City's two existing WPPs. Over 200 variables were initially considered, each with differing numbers of options, creating a vast combinatorial problem. A number of system reconfiguration options were also considered. In particular, the study terms of reference required that the most appropriate pressure zone configuration for the SUC be determined. Ultimately, 4 different zone configurations were considered for this part of the system.

The potential capacity requirements for future infrastructure alternatives were estimated using supply-storage curves that were developed for the study. These curves are based on mass-balance calculations using diurnal demand curves for specific pressure zones and service areas. The capacity ranges for the alternatives were developed based on two extreme conditions. The first assumes no increase in distribution system storage capacity, and the second assumes no increase in existing transmission capacity, except where required for reliability purposes. From these ranges, a number of discrete sizing alternatives were developed for each future infrastructure component.

SOLUTION DEVELOPMENT

The evaluation of preliminary, capacity driven solutions resulted in updated optimization constraints. These constraints typically involved forcing the selection and/or increasing the minimum sizing of specific infrastructure elements. It was consistently found that the optimal solutions yielded improvements in water age over existing conditions when appropriate operational rules were applied under the most critical conditions. Thus changes in the Optimization Model constraints were driven by reliability needs.

The evaluation of optimization results was carried out using H20Map Water, a GIS-enabled hydraulic simulation package based on ESRI Shapefile technology. The

use of this tool allowed for efficient evaluation of solutions to support debugging of the Optimization Model, penalty factor adjustment, and compliance with design criteria. A long list of operating scenarios were developed and tested as part of the evaluation, most of which involved critical infrastructure failures. Appropriate emergency operational measures were identified for these failures as needed.

The GA is an excellent tool for generating near optimal solutions quickly, but it is slow at arriving at a final optimal solution. In order to minimize manual refinement as part of the post-processing work, a heuristic solver was developed and applied to the solution generated by the GA. The solver identified opportunities to reduce the sizing of watermains selected by the GA.

PRELIMINARY RESULTS

Preliminary optimization trials yielded sub-optimal results. After conducting tasks to troubleshoot the problem set-up, debug the programming, and tune the penalty factors, it was concluded that the number and variety of alternatives needed to be reduced. As per Goldberg (1989), approaches using GA technology are most successful when there is a relatively high degree of independence between the alternatives. In particular, variable storage, pumping and zone boundary characteristics significantly decreases the rate of solution convergence, and the associated options needed to be simplified. There were some logical trends in the preliminary results, and these were used in conjunction with traditional forms of analysis as a basis for reducing the list of alternatives.

The zone configuration alternatives were eliminated from the optimization model. Five separate optimization problems were prepared based on different fixed configurations to relieve the GA of the need to select complex decision combinations. In addition, further analysis of the original list of alternatives was carried out to eliminate those which were judged less likely to form part of the best solution. System detail was also reduced in some areas. The results from these separate optimization runs were considered reliable and contributed to the selection of a preferred future system configuration. Differences in NPV costs between the solutions were small, and the selection was ultimately driven by operational ease and flexibility. The selected pressure zone configuration involves major changes to existing zone boundaries in the SUC. The solution provides the best opportunity for off-peak pressure control, limits peak demand operational requirements, and avoids the need for a major pressure reducing valve station that would have resulted in the creation of numerous dead-end watermains.

DEVELOPMENT OF FINAL 2031 SOLUTION

With a preferred system configuration established, additional system detail was re-introduced, and further iterations of the optimization process carried out to generate a final solution for the 2031 infrastructure requirements (Figure 3). The total capital cost of infrastructure requirements for the solution is estimated at $402M, including $205M for plant expansions, $110 M for new watermains, $45M for pump station projects, $24M for reservoir expansions, and $17M for elevated tanks. The total capital cost estimate for infrastructure needed to meet 2011 demands is $79M,

including a $29M WPP expansion. Infrastructure needed to facilitate zone boundary changes in the SUC are not required until after 2011. The total capital cost estimate for infrastructure to be implemented between 2011 and 2021 is $152M.

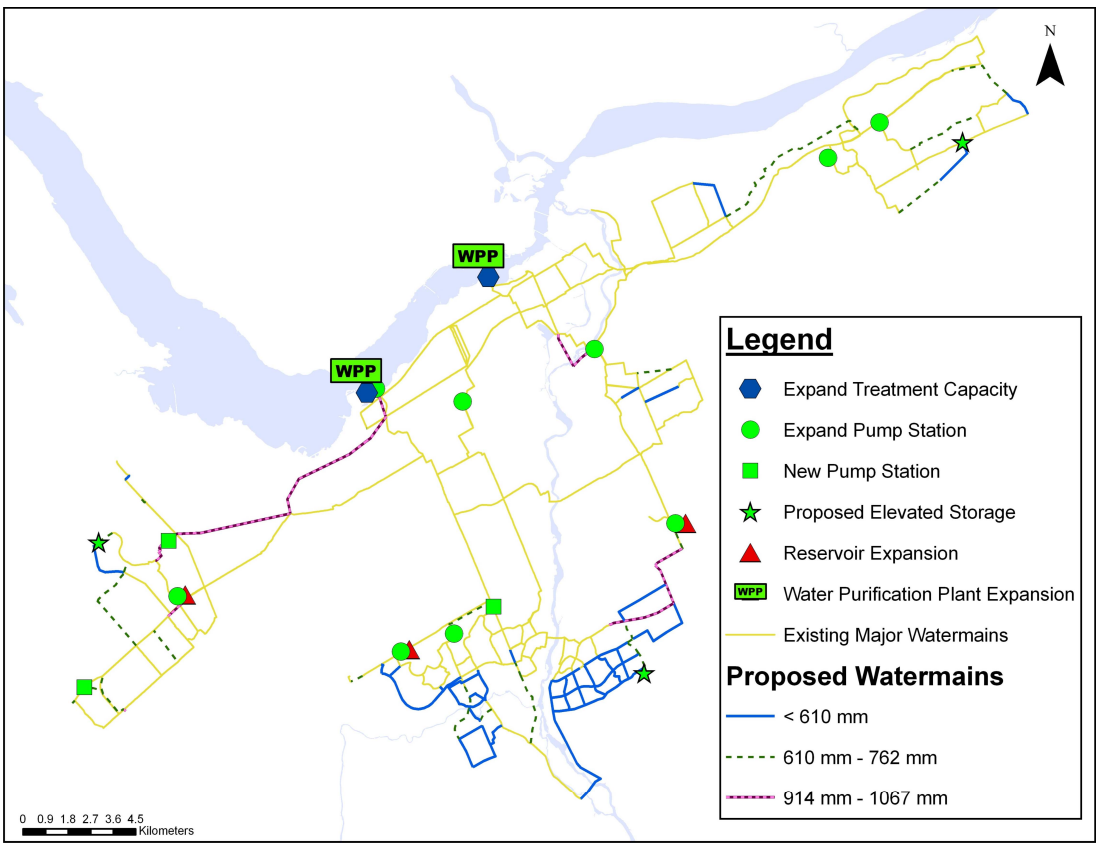

Figure 3: 2031 Infrastructure Solution

MAJOR CONCLUSIONS AND RECOMMENDATIONS

GA technology provides an effective tool that can be used as part of a multi-stage process of developing a water infrastructure Master Plan. However, high level system expansion concepts should be considered based on more traditional methods, with optimization used to assist in the evaluation of these concepts so that a preferred concept can be identified. Optimization can then play a more important role in establishing the details of the preferred concept.

The solution represents a guide to system expansion in the future, but planning efforts will be required periodically over time to update the expansion plan based on the most up-to-date information. Furthermore, the final sizing of infrastructure and specific watermain configurations in growth areas must be confirmed based on more detailed area-specific studies that consider updated growth projections, detailed planning information, and additional operational detail.

Reliable optimization results can best be achieved when a limited range of facility alternatives (i.e. Pump Stations and Storage Facilities) are considered.

Various zone configuration alternatives should not be considered within the context of a single optimization run. Alternatives involving control valves should be considered with caution as they can lead to hydraulic instabilities, leading to unreliable GA results.

High penalty factors are needed to ensure that GA solutions adequately satisfy design criteria. Fine-tuning of these factors is needed to avoid major infrastructure that provides limited benefit beyond ensuring that all criteria are strictly met at all locations. In some cases it was found that post-optimization modelling involving a more detailed representation of the existing watermain network yielded results that exceeded the design criteria in locations that had fallen slightly short of the criteria based on the raw GA results.

ABSTRACT

Water of almost any quality has value so all operators need to learn how to use less, recycle more and to keep it as clean as possible. In many cases, the mineral industry, as a significant water user and wastewater producer, has the capacity to substitute poorer quality water for mining and mineral processing. Complex optimization problems and their challenges have been considered by the researchers around the world over several past years. Tabu search (TS) is a powerful searching algorithm based on principles of intelligent search. We propose in this work a probabilistic improvement to the selection procedure of TS. In this article, two methods are presented: Rank Based Probabilistic Tabu Search (RBPTS) and Fitness Based Probabilistic Tabu Search (FBPTS). Finally, we try to find optimal water resource assignment for an industrial copper complex distribution system. Anyhow, this is an applicable case study in industry.

INTRODUCTION

Complex optimization problems and their challenges have been considered by researchers all over the world over several past years. One way to overcome such difficulties is to use heuristic algorithms based on human's intuition or inspiration from nature that seek for near optimum solutions at reasonable computational time, but cannot guarantee that a problem will be solved and obtain the exact solution. The advantage of heuristic approaches compared with exact algorithms is that the heuristics especially when solving large-scaled problems, find high quality solutions much faster than exact algorithms.

Every year, many improved heuristic algorithms are presented. In this article, the focus is on the modern intelligent optimization technique, the well-known tabu search (TS) method. The concept of tabu search was introduced by Hansen and Jaumard and Glover. Since that time, TS has been proved to be among the most powerful tools for solving various combinatorial optimization problems (for example, graph partitioning (Rolland, 1996), scheduling (Thomas, 1998), and vehicle routing problem (Wassan, 2002)). Still, the design of even more effective TS modifications for specific problems is the research topic for many scientists. In this article, our aim is to apply a probabilistic extension in the selection procedure of TS then try to solve

an industrial water resource management problem with this method.

This article is organized as follows: First, the basic definitions of Standard TS and its components are briefly described. Then the extension of TS is outlined and industrial water management is discussed, then a hypothetical water supplying problem for a mineral plant –and its components– are introduced and solved by the proposed TS. Finally, the paper is completed with conclusions.

STANDARD TABU SEARCH

Tabu search (TS) is a powerful searching algorithm based on principles of intelligent search. The very early origins of the tabu search method go to the well-known technique - the descent local search (DLS) (also known as hill climbing) (Papadimitriou, 1982). DLS starts from an initial (maybe, randomly generated) solution. Further, the search process is continued by performing the perturbations of solutions, i.e. making moves from solutions to solutions. A move is applied to the current solution in order to get a new solution from the neighborhood of the current one. The moves are controlled, if the objective function becomes better, the current solution is replaced by the neighboring one, otherwise, the search is continued with the current solution. The whole process is continued until the current solution is a local optimum, that is, no better solution exists in the neighborhood of it.

TS is an extended descend local search. TS enables to escape from local optima and explore a much larger part of the solution space compared to DLS. The key idea of TS is allowing climbing moves when no improving neighboring solution exists, i.e. a move is allowed even if the new solution from the current solution neighborhood is worse than the current one. Obviously, return to local optimum solutions, which have been previously visited, is to be forbidden in order to avoid cycling. TS is based on the methodology of prohibition; some moves become "tabu" from time to time.

The TS algorithm starts from an initial solution in the feasible space. The process is then continued in an iterative way, moving from a solution to a neighboring one. At each step of this procedure, a subset of the current solution neighboring solutions is considered and the move that improves the objective function value more is chosen. Naturally, the new solution must not necessarily be better than the current solution; if there are no improving moves, the algorithm chooses the one that increases the objective function less. In order to eliminate an immediate return to the solution just visited, the reverse move must be forbidden. This is done by storing the corresponding solution (move) (or its "attribute") in the memory (called a tabu list). The tabu list keeps information of last moves which have been done during the search process. This way of proceeding hinders the algorithm from going back to a solution reached within the last steps. However, the straightforward prohibition may sometimes lessen the efficiency of the algorithm. Moreover, it might be worth returning after a while to a solution visited previously to search in another promising direction. Consequently, an aspiration criterion is introduced to permit the tabu status to be dropped under certain circumstances. The search process is stopped as soon as a termination criterion is satisfied.

Therefore TS main components are: Initial solution, Neighborhood and movement, Tabu list, Aspiration criteria and Stopping criteria (Li, 2006).

Theoretically, different *initial solutions* could lead to different local optimum solutions in a highly nonlinear problem. The beauty of TS is that initial solution can be randomly selected but TS optimization process reduces the deviation of optimums.

The basic idea of TS optimization is to *move* from one solution to the best solution, which is not restricted by tabu list, among its *neighborhood*. If the newly found optimum solution is better than any other previously explored optimum solutions recorded in the tabu list, the list will be updated with this solution. Although any new solution may be worse than the current best result, TS keeps moving toward the best neighbor solution until the given stop criterion is met. This is to avoid being trapped in a local optimum. It is noted that different definitions of a solution neighborhood may significantly affect search efficiency as a large neighborhood requires more searching time and less movements, and vice versa.

Better solutions of recent iterations are recorded in the *Tabu list*, serving as a strategic restraint for not moving back to formerly found solutions. The tabu list should not be too short because there it might be trapped in a cycle. However if the list is too long, the search process may become inefficient. Glover (1990) suggested the magic number 7 to be the first guess.

The role of *aspiration criteria* in TS is to provide an exception to the tabu list. When only a part of the decision variable information is recorded in the tabu list, a truly better solution among those in the current solution neighborhood might be ignored. This misjudgment can be resolved by considering an aspiration criteria or recording all decision variable information in the tabu list.

Termination criteria serve as a restriction for not proceeding further searching when the optimum solution has been reached. It can be given as: (1) a defined optimum solution (2) a maximum number of iterations or (3) the number of iterations done with no improvement.

IMPROVED TABU SEARCH METHODS

As described above, in Standard TS, randomization is done at the first step of solving the problem to select the initial solution. In order to escape from local optima, TS allows uphill climbing moves when no improving neighbor solution exists. Considering this idea, two extensions of TS are proposed in the following:

In standard TS, objective function values of all neighbor solutions are calculated and sorted according to the ascending value of the objective function if a minimization problem is at hand. If the best solution of the neighborhood space represented by the first of the sorted list doesn't exist in the tabu list, TS moves to this solution, otherwise the next solution of the sorted list is considered until a solution is found which is not in the tabu list. The aspiration criterion is used if all the neighbor solutions exist in the tabu list. A situation might arise when the best of neighbor solutions isn't better than the current solution representing local optima. Any move in this situation would be a downhill move without any guarantee to get out of the local optima. A remedy to this problem is proposed here by means of a random selection of neighbor solutions. Randomization in TS can help the method not to be trapped in the local optima. In this article two selection mechanism, namely *rank-based* and *fitness-based*, conventionally used in evolutionary algorithms such as GA, are exploited when the above mentioned situation is faced.

Rank Based Probabilistic Tabu Search (RBPTS)

In this case, selection probability is defined as below:

$$Pr_i = \frac{\frac{1}{k_i}}{\sum_j \frac{1}{k_j}}$$

k_i : Rank of the i[th] solution among the neighborhood space

Pr_i : Probability of selecting the i[th] solution as the solution to move to.

This selection mechanism would give more chance to the lower ranked, i.e.; better, solutions to be selected as the next point to move to.

Fitness Based Probabilistic Tabu Search (FBPTS)

In this case, selection probability is defined as below:

$$Pr_i = \frac{\frac{1}{(Objective)_i}}{\sum_j \frac{1}{(Objective)_j}}$$

$(Objective)_i$: Objective function of the i[th] solution

Pr_i : Probability of selecting the i[th] solution as the solution to move to.

This selection mechanism would also give more chance to the solutions with lower objectives, i.e.; better solutions, to be selected as the next point to move to.

INDUSTRIAL WATER SUPPLY

Water costs money so operators need to learn how to use less, recycle more and to keep it as clean as possible for reuse and ultimate disposal. The mineral industry has an urgent need to demonstrate wise reliable water management and disposal because of public concern about water resources. This extensive concern has put more and more pressure on all significant water users to manage water more sustainable as a key asset with business value. Water plays a significant role in the economic development of regions and communities, and maintenance of the ecology. Water of almost any quality has value. In many cases, the mineral industry has the capacity to substitute poorer quality water for mining and mineral processing - for example, saline and waste water - in place of fresh water. The cost of water supply includes all direct costs of water use in site, such as exploration and extraction of groundwater costs, feasibility study costs, pump costs, license costs, cost of water supply, water treatment costs and cost of maintaining water infrastructure and monitoring equipment.

Water quantity and quality requirements vary significantly across the industry and will be affected by the locality, the mining and processing methods, and the commodity being mined.

A site water management plan should identify operational water supply,

recycling, and disposal needs using water balances, manage treatment of waste water and identify legislative and other regulatory requirements relating to water management. In order to adequately understand the water resource, baseline data relating to water resources, current and predicted water demand and the surrounding environment particularly water dependent ecosystems should be incorporated into the development of site water balances and water management plans.

Measuring and monitoring water -undertaken for the operation life - should include water inputs into the system (i.e. rainfall, supply water, groundwater extraction, surface water pumping, and recycled water), outputs from the system including regulated and unregulated discharges (i.e. rainfall run-off, seepage, evaporation) and water storage (including reconciliation of input and outputs to ensure integrity of storages). (Blum, 2003)

Decision Variables

An industrial water supply system can be modeled with a network consisting of a number of nodes, connecting lines, reservoirs of variable water level and pumping stations. There could be two kinds of connections between network nodes. Some connections transfer water (or slurry containing water) by gravity but some other may contain pumping stations to pump water under pressure. For each node one continuity equation can be written and for each connection line (line discharge) one variable can be considered. Also, for each reservoir node there is an additional variable (flow from spillway). The difference between the equations and variables is the number of decision variables that the optimizer should evaluate.

Objective Function

Objective function in this kind of problem is minimizing the total cost of plant operation. The main expenditure of the plant operation is pumping costs so the objective function is assumed to be minimizing plant pumping costs. First the energy consumption of the plant pumping system should be calculated, and then by multiplying by cost per unit of energy, total cost of operation can be calculated as bellow:

$$ObjectiveFunction: Minimize \sum_{N_{PS}} \left(Energy_i \times CPUE \right)$$

$$Energy_i = Power_i \times T$$

$$Power_i = \frac{\gamma . Q_i . Head_i}{\eta}$$

$Energy_i$: Consumed energy in ith pump station (J)
$CPUE$: Cost per unit of energy (Rials/J)
T : Duration (s)
N_{PS} : Number of pump stations
$Power_i$: Consumed power in ith pump station (W)
Q_i : Discharge of the ith pump station (m3/s)
$Head_i$: Head (m)
η : Pump Efficiency

Constraints

Typically Constraints of this problem are of two types; one type is water demand for each node that should be supplied; the second type is related to pumps and pump stations. For the second type, constraint is derived from ability of pump stations to supply the needed head for pumping the water between nodes.

$$\left(\sum_{n=1}^{N_{PS}} Head_n\right)_j \geq \left(Head_s + Head_f\right)_j$$

$$\left(\sum Q_{in}\right)_i \geq Demand_i$$

$Head_n$: Produced Head by n^{th} Pump Station

$\left(Head_s + Head_f\right)$: Needed Head for Flow in j^{th} Connection

$\left(\sum Q_{in}\right)_i$: Total Discharge to i^{th} Node

$Demand_i$: Water Demand in i^{th} Node that should be supplied

WATER CYCLE COMPONENTS OF A COPPER COMPLEX

Water in industry is used for cooling, transfer, washing, as a solvent and a substance produced in the final product compound. The most important properties of water in industry (the amount of off take, usage and returning water) are strongly related to their production & supply facilities and water systems. Essentially, water in industry is used in two ways; open and closed cycles. In open loop systems, water after off taking and been used (pure or impure), is returned to the river. In a closed looped system, the used water, after necessary productions, is returned to the loop again. In this system, water isn't discharged into the river and by using it repeatedly it remains in the cycle. The amount of off take from the source in industrial water systems is for amending fatalities of industrial producing process and sometimes for replacing water in the water cycle (Aleyasin, 2005).

Water is a vital component in copper production process from mineral rock. After the mineral rock is milled, it is solved in water and some chemical solutions are added so that the copper stands on top of the solution as foam. This foam is collected with large spoons and enters the purring process. The remaining solution in the cauldron, which is called tailing, contains more than 60% water and about 40% unsolved solid matters.

The considered mine is located in a dry region and water resources available are very few. One of these resources is the seasonal river which has little water; this is while one part of this water is allocated for agricultural use. One other water resource for this plant is underground sources.

According to the mentioned conditions, using an open cycle isn't possible. That means that the main resource of this plant should be the return water and the shortcoming should be ensured from surface water and ultimately underground water in case of necessity. For forming a closed cycle, different components are needed; for example pipe lines, pump stations, tailing dams, diversion dam, water reservoirs and treatment plants (Figure 1).

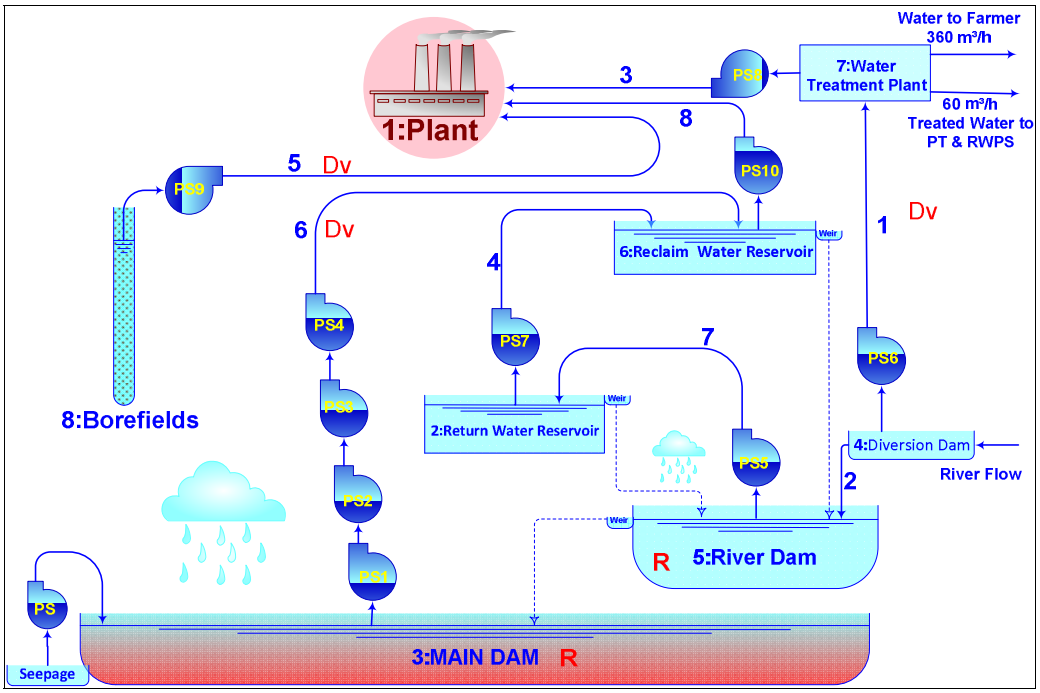

Figure 1: The Copper Complex Water Cycle

According to water components of the complex water cycle (Figure 1), water can be supplied for the complex in three ways: seasonal river, wells and finally returned water from the tailing dam.

MODELING RESULTS

For solving each problem, the needed model inputs are introduced to the model in the format of given files. Inputs are classified in two main groups: one group is inputs related to physical properties which are different for each problem according to their situations. This group is mainly inputs to the simulation model. The other kind of inputs is optimization model constants that are independent from the physical properties. Therefore these constants can be determined for a simple problem and be used for other problems. So the first step for performing a model is parameter tuning. After parameter tuning the model is ready for solving various scenarios of complex operation and decision making.

In this problem, as mentioned above, tailings exported from the plant go directly to the tailing dam pond, sediments settle and decant water is stored behind the dam. This water is pumped to the reclaim water reservoir in several stages.

This problem is solved with all the 3 mechanisms (FBPTS, RBPTS and Deterministic) and as an example the results of one mechanism are presented below (Figure 2, Figure 3 and Table 1).

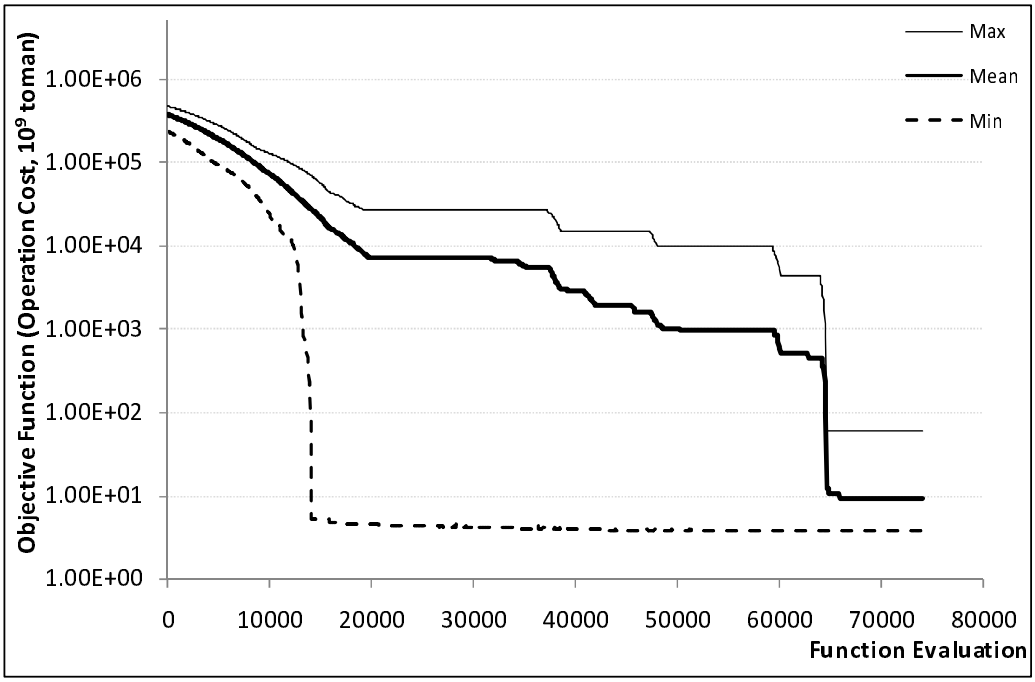

Figure 2: Objective Function Values– RBPTS

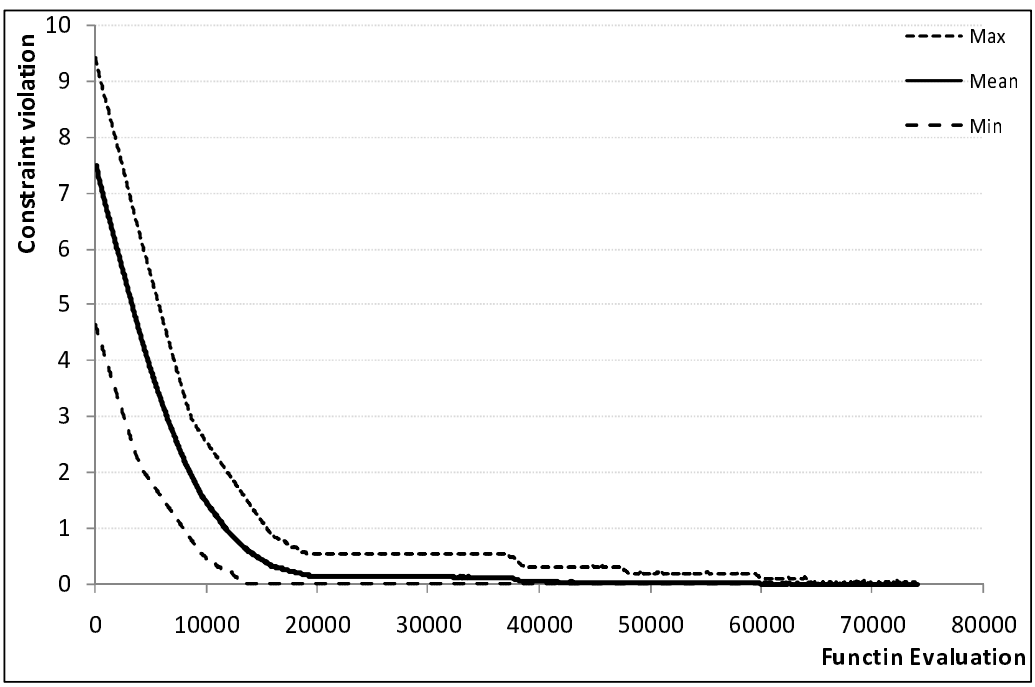

Figure 3: Constraint violation– RBPTS

Table 1: Variable Value (Operation Rule)– RBPTS

	variable		1	2	3	4	5	6	7	8	9	10	11	12
Decision Variable	water from diversion dam to treatment plant	m^3/hr	1,382	652	676	648	673	1,352	1,325	1,800	1,800	1,800	1,800	0
	water from tailings dam to water tank	m^3/hr	0	0	955	781	1,160	655	561	0	0	0	0	0
	water from wells to water tank	m^3/hr	3,500	3,500	3,500	3,500	3,500	3,500	3,494	2,251	2,589	2,948	3,430	0
State Variable	Release from diversion dam to water dam	m^3/hr	113	9	31	7	35	10	39	66	1,378	1,378	1,378	1,378
	water from treatment plant to plant	m^3/hr	858	962	232	256	228	253	932	905	1,380	1,380	1,380	1,380
	water from from return water tank to reclaim water tank	m^3/hr	687	1,338	1,368	1,489	391	687	13	1,140	1,369	1,331	1,372	1,490

RESULT ANNOTATIONS

According to objective function values, the probabilistic method will improve the objective function value considerably compared with deterministic mechanism. Furthermore, the ranking based mechanism will improve the value better than the fitness based one (**Error! Not a valid bookmark self-reference.**)

Table 2: Annual Costs

Problem / (10^9 toman)		Annual Pumping Cost	Groundwater Cost	Total Operation Cost
Case-Study Solution	Deterministic	2.68	1.48	**4.16**
	FBPTS	2.73	1.07	**3.81**
	RBPTS	2.74	1.07	**3.81**

CONSEQUENCE

In this paper components of a copper complex water distribution system have been introduced and the water flow in this cycle has been simulated and been optimized by Tabu Search method- one of the most powerful meta heuristic methods. Also, two probabilistic extensions have been made to the TS optimization process by authors. Results indicate that these extensions have been remarkably successful in getting closer to optimum solution. Finally, it can be mentioned as an essential consequence for industrial plants that using optimum-closed water cycles is economically and environmentally vital.

ABSTRACT

Energy is one of the largest water utility expenses. This cost is greatly associated with the pump operation. An optimum pump schedule can reduce the cost significantly while maintaining hydraulics in an acceptable range. In this paper, the pump station relationships are linearized using relationships among energy required, pumping flow, demand factors and tank storage or tank water levels. A linear programming (LP) optimization problem is formulated and solved for a single tank system for the optimal pump schedule to minimize energy cost. This LP model can be solved very quickly for a "near optimal" solution. Available online data can be then incorporated to update the schedule each hour in real-time. This paper describes preliminary methodologies that can be used to optimize the pump schedule and reservoir control. Future work will extend the approach to multiple tanks and pump station systems, better pump curve representations, and spatially variable demands.

INTRODUCTION

Water supply and distribution systems consume a significant amount of energy to transport water through the WDS. This consumed energy used in a form of electrical energy is one of the highest expenses for the water utility industries. Increasing energy prices make the energy expense important to water utilities.

In recent years a significant amount of research has been focused on optimizing pump operation schedules. The full range of linear, nonlinear, and heuristic optimization methods, dynamic programming and brute force search have been applied to solve the problem (Ostfeld and Tubaltzev 2008, Thorstensen 2007, Prasad et. al. 2006, Nace et. al. 2001, Savic et. al. 1997, Brion and Mays 1991). Bunn (2006) and Bunn and Hillebrand (2006) have suggested an LP method but have not presented details of the method. Most of the other method either greatly simplify the complex water distribution system or require significant time to solve the problem which limits their real-time capabilities.

Energy consumption in a water distribution system can be reduced in a number of ways; by lowering pump volumes, by reducing tank or reservoir heads against which pumps are operating for, by operating pumps during off peak hours to decrease the unit energy price, by operating pumps near the best efficiency point. All of these options are possible using online data to optimize pump schedule. We postulate that the most significant portion of these benefits is from proper use of tanks and maintaining pump efficiencies is less important.

The aim of this study is to develop an optimum pump operation model which can be solved quickly enough that online data can be incorporated in the model and solve the problem in real-time. The objective of this problem is to minimize the pump operation energy cost. The approach applies an approximation to the energy use as a function of pump station discharge.

PROBLEM FORMULATION

To date, most of the optimization approaches suggest that 10% to 20% energy cost savings are available compared to trial and error techniques or experience. On the other hand even fairly large linear programming (LP) problems can be solved in seconds on most desktop computers. With online data in hand a linear model can be updated very easily and problem can be solved quickly enough to take real-time decisions. Therefore, LP has been used to solve numerous problems from scheduling to financial market.

A water distribution system is a complex system of pump-tank-node relationship. Since LP requires the objective and constraints functions to be linear, the complex network relationships must be simplified to make the relationship linear so that LP can be adopted. The resulting model may not ensure that the global optimum solution of the pump scheduling problem. However, if a comparable solution (i.e., one within a few percent) can be quickly determined then the benefits of rapid solution may be balanced with inaccuracies introduced by linearization.

The model is formulated to minimize pumping energy such that hydraulic constraints are met. Mathematically the problem can be stated as:

$$\text{Minimize } \sum_{T=1}^{24} C_T E_T(Q_{p,T}, H_T) \tag{1}$$

subject to:

$$H_{min} \le H_T(H_{T-1}, Q_P) \le H_{max} \tag{2}$$

$$Q_{Pmax} \ge Q_P \ge 0 \tag{3}$$

where C_T is a conversion factor to convert energy consumed during period T, i.e., E_T to dollars. E_T is the power function of pump station ($Q_{,Tp}$) and (H_T) is the initial water

level in the tank at time *T*. The tank water level, H_T, is a function of the previous hour water level H_{T-1} and Q_{pT-1} and is constrained to between the minimum (H_{min}) and maximum (H_{max}) allowable tank water levels. The pump station flow is also constrained (Eq. 3) by maximum and minimum limits so that the range of the model does not go beyond the limit of the linear approximation of the system. The model is formulated hourly basis for 24 hours. As seen, this initial model is applicable to a single tank system. Future work will consider multiple tanks. $\boldsymbol{Q_p}$ and $\boldsymbol{H}$ are the sets of LP decision variables with $\boldsymbol{Q_p}$ can be considered as the control variable with $\boldsymbol{H}$ as the state variable.

Eq. 2 is a function of previous hour tank water level and pump station based on conservation of mass or:

$$H_T = H_{T-1} + \frac{(Q_{P_T} - Q_{D_T})\Delta T}{A_T} \tag{4}$$

where Q_{P_T} and Q_{D_T} are the pump station flow and system demand, respectively, at time *T*. A_T is the tank's cross sectional area and ΔT is the length of time step. Since the tank's cross sectional area and time interval are constant in the equation and the demand and previous hour tank's water level are known at the beginning of the time step, H_T can be determined given Q_{pT}

Similarly, the consumed energy is approximated as a linear function of the pump station flow and initial tank level as:

$$E_T = m_T Q_{P_T} + I_T(H_T) \tag{5}$$

where m_T is the slope of the energy curve which is function of pump station flow, Q_{P_T} and I_T is the interceptor of the energy equation which is function of tank water level. The next section describes how this function can be developed.

METHODOLOGY

Pump scheduling by linear programming consists of five steps. The first step is to collect the WDS physical data. Using this data, the energy functions are then developed by extensive simulation. Both of the previous steps are completed off-line prior to the real-time application. In real-time, the third step is to forecast demands. Finally, linear programming model is formed with those demands and the derived functions to determine the optimal pump station discharges for each period. Finally, those discharge values are converted to actual pump operations.

Zhong and Lansey (1991) proposed using a pump station head as a decision variable in an NLP problem with the pump station discharge being an implicit variable computed in the network hydraulic model. They developed a nonlinear

regression relationship between pump station head, discharge and energy consumption. The curve was based on data generated from simulating alternative pump combinations.

The approach here for developing an energy function is different in that it combines the energy consumption to the pump discharge for specific tank level and system demands. For this initial step in formulating this problem, a single linear equation is used. However, this relationship is not necessarily always linear. The shape of the curve suggests that a piecewise linear relationship between these two parameters may be more appropriate than a single linear relationship and will be pursued in the next steps of this research.

EXAMPLE NETWORK

The network that is analyzed in this study consists of 37 pipes, 19 nodes, one tank (node 21) and one source (node 20) with four pumps (Figure 1). The tank elevation and diameter are 215 ft and 40 ft, respectively. The hydraulic time step and pattern time step are each 1 hour. The tank level was permitted to fluctuate between 222 ft to 250 ft. Hourly demand factors ranged from 0.5 to 1.7. Four pumps are installed in the pump station at the reservoir source.

Given the physical and demand data, the energy and flow relationships can be developed. To do so, the network is simulated for each demand factor for each pump combination for a range of water levels. With four available pumps, 15 pump combinations are possible (the no pumping option is not considered). Figures 2a -2c show the plots of energy required and pump station flow for different demand factors. For each demand factor the plots for different tank water levels are similarly concave upward. Only combinations that satisfy pressure requirements are included in the plots. If multiple pump combinations supply the same discharge with different energy demands, the higher cost combination is dropped. The resulting points are the operating points for the pumps at the given demand level and tank level. For a single tank system, the network hydraulics are completely embedded in the energy consumption relationship.

Recall that the pump station flow is the LP decision variable. Since the pump station flow, Qp, and system demand, Q_D, are then known, the flow into the tank and the resulting change in water level can be computed by Eq. 4.

To demonstrate the methodology, the energy consumption versus pump discharge are fit with a single regression line for each tank water level and constant demand factor combination (Figure 3). The largest flow rate point is not included in the regression. The regression line equations are also shown. As seen, the slopes for all combinations are virtually equal so the average slope value is used. The lines do shift vertically. Changes in y-intercepts are related to the tank level that is not known a priori. Tank level, however, is a linear function of the discharge by Eq. 4 and the

energy consumption can be computed using Eq. 5. Figure 4 shows a linear regression to fit for $I_T(H_T)$. This relationship retains the linearity of the problem.

With these energy relationships, the LP can be solved for the optimal pump station discharges. The optimal solution is listed in Table 1.

Table 1: Optimal pump station discharges for application system

Time (hr)	Pump station discharge (gpm)	Time (hr)	Pump station discharge (gpm)	Time (hr)	Pump station discharge (gpm)
0:00	3201	8:00	8852	16:00	8493
1:00	6409	9:00	7	17:00	8141
2:00	10775	10:00	3300	18:00	7718
3:00	1386	11:00	3833	19:00	7679
4:00	5760	12:00	7728	20:00	7646
5:00	10135	13:00	7684	21:00	7041
6:00	94	14:00	11978	22:00	7038
7:00	4489	15:00	3986	23:00	7028
Total required energy to pump 24 hours flow = 21556 kWh					

The next step then is to convert the optimal pump station flow to a discrete set of pumps. An optimal pump discharge that falls on a pump combination point will operate at that discharge and consume the corresponding energy. If the discharge does not fall exactly on a pump combination point, some error will result in the approximate cost and tank water level when a nearby pump combination is chosen. Our supposition is that tank level control is the dominant available energy savings. Thus, small differences in pump operation decisions will not significantly alter the optimal solution cost. In addition, uncertainty in predicting future demands will change the solution over time. Since this approach can update a solution at each time step, the adjustments to demand predictions will mitigate some of the cost differences.

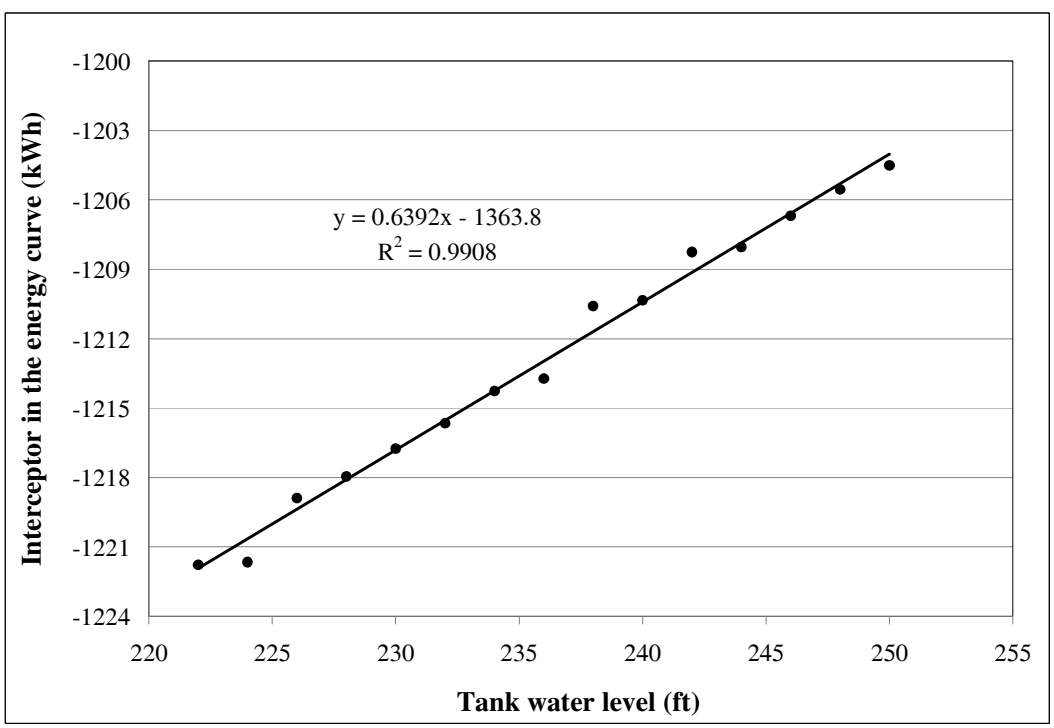

Figure 4. Typical regression relationships between energy curve interceptor and tank water level.

DISCUSSION AND CONCLUSIONS

The advantages of real-time optimal pump schedule have been long discussed. However, most approaches attempt to solve the problem exactly at the expense of high computation time. In this paper, a linear program model is posed that simplifies the complex water distribution system in a reasonable way. The linear programming model is solved quickly so that new data can be incorporated into the model in real-time. Thus, a real-time pump scheduling tool can be created.

Several difficulties arise due to the approximation. The first is converting the LP continuous solution to a discrete solution and the inaccuracies of the linear approximation. As described above, if a discharge at a given time step does not match a pump combination some inaccuracies will occur. Again, however, the majority of cost savings are expected to occur by storage management. A comparison to an exact method should be made to quantify the differences. A possible extension to this methodology is to pass the LP solution to a stochastic search or integer programming with a limited set of pump combinations.

A second problem is the linear regression does not fall through all pump combinations. An obvious improvement is to use a piecewise linear model over the single linear regression. The concave slopes of the energy consumption-discharge function are amenable to a minimization problem.

Next, this approach is only applied to a single tank. Extensions to multiple tank zones may be approximated by the proportion of flows sent to each tank. Finally, pump switch constraints can not be directly included. The two stage approach of passing the solution to a second discrete optimization method that could include these constraints is possible but may result in a local optimum. On the other hand, variable energy costs can be included with no additional difficulty.

Las Vegas Valley Water District

Abstract

Determining the hydraulic criticality of distribution system components is key to asset management and emergency response. Evaluation of the hydraulic criticality of large distribution system facilities involves compiling a significant amount of information such as spatial data, customer information and hydraulic model results. An integrated approach which leverages information compiled during the hydraulic demand distribution process for evaluating hydraulic criticality will be outlined. Benefits of the integrated approach for a) asset management, b) shutdown analysis and c) emergency response will be presented.

Introduction

Potential consequences of failure of an individual element of a water distribution system include loss of service to critical customers, entry of contaminants into the distribution system and reduced or no fire protection due to inadequate pressures and inability to maintain sufficient supply resulting out of loss of hydraulic integrity from the failure. Determining hydraulic criticality of a water distribution facility is therefore essential for asset management, emergency response, planning shutdowns and water quality evaluation.

There are almost 1 million miles of distribution piping (excluding service lines) in the United States, the majority of which will be reaching the end of their life spans in the next 30 years (Ray, 2007 and WSTB, 2005). The United States Environmental Protection Agency's (EPA, 2005a) most recent Drinking Water Needs Infrastructure Survey, conducted in 2003 and released in 2005, projects that the US will need to invest $276.8 billion over the next 20 years to repair/replace deteriorating water distribution infrastructure. The size of the drinking water infrastructure funding gap has been estimated by EPA at $45 billion to $267 billion, depending on the revenue growth scenario and spending levels (EPA, 2002a and Marlow, 2009). With limitations on available budgets, prioritizing criticality of assets is essential for optimal repair, rehabilitation and replacement of water distribution facilities.

Traditionally, decisions to rehabilitate or replace water pipes have been based on general indicators such as failure history, age, material, size and type of pipe. Reliance on these indicators alone may lead to sub-optimal decisions. To be optimal, information about the actual condition of pipe and its criticality is needed.

For high risk mains the effects of even a single main break are serious, so prevention becomes much more desirable (EPA, 2005b). The ability to prioritize and schedule repairs and replacements based on pipe condition and hydraulic criticality can be especially valuable for systems that have a substantial amount of high-consequence pipes that are approaching the ends of their service lives, but also have insufficient funds to address all the deteriorated pipes at one time. In this situation, the order in which pipes are repaired, rehabilitated, or replaced is very important, because the adverse effects of failures can be minimized by first addressing the pipes that have the highest failure consequences.

The useful life of pipe, which comprises most of the assets in water systems, varies considerably based on a number of factors. Deterioration rates of pipe will vary considerably as a function of climatic conditions, pipe material, soil properties, and corrosiveness of the water (EPA, 2002a). The best way to determine the remaining useful life of a facility is to conduct a condition assessment. The lack of condition assessment for water facilities can cause repair and replacement to be scheduled either too early or too late. Either error can cause adverse effects (EPA, 2005b). It is cost-prohibitive to conduct condition assessment for every facility in the system. In addition to factors such as material, age and soil characteristics, hydraulic criticality can be used for cost-effective prioritization for water facilities conditional assessment.

Water distribution systems are occasionally subject to emergencies or planned shutdown activities during which the system can no longer provide the minimum level of service to customers. Examples of emergency response situations include facility/equipment failures and power failures (WSTB, 2005). Planned shutdown activities include stopping the treatment plant, shutting down a well, reservoir shutdown for inspection, cleaning or repairs, installation of new pipe connections, pipe rehabilitation or break repairs, and valve repairs. These emergency situations and planned shutdowns can result in a reduction in system capacity and pressure, loss of supply to critical customers and reduced or lack of fire protection. Knowing the hydraulic criticality of a water distribution facility will facilitate a better operational response to emergencies and planned shutdowns, and minimize impact to customers.

Integrated Approach

In simple terms, determination of the hydraulic criticality of a distribution system facility involves:

a) Compilation of spatial and attribute data of system facilities
b) Prediction of system behavior during the failure such as loss of system pressure and capacity

c) Combining predicted system behavior with customer and spatial information to estimate consequences of facility failure

The tasks outlined above for determining hydraulic criticality of large distribution system facilities involve compiling a significant amount of information such as spatial data, customer information and hydraulic model results. The spatial data includes location and spatial relationship (topology) of distribution system facilities such as pipes, valves, pumping stations and storage reservoirs. Customer information includes service criticality, connection point and consumption. Hydraulic model results include system pressures, velocities and supply capacities. In addition, relationships need to be established between system facilities, customers and model results. Because the process and the associated large data requirements are resource intensive, an integrated approach is required to optimize resources and benefits. The following sections describe an integrated approach for evaluating the hydraulic criticality of system facilities.

Prediction of System Behavior during a Facility Failure

As stated above, the first step in evaluating hydraulic criticality is compiling system facilities information. Spatial data (GIS) systems typically keep a good inventory of the system data. GIS software has long supported the concept of topologically connected Geometric Networks with directional flows, sources/sinks, etc. Attempts have been made to predict system behavior during a facility failure using the topology in Geometric Networks. Although these methods, in the absence of a hydraulic model, may indicate portions of the network and customers without supply, they fail to predict the true system behavior for the connected portion of the network. For example, a system might still be connected during a facility failure but the residual pressures might be so low that supply is lost to customers in the connected portion of the network and a potential exists for intrusion of contaminants into the network. Therefore, prediction of system behaviors using geometric networks could result in misleading estimations of failure consequences. Hydraulic models provide a more accurate prediction of system behavior and failure consequences.

Model Construction

Historical emphasis when creating spatial data has been field-accurate mapping to support map generation and spatial analysis. Hydraulic modeling algorithms require a more stringent set of conditions on the data (Jacobsen et al, 2007). The challenge lies in representing system facilities in the hydraulic model and in keeping pace with spatial data updates.

Skeleton Models

Historically, computing power and software limitations necessitated that only the most significant features of the distribution system are represented. This limitation inhibited modeling efforts that attempted to include all the pipes in a large distribution system such as the Las Vegas Valley Water District's (District's) (Jacobsen et al, 2007). In order to work within these hardware and software constraints, the concept of skeletonization was applied. Typically, a model would be

constructed by taking only the most significant portion of the distribution system (for example, all pipes of 12-inch diameter and larger) and by aggregating pipes that have the same diameter, age, material and roughness. The District has been using skeletonized models since 1987. However, it is difficult to accurately represent system looping in skeletonized models. Without proper representation of looping, it is difficult to evaluate system redundancy and response to a facility failure. In addition, because of the conceptual nature of skeletonized models, it is arduous to directly relate system behavior with failure consequences.

All-pipes Model Development

In recent years, advances in hardware and software technologies have provided the ability to include all the pipes in the distribution system. An all-pipes hydraulic model with 170,000 pipes was developed at the District utilizing a one-to-one relationship between model features and GIS features. Figure 1 shows a comparison of a section of the skeletonized model on the left with the same section using all pipes in that area to the right. A one-to-one relationship between model data and spatial data allows seamless spatial analysis capabilities with model output and spatial layers. Figure 2 shows an All-Pipes Model that has a one-to-one relationship with spatial (GIS) data.

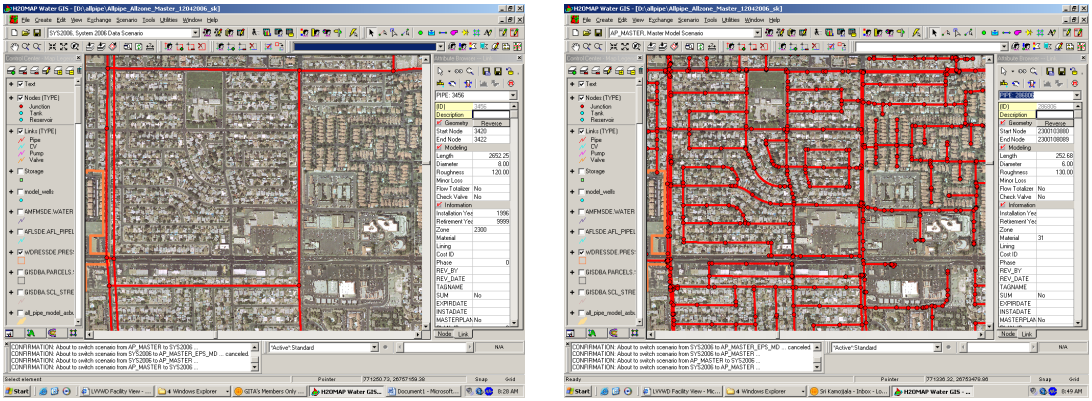

Figure 1. Skeletonized and All-pipes Models

The benefits of utilizing an all-pipes model with a one-to-one relationship with GIS for hydraulic criticality are many:

- More accurate hydraulic modeling, specifically in evaluating system redundancy and looping
- More direct integration with other systems/applications such as customer and spatial information systems
- Streamlined model maintenance
- Better spatial accuracy and quality of data
- More complete water quality analysis

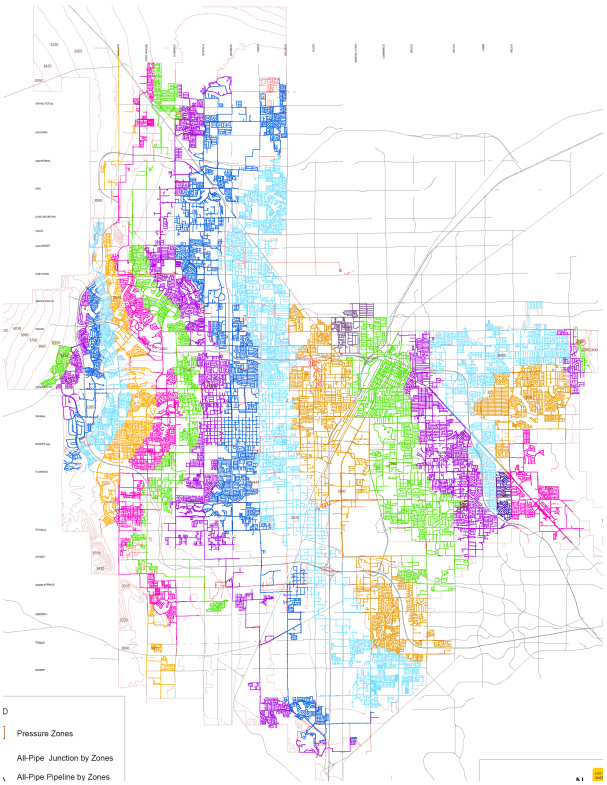

Figure 2. All-pipes Model

Predicting Consequences of a Failure

Once the system behavior is predicted, the behavior of the system needs to be related to customers and spatial data to determine the failure consequences. Simplified methods such as the ratio of demand met with failure to the original system demand have been used to determine the impact to customers (Valkovic, 2004). However, these methods do not provide the information on who is impacted and the criticality of service. To determine the impacted customers, it is essential to tie customers directly to the facilities serving the customers. This can be achieved by identifying all the services connecting to a distribution pipe. The following section describes how relating a pipe to customers served can be accomplished during the hydraulic model demand allocation process.

Demand Allocation and Relating Customers to Pipe Served

There are several methods of demand allocation. All these methods require handling and analyzing a large amount of spatial data, such as landuse and billing (actual consumption) information. Historically, demand has been assigned using semi-automated processes based on the skeletonized model. But with the all-pipes model, manual processing is not feasible; therefore, automated tools are required. Automated methods reported in literature for demand allocation include Meter

Summation, Closest Node and Closest Pipe methods (Jacobsen and Kamojjala, 2005). However, the Connected Pipe method as depicted in figure 3 provides an ideal alternative for hydraulic criticality evaluation.

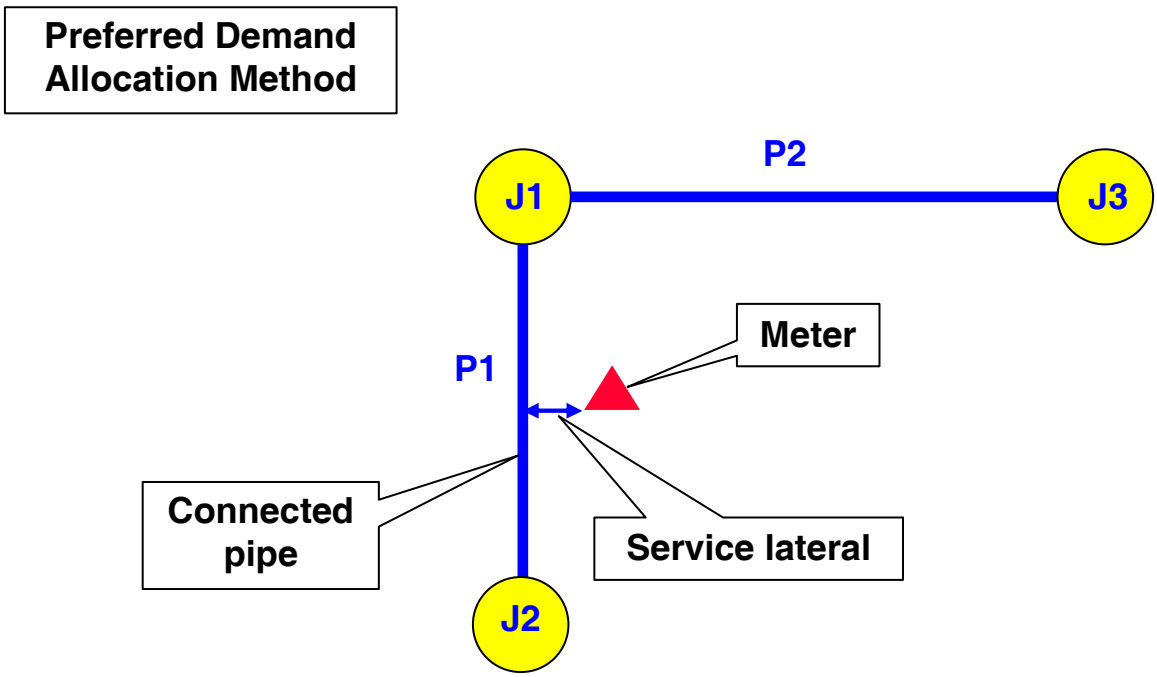

Figure 3. Preferred Method for Demand Allocation

The advantages of this method are:

- It relates pipes to accounts/parcels which in turn makes it easy to relate predicted system behavior during a facility failure to consequences such as impacted customers and is very useful in responding to emergencies or planning a shutdown
- It leverages integration of GIS and CIS
- It provides better spatial distribution for the system model

Determination of Hydraulic Criticality of a Water Main

Evaluating the hydraulic criticality of distribution system water mains involves systematically performing hydraulic analysis for each pipe by closing the pipe and the segments required to isolate the pipe from the hydraulic model. The following example illustrates determination of the hydraulic criticality of a water main. During a water main break (failure), it is critical to quickly identify the distribution system valves that must be closed in order to minimize water loss, potential flooding, or possible contamination. Repairs must be performed quickly so that service can be resumed. Using GIS and modeling tools, valves are rapidly identified for isolation.

After removing the isolated segments from the network, a hydraulic analysis is performed to predict system behavior. System behavior is combined with spatial data and customer information to evaluate the impact on existing services. Figure 4 shows a comparison of pressures before and after a shutdown. Response to emergencies, such as main breaks, can be provided quickly and accurately using integrated tools (Jacobsen and Kamojjala, 2005). A list of affected customers is generated for appropriate notification (Figure 5).

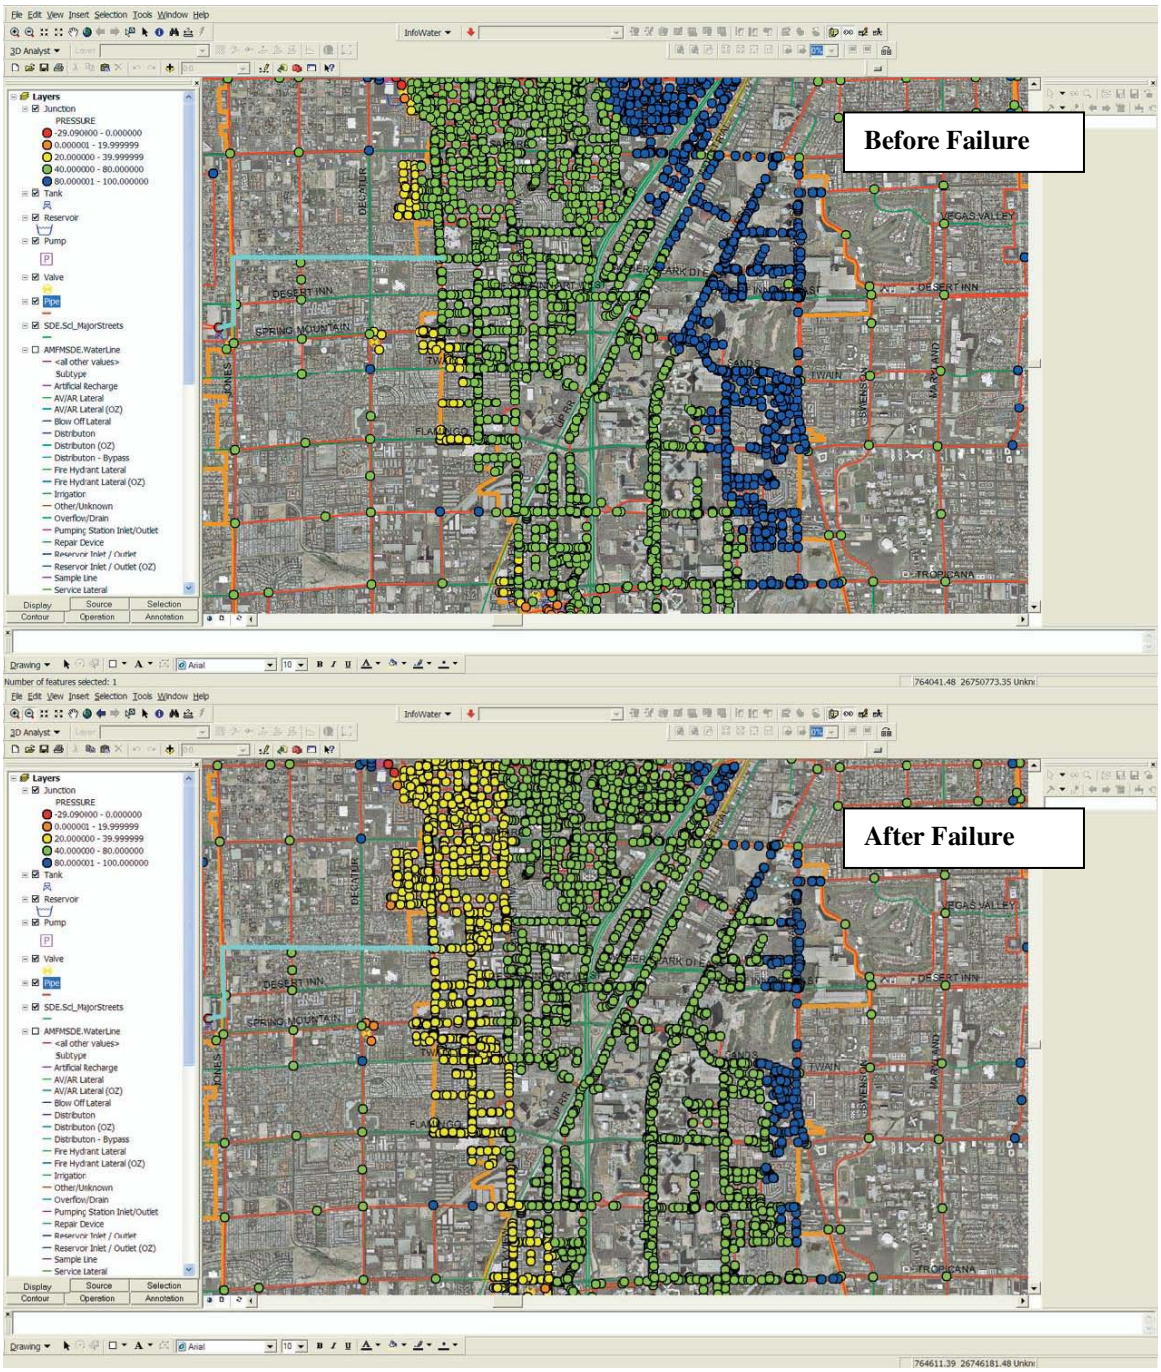

Figure 4. Comparison of Junction Pressures – Before and After Failure

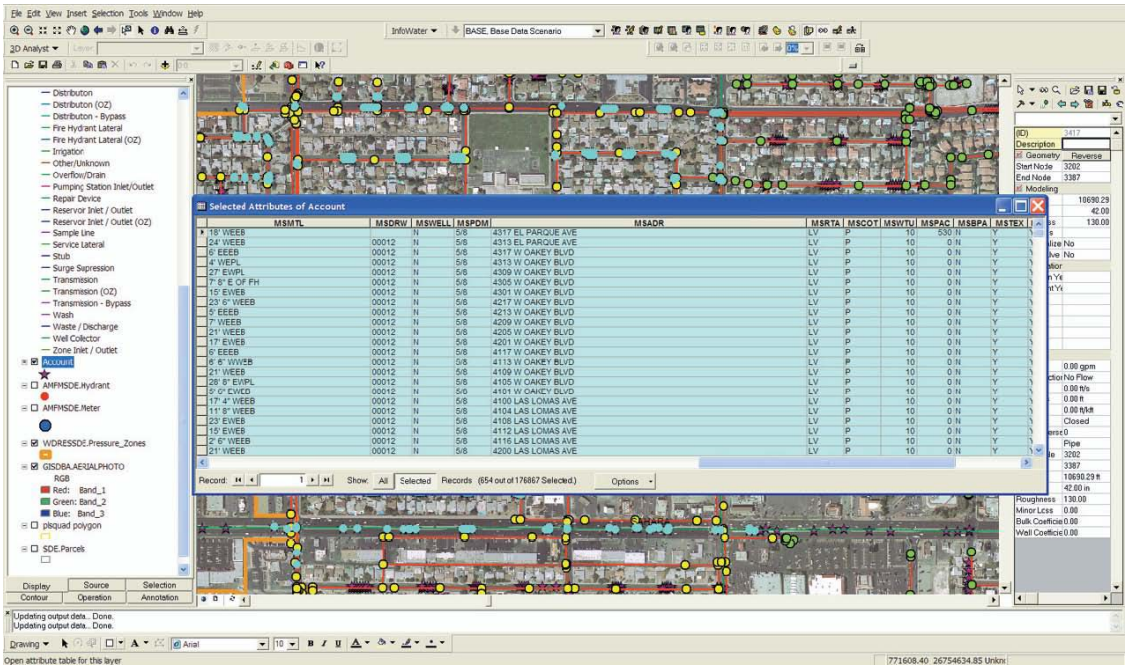

Figure 5. Impacted Customer List

Reducing the Criticality of a Facility

Once a critical facility is identified, it may be possible to mitigate the criticality by installing additional valves, adding pipes to loop the system, providing another feed to the pressure zone or providing a redundant service to a critical customer. Mitigating criticality is very useful in situations where factors such as location, traffic, depth of cover, right-of-way limitations, utility congestion, or unstable soil conditions impose limitations on planned rehabilitation or replacement efforts. By properly evaluating and mitigating criticality of a facility, the impact of an emergency failure may be greatly reduced.

Conclusions

With limitations on available budgets, prioritizing criticality of assets is essential for optimal repair, rehabilitation and replacement of water distribution facilities. Hydraulic criticality of distribution system facilities can be used for prioritizing assets not only for repair and replacements but also for condition assessment. Added benefits of hydraulic criticality evaluation are efficient emergency response and shutdown planning. Recent developments in hydraulic modeling and automated tools help in simplifying the process of evaluating hydraulic criticality. An integrated approach to hydraulic criticality evaluation will optimize resources and benefits.

ABSTRACT

The purposes of placing sensors in water distribution systems vary from complying with water quality regulations, monitoring accidental contamination events, and detecting intentional contamination events. The information available to water utilities varies: some only have information on the topological structure of their systems; some have calibrated hydraulics models for their systems; and some even have water quality models for their systems. Different sensor location models have been proposed for the different purposes, targeting the objectives of maximizing the coverage, minimizing the contaminant travel time prior to detection, minimizing the contaminated water consumed prior to detection, and/or minimizing the population at risk prior to detection. These different sensor location models require different computational efforts and the availability of information on water distribution systems to different extents. The current sensor location models proposed mainly include graph-theory-based model (network analysis), deterministic optimization models, stochastic optimization models and robust optimization models. In this paper, we develop a protocol to help water utilities to select sensor location models based on the specific purposes of sensor placement, the information available to the water utilities, and the computational requirements of the models.

INTRODUCTION

A typical water distribution system consists of water supply sources, pipes, tanks, pumps and valves. The flow of water in a distribution system is driven by the consumption from consumers and the external pressure from the pumps. Chemical and biological agents in the system travel with water and some even react with other agents in water and the wall of the pipes. It is not feasible to conduct experiments to get information on how water flows and contaminants travel in a water distribution system without interrupting the normal consumption behavior of the consumers. Researchers and practitioners often turn to modeling the structure of water distribution systems, water flow behavior (hydraulics) and contaminants' behavior (water quality) in water distribution systems. Building hydraulic models and water quality models for a water distribution system requires significant calibration efforts. Some water utilities have only the information on the topological structure of their systems, some water utilities have hydraulic models for their systems, and some even have water quality models for their systems.

It is relatively easy to build a mathematical model for the topological structure of a water distribution system. By expressing sources, tanks, and junctions as *nodes*, and pipes, valves and pumps as *edges*, one can use a binary matrix ($N \times N$) to characterize the network structure of a water distribution system, with N being the number of the nodes in the network. In the matrix cell, if there is an edge between node i and node j, then the cell value c_{ij} is equal to 1, and if there is no edge between node i and node j, then the cell value c_{ij} is equal to 0. If a water utility has a calibrated dynamic hydraulic model (based on mass balance and energy conservation) for their system, one can obtain water flow behavior in the system with one run of the simulation and the computational effort is affordable to all the water utilities. If a water utility has a calibrated water quality model for their system, one can simulate contaminant travel behavior in the water distribution system. Without prior knowledge, a contamination event has to be assumed to be possible at any time, any location, and for any duration, which requires the simulation of a large number of contamination scenarios. The computational requirements for a medium-sized to large water distributions systems could be daunting. Krause et al. (2006) shows that it takes 8 days to simulate contamination events that could occur at 5 min intervals over a 24 h period from any of the 12,527 nodes in a modest-sized distribution network by using 30 parallel processors.

Substantial research has been conducted to design sensor location schemes in a water distribution system either for the purpose of enhancing water security (related to intentional and accidental contamination event) or for the purpose of complying with water quality regulations (Lee and Deininger 1992; Kessler et al. 1998; Ostfeld

and Salomons 2004; Berry et al. 2005, 2006; Grayman et al. 2006; Gueli 2006; Krause et al. 2006; Propato 2006; Shastri and Diwekar 2006; Ostfeld et al. 2008; Xu et al. 2008). Research on this topic has evolved from single objective like maximizing the areas covered (Lee and Deininger, 1992), minimizing the contaminated water consumed prior to detection (Kessler et al. 1998; Ostfeld and Salomons, 2004), minimizing the contaminant travel time prior to detection, and minimizing the population at risk prior to detection (Berry et al., 2005) to multi-objectives (Krause et al. 2006). The optimization models developed for placing sensors in water distribution systems so far mainly include graph-theory-based model (network analysis) (Xu et al. 2008), deterministic optimization models (Kessler et al. 1998; Kumar et al. 1999; Krause et al. 2006), stochastic optimization models (Berry et al. 2006), and robust optimization models (Carr et al. 2006; Xu et al. 2009). Figure 1 shows the major models available for placing sensors in water distribution systems and the basic information required from water utilities.

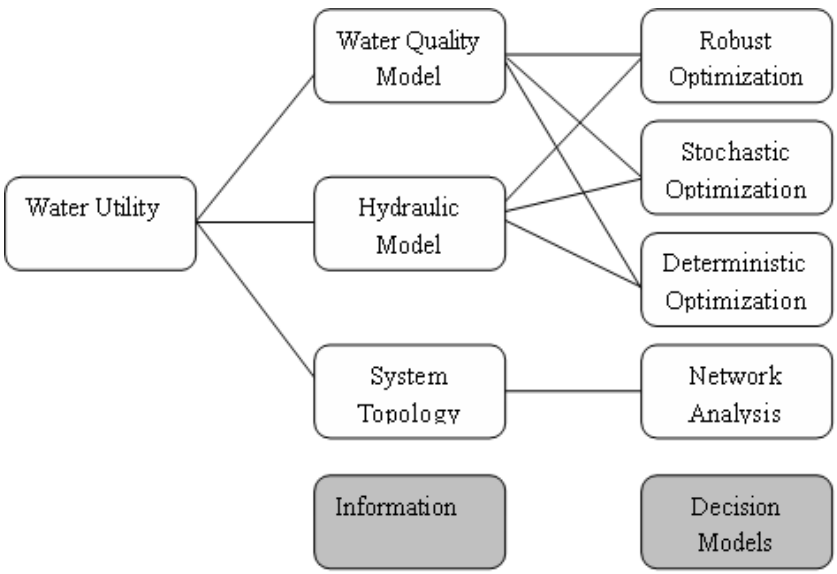

Figure 1. The relationship between the models and the basic information needed for using each type of models

In this paper, we propose a protocol to inform water utilities to make decisions on what models to choose given the information they have about their distribution systems (e.g., topology of the system, hydraulic model of the system, water quality model of the system), their specific purposes (e.g., to detect accidental contamination event, to detect intentional contamination event, or monitor water quality due to internal deterioration), and their computational capacity, based on our previous research (Krause et al. 2006; Xu et al. 2008, 2009). In the following, we describe the details of the models.

MODEL DESCRIPTION

Making difficult decisions with analytical approaches largely depends on what information is available. Two sets of information are needed for making decisions on where to place sensors in water distribution systems: information on the water distribution system, and information on the "contamination events". Some water utilities only have information on the topological structure of their systems, while others have information on how water flows and how chemicals travel in their system. "Contamination events" are also difficult to characterize. For internal deterioration, water quality (e.g., chlorine residual, bacteria etc.) decreases with time and distance from the source, and for external contamination events, there are uncertainties as to where, when and for how long the contamination event might occur (as depicted in Figure 2). Considering these information constraints, four types of models are summarized to locate sensors in water supply networks to detect water quality anomalies: graph-theory based model (network analysis), deterministic optimization models, stochastic optimization models and robust optimization models.

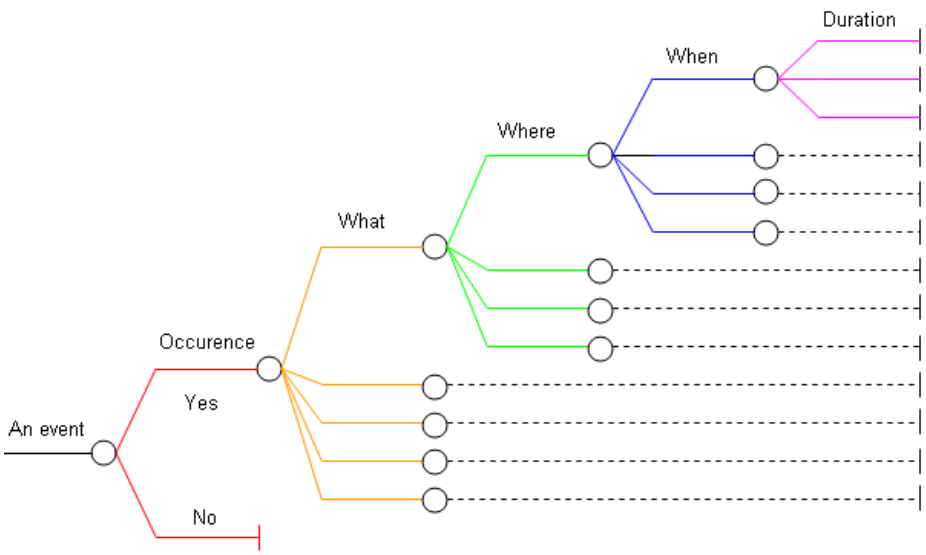

Figure 2. Illustration of the uncertainty of external contamination at a water distribution system with a scenario tree

Graph-theory based network analysis. A water distribution system can be expressed as a network, where *nodes* represent sources, tanks, and junctions, while *edges* represent pipes, valves, and pumps. Xu et al. (2008) express a water distribution system as a network, and adopt the network measures betweenness centrality and receivability to help identify structurally important nodes for sensor placement.

Betweenness centrality defines the centrality of a node in terms of the degree to which the node falls on the shortest path between other pairs of nodes. If a node has a high betweenness centrality, then it lies on the path of many pairs of nodes. In a water distribution network, a node with high betweenness centrality would be between many potential upstream contamination events and downstream receptor populations. Nodes with high betweenness centrality are potential locations for sensors (Xu et al. 2008). For a simple small water distribution network, nodes with high betweenness centrality can be found by visual inspection. For example, in the illustrative 6-node water distribution system (Figure 3), node 4 has a high betweenness centrality. As the size of a water distribution system increases, mathematical equation as proposed in Freeman (1977) are used to determine the betweeness centrality of each node and to identify the nodes with high betweeness centrality.

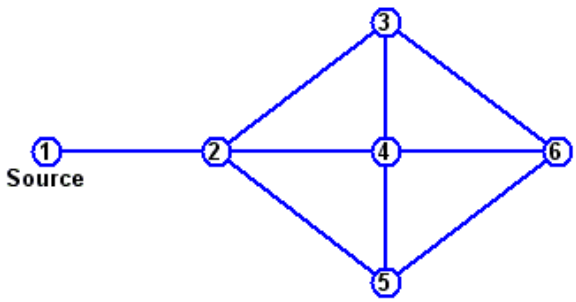

Figure 3. An Illustrative hypothetical water distribution network

Xu et al. (2008) show that nodes with high betweenness centrality in a water distribution system tend to cluster together. If sensors are placed solely based on the value of betweenness centrality, these sensors would be redundant. To avoid this, the water distribution network can be divided into sub-networks and then nodes with high betweenness centrality in each sub-network are selected as sensor location nodes. The merit of this method is that the only information needed is the topological structure of a water distribution system and the computational effort for detecting sub-networks and calculating betweenness centrality for each node is affordable to most water utilities.

Receivability of a node describes the number and set of nodes in a network that have paths to the studied node. Its counterpart, reachabiltiy, has been used extensively in previous research to derive water flow information. The water flow information is then used as input to optimization models used to place monitoring stations or sensors (Kessler et al. 1998, Berry et al. 2005, and Watson et al. 2004). Here, we use receivability to serve as a basis for placing sensors instead of serving as input to an optimization model. A set of nodes that collectively provides the highest

receivability is a potential sensor network. To derive receivability for each node requires a water distribution system be expressed as a directed graph with the direction being water flow direction. Thus, a hydraulic model for the water distribution system is needed to use receivability to identify sensor locations. In identifying the set of sensors which collectively provides the highest receivability (implying a maximum coverage), a greedy heuristic algorithm is used. The computational effort for deriving water flow information with hydraulic models and for identifying the set of sensors locations with greedy heuristic algorithm is likely affordable to all water utilities.

Deterministic optimization model. Various deterministic optimization models have been proposed for placing sensors in water distribution systems. The inputs required for a deterministic model are either a representative instance of water flow and contaminant behavior or the expected value of many instances of water flow and contaminant behavior. Example models include maximum covering model (Lee and Deininger 1992), set covering model (Kessler et al. 1998; Kumar et al. 1999), and a mixed-integer model (Krause et al. 2006) etc..

The inputs (information) required for the different deterministic models vary. Lee and Deininger (1992) applied a maximal covering model to place monitoring stations in water distribution systems; they require water hydraulics of the distribution system. Kessler et al. (1998) applied a set covering model to identify the least number of monitoring stations needed to make sure that the maximum volume of contaminated water consumed does not exceed a certain amount; the information required for this model is the hydraulics of the distribution system. Kumar et al. (1999) modified the model proposed by Kessler et al. (1998) and tried to apply a set covering model to identify the least number of monitoring stations needed to make sure that any contamination events could be detected within a certain time period after the contamination event occurs. Again, the basic information needed for this model is the hydraulics of the water distribution system. Krause et al. (2006) applied a mixed-integer model to place sensors for the objectives of (1) minimizing the contaminant travel time prior to detection, (2) minimizing the population at risk prior to detection, (3) minimizing the contaminated water consumed prior to detection, (4) maximizing the detection likelihood, and/or (5) optimizing the combination of the objectives in (1)-(4). Krause et al. (2006) used simulation of millions of random contamination events, predicting the expected values of water flow and contaminant travel information, and used the expected values as the inputs to the model.

The deterministic models for placing sensors in water distribution systems are mostly facility location models. Most facility location models for a general network are *NP* hard (Drezner and Hamacher 2002). Krause et al. (2006) use greedy

heuristics algorithm to solve their optimization models and found that greedy heuristics algorithm can always find an optimal or near optimal solution in the context of placing sensor distribution systems. In Krause et al. (2006), solving the optimization model with the greedy heuristics algorithm is likely affordable to all water utilities, while the computational efforts required for the initial simulation of random contamination events are daunting.

Stochastic optimization model and robust optimization model. Stochastic optimization models and robust optimization models both address the uncertainties inherent in the problem of placing sensors in water distribution systems. Stochastic optimization models optimize the expected value of an objective (e.g. minimizing the expected volume of contaminated water consumed prior to detection) (Berry et al. 2006). Robust optimization models (Xu et al. 2009) minimize the consequences of the worst cases.

Berry et al. (2006) formulated a *p*-median problem to minimize the expected impact across a set of predefined scenarios. The "distance" x_{ai} is the total impact associated with a contamination scenario (scenario a) until a sensor placed at node i raises an alarm. The authors assume a risk-neutral position in placing sensors and do not give special consideration to extreme scenarios. When the contamination events are intentional events, and the attackers are intelligent attackers, trying to maximize the damage, it is prudent to take this into account in designing sensor placement schemes. One special case is that the attackers have perfect information on the water distribution system. Xu et al. (2009) proposed a set of robust optimization model to minimize the maximum volume of contaminated water consumed, and to maximize the minimum possible number of nodes that are not covered by the sensors. Both stochastic optimization models and robust optimization models require a thorough understanding of how water flows and contaminant travels. Solving the robust optimization models to optimality is much more difficult than solving its deterministic counterpart. Xu et al. (2009) adopt a heuristics algorithm proposed by Serra and Marianov (1998) to solve the robust optimization model.

CONCLUSIONS

When a water utility only has the information on the topological structure of their system and/or their computational capacity is limited, a graph-theory based network analysis method, describing a water distribution system as a network, can be used to identify structurally important nodes. When a water utility has the information on the hydraulics of a water distribution system, water flow behavior can be simulated, deterministic, stochastic and robust optimization models can be applied to identify optimal sensor locations. The computational effort for simulated water

flow behavior with hydraulic model is affordable to almost all the water utilities while the computational effort required for solving optimization models can be high. When a water utility has a water quality model for their system, contaminant behavior can be simulated, and deterministic, stochastic and robust optimization models can be applied to identify optimal sensor locations. The computational load for simulated random contamination event is significant.

ABSTRACT

The pressure similarity method is proposed to get the optimal distribution of pressure measurement points for water distribution networks. This kind of optimal distribution is mainly composed of two steps. Firstly, the pressure similarity coefficients of any two nodes should be calculated to obtain the similarity coefficient matrix. Then all the nodes can be grouped through clustering analysis on the matrix and the pressure measurement points can be chosen out. The application on a practical network shows that the pressure similarity method can reflect the regional characteristics of network pressure and the result is reasonable. This method is very useful for network further study such as state simulation, optimal scheduling and accident early-warning.

INTRODUCTION

Nodal pressure is an important operation parameter of water distribution networks. Proper location of pressure measurement points can accurately reflect the network state which is the basis of optimal scheduling and accident early-warning.
Presently, the optimal distribution of pressure measurement points is based on the influence coefficient method. That is choosing the pressure measurement points according to the nodal pressure changes caused by nodal demands variation (Reddy *et al*. 1996; Huang and Cong 2001; Haestad *et al*. 2003; Davidson and Bouchart 2006). Therefore, this method can be used in monitoring the water use and its influence. But in city water supply it is sometimes necessary for pressure measurement points to reflect the pressure of certain district (Cheryl and James 1998). The influence coefficient method can not meet the requirement. So in this paper another optimal location method based on pressure similarity is proposed to show the regional characteristics of pressure distribution.

PRESSURE SIMILARITY METHOD

Pressure similarity coefficient. Pressure similarity coefficient is proposed to reflect the regional characteristics of pressure distribution. The definition is:

$$\chi_{ij} = 1 - \frac{|H_i - H_j|}{|H_{\max} - H_{\min}|} \quad (i, j = 1,2,\cdots,n) \tag{1}$$

where H_i and H_j are pressure values of node i and j; $H_{\max}$ and $H_{\min}$ are maximum value and minimum value of nodal pressures; n is total number of nodes.
By calculating the pressures under every operation condition, χ_{ij} can be determined by arithmetic mean or weighted average according to Eq.(1) (Shastri and Diwekar 2006). All the coefficients can be written as a matrix $\boldsymbol{X}_{n\times n}$.

Clustering analysis and choosing pressure measurement points. Nodes are grouped through fuzzy clustering, which means classifying the similar objects based on certain clustering principles and fuzzy judging criteria (Wang and Wang 1989). Here the objects are network nodes and the clustering principle is grouping the nodes by comparing χ_{ij} between any two nodes. The procedure can be divided into the following steps:

(1) *Matrix standardization*. Standardization is changing the original data of matrix $\boldsymbol{X}$ to be limited in [0,1] according to the requirements of fuzzy matrix (Xie and Liu 2005). Usually two kinds of transformation are needed. Firstly, the standard deviation transformation should be carried out on matrix $\boldsymbol{X}$:

$$\chi_{ik}^{'} = \frac{\chi_{ik} - \overline{\chi_k}}{S_k} \quad (i, k = 1,2,\cdots,n) \tag{2}$$

where $\overline{\chi_k}$ is average value of column k, $\overline{\chi_k} = \frac{1}{n}\sum_{i=1}^{n}\chi_{ik}$; and S_k is standard deviation of column k, $S_k = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(\chi_{ik} - \overline{\chi_k})^2}$. Thus, the matrix $\boldsymbol{X}^{'}$ composed of $\chi_{ik}^{'}$ can be obtained.
Then the data of column k in matrix $\boldsymbol{X}^{'}$ should be changed as follows:

$$\chi_{ik}^{''} = \frac{\chi_{ik}^{'} - \chi_{k_{\min}}^{'}}{\chi_{k_{\max}}^{'} - \chi_{k_{\min}}^{'}} \quad (i, k = 1,2,\cdots,n) \tag{3}$$

where $\chi_{k_{\min}}^{'}$ and $\chi_{k_{\max}}^{'}$ are minimum value and maximum value in column k. Finally the standardized matrix $\boldsymbol{X}^{''}$ composed of $\chi_{ik}^{''}$ is obtained and $0 \le \chi_{ik}^{''} \le 1$.

(2) *Establishing fuzzy similarity matrix* $\boldsymbol{R}$. Based on the standardized matrix $\boldsymbol{X}^{''}$ the similarity coefficient of any two nodes r_{ij} can be calculated. And the fuzzy similarity matrix $\boldsymbol{R}$ composed of r_{ij} can be obtained as well. The element of $\boldsymbol{R}$ is calculated through Euclidean distance:

$$r_{ij} = 1 - \sqrt{\frac{1}{n}\sum_{k=1}^{n}(\chi_{ik}^{''} - \chi_{jk}^{''})^2} \quad (i, j = 1,2,\cdots,n) \tag{4}$$

(3) *Clustering*. All nodes are grouped by net-making method and several results are achieved with different λ values, which are determined by the values of $\boldsymbol{R}$ elements. Among the grouping results, the optimal one under the optimal λ value can be selected out based on F-statistics:

$$F = \frac{\sum_{j=1}^{r} n_j \| \bar{x}^{(j)} - \bar{x} \|^2 \Big/ (r-1)}{\sum_{j=1}^{r} \sum_{i=1}^{n_j} \| x_i^{(j)} - \bar{x}^{(j)} \|^2 \Big/ (n-r)} \tag{5}$$

where $\bar{x}$ is sample central vector; r, n_j, $x_i^{(j)}$, $\bar{x}^{(j)}$ are classification numbers, sample numbers of class k, sample values and clustering center under certain λ value.

(4) *Choosing pressure measurement points*. In the grouping result under optimal λ value, the nodes, which have the minimum Euclidean distance with other nodes, should be chosen as the pressure measurement points.

COMPUTER PROGRAM DESIGN

According to the procedure of pressure similarity method, a computer program is designed for automatic distribution of pressure measurement points. The flow chart of the program algorithm is shown in Figure 1.

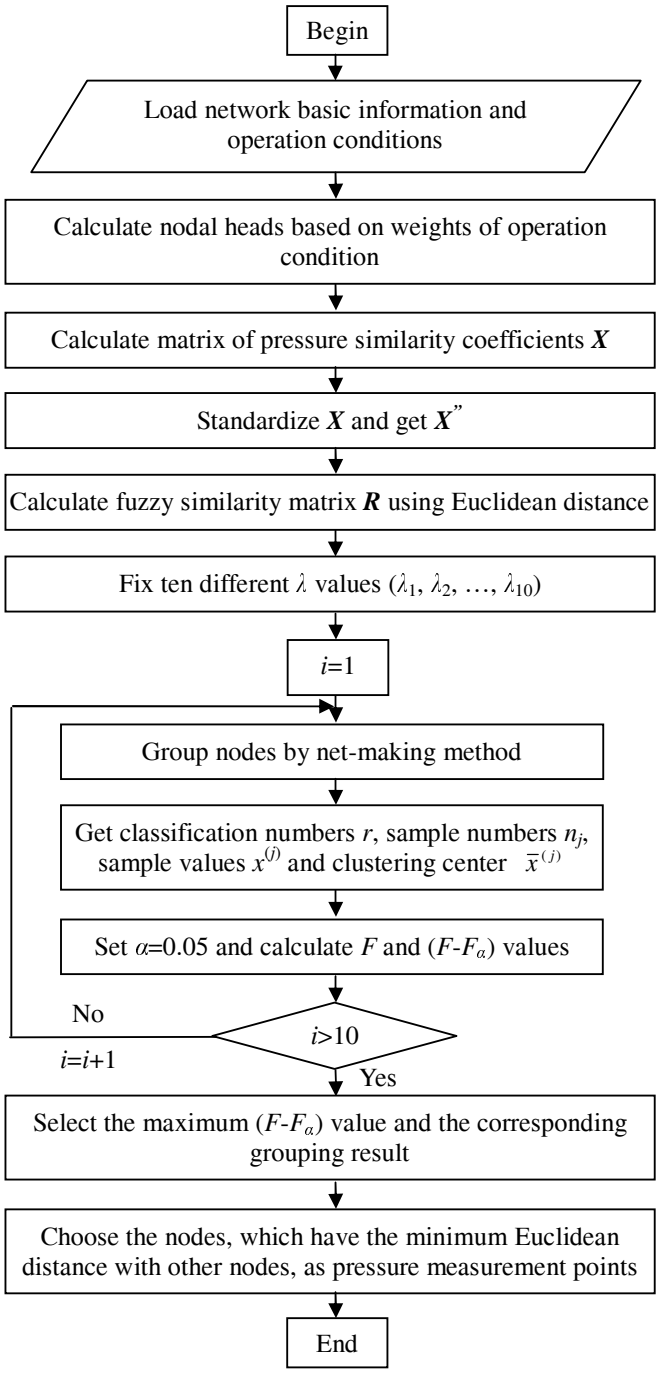

Figure 1. Flow chart of computer program on pressure similarity method.

APPLICATION

Taking an urban water distribution network as an example, the pressure measurement points were analyzed and distributed by the computer program of pressure similarity method. The network was composed of 29 nodes, 44 pipes and 16 loops. The water source was at node 29 and the maximum water supply volume was

173.61L/s. The network structure was shown in Figure 2.

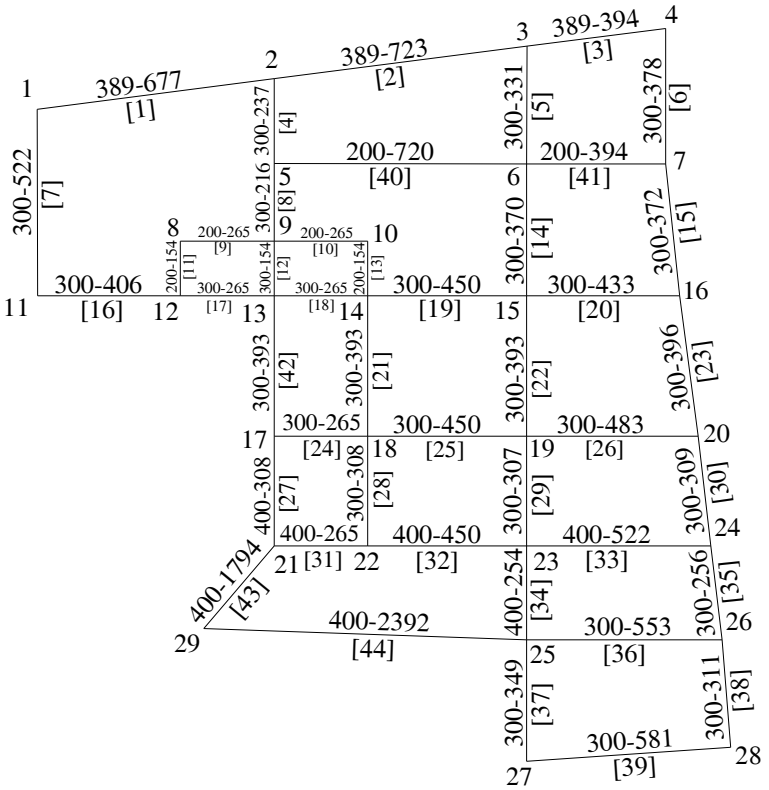

Figure 2. Schematic of example network.

According to the operation conditions and the corresponding weights, the nodal heads were calculated. And the results were shown in Table 1.

Table 1. Nodal heads of the example network.

Node No.	Nodal heads, m	Node No.	Nodal heads, m	Node No.	Nodal heads, m
1	560.58	11	560.69	21	561.26
2	560.59	12	560.64	22	561.17
3	560.60	13	560.70	23	561.15
4	560.60	14	560.73	24	561.10
5	560.61	15	560.73	25	561.15
6	560.62	16	560.72	26	561.13
7	560.63	17	561.06	27	561.17
8	560.64	18	560.98	28	561.13
9	560.66	19	560.94	29	564.84
10	560.69	20	560.92		

According to weighted nodal heads and Eq.(1) to (5), F-statistics under different λ values were work out. Eight F-statistics were higher than $F_{0.05}$ and when λ was 0.990, the discrepancy between F-statistics and $F_{0.05}$ got to the maximum. Therefore, the optimal value of λ is 0.990 and the corresponding result of six groups was the optimal one. F-statistics under different λ values were shown in Table 2.

Table 2. *F*-statistics under different λ values.

λ values	Classification numbers r	F-statistics	$F_{0.05}(r\text{-}1,n\text{-}r)$	$F\text{-}F_{0.05}$
1.000	29	0	249.8	—
0.999	25	10921.4	5.8	10915.6
0.998	19	12596.0	2.8	12593.2
0.996	16	4384.2	2.5	4381.7
0.995	13	3998.7	2.4	3996.3
0.994	9	3976.8	2.5	3974.3
0.990	6	14724.3	2.6	14721.7
0.980	3	1255.0	3.4	1251.6
0.950	2	308.3	4.2	304.1
0.100	1	0	—	—

Based on the optimal grouping result, the pressure measurement points can be chosen out by calculating Euclidean distance of every node in each group. They are node 6, 27, 17, 18, 20 and 28. It was clear that the pressure measurement points were well-distributed and representative. Most of the points were near water source, network ending and dividing line of water supply.

CONCLUSION

The pressure similarity method is proposed for optimal distribution of water distribution networks. And based on the method a computer program is developed. Through the application on an urban water supply network, it is proved that the pressure similarity method is reasonable and most of the points were near water source, network ending and dividing line of water supply. Therefore, the method is useful in district monitoring of water distribution networks.

ACKNOWLEDGEMENTS

The study fulfilled a main part of TRAPOYT (the Teaching and Research Award Program for Outstanding Young Teachers in Higher Education Institutions of MOE, P.R.C.), and also a part of the Project No. GG06200 of Xi'an Key Technologies R & D Program. The authors would like to express their gratitude to the agencies involved and participants of the study.

Abstract

As multi-core personal computers (PC) have become popular and widely available for various computation tasks, developing parallel computing methods are imperative for taking the full capacity of the multi-core machines. This paper reports on the analysis and comparison of different paradigms for portable parallel computation on single multi-core PC and a cluster of PCs. It summarizes the strength and weakness of various parallel and distributed computation models. A scalable and portable parallel optimization framework has been developed and applied to water distribution pump scheduling to improve energy efficiency. It is implemented as a generic optimization method for hydraulic engineers to optimize the pump operation policy in order to maximize energy cost efficiency. An example study is presented to demonstrate the application of the parallel and distributed optimization model. The results show a linear speedup has been achieved for the parallel optimization of pump scheduling.

Keywords: optimization, water distribution systems, parallel computing, pump scheduling and genetic algorithm

INTRODUCTION

Parallel computing has been a research topic for decades. It is employed to achieve the speedup in computation efficiency for solving engineering and scientific problems that requires for intensive computation. Parallel computing is conventionally applied to those computing-intensive cases so that the problems can be effectively solved. In the meantime, sequential computing programs have been benefited from the efficiency enhancement of personal computer (PC) since 1980's. The faster a PC is built, the faster the sequential computing programs could run. Such a 'free lunch' is over when the CPU speed is reaching the limit at which energy consumption is the primary concern so that computer industry has to shift from single-core paradigm to multi-core PCs configuration. It is highly unlikely a faster CPU will be made for PC but multi-core machines are becoming the mainstream of PC industry. Therefore, parallel computing is

not only an approach for solving computation-intensive tasks but also essential for making use of the computing power offered by multi-core PCs that are readily accessible by engineers.

In water distribution system analysis, hydraulic and water quality simulation methods are developed and implemented for sequential computation. Some parallel computing research has been carried out for solving large network simulation and the optimization problems that usually request for iterative execution of the simulation model. Alonso et al. (2000) developed high performance computation (HPC) methods for hydraulic analysis, water quality simulation and leakage minimization. HPC hydraulic simulation was developed by replacing the minimum degree graph search algorithm with the multilevel nested dissection algorithm, which resulted in two triangular linear equation systems solved by using multi-frontal or parallel Choleski factorization. Parallel water quality solution was obtained by partitioning a network into many small portions, each of which was solved by using the previously developed water quality analysis method. Leakage minimization is formulated to optimize the PRV settings at each time step over an extended period of time (e.g. 24 hours) while the leakage optimization is to minimize the emitter flows at nodes. The optimization problem is approximated with a series of quadratic problems that are solved by employing a sequential quadratic programming (SQP) method. The parallel leakage minimization is achieved with the assumption that the leakage is not affected by any control facilities (tanks and pumps) but totally controlled by PRV settings, thus the time-dependent PRV setting optimization is subdivided into an independent optimization problem at each time step and solved on the allocated machine. Balla and Lingireddy (2000) developed distributed genetic algorithm (GA) model for model calibration. The distributed GA optimization is implemented by using Microsoft Window's native peer-to-peer networking/communicating protocol. A cluster of PCs were used to share the computation load in the way that one PC was dedicated as manager process/machine to perform GA search, distribute the solutions to and collect fitness evaluation values from the worker processes/machines, on which hydraulic simulation and fitness calculation were performed, and fitness values were returned to the manager process. Kumar et al. (2006) presented a parallel computing approach for optimal design of water distribution systems. The distributed computing method was based on Java socket interface methods for communication across a network of PCs. In the meantime, great advancement has been made in third party development tools for developing high performance computing method. This paper reports the review on a variety of parallel computing models based on message passing interface (MPI), one of the most popular parallel computing paradigms. Due to its requirement for evaluating hundreds of possible solutions by using extended period simulation (EPS), pump scheduling is chosen as an example for applying the parallel computing paradigm. The ultimate goal is to develop a scalable, portable and robust framework for high performance optimization of water distribution operations.

Parallelism Paradigms

There are two types of computation parallelism at instruction level, data parallelism and task parallelism. Both data and task parallelisms can be achieved by different programming languages, libraries and application programming interfaces (APIs). Message passing interface (MPI) and Open Multi-Processor (OpenMP) are among the most commonly-used libraries for task parallelism and data parallelism.

Task Parallelism

Task parallelism is a parallel computing program that a computing problem is divided into many computing tasks and that different calculations can be performed on different computing processes (CPUs or nodes). Each of the computing tasks can be performed with either the same or different sets of data. Task parallelism usually scales with the number of computing nodes. There are various methods for achieving task parallelism computing, a message passing communication is usually employed for a scalable and portable implementation.

Message Passing Interface is a specification of the application programming interface (API) that allows many computers to communicate with one another. It is used for parallelizing computing task over a cluster of machines or on supercomputers, where each of the CPU is representing a computing node or process. It is a language-independent communications protocol supporting both point-to-point and collective communication. MPI is designed for developing high performance computing applications with scalability and portability. It is one of the popular models used in high-performance computing.

MPI consists of more than 115 functions (Gropp, Lusk and Skjellum 1999). Various MPI implementations are as follows.

1. DeinoMPI is an implementation of MPI-2 for Microsoft Windows. This is the release version 1.1.0 with downloads for both Win32 and Win64 machines.

2. PureMPI.NET is a completely managed implementation of the message passing interface. The object-oriented API is simple, and easy to use for parallel programming. It has been developed based on the latest .NET technologies, including Windows Communication Foundation (WCF). This allows you to declaratively specify the binding and endpoint configuration for your environment, and performance needs. When using the SDK, a programmer will definitely see the MPI'ness of the interfaces come through, and will enjoy taking full advantage of .NET features - including generics, delegates, asynchronous results, exception handling, and extensibility points.

3. MPI.NET is a high-performance, easy-to-use implementation of the Message Passing Interface (MPI) for Microsoft's .NET environment. MPI is the *de facto* standard for writing parallel programs running on a distributed memory system, such as a compute cluster, and is widely implemented. Most MPI implementations provide support for writing MPI programs in C, C++, and FORTRAN. MPI.NET provides support for all of the .NET languages (especially C#), and includes significant extensions (such as automatic serialization of objects) that make it far easier to build parallel programs that run on clusters.

4. MPICH2 is a high-performance and widely portable implementation of the Message Passing Interface (MPI) standard (both MPI-1 and MPI-2). The goals of MPICH2 is to provide an MPI implementation that efficiently supports different computation and communication platforms including commodity clusters, high-speed networks and proprietary high-end computing systems.

5. MSMPI is the Microsoft's implementation of MPICH2 for Windows Compute Cluster Server and High Performance Computing Server.

Data Parallelism

Data parallelism is inherent in program loops, which focuses on distributing the data across different computing nodes to be processed in parallel. Parallelizing loops often leads to similar operation sequences or functions being performed on elements of a large data structure. Many scientific and engineering applications exhibit data parallelism. The most commonly adopted programming language for data parallelism is Open Multi-Processors (OpenMP).

The OpenMP is a set of APIs that support multi-platform shared memory multiprocessing programming in C/C++ and FORTRAN on UNIX and Microsoft Windows platforms. It consists of a set of compiler directives, library routines, and environment variables that influence run-time behavior. Jointly defined by a group of major computer hardware and software vendors, OpenMP is a portable, scalable model that gives programmers a simple and flexible interface for developing parallel applications for platforms ranging from the desktop to the supercomputer. An application built with the hybrid model of parallel programming can run on a computer cluster using both OpenMP and Message Passing Interface (MPI). A brief comparison of MPI and OpenMP is given in Table 1.

Table 1 Comparison of MPI and OpenMP

Criteria	OpenMP	MPI
Platform	Symmetric Multiprocessing(SMP)	Both SMP and Clusters
Parallelism	Fine grain parallelism	Coarse grain parallelism
Performance	Better on SMP	Better on Cluster

With OpenMP computation loops are often parallelized by using compiler directives, so the code runs in serial until it reaches the parallelized loop where concurrent computation is taking place. Conversely, with MPI the entire code is launched on each computing node and computing task is designated to the node by using MPI communication methods and APIs that are rich and flexible enough to implement various parallel computing models to distribute the computing tasks. To ensure the maximum speedup, both task and data parallelism can be mixed in a hybrid model.

Hybrid Parallelism

A hybrid parallelism is to implement both task and data parallel computation in the same application to obtain the maximum speedup. A number of hybrid computation models (Rabenseifner 2003) have been compared and summarized as follows.

1. Pure MPI: Task and data parallelisms are achieved by just using MPI library. The communications within one task process and across multiple task processes are implemented as a flat massively parallel processing (MPP) system.

2. MPI and OpenMP: Task parallelism is implemented by calling MPI communication methods across several computing nodes. Within each parallel task process, OpenMP is used for data parallelism.

3. Pure OpenMP: Based on virtual distributed shared memory systems (DSM), the application is parallelized only with shared memory directives of OpenMP.

The hybrid parallelism models offer advantages for the clusters of SMP computing nodes, but have some serious disadvantages based on mismatch problems between the hybrid programming scheme and the hybrid architecture, including:

1. With pure MPI, minimizing the inter-node communication requires that the application-domain's neighborhood-topology matches with the hardware technology. Otherwise, more data is shipped over the inner-node network instead of using the shared memory based communication within nodes. On the other hand, Pure MPI also introduces intra-node communication on the SMP nodes that can be omitted with hybrid programming.

2. With MPI and OpenMP programming, the intra-node communication overhead, introduced by pure MPI method, can be substitute by direct access to the application data structure in the shared memory. However, this programming style is not able to achieve full inter-node bandwidth on all platforms for any subset of inter-communicating threads. For instance, with manager only style, all non-communicating threads are idling. CPU time is also wasted, if all CPUs are already able to saturate the inter-node bandwidth. With hybrid manager only programming, additional overhead is induced by all OpenMP synchronization, but also by additional cache flushing between the generation of data in parallel regions and the consumption in subsequent message passing routines and calculations in subsequent parallel sections.

3. Overlapping of communication and computation is a chance for an optimal usage of the hardware, but it causes serious programming effort in the application itself, in OpenMP parallelization and load balancing.
4. Although pure OpenMP is simple and runs efficiently in shared-memory multiprocessor platforms, its scalability is limited by memory architecture.

Different programming schemes on clusters of SMPs show different performance benefits or penalties on the hardware platform. In order to obtain the best performance results, we have to choose the schemes bases on both the hardware and computer algorithm. In the project of pump scheduling optimization, we choose the latest release of MPICH2 as our parallel computation interface. It is also readily compatible with MSMPI supported by Microsoft Window Server 2008 and its High Performance Computing Server.

Pump Scheduling

A pump scheduling method (Wu 2002 & 2004) is developed for hydraulic engineers to optimize the pump operation for a water distribution system. It employs a powerful genetic algorithm (GA), a generic search paradigm based on the principles of natural evolution and biological reproduction, to search for optimal pump operation schedule. The solutions are obtained by minimizing the operating cost over a control horizon while meeting the systematic operation criteria of junction pressures, pipe flow velocity and the constraints of system storages given demand loading conditions. The GA used in pump scheduling is fast messy genetic algorithm (fmGA), one of most competent genetic algorithms, to the optimization of pump operation while meeting a set of system operating criteria. Due to its intensive computation required for evaluating many possible solutions, the sequential implementation of fmGA-based pump scheduling is extended to the parallel version of GA-based optimization to improve computation efficiency.

In sequential computing model, one process is used for pump scheduling optimization. The solutions are generated to represent the possible operation strategies for the target pumps to be optimized. All the solutions are evaluated sequentially by calling EPS and objective function. The sequential computing paradigm heavily relies on the computation capability of the single process/CPU. However, the solutions can be evaluated in parallel so that the computing efficiency is expected to be dramatically improved.

Parallel Computation Model

A manager/worker model, as shown in Figure 1, is proposed for pump scheduling optimization. After GA initialization, manager process sends chromosomes to worker processes where EPS and fitness calculation is performed for solution evaluation. Then manager process collects the fitness value of chromosomes from worker processes. The manager process is also responsible for GA operations (selection and reproduction) to search for the optimal chromosome based on the searching criteria. A task parallelism model is implemented over a cluster of computers so that we can greatly enhance our computation capability while making the best use of computer resources. MPICH2 is employed as the communication API among computers. The communication and computation scope for manager/worker task parallelism is as follows:

1. Manager process sends chromosomes to worker processes for evaluation.
2. Worker process performs solution evaluation.
3. Worker processes sends the fitness value back to manager process.
4. Manager process searches for the optimal chromosome based on fitness value.

Pseudo code snippet is below.

```
Manager Process:
        Initialize chromosomes;
        Send chromosomes to workers for evaluation;
        Collect fitness values of chromosomes from workers;
        Find the optimal chromosomes;
Worker Process:
        Receive chromosomes from manager process;
        Evaluate chromosome using objective function;
        Send the fitness value back to manager process;
```

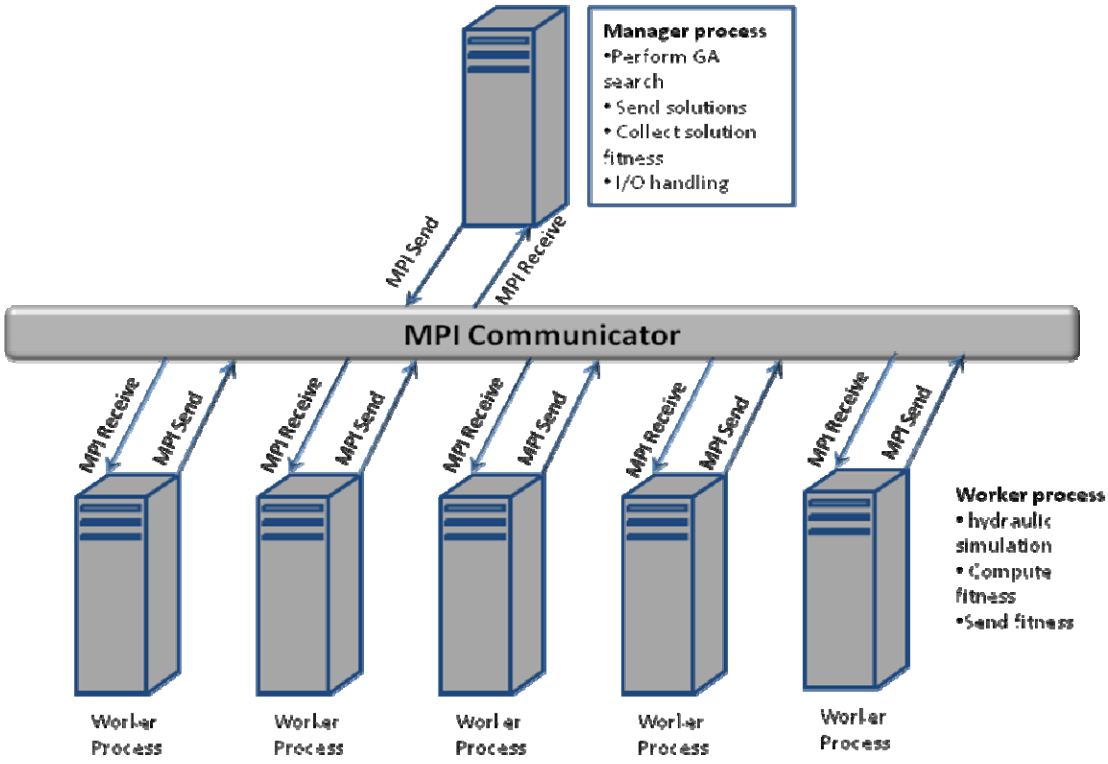

Figure 1: Manager-worker Parallel Computation Model

Example Study

A case study has been conducted by using the example previously studied in sequential computing model (Wu 2004). The sample system was previously studied by using mathematical programming and simulated annealing (Mays et al. 2000). It provides a good comparison basis for testing the pump optimization method.

The example system is illustrated in Figure 3. It consists of 115 pipes, 2 pumps and 3 tanks and 91 junctions and 2 reservoirs. The system is supplied by two water sources including River and Lake through two pumps PMP-10 and PMP-335. The aim is to search for the optimal pump operating status (ON or OFF) or relative speed factor (between zero and the maximum speed limit) for each time interval over a control time horizon such that the energy cost for these pumps is minimized over 24 hours while satisfying system requirements.

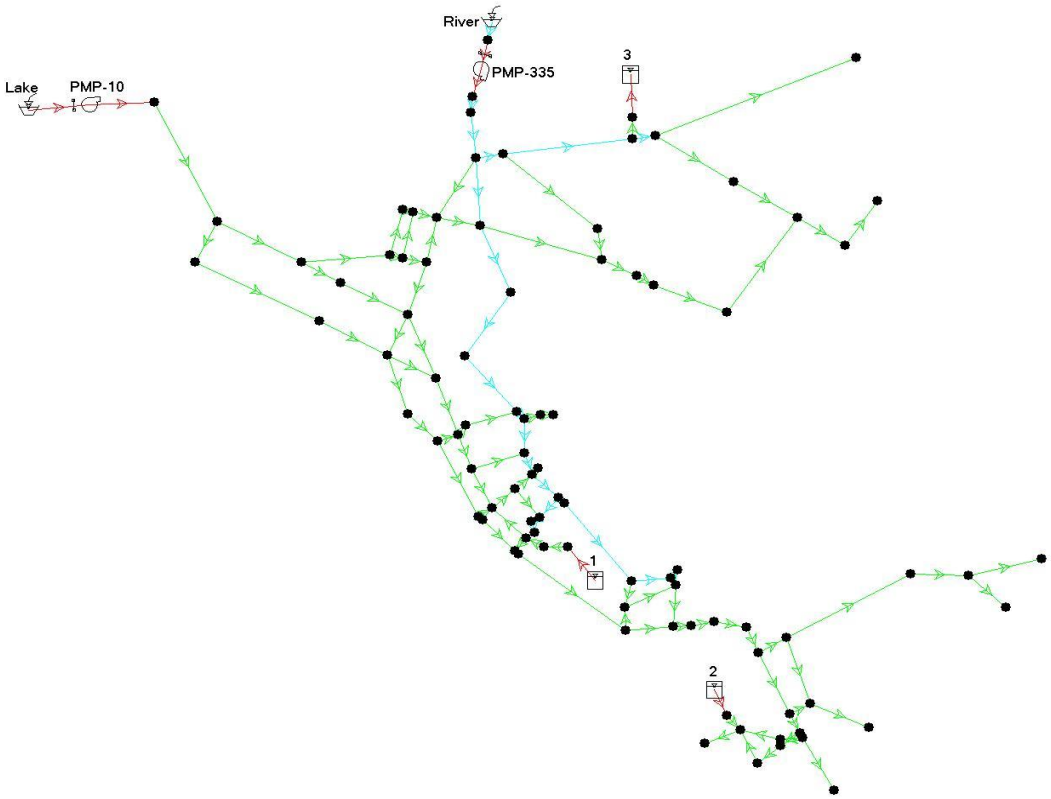

Figure 2: Layout of Case Study Water Distribution System

Test Result

Test runs are performed on a dual core machine with different processes. The parallel computing model has successfully found the same optimal schedule policy as the sequential model, as illustrated in Table 2.

Table 2: Comparison of Search Result

Criteria	Sequential Model	Parallel Model
Trials	30,005	30,005
Fitness	247.95	247.95
Violation	0.0000	0.0000

As shown in Figure 3. the test result shows that 3 processes is achieving the best speedup for running the manager-worker parallel pump scheduling on a single dual-core PC, which is able to save more than 50% of execution time than sequential model. However, if we increase the number of processes from 3 to 4, then the performance deteriorate due

to the resource contention. When the number of worker processes is greater than the number of CPUs available, worker processes are competing for the limited resources and the computing speed is slow. In general, the $(N + 1)$ processes seem to gain the maximum speedup on an N-core CPU for manager-worker parallel computing.

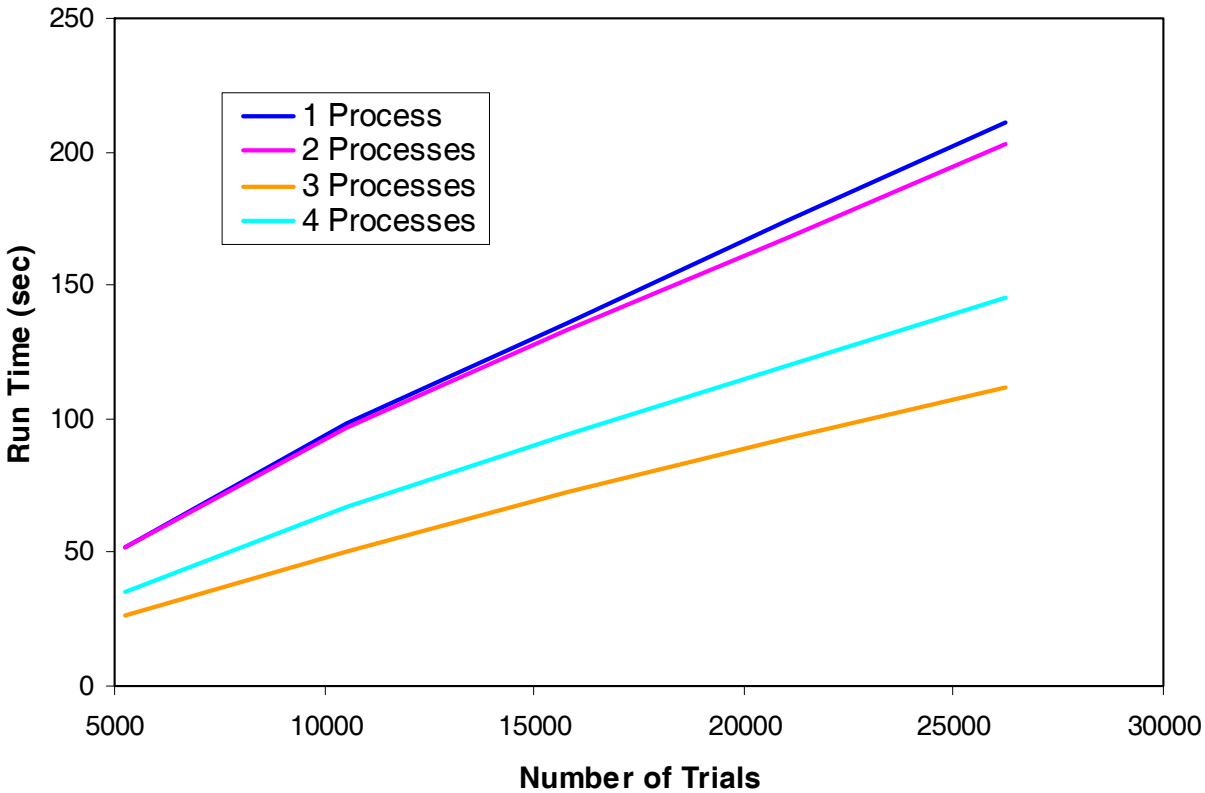

Figure 3 Computation Performance of Parallel Pump Scheduling Optimization

Conclusions

Parallel computation research is not only a promising research topic but also an essential requirement for fully making use of computing capacity offered by multi-core PCs. Computation parallelism shall received more attentions than ever since the computer industry is changing its single core paradigm to multi-core configuration. With mainstream support of computing industry, such as Microsoft concurrency computing libraries, Windows Server 2008 as well as Microsoft High Performance Computing Serve, the paradigm shift is under way from sequential to parallel computing. This research demonstrates the parallel computing speedup in solving for the computation-intensive pump scheduling optimization problem. Parallel computing can be employed for solving many other problems in water distribution analysis with significant speedup. The enhanced computing efficiency enables engineers to make use of the latest many-core PCs and enable them to explore more solution alternatives for enhanced project productivity and solution quality.

Abstract:

One of the critical public safety roles for water distribution systems (WDS) is suppression of urban fire events. Previous studies have investigated WDS rehabilitation for mitigation of potential fire events with a major focus on improving fire flows by pipe enlargement. However, pipe enlargement can cause water quality problems and place public health at risk during normal operational periods. Thus a novel approach is required to effectively address the conflicting goals of the WDS: reliable delivery of water during normal as well as emergency conditions, meeting water quality standards, and finding cost-effective design and rehabilitation options.

In this study an evolutionary computation-based multi-objective optimization-simulation framework is developed to design effective mitigation strategies for urban fire events for water distribution systems with three objectives: (1) minimizing fire damages, (2) minimizing water quality deficiencies, and (3) minimizing the cost of mitigation. An elitist non-dominated sorting genetic algorithm (NSGA-II) is modified by incorporating an evolution strategy (ES) to address difficulties for heuristic algorithms posed by WDS problems. Implementation of this methodology generates Pareto-optimal solution surfaces that express the trade-off relationship between fire damage, water quality, and least cost objectives. Thus, the method provides decision makers with the flexibility to choose a mitigation plan for urban fire events best suited for their circumstances. Each Pareto-optimal solution comprises a set of pipes to be enlarged to achieve increased fire flow and the corresponding diameters of these pipes. The algorithm is illustrated with several test functions. The Micropolis virtual city is then used to demonstrate the application of the proposed methodology to a complex WDS.

Introduction

The goal of a water distribution system (WDS) is to deliver water to the consumers in sufficient quantity and quality, even in case of emergencies such as power outage and urban fire events. Previous studies have investigated WDS rehabilitation for mitigation of potential fire events with a major focus on improving fire flows by pipe enlargement. However, any changes in water demand or water use pattern caused by pipe rehabilitation or new development often cause slower flow through the network which, in turn, results in greater decay of disinfectant, hence cause increase in pathogenic bacteria and influence water quality. This type of water quality problem can be reduced by installing chlorine booster units in the system other than at the water treatment plant.

Kanta and Brumbelow (2008) studied vulnerability and risk of water distribution systems (WDS) posed by urban fire events under both accidental failure and intentional failure scenarios. During the study, several mitigation packages were designed based on hardening sets of pipes to improve the system's resiliency to provide fire fighting flows. Bristow et al. (2007) studied different mitigation strategies to improve water distribution systems' ability to meet fire fighting demand and water main enlargements were generally the most effective strategies but involved relatively high

costs. Main enlargements increased the system's capacity to meet fire fighting demand but also increased water age under normal demand condition. Brumbelow and Bristow (2008) investigated tradeoffs between WDS emergency supply and water quality needs and proposed 17 mitigation packages to improve the system's capacity to provide fire fighting flows without compromising the daily water quality needs. All the previous studies utilized simulation based methodologies which were iterative and hence call for a systematic approach to improve WDS resiliency during fire events without compromising other system goals: meeting water quality standards mandated by regulation and finding cost-effective design and rehabilitation options.

The goal of this project is to develop a methodology to design effective mitigation strategies for urban fire events for water distribution systems with three objectives: (1) minimizing fire damages, (2) minimizing water quality deficiencies, and (3) minimizing the cost of mitigation. This goal can be achieved by identifying pipes for replacement and their corresponding diameters and the location of addition booster units. When more than one objective is considered in an optimization problem, no single solution may produce the best result with respect to all objectives. In such a case a set of solutions known as the Pareto optimal solutions or non-dominated solutions (Hans 1988) exist, none of which is worse than any other with respect to all objectives. The Pareto optimal solutions provide the decision makers more information and flexibility in selection of a solution. In the present study, a novel multi-objective evolutionary algorithm named Non-Dominated Sorting Evolutionary Strategy (NSES) will be used. The following sections describe the development of the methodology, implementation, and results in detail.

Problem Statement

The proposed model has three objectives: (1) minimizing the aggregated fire damage (f_1), (2) minimizing the maximum water quality deficiency (f_2), and (3) minimizing normalized mitigation cost (f_3). The multi-objective optimization problem, therefore, can be mathematically formulated as follows:

$$\text{Minimize } f_1 = \sum_{i=1}^{n} \alpha_i \frac{Q_{i_{\text{Re quired}}} - Q_{i_{\text{Available}}}}{Q_{i_{\text{Re quired}}}} \tag{1}$$

$$\text{Minimize } f_2 = \max_j \frac{C_{j_{\text{Re quired}}} - C_{j_{\text{Available}}}}{C_{j_{\text{Re quired}}}}; \; j=1, 2, \ldots, m \tag{2}$$

$$\text{Minimize } f_3 = \frac{\sum_{k=1}^{np} C_k^P + \sum_{l=1}^{nb} C_l^B}{\sum_{k=1}^{N} C_k^P} \tag{3}$$

Subject to:

$$D_k \in \{d\}; \; k = 1, 2, \ldots, np \tag{4}$$

$$np \le \phi \tag{5}$$

$$nb \le \theta \tag{6}$$

Where, $Q_{i_{\text{Re quired}}}$ = required fire flow (gpm) for hydrant i; $Q_{i_{\text{Available}}}$ = available flow (gpm) at minimum allowable residual pressure at hydrant i (typically set at 20 psi by local code); α_i = weighting coefficient for hydrant i; n= total number of fire hydrants considered for fire flow evaluation; $C_{j_{\text{Re quired}}}$ = minimum required residual chlorine concentration (mg/l) at monitoring node j;

$C_{j_{Available}}$ = available residual chlorine concentration (mg/l) at monitoring node *j*; *m*= total number of monitoring nodes; C_k^P = cost of pipe *k*; C_l^B = cost of booster station *l*; D_k =diameter (inch) of pipe *k*; *d*= commercially available discrete pipe sizes (inch); *N* = total number of pipes in the network; *np*= number of pipe decision variables; ϕ = user defined maximum number of pipes to be replaced; *nb*= number of booster station decision variables; and θ = user defined maximum number of boosters to be installed.

Non-dominated Sorting Evolution Strategy (NSES)

An evolutionary computation (EC)-based approach is used to solve the multi-objective problem. Evolutionary algorithms are population based heuristic search algorithms based on the process of natural selection. Initially developed by Holland, Genetic Algorithm (GA) is the most common EC-based approach among engineering applications. Many genetic algorithm based applications in water distribution system can be found in the literature such as Prasad and Park (2004) and Prasad et al. (2004), among others. Evolutionary Strategy (ES) is another EC-based approach first introduced by Rechenberg and Schwefel which uses a population of individuals to search for the best solution (Eiben and Smith 2007). Each individual (or solution) in the population consists of a set of 'genes' that represent the decision variables. The performance of each individual is evaluated by a fitness function. While GA uses both crossover and mutation, ES is solely based on a probabilistic mutation operator. To mutate a value of a real-valued decision variable, the sample is taken from a normal distribution with mean as the current value of the variable and standard deviation as an algorithmic parameter. The performance of the ES-based search is very sensitive to the value of the standard deviation; thus determination of this parameter requires extensive tuning (Zechman and Ranjithan 2009). ES also allows an alternative approach, called *adaptive mutation*, in which the standard deviations are also included in the chromosome representation (Eiben and Smith 2007).

Several EC-based methodologies are available for addressing multi-objective problems such as, NPGA (Horn et al. 1994), NSGA (Srinivas and Deb 1995), SPEA (Zitzler and Thiele 1999), PAES (Knowles and Corne 1999), and NSGA-II (Deb et al. 2002), among others. The goals of a population-based multi-objective optimization problem are to find: (i) solutions that are close to the Pareto front, and (ii) solutions that are well distributed and spread out along the Pareto front. To solve this multi-objective optimization problem, a fast elitist non-dominated sorting genetic algorithm (NSGA-II) is modified by incorporating an ES to address difficulties for heuristic algorithms posed by WDS problems. Proposed by Deb et al. (2002), NSGA-II is a population based multi-objective genetic algorithm which produces Pareto-optimal solutions in the objective spaces. It has been found in the literature that NSGA-II can converge toward the true Pareto-front uniformly and can distribute non-dominated solutions along the front evenly (Prasad et al. 2004). Traditionally as in GA, NSGA-II utilizes both crossover and mutation operators to facilitate both exploration and exploitation during the heuristic search and generates better solutions in subsequent generations. In WDS problems the significance of the crossover would be exploring an alternate flow path within the distribution network, which could be implemented by introducing a path search algorithm. However, this approach would significantly increase the computation time. Therefore, NSGA-II algorithm is here modified as non-dominated sorting evolutionary strategy (NSES) by implementing evolutionary strategy (ES) based search technique with the elitist non-dominated sorting algorithm. The structure and implementation of NSES operators to the WDS problem are described in the following sections.

Representation: In any population based search, the decision variables are encoded as an array, which, when decoded, represents a solution. The efficiency of an ES-based search depends upon the representation of a solution (Zechman and Ranjithan 2009). For example, if an individual is

represented by a large array of decision variables, it may increase the time of convergence of the algorithm. Typically, ES uses real-valued vectors for representing an individual.

To represent the multi-objective problem, it is assumed that a maximum number of pipes to be replaced for mitigation/rehabilitation is known. In this paper it is assumed that additional chlorine boosters will not be added, but the general problem formulated above includes this possibility. Therefore, the only sets of decision variables are the pipes to be replaced and their corresponding diameters. Rehabilitation locations are represented by an array of integer values, each of which specifies the pipe ID; and the pipe diameters are represented by a separate array of integer values.

An adaptive search is applied during implementation of this methodology. For an adaptive search, each decision variable is represented by a set of two genes. One gene represents the value of the variable, x_j, and another gene represents the standard deviation, σ_{xj}, which is used to mutate the gene representing the variable value. Assuming the number of pipe rehabilitation decisions is *n*, the chromosome representation of the problem is shown in Figure 1.

I_1	I_2	……	I_n	σ_{I_1}	σ_{I_2}	……	σ_{I_n}

Representation: Pipe ID (rehabilitation location)

d_1	d_2	……	d_n	σ_{d_1}	σ_{d_2}	……	σ_{d_n}

Representation: Pipe diameter

Figure 1. Chromosome representation

Mutation: In ES, there is a strong emphasis on the mutation operator for creating offspring. Mutation is migration from the current set of solutions to better solutions using small incremental steps. In ES, the adaptive mutation for each variable value x_j is performed in two steps: first, the standard deviation, σ_{xj}, is mutated using a separate normal distribution to generate $\sigma_{xj}^{'}$; then using the mutated standard deviation, $\sigma_{xj}^{'}$, the variable value x_j is mutated as $x_j^{'}$. The mutation mechanism is specified as follows (Eiben and Smith 2007):

$$\sigma_{xj}^{'} = \sigma_{xj} \cdot e^{\tau^{'} \cdot N(0,1) + \tau \cdot N_j(0,1)} \tag{7}$$

$$x_j^{'} = x_j + \sigma_{xj}^{'} \cdot N_j(0,1) \tag{8}$$

Here, τ and τ′ are parameters such that $\tau^{'} \propto \frac{1}{\sqrt{2n}}$ and $\tau \propto \sqrt{2\sqrt{n}}$; *n* is the problem size (number of decision variables); $N(0,1)$ denotes a draw from the standard normal distribution; and $N_j(0,1)$ denotes a separate draw from the standard normal distribution for each variable *j*. The proportionality constants for both τ and τ′ are external parameters to be set by the users.

To mutate the location of pipe rehabilitation, a special mutation operator is adopted from Zechman and Ranjithan (2009). The current pipe is mutated by random assignment of another topologically close potential pipe using an adjacency list. The adjacency list of each pipe of a water distribution system represents a connectivity map of one pipe to other pipes in the network. In such a

case, the standard deviation value, σ_{I_k}, associated with a pipe ID, I_k, indicates the maximum number of links between that pipe and the pipe to be selected.

Selection: In ES-based algorithm, two different types of selection operators are used: *Parent selection* and *survivor selection* (Eiben and Smith 2007). In the first generation, an initial population of size μ is generated. In each generation, *parent selection* operator is applied based on a uniform distribution to randomly select λ individuals from the pool of μ individuals, where $\lambda > \mu$. Each of these λ individuals is then mutated to create λ offspring.

After creating λ offspring, their fitness values are calculated. The *survivor selection* operator is applied to select best μ individuals deterministically, either from the set of offspring individuals only (denoted as (λ,μ) selection) or from the combined set of parent and offspring individuals (denoted as $(\lambda+\mu)$ selection). In this paper, the investigation is based on a $(\lambda+\mu)$ selection.

Non-dominated Sorting: The non-dominated sorting approach was adopted from Deb et al. (2002). First, elitism is introduced by combining both parent individuals (μ) and offspring (λ). Then each solution is compared with every other solution in the combined population and the individuals are sorted into several fronts such as F_1, F_2, F_3, etc. The first front F_1 contains the best non-dominated solutions in the combined population. Solutions in this front have a non-dominated rank = 1. The second front F_2 contains the solutions that are dominated by the solutions in the first front F_1 but dominate all other solutions in the combined population. Solutions in this front have a non-dominated rank = 2. Similarly, the front F_3 contains the solutions that are dominated by the solutions in the fronts F_1 and F_2 but dominate all other solutions in the combined population. Solutions in this front have a non-dominated rank = 3; and so on.

Crowding Distance Estimation: To maintain the diversity in the population a density estimation technique is adopted from NSGA-II (Deb et al. 2002). This operator measures the density of a particular solution in terms of the average distance of two other solutions on either side of this solution along each of the *m* objectives. Solution with larger crowding distance indicates better diversity in the population.

Algorithmic Steps: The algorithmic steps of NSES procedure are:

1. Generate an initial population of μ individuals.
2. Apply a parent selection operator to select λ individuals.
3. Apply an adaptive mutation operator to create λ offspring.
4. Combine μ individuals with λ offspring to form a pool of $(\lambda+\mu)$ individuals.
5. Evaluate fitness of the combined population with respect to all three objectives using equations (1), (2), and (3).
6. Apply non-dominated sorting operator to sort the solutions into non-dominated fronts.
7. Apply $(\lambda+\mu)$ selection to select best μ individuals deterministically starting from front F_1. If $\mu < |F_i|$ then apply crowding distance operator to select the most diverse solutions.
8. Terminate the procedure if convergence is achieved, otherwise, go to step 2.

Performance Measure of NSES Algorithm

To validate the proposed approach, the NSES algorithm is applied on five test functions, which have been adopted in Deb et al. (2002) and a performance metric Δ is evaluated for each of the test functions. The metric Δ represents a measure of deviation of the solutions of the best non-dominated front in the final population (Deb et al. 2002). In multi-objective problems diversity among the Pareto-optimal solutions is very important. Thus the algorithm with a smaller deviation metric Δ shows better performance. The metric Δ is computed as follows (Deb et al. 2002):

$$\Delta = \sum_{i=1}^{|F_1|} \frac{\left| d_i - \overline{d} \right|}{|F_1|} \tag{9}$$

Where, F_1 = best non-dominated front in the final population; $|F_1|$ = number of solutions in front F_1; d_i = Euclidean distance in the objective space between two consecutive solutions in F_1; and $\overline{d}$ =average of these distances d_i. Table 1 shows the mean deviation $\overline{\Delta}$ and its variance from 10 iterations for each of the test functions using NSES. The performance of NSES algorithm is compared with that of NSGA-II and PAES (Knowles and Corne 1999) listed in Deb et al. (2002) and presented in Table 1. To perform an equal comparison, the total number of function evaluations in NSES is kept the same as that of both NSGA-II and PAES. The smallest values of $\overline{\Delta}$ for all test functions using NSES indicate that the proposed algorithm performs better than the other two.

Table 1. Comparison of mean and variance of performance metric Δ evaluated using NSES, NSGA-II, and PAES

Algorithm	MOP2		MOP3		MOP4		EC4		EC6

Application of Model

A virtual city water distribution system data, Micropolis (Brumbelow et al. 2007), is used to demonstrate the NSES procedure to solve the multi-objective problem. The current version of Micropolis has one pumping station (consisting of 3 pumps), one treatment facility, one storage facility (water tank), 1088 pipes, 1210 non-hydrant nodes, 196 valves, and 52 fire hydrants. Currently, a disinfectant dose of 4 mg/l is added at the treatment plant and there is no additional chlorine booster station in the system. Among 1088 pipes, there are 577 water mains each of which is considered as a potential pipe rehabilitation location. The diameter of rehabilitated pipes could be selected from the set of {6, 8, 10, 12, 14, 16, 18, 20, 24} inch diameter commercially available class 50 ductile iron pipes. The fire fighting capacity of the water system could be evaluated at all 52 fire hydrants; which would make the analyses computationally expensive. Therefore, to represent the system-wide fire fighting performance without contributing to computational burden, three fire hydrants are considered which cover the central business district, industrial area adjacent to the central business district, and heavily populated multi-family residential area on the north-eastern part of the city.

To evaluate the aggregate fire damage (Eq. (1)), the weighting coefficients, α, are determined as replacement building cost of assets within a search radius of 1000 ft of each hydrant over the total cost of assets within the search radius of all three fire hydrants. A required fire flow of 1000 gpm is considered at all three fire hydrants. Apart from the fire hydrants and the demand nodes, there are a total of 751 nodes representing valve nodes and junctions. From the set of 751 nodes, ten are selected as representative water quality monitoring nodes. The Surface Water Treatment Rule (SWTR) requires the water distribution systems to maintain a “detectable” disinfectant residual level of 0.2 mg/l (for chlorine) throughout the system. Therefore, the required minimum residual chlorine

concentration of 0.2 mg/l is used at all ten monitoring nodes to evaluate water quality deficiency (Eq. (2)). A normalized cost is evaluated as cost of pipe replacement over the cost of rebuilding the network (Eq. (3)). The network is shown in Figure 2.

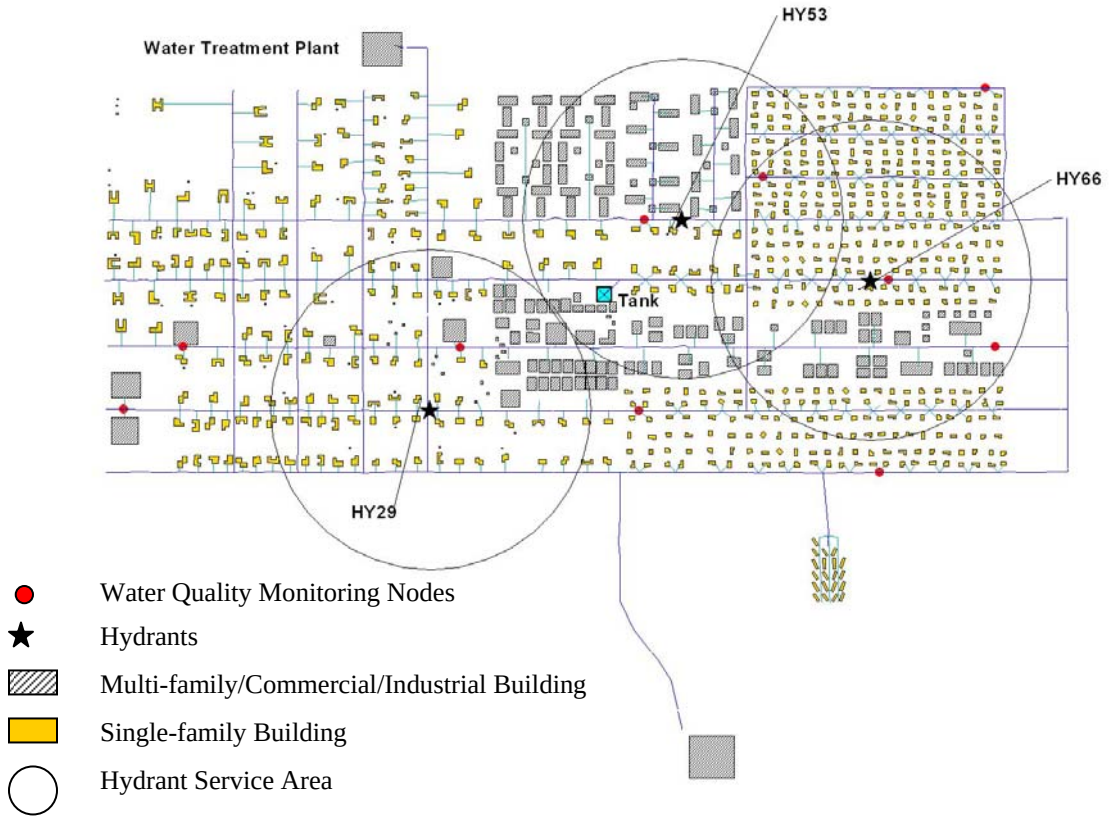

Figure 2. Building map of Micropolis with water distribution system shown in thin lines

The solution approach defined in the previous section is implemented in a computer code in Visual Basic 6.0 that utilizes iterative solution of the water distribution system's hydraulics and water quality under the objectives and constraints defined by equations (1) through (6). The NSES model is coupled with EPANet Programmer's Toolkit (Rossman 1999) to simulate the hydraulics and water quality in the network. To evaluate the aggregated fire damage a single period simulation is performed, and to evaluate the water quality deficiency the hydraulics and water quality in the network are simulated separately without a fire flow over a 168-hour time period to allow the system to reach a dynamic equilibrium condition with respect to disinfectant concentrations. It is assumed that only ten pipes needed to be replaced to increase the system-wide firefighting capability. The NSES procedure was run for 100 generations. The parameters used during implementation of NSES-based search are: μ=15, λ = 100, and *stopping criterion* = number of generations.

Results and Discussion

To test the robustness of the proposed methodology, ten independent trials were performed. The X-Y-Z scatter plots of the Pareto fronts from all of the ten trial solutions are compared in 'fire flow-water quality-cost' objective space where each point represents a solution indicating the aggregated fire flow, minimum residual chlorine, and the corresponding mitigation cost to implement

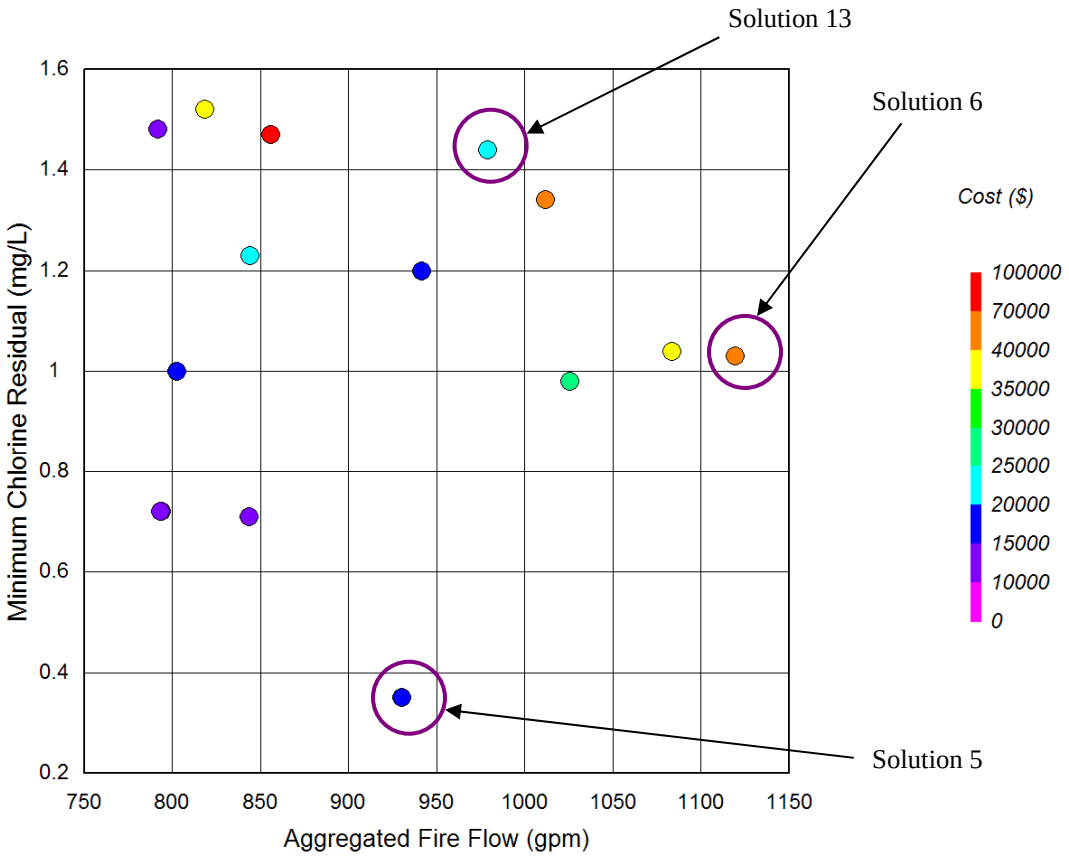

Figure 3. X-Y-Z Scatter plot of Pareto-optimal solutions after 100 generations

that solution. Since the model minimizes the aggregated fire damage, the maximum chlorine deficiency, and the normalized cost of mitigation, consequently, the model returns maximized aggregated fire flow, maximized minimum residual chlorine, and minimum cost solutions. Although the true Pareto front of this problem is not known a priori, the scatter plots of the Pareto fronts represent that the search is consistent for all of the ten trials. To get a better understanding of the Pareto front for the WDS problem, final solutions from a single trial are shown in a scatter plot in Figure 3 and the achieved objectives from the Pareto-optimal solutions are listed in Table 2.

In existing condition, the available fire flows at hydrants HY29, HY53, and HY66 are 469 gpm, 873 gpm, and 869 gpm, respectively. Thus, all 15 solutions yield significant gain at hydrant HY29 and moderate gains at both hydrant HY53 and hydrant HY66 with a few exceptions. The minimum residual chlorine levels in both the existing condition and in the final solutions are above the regulated minimum value of 0.2 mg/l. From the above table, it is evident that the NSES algorithm generates non-dominated solutions in the objective space; which means no one solution is better than the other with respect to all three objectives. To explain the trade-off relations between the objectives in detail, three non-dominated solutions, solution-5, solution-6, and solution-13, are selected. It can be concluded from Table 2 that solution-5 is better than the other two in terms of the third objective: cost, but inferior to the others in terms of both aggregated fire flow and minimum residual chlorine. Solution-6 produces more than required fire flow volume of 1000 gpm and hence superior to the other two in terms of the first objective but inferior to the others in terms of cost. Similarly, solution-13 is superior to the others in terms of the second objective: residual chlorine, but inferior to solution-6 in terms of aggregated fire flow, and inferior to solution-5 in terms of cost. This

comparison clearly indicates that a tradeoff relation exists between the conflicting goals of WDS: fire flow, water quality, and cost.

Table 2. Comparison of solutions in multi-objective space

Solution ID	Hydrant Fireflow *HY29* *gpm*	*HY53* *gpm*	*HY66* *gpm*	Aggregated Fireflow *gpm*	Minimum Residual Chlorine *mg/l*	Cost *$*
Existing	469	873	869	791	0.71	0
1	484	870	866	792	1.48	13,429
2	480	874	869	794	0.72	6,912
3	479	907	895	818	1.52	36,604
4	739	888	878	856	1.47	93,332
5	1138	882	872	930	0.35	16,770
6	1807	942	957	1119	1.03	61,545
7	730	874	869	844	0.71	12,387
8	1422	924	931	1025	0.98	27,972
9	479	874	869	794	0.72	14,421
10	866	1051	1041	1012	1.34	63,504
11	1654	937	949	1084	1.04	37,852
12	1198	880	871	941	1.20	18,674
13	1249	915	902	979	1.44	23,033
14	503	937	911	844	1.23	20,890
15	487	884	875	802	1.00	15,403

Conclusion

This methodology clearly generates Pareto-optimal solution surfaces that express the trade-off relationship between fire damage, water quality, and least cost objectives; thus provides decision makers with the flexibility to choose a mitigation plan for urban fire events best suited for their circumstances. However, the solutions indicate that there were limited or no solutions in 'high fire flow-low water quality-high cost' region. This is due to the fact that the system wide fire flow capacity is evaluated as aggregated fire flow considering three hydrants: HY29, HY53, and HY66 with weighting coefficients of 0.2, 0.55, and 0.25, respectively. Thus, any little improvement at hydrants HY 53 and HY66 contributes to greater aggregated fire flows resulting from small changes in the diameter. Further investigation is required by incorporating more hydrants in evaluating aggregated fire flow and larger number of monitoring nodes needed to be included to evaluate system-wide minimum residual chlorine level.

Concerns about the security of water distribution systems have lead to increased interest in sensor placement in water distribution systems. Due to the cost of both placing and maintaining these sensors, the number of sensors used must be limited. These constraints make the sensor deployment locations crucial in a water monitoring system. Many studies, based on differing algorithms and objective functions, have sought to determine ways to optimize sensor location. These studies have largely relied on current water quality models that assume perfect mixing at pipe junctions. However, it has been shown that using a water quality model that accounts for imperfect mixing (AZRED) at pipe intersections produces outcomes that differ from those produced by studies that assume perfect mixing and, consequently produces a different scheme for optimal sensor placement. The current work uses a multiobjective approach that relies on the non-dominated, sorted algorithm II. The study seeks, first, to contrast the use of the AZRED water-quality model to the use of water quality models that assume perfect mixing, and, second, to propose a more comprehensive approach to sensor placement. By using a simpler objective of optimizing for complete sensor coverage, the study will expand on pervious work that made this comparison. An example network is analyzed using both AZRED and EPANET, and the results are compared.

1. INTRODUCTION

Sensor Placement in Water Distribution Systems

The Safe Water Drinking Act, issued by the United States Environmental Protection Agency in 1990, requires water utilities to monitor water distribution systems (WDS) for water quality. Since the passing of this act, there has been increased interest in sampling and, in turn, determining the best sampling locations. Lee and Deninger (1992) first approached the problem using optimization tools to determine the best locations; their analysis was based on fractions of water contributed to monitoring locations of a water distribution network. Since that time, there have been many advances in methodologies for monitoring water quality

The terrorist events of September 11th generated a greater demand for increasing the security of water distribution systems, and many subsequent studies, recognizing the possibility of intentional contamination, have focused on sensor placement.

A primary goal in designing a sensor placement scheme should be to give the water distribution operator the best possible tool for making informed decisions about which locations to monitor. Ideal would be a sensor network that provides (1) rapid and (2) accurate detection of an event that takes place anywhere in the system. Obtaining such perfection is, however, simply impossible, given the current technology and budget constraints. Because continuous, ubiquitous monitoring is expensive, the number of sensors deployed must be kept to the minimum needed to achieve threshold levels of accuracy and timeliness as determined by the designer who wishes to make good use of limited resources and must simultaneously weigh the importance of several goals.

Multiobjective Optimization

In contrast to single objective schemes, a multiobjective optimization scheme accounts for several different objective functions simultaneously. Formally, this can be written $F(x) = [f_1(x), f_2(x),..., f_M(x)]^T$ where F(x) is the multiobjective function that is composed of $f_1(x), f_2(x),..., f_M(x)$ which are a set of objective functions, and $x = (x_1, x_2,..., x_n)^T$ is the decision variable vector. The goal of this type of optimization is to find the set of all of the best solutions, subject to any constraints imposed by the problem. The best solutions are solutions such that no other solutions may be found that improve any of the objective functions without making another objective function value worse. This set of solutions is called the Pareto optimal solution set.

AZRED Water Quality Model and Optimization

Most WDS water quality modeling software relies on the assumption of perfect mixing at all junctions within the system. Van Bloemen Waanders et al. (2005) showed, through computational fluid dynamics (CFD), of a cross fitting that this assumption would cause significant errors. They determined that two incoming adjacent flows bifurcate rather than mix. Romero-Gomez et al. (2008a), in describing this mixing phenomenon over a large range of the Reynolds number using CFD and Austin et al. (2008), established an experimental database to model mixing behavior in the turbulent flow regime. Both computational and experimental results demonstrated that nodal mixing could be dramatically different from those produced by a perfect mixing model. Choi et al. (2008b) showed that mixing was mostly dependent on relative inflows and outflows rather than on Reynolds number, and that some modeling simplifications could be made in order to obtain a reasonable estimate of mixing over both the laminar and transitional flow regimes as well. Along with cross fittings, wye and tee junctions have been investigated and shown to exhibit imperfect mixing behavior. These include situations in which more than one tee or wye type fitting have been placed in close proximity. Choi et al. (2008b) developed a database for these other fitting configurations.

The AZRED water quality model is a modified version of EPANET, one that implements an imperfect mixing model for cross, double tee, and tee and wye fittings. The program was created by a group of researchers at the University of Arizona (Choi et al., 2008a; AZRED, 2009) and based on data sets collected through experimental trials.

The program uses EPANET's standard hydraulic water quality solvers but alters the water quality code by calculating concentrations downstream from junctions based on imperfect mixing, when appropriate, and using an interpolation of data. Romero-Gomez et al. (2008b) demonstrated that AZRED could be used as the water quality model in the single objective optimization scheme to maximize system coverage (i.e., likelihood of detection). A minimum hazard level was used in this study to construct a pollution matrix with a binary variable to signal whether or not a contamination above the minimum hazard level had been detected. It was shown that, depending on the minimum hazard level, the water quality model (perfect mixing vs. AZRED) had a significant influence on the number of sensors required for complete coverage and that, due to the increased accuracy of the water quality model, sensor designs based on AZRED should be more reliable than those based on perfect mixing. Here, we pose a multi-objective optimization problem to extend the comparison of perfect and imperfect mixing assumptions.

2. METHODS

Optimization Functions

The optimization problem is formulated using the three objective functions proposed by Preis and Ostfeld (2008): sensor detection likelihood, sensor detection redundancy, and sensor expected detection time.

Detection Likelihood

Detection likelihood is the probability that a random event in the pollution matrix will be detected at one of the sensor locations. This metric is intended to indicate the degree to which the sensor locations cover the network. A network with high detection likelihood has a good chance of detecting a random event, while an arrangement of sensors with low detection likelihood has a low detection probability. More formally, the sensor detection likelihood is given as:

$$f_1 = \frac{1}{S}\sum_{r=1}^{S} d_r \tag{1}$$

where f_1 is the sensor detection likelihood, d_r=1 if there is detection at least one of the sensor locations or d_r=0 otherwise, and S is the total number of pollution events. The detection likelihood indicates the proportion of events in the randomly generated set that would be detected. As such, it is desirable to maximize its value.

Detection Redundancy

Detection redundancy is defined as the probability that if an event occurs, a redundant detection will also occur. Thus, sensor detection redundancy is intended to increase the reliability of the sensor network by reducing the number of false detections that can occur at a single sensor. Mathematically, the term is defined as:

$$f_2 = \frac{1}{\sum_{r=1}^{S} d_r}\sum_{r=1}^{S} R_r \tag{2}$$

where f_2 is the sensor detection redundancy, and R_r=1 if the redundancy condition is met and R_r=0 otherwise. In our specific examples, three sensors are used as the number that must be triggered in order to have a redundant condition. Sensor detection redundancy is to be maximized.

Detection Time

Expected detection time is a metric defining the time that passes from the moment when an event occurs until it is detected. This metric thus specifies the expected time that a given sensor configuration should need in order to initially detect a contamination. The metric is calculated as:

$$f_3 = E(t_d) \tag{3}$$

where f_3 is the sensor detection time, t_d is the time from contamination until the first sensor detection, and $E(t_d)$ is the expected value of t_d. To mitigate harm caused by a contamination event, detection time is minimized in order to minimize the amount of time that passes before action can be taken. The sensor detection time is to be minimized in order to minimize the time that passes before action can be take to mitigate harm caused by a contamination event.

Pollution Matrix Generation

The purpose of the pollution matrix is to organize the results of a set of simulated pollution events into a form that can be easily evaluated by our objective functions (Ostfeld and Salomons, 2004). In this study, a pair of pollution matrices was created for each of the networks. One matrix was derived from a water quality analysis using EPANET, while the second other matrix was developed using AZRED as the simulation model. Aside from the difference of the water quality solver, each matrix was created using the same procedure that was automated through a C++ program using the EPANET toolbox. The program ran both hydraulic and water quality simulations for each pollution event. In the pollution matrix, each line contains the record of a contamination event with a corresponding injection node, mass rate, time, and duration. The pollution information follows the injection information and indicates the concentration of each contamination initially detected for each node being considered. The time of first detection, and the duration of the contamination at that node is also included. Separate pollution matrices were constructed for each minimum detection limit (MDL) that was set to represent which represented the pattern of detection based on the corresponding level where detection would occur.

NSGA-II Optimization Algorithm

The nondominated, sorted genetic algorithm developed by Deb et al. (2000) and implemented by Preis and Ostfeld (2008) was used as the optimization solver by modifying the function evaluation routine to incorporate AZRED as well as EPPANET. Briefly, the NSGA-II algorithm is a multiobjective genetic algorithm that generates a random set of strings to represent the initial population of sensor locations. Each string's fitness is then evaluated for all objective functions. The strings are then sorted and nondominated strings are identified. One string dominates another when:

1. Have a fitness value as good as the other string for all fitness functions
2. Have a fitness value better than the other string for at least one objective function.

Nondominated strings are then sorted according to the average distance between the fitness vectors of the other strings, and solutions that favor greater distances (diversity in the solution) are selected. The algorithm then produces a new generation of strings based on selection, mutation, and a crossover based on the best set of available solutions from the previous generation. This process of evaluation, sorting, and new population generation is repeated until a stopping criteria is reached. In this study, the solutions were all run for 1,000 generations.

Network Descriptions

This exemplary network is part of the EPANET freeware package and consists of 120 links, 90 nodes, 3 elevated tanks, and 2 pumps that connect to 2 reservoirs (a lake and a river). Eight nodes from the network are configured as 4-way junctions (circled in Figure 1) and were thus modified in order to comply with the requirement of AZRED for such junctions. The modifications led to a combination of all the types shown by Choi et al. (2008b): two crosses, two double-tee, one YU-type, and three YN-type junctions. The location and characteristics of the new junctions are listed in Table 1.

EPANET example Network3 is used as the application network in this study. The network was slightly altered so that it would better suite the study. These alterations follow those implemented by Romero-Gomez et al. (2009). Incomplete mixing occurs at nodes (a) having two incoming and two outgoing pipes or (b) that are a special connection. In original Nework3, only cross junctions (type (a)) are available. Therefore, changes were made in the network to introduce special junction types, which were modeled in AZRED (cross, double tee, etc.) and that both the entering and exiting pipes in these nodes where all the same size. The changes introduced 8 special junctions that would produce imperfect mixing: two crosses, two double-tees, one YU-type, and three YN-type junctions (for junction types, see Choi et al., 2009). To ensure that only pipes of the same size entered and exited the special junctions, extra nodes were added around each junction along with a short length of added pipe. These nodes were not used as injection or detection locations.

3. RESULTS

The pollution matrices were created by including events for every possible combination of events from a list of injection mass rates, injection durations and start times. All of the possible event locations were used for each of these combinations. The pollution matrices for Network 3 was done with 2 mass rates of 50000, and 100000 mg/min, durations of 2 and 4 hrs, with 4 start times distributed evenly throughout the day. Sets of pollution matrices were created for each MDL (0, 0.1, 0.01, 0.001, and 0.0001 mg/L).

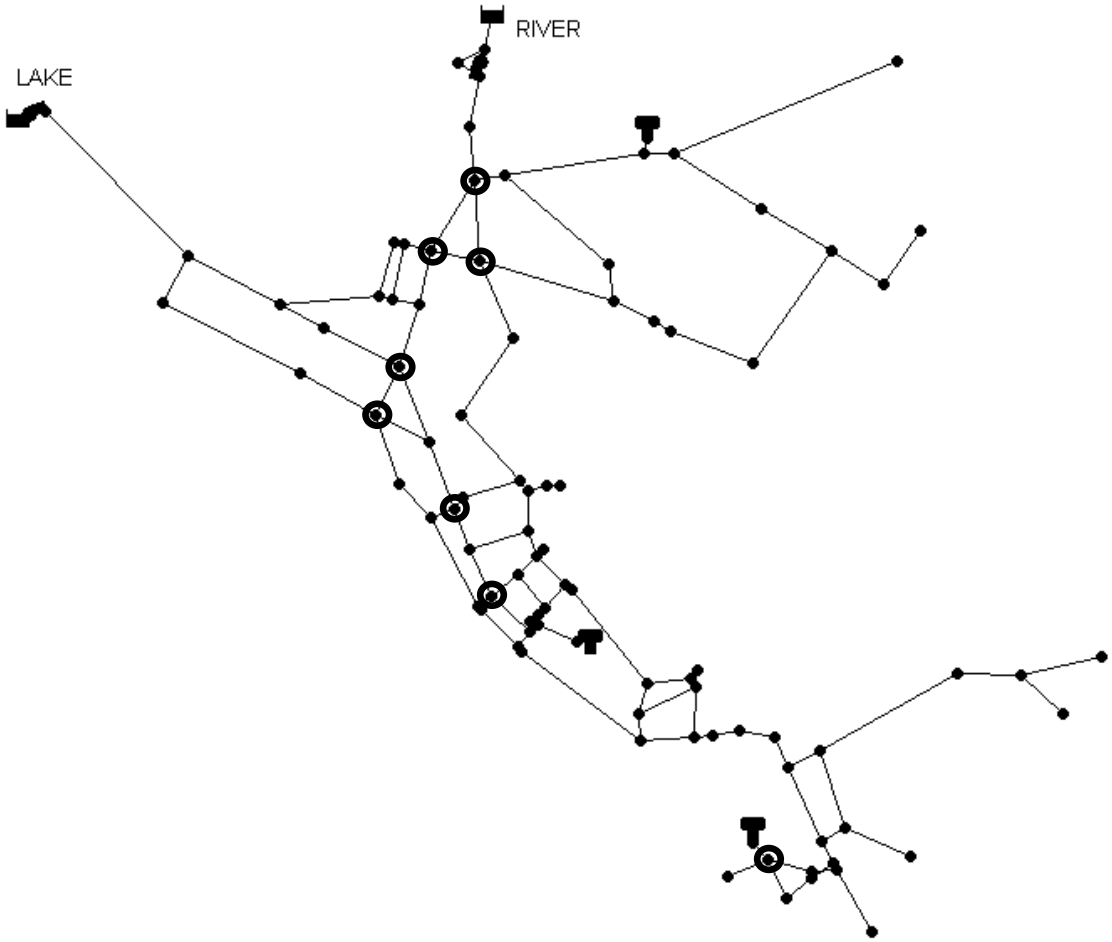

Figure 1. Network 3 from EPANET examples. Network was modified at the circled nodes that correspond to 4-way junctions.

Table 1. Modifications on Network 3 example from the EPANET package (for modified junction types, see Choi et al., 2009).

Node ID	Type	Junction diameter (D)	Dimensionless distance (L/D)
121	YN	24	2.0
120	N	10	1.0
119	X	20	-
115	YN	10	3.0
193	N	12	2.5
189	X	12	-
255	YU	10	1.0
111	YN	12	2.0

Incomplete mixing causes concentration changes downstream of a junction where mixing is incomplete. If additional junctions have incomplete mixing downstream, the difference between the plumes for perfect and imperfect mixing may amplify. The concentration differences are apparent when applying alternative a minimum detection levels (MDL). These differences can be seen between the Pareto fronts for the two mixing conditions. The Pareto fronts for detection likelihood and detection redundancy are shown in Fig. 2 for 4 MDLs.

As the MDL is increased, contamination events are missed at more locations resulting in a shift on the Pareto front. Comparing the results from EPANET and AZRED we see that at most MDLs there is a slight difference between the two methods that diminishes as the MDL is decreased. Little difference can be seen at the 0.0001 mg/L level and with perfect sensors (an MDL of zero) the results for EPANET and AZRED were very similar and are not shown. At low MDLs, any contaminant is detected and a small concentration discharging from an imperfectly mixed node is equivalent to a uniformly mixed higher concentration and will be detected at the assumed precise meters. The differences between the two methods are especially prominent with points that are at the upper range of the detection likelihood parameter. In this portion of the Pareto front differences between EPANET and AZRED are forcing significant changes in concentrations downstream of the special junctions. These changes are not very large but could lead to a better decision for sensor location when using AZRED.

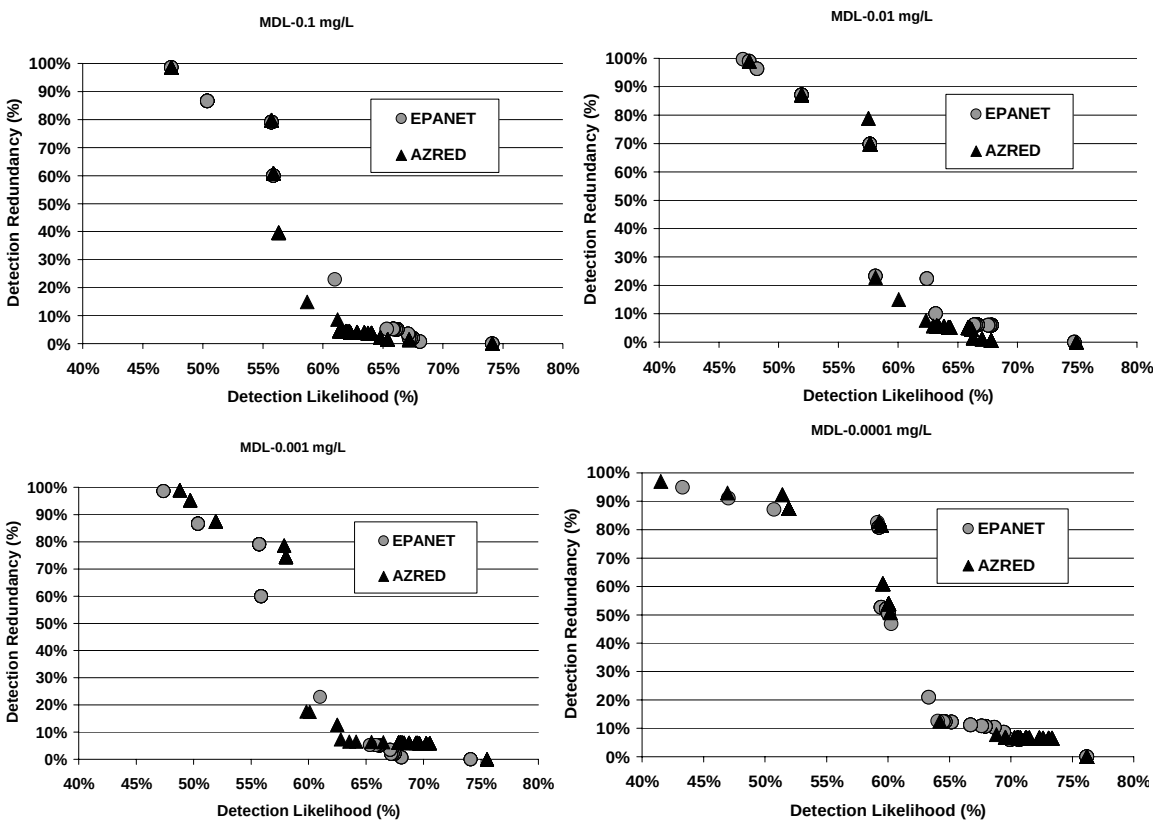

Fig. 2. Pareto fronts for Network3, showing the relationship between detection likelihood and detection redundancy for differing MDLs. Note the detection limit and water quality model's effects on the Pareto fronts.

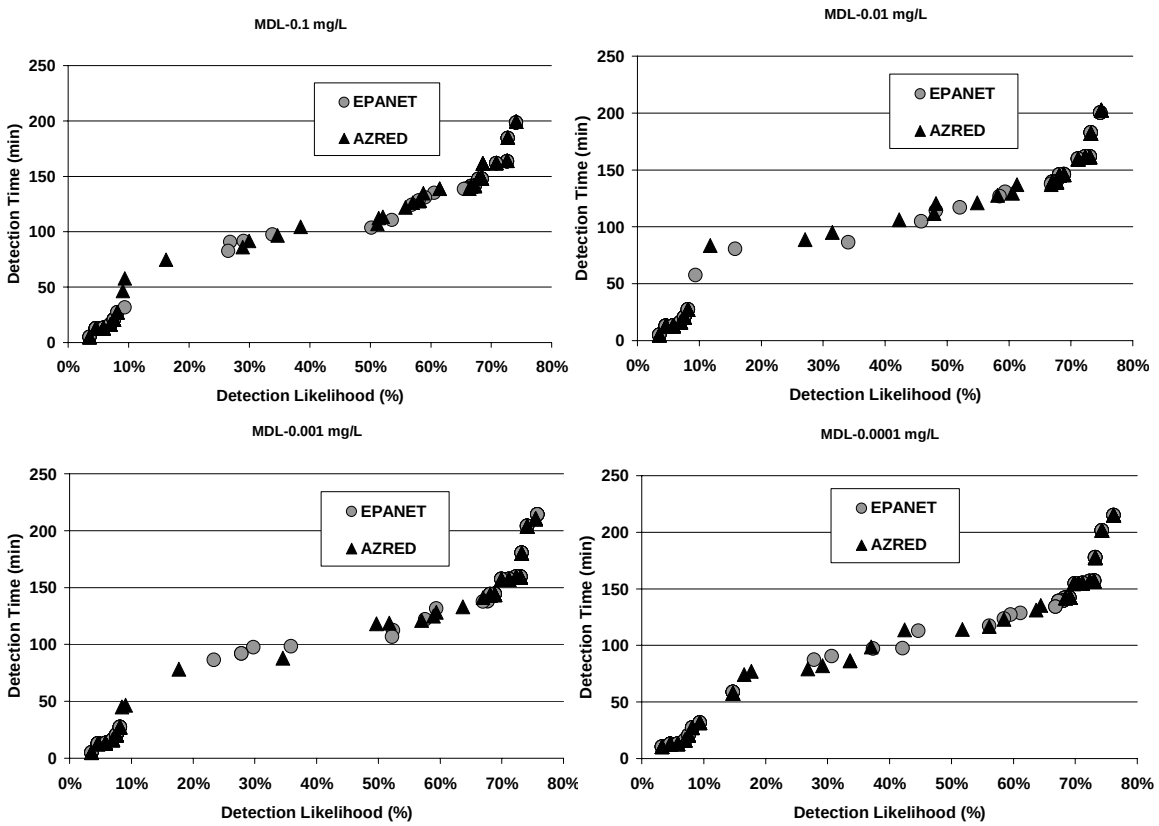

Fig. 3. The Pareto fronts for Network 3 showing the relationship between detection likelihood and detection time for alternative MDL. Note the detection limit and water quality model's effects on the Pareto fronts.

The Pareto fronts comparing the detection likelihood and detection time objectives are shown in Fig. 3 with alternative MDLs. First, the objectives are in conflict smaller detection time and larger detection likelihoods are desirable. Next, the differences between the two mixing models are not as significant as they were for the previous objectives. Given the size and layout of this network, detection time is not sensitive to small changes, while the plume spread is somewhat more variable. A more highly looped or larger network with more nodes that cause incomplete mixing may produce more significant differences compared to those of this system and should be examined.

4. CONCLUSION

Optimal locations for sensor placement in a simple network and under both perfect and imperfect mixing conditions were determined using the multiobjective approach of Preis and Ostfeld (2008). For this network, differences between the two results were not significant. When perfect sensors were assumed (or in any case where concentration is not important but simply the presence of a contaminant), the two mixing models provided very similar results. Differences in the sensor placement designs and the objectives increased with higher (more realistic) MDLs. Although the differences were small in this case, more study should be completed to determine if sensor placement designs would be altered under imperfect mixing conditions in larger and more highly looped networks.

Robust Sensor Placement for Detecting Adversarial Contaminations in Water Distribution Systems

Andreas Krause* Carlos Guestrin†

Abstract

Drinking water distribution systems (WDS) are complex and dynamic systems. The intentional introduction of a contaminant could theoretically be detected by a network of sensors placed at nodes in the system. Optimizing the placement of these hypothetical sensors for metropolitan area size WDS is an important research challenge. Recently, the Battle of the Water Sensor Networks led to the development of several promising techniques for deploying sensors in large, complex networks. However, this challenge focused on designing sensor networks that detect random, accidental contaminations well. In order to guard WDSs against malicious attacks, sensor network detection performance has to be optimized with respect to the worst possible contamination. We recently developed a new algorithm, SATURATE, that can efficiently solve large robust sensor placement problems. The obtained solutions are provably close to optimal. Our algorithm can handle imprecise sensors that can fail. Our method can also be used to obtain placements that simultaneously perform well both for malicious (i.e., worst-case) contaminations, as well as accidental (i.e., average-case) contaminations. We report results from applying our method to a large hypothetical distribution system with more than 12,000 nodes.

1 INTRODUCTION

Drinking water distribution systems (WDS) are complex and dynamic systems. The intentional introduction of a contaminant disrupts the system and could theoretically be detected by a network of sensors placed at nodes (pipe junctures or households) in the system. Optimizing the placement of these hypothetical sensors for metropolitan area size WDS is an important research challenge. Because the system has many nodes and multiple states, the number of possible contamination events is significant, and the

*Computer Science, Division of Engineering and Applied Science, California Institute of Technology, Pasadena, CA, USA; Email: krausea@caltech.edu

†Computer Science Dept. and Machine Learning Dept., School of Computer Science, Carnegie Mellon University, Pittsburgh, PA, USA; Email: guestrin@cs.cmu.edu

likely number of costly sensors available for deployment is low, the optimal placement of these sensors to minimize the effect of the introduced contaminant on the population is a critical issue.

Recently, the Battle of the Water Sensor Networks [Ostfeld et al., 2008] led to the development of several promising techniques for deploying sensors in large, complex networks with more than 12,000 junctions. However, this challenge focused on designing sensor networks that detect random, accidental contaminations well. In order to guard WDSs against malicious attacks, sensor network detection performance has to be optimized with respect to the worst possible contamination. Existing exact techniques for optimal robust sensor placement are difficult to scale to WDS of metropolitan area size, and so heuristic search procedures, which do not have any guarantees about the quality of the obtained solutions are used. Thus, the resulting sensor placements can potentially perform arbitrarily badly when compared to the optimal solution.

We recently developed a new algorithm, SATURATE, that can efficiently solve large robust sensor placement problems [Krause et al., 2008b]. The obtained solutions are provably close to optimal. Our algorithm can handle imprecise sensors that can fail. Our method can also be used to obtain placements that simultaneously perform well both for malicious (i.e., worst-case) contaminations, as well as accidental (i.e., average-case) contaminations.

We apply our method to a large hypothetical distribution system with more than 12,000 nodes. Optimization was based on multiple criteria including (1) minimizing the time to detection and (2) minimizing population effected prior to detection.

Our results show significant improvement over existing techniques, such as state-of-the-art Simulated Annealing algorithms. Furthermore, they indicate that sensor placements that detect average contaminations well can exhibit very poor detection performance on worst-case contaminations. Using our algorithm, we obtain placements that perform nearly as well in the average case, but significantly better in the worst-case. Further, our optimization algorithm has applications for robust placement of sensors in other complex, dynamic systems, as well as robust experimental design.

2 PROBLEM STATEMENT

Following our approach described by Krause et al. [2008b,a] we model the WDS as a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where the nodes $\mathcal{V}$ represent the junctions and the edges $\mathcal{E}$ represent the pipes connecting the junctions. In order to model contamination spreading dynamically over this network, we consider a set of *intrusion scenarios* $\mathcal{I}$; each scenario $i \in \mathcal{I}$ models the spreading of contamination starting from a given node $s \in \mathcal{V}$ in the network. By placing sensors at a set of junctions $\mathcal{A} \subseteq \mathcal{V}$, we can detect such a contamination, and thereby minimize the adverse effects on the network.

More specifically, for each possible contamination scenario $i \in \mathcal{I}$ and for each node $v \in \mathcal{V}$ we define the detection time $T_i(v)$ as the time when the contamination affects node v (and $T_i(v) = \infty$ if node v is never affected). We furthermore define a penalty function $\pi_i(t)$ which models the penalty incurred for detecting contamination i at time

t. We require $\pi_i(t)$ to be monotonically non-decreasing in t (i.e., we never prefer late over early detection), and bounded above by $\pi_i(\infty) \in \mathbb{R}$. We extend π_i to observation sets $\mathcal{A}$ as $\pi_i(\mathcal{A}) = \pi_i\left(\min_{s\in\mathcal{A}} T_i(s)\right)$. Equivalently, we can define the *penalty reduction* $F_i(\mathcal{A}) = \pi_i(\infty) - \pi_i(\mathcal{A})$. Krause et al. [2008a] show how realistic objective functions employed in the Battle of the Water Sensor Networks [Ostfeld et al., 2008], such as the reduction in time to detection (Z_1), population affected (Z_2), contaminated water consumed (Z_3) and improvement in detection likelihood (Z_4) can be modeled by appropriate choice of the penalty function π_i.

In the BWSN challenge, a probability distribution over the contamination events is specified, assigning each contamination event $i \in \mathcal{I}$ a probability $p(i)$. The goal is then to place a set of k sensors maximizing the *expected penalty reduction*,

$$\max_{|\mathcal{A}|\leq k} \frac{1}{|\mathcal{I}|} \sum_{i\in\mathcal{I}} p(i) F_i(\mathcal{A}). \tag{2.1}$$

Assuming a probability distribution over contamination events can be appropriate if the goal is to place sensors that effectively detect accidental, random contaminations. However, in order to protect a WDS against an adversary that contaminates the network knowing the sensor locations, it is more appropriate to optimize considering the *worst possible* contamination event. Krause et al. [2008a] show that this can be achieved by optimizing

$$\max_{|\mathcal{A}|\leq k} \min_{i\in\mathcal{I}} F_i(\mathcal{A}). \tag{2.2}$$

3 OPTIMIZATION APPROACH

One can show that the optimization problems (2.1) and (2.2) are computationally complex (NP-hard), such that we cannot expect to find the optimal solution in reasonable time. In this section, we will discuss algorithms, originally proposed by Krause et al. [2008a] and Krause et al. [2008b] that efficiently find provably near-optimal solutions to these problems.

3.1 Placing sensors to detect accidental contaminations

A natural approach to finding approximate solutions is the *greedy algorithm*: This algorithm starts with the empty placement, $\mathcal{A} = \emptyset$, and proceeds iteratively. At the j-th round, it will select the sensor

$$s = \operatorname*{argmax}_{s\in\mathcal{I}} F_{ac}(\mathcal{A} \cup \{s\}),$$

i.e., the sensor which will decrease the expected penalty the most, and adds it to the current set $\mathcal{A} \leftarrow \mathcal{A} \cup \{s\}$. Hereby,

$$F_{ac}(\mathcal{A}) = \frac{1}{|\mathcal{I}|} \sum_{i\in\mathcal{I}} p(i) F_i(\mathcal{A})$$

is the *expected* penalty reduction achieved when placing sensors at locations $\mathcal{A}$. The algorithm stops after k nodes have been selected. Krause et al. [2008a] show that this algorithm performs *near-optimally*: The greedy algorithm will always pick a set $\mathcal{A}$ such that $F_{ac}(\mathcal{A}) \geq (1 - 1/e)F_{ac}(\mathcal{A}^*)$, where $\mathcal{A}^*$ is the optimal placement of k sensors.

The key insight to the analysis of Krause et al. [2008a] is that the penalty reduction satisfies *submodularity*, a diminishing returns property formalizing the intuition that adding another sensor helps more if we have placed few sensors so far, and less if we already have placed many sensors. A fundamental result by Nemhauser et al. [1978] then proves the near-optimal performance of the greedy algorithm.

3.2 Placing sensors to detect adversarial contamination

While the average case objective F_{ac} is submodular, and hence the greedy algorithm provides near-optimal sensor placements, the same does not hold for the *worst case* penalty reduction

$$F_{wc}(\mathcal{A}) = \min_{i \in \mathcal{I}} F_i(\mathcal{A}).$$

In fact, Krause et al. [2008b] show both experimentally and theoretically that the greedy algorithm performs arbitrarily poorly in this setting. Krause et al. [2008b] develop an efficient algorithm, SATURATE, that provides near-optimal solutions for this problem. While we cannot give a detailed description and analysis of the algorithm here due to space limitations, we will present a high level overview. Suppose we would like to find a set of k nodes to place sensors, maximizing the worst-case performance. The SATURATE algorithm proceeds in the following steps. It maintains a search interval $[c_{min}, c_{max}]$ which is reduced in every iteration. Initially, $c_{min} = 0$, and $c_{max} = \min_{i \in \mathcal{I}} F_i(\mathcal{V})$.

1. SATURATE sets $c = (c_{min} + c_{max})/2$. If $c_{max} - c_{min} < \varepsilon$, the algorithm stops and returns the best candidate solution found so far.

2. It applies the greedy algorithm to the *average truncated* objective $\widehat{F}_c(\mathcal{A}) = \frac{1}{|\mathcal{I}|} \sum_{i \in \mathcal{I}} \min\{c, F_i(\mathcal{A})\}$. This algorithm will return a set $\mathcal{A}_c$, such that $|\mathcal{A}_c| \geq k$.

3. If $\widehat{F}_c(\mathcal{A}_c) = c$, then SATURATE considers $\mathcal{A}_c$ a candidate solution, and repeats step 1 with $c_{min} = c$. If $\widehat{F}_c(\mathcal{A}_c) < c$, then it repeats step 1 with $c_{max} = c$.

Hereby, ε is a tolerance parameter that can be chosen arbitrarily small. Krause et al. [2008b] prove that after the algorithm converges, the solution returned is near-optimal, in a strong complexity-theoretic sense, i.e., under widely accepted complexity theoretic assumptions, there cannot exist an efficient algorithm that provides better guarantees about the solution quality in general.

3.3 Trading off average-case and worst-case performance

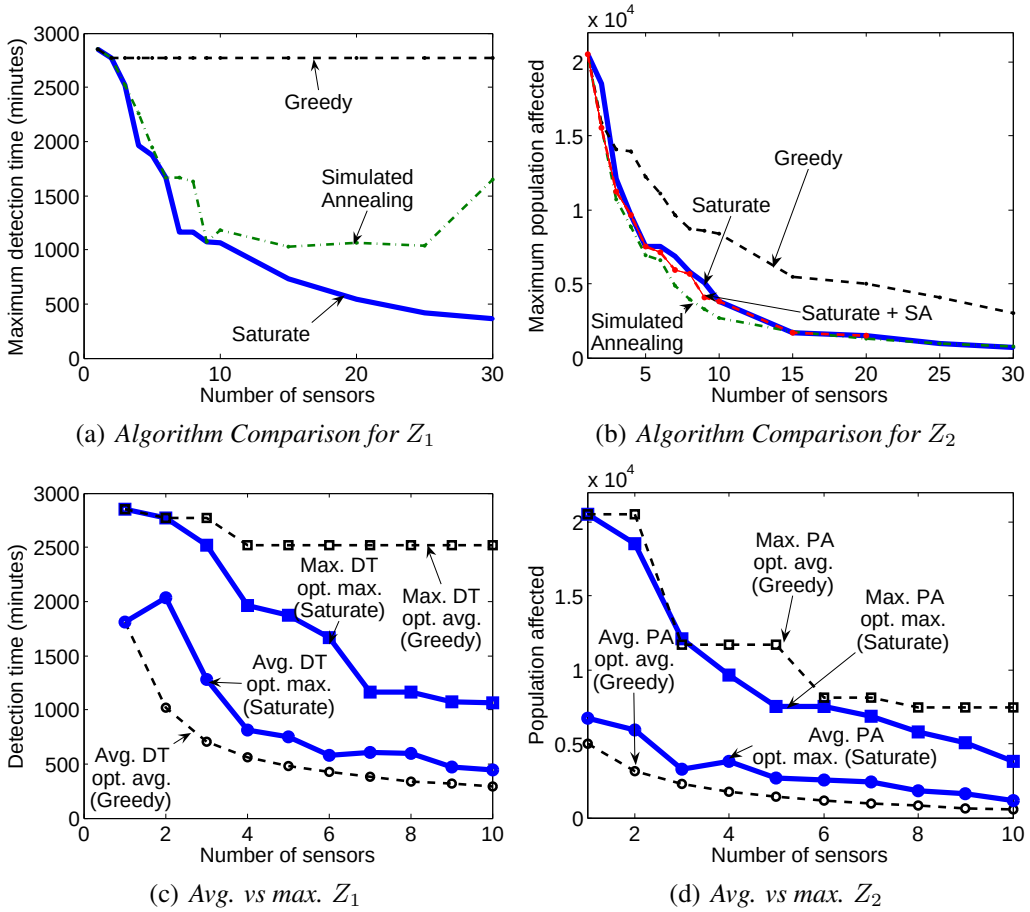
In some applications, optimizing the worst-case performance $F_{wc}(\mathcal{A}) = \min_i F_i(\mathcal{A})$ might be a too pessimistic approach. On the other hand, ignoring the worst-case and

only optimizing the average-case (the expected performance under a distribution over the objectives) $F_{ac}(\mathcal{A}) = \frac{1}{m}\sum_i F_i(\mathcal{A})$ might make too strong assumptions, and hence be too optimistic. In general, we might be interested in solutions, which perform well both in the average and worst case.

Krause et al. [2008b] describe a multicriterion optimization problem, where we intend to optimize the *vector* $[F_{ac}(\mathcal{A}), F_{wc}(\mathcal{A})]$. In this setting, we can only hope for *Pareto-optimal* solutions [Boyd and Vandenberghe, 2004]. A set $\mathcal{A}^*$, $|\mathcal{A}^*| \leq k$ is called *Pareto-optimal*, if it is not *dominated*, i.e., there does not exist another set $\mathcal{B}$, $|\mathcal{B}| \leq k$ with $F_{ac}(\mathcal{B}) > F_{ac}(\mathcal{A}^*)$ and $F_{wc}(\mathcal{B}) \geq F_{wc}(\mathcal{A}^*)$ (or $F_{ac}(\mathcal{B}) \geq F_{ac}(\mathcal{A}^*)$ and $F_{wc}(\mathcal{B}) > F_{wc}(\mathcal{A}^*)$).

One possible approach to find such Pareto-optimal solutions is constrained optimization: for a specified value of c_{ac}, we desire a solution to

$$\mathcal{A}^* = \operatorname*{argmax}_{|\mathcal{A}|\leq k} F_{wc}(\mathcal{A}) \text{ such that } F_{ac}(\mathcal{A}) \geq c_{ac}. \tag{3.1}$$



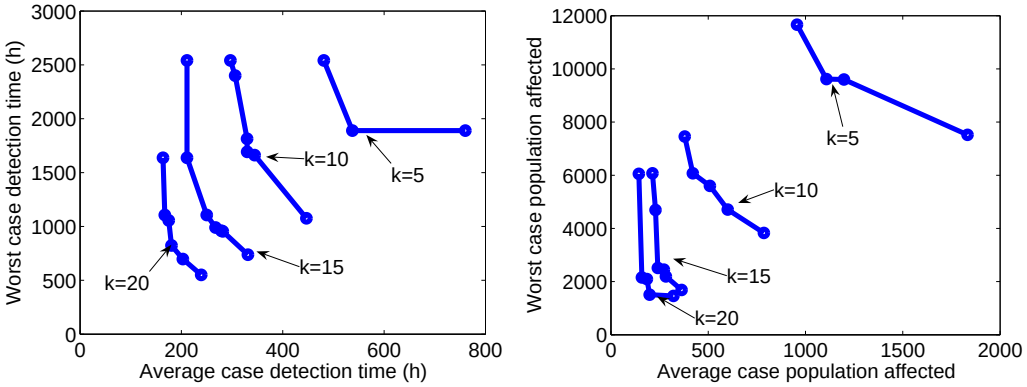
By specifying different values of c_{ac} in (3.1), we would obtain different Pareto-optimal solutions. Krause et al. [2008b] show how SATURATE can be modified to near-optimally solve Problem (3.1). In Section 4 we show how this modified algorithm can be used to find sensor placements in WDS that perform near-optimally *both* in the average-case and in the worst-case.

4 EXPERIMENTAL RESULTS

Experimental setup. In August 2006, the Battle of Water Sensor Networks (BWSN) [Ostfeld et al., 2008] was organized as an international challenge to find the best sensor placements for a realistic metropolitan water distribution network, consisting of 12,527 nodes. In this challenge, a set of intrusion scenarios is specified, and each scenario is simulated using EPANET 2.0 [Rossman, 1999] is used to simulate the spread of the contaminant for a 48 hour period. An intrusion is considered detected when one selected node shows positive contaminant concentration [1]. BWSN considered a variety of impact measures, including the time to detection (called Z_1), and the size of the affected population calculated using a realistic disease model (Z_2). The goal of BWSN was to minimize the *expectation* of the impact measures Z_1 and Z_2 given a *uniform distribution* over intrusion scenarios. In our experiments, which are described in more detail by Krause et al. [2008b], we consider scenarios that affect at least 10% of the network, resulting in a total of 3424 scenarios.

Comparison of SATURATE with other algorithms. Figures 1(a) and 1(b) compare the greedy algorithm, SATURATE and a highly fine-tuned simulated annealing (SA) algorithm for the problem of minimizing the worst-case detection time (Z_1) and worst-case affected population (Z_2). The figures show the achieved worst-case penalty reductions achieved by placing an increasing number of sensors using the three algorithms.

[1] As discussed by Krause et al. [2008a], "noisy detection" can be taken into account as well.



(a) *Algorithm Comparison for* Z_1 (b) *Algorithm Comparison for* Z_2

(c) *Avg. vs max.* Z_1 (d) *Avg. vs max.* Z_2

Figure 1: (a,b) compare SATURATE, greedy and Simulated Annealing (SA), when optimizing worst-case detection time (Z_1, (a)) and affected population (Z_2, (b)). SATURATE performs comparably to SA for Z_2 and strictly outperforms SA for Z_1. (c,d) compare optimizing for the worst-case vs. average-case objectives. Optimizing for the worst-case leads to good average case performs, but not vice versa.

Interestingly, the behavior is very different for the two objectives. For the affected population (Z_2), the greedy algorithm provides acceptable performance, and SA sometimes even outperforms SATURATE. For the detection time (Z_1), however, the greedy algorithm did not improve the objective at all, and SA performs poorly. The reason is that for Z_2, the maximum achievable penalty reduction, $F_i(\mathcal{V})$, vary drastically, since some scenarios have much higher impact than others. Hence, there is a strong "gradient", as the worst-case objective changes quickly when the high impact scenarios are covered. This gradient allows greedy and SA to work well. On other hand, for Z_1, the maximum achievable penalty reductions, $F_i(\mathcal{V})$, are constant, since all scenarios have the same simulation duration. Unless *all* scenarios are detected, the worst-case detection time stays constant at the simulation length. Hence, many node exchange proposals (i.e., steps in the local search) considered by SA, as well as the addition of a new sensor location by greedy, do not change the worst-case objective, and the algorithms have no useful performance metric.

Figures 1(c) and 1(d) compare the placements of SATURATE (when optimizing the

(a) *Pareto curve for* Z_1 (b) *Pareto curve for* Z_2

Figure 2: Experiments on trading off worst-case and average-case penalties minimizing detection time (a) and affected population (b).

worst-case penalty), and greedy (when optimizing the average-case penalty, which is submodular). Optimizing the worst-case performance leads to reasonable performance in the average case performance, but not necessarily vice versa (especially when considering the detection time).

Trading off worst-case and average-case performance. We also performed experiments trading off the worst-case and average-case penalty reductions, using the approach discussed in Section 3.3. We first ran the greedy algorithm to optimize the average-case performance, and then ran SATURATE to optimize the worst-case performance. We considered the average-case performances c_{ac}^{greedy} and $c_{ac}^{Saturate}$ obtained by both algorithms, and uniformly discretized the interval bounded by these average-case performances. For each performance level c_{ac} in the discretization, we use the modified SATURATE algorithm as described in Section 3.3, maximizing the worst-case performance, subject to a constraint on the average-case performance. Each possible value of the constraint on c_{ac} can lead to a different solution, trading off average- and worst-case performances. Figure 2(a) presents the tradeoff curve obtained in this fashion for the detection time (Z_1) metric, for different numbers k of placed sensors. We generally observe that there is more variability in the worst-case performance than in the average-case performance. We can also see that when placing 5 sensors, there is a prominent knee in the tradeoff curve, effectively achieving the minimum worst-case penalty but drastically reducing the average-case penalty incurred when compared to only optimizing for the worst-case performance. The other tradeoff curves do not exhibit quite such prominent knees, but nevertheless allow flexibility in trading off worst- and average-case performances. Figure 2(b) presents the same experiment for the population affected (Z_2) metric. Here, we notice prominent knees when placing $k = 15$ and 20 sensors. We can generally conclude that trading off average- and worst-case performances allows to effectively achieve a compromise between too pessimistic (only optimizing for the worst case) and optimistic (only optimizing for the average case) objectives.

5 RELATED WORK

Carr et al. [2006] consider the problem of robust sensor placements in water distribution networks. They formulate Mixed Integer Programs for selecting sensor placements robust against uncertainty in adversarial strategies and in water demands. Due to computational complexity of Mixed Integer Programming, in their experiments, they used only small networks of at most 470 nodes. SATURATE can potentially be applied to handle uncertainty in demands as well, which is an interesting direction for future work. Watson et al. [2006] consider different notions of robustness in the context of water distribution networks, intended to remove some of the pessimistic assumptions of purely robust sensor placements. They develop integer programs, as well as heuristics, and apply them to networks of similar size as the one considered in this paper. Their local search heuristic performs a sequence of local moves similar to those performed by the simulated annealing algorithm considered in Section 4, and does not provide any theoretical guarantees.

Closely related to the problem of robust sensor placement for contamination detection is the k-*center* problem. In this problem, one is given a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ along with a distance function defined over pairs of nodes in $\mathcal{V}$. The goal is to select a subset $\mathcal{A} \subseteq \mathcal{V}$ of size at most k, such that the maximum distance between any unselected node $s \in \mathcal{V} \setminus \mathcal{A}$ and its nearest center $s' \in \mathcal{A}$ is minimized. For this problem, Minieka [1970] discuss a technique reducing the solution of this problem to a sequence of set cover problems combined in a binary search, similar in spirit to SATURATE. However, they do not discuss any implications regarding approximation guarantees, and do not consider the case of arbitrary submodular functions. Mladenovic et al. [2003] presents a Tabu search heuristic for k-center, also without theoretical guarantees. Gonzalez [1985] and Hochbaum and Shmoys [1985] present a 2 approximation for the k-center problem in the case of symmetric distance functions satisfying the triangle inequality. Panigrahy and Vishwanathan [1998] present a $\log^*(n)$ approximation in the case of distance functions satisfying the asymmetric triangle inequality, which is shown to be best possible by Chuzhoy et al. [2005].

Anthony et al. [2008] consider robust and stochastic notions of facility location problems (such as k-center and k-median, where, instead of the maximum distance the average distance is optimized). In contrast to the robust problems in this paper that require to select k elements to *maximize* the minimum value achieved by these k elements over the m scenarios, the problems described by Anthony et al. [2008] require to select k "centers" in a metric space to *minimize* the maximum cost incurred over the m scenarios—where the cost is some function of the distances between non-selected vertices to the selected centers. For several such robust cost-minimization problems in cases where distances satisfy the symmetric triangle inequality, they present an algorithm that opens k "centers" and achieves an approximation ratio of $\mathcal{O}(\log n + \log m)$ (where n is the number of nodes in the graph, and m is the number of scenarios).

6 CONCLUSIONS

In this paper, we presented our recent results [Krause et al., 2008a,b] addressing the problem of optimizing the placement of sensors for detecting contamination in metropolitan area size WDS. We considered both the problem of placing sensors that detect random, accidental contaminations well (as modeled in the Battle of the Water Sensor Networks challenge), and the problem of guarding WDSs against malicious attacks, where sensor network detection performance has to be optimized with respect to the worst possible contamination. We described an algorithm, SATURATE [Krause et al., 2008b], that can efficiently solve large robust sensor placement problems. The obtained solutions are provably close to optimal. Our algorithm can handle imprecise sensors that can fail. Our method can also be used to obtain placements that simultaneously perform well both for malicious (i.e., worst-case) contaminations, as well as accidental (i.e., average-case) contaminations. We reported results from applying our method to a large hypothetical distribution system with more than 12,000 nodes. Our results show significant improvement over existing techniques, such as state-of-the-art Simulated Annealing algorithms.

ABSTRACT

Understanding the potential health impacts that can occur from contamination events in drinking water distribution systems has been the subject of much research in recent years. Both the characterization of these impacts on distribution systems and the design of contamination warning system (CWS) sensor networks rely on models that vary widely in detail and representation of the actual system. A complete representation of the distribution system for even a medium-sized city can be enormously complex. Macro skeletonization is used to describe the aggregation of the network's nodes and pipes. Micro skeletonization is used to describe the aggregation of all post-service connection piping and system detail to the model node.

Models typically do not include information (pipe detail) beyond the service connection. In water systems dominated by multi-story buildings, such as commercial and residential high-rise buildings, considerable infrastructure (pipes, pumps, and tanks) are absent from the model. Previous work has evaluated the effects that varying levels of macro skeletonization have on the performance of sensor network monitoring designs. However, research investigating the impact to sensor network design performance due to the lack of post service connection piping and system detail is lacking.

This paper reports on the modeling of CWS sensor network designs for two real water systems. The first system is small and simple and the model has been artificially modified to include multi-story buildings. The second water system is actually dominated by multi-story buildings but its base model does not contain any micro-level detail. Geographical information system (GIS) tools and site-specific information are used to construct and arrange reasonable representations of the high rise buildings into the model. For each water system, EPANET simulations are performed along with public health impacts assessments and sensor network design optimizations. Evaluations are made between the skeletonized models (base models without post-service connection detail) and the multi-story building-enhanced models to assess the performance of sensor networks to reduce public health impacts.

1. INTRODUCTION

The intentional or unintentional contamination of a water distribution system can cause significant problems, including public health and economic impacts. Understanding the potential impacts which can occur from contamination events in drinking water distribution systems has been the subject of much research in recent years. For example, Nilsson et al. (2005) and Khanal et al. (2006) examined exposures of small water distribution system networks to contamination events. Murray et al. (2006) developed a model for the spatial and temporal distribution of health impacts in a distribution system. Davis and Janke developed a probabilistic model for the timing of tap water ingestion and illustrated the importance of the exposure model in estimating impacts when a water distribution system is contaminated (Davis and Janke, 2008a and Davis and Janke, 2008b).

Recent research has also focused on the development and application of optimization algorithms to determine where best to place sensor monitoring stations as a principal component of contamination warning systems (CWS) (Berry et al. 2006, Skadsen et al. 2008, Murray et al. 2008). CWS monitor water quality in order to detect intentional or unintentional contamination events.

Grayman and Buchberger (2006) developed an exposure model to estimate human exposures from water contamination events at the building fixture level based on the contaminated water traveling from the service connection and through a residential building. This work provided a conceptual approach for using EPANET to calculate public health exposures to contaminants in the tap water delivered at the fixture level. Later work by Grayman et al. (2008) discusses the potential vulnerability of large venue buildings in New York City by constructing example high-rise buildings to study building occupant exposure patterns. From this work, it was demonstrated how models of high-rise buildings can be constructed to study contamination events that originate from the distribution system supplying the building or from within the building. The study found that contaminant transport in residential buildings was sensitive to detailed fixture level water usage patterns defined by the occupants of the residence. The study also found that for high-rise buildings, contaminant transport into the building from the distribution system was primarily sensitive to the operational conditions of the building's water system, i.e., the timing of pump operation that fill internal tanks within the building.

The accurate prediction of potential impacts from water contamination events and the design of a CWS rely on calibrated hydraulic and water quality models. Distribution system models vary widely in detail and representation of the actual system (Walski et al. 2003). Complete model representations of the distribution system, especially for a large or even medium-sized city, can be enormously complex and difficult to run with available software tools. "S*keletonization"* is known as the process used to select the most significant attributes of the hydraulic network that can collectively still represent the overall behavior of the system (Walski et al. 2003). The level of detail in distribution system models can be described by the number of junctions in the model to the number of customer service connections representing the population served. Ratios of nodes to

service connections in the range of 1 to 5 characterize the most detailed distribution system models. If macro-skeletonization is used to describe the aggregation of the network's nodes and pipes, micro-skeletonization could be used to describe the aggregation of post-service connection piping and system detail to the model node.

Models typically do not include information, i.e., pipe detail, beyond the service connection. For water systems dominated by multi-story buildings, e.g., commercial and residential high-rise buildings, considerable infrastructure (pipes, pumps, and tanks) are absent from the model. Previous work has evaluated the effects that varying levels of macro-skeletonization have on the performance of sensor network monitoring designs; however, research is limited on the impact to sensor network design performance due to the lack of post-service connection piping and system detail (Janke et al. 2007).

This paper investigates the role that complex post-service connection plumbing plays on the estimation of public health impacts from contamination events and the effect that such complexity has on the performance of sensor networks supporting a CWS. The outcomes or performance of the sensor network designs are expressed in terms of potential public health impacts given appropriate intervention on the basis of implementation of a CWS.

The methodology used is provided in Section 2. This includes a description of the network models and the artificial enhancements implemented to include post-service connection detail, a brief overview of the exposure and health impacts assessment approach used, and the modeling and simulation approach used to estimate public health impacts and to design sensor monitoring networks. In terms of notation, impacts refer to the number of people sickened. Sensor design refers to the optimal locations to place sensors to provide useful information to minimize public health exposures.

2. METHODOLOGY

2.1 Model Development

Two real network models were used in the study, Network A and Network B. Their corresponding enhanced, multi-story representations are called Network A-MS and Network B-MS, respectively. Each base model represents a portion of an actual water distribution system. Table 1 provides a description of Network A, A-MS, and B-MS water system models. Data on the base Network B is not provided in order to not reveal the water system.

Table 1. Description of Networks A, A-MS, and B-MS water system models.

Network	Junctions	Reservoirs/Wells	Tanks	Pipes	Pumps	Valves
A	407	1	2	448	3	9
A-MS	959	1	186	1,000	187	9
B-MS	7,692	13	1,107	9,565	1,108	152

Networks A and A-MS represent a relatively small distribution system serving approximately 6,400 people. Figures 1 and 2 show Network A and Network A-MS, respectively. A commercial high-rise and a residential high-rise building were added to most demand nodes in Network A to create its analog network, A-MS. There were approximately 10 non-zero demand nodes which were not enhanced with the multi-story buildings due to network instability. The commercial and residential buildings differed in their demand patterns and the allocation of demand from the central, original model node. Demand from the original, non-zero demand node was randomly allocated to its associated commercial and residential counterparts. The demand patterns for the hypothetical commercial and residential buildings are shown in Figure 3. These demand patterns were developed based on the expert knowledge of the authors. The building representations were constructed in a Microsoft® EXCEL spreadsheet (manually) and then incorporated into EPANET as an input file. Each building representation consisted of three nodes, a pump, and a tank. Included in Figure 2 is an example schematic representation of the commercial and residential high-rise buildings added to the model. Although not easily visible in Figure 2, note that this representative example has been applied to nearly all the demand nodes in the model.

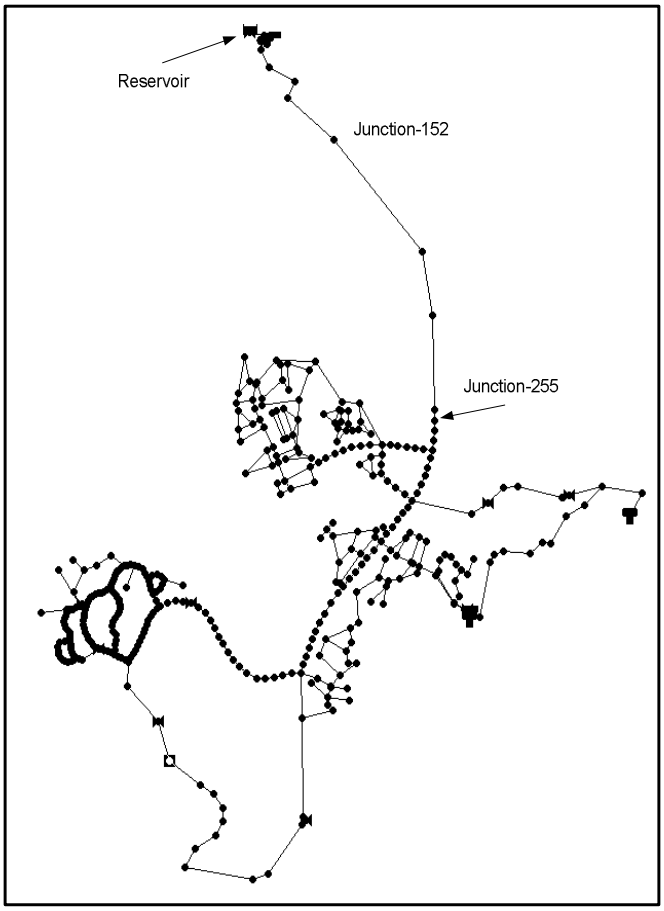

Figure 1. Network A model.

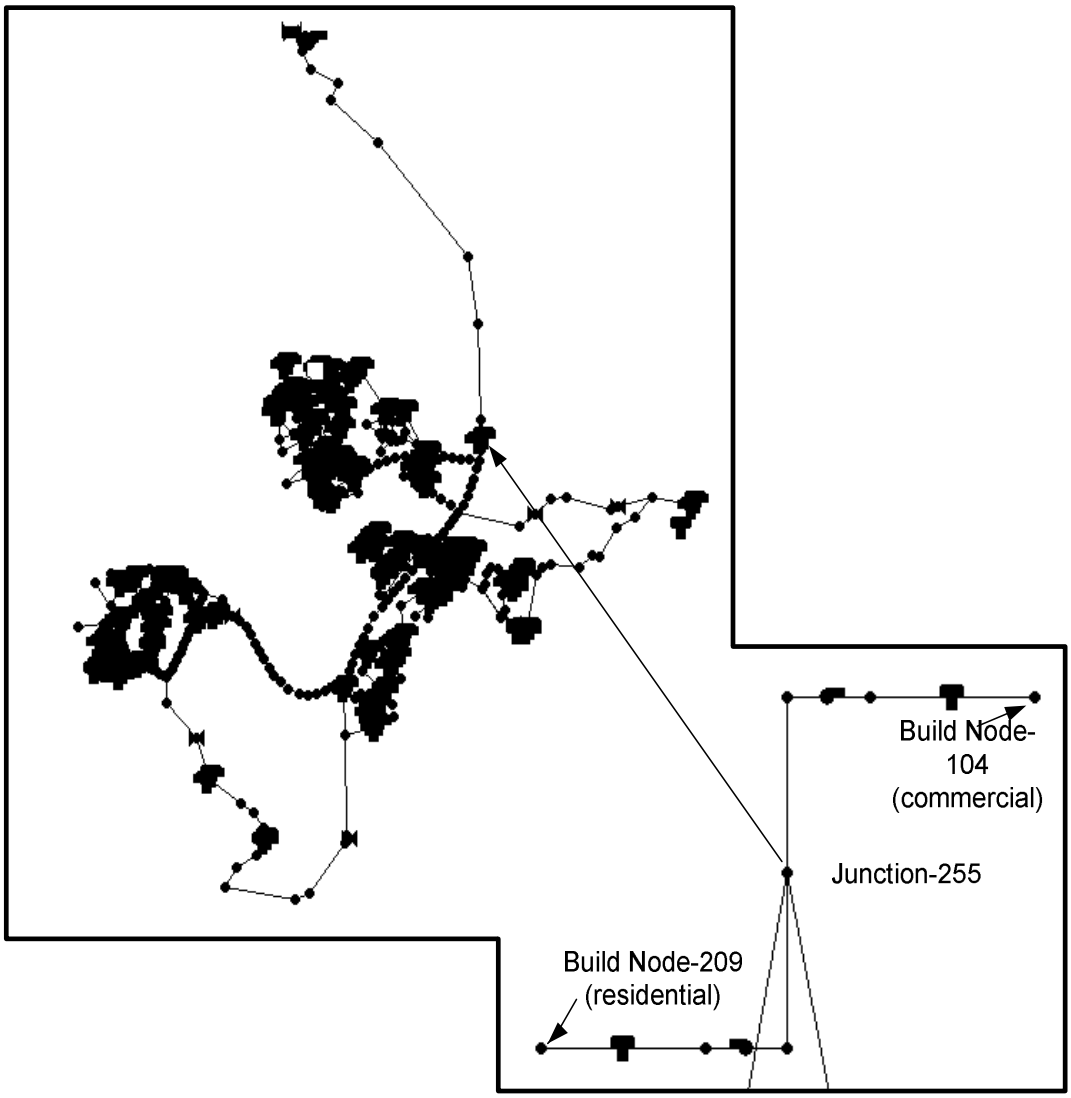

Figure 2. Network A-MS model and representative example of commercial and residential buildings added to nearly all demand nodes in the model.

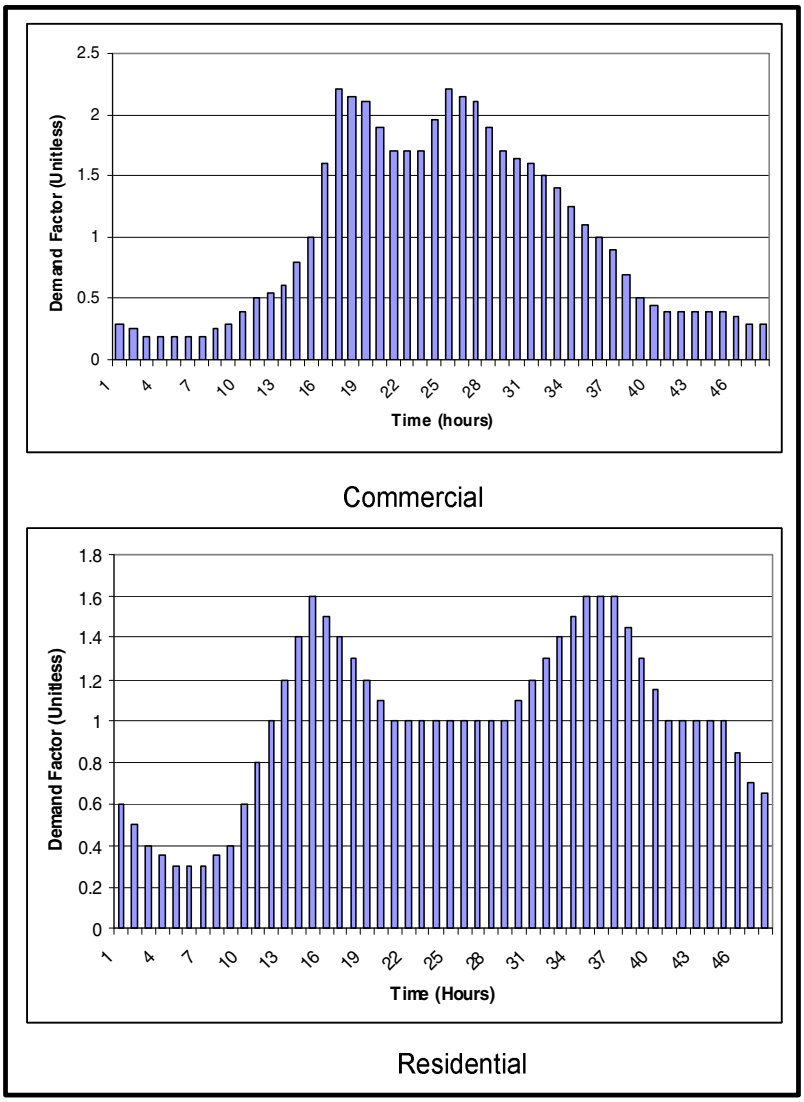

Figure 3: Commercial and residential demand patterns for Network A-MS. Patterns are hypothetical and repeat every 48 hours.

Based on modeling calculations using EPANET, Network A has an average water age of 61 hours and a median age of 59 hours, while Network A-MS has an average water age of 99 hours and median age of 96 hours.

The construction of the high-rise buildings in the Network B-MS model was performed by examining actual water demand data from the utility to determine the number of multi-story buildings to be added to each demand node in the model. Additionally, site-specific geographical information system (GIS) data were used to estimate the number and type of buildings (number of floors) which are served by the distribution system. The Network B model has an average water age of 4 hours and median age of 3 hours; while B-MS has an average water age of 5.3 hours and a median age of 4.5 hours.

Placement of the multi-story buildings in the model was performed manually. In representing the high-rise buildings in the modified model, two types of buildings were added: high-rise and super high-rise buildings. A high-rise building was defined to have an average water use of 20 gallons per minute (gpm); while a super high-rise building was defined to use 60 gpm. Although somewhat arbitrary, these allocations were used to generally reflect the total number of buildings served by the water system, as represented by the base model. When a base model node's demand was less than 20 gpm, no buildings were added to the node. Base nodes were redefined as low-rise buildings. The representations of the two types of high-rise buildings (commercial and residential) added to the model were consistent with Network A-MS. The type of GIS data available and used to determine the number and type (super high-rise, high-rise, low-rise) of buildings added or designated at each demand node in the model consisted, for example, of information on lot size (sq. ft.), building number and area (sq. ft.), and water use billing data. Table 2 illustrates the construction of the super high-rise, high-rise, and low-rise buildings added to each demand node in the B-MS model. Note, for example, Junction-A in Table 2, for this node no super high-rise buildings and only one high-rise building was added to the model. Although approximately 70 gpm remained as the residual demand at the base node, no additional super high-rise or high-rise buildings were added to this node because the total number of buildings added to the model was correlated with the total number and type of buildings present in the actual system.

Table 2. Illustration of how super high-rise, high-rise, and low-rise buildings were allocated using base demand in the Network B-MS model.

Allocation of Demand to Construct Buildings				
Network Nodes & Base Demand		60 gpm	20 gpm	Remaining Residual Demand
Node ID	Base Demand (gpm)	# of Super High-Rise Buildings	# of High-Rise Buildings	Base Node: Low-rise Building (gpm)
Junction-A	110.82	0	2	70.82
Junction-B	163.99	1	1	83.99
Junction-C	6.55	0	0	6.55

2.2 Population Model

Demand-based population models were developed for each network. For Network A, the population was estimated based on a per capita water usage rate of 200 gallons per day, which equated to a network population of approximately 6,400 people. For Network B, the population served represented approximately 600,000 people. The distribution of the 600,000 people across the non-zero demand nodes was performed using a per capita demand rate of 253 gallons per day. The total population of each building-enhanced model was checked to ensure consistency with the base model.

2.3 Contamination Scenario

The following was simulated for each model: (1) the independent injection of a hypothetical contaminant at each of the non-zero demand nodes in the network, (2) transport of the contaminant in the network following injection, and (3) exposure, dose, and dose response to those individuals who ingest the contaminated tap water from the network. A contamination scenario of one hour in duration was evaluated in each model. For example, for the Network A model, 106 independent simulations were run, one for each non-zero demand node. Each of these 106 simulations corresponded to one contamination event resulting from an injection at the particular node of interest. For Network A-MS, the same 106 simulations were run. The same procedure was followed for Networks B and B-MS. For Networks A and A-MS, the contaminant release started at 12:00 AM. For Networks B and B-MS, the contaminant release started at 5:00 AM.

TEVA-SPOT (version 2.1.2) was used to simulate the contamination scenarios in each water distribution system model (EPA, 2009). TEVA-SPOT is a software tool developed to identify and analyze the consequences of intentional contamination introduced into drinking water distribution systems and use the quantitative information gained (termed impacts data) to determine where best to place a limited number of sensors to support a CWS. TEVA-SPOT (version 2.1.2) uses EPANET (Rossman, 2000) (version 2.00.10) as its primary simulation engine.

For each one hour contaminant release scenario, the injection mass was sufficiently large that significant contaminant concentrations and, therefore, exposures were obtained in each network. The same contaminant mass quantity was used for all networks. The contaminant behaves as a conservative constituent following injection.

Public health impacts were determined for ingestion of tap water only. Receptor (a person who ingests contaminated tap water) doses were determined in TEVA-SPOT using the fixed five timing of exposure model, which has been previously described (Davis and Janke, 2008a). The fixed five timing exposure model uses five times for ingestion of water based on results from time-use studies of when ingestion occurs. This timing model is based on the assumption that ingestion occurs in equal amounts at five fixed times, corresponding to three meals and midpoints between meals. Ingestion volume is based on the assumption that all individuals ingest 1 L of tap water per day (EPA, 2000). The resulting dose that a receptor receives of the contaminant is expressed as contaminant mass per unit of body mass (e.g., in units of mg/kg). All exposed individuals are assumed to have the same body mass, i.e., 70 kg, to determine impacts. Probit dose response parameters, e.g., lethal dose to 50% of population and beta slope factor, were input into TEVA-SPOT consistent with the behavior of the assumed contaminant. Public health impacts refer to the number of people sickened. Mean impact results were determined along with the principal percentile scenarios (10^{th}, 25^{th}, 50^{th}, 75^{th}, 90^{th}, and 100^{th}) from the complete ensemble of scenario results.

2.4 Sensor Network Designs

Sensor network designs were developed in TEVA-SPOT (version 2.1.2) using the heuristic algorithm and optimized for mean population exposed (pe-mean) objective. Optimization of average public health impacts means that each contamination release scenario was assumed to be of equal weight and therefore sensor placement was optimized over the average impact of all such releases, i.e., all non-zero demand nodes associated with the base, original model.

Sensor network design set sizes of 2, 5, and 10 sensor locations were selected for Networks A and A-MS. For Networks B and B-MS, additional sensor network design set sizes of 15, 20, 30, 40, and 50 were determined and compared.

Sensors were assumed to behave as perfect sensors and, therefore, able to detect the contaminant at any concentration above zero. TEVA-SPOT offers the capability to specify a contaminant detection limit, i.e., contaminant concentration below which the sensor will not signal the contamination event as well as the ability to specify the probability of sensor failure, but neither of these features was used in these preliminary analyses.

In terms of estimating public health impacts after sensor detection, it was assumed that public health response was instantaneous and, therefore, a zero hour response delay time was used in TEVA-SPOT. Response delay time is defined as the period in time from the initial, uncertain detection of the contaminant, by water quality sensors, to the confirmation of detection and the elimination of further exposures.

Sensor network designs were developed for the base (original) model. Sensor network designs of the same specifications were also created for each enhanced model. The comparison between the original model's sensor network design and the design from its analog was performed in TEVA-SPOT by fixing the optimized, original model's sensor locations into the building-extended model and running TEVA-SPOT. Comparisons of the public health impact results were then made using the percent difference of the original model's design with that of the building-enhanced design. Additionally, each sensor network design (original and building-enhanced) was evaluated for their ability to reduce the impacts from the base case of no sensors. Again, the building-enhanced models were used to assess sensor network design performance.

3. RESULTS

3.1 Impacts – No Sensor Monitoring

Table 3 provides selected percentile and mean public health impact results for each network given no sensor monitoring stations. These are the number of people sickened. For Network A and A-MS, it is the number of people sickened out of a possible 6,400 people. For Networks B and B-MS, it is the number of people sickened out of a possible 600,000. Impacts were rounded to the nearest whole number. The distribution of impacts across all of the scenarios evaluated for Networks A and A-MS do not differ except for the 90^{th} and 100^{th} percentile releases, which increase for the 90^{th} percentile

scenario and decrease for the worst case scenario under the building-enhanced model. Comparing Networks B and B-MS, the results for the building-enhanced model decrease for the higher percentile cases of 75th to 100th and increase for the lower percentile scenarios, with the mean being slightly less under the building-enhanced model.

Table 3. Public health impact results for the no sensors case for Networks A, B, A-MS and B-MS.

Statistic (based on demand node ensemble of base network)	Network A (# of people sickened)	Network A-MS (# of people sickened)	Network B (# of people sickened)	Network B-MS (# of people sickened)
10th	0	0	0	300
25th	10	20	900	1,300
50th	100	100	2,300	2,500
75th	600	600	4,200	4,000
90th	1,200	1,700	6,700	6,000
100th	3,500	2,500	17,000	13,000
Mean	500	500	3,000	2,900

The generally decreased health impacts for the building-enhanced models are consistent with the results reported in the conceptual work by Grayman and Buchberger (2006). This earlier work showed that post service connection plumbing caused a significant delay in time and decrease in concentration for the contaminant to reach the customer when a contaminant was released into the distribution system (Grayman and Buchberger, 2006). Comparing the worst case scenario results for Networks A and A-MS supports these findings with respect to the decreased concentration of contaminant. For Network A, the worst case scenario selected was junction-152; while for Network A-MS, the worst case scenario selected was junction-255. Comparing these two scenarios under just the A-MS model reveals that junction-152 now affected fewer people than under the original model, i.e., 2,000 exposures, with 90% of these impacts spread across 67 receptor nodes; while, junction-255 became the worst case release location with impacts of 2,500, 90% of these impacts were spread across 70 receptor nodes.

3.2 Sensor Network Designs & Performance

Table 4 provides the sensor network design performance results for Networks A and A-MS. Sensor network designs developed for Network A were evaluated in Network A-MS to compare results with the building-enhanced sensor network designs of Network A-MS. Results for percent difference (fourth column) are for Network A designs compared to A-MS designs. For example, for the 5 sensor building-enhanced design of Network A-MS, 10 people are sickened as opposed to 30 people for the Network A design. The percent difference is with respect to the building-enhanced design, hence (30-10)/10 equals 2, expressed as a percentage is 200%. Similarly, the results for percent reduction (fifth column) are with respect to the no sensors case for A-MS. Impact numbers were rounded to the nearest whole number as were the percent difference and percent reduction values. For the 2, 5, and 10 sensor network design sizes evaluated for Networks A and A-MS, the

building-enhanced designs performed between 25 and 200 percent better than their respective designs developed from the original model. The building-enhanced designs reduced public health impacts as compared to the no sensors case an additional 10 percent as compared to the original, Network A model's designs.

For Network A-MS, the optimal design of 2 sensors had an average event detection time of 4.6 hours. Similarly, the median and 95th percentile event detection times were 3.5 and 10.9 hours, respectively, for the optimal A-MS design of 2 sensors. The Network A's 2 sensor design had a average detection time of 5.28 hours, 50th percentile detection time of 4.3 hours, and a 95th percentile detection time of 12.8 hours. The 2 sensor design developed for the original Network A model and then evaluated in the A-MS model did not perform as well. The total number of events detected in the A-MS model was 75 for both designs. The total number of events evaluated in Network A-MS was 106.

Similar results were determined for Networks B and B-MS. For the larger range of sensor set sizes evaluated for Networks B and B-MS, the building-enhanced designs performed between 2 to 27 percent better than their respective designs developed using the original model. Generally, the percent improvements increased with increasing numbers of sensors. The building-enhanced designs reduced public health impacts for the no sensors case from about 2 to 9 percent as compared to the original, Network B model's designs.

For Network B-MS, the optimal design of 5 sensors had an average event detection time of 9.3 hours, median time of 8 hours, and a 95th percentile event detection time of 17 hours. The Network B optimal design of 5 sensors when evaluated in the Network B-MS model had an average event detection time of 10 hours, median time of 8 hours, and 95th percentile time of 26 hours. The optimal design for B-MS detected 1,430 events whereas the original model's design detected 1,240 events. The total number of events evaluated in Network B-MS was approximately 2,200.

For both networks, the building-enhanced sensor network designs differed in location from their original model analogs, with little overlap, although spatially the designs looked very similar. It is important to note that none of the added, building-specific nodes were selected by the sensor placement algorithm for either the A-MS or B-MS models.

Table 4. Comparison of sensor network design performance for Networks A and A-MS. All sensor designs were evaluated in Network A-MS. Mean impact estimates (# of people sickened), percent differences, and percent reductions are rounded to nearest whole number.

Sensor Network Design	Number of Sensors	Mean Impacts (# of people sickened)	Percent Difference from Network A-MS Optimal Design	Percent Reduction from No Sensors Case for A-MS
Network A-MS, No Sensors	0	500		
Network A-MS – Optimal Design	2	40		90
Network A – Optimal Design	2	50	25	90
Network A-MS – Optimal Design	5	10		100
Network A – Optimal Design	5	30	200	90
Network A-MS – Optimal Design	10	4		100
Network A – Optimal Design	10	10	150	100

4. DISCUSSION

The results presented indicate that the lack of post-service connection plumbing in distribution system models can have a significant effect on sensor network design performance. In comparisons of the smaller Networks A and A-MS, the improved sensor network performance obtained from the building-enhanced model designs ranged from 25 to 200 percent over the analogous designs developed with the original model. For the larger Network B, the building-enhanced B-MS sensor network designs improved sensor network performance by 10 to 30 percent over the analogous designs developed with the original model. Analysis of the event detection times further supported these findings for improved performance of the sensor network designs developed with the building-enhanced models. Sensor network designs developed with the building-enhanced models were able to detect contamination events faster than the corresponding designs developed for the base model. These results are preliminary and are based on perfect sensors and an instantaneous response to reduce public health impacts. These results are also only based on contaminant release duration of 1 hour.

The results reported here support earlier findings that by adding post service connection pipe and infrastructure detail to network models results in a significant delay in time and decrease in a contaminant's concentration to occur from the model node to the customer. The delay in time for the contaminant to reach the customer is due to the longer travel path. The decrease in concentration of the contaminant is due to greater mixing and dilution occurring.

5. NEXT STEPS

Research is underway examining the role that response time and contaminant detection limit has on the results presented above. Ongoing research is also examining the role that contaminant release duration has on such results. It is not clear whether the differences reported here represent significant differences, when site-specific and logistical constraints for sensor placement are taken into consideration.

Additionally, it is not clear if the population exposed objective evaluated is the most suitable to assess the sensitivity to post service connection plumbing details. For instance, would the objective to minimize extent of contamination (linear feet of pipe contaminated) be equally, more, or less sensitive? Similarly, would the objective for minimizing the time of event detection provide similar results? Additional research is needed to study and hopefully answer these questions in order to develop guidance on the application of sensor placement optimization tools, like TEVA-SPOT, to water distribution systems dominated by multi-story buildings.

COMPARATIVE EVALUATION OF TWO ALGORITHMS FOR LOCATING CONTAMINANT INGRESS POINTS

Hailiang Shen, Edward McBean, Mirnader Ghazali
School of Engineering
University of Guelph
Guelph, Ontario, Canada

ABSTRACT

A procedure involving Data Mining based on Flow Direction and shortest flow time (DMFD) is described, which consists of two components: (i) possible ingress nodes (PINs) identification and (ii) probability quantification. PINs identification is completed based on the flow information, i.e. the flow direction and time in each pipe. Through shortest time which is calculated by Dijksta algorithm, from one node to a specific sensor, ingress time in the node is obtained. A distance metric is described to quantify the probability of one node as PIN. A multi-stage response is described to decrease the elapsed time before a contaminant ingress event is identified and responded to, which is essential to minimize the risk from consumption of the hazard. The roles of two algorithms, namely a Data Mining method based on Injection and Detection information (DMID) and DMFD, are examined. A case study is employed in a network with 285 nodes and 5 sensors. The five sensors all alarm to the injection event. With DMID, the number of PINs is decreased from 44 in the 1st stage to 18, 11, 11 and 11 subsequently; For DMFD, the number is reduced from 44 in the 1st stage to 21, 21, 21 and 21 in the following stages; DMID identifies the true intrusion node 44 with the highest probability in the five stages, while DMFD identifies it with the highest probability in the 3rd and 4th stage; the run time of both DMFD and DMID is less than 2 min, which suggests the two are effective in guiding emergency response.

INTRODUCTION

In recent years, issues related to the quality of water within distribution networks are drawing increased attention from utilities since in most situations the water is beyond the last barrier which can assist in providing safe water to consumers. However, while it is of interest to be concerned with the quality of the water throughout the entire distribution system, it is infeasible to monitor the quality at more than a few nodes within the distribution network.

Given the preceding, and although significant efforts to protect against contaminant intrusion into the water distribution system are being extended, excursion events do occur. In response, of interest is the degree to which in-system monitoring systems with a limited number of sensors in combination with algorithms for contaminant trace back can identify the location of the source of the incursion or, possible injection nodes (PINs). Efforts to minimize the elapsed time to detection are appropriate to reduce health risk to water consumers and accomplished using a "multi-stage response".

LITERATURE REVIEW

A number of algorithms have been proposed for identifying locations of contaminant ingress into water distribution systems. For example, Shang et al. (2002) proposed

particle backtrack algorithms (PBA) to trace back the water parcel to source nodes to construct water quality parameter relationships between outputs and input, assuming a precise hydraulic condition is available. de Santic et al. (2006) extended PBA to locate all PINs and times by assuming contaminant injections occur at network junctions and over discrete time intervals. This approach may identify a large number of PINs. For an emergency response, it is only feasible to respond to a few PINs and hence this algorithm has limited utility since there are no probability assignments.

Preis et al. (2008) formulated the contaminant ingress identification problem as one of optimization and solved it using a Genetic Algorithm (GA). The decision variables (DV) are injection node(s), injection time(s), injection duration(s) and mass rate(s); the single objective is the minimization of the difference between modeled (it is a function of the DV and network parameters) and measured water quality within the sensor alarm period; since an injection event can happen in any node within the network, at any time, with any duration and mass rate, no constraint applies on the optimization problem. The algorithm may incur long running times and issues of convergence.

In DMID (data mining based on injection and detection information), a database containing injection and detection information is constructed to employ the procedure (Huang et al., 2008). The overall time consumed in DMID is related to the initial database construction which may require several days for large networks; however, since the database is constructed prior to a contaminant intrusion event (i.e. as part of a preceding analysis), the database construction time is not a significant issue although this may become a problem when the calibration of an hydraulic model occurs frequently. The ability of DMID in multi-stage response is described by Shen et al. (2008) in detail.

DATA MINING FLOW DIRECTION ALGORITHM

DMFD (data mining based on flow direction and shortest flow time), is based on flow time and direction in each pipe. The flow information is obtained by performing a hydraulic simulation with EPANET software. Two assumptions for the algorithm development are required:

i) If contaminant ingress occurs at one specific node, the contaminant will reach the sensor through the shortest time (through the shortest path). It is assumed that even in the situation of a contaminant which decays and/or is removed via water consumption, the contaminant concentration is sufficiently large that the monitoring system will detect its presence; and,

ii) Contaminant flow velocity is the same as that of water.

In the first stage within the multi-stage response procedure, the DMFD is executed to identify potential locations of ingress (albeit, with only a single sensor response, the range of possible ingress location may be quite large, but this approach avoids the need to wait until the second sensor (and the third, or more sensors) is impacted). Thus, the mean time for identifying the first response may assist in minimizing exposures of water consumers to the contaminant; in the second stage, with an alarm from both the first and second sensors, the PINs are decreased in number. This multi-stage approach, involving successive narrowing of possible source nodes, may be effective in minimizing the

timeframe for response action to the contaminant ingress. The implementation of the multi-stage response is completed with the DMFD, and is compared with DMID in term of PINs identification and probability quantification.

FLOW-DIRECTION MATRIX

A constant hydraulic condition is assumed. The first step in the procedure involves the development of the Flow-Direction Matrix. The data assembly includes: pipe index, pipe start and end node index, the flow direction in each pipe (a value of 1 indicates water flows from a specific node to a specific end node, '0' indicates the hydraulic head is the same in both the start and end node, and thus no flow occurs between the two nodes), velocity within pipe, pipe length, and flow time within the pipe. The assembly of information is stored in tabular format as per illustrated in Table 1, which serves as the base for algorithm development.

Table 1 Flow Information Within Each Hydraulic Time Step

Pipe index	Start node index	End node index	Direction	Velocity	Length	Time

Dijkstra's algorithm (Dijkstra, 1959) is a graphical search algorithm that solves the single-source shortest path problem for a graph with non-negative edge path costs, outputting a shortest path (SP) tree. This algorithm can be used to find the SP between two given vertices, or the shortest paths from source to each vertex in the graph. It searches SP from the source to the target by following the direction of edge flow. A water distribution network is a node-link system, which can be represented by a vertex–edge in a graph, and thus can be searched by graph theory. In contaminant ingress source identification for a water distribution network, of concern is the identification of the upstream node, given the downstream node, a modification of the Dijkstra algorithm is possible. The reverse direction of the flow is 'searched' instead of following the flow direction.

In the contaminant ingress source identification problem, of interest is the procedure to search the shortest flow time is formulated as follows:

Initialize the sensor S alarm time as 0 second, set $N_{DOWN,\ 0,\ N} = S$ (DOWN refers to downstream, 0 is the 0^{th} search forward, N is the node ID), i = 0, set $N_{DOWN,\ i} = N_{DOWN,\ 0,\ N}$.

(i) Find the upstream nodes of $N_{DOWN,\ i}$ based on Table 1 contents, and denote these relationships as $[N_{UP,\ i}]\ N_{DOWN,\ i\ ,j}$ (where UP refers to the upstream, i is the i^{th} search forward, j is the node ID within $N_{DOWN,\ i}$); union of $[N_{UP,\ i}]$ of each downstream nodes need to be put in the Next Search Nodes List (NSNL),

(ii) Update $[N_{UP,\ i,\ k}]$ (k is one node ID within $N_{UP,\ i}$) intrusion time, $N_{UP,\ i,\ k}(t) = N_{DOWN,\ i,\ j}(t)$ + flow time of pipe k-j; for node ID, k may be the upstream node of several downstream nodes, thus, take $N_{UP,\ i,\ k}\ (t) = MIN(N_{UP,\ i,\ k}(t))$,

(iii) Take $[N_{inter}] = [N_{UP,\ i}] \cap [N_{UP,\ i-1}]$, if $[N_{inter}] \neq \phi$ (null), $N_{UP,\ i,\ k}\ (t) = MIN(N_{inter}(t))$; set $N_{DOWN,\ i} = N_{UP,\ i}$,

(iv) The possible contaminant ingress nodes and their intrusion times are PINs= $\bigcup_{0}^{i} N_{UP,i}$ (t); i=i+1,

(v) Repeat step (ii)-(v) until the $N_{UP,\,i} = \phi$, i.e. all nodes reach source node (s).

The outputs of each search forward are:

i) NSNL,

ii) PINs up to the current search step.

To demonstrate the performance of the DMFD algorithm, consider the sample network composed of 5 nodes and 2 loops, where D and A are the source and sink nodes respectively.

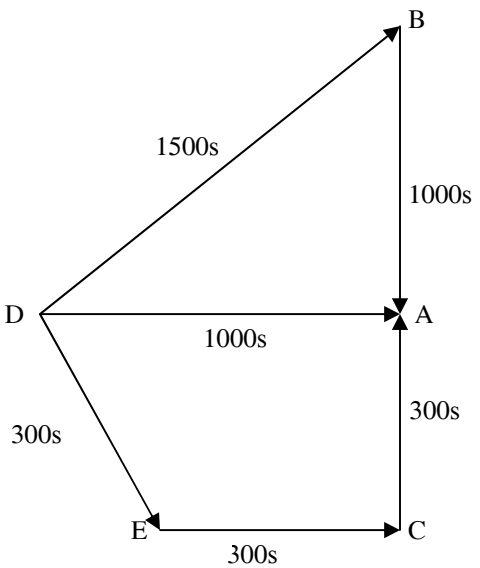

Figure 1 Example Network

Legend: 1000s equals the flow time of water in pipe B-A, (B-A is one pipe, and the water flows from node B to A) A, B, C, D and E are the node IDs.

Example

First search: The first search moves backward or upstream from A to find the PINs related to B, C and D. The relationship is denoted as [B, C, D] A, where A is the downstream node and [B, C, D] are the upstream nodes. The NSNL are B, C, and D.

If the contaminant ingress event happens in node B, the intrusion time should create an alarm at node A minus the flow-time in pipe B-A. Thus, the intrusion time at node B should be 1000s before the node A alarm time, which is denoted as B(1000s), (where B is the possible intrusion node and the label 1000s is the possible intrusion time), likewise for C (300s) and D (1000s).

The outputs of the first search are:

i) NSNL: [B, C, D],
ii) PINs up to this step: B(1000s), C(300s), D(1000s).

Second search: Find upstream nodes, and denote the relationships as [D]B , [E]C , [ϕ]D (D is the upstream node of B, E is the upstream nodes of C, and D has no upstream nodes.)
For node D, since there is no upstream node(s) contributing water to it, NSNL contains only D and E. The upstream node information is updated.
D = B(1000s) + $t_{B\text{-}D}$ = 1000s+1500s = 2500s, and
E = C(300s) + $t_{E\text{-}C}$ = 300s + 300s = 600s.
Compare with the output in the first search to get the outputs of the second search.
D = MIN (D(this step), D(previous step)) = MIN(2500s, 1000s), if contaminant ingress event happens in node D, the contaminant will flow via the shortest flow time 1000s and arrive at A.
There is no node E in the first search, thus E = 600s.
The outputs of the second search are:
i) NSNL: [D, E],
ii) PINs up to this step: B(1000s), C(300s), D(1000s), E(600s).

Third search: Find upstream nodes, and denote the relationships as [ϕ]D, [D]E, (where node D has no upstream node, and node D is the upstream node of E; D is the only node in the NSNL)
Update upstream nodes ingress time: D = E(600s) + $t_{D\text{-}E}$ = 600s + 300s = 900s.
D = MIN (D (this step), D (previous step)) = MIN(900s, 1000s) = 900s.
The outputs of the third search are:
i) NSNL: [D],
ii) PINs up to this step: B(1000s), C(300s), D(900s), E(600s).

Fourth search: Find upstream nodes, and denote the relationships as [ϕ]D, where D has no upstream node, so terminate the search.
The outputs of the fourth search are:
i) NSNL: ϕ,
ii) PINs up to this step: B(1000s), C(300s), D(900s), E(600s).

PINs INDENTIFICATION AND PROBABILITY QUANTIFICATION

Assume only a single intrusion event happens. In the first stage, the first sensor alarm, $PINs^1$ are identified with the procedure described. No probability can be assigned to $PINs^1$, or all $PINs^1$ have the same probability. In the subsequent stages, more sensors alarm, and $PINs^i$ are identified with the following conditions.
i) $PINs^i$ make the i^{th} sensor alarm,
ii) $PINs^i$ are within $PINs^{i-1}$.

Assume node N is the true intrusion node. In the first stage, sensor S1 alarms at time t1; in the following stage i, sensor Si alarms at time ti. From the procedure described above, sensor alarm time is initialized as zero, and the shortest times from N to S1 and Si are

calculated as ST1 and STi respectively. The intrusion time in N is ST1 and STi within the two stages. Without uncertainty from nodal demand and measurement, ST1 – STi is precisely the same as t1 – ti. Thus, the distance between abs(ST1 – STi) and abs(t1 – ti) can be used as one metric to quantify the probability of N as one PIN: the shorter the distance, the higher the probability.

CASE STUDY

The network after Huang et al. (2006) is presented in Figure 1 for the purpose of comparing DMFD and DMID in terms of the ability in PINs identification and probability quantification. The five sensor locations are optimized as per Huang et al. (2006).

In DMID, the following assumptions are made: i) the contaminant is conservative or the decaying coefficients in pipe are zero, ii) only single ingress location exists. Other parameters in database construction are: simulation duration, 72 hours; injection time interval, 1 hour; injection mass rate, 10^{10} to avoid being diluted or consumed to null.

The simulation single ingress event happens in node 44. Its detection information (i.e. the first detection time in each sensor) is listed in Table 2. The PINs in each stage are presented in Figure 2. For DMID, in the five stages, the number of PINs is subsequently narrowed from 44 to 18, 11, 11 and 11. For DMFD, the number of PINs is decreased from 44 in the first stage to 21 in the following four stages.

The procedure for the probability quantification in DMID is described by Shen, et al.(2008), and used herein. The probability is quantified by a Euclidean distance metric in response versus time 2-D coordinate, the shorter the distance, the higher the probability. The probability quantification is presented in Figure 3 through 7. In Figure 3, DMID identifies node 44 with the highest probability; DMFD cannot assign probabilities to each PIN. As presented in Figure 4, DMID identifies node 44 with the highest probability; DMFD identifies node 10 with the highest probability because its corresponding distance is the nearest to zero, and node 44 is identified as one PIN although it is not with the highest probability. In Figure 5 and Figure 6, for both DMID and DMFD, node 44 is identified with the highest probability as the location of ingress. In Figure 7, DMID identifies node 44 with the highest probability, and in the subplot, it shows the magnitude of the probabilities of PINs[5] are quite similar.

RESULTS AND CONCLUSION

This paper describes a multi-stage response procedure and its implementation with DMFD. Within each stage, Dijkstra's algorithm is applied to label the shortest time from each PIN to specific sensor as the ingress time of the PIN. One metric based on distance is used to quantify probability of PIN. In DMID, the database construction process may take hours to days, which limits its application in real time. While DMFD eliminates the database construction process and thus provides possibility for real time application when precise hydraulic condition is available.

As demonstrated in the case study, in the first stage, the two methods can identify the same PINs in the first stage, which suggests the effectiveness of DMFD in PINs identification. In the subsequent stages, DMFD identifies more nodes as PINs, which indicates it is inclined to provide conservative estimates of PINs while more sensors are providing information. In the following stages, DMID can identify the true intrusion node 44 with the highest probability, while DMFD can identify node 44 in the 3rd and 4th stage with the highest probability. The program run time of the two methods is within 2 minutes, and thus is sufficient to guide emergence response.

FUTURE WORK

In DMID, the number of PINs is sensitive to the assignment of value 'm' applied in the query sentences. It is set to 30 min for this research.
DMFD does not have the ability to deal with extended period simulation in the network. This functionality will be incorporated in the future.

ABSTRACT

Negative pressures were measured in a full-scale distribution system following low pressure events at a water treatment plant. Transient analysis was used to model three downsurge events and compare the simulated pressure profiles with field measurement data. The objective of this work is to assess the source of uncertainty and variability associated with the estimation of intrusion volumes calculated by a transient analysis model. This assessment was conducted by comparing actual field pressure measurements and model outputs under various model settings (e.g., cavitation head, wave speed). For the three downsurge events, the modeled pressure profiles matched reasonably well with the measured pressures, as long as the pressures remained positive at a site. When the pressures reached negative values, the amplitude of the modeled pressures was larger than that of the recorded pressures. The difference between measured and modeled pressure is strongly related to a greater energy dissipation in the real distribution system, which is affected by the uncertain presence of air in pipes, the level of network skeletonization, and the allocation of demand. The estimation of intrusion volumes and risk for public health is directly affected by the pressure results obtained using transient analysis. Comparison to field data is therefore important to evaluate the accuracy of such a process.

INTRODUCTION

There is a growing interest in the occurrence of negative pressures in drinking water distribution systems and their potentially negative impact on tap water quality. The importance of sustaining positive pressures throughout the distribution system in order to minimize intrusion was pointed out by LeChevallier et al. (2003a). In 2002, the U.S. Environmental Protection Agency (USEPA) listed intrusion as a potentially significant public health concern (LeChevallier et al. 2002). Aggravating factors are the aging of distribution infrastructures, the presence of contaminated water and soil around water mains (Besner et al. 2008; Karim et al. 2003), and the confirmed

incidence of negative pressure events in full-scale water systems (Besner et al. 2007a; 2007b; Fleming et al. 2006; Friedman et al. 2004). However, it is still difficult to determine if intrusion represents a critical risk to water quality. Transient analysis represents an interesting tool, but one must first verify that the transient hydraulic results adequately simulate the field observations. Comparison of computed pressures with corresponding recorded data is the initial step in such a process. Yet, few studies comparing transient field data with transient output from a numerical model are available, though there are several exceptions (McInnis and Karney, 1995; Kirmeyer et al., 2001; LeChevallier et al., 2003; Gullick et al., 2005; Friedman et al., 2004; Fleming et al., 2006). Among these authors, only Friedman et al. (2004) and Fleming and colleagues (2006) compared measured negative pressures with simulated pressures. The largest modelled network included 1700 nodes.

OBJECTIVES

The main objective of this research is to assess the public health risk associated with intrusion events in a distribution system. In order to do so, the source of uncertainty and variability associated with the estimation of intrusion volumes calculated by a transient analysis model must first be assessed. This paper describes the initial phase of this assessment, with the modeling of three downsurge events and the comparison of the simulated pressure profiles with field measurement data.

METHODOLOGY

The distribution system considered serves a population of about 380,000 with an average annual water demand of approximately 210,000 m^3/d (52.8 MGD). It is supplied by three water treatment plants (WTP) using surface water as their raw water source. Each WTP supplies to different network areas that are not delineated by isolation valves, making the three distribution systems hydraulically interconnected. Apart from the clearwells at the WTPs, no storage tanks or pump stations are needed on the water network because of the low profile topography. The distribution system has a total length of 1590 km (988 mi). The distribution system area studied is nominally supplied by a single WTP, as shown in Figure 1.

Ongoing pressure monitoring of the study area and the supplying water treatment plant was carried out for 17 months (June 2006 to November 2007), using high-speed pressure transient data loggers. Modeled events occurred during the summer of 2006.

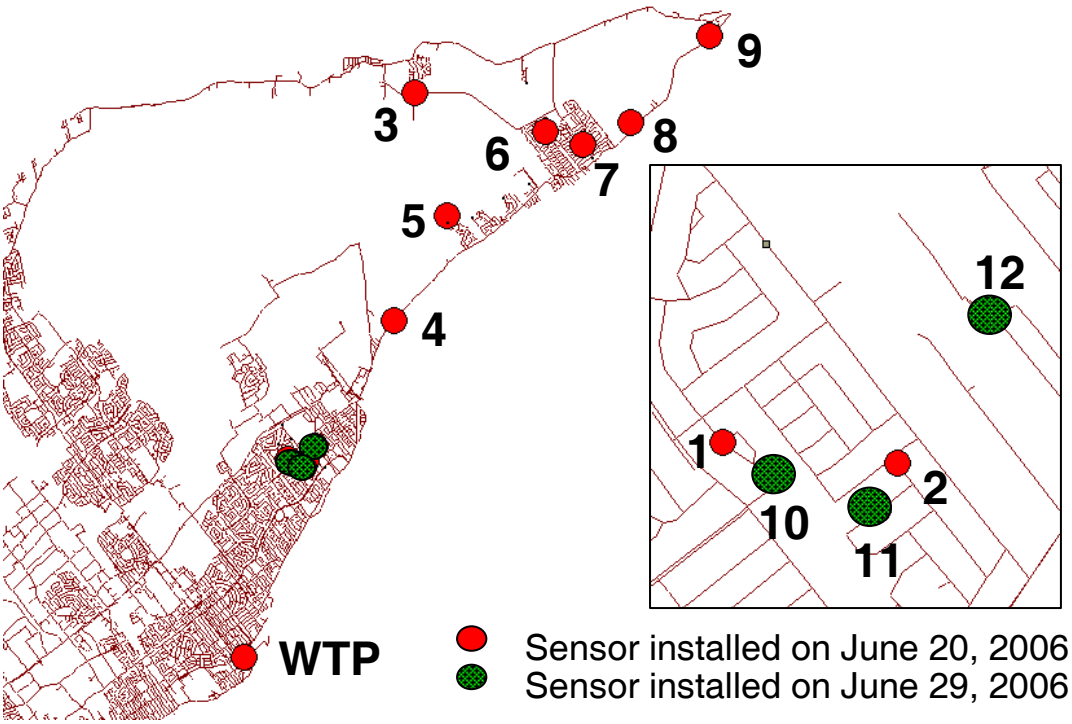

Figure 1. Location of high-speed pressure transient data loggers in the distribution system (number indicates sensor ID).

Pressure monitoring was conducted using two types of high-speed pressure transient data loggers. The RDL 1071L/3 model (Radcom Technologies, Woburn, MA) was installed directly on a transmission main at the outlet of the water treatment plant. This sensor can measure up to 20 pressure values per second within a range of -103 kPa to 1551 kPa (-15 psi to 225 psi). The other type of logger used (HPR31 model, Telog Instruments, Victor, NY) could read up to 4 pressure values per second over its -103 kPa to 1379 kPa (-15 psi to 200 psi) range; it was installed on fire hydrants in the distribution system.

Three specific downsurge events, originating from the water treatment plant and resulting in negative pressures in the distribution system, were modeled. These events were recorded in 2006 on June 27th, August 2nd, and August 22nd. They were caused by a power failure during which the electrical signal was disrupted for a brief moment, requiring the manual restarting of the pumps by the plant operator. Figure 2 illustrates a typical downsurge recorded at the water treatment plant.

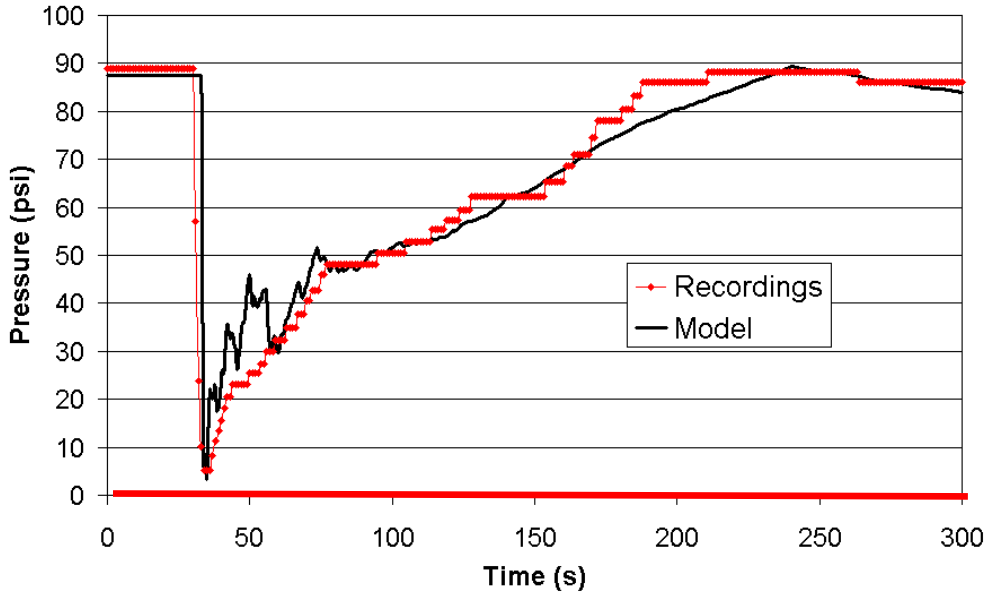

Figure 2. Downsurge recorded at the water treatment plant on August 22nd 2006, together with the modeled pressure profile.

Surge modeling, conducted with the InfoSurge software (MWH Soft, Arcadia, CA), was required to simulate these transient pressure events since they typically lasted less than 5 minutes.

The transient model was built from the extended period simulation (EPS) hydraulic model used by the water utility. Because the original model contains 29,213 nodes and 32,266 links, preliminary steps for the transient model construction included the skeletonization of the EPS model, aiming at reducing the number of links to below 20,000, the maximum limit of the employed software. This was achieved by eliminating the interior nodes of all series pipes with the same attributes (diameter, etc). The model size was decreased to 14,002 nodes and 17,055 pipes, whilst the total length of piping and the total demand remained unchanged.

Typical wave speeds based on pipe material were assigned to mains (Boulos et al., 2006): 1060 m/s (3480 ft/s) for cast iron, 1200 m/s (3940 ft/s) for ductile iron, 600 m/s (1970 ft/s) for concrete, 300 m/s (985 ft/s) for PVC, and 1200 m/s (3940 ft/s) for steel. Minor adjustments in wavespeed for pipe class and bedding conditions were not considered as part of this study.

For each low pressure event, the model's boundary conditions were defined using the pressure and flow out of the 3 WTPs supplying the distribution system. For the WTP supplying the studied area, up to nine high-pressure pumps are available to deliver water into the distribution system. However, because there is no record of which pumps were operating at a specific time in the past, one equivalent pump providing the flow and pressure conditions at the time of the low pressure event was modeled.

The downsurge was created by simulating a sudden pump shutdown using a pump speed change curve.

RESULTS AND DISCUSSION

Before considering the intrusion volumes, the transient model has to be calibrated. It was observed that a calibrated EPS model does not necessarily result in a calibrated transient model. It was also noted that negative recordings may provide useful information to properly calibrate a transient model. Indeed, the pressure profile modeled with a typical wave speed corresponds reasonably well with the measured profiles for locations where the pressure remains above zero for the entire duration of the simulation (Figure 3). However, the correspondence between recordings and pressures computed with typical wave speeds is considerably less accurate for the nodes where the pressure drops below zero (Figure 4).

It should be noted that the cavitation head in the model was set to a very low value (-1000 m) (-1422 psi) instead of the realistic value of -10.1 m (-14.4 psi) (at 20°C). This modeling approach was motivated by the fact that simulation results showed water column separation taking place at some nodes, yet measured data showed that the cavitation head was never reached at the monitoring locations.

As shown in figure 4, the modeled negative pressures were usually lower than the recorded pressures. Hence, the energy dissipation in the real network is greater that the modeled dissipation. This can be explained by attenuation mechanisms happening in the field that are not taken into account in the model. The most likely cause of attenuation in the real system is the presence of accumulated air, which is very difficult to evaluate and cannot be modeled directly with the transient analysis software. A modeling artifice is suggested in order to obtain better-fitting pressure profiles, and, in the end, more realistic intrusion volumes. The proposed solution is to reduce the typical wave speed by 70% in cast iron pipes. This wave speed reduction mimics other attenuation mechanisms. The wave speed was decreased only in cast iron pipes after testing several other alternatives, and because cast iron is the most common material in the studied network. Even if this modeling scheme is introducing a false delay in the arrival of the low pressure wave, it remains an attractive solution because of its simplicity and because of the better pressure fit, and thus can be assumed to be more likely to yield realistic volume estimates and number of nodes affected by negative pressures.

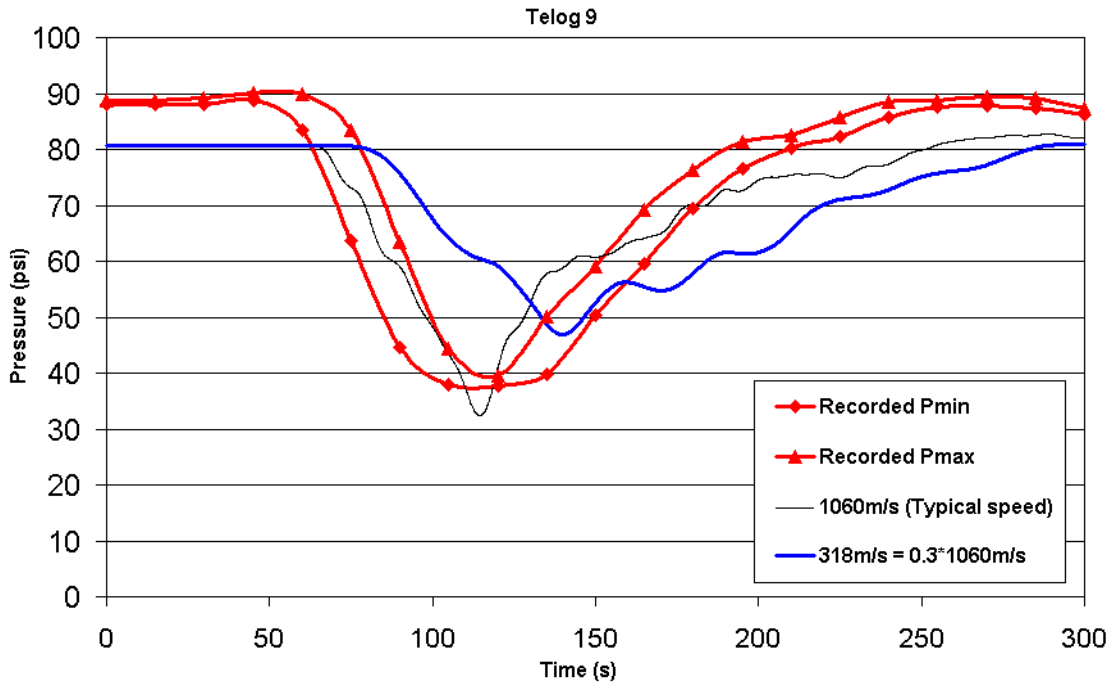

Figure 3. Recorded and modeled pressure profiles at Telog 9.

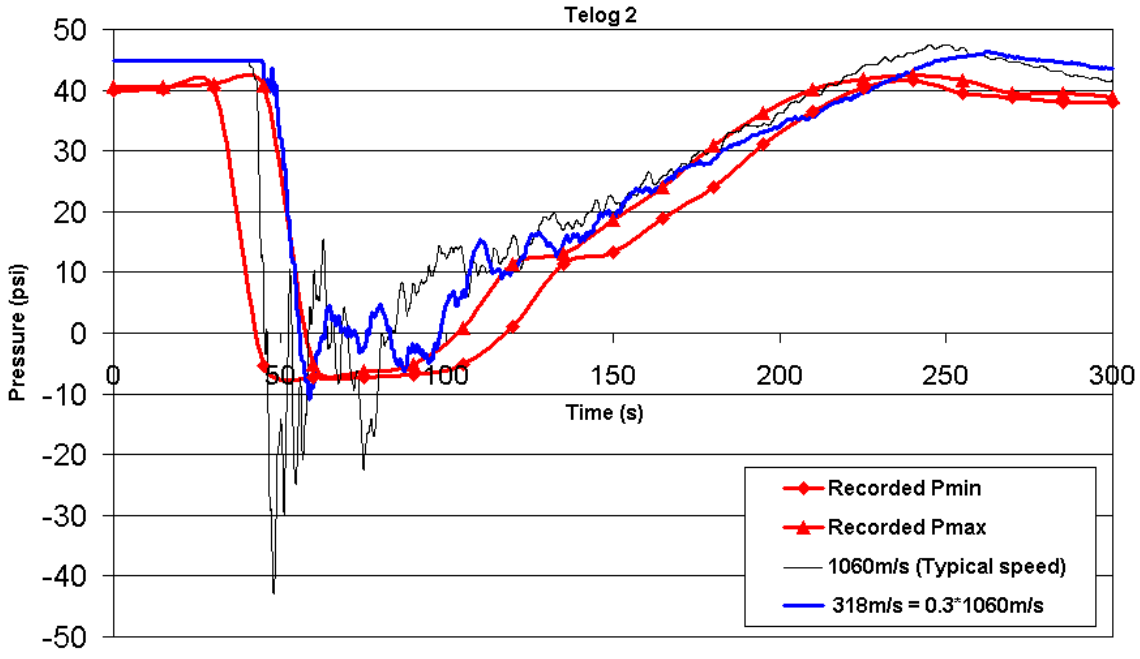

Figure 4. Recorded and modeled pressure profiles at Telog 2.

Intrusion volumes were evaluated for two pathways: pipe leaks and submerged air-vacuum valves located in flooded vaults. The results were based on simulations considering the pressure profiles obtained with 30% of the typical wave speed in cast iron pipes, as these were found to be more in agreement with field pressure results.

For the low pressure event recorded on August 22nd 2006, when the model is run with this wave speed, the total intrusion volume through pipe leaks is 45 L in the entire distribution system (Exit head = 1.4 m, Percentage of leakage = 20%). This volume is six times smaller than the volume computed when the typical wave speeds are used, and represents only $5x10^{-5}$ % of the system's total demand. The intruded volume of 1733 L through submerged air-vacuum valve (45 flooded vaults, Orifice diameter = 50 mm) drops to 102 L when the reduced wave speed in cast iron pipes is used. The wave speed, and its direct impact on the number of nodes experiencing negative pressure, therefore has a significant effect on the intrusion volumes.

CONCLUSION

The objective of this paper is to create a reliable transient model of a large distribution system. The simulated pressure profiles were compared to transient field data. For the three downsurges generated by a power failure at the water treatment plant, the computed pressures matched quite well the measured pressures for the monitoring locations where the pressure remained positive. However, the amplitude of the modeled pressures was larger than that of the recorded pressures whenever the pressure fell below zero. The difference between measured and modeled pressure is strongly related to a greater energy dissipation in the real distribution system, which is possibly accounted for by the uncertain presence of air in pipes, the level of network skeletonization, the allocation of demand and unknown pipe properties (e.g., pipe diameter, friction factor, thickness and material). It should be noted that many uncertain and unknown parameters in transient analysis make the calibration of the model with field data difficult, making the transient system underdetermined. The subsequent work of estimating intrusion volumes and risk for public health is directly affected by the pressure results obtained using transient analysis. Field data are therefore important to evaluate the accuracy of such a process.

Abstract

Water distribution systems are typically designed based on hydraulic and cost considerations. In the United States, most urban water systems are looped systems with large pressure zones that serve customers in regions of different elevation. In the United Kingdom, water distribution systems are frequently further subdivided into zones of several thousand connections called district metering areas (DMAs) in order to track and control water leakage. In two case studies, starting with existing large looped water system designs, the current systems are redesigned to: (1) approximate a typical DMA design; and (2) provide additional control and isolation capability in order to improve the water security of the system. The systems are then compared in terms of four metrics: (1) fire flow; (2) water age; (3) water security; and (4) reliability. Though the results of the analysis may not necessarily be generalized beyond the case study examples, the methodology provides a mechanism for evaluating alternative water system designs, and provides insight into the effects of water security criteria on system design.

Distribution systems, hydraulic modeling, water security, water quality

BACKGROUND

Water supply utilities are facing significant challenges within their distribution systems of both rehabilitating and replacing aging infrastructure, and developing new infrastructure in response to shifting population and development patterns. In most cases, aging infrastructure is replaced with new piping material that approximately mimics the location and characteristics of the original design (i.e., replace an existing cast iron pipe with a PVC pipe of the same size and routing). New infrastructure is generally designed to meet traditional standards associated with water consumption on a typical maximum demand day with a fire flow demand superimposed. Design objectives typically include minimizing cost and providing redundancy and reliability.

In the past decade, concerns about water security and water quality deterioration in distribution systems have been raised. However, there has been only limited work to determine how these concerns may be addressed in the design of new water systems or rehabilitation of existing systems.

In the United States, water distribution systems are typically designed as either looped systems or branching systems or a combination of both. In the United Kingdom, district meter areas (DMA) are frequently superimposed on a looping or branched system and used as an important element of distribution system design. Each approach to design has implications in terms of cost, reliability, system control, and other factors. The characteristics of each of these system designs are described below.

- Looped systems: In a looped system, larger transmission lines and interconnected local delivery pipes are used to deliver water to customers. There is extensive looping in both the transmission system and in the local lines so that there are generally multiple paths that water can follow from the treatment plant to customers.
- Branched systems: A branched system corresponds to a tree with larger pipes feeding smaller branches. In the extreme case, there are no loops and any disruption of a pipe causes outages to all downstream customers. Branched systems are most commonly found in rural water systems.
- District Meter Areas (DMA): A DMA consists of an isolated water distribution system zone for which there can be both control and calculation of flow amounts. It is an important concept in leakage management because the volume of flow into and out of the zone can be measured and abnormal usage can signal the presence of a leak problem. Zones generally contain between 1000 and 5000 connections and all inflow and outflow from each zone is metered.

An alternative design aimed specifically at improving security was suggested in a DHS sponsored study that is currently under review (Baker, 2007). This design incorporates elements of the three basic design concepts described above. The essence of this alternative is provided in the following statement:

> "The strategy is to configure the system using distribution blocks limiting their size to a maximum number based on the "acceptable" size of the contamination dispersion plume within the system. The maximum number of people served by one block could, for example, be limited to 5,000 people. It is important to note that block size and potential exposure are related. The larger the block size, the greater the potential exposure. Depending on the system, there may be a higher cost to implement smaller block sizes. Assuming the contaminant is fed into the distribution system through a house service or hydrant, the strategy is to limit the area of the distribution system where the contaminant could flow. Water would enter the "block" from the transmission system. No water would be allowed to leave the distribution block, i.e., all water entering the block would be consumed within the block."

Many of the concepts inherent in the DHS report are embodied in a distribution system that is divided into DMAs (Farley, 1985; Twort et al, 2000). Areas of similarity

include use of distribution blocks and controlled flow between transmission lines and the distribution blocks.

METHODOLOGY

In order to evaluate the effectiveness of different designs, a case study approach has been employed. Each case study starts with a hydraulic model of an existing water system design. The existing design is then modified to create alternative designs and the response and effectiveness of the original design and the redesigned water distribution systems are tested and compared. The redesigns are based largely on the concepts described in the DHS report (Baker, 2007) and the design of DMA-based systems. In order to evaluate the performance of alternative designs, four separate metrics are applied: (1) ability to provide fire flow requirements; (2) water age (as a surrogate for water quality); (3) water security as measured by health impacts resulting from a contamination event and by the length of pipes contaminated; and (4) a reliability index.

CASE STUDY 1

The initial case study focuses on one of the water systems used as part of the Battle of the Water Sensor Networks (BWSN) competition conducted at the Water Distribution System Analysis Symposium in 2006. This network serves approximately 150,000 people and is composed of 12,523 nodes and 14,822 pipes. An extended period simulation (EPS) EPANET model of the system is available representing average day conditions. The modeled system contains two reservoirs, two tanks, four pumps and five valves. The network is an approximate representation of a real world system. However, the geographic representation and names of the network have been adjusted and distorted in order to protect the identity of the system.

This system is typical of a looped urban distribution system. However, there is little topography in the service area, and as a result, is designed as a single pressure zone.

The present system was manually redesigned using the EPANET model as an aid in order to fit the DMA concept that is popular in the U.K. The system was divided into 43 DMAs by closing selected pipes (representing the closure of valves) and, in a few cases, adding or modifying other pipes. Target size for DMAs was in the range of 500 to 5000 connections each. This encompasses the DMA size of 2000 to 5000 connections suggested by Farley (1985) and the DMA size of 500 to 3000 connections suggested by Twort et al (2000). Preferably there should only be a single feed main for each DMA although this is not always possible. Farley (1985) suggests that feed lines should not exceed 300 mm (12 inches) in order to avoid costly meters. However, this too is not always feasible and may not be as significant an issue given improvements in metering since 1985. In some cases, many small lines serving only a few customers may be connected directly to a transmission line making their inclusion in DMAs difficult. In these cases, such lines may be excluded from the district metering system.

Since information on the number of connections at each node was not available, an average relationship between connections and water demand (known at each node) was developed. The total number of connections in the system is 77,916 and the average water usage is 16,408 gallons per minute. This corresponds to an average water use of 0.211 gpm/connection (or 304 gallons/day/connection). The distribution system network and resulting DMA zones are shown in Figure 1 and the characteristics of the DMAs summarized in Table 1.

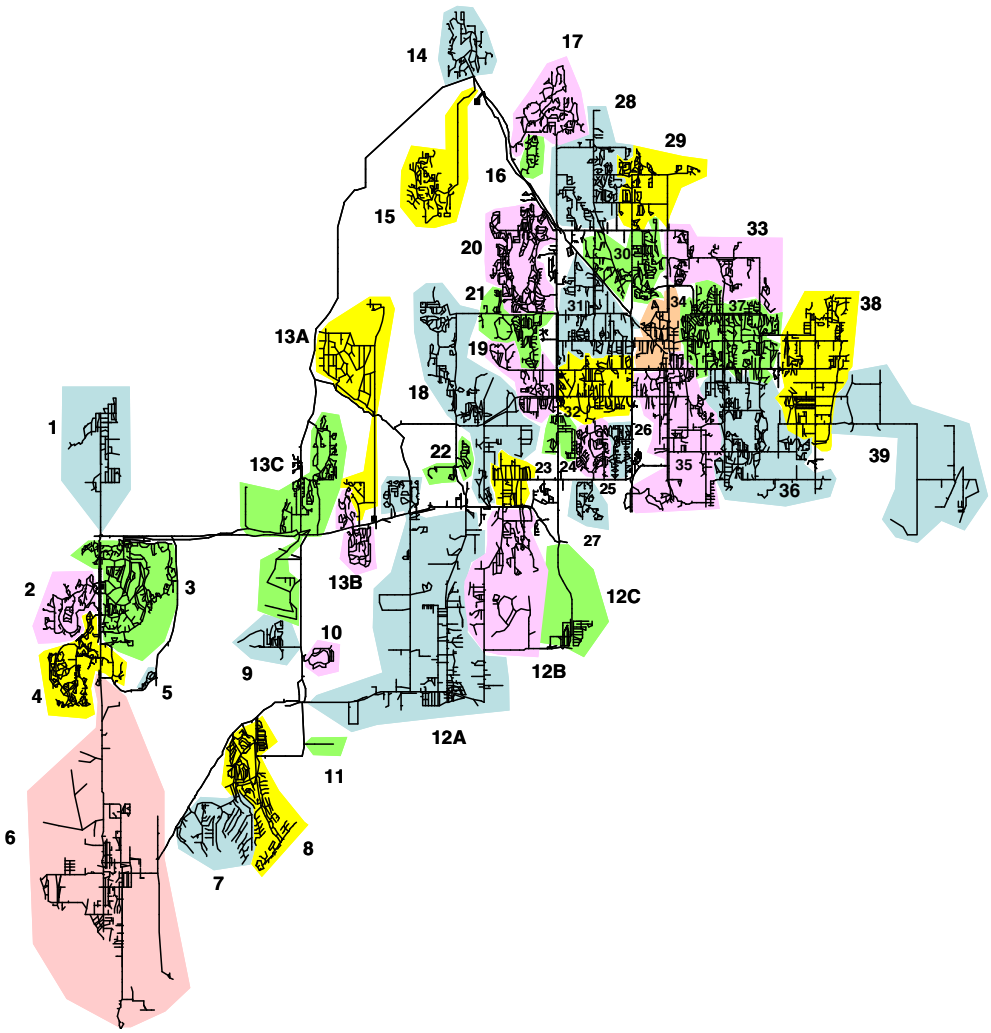

Figure 1. Case Study #1 Distribution System showing DMA Boundaries

The actual process of converting the model to represent a DMA-based water system was a manual, iterative process in which DMA boundaries were defined, feed lines identified, pipes (isolation valves) closed and, in a few cases, pipes modified or added. The modified EPANET model was repeatedly evaluated in the process to ensure the integrity and the hydraulic reliability of the redesigned system. Generally, the process of defining DMAs was more difficult in the central, denser looped part of the network than in the edges of the network. In the outlying parts of the system, frequently a DMA could be defined by simply "installing" a meter. At the other extreme, in the

central part of the system that was highly looped, multiple (sometimes exceeding over a dozen) pipes required closure in addition to multiple feeds and some existing pipe modifications.

In the process of creating the 43 DMAs, a total of 53 feed lines (meters) were defined, 163 pipes were closed, and only 11 pipes were added or modified. In all cases, the modified pipes involved the addition of only short stretches of pipes. In all cases except for one, there is no outflow from a DMA into either the transmission system or into another DMA. Of the 52 meters feeding DMAs, thirty meters are on 12" diameter lines while ten meters are on 8" and 10" diameter lines and ten are on 16" and 18" lines. The average number of connections per DMA is 1996 and, of the 43 DMAs, all but four fell within the target size of 500 to 5000 connections (three were smaller than 500 connections and one is slightly larger than 5000 connections). Less than ten percent of the total pipe length was excluded from DMAs.

The performance of the alternative designs is evaluated in terms of the four general metrics: (1) fire flow; (2) water age; (3) water security; and (4) reliability.

Fire flow Metric

One test of the efficacy of the DMA-modified system is its ability to provide sufficient fire flow. In creating DMAs, some pipes feeding an area are closed and this could have the impact of restricting the amount of flow entering a DMA or reaching remote portions of the DMA. The most critical situation that could be impacted by this would be low pressures resulting from large water demands associated with fire flow. In order to test this situation, the model was tested under a maximum demand day situation with a fire flow demand superimposed. The conditions used in this test approximated typical design standards used in the U.S.

The average day demand conditions represented by the model were converted to maximum day demands by applying a 1.4 global multiplier to all demands. Then, a 2-hour fire flow was superimposed from 12 PM to 2 PM. Initially, a value of 1400 gpm was used as the fire flow demand. Based on industry standards, a typical residential fire flow requirement is 750 to 1000 gpm while commercial fire flow requirements (without sprinklers) typically start at 1500 gpm. For each DMA, an interior node on a 6" or 8" pipe was selected as the location of the fire flow. There is no guarantee that this node would be the most critical node but short of performing an exhaustive test of all nodes, this provides a reasonable test of the ability of the system to adequately respond to a fire condition. The fire flow situation was tested by sequentially and separately applying a fire flow demand to each of the selected nodes. Initially, a 1400 gpm fire flow was applied and pressures at all nodes were checked to ensure that they were greater than 20 psi. If pressures were below 20 psi, then the fire flow demand was iteratively lowered until acceptable pressure levels were reached.

The analysis showed that for 75% of the DMAs, acceptable pressures (i.e., > 20 psi) resulted with the 1400 gpm fire flow. It should be noted that many of these DMAs could support fire flows much greater than 1400 gpm but the actual maximum fire

flow rate was not determined. For the remaining 25% of the DMAs, allowable fire flow values ranged from 400 gpm to 1200 gpm. The same procedure was used to test the same nodes in the looped model. The looped model frequently performed better (i.e., allowed for greater fire flow values), yet the difference between the two models was quite small.

Water Age Metric

Water age is frequently used as a surrogate to represent potential water quality deterioration in a distribution system. In this case study, a 192-hour hydraulic and water age simulation was run in the model for the original looped system and for the DMA-based system. The average water age during the final 24-hour period was then used to compare the results from the model. For each model, both the average water age and the demand-weighted average water age were calculated. The results are presented in Table 1.

Table 1. Comparison of Calculated Water Age for Alternative Designs

	Looped System	DMA System
Average water age (hours)	30.71	31.51
Demand weighted water age (hours)	20.88	20.77

As illustrated, there is no systematic difference in the calculated average water age between the alternative designs. Though there can be significant variations in water age by node, when viewed as a whole, no systematic difference was found.

Water Security Metric

Two water security metrics are used to compare designs. The first metric is the number of persons potentially exposed to a contamination incident. A method to estimate the potential health impacts resulting from contamination incidents in drinking water distribution systems developed by Murray et al, 2006, and implemented in the TEVA-SPOT software (USEPA, 2008), is used for this analysis. The second metric is the number of pipe feet contaminated during a contamination incident.

For this analysis, the contamination incident is assumed to occur when a 55-gallon drum of a biological agent with a concentration of 1E11 organisms/Liter is introduced at midnight for a period of 24 hours into a specific node in the network. The dose response curve is described by a probit function with a slope of 0.52 and an LD50 of 1.94E6. Each person drinks 2 Liters/day of water from the network, timed proportionally to the demand pattern at each node. Contamination incidents are simulated at all network nodes with positive demand (10,551 for this network, labeled Injection Node Set 1) and then the average impacts are calculated over this set of scenarios. A smaller set of all nodes with positive demand *and* within a DMA is also considered (9,924 nodes, labeled Injection Node Set 2) and results for both cases are presented below. The total impacts after 96 hours are shown in Table 2. This analysis assumes that no security measures are in place to prevent or reduce the impacts of

these incidents, nor are any measures taken to provide treatment to exposed persons. Thus, the results are overestimates of the likely public health impacts.

Table 2. Comparison of Water Security Metric for Alternative Designs

Metric	Injection set	Looped System	DMA System
Average # of people exposed	Injection node set 1	1,630	650
	Injection node set 2	1,420	440
Average feet of pipe contaminated	Injection node set 1	230,700	44,600
	Injection node set 2	209,700	23,200

The results show that the DMA System reduces the estimated number of persons exposed by more than 60% as compared to the original looped system, and the number of pipe feet contaminated by more than 80%.

Reliability Metric

An important concept in the design of a water distribution system is reliability in case of some unexpected hydraulic or mechanical failure. Todini (2000, 2008) proposed a resilience index as a measure of the degree of redundancy in a network. Resilience is defined as the intrinsic capacity of a network to overcome sudden failures, and it is measured as the ratio between the surplus of power delivered to users and the maximum power that can be dissipated in the network when meeting exactly the design criteria. A value of 30 psi was used as the design (minimum) pressure criteria. The availability of power allows water to find alternative pathways through the distribution system. Therefore, the resilience index provides an overall relative measure of redundancy with a higher resilience index value corresponding to higher redundancy. The resilience index was calculated over a 51-hour period for both the looped system and DMA system and an average, maximum and minimum value calculated for each system as shown in Table 3.

Table 3. Comparison of Resilience Index for Alternative Designs

	Looped System	DMA System
Average index	0.836	0.802
Maximum index	0.930	0.910
Minimum index	0.644	0.570

In all cases, the resilience index is slightly higher for the looped system than the DMA system (4% higher on average). However, the small differences for the indices between the looped and DMA systems, suggests that in this case, little is given up in reliability when moving from a looped system to a DMA system.

CASE STUDY 2

The second case study focuses on a portion of a municipal water system fed from a single water treatment plant and serving approximately 100,000 people. The distribution system encompasses approximately 400 miles of pipes. The network

model is composed of approximately 3,300 junctions and 3,800 pipes. Average water use for this area is 30 MGD.

An EPS EPANET model of the system was available representing average day conditions. The modeled system contains 34 tanks, 61 pumps and two valves. The service area topography has a range of approximately 900 feet and is divided into multiple pressure zones based on topography and connectivity. The network is an approximate representation of a real world system though the geographic representation and names of the network were adjusted and distorted in order to protect the identity of the system.

A manual procedure similar to the method used in Case Study 1 was employed to divide the service area into DMAs. Based on an estimate of 40,000 connections, an average relationship between connections and water demand (known at each node) was developed. This corresponds to an average water use of 0.53 gpm/connection (or 762 gallons/day/connection). The resulting DMA zones are shown in Figure 2.

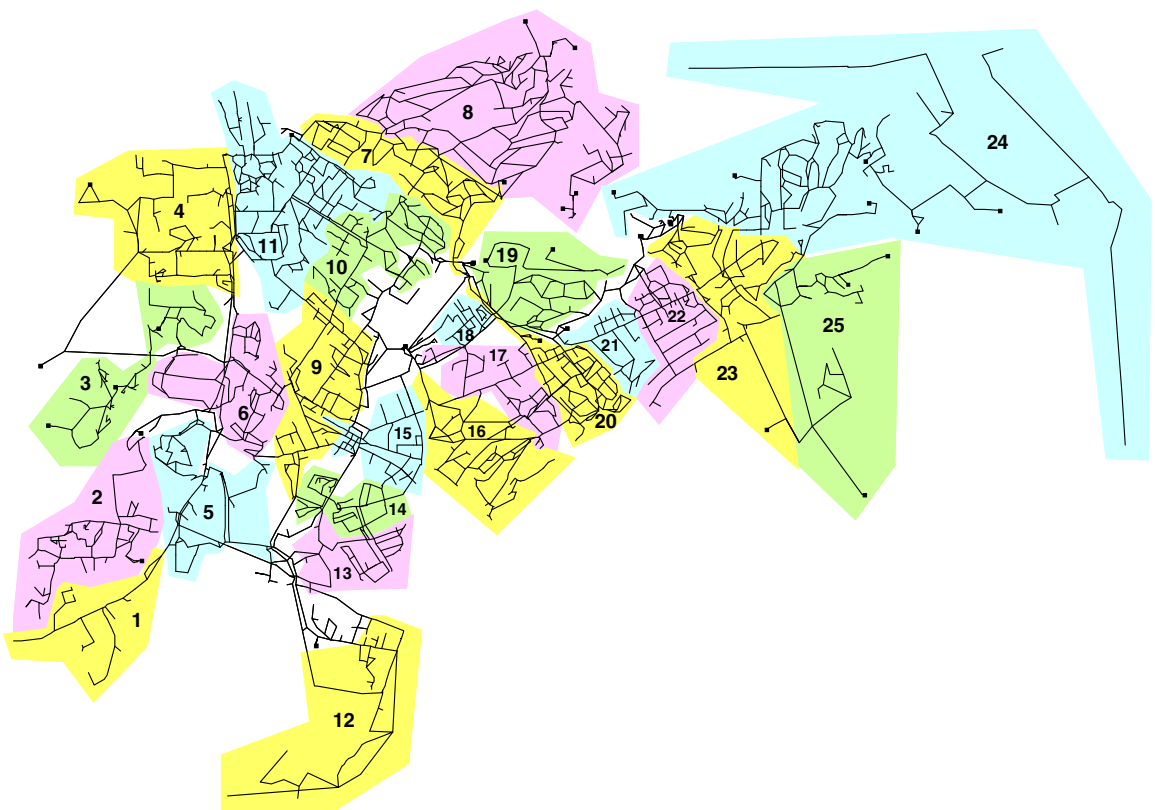

Figure 2. Case Study #2 Distribution System showing DMA Boundaries

The average number of connections per DMA is 1,517 and all DMAs were within the target size of 500 to 5,000 connections with the exception of one DMA that had 469 connections. It is estimated that less than two percent of the pipe length containing service connections was excluded from DMAs. In most cases, these pipes were fed directly from large transmission lines and it was impractical to include them in DMAs.

In most cases, the backbone transmission system was not included within DMAs but rather, delivered water to the DMAs. All but two of the DMAs that were created were fed by a single meter. The remaining two DMAs were fed by two meters. In the DMA creation process, a total of 102 pipes were closed, and only 2 pipes were modified. In all cases except for two sets of DMAs, there is no outflow from a DMA into either the transmission system or into another DMA. In most cases the meters were on pipes with diameters that exceeded the suggested 12" maximum size. This was necessitated by the current pipe configurations.

Fire flow Metric

A similar fire flow analysis similar to that used for Case Study #1 was applied to Case Study #2. The analysis showed that for 19 of the 25 DMAs, acceptable pressures (i.e., > 20 psi) resulted with the 1,400 gpm fire flow. It should be noted that many of these DMAs could support fire flows much greater than 1400 gpm but the actual maximum fire flow rate was not determined. For the remaining six DMAs, allowable fire flow values ranged from 800 gpm to 1,100 gpm. The same procedure was used to test the same nodes in the looped model. In the looped model all but two of the nodes supported a fire flow of at least 1,400 gpm and the difference between the two models was quite small.

Water Age Metric

Water age was used as a surrogate to represent potential water quality deterioration in a distribution system. In Case Study #2, a 960-hour hydraulic and water age simulation was run in the model for the original looped system and for the DMA-based system. The average water age for the last 24-hour period was then used to compare the results from the model. For each model, both the average water age and the demand-weighted average water age were calculated. The results are presented in Table 4. As illustrated, there does not appear to be an appreciable systematic difference in the calculated average water age between the alternative designs.

Table 4. Comparison of Calculated Water Age for Alternative Designs

	Looped System	DMA System
Average water age (hours)	69.14	73.33
Demand weighted water age (hours)	60.39	56.49

Water Security Metric

The simulation methodology and specific contamination incidents described for the first case study are utilized again here. Injection Node Set 1 includes all 1,621 nodes with positive demand, while Injection Node Set 2 includes 1,513 of these nodes that are within the DMA. The results presented in Table 5 show that the DMA System reduces the estimated number of persons exposed by more than 70%, and the number of pipe feet contaminated by more than 85%.

Table 5. Comparison of Water Security Metrics for Alternative Designs

Metric	Injection set	Looped System	DMA System
Average # of people exposed	Injection node set 1	6,500	1,870
	Injection node set 2	5,850	1,180
Average feet of pipe contaminated	Injection node set 1	415,000	55,700
	Injection node set 2	390,520	30,800

Reliability Metric

The resilience index was used as a measure of the reliability (redundancy) of the distribution system with higher values of the index corresponding to greater reliability. The resilience index was calculated over a 48-hour period for both the looped system and DMA system and an average, maximum and minimum value calculated for each system as shown in Table 6.

Table 6. Comparison of Resilience Index for Alternative Designs

	Looped System	DMA System
Average index	0.267	0.276
Maximum index	0.547	0.651
Minimum index	0.075	0.076

In all cases, the resilience index is slightly higher for the DMA system than the looped system (3% higher on average). This suggests that there was no loss in reliability when moving from a looped system to a DMA system and in fact, a slightly greater degree of reliability resulted.

CONCLUSIONS

Two case studies were conducted using computer modeling of distribution systems in the United States to evaluate distribution system design in terms of several metrics. In each case, the current looped water distribution system was redesigned to incorporate aspects of district metering areas (DMAs) and other concepts that may reduce the impacts of security breaches. Following are several conclusions reached concerning these results. Though the results of the analysis may not necessarily be generalized beyond the case study examples, the methodology provides a mechanism for evaluating alternative water system designs, and provides insight into the effects of water security criteria on system design.

1. The process of converting from a looped to a DMA-based distribution system required many pipe closures and additions of check valves. However, on paper, the design changes were relatively minor to implement.
2. Conversion from a looped to a DMA-based distribution system resulted in only slight decreases in the availability of fire flow.
3. The reliability of DMA-based systems as compared to looped systems (as measured by a resilience index) was approximately the same.
4. There was no systematic change in water age when moving from a looped system to a DMA-based system.
5. When the distribution systems were changed from looped systems to DMA-based systems, there was a very significant improvement in water security

related metrics. The two metrics used to represent water security were the number of persons potentially exposed to a contamination incident and the number of pipe feet contaminated during a contamination incident. The DMA-based systems resulted in improved water security as measured by reductions of both metrics by 60 to 85%.

The results of this analysis suggest that significant improvements in water security could be achieved through redesign of both existing and new distribution systems without significantly impacting other design criteria. Further investigation of this concept is certainly warranted.

ACKNOWLEDGMENTS

The authors would like to acknowledge the assistance of the following people: Dr Raziyeh Farmani of the University of Exeter for her assistance in calculating the resilience indices; Don Ballantyne of MMI Engineering for his thoughtful comments and original insights on the design of water systems to improve security; and Robert Janke and Terra Haxton of the United States Environmental Protection Agency's (EPA) National Homeland Security Research Center for their insightful comments and suggestions. The EPA's Office of Research and Development collaborated in and partially funded this work. This research has been subjected to the Agency's review and approved for publication. The views and opinions expressed herein do not necessarily state or reflect those of the Agency.

ABSTRACT

Chlorine residual concentration is used as a protection from accidental and intentional intrusion of microbial contaminants in distribution systems. Monitoring chlorine residual with real-time sensors may enable detection of such intrusions. However, this necessitates prediction of chlorine levels and how they change under normal conditions and in the event of a microbial intrusion event. Existing multi-specie models require knowledge of specific reaction kinetics between chlorine and complex cellular matrices that are unlikely to be known *a priori*. Rather, we propose utilization of a parallel first order rate expression describing microbially-induced chlorine decay over a wide range of conditions. The model can be parameterized using a limited number of batch experiments. The model formulation is then integrated into EPANET-MSX using the programmer's toolkit. We present simulations of a series of microbial events in a small distribution system using the model. Our results indicate that change in residual induced by microbial intrusion events can be simulated in distribution system models. Chlorine residual signals can thus be predicted. Event detection is limited by lack of control of chlorine concentration at the time and location of the contaminant event, the unique species-specific chlorine reaction kinetics, and the changing demand patterns in the system.

INTRODUCTION

While modern drinking water treatment technologies have dramatically improved the biological quality of finished drinking water, emerging deficiencies in the distribution system are resulting in increasing numbers of infectious waterborne

disease outbreaks within the United States (Liang et al., 2006). The rate of incidence of outbreaks is projected to increase due to the aging of drinking water infrastructure beyond its intended design life resulting in more cracked, broken, or otherwise structurally compromised pipes (Geldreich et al., 1992). Also, the increased development of a non-potable water infrastructure for irrigation or industrial uses has resulted in more incidents of inadvertent cross connections which may contribute to biologically compromised water (Lahti and Hiisvirta, 1995). Further, there is on-going concern over threats of intentional biological contamination within distribution systems that could result in catastrophic morbidity and mortality (American Water Works Association, 2002; National Research Council, 2002).

Current regulations require water utilities to monitor the biological quality of distribution system water, which is often accomplished via grab samples and species or group specific assays such as heterotrophic plate counts. These methods result in temporally and spatially sparse data sets that do not provide adequate warning of a biological contamination event. Also, species specific detection is considered an impractical approach for early warning of contamination events given the large number of potential pathogenic biological contaminants that exist. A more practical approach that may enhance the probability of pathogen detection is an intelligent infrastructure equipped with sensors that monitor traditional drinking water parameters that are sensitive to biological contamination. In previous work, we have shown that free chlorine residuals at concentrations typically found within the distribution system are very sensitive to an array of bacterial species, including species that are resistant to chlorine as a disinfectant (Helbling and VanBriesen, 2007). Further, commercially available chlorine sensors have been shown to rapidly respond to injected contaminants within a distribution system (Helbling and VanBriesen, 2008; Hall et al., 2007) and batch determined reaction kinetics have been used to predict *in situ* chlorine response to injected bacterial species, which was validated by sensor response (Helbling and VanBriesen, 2008).

Much research has been published on placement algorithms for drinking water sensors used for contaminant detection, but these studies typically assume the availability of "perfect" sensors that can detect all potential contaminants with very low detection limits (Krause et al., 2008; Ostfeld and Salomons, 2004; Ostfeld et al., 2008; Xu et al., 2008; Berry et al., 2006; Berry et al., 2005). Of course, "perfect" sensors are not likely to ever be available, so in this work we consider the placement of *chlorine sensors* within a distribution system in relation to how *in situ* chlorine concentrations respond to biological contamination downstream from an event. Before we can consider placement algorithms optimized for non-specific detection of contamination events with chlorine sensors, we must first consider how one can model chlorine response to biological contaminants within a distribution system. Under normal operating conditions, free chorine concentrations can be modeled with water quality simulators such as EPANET (Rossman, 2000), which considers chlorine reactions within the bulk water and with pipe walls. An enhanced version of EPANET including an extension for multi-species reactions (EPANET-MSX, Shang et al., 2007) allows for the inclusion of additional reactive species. These reactions

are input within EPANET-MSX as a series of ordinary differential equations that represent all of the reactions between all of the reactants within the system.

With EPANET-MSX and the integral programmer's toolkit, sophisticated user defined scenarios can be simulated. The primary objective of this work was to develop a model within EPANET-MSX capable of simulating the dynamic response of free chlorine within a community distribution system to injected loads of specific bacterial contaminants. By modeling these interactions and the resulting propagation of chlorine response we can assess the potential of chlorine sensors to be used as sentinels of biological contamination within distribution systems. The following describes the development of the model and preliminary results of the simulations.

MODEL

Because EPANET-MSX allows for simple incorporation of rate expressions, the initial attempts at building the model were to define the reactant system as a set of ordinary differential equations. The most logical system of equations to describe chlorine response to biological contaminants is the set of equations:

$$\frac{dC}{dt} = -k_b C - k_w C - \sum_1^n k_n X_n C$$

$$\frac{dX_n}{dt} = \sum_1^n k_n \theta_n X_n C$$

where, k_b is the bulk water chlorine decay rate (determined in batch reactors); k_w is the pipe wall chlorine decay rate (determined from (Hallam et al., 2002)); C is the chlorine concentration; X_n is the total concentration of oxidizable cellular material of each biological reactant n (proteins, lipids, nucleic acids, etc.); k_n is the chlorine decay rate induced by biological reactant n; and θ_n is the stoichiometric coefficient relating how each biological reactant n reacts with chlorine. The parameters k_n and θ_n must be estimated first from experimental data. The parameter Q is used to define the fraction of each biological reactant in the system (for n=2, X_1=Q*X and X_2=(1-Q)*X). We utilized 4th order Runge Kutta to solve this set of ordinary differential equations and to estimate the parameter values based on data derived from over 100 batch experiments conducted over a range of initial free chlorine concentrations and with *Escherichia coli, Staphylococcus epidermidis*, or *Mycobacterium aurum* suspended in a chlorine demand free phosphate buffer (pH=7.2).

The most rigorous approach would be to consider *each* macromolecular reactant as a separate species by assuming $n \rightarrow \infty$. However, this approach is impractical it is not possible to analyze the specific biochemical reactions occurring in such a system with such detail. Further, it is also likely that initial oxidation of a rapidly reacting species would result in a product that also contains viable oxidation sites that react slowly; in other words X_1 can react and form X_2. Although a likely mechanism, it is again impractical to try to estimate the occurrence of these pathways without much deeper biochemical analyses. Therefore, in order to simplify the

conceptual model and for ease of calculation, we first analyze the set of equations considering only X_1 (a concentration of rapidly reacting cellular material) and X_2 (a concentration of slowly reacting cellular material) i.e. n=2.

The first complication in employing this model arose with the need to define input values for X_1 and X_2. How does one quantify an aggregation of cellular material that can be subsequently divided into rapidly and slowly reacting fractions? In reality, chlorine is likely reacting with specific oxidation sites on the various macromolecular components of the matrix. Any given macromolecular component may react differently and contain any number of potential oxidation sites. The decision was made to quantify the amount of total organic carbon (TOC) associated with each microbial suspension via UV-persulfate oxidation (2005) and use that concentration as a surrogate for all oxidizable cellular material. Using the input values of initial chlorine and the measured total organic carbon concentrations, 4th order Runge Kutta was used to estimate the parameters Q, k_1, k_2, θ_1, and θ_2 and the time dependent values of X_1, X_2, and C were obtained for each of the experimental data sets derived from the 100+ batch experiments. The estimated parameter values were obtained by minimizing the sum of the squares of the residuals between the observed and predicted chlorine concentrations (Microsoft Excel 2003, Solver).

The results showed that the estimated parameter values were inconsistent, with Q and k_1 varying over three orders of magnitude and k_2 varying over 6 orders of magnitude with no correlation to initial chlorine or cell concentrations. This suggests that this simplified conceptual model is not adequately representing the mechanisms and reactions occurring in this system. Further, while time dependent values of X_1 and X_2 are provided by the solution, there is no way to check whether these values are realistic as there is no way to quantify the change in concentration of cellular material over time within the experimental setup. A rudimentary sensitivity analysis on the input value X also showed that the estimated parameters are all very sensitive to relatively small changes in X, which is not ideal given the uncertainty inherent within the use of X as an input parameter.

Due to these complications, an alternative way to model the system's reactions was investigated by assuming an excess of cellular material reactant (a logical assumption for a contamination event) and employing pseudo nth order decay models. The models considered included: a pseudo first order model; a pseudo nth order model; a limited pseudo first order model; a limited pseudo nth order model; and a parallel pseudo first order model (**Equation 1**). This approach is consistent with the literature in this field for estimating chlorine decay associated with complex natural organic matter (which also contain several reactive components) within the distribution system (Haas and Karra, 1984; Powell et al., 2000b). Each of these models was used to fit the experimental batch data and values for the correlation coefficient (r^2), the residual mean square error (RMSE), the Akaike information criterion (AIC), and Bayesian information criterion (BIC) were determined. The results of the analysis showed that for nearly all batch studies, the parallel pseudo first order model had the highest r^2, and the lowest RMSE, AIC, and BIC. Further, the

parameter values for the parallel pseudo first order expression were deterministic for each microbial species and the estimated values of Q, k_1, and k_2 were strongly correlated with initial chlorine and cell concentrations (Helbling and VanBriesen, 2009). For these reasons, we continued toward a working model by using the parallel pseudo first order expression. The next challenge was how to incorporate this expression and its dynamic parameters into EPANET-MSX.

The analytical solution of the parallel pseudo first order expression is:

$$C_t = (1-Q) * C_0 * \exp(-k_1 t) + Q * C_0 * \exp(-k_2 t) \quad (1)$$

where, Q is the fraction of the chlorine that reacts with the slowly reacting cellular material (or just the stoichiometricly adjusted fraction of slowly reacting cellular material); k_1 is the rate in which chlorine reacts with rapidly reacting cellular material; and k_2 is the rate in which chlorine reacts with slowly reacting cellular material. Additional parallel terms could be added to account for cellular material that reacts at different rates (n>2), but analysis of the AIC and BIC of data fits after adding additional parallel terms did not improve the ability of the model to fit the data (data not shown). Thus we concluded that, for models of a parallel first order form, a two term model is most suitable for this application. However, EPANET-MSX requires input in the form of rate expressions. The following describes how the parallel pseudo first order expression was incorporated into EPANET-MSX.

The total chlorine concentration within the reacting system is the sum of the chlorine reacting with the rapidly and slowly reacting cellular material. With Q defined as the fraction of slowly reacting cellular material in the system, this is expressed mathematically as shown in Equations 2 - 4.

$$C_t = C_{fast} + C_{slow} \quad (2)$$

$$C_{fast} = (1-Q) * C \quad (3)$$

$$C_{slow} = Q * C \quad (4)$$

The rate coefficients k_1 and k_2 define the rate in which chlorine reacts with the rapidly and slowly reacting cellular material, therefore the rates of change of each of the chlorine fractions are given by Equations 5 and 6.

$$\frac{dC_{fast}}{dt} = -k_1 * C_{fast} \quad (5)$$

$$\frac{dC_{slow}}{dt} = -k_2 * C_{slow} \quad (6)$$

Analytical solutions of Equations 5 and 6 are given as Equations 7 and 8.

$$C_{t,fast} = C_{0,fast} * \exp(-k_1 t) \quad (7)$$

$$C_{t,slow} = C_{0,slow} * \exp(-k_2 t) \quad (8)$$

Substitution of the analytical solutions in Equations 7 and 8 into Equation 2 yields,

$$C_t = C_{0,fast} * \exp(-k_1 t) + C_{0,slow} * \exp(-k_2 t) \quad (9)$$

and substitution of Equations 3 and 4 into Equation 9 yields the final analytical solution for the parallel pseudo first order model (Equation 1), as frequently cited in the literature. Therefore, it is in this form, as two separate pseudo first order rate expressions (Equations 5 and 6), that the parallel first order expression is implemented within EPANET-MSX. This is consistent with the concepts of mass balance and reaction kinetics within EPANET-MSX.

The model was used to simulate the response and propagation of chlorine demand signals throughout a community distribution system. Use of the model is initiated by the following work flow: define network structure, system demand, dosed chlorine concentration, booster locations and doses, k_b, and k_w; initiate a hydraulic and water quality analysis within EPANET; define the time and location of the contamination event; the model determines the chlorine concentration at the time and location of the contamination event; the model determines the dynamic values for the parallel pseudo first order model, which are dependent only on contaminant type and initial chlorine concentration; the model calculates multi-species reactions and concentrations; repeat for each time step over the duration of the pulse contaminant input. The mechanics of the model were written in C++ and incorporated into EPANET-MSX using the programmer's toolkit. More details are available in Helbling and VanBriesen (2009).

RESULTS

Contamination simulations were carried out in the small network shown in **Figures 1** and **2**. This network was used in the Battle of the Water Sensor Networks (Ostfeld et al., 2008) and is available online at (ECWS). System architecture and demands have been previously defined for this network (Ostfeld et al., 2008) and k_b and k_w values were taken as typical values reported in the literature (Hallam et al. 2002; Powell et al., 2000a). A typical EPANET hydraulic and water quality analysis was then performed for an 8-day duration with the first 4-days of data discarded as an equilibration period.

For the first set of contamination simulations, the objective was to determine how chlorine demand signals propagate within a community distribution system. To establish a best-case scenario for signal propagation, Node J-30 (**Figure 1**) was selected as it is the Node with the highest degrees of centrality and reachability (Xu et al., 2008). Because a single Node was selected, we then decided to test how demand patterns may effect chlorine demand signal generation and propagation by selecting 8 contamination times spaced 3-hours apart over a 24-hour period. Therefore, we simulated the injection of *E. coli* and *M. aurum* at Node J-30 at 8:00AM,

11:00AM,…,5:00AM for a 40-minute duration embedded within Days 5 and 6 of an 8-day hydraulic and water quality simulation. Chlorine concentrations at each Node and at each 30-minute water quality time step was compared over Days 5 and 6 between the base case water quality simulation (no contaminant injected) and each of the contaminant injection scenarios. Detectable chlorine demand signals were defined as those generating a change in "typical" background concentration of >25% and are shown in a spatial analysis in **Figure 1**. It is clear from **Figure 1** that, while chlorine demand signal propagation is dependent on temporal demand patterns, significant changes in chlorine residual are evident at locations downstream and distant to Node J-30. Also of note are the differences attributable to the differences in reaction rates of each species tested; *E. coli* reacts quite rapidly while *M. aurum* reacts more slowly. For more details on the injection scenarios and results, see Helbling and VanBriesen (2009).

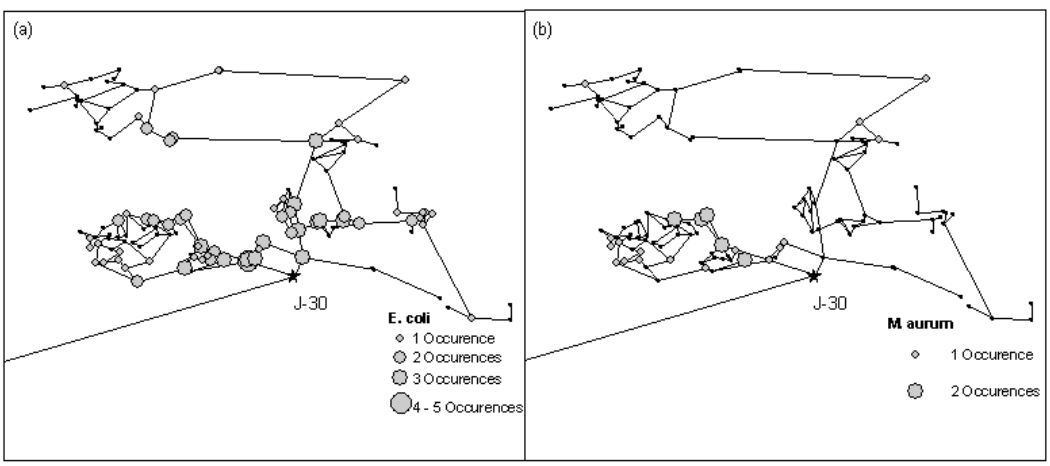

Figure 1: Spatial analysis of the number of occurrences of a >25% change in chlorine concentration for each of the: (a), eight *E. coli*; and (b), eight *M. aurum* injection simulations

Another spatial analysis considers each of the 16 simulations (8 *E. coli* plus 8 *M .aurum)* and determines the 10 nodes that see the greatest change in chlorine concentration during each contamination simulation. These 10 nodes would provide the greatest likelihood of detection in the case of a contamination event acting at Node J-30 while highlighting nodes that are less sensitive to species induced reaction rates. **Figure 2** shows that the majority of these nodes depend on system demand patterns that favor transport to the west of Node J-30. But interestingly, a significant number of nodes downstream and several nodes removed from Node J-30 are also consistently in the top ten nodes that see the greatest change in chlorine concentration. This result emphasizes that, when selecting locations for sensors as sentinel systems, nodes more downstream from centrally located nodes (like J-30) are ideal candidates for placing sensors as they are reachable by a larger number of nodes.

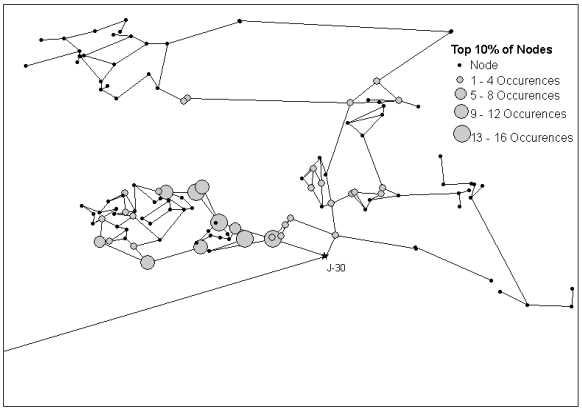

Figure 2: Spatial view of the top 10 most effected nodes over each of the 8 simulated contamination events for each contaminant

Another consideration for placement of chlorine sensors as sentinel systems is whether or not higher "typical" chlorine concentrations at the point of detection (the sensor location) can enhance detection; as it has been previously that higher chlorine residuals may result in greater changes in chlorine concentration during contamination events (Helbling and VanBriesen, 2007). To check this, we located all of the nodes that see a change in "typical" background concentrations of >25% during any of the 16 contaminant simulations and defined them as "sensitive nodes". We then need to determine if the chlorine concentrations are indeed higher at these sensitive nodes at the time of contamination. In **Figure 3**, we plot the distribution of chlorine concentrations at all nodes *and* at only the "sensitive nodes" at the time of maximum detection in the base case. The distribution shows that the median value of chlorine concentration in the system at the time of maximum detection during all simulated contamination events is approximately 0.40 mg/L. The median chlorine concentration at nodes that see a change in "typical" background concentrations of >25% is 0.58 mg/L. These distributions reinforce the hypothesis that higher chlorine residuals may result in greater changes in chlorine concentration during contamination events.

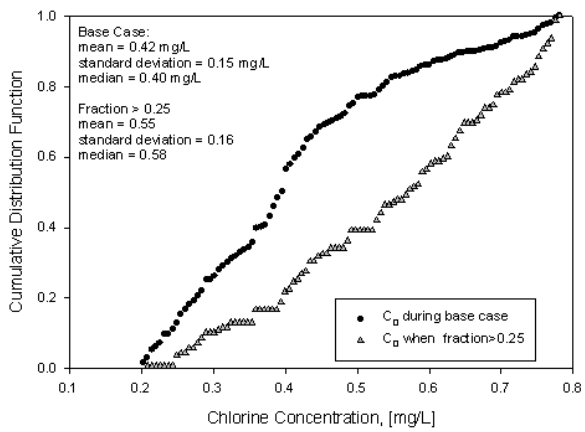

Figure 3: Distribution of chlorine concentrations at all nodes (black circles) and at sensitive nodes (gray triangles).

CONCLUSIONS

- A parallel pseudo first order decay model best fits experimentally determined chlorine demand generated by dense microbial suspensions for each species studied and for any cell or chlorine concentration
- Propagation of chlorine demand signals are dependent on distribution system architecture, demand patterns, and contamination location.
- Propagation of chlorine demand signals are dependent on species reaction kinetics and different species can result in maximum demand at different nodes
- Propagation of chlorine demand signals are dependent on chlorine residual concentrations both at the contaminated node and at the node of detection; greater residual concentrations result in enhanced detection capabilities.

Abstract: Bayesian analysis is applied to the problem of probabilistic source characterization in water distribution systems. An implementation of the Markov Chain Monte Carlo (MCMC) method is tailored to water distribution systems. The likelihood function, a key component of Bayes' rule, is approximated using a Monte Carlo-based stochastic water demand model. Limitations of the approach are also discussed.

keywords: uncertainty, inverse modeling, source identification, infrastructure security

1. Introduction

Research on water distribution analysis is understandably expanding as there is an increased focus on the security of water and other critical infrastructure. An important goal of water security is the development of an early warning system for water distribution systems. This paper focuses on the problem of source characterization immediately following detection of contaminant by a sensor network in a water distribution system.

Generally, contaminant source identification has been treated as an inverse problem without any stochastic modeling and a "best" prediction of the source (e.g., Waanders et al. 2003; Shang et al., 2005; Laird, 2005a; Preis et al., 2006; Guan et al., 2006). Some have adopted a probabilistic approach (e.g., Propato, 2007; Pousakis et al., 2003; Shang et al., 2008), but with the stochastic modeling limited to sensor measurement error. Dawsey and Barbara (2006) use Bayesian belief networks to identify the contamination node but they do not characterize its magnitude nor duration. This paper focuses on the development of a Bayesian approach to address several problem features, including multiple sources of stochastic behavior (e.g., in nodal water demand), uncertainty in multiple source characterization parameters (e.g., magnitude, start time, and location), and prior knowledge relating to possible source characterization scenarios.

In this paper, the serious computational challenges in applying Bayesian analysis to the problem of source characterization are addressed. For computational efficiency, the method of Markov chain Monte Carlo (MCMC) is applied. The contribution of the paper is an

MCMC implementation of Bayesian analysis tailored to water distribution systems.

In the write-up of the MCMC implementation, a simplified contamination case is considered, where the source location, start time, and magnitude are unknown. The anticipated ultimate use of MCMC is to allow for more uncertainty in the description of the source, e.g., allowance for multiple sources and multiple contaminant injection time profiles. The simplified case is targeted because it permits the development of a benchmark solution against which the MCMC implementation can be compared. The numerical scheme to identify the benchmark solution, a compute-intensive grid-based integration of Bayes' Rule, cannot be scaled up further while retaining accuracy.

This emphasis of this paper is on the MCMC method development. The method has been tested for a specific example network (EPANET2 example 3) but with simplifying assumptions with respect to the dynamics; the mean demand is assumed time invariant. A parallel implementation is being developed to relax this assumption and to incorporate hydraulic measurements and will be reported on in future work.

The organization of the paper is as follows. In section 2, the MCMC implementation is developed. In section 3, the limitations of the MCMC implementation are discussed.

2. Methods

In the modeling context, Bayesian analysis provides a basis for updating the probability of alternative model fits θ. In the water distribution source characterization problem, θ may refer to a vector of unobservable model parameters, including for example the contaminant source location, start time, and injection time profile. The initial uncertainty in the source characterization is described with the assignment of the prior probability, p(θ). The prior probability may incorporate expert knowledge regarding, for example, aging parts of the water distribution network that are vulnerable to a contamination incident. The problem of Bayesian analysis is to incorporate data, *y*, so that p(θ) can be revised to posterior probability, p(θ|*y*). In the source characterization problem, the data would originate from the sensors in the sensor network. In Bayesian analysis, this updating of p(θ) to p(θ|*y*) is governed by Bayes' theorem, a rule of probability:

$$p(\theta|y) = \frac{p(y|\theta)p(\theta)}{\int_{\theta} p(y|\theta)p(\theta)d\theta} \qquad (1)$$

The numerator of Bayes' rule consists of the product of the likelihood probability, p(*y*|θ), and the prior probability p(θ); the denominator is the integral of this product over all θ and can be thought to be a normalization constant to ensure that the posterior probabilities sum to unity.

Given a small number of components of θ, a grid-based integration scheme for evaluating the

denominator in Bayes' Rule may be possible and accurate. However, given a large number of components of θ numerical evaluation is often difficult and inaccurate; in such cases, MCMC is required (Gilks et al, 1996, p. 3).

MCMC involves drawing samples θ_j from a target distribution, which for Bayesian analysis is the posterior distribution $p(\theta|y)$, by running a specially constructed Markov chain. Provided the chain was run for a sufficient number of iterations, a random sample from the points in the chain would represent a random sample from the target distribution (Gilks et al, 1996). The Metropolis-Hastings algorithm, of which all MCMC implementations are special cases (Gilks et al, 1996), is given in Figure 1. The attractiveness of MCMC for Bayesian analysis is that in the computation of the ratio R, the problematic integral in Bayes' Rule (which is the same for all θ_j) cancels out.

For j = 1 to J

Sample θ_j^* from $j(\theta_j^*|\theta_{j-1})$

R= TargetDensity(θ_j^*)/TargetDensity(θ_{j-1})

$$A=\frac{j\left(\theta_{j-1}\middle|\theta_j^*\right)}{j\left(\theta_j^*\middle|\theta_{j-1}\right)}.$$

AcceptProb = min(R·A, 1)

If Rand() <= AcceptProb Then

Set $\theta_j = \theta_j^*$

Else

Set $\theta_j = \theta_{j-1}$

End If

Next J

where:

J is the sample size

θ_0 is the starting point (arbitrarily selected)

θ_j is the j^{th} iteration of the Markov chain

θ_j^* is the candidate point for inclusion as the jth iteration of the Markov chain; it is a random draw from the proposal distribution $j(\theta_j^*|\theta_{j-1})$

TargetDensity() is the probability density function from which samples are desired; for Bayesian analysis, the target density is the posterior density as given by Equation 1.

AcceptProb is the acceptance probability for the candidate point θ_j^*

Rand() is a random draw from a uniform distribution with a low=0 and high=1

Figure 1. Algorithm for sampling a target probability distribution with the Metropolis-Hastings algorithm.

The key aspect of the Metropolis-Hastings algorithm is the proposal, or "jumping", probability distribution from which a candidate point for inclusion in the chain, θ_j^*, is proposed based on the previous point θ_{j-1}. The key is to select a proposal distribution to ensure "good mixing" (not getting stuck exploring an area of locally high probability density to the exclusion of other modes of high density). However, other aspects (not shown in Figure 1) are also typically included in the implementation of MCMC: allowance for a "burn-in time" so that results are not skewed by the initial point that often is in a region of very low probability density, the adjustment of the proposal distribution based on the analysis of early results, and use of stopping criterion based on convergence tests. The challenge of this study was to develop an overall algorithm specific to the source characterization problem.

2.1. Application to the water distribution source characterization problem

In the description of the methodology that follows, several important assumptions are made. Among the assumptions, there is a single but unknown node X that is the source of contamination. The contaminant injection rate is a step function, beginning at an unknown time T and continuing indefinitely with a fixed but unknown magnitude M. Thus, overall $\theta=\{X,M,T\}$. Finally, there is one categorical sensor that yields at a time step t an indication of the concentration, C_t:

$$S_t = \begin{cases} U = \text{Undetected} & C_t < C^* \\ L = \text{Low} & C^* \le C_t < C^{**} \\ H = \text{High} & C_t \ge C^{**} \end{cases} \qquad (2)$$

C^* is the detection limit whereas C^{**} marks the cutoff between "Low" and "High". Over time, sensor data $y(t) = [S_0, S_1, \ldots S_{t-1}, S_t]$ is accumulated. Further, it is assumed that the sensor is perfect, i.e., there is no sensor measurement error; this is not a limitation of the approach (see Likelihood Model section below for explanation). The components of θ are a mixture of continuous and discrete variables—start time T and magnitude M are continuous while the contamination node X is discrete. In addition, the observations $y(t)$ are discrete. Hence, the appropriate version of Bayes' Rule should reflect that there is probability of an observation and not probability density:

$$p(\theta|y(t)) = \frac{P(y(t)|\theta)p(\theta)}{\int_\theta P(y(t)|\theta)p(\theta)d\theta} \qquad (3)$$

where P() refers to probability. (Also note that y has been replaced with y(t) to reflect that the data available is a function of time.)

Likelihood Model: P(*y(t)*|θ)

There are several sources of stochastic behavior in a water distribution system: stochastic water demands, sensor measurement error, and hydraulic and contaminant transport modeling errors. Here we focus exclusively on water demands. Sensor error is excluded from the analysis simply to focus on sources of random behavior such as water demand that must be propagated through the water distribution model to obtain a probabilistic prediction of water quality at the location of the sensor; in contrast, sensor error is simpler to incorporate as it can be added to the model prediction with introduction of an error term (e.g., see Shang, 2008).

We selected among the simplest of stochastic water demand models while recognizing that the Bayesian approach does not preclude use of an improved stochastic model. A simple stochastic model is considered: the variation about the deterministically estimated demand for node i, $\overline{D}_i(t)$, is described by a normal distribution:

$$Demand_i(t) = \text{Normal}(\overline{D}_i, \text{COV} \cdot \overline{D}_i) \qquad (4)$$

where the arguments for the Normal distribution are mean and standard deviation, respectively; COV is the coefficient of variation.

The likelihood, P(*y(t)*|θ), can be approximated with application of standard Monte Carlo simulation to the water distribution model EPANET 2.0. EPANET 2.0 is a program that performs extended period simulation of hydraulic and water quality behavior within pressurized pipe networks. N realizations of the water demands across all nodes and time steps can be generated, and for each realization, EPANET can be run to obtain N realizations of *y(t)*. The probability of each signal outcome at the sensor node is equated with the observed frequency within the set of N realizations.

MCMC proposal distribution

The selection of the proposal distribution, $j\left(\theta_j^* \middle| \theta_{j-1}\right)$ is the most important and problem-specific part of the Metropolis-Hasting algorithm. It was necessary to tailor a proposal distribution to the water distribution source contamination problem. The general recommendation of Gelman et al. (1995) was adopted: the proposal distribution was adjusted based on an initial preliminary investigation. We consider three phases: the jumping distributions are referred to as Phase I, Phase II and Phase III jumping distributions, and resulting chains as Phase I, II, and III Markov chains.

Below, one implementation of a general approach is proposed. The approach assumes bounded prior distributions for magnitude and time. As described below, the approach can be adapted to accommodate unbounded prior distributions (e.g., lognormal distribution for magnitude). Here, we use convenient distributions, the uniform and triangular, to emphasize the key aspects of the approach. Figure 2 provides a graphical indication of the approach.

Phase I proposal distribution

The Phase I proposal distribution specifies how the candidate for inclusion as the j[th] sample in the chain, $\theta_j^* = \{X_j^*, M_j^*, T_j^*\}$ is selected based on the previous sample in the chain, $\theta_{j-1} = \{X_{j-1}, M_{j-1}, T_{j-1}\}$. The Phase I proposal distribution $j^1(\theta_j^* | \theta_{j-1})$, is specified with assignment of independent jumping distributions for the three components of θ:

$$j^1(\theta_j^* | \theta_{j-1}) = j_X^1(X_j^* | X_{j-1}) j_M^1(M_j^* | M_{j-1}) j_T^1(T_j^* | T_{j-1}) \quad (5)$$

With the reasoning that nodes with substantial probability are likely to be located near to one another, the candidate node X_j^* is selected from the set of nodes adjacent to the most recent node X_{j-1}. However, to allow for the possibility that there is more than one pocket of posterior density, we allow for some small probability *p* of randomly jumping to a non-adjacent node in the network:

$$j_X^1(X_j^* | X_{j-1}) = \begin{cases} j \in Adj_{X_{j-1}} & \frac{1}{K_{X_{j-1}}} \\ j \notin Adj_{X_{j-1}} & p \end{cases} \quad (6)$$

In testing, it was observed that often for adjacent nodes there was a large difference in the range of posterior magnitude and start time. As a consequence, for these two components of θ we resorted to an independent MCMC implementation: the candidate magnitude and start times, M_j^* and T_j^*, were drawn from distributions that were independent of M_{j-1} and T_{j-1}, respectively.

Uniform probability distribution functions were used as the proposal distributions for magnitude and start time. Uniform(x,a,b) refers to the probability density of x given lower and upper bounds, a and b; DiscreteUniform(x,a,b) is the discrete version yielding the probability of x. The proposal distributions from which magnitude and start time were selected are:

$$j_M^1(M_j^* | M_{j-1}) = Uniform(M_j^*, a_M, b_M) \quad (7)$$

$$j_T^1(T_j^* | T_{j-1}|) = DiscreteUniform(T_j^*, a_T, b_T) \quad (8)$$

The parameters a_M and b_M, and a_T and b_T, are the lower and upper bounds of the prior distributions assigned to magnitude and start time, respectively.

With the jumping distribution as specified in Eq. 7-9, factor A in Figure 1 can then be computed. The value of A in Phase I, A_1, is:

$$A^1 = \begin{Bmatrix} j \in Adj_{X_{j-1}} & \frac{K_{X_{j-1}}}{K_{X_j^*}} \frac{Uniform\left(M_{j-1}, a_M, b_M\right)}{Uniform\left(M_j^*, a_M, b_M\right)} \frac{DiscreteUniform\left(T_{j-1}, a_T, b_T\right)}{DiscreteUniform\left(T_j^*, a_T, b_T\right)} \\ j \notin Adj_{X_{j-1}} & \frac{p}{p} \frac{Uniform\left(M_{j-1}, a_M, b_M\right)}{Uniform\left(M_j^*, a_M, b_M\right)} \frac{DiscreteUniform\left(T_{j-1}, a_T, b_T\right)}{DiscreteUniform\left(T_j^*, a_T, b_T\right)} \end{Bmatrix} \quad (9)$$

The terms involving magnitude and time cancel out due to the use of uniform distributions, i.e., $Uniform\left(M_{j-1}, a_M, b_M\right) = Uniform\left(M_j^*, a_M, b_M\right)$ and $DiscreteUniform\left(T_{j-1}, a_T, b_T\right) = DiscreteUniform\left(T_j^*, a_T, b_T\right)$. As a result, the expression simplifies to:

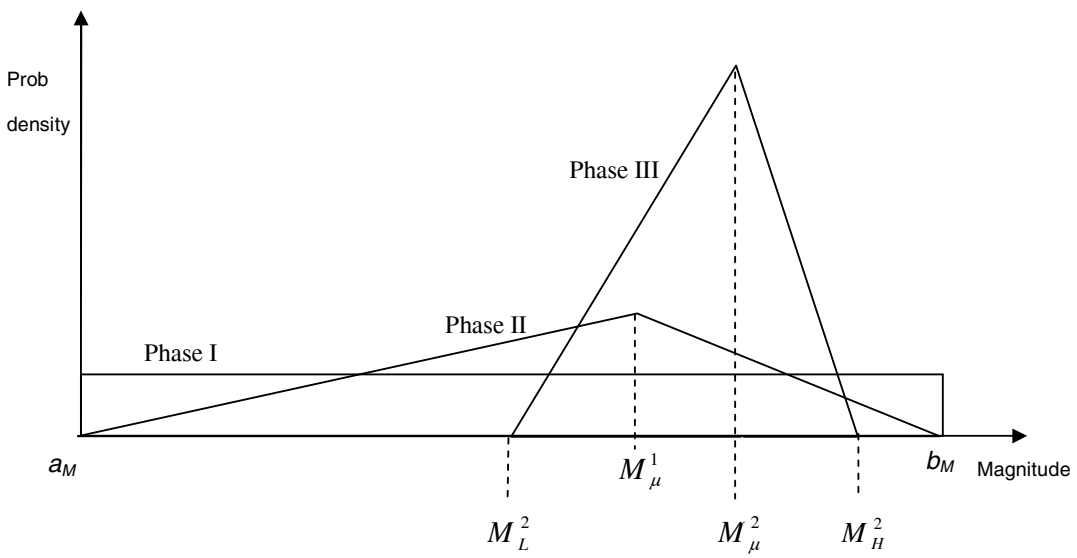
$$A^1 = \begin{Bmatrix} j \in Adj_{X_{j-1}} & \frac{K_{X_{j-1}}}{K_{X_j^*}} \\ j \notin Adj_{X_{j-1}} & 1 \end{Bmatrix} \quad (10)$$

Phase II proposal distribution

It is hoped that the Phase I results give some indication of the posterior distribution. This information on the posterior distribution can then be incorporated into the Phase II proposal distribution.

Rather than selecting from the set of adjacent nodes, the candidate node X_j^* is in Phase II based on the frequency with which it was selected in Phase I, $freq_i^1$:

$$j_X^2\left(X_j^* \middle| X_{j-1}\right) = freq_i^1 \quad (11)$$



The proposal distribution for magnitude is revised with knowledge of the Phase I estimate of the posterior mean. This revision is illustrated in Figure 2. The uniform proposal distribution in Phase I is replaced by a triangular distribution. The function Triang(*x,a,b,m*) yields the density of *x* given lower and upper bounds *a* and *b*, and mode *m*. The lower and upper bounds remain unchanged from the Phase I distribution; the mode is set equal to the Phase I-estimated posterior mean, M_μ^1:

$$j_M^2\left(M_j^* \middle| M_{j-1}\right) = Triang\left(M_j^*, a_M, b_M, M_\mu^1\right) \quad (12)$$

Use of this triangular distribution concentrates the sampling of candidate magnitude values around those observed in Phase I but, in acknowledging the approximation error in Phase I, still allows for values from the full range of values in the prior distribution. The revision of the proposal distribution for start time is similar but uses a discrete version of the triangular distribution:

$$j_T^2\left(T_j^* \middle| T_{j-1}\right) = DiscreteTriang\left(T_j^*, a_T, b_T, T_\mu^1\right) \qquad (13)$$

Figure 2 Illustration of the revision of the proposal distribution for magnitude. The revision of the start time proposal distribution differs only in that discrete versions of the distributions are used.

This Phase II jumping distribution is now fully an "independent" MCMC implementation as $j^2\left(\theta_j^* \middle| \theta_{j-1}\right) = j^2\left(\theta_j^*\right)$. The factor *A* in Phase II, is:

$$A^2 = \frac{freq_{X_{j-1}}^1}{freq_{X_j^*}^1} \frac{Triang\left(M_{j-1}, a_M, b_M, M_\mu^1\right)}{Triang\left(M_j^*, a_M, b_M, M_\mu^1\right)} \frac{DiscreteTriang\left(T_{j-1}, a_T, b_T, T_\mu^1\right)}{DiscreteTriang\left(T_j^*, a_T, b_T, T_\mu^1\right)} \qquad (14)$$

Phase III proposal distribution

The proposal distribution for X in Phase III is left unchanged from Phase II, with the exception that frequencies from Phase II, $freq_i^2$, are used:

$$j_X^3\left(X_j^* \middle| X_{j-1}\right) = freq_i^2 \qquad (15)$$

The proposal distributions for the θ components M and T are again based on triangular

distributions with the modes set equal to the best estimate of the posterior means, M_{μ}^{2} and T_{μ}^{2}. However, as was depicted in Figure 2, in this final phase more narrow triangular distributions are used, with the bounds set equal to the minimum and maximum values as observed in Phase II, M_{L}^{2} and M_{H}^{2} for magnitude and T_{L}^{2} and T_{H}^{2} for start time:

$$j_{M}^{3}\left(M_{j}^{*}\middle|M_{j-1}\right)=Triang\left(M_{j}^{*},M_{L}^{2},M_{H}^{2},M_{\mu}^{2}\right) \tag{16}$$

$$j_{T}^{3}\left(T_{j}^{*}\middle|T_{j-1}\right)=DiscreteTriang\left(T_{j}^{*},T_{L}^{2},T_{H}^{2},T_{\mu}^{2}\right) \tag{17}$$

The factor *A* in Phase III is computed as:

$$A^{3}=\frac{freq_{X_{j-1}}^{1}}{freq_{X_{j}^{*}}^{1}}\frac{Triang\left(M_{j-1},M_{L}^{2},M_{H}^{2},M_{\mu}^{2}\right)}{Triang\left(M_{j}^{*},M_{L}^{2},M_{H}^{2},M_{\mu}^{2}\right)}\frac{DiscreteTriang\left(T_{j-1},T_{L}^{2},T_{H}^{2},T_{\mu}^{2}\right)}{DiscreteTriang\left(T_{j}^{*},T_{L}^{2},T_{H}^{2},T_{\mu}^{2}\right)} \tag{18}$$

3. Limitations

A simple categorical sensor with three outcomes (U, L, and H) was considered in the development of the method. With little modification, a sensor with a continuous reading could be incorporated. To accommodate a continuous sensor, from the Monte Carlo-based stochastic model results the probability *density* of measurements would need to be estimated using density estimation methods. To approximate density, kernel density estimation methods can be utilized (Silverman, 1986).

The specific MCMC implementation presented considered three components of θ: the source node (X), the associated magnitude (M) and the start time (T). This set is likely too limiting. As there is a cutoff C* for detection, it may be that two sources are needed to trigger the sensor. The allowance for two sources would add one more component of θ. Moreover, the contaminant injection time profile used, a step function from zero to a fixed magnitude, is too limiting. Other time profiles, including pulses, or ramped up injections into the system could be imagined in addition to profile type; each of these profiles would require additional components of θ such as the duration of the pulse or slope of the ramp-up. The allowance for multiple sources and alternative injection time profiles would quickly increase the number of components of θ.

The main limitation to an MCMC approach will remain computation time. If adding parameters to θ, a parallel or distributed implementation of MCMC likely would be required. Fortunately, the MCMC procedure is amenable to parallel and distributed computing (Altekar et al., 2004). A parallel or distributed computing scheme is needed if additional sensors

(water quality and hydraulic sensors) are to be incorporated; with multiple sensors, larger Monte Carlo sample sizes are needed to estimate the frequencies (or density) for the set of measurements that are observed, as the number of sensor measurement combinations that can occur greatly increases.

ABSTRACT

If a chemical or biological agent is released into a water distribution system, sensors that are installed in the pipe network may detect the contamination as it travels through the system. To minimize the adverse impact of the contaminant release, the source must be characterized to determine the extent of the contamination and to remediate the contaminated area. We develop an adjoint-based backward modeling approach that uses the collected sensor data to identify the location and timing of the release. In the adjoint model, the sensor location is treated as a source of probability, and the probability is transported upgradient and backward in time to obtain probability density functions (PDFs) that describe the random time in the past that the observed contamination was at a particular upgradient position. These PDFs can be used to identify the source location and release time. Conditioning these PDFs on the measured concentrations improves their accuracy and decreases their uncertainty. We demonstrate the effectiveness of this method by using it to characterize a contaminant source in a hypothetical water distribution system.

INTRODUCTION

A water distribution system is made up of pipes and storage tanks that carry water from sources to users. Due to their spatial extent and their many potential injection points, water distribution systems are vulnerable to outside threats such direct injections of chemical or biological agents into the distribution system (Ostfeld, 2006). If a contamination event occurs, the source must be characterized with respect to the contaminant type, injection time and duration, mass loading rate, and location of injection. If sensors are installed to detect contamination in the distribution system, the data recorded at these sensors can be used to provide information about

the source characteristics.

Several inverse methods have been used to characterize contaminant sources in water distribution systems. To determine possible source nodes, release times, and mass loadings, Laird et al. (2005) used a nonlinear optimization method based on multiple sensors. Using an origin tracking algorithm they were able to identify possible source scenarios but were not necessarily able to quantify the number of sources. By applying mixed integer optimization to the array of feasible solutions, Laird et al. (2006) estimated the number of sources. Guan et al. (2006) characterized contaminant sources in the water distribution system of Dover Township, New Jersey using a simulation and optimization approach that was adapted from a method developed by Guan and Aral (1999) and Aral et al. (2001) for use in groundwater contamination. Preis and Ostfeld (2006) used a model tree approach coupled with linear programming. In this method, a water quality simulator such as EPANET is run multiple times with different source scenarios, and the results are formed into a model tree. Classification rules are generated by the model tree, which are then used with sensor data in a linear programming method to characterize contamination sources. Preis and Ostfeld (2007) used a genetic algorithm coupled with EPANET to identify the location, release time, duration, and source mass of a contaminant source in a water distribution system. DiCristo and Leopardi (2008) use a two-step method to identify the source node in a water distribution system. In the first step, the candidate nodes are selected using pathway analysis (Lee and Deininger, 1992); then a linear optimization problem is solved to identify the source node from among the candidate nodes.

These approaches assumed that sensors continuously record concentrations of released chemicals; however cost-effective sensors of this type are not currently available (ASCE, 2004). Rather, sensors are available that measure water quality indicators such as turbidity and pH, and these can be used to detect the presence or absence of contamination. Dawsey et al. (2006) and Preis and Ostfeld (2008) developed methods for determining a source zone using information from this type of sensor. These methods can be used to reduce the number of possible source nodes.

In this paper, we present a conditioned backward probabilistic modeling approach to identify possible sources of contamination in a water distribution system. In backward modeling the sensor location is treated as a source of probability, and the probabilities are propagated upgradient and backward in time. The governing equation for the backward model is the adjoint of the forward transport equation. Adjoint-based backward modeling has been used to identify contamination in groundwater systems (Neupauer and Wilson, 1999, 2001, 2002), in optimal control of point source effluent releases to rivers (Piasecki and Katopodes, 1997) and estuaries (Piasecki and Sanders, 2002), in estimation of historical contaminant distributions (Michalak and Kitanidis, 2004), and other applications. In our method, the adjoint state is related to a probability density function (PDF) of the time in the past that contamination that was observed at a sensor could have been at an upstream node. These PDFs can be used to identify the source location or release time. In the next

section, we present the governing equations of water quality simulations in water distribution systems. Following that, we present the adjoint approach for obtaining the backward travel time PDF. Finally, we introduce a conditioning step in which the backward travel time PDF is conditioned on the measured concentrations at the sensor.

SIMULATION OF WATER QUALITY

Many water distribution models such as EPANET (Rossman, 2000) simulate water quality in pipes using an advection-reaction equation given by

$$\frac{\partial C_i}{\partial t} + \frac{Q_i}{A_i}\frac{\partial C_i}{\partial x_i} = kC_i \tag{1}$$

where C_i, Q_i, and A_i are the concentration, flow rate, and area of Pipe i, t is time, k is a first-order reaction rate, x_i is travel distance in Pipe i, with $x_i = 0$ at the upstream end of the pipe, $x_i = L_i$ at the downstream end of the pipe, and Q_i is defined as positive in the direction of x_i . For each Pipe i, let the upstream and downstream nodes be denoted as u_i and d_i, respectively. Assuming complete mixing at the nodes, the boundary condition for (1) is

$$C_i(x_i = 0, t) = C^*_{u_i}(t), \tag{2}$$

where

$$C^*_j = \frac{\sum_{i \in d_i = j} Q_i C_i\big|_{x_i = L_i} + U_j}{D_j + \sum_{i \in u_i = j} Q_i}. \tag{3}$$

where C_j^* is concentration of water leaving Node j, and D_j and U_j are the demand and source loading, respectively, at Node j. The initial concentration in Pipe i is $C_i(x_i,0) = 0$.

If the source loading U_j is known, (1) - (3) can be solved to obtain concentrations at all nodes as a function of time. These nodal concentrations can be related to a forward travel time probability density function (PDF) that describes the random time T at which a contaminant particle that was released at Node l will be present at Node j. Based on results presented in the groundwater literature (e.g., Jury, 1982; Dagan, 1989, Dagan and Nguyen, 1989), the forward travel time PDF, $f_l(t,j,l)$, is defined as the ratio of max flux of the contaminant at Node j to the total mass of contaminant contributed by the source at Node l, given by

$$f_T(t;j,l) = \frac{C_j^*(t)\sum_{i\in d_i=j} Q_i(t)}{M_l} = \frac{dC_j^*(t)}{dM_l}\sum_{i\in d_i=j} Q_i(t) \quad , \tag{4}$$

where M_l is the mass of contaminant entering Node l, and $dC_j(t)/dM_l$ is the marginal sensitivity of concentration at Node j to a source mass at Node l. The cumulative distribution function (CDF) of travel time, which describes the probability that a particle will travel from Node l from Node j prior to time $t = T$, is obtained by integrating the PDF in (4) from time $t = 0$ to $t = T$.

BACKWARD TRAVEL TIME PROBABILITY DENSITY FUNCTION

If contamination is observed at sensors in a water distribution system, but the source of contamination is not known, (1) - (3) can be used to determine the source characteristics (source location, release time, source mass, etc.); however, the approach is inefficient. The equations would have to be solved for all possible combinations of source location, release time, and source mass, and the simulated nodal concentrations would be compared to the sensor readings, with the final source characteristics identified as the combination that produces the smallest misfit between the simulated concentrations and sensor readings. This process can be automated using various inverse methods, such as those described above.

Alternatively, a backward travel time PDF can be obtained that tracks the movement of the contamination from the sensor where it was measured upgradient to all possible source locations. The governing equation of the backward model is the adjoint of the governing equation of the forward model (1), given by (Neupauer, 2009)

$$\frac{\partial \psi_i}{\partial \tau} - \frac{Q_i}{A_i}\frac{\partial \psi_i}{\partial x_i} = k\psi_i \quad , \tag{5}$$

where ψ_i is the adjoint state of C_i and is identical to the marginal sensitivity of C_i to a source release of mass M_l at Node l, such that $\psi_i = dC_i/dM_l$ (Neupauer, 2009), and τ is backward time which is defined as time prior to observation at the sensor. The main differences between the forward and backward equations are the reversal of the time variable in the backward equation and the change in sign on the advection term. With these changes, the backward equation allows for upgradient movement of the adjoint state in backward time. The initial condition on (5) is $\psi_i(x_i, \tau = 0) = 0$.

The boundary condition on ψ_i is the adjoint state of the nodal concentration C^* at the downstream end of the pipe ($x_i = L_i$), given by (Neupauer, 2009)

$$\psi_i(x_i = L_i, \tau) = \psi_{d_i}^*(\tau) \quad , \tag{6}$$

where

$$\psi_l^* = \frac{\sum_{i \in u_i = l} Q_i \psi_i - h_l}{\sum_{i \in d_i = l} Q_i} \quad , \tag{7}$$

where h_l is a performance functional that depends on the observation of contamination at the sensor, and $\psi_l^* = dC_j^*/dM_l$ is the adjoint of C_j^*. The performance functional in (7) is defined as (Neupauer et al., 2009)

$$h_l(\tau) = \begin{cases} T_d^{-1} & l = j \text{ and } \tau_s < \tau < \tau_s + T_d \\ 0 & \text{otherwise} \end{cases} \quad , \tag{8}$$

where T_d is the duration of the observation at a sensor at Node j, and τ_s is the time in backward time at which contamination was most recently observed at Node j. The adjoint state is related to the travel time PDF through (Neupauer et al., 2009)

$$f_T(\tau; l, j) = \psi_l^*(\tau) \sum_{i \in u_i = l} Q_i(\tau) \quad . \tag{9}$$

From (9), the cumulative distribution function CDF of backward travel time is

$$F_T(\tau; l, j) = \int_0^\tau \psi_l^*(\tau') \sum_{i \in u_i = l} Q_i(\tau') d\tau' \quad .$$

The CDF represents the probability that a contaminant particle that was observed at a sensor at Node j was at Node l prior to backward time τ.

To calculate the backward travel time PDF, the adjoint equations (5) - (7) are solved once for each sensor observation to obtain $\psi_l^*(\tau)$ for all upstream Nodes l. These adjoint states used in (9) to obtain the backward travel time PDF that represents the possible times in the past that the observed contaminant particle was at any upgradient Node j. If contamination is observed at multiple sensors, the backward travel time PDFs for the individual sensors can be combined into a joint backward travel time PDF that represents the backward time τ at which the contaminant particles observed at all sensors could have been at any upgradient Node j. The joint backward travel time PDF is given by

$$f_T(\tau; l, j_1, j_2, \ldots j_{N_s}) = \alpha \prod_{n=1}^{N_s} f_T(\tau; l, j_n) \quad , \tag{10}$$

where $f_T(t;l,j_1,j_2,\ldots j_{Ns})$ is the joint backward travel time PDF, $f_T(\tau;l,j_n)$ is the backward travel time PDF for sensor j_n, N_s is the number of sensor measurements, and α is a constant that ensures that the total probability is unity.

CONDITIONED BACKWARD TRAVEL TIME PROBABILITY DENSITY FUNCTION

The individual and joint backward travel time PDFs described above account for the presence of contamination at sensors, but not for the measured concentrations. If concentrations measurements are available, the travel time PDFs can be conditioned on the measured concentrations. Neupauer and Lin (2006) developed a method for conditioning the backward travel time PDF on the measured concentrations for an instantaneous point release of groundwater contamination at a known location but of unknown mass m. We adapt this method here for a uniform release of contamination at a single node in a water distribution system.

We assume that the measured nodal concentration, $\hat{c}_j^*$, at a sensor at Node j contains normally-distribution random measurement error; and therefore it is a random variable described by a PDF, $f_{\hat{C}^*}(\hat{c}_j^* | M,T;T_d)$, given by

$$f_{\hat{C}^*}(\hat{c}_j^* \mid M,T;T_d) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left\{ -\frac{\left(\hat{c}_j^* - c_j^*(M,T;T_d)\right)^2}{2\sigma^2} \right\}, \qquad (11)$$

where σ^2 is the variance of the measurement error and $c^*_j(M,T,T_d)$ is the true concentration at Node j due to a source release of mass M at time T for a duration of T_d. We assume in this work that the contamination is released uniformly at Node l for a known duration of T_d. Other source scenarios are possible; however, for simplicity, we limit our presentation here to this uniform source. The PDF of measured concentration is conditioned on the random source mass M, random release time T, and duration of release of contamination T_d from a source at Node l.

Following the approach of Neupauer and Lin (2006), we first develop a joint PDF, $f_{M,T|\hat{\mathbf{C}}^*}(M,T|\hat{\mathbf{c}}^*,l;T_d)$, of the unknown source mass M and the release time T for a source at Node l conditioned on measured concentrations, where $\hat{\mathbf{C}}^* = [\hat{C}^*_1, \hat{C}^*_2, \ldots, \hat{C}^*_{Ns}]$ is an N_s-length vector of random concentrations, and $\hat{\mathbf{c}}^* = [\hat{c}^*_1, \hat{c}^*_2, \ldots, \hat{c}^*_{Ns}]$ is an N_s-length vector of specific values of concentrations. Using Bayes' theorem, we defined this joint PDF as

$$f_{M,T|\hat{\mathbf{C}}^*}(m,\tau \mid \hat{\mathbf{c}}^*,l;T_d) = \frac{f_{\hat{\mathbf{C}}^*|M,T}\left(\hat{\mathbf{c}}^* \mid m,\tau;T_d\right) f_M(m) f_T\left(\tau;l,j_1 \cdots j_{N_s}\right)}{\iint f_{\hat{\mathbf{C}}^*|M,T}\left(\hat{\mathbf{c}}^* \mid m',\tau';T_d\right) f_M(m') f_T\left(\tau';l,j_1 \cdots j_{N_s}\right) dm' d\tau'}, \qquad (12)$$

where $f_{\hat{\mathbf{C}}^*}(\hat{\mathbf{c}}^* | M,T;T_d)$ is the joint PDF of the vector of measured concentrations, $f(m)$ is a PDF of source mass (which, in the absence of any other information, is assumed to be a uniform distribution), and $f_T(\tau,l,j_1 \ldots j_{Ns})$ is the unconditioned joint backward travel time PDF from (10). Assuming that the measurement error in the sensor measurements are uncorrelated, $f_{\hat{\mathbf{C}}^*}(\hat{\mathbf{c}}^* | M,T;T_d)$ can be expressed as the product of $f_{\hat{C}^*}(\hat{c}_j^* | M,T;T_d)$ for $j = 1, 2, \ldots N_s$. Integrating (12) over the domain of possible source masses results in the backward travel time PDF conditioned on measured concentrations, given by

$$f_{T|\hat{\mathbf{C}}^*}(\tau \mid \hat{\mathbf{c}}^*, l; T_d) = \beta \int \prod_{n=1}^{N_s} \left[f_{\hat{C}_n^* | M,T}\left(\hat{c}_n^* \mid m, \tau; T_d\right) f_T(\tau; l, j_n) \right] dm \quad , \tag{13}$$

where β is defined such that the total probability is unity. In (13), the first PDF on the right hand side comes from (11) and the second PDF comes from (9), and the product is evaluated for all sensor measurements.

ABSTRACT

A contamination source identification methodology should be continuously run in real time to provide timely information about contamination event status. The method should be robust with respect to uncertainty and variability in factors affecting the network hydraulic model. This work assesses the impact of hydraulic modeling errors on the performance of a source identification algorithm. Preliminary results evaluate the effect of demand estimation errors on the performance of the identification algorithm. Results suggest the source identification method can be robust to the types of errors investigated. It is stressed, however, that broader conclusions can not be drawn, because the tests consider only one network test case, and the true statistical characteristics of stochastic demands are unknown. Furthermore, the particular example chosen assumes optimistic scenarios for demand estimation. The results provide a methodology and motivation for continuing to investigate the true performance characteristics of real-time contamination source identification algorithms.

Keywords: contamination source identification, real-time calibration model.

INTRODUCTION

A considerable effort has been directed toward developing algorithms for contamination source identification in water distribution systems. Research is underway to extend these algorithms for reliable application in a real-time procedure. To evaluate these methods in a realistic manner, however, various uncertainties must be considered which affect distribution system hydraulics, including model inaccuracies, measurement errors, and calibration errors.

Several methodologies address contamination source identification for water distribution systems assuming system hydraulics are known without error. Unfortunately only limited hydraulic data are available for assessing the state of the system. Further, monitoring stations envisioned for surveillance may fail to detect the real presence/absence of a contamination. Yet the work on source identification has almost exclusively assumed that event detection is also without error.

Disregarding the possibility of false positive and false negative contamination events, and ignoring the uncertainty in hydraulics, could lead to incorrect identification of contamination locations and times. Consequently, this could degrade the effectiveness of remedial actions, and result in greater public health impacts. The contamination source identification approach proposed by De Sanctis et al. (2006) assumes an accurate hydraulic model and perfect water quality sensor information. In De Sanctis et al. (2008), their method is extended to combine imperfect event detection information with the results of a backtracking analysis (EPANET-BTX), to determine the probability of each node-time pair being a contamination source. Here, we retain the original contamination source identification algorithm (De Sanctis et al. (2006)), along with the assumption of perfect event detection, but assume a hydraulic model with real-time water demanded patterns estimated using flow and pressure measurements and an extended Kalman filter predictor-corrector method (Shang et al. (2006)). This method estimates the water demand patterns and the associated uncertainty. By relying on the estimated hydraulic model with water demand uncertainty, it is possible to estimate how reliably the contamination sources can be identified in water distribution systems.

A simulation study using a network with a hydraulic and water quality sensor system is presented to show the time varying candidate contamination sources. The effect of the estimated demand patterns on the source identification is investigated, assuming true stochastic demands described by a time series model with temporal demand correlation. Since the demand estimation performance depends on many factors different cases are examined. One of these cases is the use of several sampling designs for the hydraulic measurements. Furthermore, the performance is evaluated for different magnitudes of the demand pattern variability. This is accomplished by varying the white noise error associated with a time series model.

A comparison is made between the source identification results using estimates of demand patterns, versus perfect hydraulics. The robustness of the source identification is also evaluated with respect to varying the water quality sampling. All the comparisons show the importance for incorporating information regarding demand uncertainty on contaminant source identification.

METHODOLOGY

The *Contamination Status Algorithm* (*CSA*), De Sanctis et al. (2006), is a method to identify all the possible contamination sources in space and time. It updates the contamination possibility status of all nodes and time intervals using the network flow paths that deliver water to water quality monitoring stations. These monitoring stations are assumed to detect the presence/absence of contamination in a water distribution system. The network flow paths for each station are determined using the *particle backtracking algorithm* (Shang et al. (2002)), as implemented in *EPANET-BTX*, a pre-release version of the EPANET backtracking extension that uses the EPANET hydraulic network model. The status assigned to each node-time pair by the CSA is one of the following: *candidate* – possible contamination source, *safe* – not a possible contamination source, and *unknown* – insufficient information to classify the source as candidate or safe.

Here the possible contamination sources are identified using a real time hydraulic model for which the water demands are continuously estimated from hydraulic measurements stored in a SCADA Database. Water quality status from an event detection algorithm is assumed to be perfect (a *probabilistic CSA* has been described to incorporate false positive or false negative rates into the standard CSA algorithm) (De Sanctis et al. (2008)). In order to evaluate the CSA approach for real time source identification we need to verify the robustness of the algorithm with respect to uncertainty and variability in the input data. The deviations between source identification results using accurate hydraulic information, versus those using estimated hydraulic characteristics, is one valid approach to measure the robustness of the identification algorithm under realistic conditions. In this work the time-varying water usage rates at network nodes represent the main uncertain hydraulic model input. Other model parameters are assumed to be accurately identified, including system operation conditions, pipe roughness, and internal diameters. The water demands are estimated using EPANET-RTX, a pre-release version of the EPANET Real-Time eXtension (Shang and Uber (2008)) which implements the predictor-corrector estimation method described by Shang et al. (2006).

The computational procedure implemented here is divided into three main steps:

1. Generation of a synthetic true model
2. Generation of an ensemble of estimated models
3. Comparison of CSA results using different input models

First, the true model is synthetically generated; the true model is intended to represent a realistic set of conditions, incorporating stochastic demand variability. Hydraulic measurements and water quality measurements are simulated using the true model. Simulated flow and head values are used with EPANET-RTX to estimate the real-time water usage rates, while simulated water quality information is converted to a binary alarm/normal state and processed by the CSA.

Second, an ensemble of hydraulic model scenarios is generated based on different sets of estimated real-time demands. Each set of real-time demands is estimated using different simulated measurements for the calibration algorithm. The estimation performance of the calibration system depends strongly on the sampling design (Bush and Uber (1998); Kapelan et al. (2003)). In particular, the performance varies based on the number of measurements, and their locations, accuracy, and frequency. For this reason, random sets of flow and pressure measurement locations are used to study the effects of demand estimation accuracy.

Third, each estimated hydraulic model scenario is used with the CSA to identify possible contamination sources. Then, these results are quantitatively analyzed to evaluate the contamination source identification approach subject to real-time demand estimation errors. Comparisons over time between results from the estimated model and those from the true model are evaluated using various accuracy metrics.

DATA ANALYSIS

In this section four different metrics are presented. Some of them are used to evaluate the influence of hydraulic modeling errors on CSA performance and one is used to evaluate error on the patterns.

1. $Metric\ R_c$, R_s: is the percentage of Candidate (R_c) or Safe (R_s) node-time pairs at any analysis time. R_c represents the number of node-time pairs identified as candidates divided by the total number of node-time pairs in an historical analysis time frame. Similarly, R_s is the percentage of safe node-time pairs, or those excluded as possible contamination sources.

2. $Metric\ \eta$: is the number of times CSA correctly identifies the contamination source, divided by the number of times the CSA misidentifies the source, over a simulation duration (T). At any analysis time, the CSA is considered correct if either of two conditions hold: 1) the true source *is* within the historical analysis time frame, and the group of identified candidate node-time pairs contains the true source, or 2) the true source *is not* within the historical analysis time frame, and the number of candidate node-time pairs is zero. In any other case the CSA methodology is considered to be incorrect.

3. $Metric\ \epsilon$: is the pattern estimation error (Shang et al. (2008)):

$$\epsilon = \frac{1}{T} \times \frac{1}{n_p} \sum_{k=1}^{T} \sum_{j=1}^{n_p} |\frac{\bar{y}_k^j - y_k^j}{y_k^j}| \tag{1}$$

   where $\bar{y}_k^j$ is the estimated pattern value at time step k for pattern j, y_k^j is the true pattern value for time step k and pattern j, and n_p is the number of patterns. Since the estimation performance depends on sampling design, this metric is a way to select sets of measurements that lead to estimated models with varying levels of demand pattern error. For the results presented below, we select two estimated models corresponding to the minimum and maximum pattern estimation error, from among all models estimated.

4. $Metric\ norm$: is the 2-norm (Euclidean distance) between the R_c vector over all time steps using the true model, and that using an estimated model.

APPLICATIONS

Example design

The real-time CSA applications have been carried out to analyze the ability to identify under uncertain condition the correct source injections using a midsize network. The distribution system used for the simulations is the well-known "Net3" network (Figure 1). The network includes 2 reservoirs, 3 storage tanks, 92 junctions, 117 pipes, and

2 pumping stations. Network data, and pumps characteristics are described in Vasconcelos et al. (1996).

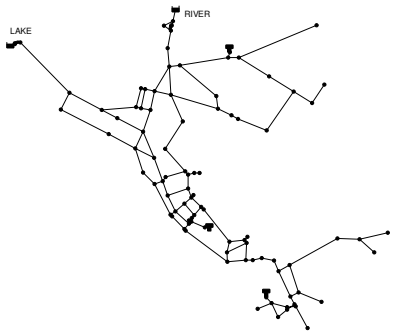

Figure 1: Example network for simulation analysis.

The true model hydraulic scenario includes water four demand patterns that follow the same time series model, with a 1 hour time step. Each pattern uses independent white noise realizations, so the four patterns are independently generated. The assumed true pattern is described as an ARIMA $(0,0,1)(0,1,1)_{24}$ process:

$$y_k = y_{k-24} + (1 - 0.15B)(1 - 0.85B^{24})\epsilon_k \tag{2}$$

where y_k is the pattern value at time step k, ϵ is the white noise distributed with $N(0, 0.06^2)$, and B is the backward shift operator (Box and Jenkins (1976)). The true model water quality scenario includes a single non-reactive contaminant source modeled using a mass booster with a strength of 20000 mg/min and duration of one hour (from time 2:00 h to 3:00 h AM during the third simulation day). For these preliminary results only one source location is analyzed and the true contamination source is node 157 on the north side of the network (Figure 1). The total simulation duration is 10 days. Three water quality monitoring stations are placed at node IDs 35, 203, and 111. Event status (positive/negative) is generated at these locations at the beginning of every hour, and assumed to be perfect. These events are synthetically generated from the water quality simulation using the true hydraulic model, where positive events are generated whenever the simulated concentration was non-zero.

The estimated model includes the same four demand patterns as in the true model, but estimated using the simulated measurements using EPANET-RTX. To calibrate the model four flow measurements and four head measurements were randomly selected from the true model. The hydraulic measurements are assumed to be affected by measurement errors, which are distributed as $N(0, 0.2^2)$ for the flows and $N(0, 1.0^2)$ for the heads. Each estimated pattern is assigned to the same group of nodes as in the true model (perfect pattern assignment). An ensemble of 5000 estimated models was generated using randomized hydraulic measurement locations, and the estimation accuracy ϵ was computed for each estimated model.

Preliminary results

For the true hydraulic model, the CSA gives the results shown in Figure 2. The top plot shows the percentage of candidate sources ($R_c(t)$) versus the simulation time t for a 24 hour historical analysis time frame. The first candidate nodes are identified 9 hours after the true injection time and the percentage of candidate sources is 1.7%. The maximum percentage of candidate sources (14%) is recorded at hour 92:00. The bottom plot in Figure 2 shows the time-varying percentage of safe nodes. As expected, the curve mirrors the plot of candidate node percentage, consistent with higher number of positive status events from the water quality sensors. Further analysis shows CSA results when the hydraulic model is not accurate. The water quality event status information is also obtained from the true hydraulic/water quality model. A time-varying percentage of candidate sources $\overline{R}_c(t)$ versus analysis time t is computed for two estimated models corresponding to the best pattern estimation error ($\epsilon = 0.0164$) and worst pattern estimation error ($\epsilon = 0.795$). Figure 2 shows the comparison of the time-varying percentage of candidate and safe sources for the three models (true, best, and worst estimated models). In these plots it is difficult to discern the differences between the CSA performance for these three models, as those differences are small for this test case.

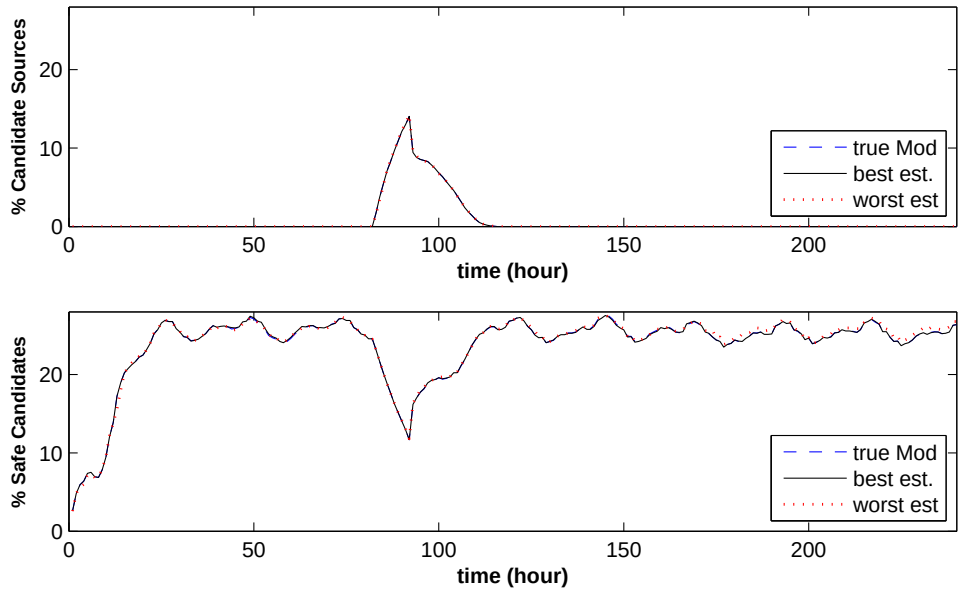

Figure 2: (Top) Percentage of candidate sources for the true model in a 24 hour historical analysis time frame versus analysis time. Comparison with estimated models for best and worst pattern estimation error. (Bottom) Percentage of safe candidates for the true model in a 24 hour historical analysis time frame versus analysis time. Comparison with estimated models for best and worst pattern estimation error.

Figure 3 shows the difference at each analysis time between $R_c(t)$ computed for the true and the two estimated hydraulic models (best estimated patterns, on left, and worst estimates, on right). The first and second row of Figure 3 are the series for the

candidate node-time pairs, and the safe node-time pairs, respectively.

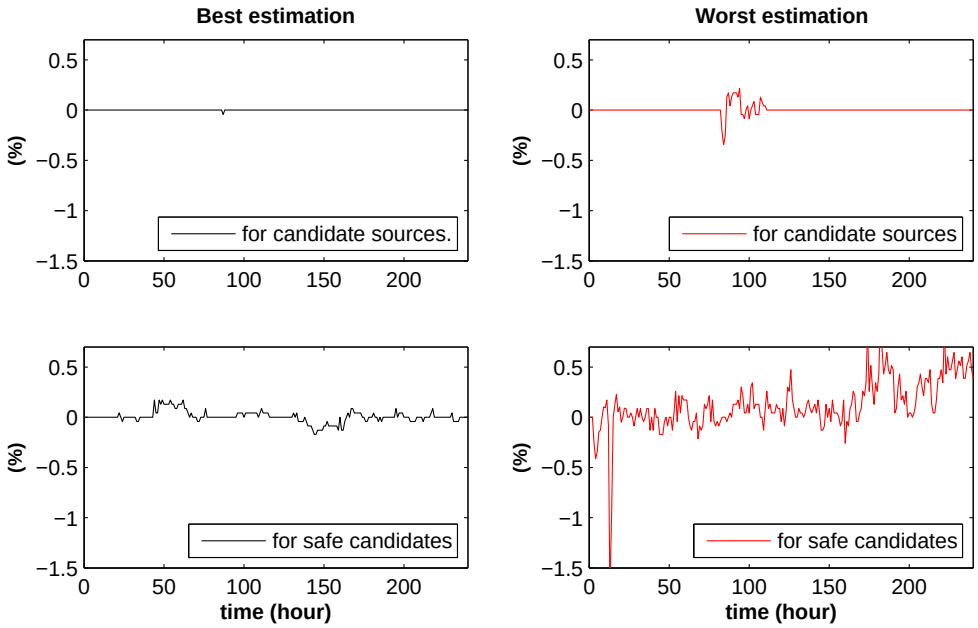

Figure 3: Difference over time between candidate sources for the true model and for the best real-time water demand estimates (left), or fr the worst estimates (right). (Second row) Differences over time for the safe candidates.

To investigate further the sensitivity of the methodology to demand errors, the white noise error standard deviation assumed when estimating the hydraulic models was varied. The standard deviations for the white noise were assumed to equal 0.01, 0.02, 0.04, 0.06, 0.1, 0.2, and 0.4 when estimating the hydraulic models using synthetic data, while the white noise for the true demand model remained 0.06. Figure 4 shows the pattern estimation error for the best and worst estimated models as a function of the assumed white noise standard deviation. For each standard deviation EPANET-RTX was used to estimate an ensemble of demands corresponding to random hydraulic measurement locations; from these a best and worst estimated model were selected. As could be expected, the errors of the worst estimated hydraulic model show a minimum at approximately the true white noise standard deviation of 0.06. Figure 5 shows the 2-norm (Euclidean distance) between the R_c vector over all time steps obtained using the true model, and that using either the best or worst estimated model, as a function of the assumed white noise standard deviation. This difference between true hydraulic model CSA performance, and that using the best and worst hydraulic models, are shown for the candidate node-time pairs, and the safe node-time pairs. As expected, there is a significant degradation of CSA performance between the best and worst estimated hydraulic models, and the results obtained using the true standard deviation (0.06) are near the best performing CSA results.

The accuracy metric η is presented in Table 1 for a varying number of water quality sensors. These represent how well the CSA algorithm performs using the true model.

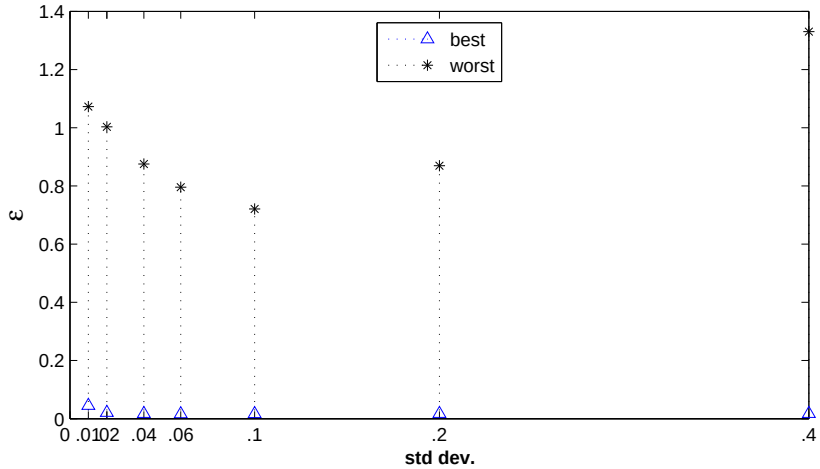

Figure 4: Pattern estimation error for the best and worst estimated models versus the standard deviation used to generate the white noise error for estimated model.

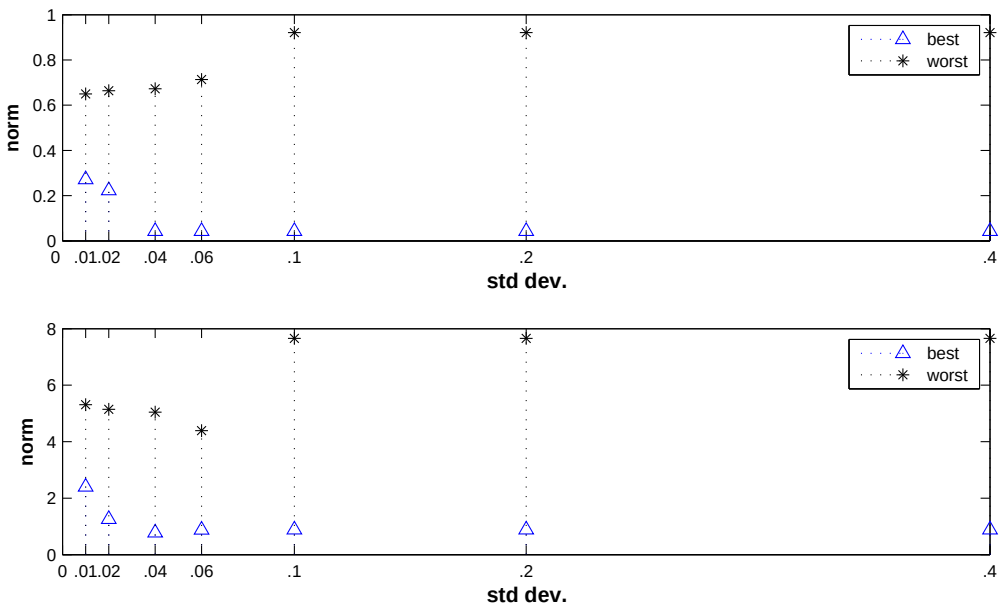

Figure 5: The 2-norm (Euclidean distance) between the percentage of candidatesidentified by CSA using the best or worst estimated models, and the true model (top). The same statistics for the percentage of safe node-time pairs (bottom).

Table 1: Metric η for the true model versus number of sensors

N. sensors	3	6	8	10	12	14	16
Metric η	7.89	6.50	6.50	6.74	6.74	2.81	2.81

Many factors affect the real-time identification of contamination sources, and this work extends the original investigation of the CSA algorithm to include uncertainty and variability in time varying water demands. The analyses here are a first attempt, and further investigations are needed. It is necessary to more accurately and completely model both the true stochastic demands, and the likely errors that are practically unavoidable when trying to estimate them. Further, in a real-time system the true model is not available to the water utilities, instead only a set of different measures from monitoring stations already installed across the system are available. Usually these hydraulic measurements and the system operations are stored in a SCADA Database. For this reason an evaluation of the best and worst pattern estimation can be handle by substituting in eq. 1 the measurements from the database and the synthetic measurements from the estimated models instead of the pattern values. To evaluate the performance of CSA a first set of metrics has been suggested. Metric R_c represents the specificity of the algorithm because gives an indication of how unique is the solution. Smaller is its value and more specific is the algorithm in identifying the true source. The $norm$ of the difference between R_c and $\overline{R}_c(t)$ for true and estimated models seems a valid metric to quantify the effect of patterns estimation on the identified candidate sources. Metric η is a general measure of how correctly the algorithm performs. It can be applied to evaluate CSA results when hydraulic model is accurate or not. For example in case of bad estimated water demands there might be the risk that CSA does not identify the true source among the candidates. η can be also used for the probabilistic CSA approach to compare the effect of perfect or imperfect measurement readings. Despite of these good preliminary results, further analysis is necessary to confirm the efficacy of these metrics.

CONCLUSIONS

A real-time contamination source identification algorithm has been illustrated. The approach uses a hydraulic model with real time estimation of water demands, and could be implemented to reduce the risk of contamination for drinking water. The preliminary results suggest that the contamination source identification process might be robust to errors in the estimated hydraulic model. The number of identified candidates was limited even when using a relatively poor real-time estimation of the demand patterns. Still, it is necessary to more accurately and completely model both the true stochastic demands, and the likely errors that are practically unavoidable when trying to estimate them. Other uncertainties should also be addressed in future work, including false positive and false negative readings from event detection algorithms. By incorporating both realistic water demand uncertainty and imperfect water quality event detection, it is hoped that the true reliability of the contamination source identification process could be identified.

ABSTRACT

The objective of an urban water supply scheme (UWSS) is to provide safe and adequate drinking water to the public on sustainable basis. Most of these WSSs are vulnerable to natural hazards like earthquake, cyclone, landslides, and excessive rainfall etc., and the willful physical, chemical, biological, and cyber attacks. While the risk due to natural catastrophes remains high, the risk due to man-made disasters has also been increasing during the last few decades. Almost every nation is facing the problem of terrorism, as it is impossible to satisfy all sections of society within a state, a country, or a group of countries at global level. In order to express their dis-satisfaction and anguish, the disillusioned individuals or group of individuals indulge in the terrorist activities targeting the infrastructures so as to create panic among larger section. The events like September 11, 2001, attack on Indian Parliament, religious places, and recent attack of November 26, 2008 in Mumbai (India), and consistent threats of use of chemical & biological weapons in various parts of the world has compelled the researchers and managers to plan the operation and management of water supply schemes from a different perspective as it is one of the most important infrastructure for the sustenance of society. Precautions are required against the physical, chemical, biological, and cyber attacks on water supply systems.

Present study aims at highlighting these security threats and emphasizes on the need for safety review of the water supply schemes in developing countries like India as these are the life-line of a nation. Some of the threats are inherent as almost all the urban water supply schemes in India and other developing countries are of intermittent type. As a result,

pressure in pipelines is low during some part of the day and people are storing water in individual storage tanks, which deteriorates the water quality. Further, there is not much awareness about the emergency do's and don'ts. The actions desired are at all stages of disaster management life cycle that includes response, recovery, mitigation, prevention, and preparedness.

INTRODUCTION

Since the dawn of civilization, mankind has shown a preference to settle near water bodies due to assured supply of water for drinking and water for food, as water and food are the basic necessities for the survival of living beings. With the fast increasing population, and increased human activities, the available water resources are under stress and needs better management. Water resource systems are developed and managed to serve multiple objectives like drinking water, power, irrigation for food, and industrial uses on sustainable basis and are termed as life-line of a nation. These systems may comprise of large storage by creating barrier on rivers in the form of dams and cogent distribution systems. So, any threat to these systems creates panic among people and puts the government under pressure. Recognizing this, water has been used as a strategic objective in armed conflicts throughout the history. For example, in 1948, during the first Arab-Israeli war, Abrab forces cut off the West Jerusalem water supply. In 1982, Israel cut off the water supply of Beirut during the siege. In Kosovo (1999), water supplies/ wells were contaminated by Serbs, who disposed of the bodies of Kosovar Albanians in local wells, etc. Besides the man-made deliberate attempts to endanger the water supply systems, there can be failures of the water resources structures/ water supply system components due to design failure and excessive stresses. Further, there can be natural calamities like that of earthquake, floods, Tsunami, etc. which may affect the supply of water to the public at large.

The objective of this study is to highlight the threat perceptions to water supply systems, vulnerability assessment, and its management so as to reduce the impact of these threats on the survival of mankind.

THREAT PERCEPTIONS TO WATER SUPPLY SYSTEMS

Water utilities construct, operate, and maintain water supply systems. The basic function of these water utilities is to obtain water from a source, treat the water to an acceptable quality,

and deliver the desired quantity of water to the appropriate place at the appropriate time. After utilization, the waste so generated is carried through the sewerage system. The domestic sewage, industrial sewage, and the storm sewage (commonly called as storm drainage or drainage) are collected separately or combined, treated, and finally disposed off. A typical water cycle in an urban area can be divided into following sub systems (Fig.1):

1- Source, treatment and clear water storage

2- Pumping, distribution storage and distribution system

3- Sewage collection system

4- Sewage treatment plant and disposal

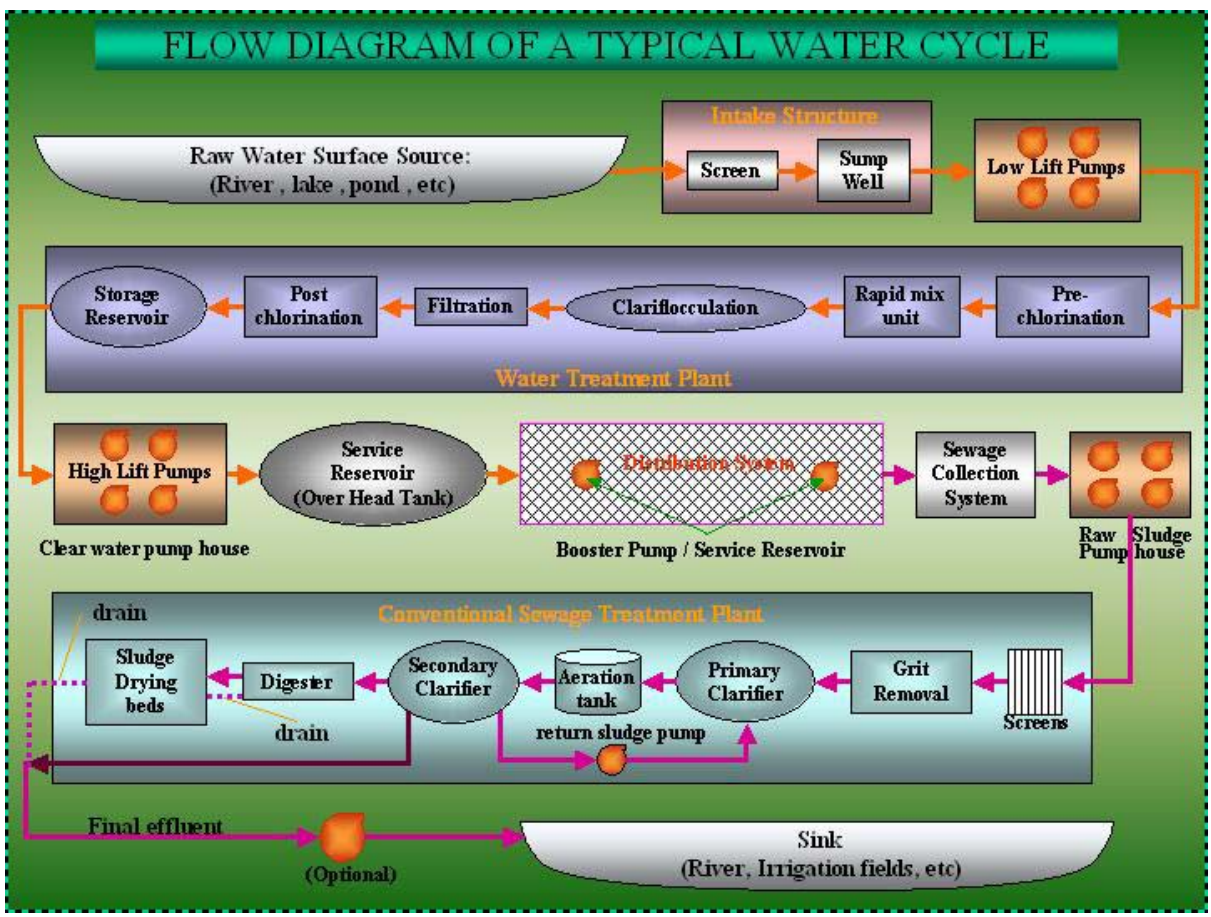

Fig. 1 Line diagram of a typical urban water cycle

The objective of such a WSS is to supply desired quantity of water with desired quality at consumer's tap level and then collect the waste so generated, treat it then dispose off in the

water body. Since the water travels from raw water source to consumer's tap via various components like water treatment plant and distribution system, etc. it is subject to failure due to many reasons. Reasons of failure of one or more components can be classified under two major categories. These are :

i) Natural

ii) Man-made, which may further be classified as unintentional and intentional.

Another way of categorizing the failure of WSS is

i) Physical failure of component(s)

ii) Chemical failure

iii) Biological failure

iv) Cyber failure

The natural causes of water supply system failure are floods, cyclones, earthquakes, windstorms, avalanches, etc. While natural disasters occur on all continents, the number of people affected is greater in the developing world, primarily because the systems are not that much resilient as those in developed countries. The first and foremost effect of natural disasters is on power, roads, and buildings. As a result, the basic infrastructure gets damaged and it takes longer time to restore the basic components to working condition as well as to restore the power which is essential for pumping and other units of the water supply scheme.

The man-made disasters can be because of inadverant decisions taken by the decision makers about the development and the environment, and secondly because of the willful attacks of the terrorist. Terror, which may be defined as a state of intense fear, is often the result of violence committed by one or more group to intimidate individuals, segments of society, or governments to meet the group's demands. Thus, in order to create panic in the society, or among the enemy, people may choose to attack the water supply schemes. These attacks may be in the form of physical, chemical, biological, or cyber. Physical attacks may result in complete disruption of the functioning of one or more components of the water supply scheme. This may include the damage to raw water pumping station, water treatment plants, and over-head service reservoirs, etc. The chemical attacks may include the poisoning of raw water or the potable water in the distribution system itself. Biological attacks may again be

in the form of deteriorating raw or finished water quality biologically. More recent form of attacks is the cyber attacks so that the information system is disrupted which will affect the functioning of the overall management of the water supply scheme.

VULNERABILITY ASSESSMENT

In order to assess the risk and threat perception to water supply schemes, following questions should be addressed (Haimes (1998)):

1. What can go wrong?
2. What is the likelihood that it will go wrong?
3. What are the consequences?
4. What options are available?
5. What are the associated tradeoffs in terms of cost, risks, and benefits?
6. What are the impacts of decisions on future options?

These questions lead to precisely the scope of risk management. The common elements of vulnerability assessments for a typical water supply system includes :

- The elements of the water supply system, including its mission & objectives;
- Identification of adverse consequences and the critical elements that are subject to malevolent acts.
- Assessment of the likelihood of such a malevolent act
- Evaluation of existing countermeasures;
- Analysis of current risk & development of an emergency plan for risk reduction.

In order to develop an infrastructure risk model (IRM), one should carry out the Fault Tree Analysis (FTA) of the system (Kansal, 2005). FTA is a deductive method which is normally used in quantitative way, although it requires initially a qualitative study of the system. FTA of the system will include the identification of its components, hierarchical structure, functions, states, and vulnerability. In order to identify risk to a system, it is desired to know about the system itself. Thus, decomposition of the system into various components and its hierarchical structure is an important input. The vulnerability to risk are function of access and exposure. For example, if a component is easily accessible, it is more vulnerable to risk

as compared to limited access component. Similarly, if a component is more exposed, it is more vulnerable, whereas, the under ground structures are less vulnerable to external attacks. A low vulnerability score for a component is an advantage. Mathematically, if 'α_i' and 'β_i' are the accessibility and exposure of a component on subjective scale (0-1), then the component vulnerability can be expressed as :

$$V_i = \alpha_i * \beta_i$$

If the various components are in series, the overall vulnerability can be estimated as the product of the individual vulnerabilities, whereas, if the components are in parallel, then vulnerability can be taken as the summation of components vulnerabilities.

EMERGENCY RESPONSE PLANNING RISK MANAGEMENT

In the context of prevailing political situation at international level and cross-border terrorism, there is an urgent need to study the vulnerability of such basic amenities. Hardening of water distribution system, which refers to rendering the system less vulnerable to various types of threats, can be grouped into four categories (Haimes et al., 1998) :

- Security
- Redundancy
- Robustness
- Resilience

Many studies have been undertaken in USA (Mays, 2004) for checking the security aspects of various public utilities. For example, the US department of justice conducted a security survey of federal facilities vulnerability (1995)) in response to the bombing of Murrah Federal Building in Oklahoma City in April 1995. The study recommended that where feasible, every federal facility should be brought upto minimum standards specified by the study for its security level. Floyd (1995) has given broad guidelines for developing a security assessment under contract with USEPA and the municipal water systems of Phoenix, Detroit, Atlanta and others. Black and Veatch (1992) have studied the various aspects of security of a major US city. The study has considered the approach of danger to three classes of

community resources such as the human population, business and industry and physical environment.

Redundancy refers to the ability of a certain component of a system to assume the functions of failed components without affecting the performance of the system. For a WDS, redundancy may take the form of properly designed extra pipes in-built in the system, multiple means of system control, duplication in managerial emergency response and the standardization of design of system components. Redundancy can also be achieved through interconnection of WDSs (Castillo et al, 1997). A redundant capability in response to emergency situations assumes a greater chance of containing damage to the system resulting from terrorist act. In other words, redundancy is a corrective measure in case of terrorist attack.

Robustness refers to the degree of insensitivity of a system design to errors in the estimates of certain design parameters that affect the design choice. Hardening a system involves modifying a system's design in effect, choosing a new optimal design. Developing new designs that are robust at a probability level equal to or higher than the original design enhances the hardness of the system rendering it less sensitive to terrorist threats.

Resilience is the ability of a system to be operated close to its optimal design after an adverse event a suitable response to damaging action has been made, such that the economic losses due to aging events may be contained within a certain limit.

Water supply authorities should take urgent note of the requirement of such studies. Approaches are needed for the quantitative analysis of the potential consequences of specific attack scenarios, quantitative risk analysis can be system specific incorporating the case studies like, identification of conventional ways in which a WDS can be disrupted, identification of critical sections of the system that are vulnerable to such attacks which may disrupt the supply for days, for weeks and for months, etc. Accordingly, high priority action plans must be clearly stated and formulated. The cost-benefit analysis of hardening the WDS against the possible attacks should also be studied. The water utilities should have an emergency operations/ response plan in co-ordination with local administration. It should be able to take care of various types of incidents like structural damage (man-made or natural),

contamination event, and events like intrusion through supervisory control & data acquisition (SCADA).

DEVELOPMENT OF NEXT GENERATION ANTI-CONTAMINATION CAPABILITIES FOR WATER SUPPLIES

Water supply systems are spatially diverse and therefore have inherent potential to be vulnerable to a variety of threats like physical, chemical and biological. Water supply systems are designed to deliver adequate water under desired pressure. The disruption could be from raw water source to consumer's tap level. Each of the water supply system element presents a unique challenge to the water utility in safeguarding the water supply. For example, destruction of storage structure, pumping house, treatment facilities, finished water tanks and reservoirs, explosive release of chlorine gas, biological contamination, etc. can cause panic among the people. Since each of these elements is unique it requires a special type of remedial measure.

Contamination if generally viewed as most serious potential terrorist threat to water supply systems. Chemical or biological agents could spread throughout a distribution system and result in sickness or death among the consumers. Some of the contamination might not be noticed unless the emergency rooms report an increase in patients with a particular set of symptoms. There have been report of accidental contamination which resulted in many fatalities in various parts of the world.

Water quality modeling in helps in tracking the water quality changes during the journey from raw water source to the consumer. The water quality simulations to track the propagation of water borne substances in the distribution network are based on the hydraulic characteristics of flow such as flow paths taken by water, the travel and residence time, mixing of water from different sources and corresponding dilution effects. Consumer perception and industry regulation are now focusing on the need for utilities to study water quality variations within the water distribution system and their causes and effects. Recent developments in computer software now provide a capability to build representative models, which can simulate the propagation and concentration of water quality parameters under

steady and dynamic flow condition. The software like EPANET are commonly used for such purposes.

Water quality monitoring is an effort to obtain information on the physical, chemical, biological and radiological characteristics of water via statistical sampling. It is an important aspect of overall water quality management. Quality monitoring in a drinking water supply scheme is undertaken at all the three levels, viz, the source, the treatment plant and the distribution system. A major managerial and technical barrier exists because of lack of proper guidelines for identifying suitable monitoring stations in a WDS. In absence of guidelines, most water utilities go for monitoring at accessible locations. Though it is an important factor, but logically the monitoring station should be those locations that are in low demand zones and are more vulnerable from water quality point of view. However, in most situations, it is not possible to rank the vulnerability of various locations. Thus, a systematic and scientific approach is needed for selecting the monitoring stations which represent the entire network.

The decay in water quality may occur because of (i) internal factors within the distribution system such as long residence time which provides more time for reaction of water borne substances within the bulk and with wall materials; and/ or (ii) external contaminants intruding into the system.

Water quality monitoring in distribution systems of most Indian Metropolitan cities has been carried out in an ad-hoc manner. There is no scientific justification for choosing the location, sampling frequency and the number of sampling stations required to be installed. The monitoring practices can be based on two basic principles (Kumar et al. (1997,1999):

i) Determining the gradual deterioration in quality of finished water within the WDS due to decay of residual disinfectant level, and

ii) Detecting the sudden deterioration of water quality in WDS due to external contamination at one or more nodes.

Strictly speaking, to ensure good water quality at all demand nodes, one should monitor water quality at all the demand nodes, which is practically impossible for a large WDS. To ascertain that internal decay of quality within the WDS is covered with an optimal set of

monitoring stations, one can find out ways and means. Similarly, one can identify the ways & means for identifying the contamination & spread of contamination due to accidental contamination. Some chemical & biological sensors can be developed for identification of contamination so that users can take preventive steps so as to reduce the impact of contamination.

CONCLUSIONS

Drinking water is one commodity in which most of the countries are looking forward to improvements at a massive scale. In this paper threat perceptions to water supply schemes that directly affect quantity and quality of water received by the consumers, and which require attention on an emergency basis, have been discussed. It is felt that the research institutes have potential to develop models in these areas but most of the problems remain unresolved due to absence of coordination between research and field engineers. Thus, there is need industry-institute collaborations in this field of implementing technological up gradations to solve many a pressing problems plaguing the linking water supply systems so that the entire humanity gets better services as far as drinking water is concerned.

ABSTRACT

Since 9/11 numerous communities have installed multi-parameter monitoring stations in the distribution system as early warning systems for potential water security threats. These systems have recorded large streams of data relevant to water quality in the distribution systems. In this study data streams from a number of communities are analyzed for pertinent information as to the health and operation of the distribution system. Changes in water quality are correlated with known causes attributable to day-to-day operational changes and also anomalous events (pipe bursts, accidental back flows, cross connections, chemical over feeds, treatment plant problems, nitrification events, etc.). Information concerning what action was taken to ameliorate the problem will also be linked to the data for the identified events. We will need to consider databases such as this before we determine the best course of action to ensure our water supplies meet acceptable levels of safety from source to tap.

INTRODUCTION

The distribution system represents the last analytical frontier in the water quality industry. The monitoring of source water and treatment plant processes has progressed to a level at which we can be confident that we are providing good quality water from the plant to the distribution system. Once the water reaches our aging distribution systems, however; our knowledge as to its continued integrity is limited by the quality and amount of available data. Most monitoring in the distribution system is relegated to the occasional snapshot provided by grab sampling for a few limited parameters or the infrequent regulatory testing required by mandates such as the Total Coliform Rule in the US. The development of water security monitoring in the years since 9/11 has the potential to change this paradigm. Since 9/11 numerous communities have installed multi-parameter monitoring stations in various locations through out the distribution network as early warning systems to detect potential water security threats. These continuous on-line systems have recorded large streams of data (at some sites for a number of years) relevant to water quality in the distribution systems in which they have been deployed.

For the past several years, scientists at Hach Homeland Security Technologies (HST) have been actively engaged in the development and testing of an early warning system for detecting water quality problems including those related to an intentional terrorist attack. This paper gives a brief summary of how the developed system operates and presents results form some of the recent field-deployment efforts that have been undertaken.

In this study, data streams from a number of communities (both small and large) are analyzed for pertinent information as to the health and operation of the distribution system. Changes in water quality are correlated with known causes attributable to day-to-day operational changes and also anomalous events. Case study information concerning what, if any, action was taken to ameliorate the problem will also be reported for the identified events.

This sort of information is critical in understanding and improving the operation of our distribution systems and can also be valuable as we consider regulations that affect that operation. Any future efforts to regulate the distribution system will need to consider databases and monitoring techniques such as the one described here before we can determine the best course of action to ensure our public water supplies meet acceptable levels of quality and safety from source to tap.

THE HACH METHOD AND APPROACH.

Monitoring in the distribution system is a difficult proposition. The shear number and diversity of potential threat agents that could be utilized in an attack against the system makes monitoring for them on an individual basis an effort that is doomed to failure. To counter and detect the unprecedented number and types of compounds that may be encountered, what is needed is a broad-spectrum analyzer that can respond to any likely threat and even unknown or unanticipated events.

Rather than attempting to develop individual sensors to detect contaminants, the Hach HST approach was to utilize a sensor suite of commonly available off-the-shelf water quality monitors such as pH, electrolytic conductivity, turbidity, chlorine residual and total organic carbon (TOC) linked together in an intelligent network. The logic behind this approach is that these are tried and true technologies that have been extensively deployed in the water supply industry for a number of years and have proven to be stable in such situations. One of the difficulties encountered when designing such a device is that the normal fluctuations in these parameters found within the water can be quite pronounced.

The problem then becomes, can we differentiate between the changes that are seen as a result of the introduction of a contaminant or anomalous condition and those that are a result of normal everyday system perturbation? The secret to success, in a situation such as this, is to have a robust and workable baseline estimator. Extracting the deviation signals in the presence of noise is absolutely necessary for good sensitivity. Several methods of baseline estimation were investigated. Finally, a proprietary, patented, non-classical method was derived and found to be effective.

In the system as it is designed, signals from 5 separate orthogonal measurements of water quality (pH, Conductivity, Turbidity, Chlorine Residual, TOC) are processed from a 5-paramater measure into a single scalar trigger signal in an event monitor computer system that contains the algorithms. The signal then goes through a crucial proprietary baseline estimator. A deviation of the signal from the established baseline is then derived. Then a gain matrix is applied that weights the various parameters based on experimental data for a wide variety of possible threat agents. The magnitude of the deviation signal is then compared to a preset threshold level. If the signal exceeds the threshold, the trigger is activated.

The deviation vector that is derived from the trigger algorithm is then used for further classification of the cause of the trigger. The direction of the deviation vector relates to the agents characteristics. Seeing that this is the case, laboratory agent data can be used to build a threat agent library of deviation vectors. A deviation vector from the monitor can be compared to agent vectors in the threat agent library to see if there is a match within a tolerance. This system can be used to classify what caused the trigger event. This system can also be very useful in developing a heuristic system for classifying normal operational events that may be significant enough in magnitude to activate the trigger. When such an event occurs the profile for the vector causing it is stored in a plant library that is named and categorized by the system operator. When the event trigger is set off the library search begins.

The agent library is given priority and is searched first. If no match is found, the plant library is searched and, the event is identified if it matches one of the vectors in the plant library. If no match is found, the event is classified as an unknown and can be named if an investigation determines its cause. This is very significant because no profile for a given event need be present in the libraries for the system to trigger. This gives the system the unique ability to trigger on unknown threats and events. Also, the existence of the plant library with its heuristic ability to learn plant events results in a substantial and rapid decrease in unknown alarms over time and offers a tool for system optimization. The developed system has been subjected to strenuous testing in both laboratory and field scenarios. This has resulted in this approach being the only water quality monitoring system listed by the US Department of Homeland Security as a designated and certified antiterrorist device under the US SAFETY Act.

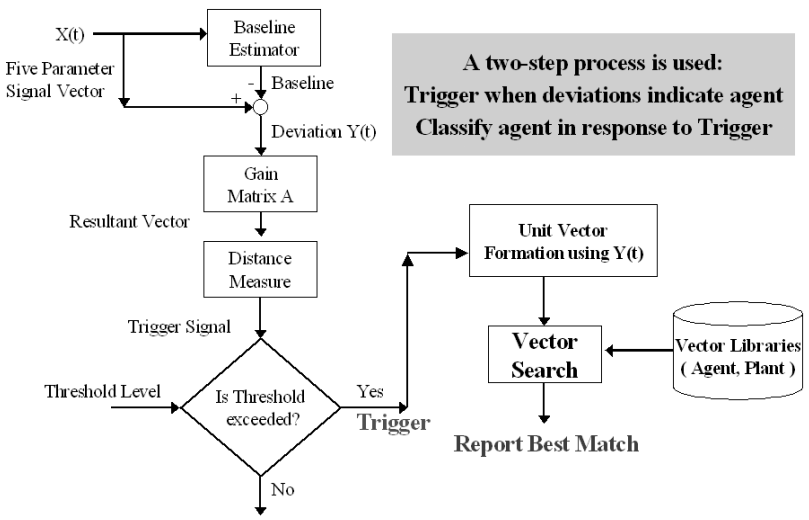

Figure 1. The use of intelligent algorithms with standard bulk parameter monitoring equipment allows for a robust system that is capable of triggering on and classifying a wide diversity of threat agents including unknown events.

FIELD TESTING OF THE DEVELOPED SYSTEM:

Prior to the onset of this project, there was a definite lack of data concerning conditions in the distribution system. Very few utilities carried out data collection in

the distribution system other than periodic grab samples. Those that did have some on-line continuous data were usually limited to only one or two parameters. Since the initiation of this program over, 500,000 hours of real time data has been collected across a wide variety of different distribution systems exhibiting different water matrix profiles revealing many interesting attributes of the distribution systems. These systems represent a variety of water quality conditions and operational situations. The site locations need to remain anonymous due to security considerations and non-disclosure agreements, but they represent a wide diversity of system sizes and geographic locations throughout the United States. The deployments are at both civilian and military sites. At the time of the preparation of this article, all deployments are within the United States. Hach HST has only recently received International Traffic in Arms Regulation (ITAR) clearance from the US Department of State to deploy the systems on an international basis. The following are a few examples of incidents that have been recorded during these real world deployments. These incidents help to demonstrate the systems ability to learn and to become a useful tool not just for security but also for every day operational improvements.

Caustic Overfeed Event

In this deployment scenario, the plant uses caustic feed to control water pH. The system experienced a trigger that when investigated was identified as an operational problem that resulted in the feed of excess caustic. The result was that the overfeed affected the pH and the conductivity of the water, causing the alarm. See figure 2.

The reason behind this was that the vendor from which the casuistic was being purchased had delivered the wrong concentration of the solution. No one had checked to see if the concentration was correct before feeding in the material. New procedures were put in place to verify incoming raw materials. The Event Monitor learned this Plant Event and can identify a recurrence of the event in the future if there is another failure in the system and it is repeated.

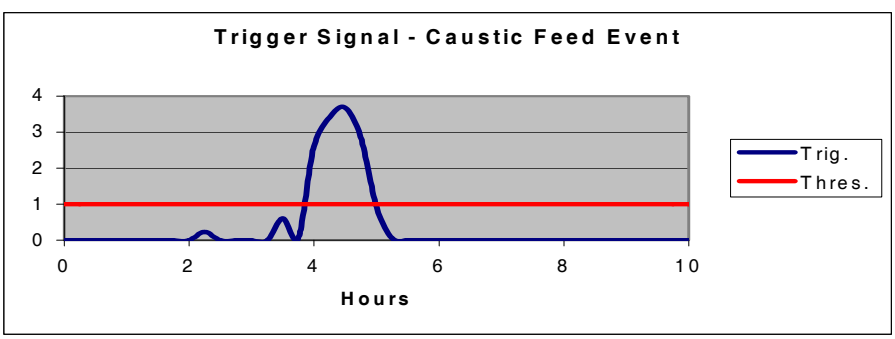

Figure 2. Caustic Event.

Effect of Variable Demand

In this deployment, daily events influencing turbidity, chlorine, pH and conductivity are not completely understood but are suspected to be caused by water

demand fluctuations in the area. This may indicate a need for more routine flushing of the areas pipes and the instillation of a chlorine booster station.

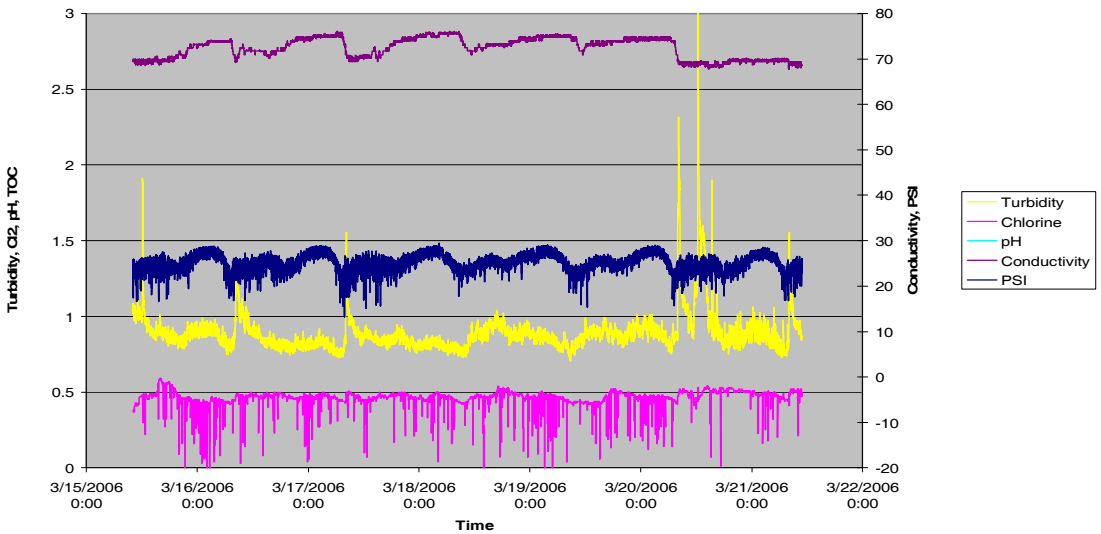

Figure 3. Variable Demand

Ammonia Overfeed Events

On March 26th, 2007; maintenance was performed at the plant supplying water to the distribution system being monitored. After the maintenance was completed, the plant was restarted and the system that feeds ammonia to create monochloramine as a residual disinfectant overfed the chemical. The person in charge of the on-line monitors immediately noticed the increase in pH and notified plant operations. Operations reported a problem with ammonia feed pumps. The problem was temporarily fixed, but a slug of ammonia was sent into the distribution system. Several customers called, complaining about an ammonia smell and taste coming from the tap. The exact amount of ammonia released was unknown, but was believed to be less than 10 ppm. The facility continued operations but temporarily switched to free chlorine as a disinfectant until July 2nd. See figure 4.

On October 3rd, the same treatment plant experienced a brief ammonia overfeed. In this case, a pump was turned on and not switched off at the proper interval. There was a drop in chlorine and a decrease in pH. See figure 5.

Between August 22 and August 23, 2007, three similar events occurred. Increases in turbidity pH and possibly TOC with drops in chlorine caused triggers. These changes resemble the large ammonia event that occurred in March. The operator believes that these could be ammonia feed events, but could not confirm it or find the fault.

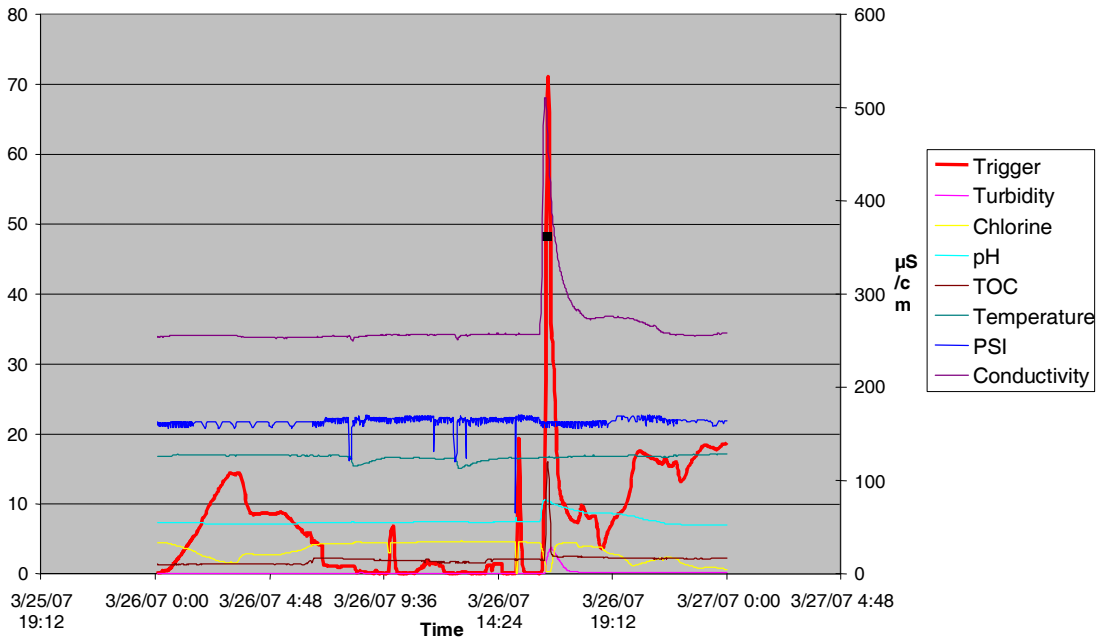

Figure 4. March ammonia overfeed event.

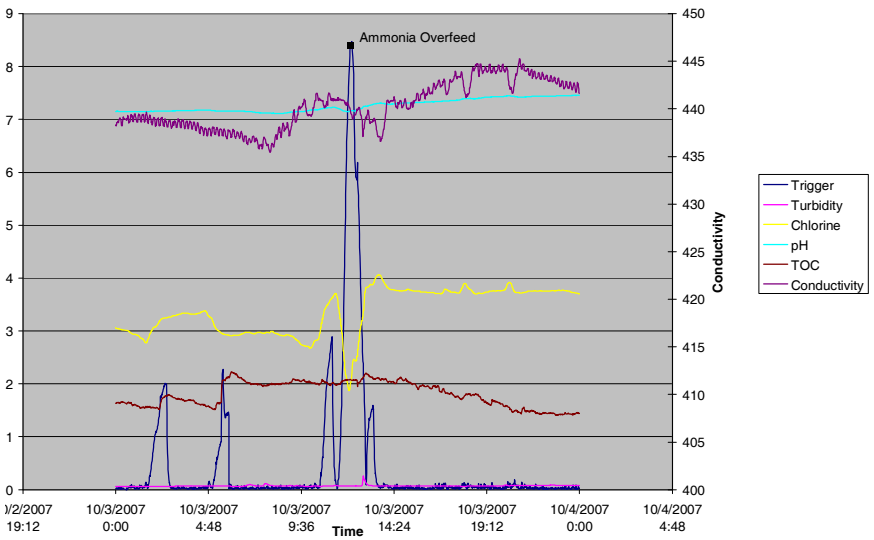

Figure 5. Second Oct 3rd Ammonia Incident

Possible Chlorine Feed Event

An April 3rd, 2007 there was a turbidity and pH increase and a decrease in chlorine and conductivity. The operator suspects that there was a problem with the chlorine feed at the plant. However this cannot be confirmed. The plant was using free chlorine at the time which rules out the possibility of an ammonia feed problem.

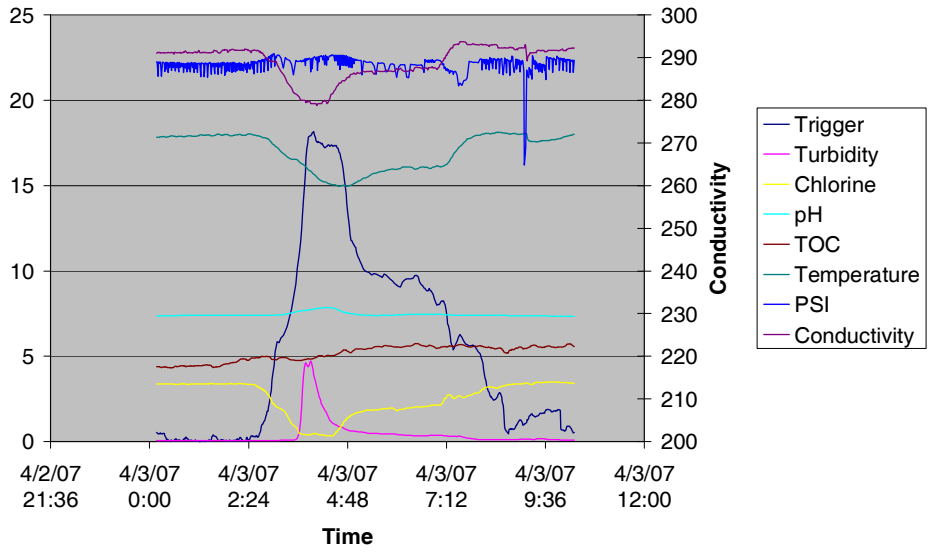

Figure 5. Potential Chlorine Feed Event.

Air Bubble Event.

In one Northern Midwestern city's distribution system, every Friday, the deployed sensors would behave extremely erratically resulting in multiple alarm signals being generated. Investigation led to the discovery of extreme amounts of entrained air bubbles being present in the system's water on Friday afternoons and evenings.

Further investigation into the root cause of the air bubbles being present revealed that school buildings in the area that were to be vacant over the weekend had a policy of using air to blow out their water lines to prevent freezing so that the heat could be turned off over the weekend and holidays. A faulty check valve at one of the schools allowed the air to bleed into the distribution system. The valve was replaced, thus closing a possible backflow route into the system. After this maintenance was performed, the erratic readings ceased.

Distribution Flushing Case Study

In this case, the water utility customers were experiencing poor water quality in certain areas of the distribution system. The systems operations team could not pinpoint the problem. A series of distribution system monitoring devices were installed at various locations throughout the distribution network. The devices were able to help in locating a number of transient dead ends and low flow areas based on the monitoring results. Using this data the team revised the normal flushing schedule for these areas. The results were improved water quality and fewer customer complaints.

Grab Sample Versus On-line Case Study

In this situation, the local water utility had in place an extensive system of water monitoring through grab samples. All indications were that the water quality was good. After installation of several water monitoring panels in the distribution system they found that the turbidity spiked to levels as high as 20 NTU during the

night and early morning hours when typically no grab samples would have been collected. They also found extremely high variability in chlorine levels during these time periods.

A series of changes to their treatment plant operations and distribution system procedures allowed the system to regain control of the water quality in the distribution system. They were able to lower the turbidity spikes to around 1.5 NTU at night and maintain more consistency in chlorine residual levels resulting in better water quality and consistency for the end consumers.

Main Break Events.

In this situation the system had only just been installed a few days previously. Hach HST personnel were informed that the instruments were behaving abnormally and were giving strange readings. An investigation of the sensors found no problems. A short time later a major main ruptured in a catastrophic mode. The system was able to detect the perturbation in water quality parameters that were precursors to the main break and trigger upon them. Unfortunately, the system was newly installed and the event was not recognized until it was too late.

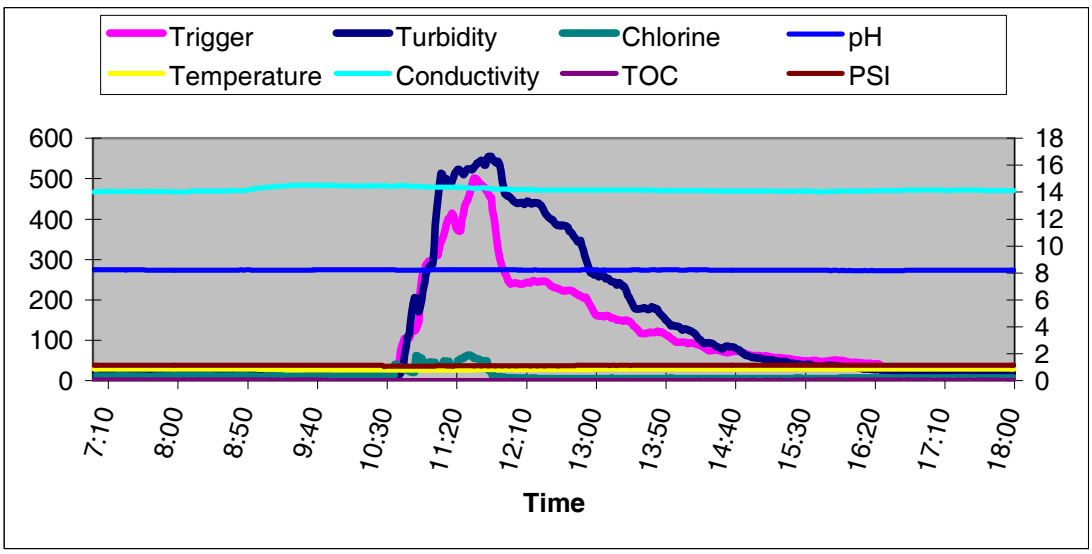

Figure 6. Erratic readings soon after installation.

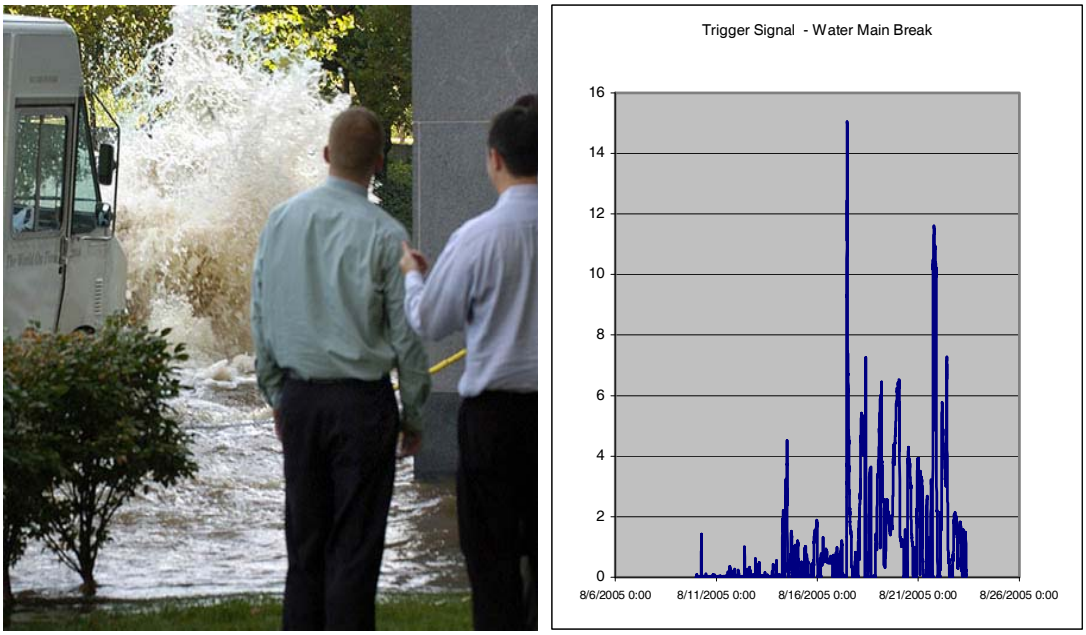

Figure 7. Photo of main break event along with graph of trigger signal.

Another incident occurred on June 29th, 2006 the pipe was an 8-inch line and was located 1.8 miles down stream from the monitoring sensors. There was an increase in turbidity and chlorine. The turbidity appears to have increased the day prior to the break.

A third break occurred on July 30th, 2006. The line was a 36" water main located 1 mile from the monitor. Conductivity, turbidity, and chlorine spiked. There appears to be two water flow interruptions to the WDMP the night before but it's unclear if they are related to the break on the 30th.

This break occurred at night on September 20th, 2006. The exact time of the break is currently unknown, although there appears to be a flow interruption to the monitoring panel the previous morning. The line involved was a 12" water main, which is 0.4 miles from the panel.

CONCLUSION

Extensive laboratory and pipe loop testing that is detailed in a separate papers[1,2,] indicate that these types of monitoring systems appear to be a good choice for detecting water quality excursions that could be linked to water security events. There are a number of advantages to using such systems. The chief advantage is that these instruments are not new. They are based on common everyday parameters with which the average industry worker is quite familiar, thus, adding a degree of comfort in operations not afforded by other new technology. As existing technologies, these instruments have been proven to be robust and dependable in prior field deployments. They represent measurements that would be of interest and use to water utility personnel above and beyond their role as water security devices. The deployment incidents detailed in this paper confirm this and also demonstrate the applicability of utilizing these everyday parameters by linking them with advanced algorithms. The field deployment studies not only demonstrate robustness in the field and the ability to recognize a wide variety of events, but these studies also demonstrate such

system's ability to learn. It is foreseeable that these devices will become much more than a system that is capable of detecting terrorist events. They could easily become a critical tool for improving everyday operations.

For example, through many years of experience, the best old hands at treatment plant operations have developed "a sense" for knowing something in the treatment system is amiss. It can be a smell, color, clarity (or lack there of), sound or just tingling in the nape of the neck. One gains this sense only by extensive experience in a particular facility. These senses do not exist in distribution systems because there has typically been little measurement done upon which to gain these "senses" and, therefore; "Bulk Parameter Monitoring in the Distribution System with Interpretive Algorithms" has the potential to become the artificial "sense" able to quickly "learn" the quirks of the distribution system and have those quirks labeled by those with extensive experience so that less experienced employees have the benefit of that knowledge without having to wait 5, 10 or more years. A good phrase to describe this knowledge base would be "institutional intuition."[3]

With the aging of the work force and rapid employee turnover "institutional intuition" has the chance of quickly dying out. Above and beyond their obvious security benefits, algorithms could be a way to circumvent this loss of knowledge and to build a knowledge base where none has previously existed. This in turn could allow improvements is system operation that may result in cost savings and definitely will result in a higher quality product being delivered to the consumer.

Abstract

In responding to contamination incidents that may occur in a water distribution network, a variety of actions (e.g., public notification and operational changes) can be pursued. A relatively common and effective operational response option utilized by water utilities to address water quality concerns is flushing. The effectiveness of flushing alternatives can be evaluated by modeling the water distribution system dynamics.

Two approaches to modeling hydrant flushing as a hydraulic response are examined in this paper: a fixed flushing rate and flow emitters. In addition, the effects of knowing the source location and the expected contamination spread are explored.

The paper generally demonstrates that the effectiveness of flushing depends on the accuracy with which the initial contaminant plume location is known. In modeling flushing as a response, use of flow emitters instead of fixed flow to model hydrant discharge should provide a more realistic description of system response to flushing.

Introduction

Many utilities across the country are evaluating and considering on-line monitoring systems to address increasing concerns about water quality and the possibility of intentional contamination events. Several research groups have developed methodologies for identifying preferred monitoring locations to provide for a contamination warning system (CWS) or a water quality surveillance program for a utility. Should the CWS detect the presence of a contaminant in a water distribution network, a variety of response actions must be examined in order to implement the most beneficial consequence management strategy, including public notifications and operational changes (e.g., valve closures and flushing). A relatively common and effective operational response option utilized by water utilities to address water quality concerns is flushing. Assuming that flushing is a feasible response, the effectiveness of flushing alternatives can be evaluated by modeling the water distribution system dynamics.

Previous research efforts (Baranowski and LeBoeuf 2008) have used hydraulic/water quality modeling and optimization tools to aid the selection of hydrant locations to flush and valves to close. The optimization objective was to minimize the impact of a

contamination incident in a water distribution system. Flushing was modeled by increasing demand at nodes representing hydrants; however, opening hydrants can occasionally result in negative pressures in the network. Since demand is actually limited by pressure in the real-world, water utility operators cannot simply assign a fixed flow rate to each hydrant. To increase the validity of a hydraulic response, the pressure dependent flushing rate should be modeled as emitter flow.

Therefore, the selected hydrant locations will be modeled as emitters to calculate the feasible flushing rate, since an emitter relates the discharge from the node to the pressure immediately upstream of the node. To evaluate the effect of utilizing emitters, the impacts of contamination incidents in an example network are examined for both fixed flow nodes and emitter nodes for selected hydrant locations.

Methodology

The objective of this research is to identify hydraulic responses that reduce the impact of a contamination event on a water distribution network following successful detection and source identification. The authors, based on knowledge of the system dynamics, selected the locations to flush. Two flushing strategies were utilized; flushing in the center of the expected plume location and flushing near the leading edge of the plume. Since in an actual contamination event the location of a contamination source triggering a sensor and the extent of the contaminant plume will most likely not be known accurately in real time, three assumptions of the plume location were utilized: accurate, over-estimation, and under-estimation.

Following identification of the hydrant locations, flushing was simulated by two different approaches. The first approach increased the demand for these locations to reflect the fixed flushing flow rate. The other approach employed the usage of emitters at the locations to simulate flushing. The emitter equation is given below,

$$Q = K * P^{\alpha}$$

where Q is the flow in gallons per minute (gpm), K is the emitter coefficient in units of gpm/psi$^{0.5}$, P is the pressure in pounds per square inch (psi), and α is the emitter exponent. The emitter coefficient was selected on a system wide basis, while the emitter exponent was set at the default value of 0.5 which is appropriate for orifices.

The metric utilized to determine the effectiveness of the flushing was percent reduction in the extent of contamination. The extent of contamination in the network was calculated for all pipes and times until the end of the simulation. The extent of contamination calculation is,

$$ExtentContamination = \sum_{\substack{i=1..N \\ j=t_{beg}..t_{end}}} contLength_{i,j}$$

where i is the pipe number, N is the total number of pipes, *contLength* is the length of contaminated pipe, and j is time from the beginning of the simulation, t_{beg}, until the end of the simulation, t_{end}. Other metrics of contamination effect could be utilized.

Example

The example network utilized was network two from the Battle of the Water Sensor Networks (BWSN) (Ostfeld et al. 2008), which consists of 12,523 nodes, two reservoirs, two tanks, four pumps, five valves, and 14,822 pipes (Figure 1). For purposes of simulation, a conservative contaminant with a set-point concentration of 100.0 mg/L was injected at the start of the simulation for two hours. Sensors were located at Junctions 3357, 4684, 10874, 11184, and 11304 as determined by Berry et al. in the BWSN (Ostfeld et al. 2008). These sensor locations were chosen based on several criteria and were similar to other designs, such as those by Wu and Walski. The initial simulation ran until detection by one of the sensors, where detection was considered as a concentration greater than 0.01 mg/L.

Starting two hours after detection of the contaminant, flushing was initiated for six hours in order to reduce the total extent of contamination. Two hours represents an optimistic time period in which to confirm that some kind of contamination is occurring, estimate the spread of the plume, determine the best hydrants to flush, mobilize the necessary crews and have them travel to the sites. The overall simulation time was 96 hours, which captured the majority of the contamination spread.

For the purpose of this paper, four flushing locations were chosen for each approach utilized. This number seemed reasonable based on information obtained from a partnering, middle-sized water utility, which stated that to avoid depressurization in their system, the maximum number of hydrants that can be flushed simultaneously is ten. Therefore, four locations were assumed to be feasible for most utilities.

Results

The injection node examined for this research effort was Junction-1742, which is shown in Figure 1 as the red circle. This scenario was detected by the sensor located at Junction-4684, represented as the blue circle in Figure 1, with a concentration of 0.17 mg/L at hour 21 in the simulation. The actual contamination spread at hour 23 (hour at which flushing is begun) is depicted in Figure 2, which is utilized for the accurate estimation of the contamination spread. Figure 3 shows the contaminant plume at hour 23 of another injection scenario detected by the same sensor, which is utilized as the over-estimation of the contamination spread. The under-estimation of the contamination spread at hour 23 is displayed in Figure 4, which is another injection scenario detected by Junction-4684. In Figures 2-4, the selected hydrant locations are represented by diamonds, where the yellow diamonds are the locations selected based on the leading edge of the plume and the orange are locations selected based on the center of the plume.

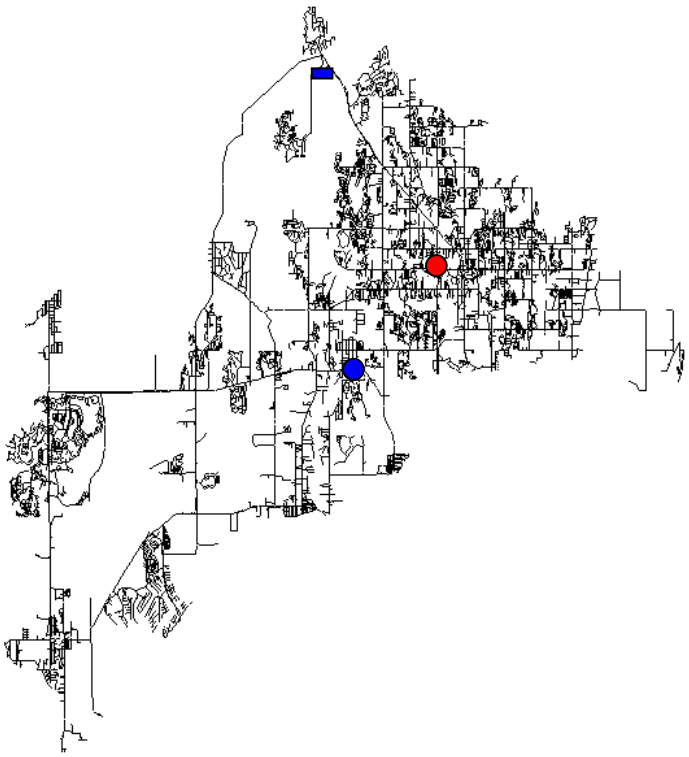

Figure 1. Schematic of example network, BWSN Network 2, where the red circle is the source location, the blue circle is the sensor location, and the blue rectangle is the reservoir.

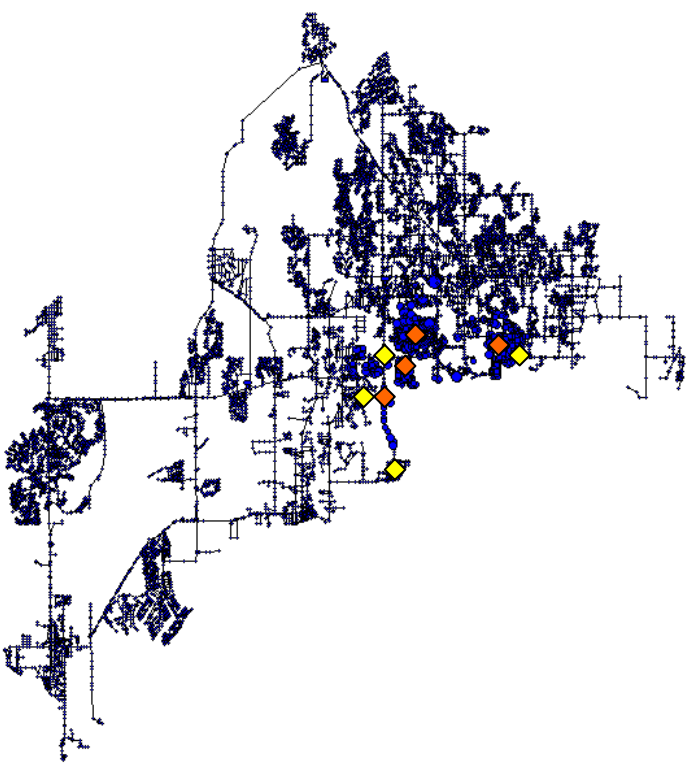

Figure 2. Schematic of accurate contamination spread at the beginning of response, where the diamonds are the hydrant locations: yellow = ahead and orange = center.

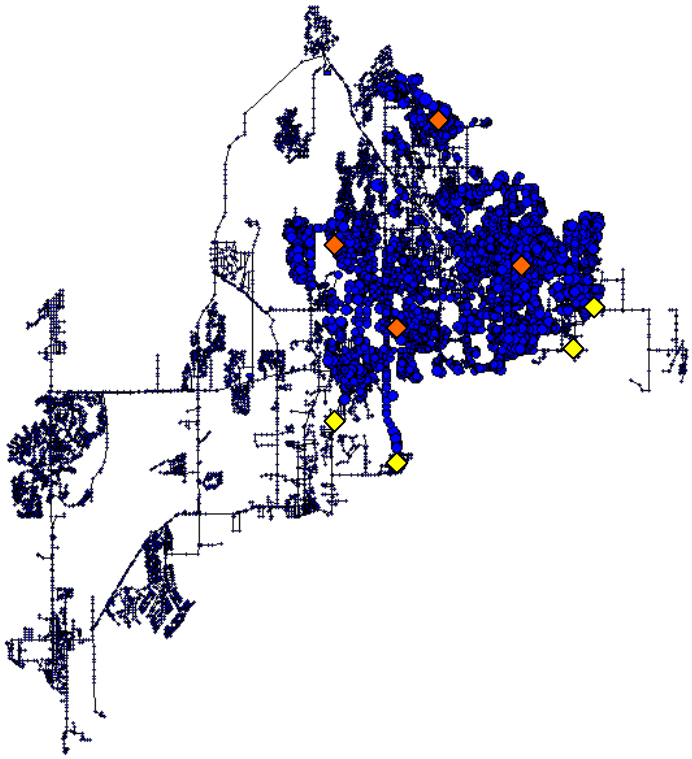

Figure 3. Schematic of over-estimation of contamination spread at beginning of response, where the diamonds are the hydrant locations: yellow = ahead and orange = center.

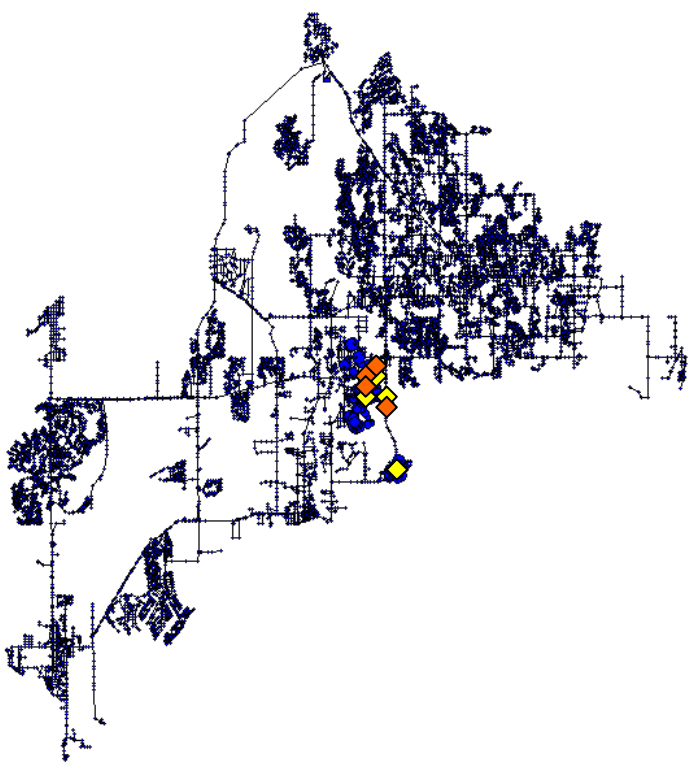

Figure 4. Schematic of under-estimation of contamination spread at the beginning of response, where the diamonds are the hydrant locations: yellow = ahead and orange = center.

The flushing locations for each of the flushing strategies and plume estimation are listed in Table 1. The flushing locations were selected by expert opinion using Figures 2 – 4 (i.e, accurate estimation, under-estimation, and over-estimation of the plume) with consideration of the flushing approach (i.e., locations ahead of the plume and in the center of the plume). The majority of flushing locations were selected on larger service pipes that supply smaller pipes within neighborhoods. The four different emitter coefficients examined in this research effort were 150, 180, 380, and 510 gpm/psi$^{0.5}$. These emitter coefficients were selected based on the lower and upper values for a 2.5 in. outlet and a 4.5 in. outlet (Walski et al. 2003). Utilizing these emitter coefficients and the average system pressure (approximately 77 psi), the corresponding flow was calculated. Based on this calculation, the fixed flushing rates explored were 1300, 1600, 3300, and 4500 gpm.

Table 1. Junction names of hydrant locations for all approaches.

Accurate Estimation of Plume		Under Estimation of Plume		Over Estimation of Plume	
Flushing Ahead	Flushing Center	Flushing Ahead	Flushing Center	Flushing Ahead	Flushing Center
10674	68	5097	1331	545	1172
9976	321	3771	4689	1515	6303
7626	4638	4651	5123	9550	5040
8238	5123	9976	8249	12352	10548

Table 2 shows the percent reduction in extent of contamination for the fixed flushing rate approach, while Table 3 displays the results for the emitter approach. Results from this research effort demonstrate the different modeling techniques that can be applied to simulate a flushing response to a contamination event. By applying the different flushing approaches, similar percent reduction in the extent of contamination objective were obtained. The greatest reduction was achieved by the flushing locations chosen in the center of the plume based on an accurate assumption of the contamination spread. Because the event was not detected until late in the simulation, flushing at four locations only reduced the extent of contamination by 40% or less.

Table 2. The percent reduction in total extent of contamination for the fixed flushing approach.

Fixed Flushing						
Demand (gpm)	Flushing Ahead of Plume			Flushing Center of Plume		
	Accurate	Under	Over	Accurate	Under	Over
1300	27.0%	26.0%	16.9%	34.0%	22.3%	12.1%
1600	26.4%	22.6%	18.6%	37.2%	19.9%	14.0%
3300	30.8%	19.9%	20.4%	40.1%	21.2%	14.9%
4500	31.7%	21.2%	26.4%	42.3%	23.2%	10.3%

Table 3. The percent reduction in total extent of contamination for the emitters approach.

Emitters						
Emitter Coefficient	Flushing Ahead of Plume			Flushing Center of Plume		
	Accurate	Under	Over	Accurate	Under	Over
150	26.0%	25.8%	20.0%	34.3%	22.6%	3.2%
180	25.8%	24.9%	21.8%	36.2%	23.0%	4.9%
380	26.9%	18.1%	20.2%	38.3%	19.0%	4.2%
510	28.9%	19.1%	20.3%	40.2%	20.6%	2.2%

For the majority of analyses, the utilization of fixed flow overestimated the achievable percent reduction by approximately three percent. In a few of the analyses, the percent reduction in the total extent of contamination did not increase with an increase in the flow or emitter coefficient. The reason this might occur is because pipes which were previously uncontaminated may become contaminated due to the flow reversals that are necessary to supply the requested demand. Thus, increasing the demand at some locations increases the number of pipes contaminated.

The benefits of employing emitters are displayed in Tables 4 and 5, which show that the number of nodes with pressures less than 20 psi is more accurately predicted when employing emitters to simulate flushing because it captures the self-limiting nature of hydrant flows. As flow increases, pressure drops to limit flow and using fixed flow fails to capture this effect. In addition, the approach utilizing emitters eliminated any nodes with negative pressures. Table 4 also shows that obtaining flows of 3300 and 4500 gpm at four hydrants is not physically possible in this system and that using those fixed flow rates gives an unrealistic picture of the volume of water that can be flushed.

Thus, to predict a more realistic estimate of the reduction in the extent of contamination, emitters should be utilized to simulate a flushing response. Future work will explore optimization of flushing locations as emitters as well as optimization when the source location is unknown.

Table 4. Number of nodes with pressures less than 20 psi for the fixed flushing approach. The number of nodes with negative pressures are listed in parentheses.

Fixed Flushing Rate	Accurate Ahead	Accurate Center	Under Ahead	Under Center	Over Ahead	Over Center
1300	0	0	0	0	3 (0)	58 (57)
1600	0	0	6 (0)	0	45 (0)	58 (58)
3300	206 (96)	132 (12)	303 (246)	308 (236)	607 (334)	207 (99)
4500	650 (276)	770 (268)	1095 (406)	1123 (389)	1374 (616)	530 (161)

Table 5. Number of nodes with pressures less than 20 psi for the emitters approach. The number of nodes with negative pressures are listed in parentheses.

Emitter Coefficient	Accurate Ahead	Accurate Center	Under Ahead	Under Center	Over Ahead	Over Center
K = 150	0	0	0	0	0	1 (0)
K = 180	0	0	0	0	0	3 (0)
K = 380	0	0	90 (0)	2 (0)	47 (0)	4 (0)
K = 510	88 (0)	7 (0)	107 (0)	15 (0)	161 (0)	4 (0)

Conclusions

This study has implications both in terms of how to decontaminate a system and how to model that decontamination. First, it shows that the effectiveness of decontamination depends heavily on the accuracy of the estimate of the plume location. Overestimating the extent of the plume and flushing accordingly not only is relatively ineffective but can actually spread the plume. If the exact location of the contaminant plume is uncertain it is best to base flushing on a conservative estimate of current spread so as not to expand the plume into clean areas.

Second, based on the results from this example, flushing the system from as close to the center of the plume as possible, can achieve the best containment of the plume. In addition, trying to flush ahead of the plume may be ineffective.

Third, modeling flushing by placing fixed demands on the model can be misleading in that it does not account for the fact that those demands reduce the pressure in the system and may be unachievable or result in negative pressure. Modeling flushing using emitters provides a more accurate estimate of flushing performance.

ABSTRACT

Drinking water distribution systems are vulnerable to biological contamination via many potential intrusion locations; thus, a comprehensive water quality indicator is critical. While previous research has focused on specific pathogen detection using molecular methods, this study seeks to confirm that bacterial indicator classes, specifically, *Alpha-*, *Beta-*, and *Gammaproteobacteria*, can be used as a more comprehensive indicator. The system population exhibits temporal variability in response to changes, such as temperature and disinfectant concentration, but this seasonal bacterial diversity study confirms that these indicator classes are a consistent presence in drinking water. Bacterial class-specific primers were designed to target *Alpha-*, *Beta-*, and *Gammaproteobacteria*, and utilized in Quantitative Polymerase Chain Reaction (QPCR) assays to detect surrogate contaminants. Preliminary results indicate that this QPCR-based approach is a faster, more comprehensive indicator than the culture-based regulatory technique.

INTRODUCTION

Drinking water distribution systems are vulnerable to biological contamination via many potential intrusion locations; thus, a comprehensive water quality indicator is critical for detection of contamination and protection of these systems. Current water quality regulations require testing for total coliform and fecal coliform or *E. coli* concentrations as indicators of possible contamination (USEPA 2001). These culture-based protocols may lead to significant underestimation of microbial diversity and concentration in drinking water (Keinanen et al. 2003, Kalmbach et al. 1997, Von Wintzingerode et al. 1997) and molecular methods may provide public water utilities with more comprehensive water quality information, specifically regarding diversity (Martiny et al. 2005, Schmeisser et al. 2003, Lee et al. 2005).

Proteobacteria constitute the largest fraction within the microbial community identified using 16S rRNA gene clone library analysis for water samples collected

from model and actual distribution systems located in different countries (Williams et al. 2004, Tokajian et al. 2005, Schmeisser et al. 2003, Kalmbach et al. 1997). In these different distribution system studies, the prevalent bacterial classes were *Alpha-*, *Beta-*, and *Gammaproteobacteria* suggesting that these classes may be stable inhabitants of drinking water networks. Although there is a consistent presence of *Proteobacteria* in these systems, some variability has been observed in response to changes in system conditions. For example, *Alphaproteobacteria* is commonly the numerically dominant group in treated bulk water samples because it can survive in the low nutrient, chlorinated environment, while *Betaproteobacteria* are observed more frequently in water with low disinfectant residuals, due to decreased chlorine resistance (Williams et al. 2004, Kalmbach et al. 1997). Seasonal differences in total organic carbon (TOC) or assimilable organic carbon (AOC) may also affect bacterial diversity as nutrient reduction decreases the bacterial re-growth potential (Williams et al. 2005, Eichler et al. 2006, Norton et al. 2000).

It is technically and economically infeasible to develop pathogen-specific sensors for all potential biological contaminants, so a faster and more comprehensive indicator is an alternative approach. If the bacterial populations in distribution systems exhibit stability, with respect to the dominant classes present, then these bacterial classes can be used as indicators and changes in the concentrations of dominant groups, such as *Alphaproteobacteria*, *Betaproteobacteria*, and *Gammaproteobacteria* can be used to signal a contamination event. In order to determine if these bacterial classes are stable enough to be used as indicators, a seasonal study was initiated to evaluate bacterial diversity under different system conditions during the year. After the stability of the bacterial population was determined, this comprehensive indicator, based on dominant bacterial classes, was applied in a more rapid molecular assay (e.g., real-time PCR) appropriate for contaminant detection in drinking water.

METHOD

Total DNA Extraction. Water samples were collected from a continuous flow location in the Pittsburgh Water and Sewer Authority drinking water distribution system. Samples were collected in two 5-liter autoclaved carboys containing sodium thiosulfate (0.03% final concentration) to quench the chlorine reaction and stored at 4ºC until filtration, which occurred within 3 hours of sampling. Samples were filtered through a 0.2 μm filter, the filter was aseptically removed from the apparatus, and placed in a culture plate for storage at -20ºC. The filter was cut into strips using a sterile razor blade, and these strips were placed in two tubes to be used in a modified DNA extraction procedure with the Wizard Genomic DNA kit (Promega, Madison, WI).

PCR. The bacterial community was characterized by 16S rRNA gene clone library analysis, in which a well-conserved sequence, the 16S rRNA gene, is amplified, sequenced, and used to identify the organisms with DNA present in the sample. PCR was used to amplify a section of the 16S rRNA gene present in the extracted DNA sample. *Eubacteria* was targeted with universal primers BAC27F (5'-

AGAGTTTGATCCTGGCTCAG) and BAC805R (5'-GACTACCAGGGTATCTAATCC). PCR reaction mixtures contained template extracted DNA, 1X PCR buffer, 200 µM each deoxynucleoside triphosphate, 2.0 mM $MgCl_2$, 100 nM each forward and reverse primer, and 0.05 U of *Taq* DNA polymerase (Invitrogen, Carlsbad, CA) per ml. The reaction vials were placed in a thermal cycler (Bio-Rad, Hercules, CA) for 3 minutes at 95ºC for initial denaturation, followed by 35 cycles of 94ºC for one minute, 55ºC for 45 seconds, and 72ºC for one minute, followed by a final extension step of 15 minutes.

Clone Library Development. The PCR products were then concentrated (due to the low DNA content) and purified using the QIAquick PCR Purification Kit (Qiagen, Valencia, CA). The purified PCR products were cloned using the TOPO TA Cloning Kit (Invitrogen, Carlsbad, CA) following the manufacturer's instructions and using a modified approach for analyzing transformants by colony PCR with transformed *E. coli* cell culture as template and plasmid-specific primers, M13F (5'-GTAAAACGACGGCCAG) and M13R (5'-CAGGAAACAGCTATGAC), to isolate the PCR products from the vector and 1.0% agarose gel electrophoresis to screen for the correct size DNA fragment. The 16S rRNA gene PCR products were sequenced on an ABI Prism 3730*xl* DNA sequencer at SeqWright DNA Technology Services (Houston, TX).

QPCR Assay. Prior to QPCR, additions of pure culture surrogate bacteria were added to a 10-liter drinking water sample to obtain a concentration of approximately 1.0E+4 CFU/ml. These spiked samples were then filtered and DNA extracted using the methods noted previously. The control sample was collected at the same time and location as the spiked sample, but received no additions prior to filtration and DNA extraction. For each contaminant scenario (control and spiked water samples), extracted DNA was analyzed to determine the quantity of total bacteria using universal primers, and *Alphaproteobacteria*, *Betaproteobacteria*, and *Gammaproteobacteria* using bacterial class-specific primers from literature or designed using Primrose software and Ribosomal Database Project (RDP). All primers were validated for group specificity and optimized prior to use.

Each 25 µl QPCR reaction contained 1X Power SYBR Green PCR Master Mix, 300 nM each forward and reverse primer, and 2 µl of DNA templates, except for the *Alphaproteobacteria* reactions, which contained 600 nM each forward and reverse primer. The real-time thermal cycle was 50ºC for 2 minutes, 95ºC for 10 minutes, followed by 40 cycles of 95ºC for 15 seconds and 60ºC for 1 minute, and a final hold of 7 minutes at 60ºC. All primer sets were run with an annealing/extension step at 60ºC, except for *Alphaproteobacteria* with a hybridization temperature of 55ºC. QPCR assays were run on a 7500 Real-Time PCR System (Applied Biosystems, Foster City, CA) and the DNA concentration of the four target groups: *Alphaproteobacteria*, *Betaproteobacteria*, *Gammaproteobacteria*, and total bacteria, was determined by comparing cycle thresholds of unknown samples against thresholds for plasmid DNA standards with known concentrations ranging from 1.0E+1 to 1.0E+9 copies/µl.

RESULTS AND DISCUSSION

Similar to other bacterial diversity studies in metropolitan drinking water distribution systems, the majority of the 369 seasonal clone sequences were most closely related to 16S rRNA gene sequences found in the *Alphaproteobacteria*, *Betaproteobacteria*, and *Gammaproteobacteria* classes (Martiny et al. 2005, Keinanen-Toivola et al. 2006, Williams et al. 2004). In addition, there were also some sequences identified as belonging to the *Actinobacteria* and *Clostridia* classes. The bacterial diversity of this distribution system is comparable to other systems where *Alpha-*, *Beta-*, and *Gammaproteobacteria* dominate the population, as shown in Figure 1. In all seasonal samples, there is a consistent presence of *Alphaproteobacteria* and *Betaproteobacteria*, which suggests that these bacterial classes may be stable indicators of population diversity, and by extension, system status.

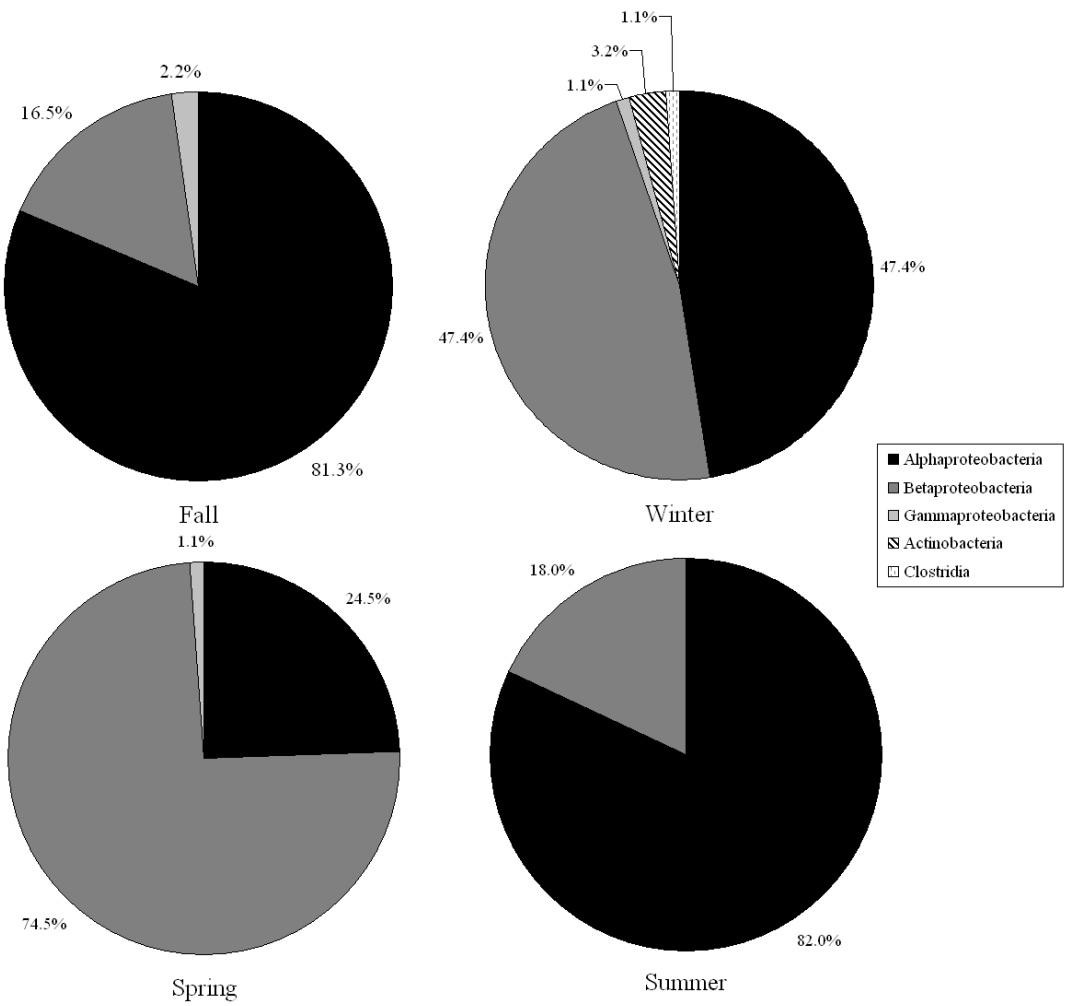

Figure 1. Bacterial class distributions for bacterial populations in drinking water samples collected during four different seasons of the year. Samples were collected starting in November 2006 and finishing in July 2007.

Based on the results of the seasonal bacterial diversity study, which suggests that *Alpha-*, *Beta-*, and *Gammaproteobacteria* are a stable presence within the distribution system and may be used as indicators of biological contamination, some preliminary batch experiments were initiated to test this hypothesis. Assuming that the percentages of *Alpha-*, *Beta-*, and *Gammaproteobacteria* will significantly change from their baseline levels when system disruption occurs, monitoring these bacterial classes is an effective method for detecting contamination in drinking water. Rapid sensing is critical for public health response, so QPCR is used to quantify total bacteria using universal primers and *Alpha-*, *Beta-*, and *Gammaproteobacteria* using class-specific primers. Preliminary results from batch experiments using five different surrogate organisms were favorable. The QPCR-based method detected all contaminants. Statistical analysis of the results is necessary to determine significance and additional experiments need to be run, but preliminary results indicate that this method is a faster and more comprehensive method than current culture-based techniques.

CONCLUSION

This seasonal study of bacterial diversity in a drinking water distribution system corroborates that *Alpha-*, *Beta-*, and *Gammaproteobacteria* are the dominant classes found in these systems. Although there was observed variability in the seasonal bacterial populations due to changes in system conditions, such as temperature and TOC, the bacterial diversity was stable with respect to the presence of the dominant classes. Thus, these indicator classes may be useful indicators of contamination. Although additional experiments and statistical testing should be conducted, preliminary results suggest that a QPCR-based method that targets dominant bacterial classes could be used in drinking water applications as a faster, more comprehensive indicator than current techniques.

Trajectory Clustering Approach for Reducing Water Quality Event False Alarms

Eric Vugrin[1], Sean A. McKenna[1], David Hart[1]

[1]Sandia National Laboratories, Energy, Resources and Systems Analysis Center, PO Box 5800 MS 1138, Albuquerque, NM 87185-1138, {edvugri,samcken,dbhart}@sandia.gov

ABSTRACT

Event Detection Systems (EDS) performance is hindered by false alarms that cause unnecessary resource expenditure by the utility and undermine confidence in the EDS operation. Changes in water quality due to operational changes in the utility hydraulics can cause a significant number of false alarms. These changes may occur daily and each instance produces similar changes in the multivariate water quality pattern. Recognizing that patterns of water quality change must be identified, we adapt trajectory clustering as a means of classifying these multivariate patterns. We develop a general approach for dealing with changes in utility operations that impact water quality. This approach uses historical data water quality data from the utility to identify recurring patterns and retains those patterns in a library that can be accessed during online operation. We have implemented this pattern matching capability within CANARY and describe several example applications that demonstrate a decrease in false alarms.

INTRODUCTION

Event detection software (EDS) tools are an integral part of contaminant warning systems being developed and deployed at water utilities. EDS constitute an integral part of contaminant warning systems (Hasan et al., 2004) and can also provide utilities with enhanced monitoring and management of daily operations. Here we focus on the CANARY EDS developed at Sandia National Laboratories (Hart et al., 2007).

A key component of the effectiveness of these EDS tools in actual operating distribution networks is their ability to reduce false positive (false alarm) detections. EDS parameters can be tuned to be more or less sensitive to changes in water quality with increasing sensitivity resulting in fewer missed detections (false negatives), but also increased false alarms. The tradeoff between false negatives and false alarms can be defined through a receiver operating characteristic curve built on historical data with simulated events and an acceptable EDS sensitivity can be defined from the receiver operating characteristic curve (McKenna et al., 2008).

Deployment of EDS tools in distribution networks has shown that changes in water quality at a monitoring location that are caused by changes in the hydraulic operations of the utility are often responsible for false positive alarms. As an example, examination of deployment of the EDS CANARY at the Greater Cincinnati Water Works (GCWW) over six month period has shown a number of instances where

CANARY produces false alarms due to opening or closing of valves, draining of tanks and changes in the status of pumps within the distribution system (Allgeier et al., 2008; Allgeier and Umberg, 2008; Umberg and Allgeier, 2008).

Development of approaches whereby EDS tools can reliably recognize changes in water quality that are due to changes in hydraulic operations are needed. One path towards this development is to incorporate indicators of the hydraulic changes directly as inputs to the EDS. The main difficulty with this approach is that the changes in hydraulic operations often occur at locations that are not near the water quality monitoring station. While these changes can be used as direct input to the EDS, the time lag between the change in operations, e.g., opening a valve to drain a tank, and the change in water quality at a particular monitoring station depends on demands occurring within the system. This dependence on current demands makes the exact timing and the strength of the resulting water quality change difficult to characterize, especially if other operational changes occur within the same time frame. Extensive knowledge and experience of the utility operations can be applied to more directly relate the operational and water quality changes, but this information is utility specific and not easily generalized across utilities. We propose a new approach that adapts trajectory clustering in order to identify patterns of water quality change.

TRAJECTORY CLUSTERING

A number of multivariate clustering algorithms have previously been applied to water quality data with the goal of classifying the water quality into clusters that indicate anomalous or background water quality (e.g., Klise and McKenna, 2006a,b. These previous efforts have been focused on clustering the actual data values to fit within a finite number of water quality classes. However, for event detection, it is not the current state of the water quality that is of interest, it is the time period during which the water quality changes from one classification (e.g., background) to another (e.g., event) that is of the most importance. If only a relatively small number of clusters are employed, the periods of change from one cluster to another will not fit well with any cluster and these data may be improperly classified. This issue led Klise and McKenna (2006a) to consider every previous data point within a moving window of specified length as a separate cluster for comparison to the current water quality. These difficulties with multivariate clustering of water quality data along with the realization that it is the periods of water quality change that are most critical have led us to focus on classification of the period of change in water quality into background or “other” categories.

Time series data streams have received renewed interest in the data mining literature. One promising technique for identifying patterns in time series data is trajectory clustering (see Gaffney, 2004). In this technique time series of data (i.e., trajectories) are clustered rather than discrete data points. Focused applications have been in the area of classifying historical storm tracks (Camargo et al., 2007; Gaffney et al., 2007). Storm track data are the prototypical data sets for trajectory clustering in that they provide a series of latitude and longitude pairs that define the center of the storm at

discrete time intervals (e.g., every 6 hours). Here we increase the dimensionality of the trajectory clustering framework to examine the water quality within n-dimensional parameter space at a series of discrete time steps. For example, we consider trajectories of the water quality within Cl, pH, turbidity and specific conductivity space (n = 4) at a series of discrete time steps as defined by the output of the water utility SCADA systems.

The approach that we propose herein for reducing false alarms in EDS's adapts trajectory clustering methods. This approach consists of two key steps: 1) create a cluster library of events from historical data and 2) compare water quality signals against entries within the library. The following sections detail those processes.

Library Creation

Several months of historical data are used to develop a library of recurring patterns within the multivariate water quality data streams. This library is created using the following process:

- Run the event detection tool. Here we use CANARY (Hart et al., 2007), with a relatively sensitive set of parameters such that large number of water quality events will be identified.
- Record the water quality signal data for a specified time period prior to the initial indication of each event. The number of time steps in the specified period are denoted by N_t.
- For each of the signals, fit a low-order regression model to the N_t recorded data. This is a single variable regression with data from each signal fit independently of the others. Time is the independent variable in each case. In the examples shown in this paper, 3rd order regression models of the form:

  $$y = \beta_1 x3 + \beta_2 x2 + \beta_3 x + \beta_4$$

  are employed resulting in four parameters that define the shape of the water quality signal trajectory over the previous N_t time steps.
- Store the regression coefficients for each event in a library and classify them into different patterns using multivariate clustering. The algorithm simultaneously clusters the regression coefficients for all signals such that the trajectory of the water quality change, rather than the actual data values corresponding to the changes are clustered.
- Calculate cluster statistics for the comparison step.

Here, the fuzzy c-means (FCM) algorithm (Dunn, 1973; Bezdek, 1981) is used to cluster the regression coefficients. It is an iterative, "soft" clustering algorithm that permits events (or in this case, sets of regression coefficients) to belong to multiple clusters. For each event, the FCM algorithm calculates the degree to which each event belongs to each cluster.

The basis of the FCM algorithm is the minimization of the following objective function:

$$J = \sum_{i=1}^{N_E} \sum_{j=1}^{N_C} u_{ij}^m \left\| x_i - c_j \right\|^2, \; 1 \le m < \infty,$$

where

- N_E denotes the number of events being clustered;
- N_C denotes the number of clusters;
- x_i denotes the events that are being clustered;
- c_j denotes the cluster center for the j[th] cluster;
- u_{ij} is the degree of membership for the x_i to cluster j. Note $0 \le u_{ij} \le 1$, and $\sum_{j=1}^{N_C} u_{ij} = 1$;
- $\| \; \|$ is a norm for measuring the distance of events from cluster centers; and
- m is a "fuzziness" parameter that can be adjusted to affect cluster membership

The FCM requires an "initial guess" for the degree of cluster memberships. To improve the efficiency of the FCM algorithm, we used hierarchical clustering (Johnson, 1967) to assign initial cluster memberships. If hierarchical clustering assigns the i[th] event to the j[th] cluster, u_{ij} is assigned an initial value of δ; otherwise, it is assigned a value of $(1-\delta)/(N_C - 1)$. The parameter δ is set to 0.8 in CANARY's implementation of the FCM algorithm.

Additionally, the FCM algorithm requires that the analyst determine the number of clusters *a priori*. CANARY selects the integer between 2 and 10 (inclusive) that maximizes the PBM index (Pakhira et al., 2003). The PBM index is used since Pakhira et al. (2003) assert that the positive integer that maximizes the PBM-index is optimal in the sense that it minimizes the number of clusters while increasing compactness and separation between clusters. The bounds of 2 and 10 clusters were selected since most examples that have been analyzed optimize the PBM index with 3 to 6 clusters.

To perform comparison of water quality events with the library, it is necessary calculate cluster statistics. Under the assumption that the clusters are normally distributed, means (μ_j) and covariance matrices (COV_j) for the j[th] clusters are calculated as follows:

$$\mu_j = \frac{\sum_{i=1}^{N_E} \left(u_{ij}\right) x_i}{\sum_{i=1}^{N_E} u_{ij}}, \qquad COV_j = \frac{\sum_{i=1}^{N_E} \left(u_{ij}\right)\left(x_i - \mu_j\right)\left(x_i - \mu_j\right)^T}{\sum_{i=1}^{N_E} u_{ij}}.$$

On-line Pattern Comparison

Creation and clustering of a water quality change template library from historical data can be performed in CANARY's off-line mode. When CANARY has a real-time link to a SCADA water quality monitoring system, it can monitor incoming data and assess how similar water quality changes are to patterns already contained in the template library. Sufficiently similar ones are typically caused by changes in operations and are not likely cause for concern. Changes that are significantly different from the template library may merit further investigation. This section describes the process that CANARY uses to compare the real-time signals with the template library.

In its on-line mode, CANARY is connected to a SCADA system that transmits water quality signals to the software. When an event is identified, polynomial regression fits are performed on the incoming data for the same signals that are considered in the template library. This regression uses all of the same parameters that were used to create the template library. The following calculations are then performed for each cluster:

$$xval_j = \left(x_{RT} - \mu_j\right)^T COV_j^{-1} \left(x_{RT} - \mu_j\right), \qquad p_j = 1 - \left[\chi^2_{DOF}\right]^{-1}\left(xval_j\right)$$

where x_{RT} denotes the regression coefficients for the new event and $\left[\chi^2_{DOF}\right]^{-1}$ denotes the inverse cumulative distribution function for the chi-squared distribution with degrees of freedom equal to the total number of regression coefficients per event. Under the assumption that the clusters are multivariate normal distributions, the value p_j denotes the percentile of the jth cluster's distribution to which x_{RT} corresponds. If no p_j values are less than a user defined tolerance level, a new cluster is added to the template library. The cluster is assigned a mean equal to the regression coefficients associated with the new event and a user-specified covariance matrix. If any p_j is less than the tolerance level, no new clusters are added to the template library. Rather, the regression coefficients corresponding to the new event are added to the library, and the FCM algorithm is re-run on the entire supplemented library. Means and covariance matrices are then calculated for each cluster as described in the preceding section.

EXAMPLE CALCULATIONS

An example pattern recognition calculation is shown here to demonstrate this approach. Nine weeks of data are available from the BDWW monitoring station within the PUB network in Singapore. The monitoring station is directly downstream of a water treatment plant and the flow in the pipe past the monitoring station (denoted as "TOPT") varies significantly as shown in the top graphs of Figure 1. Three water quality signals are used: total residual chlorine (TRC), pH and specific conductivity (CDTY) as shown the other graphs in Figure 1. Figure 1 shows nine weeks of data in the left images and an expanded view of 10 days of data in the right images. The data are collected with a 5 minute sampling interval. Figure 1 shows that the flow rate through the pipe has some effect on the water quality values, but the relationship is not straightforward and changes over time.

The linear filtering algorithm within CANARY is used to estimate each future water quality value from the preceding 288 (1 day) values. The differences between the estimated and observed data, the residuals, are shown in Figure 2. The nine week and ten day time periods as shown in Figure 1 are also shown in the left and right images of Figure 2. The residuals demonstrate a more recognizable daily pattern than do the water quality data.

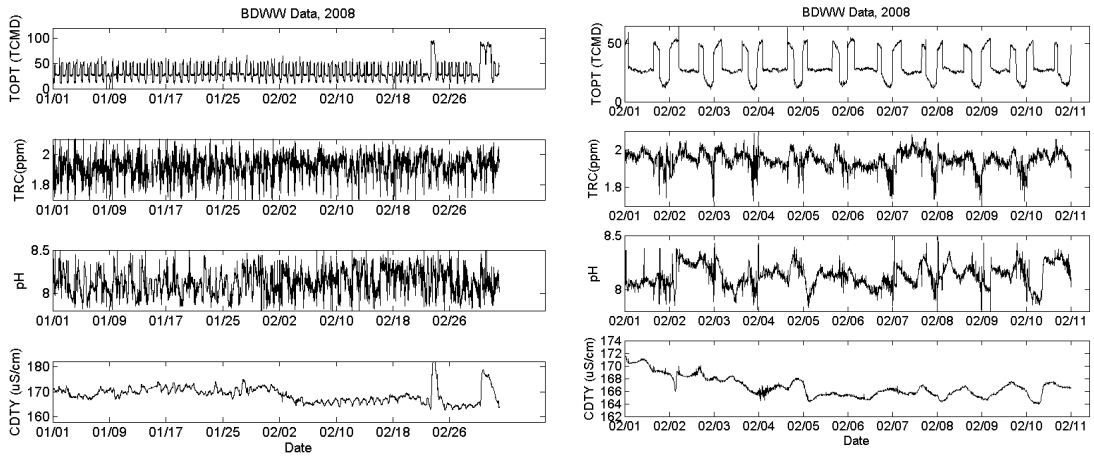

Figure 1. Example data set used for development of the pattern library. The full 9 weeks of training data are shown on the left and an expanded view of 10 days of the data are shown on the right. The total flow in thousand m^3/day (TCMD) is shown in the top graph and the bottom three plots show the water quality signals.

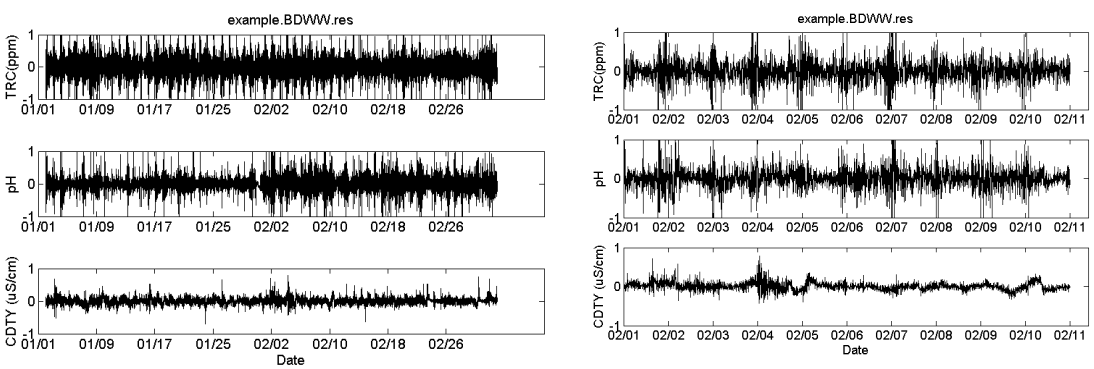

Figure 2. Residuals between estimated and observed water quality data for the example data set. The same time periods as shown in Figure 1 are shown here. The Y-axes have units of standard deviation.

To construct the water quality pattern library, a threshold of 0.8 standard deviations is applied to the residual data seen in Figure 2 and the binomial event discriminator (BED) algorithm within CANARY (McKenna, et al., 2007) is used to calculate the probability of an event (anomalous water quality) at every time step. For times where

this probability exceeds a probability threshold of 0.95, an event is triggered and the previous 90 time steps are retained and a 3rd order regression model is fit to each water quality signal in this 90 time step period. The resulting regression coefficients are then used as input to the FCM clustering algorithm.

A larger data set of roughly 35,000 time steps (approximately 120 days), extending from January 1st to April 30th, 2008 was used to calculate the patterns in the pattern library. The event detection results in a total of 100 unique water quality patterns. These patterns are grouped into 4 clusters by the clustering algorithm. Figure 3 shows the regression models fit to the water quality patterns for the clusters in which they have the highest degree of membership as well as the mean regression pattern for each water quality signal within each cluster. Twenty-three events have the highest degree of membership in Cluster 1, and there are 39, 28, and 10 events assigned to Clusters 2, 3 and 4, respectively.

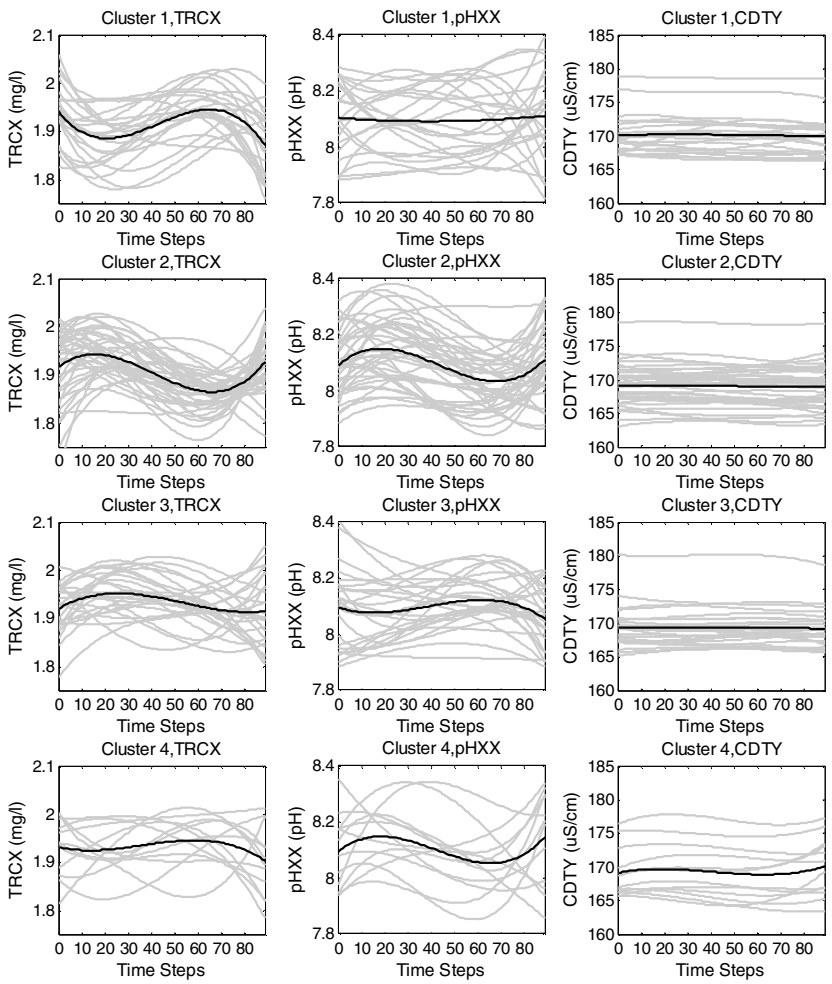

Figure 3. Cluster membership for the water quality patterns in the test data set. The black lines show the mean regression model and the gray lines show the regression models for all members of the cluster.

For each cluster, the distributions of the regression coefficients are shown using box and whisker plots in Figure 4. The clusters are primarily differentiated according to the TRCX and pHXX trajectories closest to the recognition of the event (90 time steps). CDTY does not appear to be as significant a factor in differentiating the clusters. The CDTY coefficients are relatively constant for the first 3 clusters with only Cluster 4 showing significant differences from the other clusters in the CDTY signal.

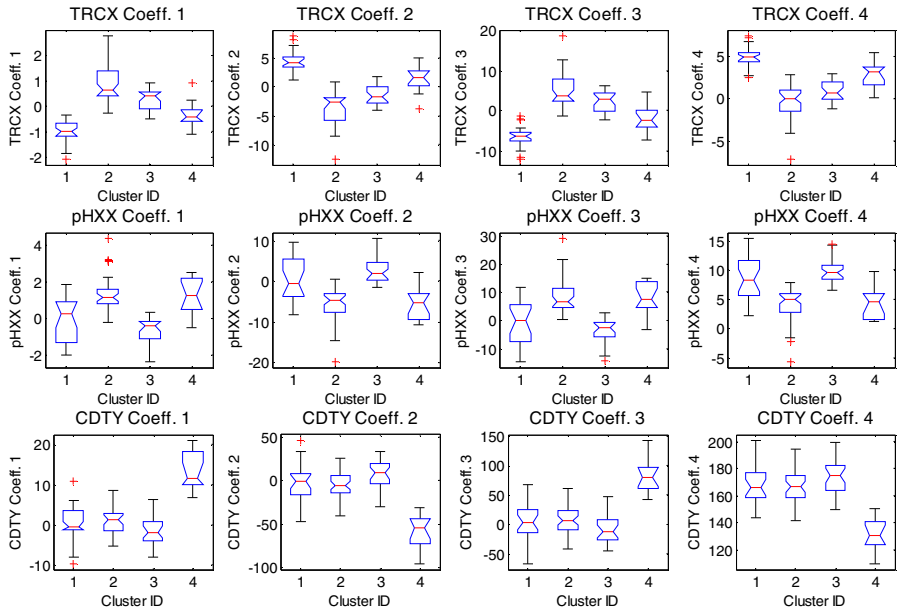

Figure 4. Box and whisker plots showing the distribution of the four regression coefficients for each cluster

Development of the clusters provides a library of recurring water quality patterns that are recognized as background variation in water quality and should not indicate water a water quality event. In order to test the capability of the trajectory clustering approach to recognize previously seen patterns and reduce false positive event detections, CANARY was then run in a manner to simulate its online mode. A testing data set consisting of approximately 30,000 time steps (approximately 100 days), extending from May 1st to August 15th, 2008, was used as input to CANARY. CANARY used the same probability threshold (0.95) to identify 102 water quality events. However, when these events were compared with the pattern library and a tolerance level (see On-Line Pattern Comparison Section) of 0.5 was used, all but 14 fell were rejected as false alarms – an 86% reduction in false alarms. For a tolerance level of 0.75, all but 11 were rejected (89% false alarm reduction). Thus, the library comparison significantly reduced the number of false alarms from CANARY.

CONCLUSIONS

Water quality within distribution networks can display considerable variation and a common source of this variation is due to changes of operational parameters. These operational changes often result in common patterns of water quality change within

multivariate space. While utility-specific rules can be developed to relate operational changes to water quality changes, a general approach that can be applied to any location and any utility is needed. Here we propose and demonstrate trajectory clustering as a general means for classification and subsequent online recognition of recurring water quality patterns. The goal of this approach is to reduce false positive alarms from EDS tools and this approach is successfully demonstrated using the CANARY software.

A training data set was used here to develop a pattern library through offline calculation. Fuzzy multivariate clustering classified distinct patterns of water quality change as summarized with low-order regression models. Event detection and classification of roughly 120 days of data resulted in detection of 100 water quality events which were then classified into four water quality patterns. Subsequent testing using the next 100 days of data resulted in detection of 102 water quality events. Through comparison of these events with the pattern library developed through training, the majority of these events, greater than 80% of them, are recognized as belonging to one of the four existing clusters. Association of these events with water quality patterns in the pattern library eliminates them from being considered as false positive alarms. Further development of this approach will include sensitivity of the results to changes in the event detection parameters and updating of the pattern library as new events are recognized.

ACKNOWLEDGEMENTS

This work was completed as part of the PUB-Sandia project on water security. Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockheed Martin Company, for the United States Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

Abstract

New software such as EPANET-MSX enables water quality models that account for multiple reactive species in the distribution system. This allows for a more complete analysis of network water quality, including processes such as adsorption and biological inactivation by a disinfectant. For each of these reaction processes, three models are presented: single-specie conservative, single-specie reactions modeled by wall demand or bulk decay, and multi-species. The implications of model selection on the resulting exposure to contaminants that undergo these reaction processes are investigated for a hypothetical intentional contamination event and a simple single pipe system.

1 Introduction

As concern for public safety and security grows, so has awareness of the vulnerability of drinking water to contamination. Most people in urban and suburban settings get drinking water from their tap via a water distribution system (WDS). Researchers are investigating a range of possible quality changes that can occur within the WDS (Schock, 2005; USEPA, 2001, 2002a,b,c). Computer models are being used to study dynamics within the WDS and to make predictions.

The capabilities of these computer models have grown along with the awareness of WDS water quality issues. Until recently, most water quality software such as EPANET had the ability to account for only a single dissolved specie (Clark and Grayman, 1998). This single specie is advected with the bulk flow, and can undergo decay or growth in the bulk water as well as wall demand from the pipe wall. Since maintaining the minimum disinfectant residual is an area of concern

among WDS operators, the single specie is often used for modeling a disinfectant like chlorine.

Single-specie modeling has several practical limitations. What about the substances that are reacting with a disinfectant? Their concentrations do not remain the same after reaction. However a single-specie approach prevents modeling both these substances and the disinfectant. Lack of ability to account for these substances may be a concern if they are potentially harmful to consumers or if it results in a less accurate model. Previous studies have shown that accounting for these substances may alter the amount and location of disinfectant injection necessary to maintain safe levels in a WDS (Boccelli et al., 2003; Propato and Uber, 2004). What about wall demand reactions? Does a specie disappear after it reacts with the wall? Conservation of mass says this does not happen, and investigators have shown that the pipe wall could act as a reservoir for harmful contaminants which could be released at some later time (Schock, 2005; Lytle et al., 2004; Copeland et al., 2007).

Multi-species modeling presents the opportunity to more realistically predict water quality as it is delivered to the consumer. Few studies on this type of modeling in WDSs have been published (Boccelli et al., 2003; Propato and Uber, 2004; Shang et al., 2008). The new water quality modeling software EPANET-MSX (Shang and Uber, 2007) enables the study of a wide variety of WDS dynamics with multiple species.

This study investigates multi-species reaction models, and how they compare with their single-specie counterparts in the context of public health assessment. In order to make this comparison, two hypothetical intentional contamination scenarios are presented using three models: single-specie conservative, single-specie bulk decay/wall demand, and multi-species. One scenario involves an injection of arsenate, a contaminant with a well-documented affinity for solids like pipe wall materials (Lytle et al., 2004; Copeland et al., 2007). The reaction models for arsenate may involve adsorption to the pipe wall. The other scenario involves an injection of the bacteria E. coli along with a nutrient broth in which the bacteria can grow and which exerts additional demand for the disinfectant. The reaction models for the bacteria may involve the reactions between the contaminant, disinfectant, and nutrient broth.

In this paper results from simulations run on a single pipe will be presented. The results will help explain reaction dynamics in more complicated networks currently being investigated by the authors.

2 Reaction Models

2.1 Multi-Species Adsorption Model for Arsenate

If arsenate were introduced into a WDS, adsorption would be one of the most significant physico-chemical processes affecting its fate and transport. Since arsenate is the oxidized form of arsenic, there is no reaction with oxidizing disinfectants

such as chlorine or chloramine that are typically present in a WDS (Ghurye and Clifford, 2001). However iron particles that may be corrosion products of iron pipes, or carried over from source waters, present a highly adsorptive surface for arsenate. Adsorbed arsenate can also be released from these particles and once again become dissolved in the bulk flow (Lytle et al., 2004; Copeland et al., 2007).

Adsorption is the physico-chemical process by which a substance, called the adsorbate, attaches to a surface, called the adsorbent. The process is reversible, and the substance may also desorb from the surface. A three-species model consisting of bulk arsenate as the adsorbate, iron particles at the pipe surface as the adsorbent, and an adsorbed arsenate specie can be used to model arsenate adsorption in a WDS. Several modeling approaches have been used for this process, also known as sorption. Empirical models such as Langmuir and Freundlich are available (James M. Montgomery, Consulting Engineers, Inc., 1985), while Surface Complexation Models (SCMs) describe the actual chemical reaction taking place between the adsorbate and adsorbent species (Schnoor and McAvoy, 2010; Dzombak and Morel, 1990). An SCM approach is used here. Although a constant pH is assumed for this work, a key strength of the SCM is its ability to handle variable pH, which has been shown to affect contaminant adsorption and desorption in WDSs (Copeland et al., 2007). The following is a simplified general chemical reaction model for sorption. While the focus here is on bulk arsenate, As, as the adsorbate, the model applies to other dissolved species in a WDS:

$$\mathrm{X} + \mathrm{As} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{XAs} \tag{1}$$

where X is an available surface site of the adsorbent, XAs is an arsenic-occupied surface site, k_1 is the rate of the adsorption reaction, and k_{-1} is the rate of the desorption reaction. If no adsorption has taken place at the beginning of the simulation, the initial value of [X] represents the maximum adsorptive capacity of a WDS in terms of available surface sites located at the pipe wall. This model can be implemented as a system of differential equations which describes the time-varying rates of change of the three species (Grossl et al., 1997):

$$\frac{d[\mathrm{As}]}{dt} = A_v(-k_1[\mathrm{X}][\mathrm{As}] + k_{-1}[\mathrm{XAs}]) \tag{2}$$

$$\frac{d[\mathrm{X}]}{dt} = -k_1[\mathrm{X}][\mathrm{As}] + k_{-1}[\mathrm{XAs}] \tag{3}$$

$$\frac{d[\mathrm{XAs}]}{dt} = k_1[\mathrm{X}][\mathrm{As}] - k_{-1}[\mathrm{XAs}] \tag{4}$$

where A_v is the ratio of pipe wall surface area per unit pipe volume in units of $\frac{\mathrm{m}^2}{\mathrm{L}}$. A_v is necessary to reconcile the units of measurement for the surface species [X] and [XAs], which will be expressed as moles per area of pipe surface, and the bulk specie [As], which will be expressed as moles per pipe volume.

To use this model for a contamination of a WDS by arsenate, the rate constants k_1 and k_{-1} must be known, as well as initial values for all the species. This requires

knowledge of the specific substance that arsenate is sorbing to at the pipe wall. While the actual make-up of the pipe wall is highly variable and uncertain, an iron oxide known as ferrihydrite is a typical component of the corrosion layer of iron pipes that is in contact with water (Sarin et al., 2004). Iron oxides such as ferrihydrite may also be present at the pipe wall for other pipe materials, the iron source being dissolved iron that has made it through the water treatment process (Lytle et al., 2004). Ferrihydrite, also known as hydrous ferric oxide or amorphous iron oxide, will be used here to model the pipe wall surface. While this simplifying assumption facilitates the experiments for this work, it is impossible to know exactly what specific reactions are happening in any given WDS without examination of the materials of that system under operating conditions. The results gained from the experiments here indicate what may be happening if these simplifying assumptions are valid.

The forward and backward rates for this reaction have been experimentally determined (Grossl et al., 1997) to be $k_1 = 7.18 \times 10^9 \frac{\mathrm{L}}{\mathrm{mol} \cdot \mathrm{hr}}$ and $k_{-1} = 2.88 \times 10^4 \frac{1}{\mathrm{hr}}$ in the pH range 6.5 - 7.5. It should be noted that these rates pertain to arsenate adsorption on a different iron oxide known as goethite. However ferrihydrite and goethite have similar capacities for arsenate on a surface-area-normalized basis and similar equilibrium constants for the sorption reaction with arsenate (Dixit and Hering, 2003).

In order to determine the initial value of [X], a physical model of the pipe wall needed to be developed. Ferrihydrite particles are often assumed to be spherical (Fuller et al., 1993), so the initial concentration of surface sites [X] was estimated by assuming the pipe wall surface was made up of hemispheres of ferrihydrite organized in a square array. The mean diameter of a ferrihydrite aggregate has been reported as 30 μm (Scheinost et al., 2001), which was used as the diameter of the hemispheres. Using an areal site density of $2.6 \frac{\mathrm{sites}}{\mathrm{nm}^2}$ (Dixit and Hering, 2003) on the surface of the hemispheres, an initial concentration of $6.78 \times 10^{-6} \frac{\mathrm{mol}}{\mathrm{m}^2}$ of surface sites on the pipe surface was calculated. This approach may underestimate the availability of sorption sites because it ignores diffusion-limited sites (Pierce and Moore, 1982; Fuller et al., 1993; Raven et al., 1998). The initial concentration of adsorbed arsenate [XAs] was assumed to be zero, and the initial concentration of bulk arsenate [As] will depend on the particular contaminant source characteristics.

It should be noted that the concentration of a dissolved substance may be different in the boundary layer adjacent to the pipe wall. This accounts for the fact that dissolved species undergo a diffusive mass transfer process to get through the laminar sub-layer of turbulent pipe flow to the pipe wall surface. While it is possible to model this additional concentration as another specie, preliminary analyses indicated that this makes little difference in the resulting bulk concentrations. For simplicity, it is assumed the concentration next to the wall is the same as the concentration in the bulk flow for all models.

2.2 Single-Specie Wall Demand Model for Arsenate

A single-specie wall demand model for bulk arsenate would necessarily fix the wall capacity [X] as a constant. Therefore it is incorporated with the rate constant for the forward reaction from the previous model to make a wall reaction rate constant $k_w = k_1 \cdot [\mathrm{X}] = 4.87 \times 10^4 \frac{\mathrm{L}}{\mathrm{hr} \cdot \mathrm{m}^2}$. In this model, the single bulk arsenate specie undergoes wall demand according to

$$\frac{d[\mathrm{As}]}{dt} = -A_v k_w [\mathrm{As}] \tag{5}$$

2.3 Single-Specie Conservative Transport Model

For both arsenate and E. coli, the conservative transport model represents an assumption that the contaminant is advected with the flow and does not undergo any sort of reaction.

2.4 Multi-Species Model for E. Coli Inactivation

This model addresses concerns of WDS contamination by biological agents. The conceptual model consists of three species: free chlorine, E. coli bacteria, and a nutrient broth. Assuming second order kinetics allows a simple way to model this three-component system as a set of differential equations:

$$\frac{d\mathrm{E}}{dt} = -k_{e1}\mathrm{CE} + k_{e2}\mathrm{BE} \tag{6}$$

$$\frac{d\mathrm{C}}{dt} = -k_{c1}\mathrm{CE} - k_{c2}\mathrm{CB} - k_{c3}\mathrm{C} \tag{7}$$

$$\frac{d\mathrm{B}}{dt} = -k_{b1}\mathrm{BC} + k_{b2}\mathrm{BE} \tag{8}$$

where E is the measure of coliform bacteria in $\frac{\mathrm{cfu}}{\mathrm{L}}$, C is chlorine concentration in $\frac{\mathrm{mg}}{\mathrm{L}}$, and B is the Tryptic Soy Broth (TSB) concentration in $\frac{\mathrm{mL\ TSB}}{\mathrm{L}}$. TSB is a common nutrient growth medium.

Simplifying assumptions reduce the number of parameters that must be estimated. At the time scale of interest, bacterial growth and resulting consumption of TSB is assumed to be negligible ($k_{e2} = k_{b2} = 0$). Chlorine demand exerted by bacterial inactivation and natural organic matter is assumed to be negligible in comparison to that due to TSB ($k_{c1} = k_{c3} = 0$). This leaves the following equations:

$$\frac{d\mathrm{E}}{dt} = -k_e\mathrm{CE} \tag{9}$$

$$\frac{d\mathrm{C}}{dt} = -k_c\mathrm{CB} \tag{10}$$

$$\frac{d\mathrm{B}}{dt} = -k_b \mathrm{BC} \tag{11}$$

Published chlorine survivability data (Rice et al., 1999) for E. coli 0157:H7 were used to estimate k_e by a least squares method. The value of k_e used here is $0.07766 \frac{\mathrm{L}}{\mathrm{mg} \cdot \mathrm{s}}$. Estimation of k_c and k_b is complicated since there is no direct way to measure the time-varying concentration of a broth media, as represented by B. Therefore chlorine measurements are used to estimate these parameters. The chlorine and broth reaction rate equations can be solved simultaneously in a parameterized form (Boccelli et al., 2003):

$$\mathrm{C}(t) = \frac{\mathrm{C}_0 - \alpha}{1 - (\alpha/\mathrm{C}_0)\exp[-(\mathrm{C}_0/\alpha - 1)\beta t]} \tag{12}$$

where $\alpha = \frac{a}{b}\mathrm{B}_0$ and $\beta = k_c \mathrm{B}_0$ (note also that from stoichiometry, $k_b = \frac{b}{a}k_c$).

The parameters α and β depend on three terms: the stoichiometric ratio $\frac{a}{b}$, k_c, and B_0. For the purposes of estimating k_c and $\frac{a}{b}$ (and thus k_b), the value of B_0 is specified as the nutrient broth's volumetric dilution ratio upon initial mixing, and is expressed in units of $\frac{\mathrm{mL\ TSB}}{\mathrm{L}}$. After initial addition, B can be understood as the concentration of a reactive substance with potential to reduce chlorine.

To estimate the parameters for the chlorine-broth interaction, time-varying chlorine concentration data for bench-scale batch mixtures of TSB in a chlorinated buffer were fit by a least-squares method. The parameter values estimated were: $k_b = 0.00937 \frac{\mathrm{L}}{\mathrm{mg} \cdot \mathrm{s}}$ and $k_c = 0.063958 \frac{\mathrm{L}}{\mathrm{mL\ TSB} \cdot \mathrm{s}}$.

2.5 Single-Specie Bulk Decay Model for E. Coli

For a bulk-decay model, pseudo first order inactivation kinetics are assumed:

$$\frac{d\mathrm{E}}{dt} = -k_{e'} \mathrm{E} \tag{13}$$

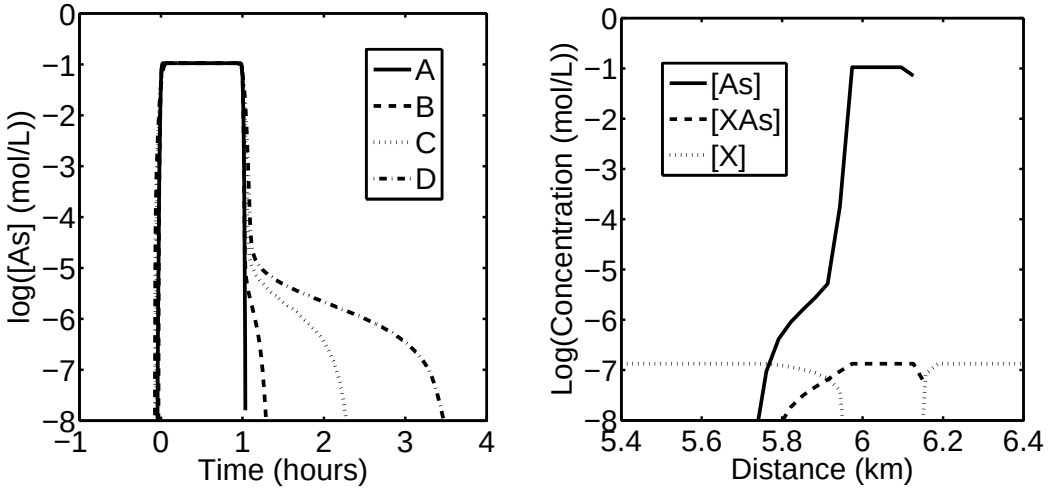
where $k_{e'}$ is the pseudo first order inactivation rate constant estimated using chlorine inactivation data (Rice et al., 1999), assuming a constant $1.1 \frac{\mathrm{mg}}{\mathrm{L}}$ background chlorine concentration. The value of $k_{e'}$ was determined to be $0.0854 \frac{1}{s}$ using a least squares method.

3 Software

To model multiple reactive species, the water quality modeling software EPANET-MSX is used (Shang and Uber, 2007). EPANET-MSX is the Multi-Species eXtension to the WDS modeling software EPANET, and both are freely available on the web (Shang and Uber, 2007). EPANET models the hydraulics of a system and has the capability to model one specie which can undergo bulk decay or growth and wall demand.

EPANET-MSX emerged to address the need to model reactive systems that can be more accurately described using a multi-species approach, such as those presented here. Using this new software, any number of reactive species in the categories of bulk species that are advected with flow and wall species that are attached to the stationary pipe wall can be accounted for. To accomplish this, EPANET-MSX requires that the number of reaction rate equations or equilibrium equations supplied by the user be equal to the number of species being modeled. For example, Equations (2)-(4) can be used to implement the multi-species adsorption model for arsenate. EPANET-MSX will be used here to run both single-specie simulations such as would be possible with stand-alone EPANET as well as the multi-species simulations they will be compared to.

4 Experimental Design for Arsenate Models



A network consisting of a single pipe was created as an EPANET input file for the hydraulic simulation. The pipe has a diameter of $D = 20$ cm. The flow in the pipe is a constant $Q = 1.6\frac{\mathrm{L}}{\mathrm{sec}}$. The pipe has several zero-demand nodes along its length that are modeled in order to obtain plots of species concentration versus distance. The injection scenarios are based on the assumption of a constant backflow of $0.0082\frac{\mathrm{L}}{\mathrm{sec}}$ with a duration of 1 hour at the start of the simulation. The limiting solubility of arsenic acid at 12.5 °C is $\frac{302\ \mathrm{g}}{100\ \mathrm{mL}}$ (Weast, 1987), which leads to a source mass rate at the beginning of the pipe, $M = 10\frac{\mathrm{mol}}{\mathrm{min}}$ arsenate.

5 Results for Arsenate Models

The concentration profiles of bulk arsenate versus time are shown in Fig. 1(a) for the multi-species adsorption model at several distances and the conservative model. The single specie wall demand model resulted in rapid and complete wall demand of arsenate, at odds with the other models. Complete wall demand occurred within 30 meters of pipe length for this model, so it is not shown here. In a single-specie wall demand model, the adsorbed specie is not modeled and so can never desorb and rejoin with the bulk flow. Also, the rate of wall demand is unrealistically high because it is proportional to the wall capacity. While in reality a pipe surface would lose capacity as it adsorbs more contaminant, the wall capacity in the wall demand model is constant and thus never decreases.

For the conservative and multi-species models, all concentration profiles have similar leading edges and reach the concentration expected from this scenario. The mass injection and flow rate combine to give an expected bulk concentration of $\frac{M}{Q} \approx 10^{-1}\frac{\mathrm{mol}}{\mathrm{L}}$. The multi-species model can be observed to add a tail to the trailing edge of the pulse input which grows as the pulse moves down the pipe.

The concentration profiles of the multi-species adsorption model versus distance are shown in Fig. 1(b). The wall species were converted to bulk concentrations by multiplying by A_v, for direct comparison to the bulk specie. Con-

(a) Log concentration of bulk arsenate versus time since pulse arrival at distances = 1.1, 6.1, and 12.2 km from injection site. T_0 represents the arrival time of the pulse at a particular distance. A is the conservative model at T_0 = 6.8 hours. B, C, and D are the bulk [As] specie from the multi-species model at T_0 = 6.8, 34.6, and 69.5 hours respectively.

(b) Log concentration versus distance from injection site at time = 35 hours after start of one-hour injection. [As] = bulk arsenate, [XAs] = adsorbed arsenate, [X] = available surface sites.

Figure 1: Arsenate Models

centrations of wall species expressed in this way can be thought of as the bulk concentration that would result if the wall species at that location were to completely, instantaneously desorb.

Fig. 1(b) shows that the adsorbed arsenate, [XAs], reaches its maximum possible surface loading while the slug of bulk arsenate, [As], is passing by. The maximum surface loading is indicated by the level of unoccupied surface sites [X] prior to contact with the bulk specie. It can also be seen that the bulk concentration in the tail added by the multi-species model can exceed the maximum possible surface loading by more than one order of magnitude at this time in the simulation.

On Fig. 1(a) it can be observed that the pulse input has undergone some numerical dispersion and so the edges of the conservative model graph are not perfectly vertical. The Lagrangian transport scheme used by EPANET as well as EPANET-MSX does not cause dispersive error in pipes, however the pipe used here had several zero-demand nodes along its length.

Nodes have a dispersive effect in this numerical scheme. Accumulation of several discrete parcels of water in the downstream node of a pipe can occur during a water quality timestep. This causes numerical dispersion when the parcels are released as a single parcel with the volume-averaged concentration of the input parcels. Decreasing the timestep will alleviate this numerical dispersion, as illustrated on Fig. 2. Each plot on Fig. 2 is the conservative model and

theoretically would appear as a rectangular pulse. Numerical dispersion causes distortion as the timestep is increased. A timestep of 10 seconds was used for the simulations presented here.

6 Implications for Arsenate Exposure Assessment

In a hypothetical intentional contamination event in a WDS, a public health concern would be the length of time the contaminant remains at a potentially dangerous level in a WDS. For acute arsenate exposure, this level can be determined using the Minimum Risk Level (MRL), which represents the smallest dose of the contaminant considered to be of concern to humans. The MRL for acute arsenate exposure is $0.3\frac{\text{mg}}{\text{person}\cdot\text{day}}$ for a 60 kg person (Center for Disease Control, 2008).

A common ingestion assumption for daily water consumption is $2\frac{\text{L}}{\text{person}\cdot\text{day}}$ (USEPA, 1997). If a consumer were to ingest their 2 L of water all at once, we would want to know if they received a dose equal to or exceeding the MRL for arsenate. A concentration of $\frac{0.3\text{mg}}{2\text{L}} = 10^{-5.7}\frac{\text{mol}}{\text{L}}$ of arsenate. For analysis of exposure to this level a simplified scenario is assumed where there is an uninterrupted path from contaminant source to consumer along the single pipe. In an actual WDS, the problem would be complicated by mixing of other waters, variable flow in pipes, and variable demand. The authors plan to consider these factors in network simulations.

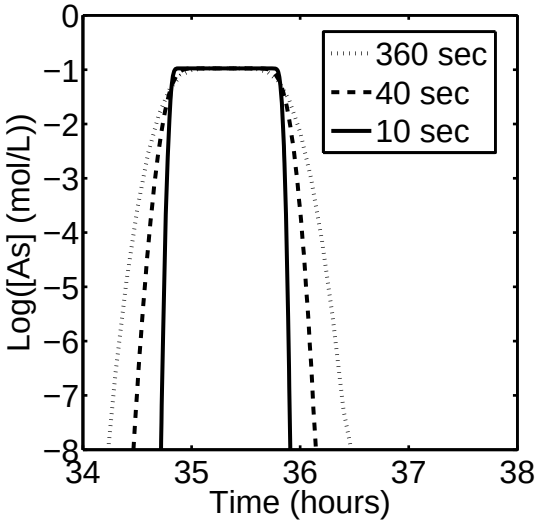


Figure 2: Log concentration of bulk arsenate versus time since beginning of one-hour injection at distance = 6.1 km from injection site. Only the conservative model is shown here to illustrate numerical dispersion. The water quality timestep was varied as indicated in the legend.

In terms of which models are appropriate under these simplified conditions, the wall demand model as formulated here is very different from the other two. Although no physical experiments were conducted, it does not seem appropriate to conclude that an arsenate injection would completely disappear and that consumers at the downstream distances studied here would never receive arsenate in their water. The differences between the conservative and multi-species models are more subtle and are best examined using semi-log plots as on Figs. 1 and 2.

The simulation indicated that the duration of exposure to levels at or above $10^{-5.7}\frac{\text{mol}}{\text{L}}$ of arsenate was 26 minutes longer for the multi-species model than for the conservative model at the location 6.1 km from the injection site pictured in Figure 1. This represents a 38% increase in exposure time. At a distance of

12.2 km downstream of the injection site, exposure time was increased by 75%. Therefore duration of the possible window of time for acute arsenate exposure for a consumer located at these distances downstream of the injection site is significantly affected by use of the conservative model instead of the multi-species model as formulated here.

In addition, there may be more adsorption sites available than are accounted for here, due to the porous nature of the material at the pipe wall (Sarin et al., 2004). Most research of arsenate adsorption onto ferrihydrite indicates the presence of diffusion-limited sites which provide additional capacity for adsorption (Pierce and Moore, 1982; Fuller et al., 1993; Raven et al., 1998). These additional sites may result in increased exposure.

7 Experimental Design for E. Coli Models

For the E. coli simulations, the same pipe diameter D and bulk flow Q are used, as well as a one-hour pulse injection of E. coli at the beginning of the simulation. The pipe has a constant initial chlorine concentration of $1.1\frac{\text{mg}}{\text{L}}$ that will interact with the TSB and E. coli. For this experiment the contaminant injection flow rate Q_i will be varied while the bulk flow Q remains constant. The effect of the changing ratio $\frac{Q_i}{Q}$ on the log inactivation of E. coli at a location 1.2 km downstream of the injection site will be examined for the various models. This distance corresponds to 7.5 hours of contact time. The contaminant injection will consist of TSB and E. coli where the ratio of E. coli to TSB is $1.2 \times 10^6 \frac{\text{cfu}}{\text{ml TSB}}$ (Rice, 2009). Initial concentrations for E. coli and TSB are calculated by dividing their mass or volumetric injection flow rates by the flow in the pipe.

8 Results for E. Coli Models

Since the conservative model has no reactions, the log inactivation of E. coli, $\ln(\frac{[\text{E}]}{[\text{E}]_0})$, will be zero as the pulse propagates down the pipe with concentration $[\text{E}] = [\text{E}]_0$. In contrast, the bulk decay model resulted in near-complete inactivation of E. coli by the time the pulse reached a distance 1.2 km from the injection site. Since a constant chlorine residual is assumed in this model, the rate of bacterial inactivation is artificially high. This phenomenon is similar to that observed in the wall demand model for arsenate and is one drawback of single-specie modeling.

In the multi-species model, the advected pulse had a uniform concentration of TSB, E. coli, and chlorine at a distance 1.2 km from the injection site. The log inactivation or log reduction values for these species using the natural logarithm are plotted on Fig. 3 against the ratio $\frac{Q_i}{Q}$. For reference, $\frac{Q_i}{Q} = 5 \times 10^{-4}$ corresponds to a contaminant injection flow rate of $Q_i \approx 6 \times 10^{-4} \frac{\text{L}}{\text{sec}}$ in this scenario.

9 Implications for E. Coli Exposure Assessment

For purposes of illustration, a 3-log bacterial inactivation criterion is used to compare the different modeling techniques. The nonreactive model has a log inactivation of zero. This model could be thought of as the most conservative when assessing public health impacts for this contaminant, since it does not simulate the disinfecting properties of a chlorine residual. The bulk decay model, similar to the wall demand model for arsenate, seems the least conservative of the three models due to the unrealistically high rate of contaminant loss.

The achievement of 3-log inactivation in the multi-species model is shown to depend on the rate of contaminant injection in Fig. 3. This model predicts that for a contaminant injection greater than $Q_i \approx 6 \times 10^{-4} \frac{\mathrm{L}}{\mathrm{sec}}$, the inactivation criterion is no longer achieved. Preliminary results indicated that with an injection flow $Q_i = 0.3 \frac{\mathrm{L}}{\mathrm{sec}}$, inactivation of E. coli was negligible.

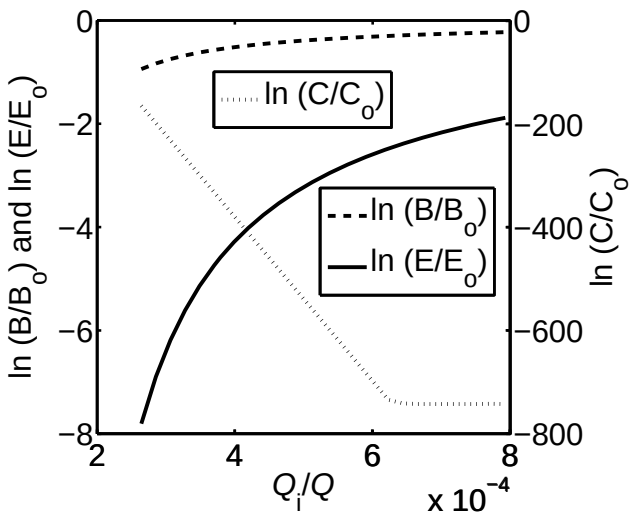

Figure 3: Log inactivation or log reduction of the species simulated by the multi-species model versus the ratio of contaminant injection flow rate to chlorinated flow rate in the pipe. The location is 1.2 km from the injection site, which the pulse input reached 7.5 hours after the beginning of the injection.

However in an actual WDS, other waters would mix with the contaminated water providing additional chlorinated flow which would further dilute the injected material, and likely alter inactivation. Furthermore, chlorinated flow patterns are highly variable and dynamic, making this example an extreme simplification of a contamination scenario. These factors will be assessed in future work.

10 Conclusion

Reaction models for arsenate and E. coli in WDSs were presented to quantify exposure in single pipe scenarios and compare the various modeling approaches. While these results are not directly applicable to more realistic networks with variable flow, demand, and mixing of different waters, they provide some insight as to what difference the models presented here may make in actual distribution system modeling and why. For both contaminants, the reactive models of bulk decay and wall demand as formulated here would likely result in unrealistically

low contaminant concentrations being delivered to consumers.

Compared to the conservative model for arsenate, the multi-species model for arsenate predicts a significantly longer duration of exposure for the particular conditions assumed here. However actual network conditions add factors with unknown impacts on results. Also, multi-species models that account for adsorption to diffusion-limited sites in the pipe wall may indicate even longer exposure times. Development of these models is needed to improve simulation of hypothetical contamination events, as well as pipe-wall accumulation of contaminants that occur at levels that are considered safe in the bulk flow. Even relatively low bulk concentrations of contaminants such as arsenic may cause accumulation at high concentrations in pipe wall materials, providing a possibility of release at higher, possibly dangerous bulk concentrations during changes in pH or other water quality or hydraulic events in a WDS (Lytle et al., 2004; Copeland et al., 2007). The SCM approach can be extended to model changes in pH for these scenarios.

For E. coli bacteria, the multi-species model predicts that inactivation depends on the ratio of contaminant injection rate to chlorinated pipe flow. For significantly large injection flows of a mixture of E. coli bacteria and TSB, 3-log inactivation may not be achieved. A conservative model provides a more cautious assessment of exposure to consumers since no inactivation would take place, however this also means it may over-predict exposure.

Additional work is needed to more accurately determine the parameters of WDS reactions. Several simplifying assumptions were made here to describe and quantify the material at the pipe wall, and the interactions between disinfectant, pathogen and broth. Experimental work that mimics WDS operating conditions could characterize pipe wall materials for more accurate parameter estimates. However WDSs vary widely in their physico-chemical properties due to differences in source water quality and water treatment practices (Sarin et al., 2004). Many WDSs probably also have these types of variation within the individual system. It should also be recognized that no single simulation will be able to characterize as uncertain an environment as a WDS. Further modeling work that employs statistical methods to account for uncertainty in WDS parameters will provide insight into the range of likely behaviors of a system.

ABSTRACT

In order to maintain water quality in water distribution systems, disinfection is performed by chemical addition. Chlorine, the most commonly used disinfectant, decays over time by reaction with organic materials in the water and produces potential harmful disinfection by-products (DBPs). Therefore, it is important to maintain the free chlorine residuals throughout the system within specified limits. Here, optimal valve operation has been combined with booster disinfection for water quality improvement. Valves are operated to alter the flow distribution in the network, prevent isolation of disinfectant and direct disinfectant laden-water to locations where it is required. A real-time optimal valve operation and booster disinfection problem is formulated as a single objective optimization approach. The objective is to minimize chlorine injection while maintaining chlorine concentrations and pressures at consumer nodes. The problem is solved using a single objective genetic algorithm. This paper presents the problem formulation methodology and its uniqueness.

INTRODUCTION

It is necessary to maintain the free chlorine residuals throughout the distribution system between minimum and maximum values. A minimum value (in the range of 0.2 mg/L) needs to be maintained to control the bacteria re-growth, and a maximum limit (at most 4.0 mg/L) is intended to avoid taste and odor complaints and the formation of potentially harmful disinfection by-products (DBPs). Therefore, it is desirable to maintain a uniform low range of chlorine residuals throughout the system.

To improve system-wide water quality, booster disinfection may be coupled with treatment plant disinfection. Multiple water quality sources for disinfection are better than single water plant disinfection to maintain uniform chlorine concentration throughout the system. Water quality can also be improved by shortening travel times within a system. On-line valves can be operated to alter the flow distribution in the

network and direct disinfectant laden-water to locations where it is required. While valve operation helps to spread the disinfectant over the system, part of the system may experience pressure drops due to increased energy loss through the valves.

This study presents algorithms for optimal valve operation coupled with booster disinfection in real-time to improve water quality. This problem is formulated as a single objective optimization approach. The objective is to minimize the injected chlorine mass while maintaining chlorine concentrations and pressure heads at consumer nodes for all times. The problem is solved using a single objective genetic algorithm (GA). To reflect the temporal and spatial variations of system demands, real-time operation schedules are developed based on real-time demand forecasting.

Some studies for booster location design and optimal operating of disinfection boosters have been completed. To reduce the computation demand of dynamic water quality simulations, some works adopted the principle of linear superposition by assuming the first order chlorine reaction and cyclical hydraulic behavior (Boccelli et al. 1998; Tryby et al. 2002; Prasad et al. 2004). Boccelli et al. (1998) showed that location of booster stations and system hydraulics are significant factors in determining the optimal injection schedule. They also reported that the best schedule was found when a booster station was located at a storage tank. Tryby et al. (2002) found that the dosage reduction potential of the designs is related to the injection control (constant dosage or flow proportional dosage) and scheduling (single interval operation and multiple interval operation) decisions, as well as the number and location of booster stations. Prasad et al. (2004) used a multi-objective genetic algorithm (MOGA) to minimize the total disinfectant dose and maximize the volumetric demand within specified chlorine limits.

There were efforts trying to reduce the computational burden of calculating response coefficients for linear superposition method (Propato and Uber 2004a and b; Lansey et al. 2007). Propato and Uber (2004a) formulated a linear least-squares (LLS) model minimizing the deviations of chlorine at the consumer nodes from a desired target value to determine optimal disinfection schedule. They showed that LLS formulation depends only on the number of boosters and their injection rates and is independent of system size, thus computationally efficient compared to earlier approaches utilizing the linear superposition method. Propato and Uber (2004b) extended their previous work to accommodate booster locations as decision variables using a mixed integer quadratic programming (MIQP) formulation. Lansey et al. (2007) used principle of linear superposition but their approach avoids long-term water quality simulations by adding constraints requiring the concentrations at the beginning and end of the design period to be the same. They introduced the initial concentrations as decision variables in the formulation.

Munavalli and Kumar (2003) used a dynamic simulation model to solve the non-first-order reaction kinetics. They used a binary genetic algorithm (GA) to determine the chlorine injection rates that reduce chlorine residuals closest to target minimum. Some studies optimizing pump operations for water quality improvements have been

reported. Sakarya and Mays (2000) optimized the pump operations to improve water quality. The decision variables are discrete-time pump operation schedules and the optimization problem is formulated and solved by interfacing the EPANET (USEPA, 2000) with a nonlinear optimization code, GRG2. Ostfeld and Salomons (2004) developed a methodology optimizing pump operations and booster disinfection. The problem was formulated for a typical demand cycle of 24 hrs given initial tank level and chlorine concentration at all nodes. They showed a trade-off between energy cost and the total chlorine dose injected.

A major assumption of the abovementioned studies is that the chlorine dosage at water quality sources and network hydraulics are periodic (cyclic) over a simulation period, that is mainly appropriate for system planning and design purposes. None of those studies considered temporal/spatial variations of system demands and non-periodic hydraulic behaviors. Study for real-time operation of system facilities considering system demand variations was never completed. Also, studies for optimal operating of valves for water quality purposes are lacking. This study formulates a methodology for optimizing operation schedule for existing control valves and booster chlorination stations in real-time based on a real-time system demand forecasting. The objective is to maintain the required minimum chlorine residual at the consumer nodes subject to constraints of minimum pressure requirement and tank water level.

MODEL FORMULATION

The optimization model is formulated and solved using a genetic algorithm (GA) linked with a water distribution simulation model, EPANET, under extended period simulation (EPS). Details of the methodology are discussed in the following sections.

Demand forecasting. The water demands are variable in space and time. For example, demands on rainy day would be less than the average uses. The pattern of demands during the weekend differs from the work day consuming pattern. Also, the spatial variations of water demands due to fire and pipe break should be reflected for water quality predictions. Here, the demand forecasting is synthetically generated for each node during the simulation period by adding random deviations to base demand patterns.

Pressure estimation. As valve operations cause pressure reductions in portions of the system, a minimum pressure requirement for each node must be maintained. Pressures are computed using EPANET and verified at the critical time in each extended period simulation (EPS) time step. Figure 1 illustrates the pressure estimation scheme used assuming an instantaneous change in demands. In normal EPANET calculations, the pressure head at time $\mathbf{t}$ is estimated based on the tank water level and demand estimates marked as open circle at time $\mathbf{t}$. However, if the demand is higher in the previous EPANET time step (closed circle) the pressure at time $\mathbf{t} - \mathbf{\Delta t}$ will be lower than at time $\mathbf{t}$. Thus, during periods when demands are

declining, the EPANET EPS result tends to overestimate the system pressure. In this study, steady state computation of pressure head using the both sets of demands is completed for each time step and the minimum values are chosen to represent the nodal pressures at that time step.

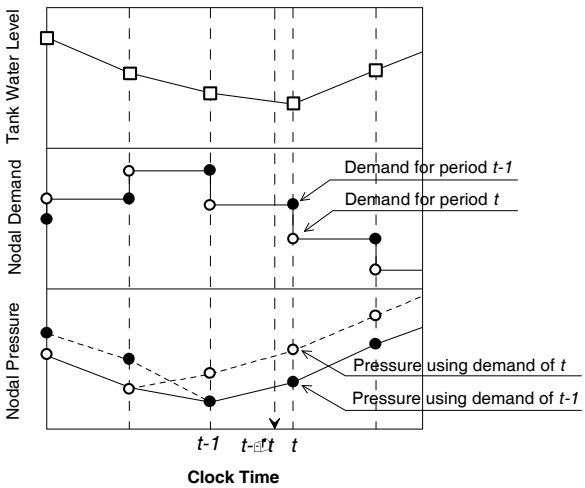

Figure 1. System pressure prediction scheme

Solution schematic. The proposed optimization framework is shown in Figure 2. A single objective genetic algorithm (GA) is linked to the EPANET toolkit that performs hydraulic and water quality simulations. Decision variables are generated through the GA operations and passed to EPANET that simulates the desired conditions and returns the pressure and water quality results to the GA. Based on the simulation results, GA generates new variables and the aforementioned steps are repeated until the predefined maximum number of generations is reached or the objective function converges within a desired tolerance.

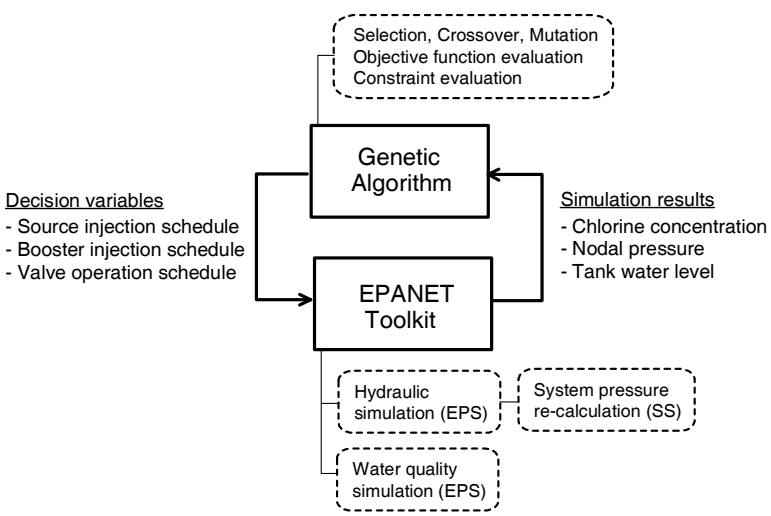

Figure 2. Optimization framework

Objective function. Since excess chlorine is undesirable, the problem objective is to maintain the chlorine concentration at consumer nodes as low as possible but above the minimum limit. The objective function is formulated as:

$$Minimize \quad F = \sum_{i=1}^{N} \sum_{t=1}^{T} q_{i,t} \times \left| C_{i,t} - \underline{C} \right|, \quad i = 1, \ldots, N \text{ and } t = 1, \ldots, T$$

where N and T are the number of nodes and the simulation time, respectively. $q_{i,t}$ and $C_{i,t}$ are the nodal demand and chlorine concentration at node i and time t. $\underline{C}$ is the specified minimum chlorine concentration (mg/L).

Constraints. The bounds for the residual chlorine concentrations are defined:

$$\underline{C} \le C_{i,t} \le \overline{C}$$

where $\underline{C}$ and $\overline{C}$ are the minimum and maximum allowable nodal chlorine concentrations, respectively.

Similarly, nodal pressure head constraints are also included:

$$\underline{P} \le P_{i,t} \le \overline{P}$$

where $\underline{P}$ and $\overline{P}$ are the lower and upper limits, respectively, and $P_{i,t}$ is the pressure head at node i and time t.

Finally, the constraint for the tank water storage is posed as the tank water level at the end of the decision period should be maintained within desired tolerance:

$$y_j^{end} - y_j^{\min} \le H, \quad j = 1, \ldots, K$$

where K is the number of tank. $y_j^{\min}$ is the minimum water surface elevation for emergency storage of tank j and y_j^{end} is the tank water level at the end of the decision period for tank j. H is the user selected tolerance in meters. Note that y_j^{end} cannot be lower than $y_j^{\min}$.

Decision variables. The model decision variables are the source and booster chlorine injection rates and valve settings for each time period. The decision time step is 1 hour. Valve settings are the percentage of valve closure that is converted to the head loss coefficients for the simulation model. The valve closure-head loss coefficient relationship is normally available from a valve manufacturer.

Simulation time window. Since the real-time operation schedules are optimized based on the forecasted demand, the simulation time window should be the same for both. Figure 3 illustrates the simulation time window used for demand forecasting and optimization runs. Here, it is assumed that the demand forecasting is conducted every 6 hours. Note that the demand forecasting time step and decision variable time step are same as 1 hour. For example, simulation (i.e., demand forecasting and model optimization) for Run 1 starts at midnight (12 am) and the next runs are sequentially

conducted with 6 hrs of time interval. Note that each run ends at the same time point, i.e., 8 pm when the lowest tank water level is detected. For each run, only the first 6 hour solutions will be implemented since a new set of decisions will be determined with improved demand forecasts after 6 hours.

A warm up period is needed to accurately depict concentrations at all locations in the system. If this is not applied and nodal concentrations are supplied to the model, EPANET will assume a linearly changing concentration between nodes. Instead, we provide the initial nodal concentrations (including tanks) for a period prior to the decision time frame and simulate that period for each EPANET run using the historical demand and decision data. This provides more accurate pipe concentrations. The warm-up period duration is selected based on system size and travel time.

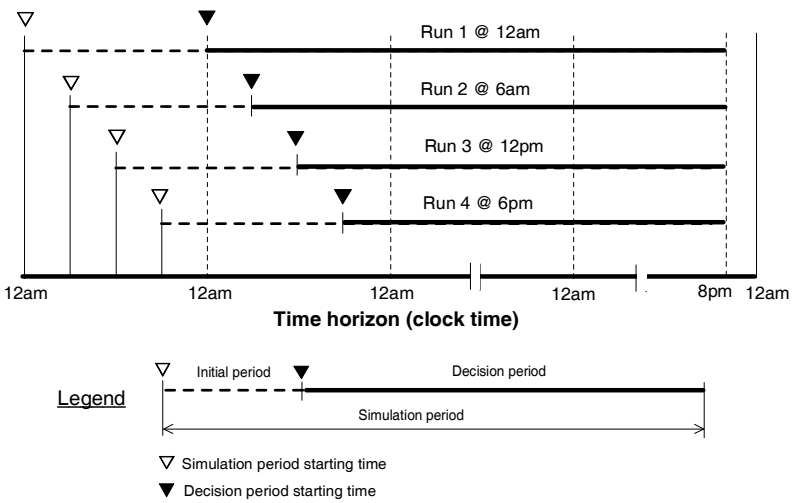

Figure 3. Simulation time window

DISCUSSION

It has been shown that booster disinfection at intermediate locations helps to reduce the total amount of chlorine dose while keeping uniform distribution of chlorine residuals for system wide (Boccelli et al. 1998; Tryby et al. 2002). A potential benefit from the valve operation is to reduce the contact time of disinfectant with the water and prevent slow moving water within the system. Therefore, by combining the valve operation with the multi-sources disinfection, more improvements in water quality are expected resulting in lower chlorine demands. The unique contributions of this study are summarized as follows.

(1) combining valve operation with booster injection to improve water quality
(2) real-time operation considering the variations of water demands and system hydraulics, that are not considered in the early studies where cyclical hydraulic behaviors are assumed for the planning and design purposes.
(3) physically meaningful approach for system pressure prediction by performing the instantaneous steady state pressure computation during changes of demand and comparing with conventional EPS simulation.

ABSTRACT

Particulate matter in drinking water is one important reason for consumer complains due to discoloured water at customer's taps and further secondary effects. To describe transport of this matter, partices were characterised, important occuring mechanisms described respectively abstracted and, based on known basics for dynamic water quality modelling, a software module developed, which will be linked with a pipe modelling software. Thus, water quality in water supply systems may be predicted and pipe fouling can be described. This shall enhance distribution system operation and planning.

SYMBOLS

c_P	particle volume concentration (1)
D_{brown}	diffusion coefficient ($m^2 * s^{-1}$)
D_{shear}	shear diffusion coefficient ($m^2 * s^{-1}$)
f_{conc}	correction factor for particle volume concentration influence on particle motion (1)
f_{shape}	particle shape factor for the Stokes equation (1)
f_{wall}	correction factor for wall influence on particle motion (1)
g	gravity = 9.81 $m * s^{-2}$
k_{vm}	proportionality constant as a function of the dimensionless distance of the particle to the pipe wall (1)
R_P	particle radius (m)
R_{pipe}	pipe radius (m)
v_{lat}	lateral migration velocity ($m * s^{-1}$)
η_F	dynamic viscosity of fluid ($kg * m^{-1} * s^{-1}$)
ρ_F	water density ($kg * m^{-3}$)
ρ_P	wet density of a particle ($kg * m^{-3}$)

INTRODUCTION

Decreasing water demand in numerous European countries causes varying hydraulic conditions in established drinking water distribution systems. Increased retention times may have an influence on chemical parameters (e.g. chlorine and oxygen depletion), physical parameters (temperature increase) as well as biological parameters (microbial activity) during distribution.

Particulate matter in drinking water is one important reason for consumer complaints due to discoloured water at customer's taps. Particles enter distribution systems at water treatment plant's outlet, may be formed by corrosion of pipe material, microbial activity or after-effects of drinking water treatment, e.g. used coagulation chemicals or adjustment of pH-value.

Investigation subject of a corporate research project was the motion behaviour of particles in drinking water distribution systems for:

- The investigation of established supply networks for impairments with deposits and particle related water quality before consumer complaints occur and
- The accentuation of water quality optimisation as additional parameter for network optimisation strategies beside common optimisation of running and capital costs.

Conclusions of the performed research work were used to write a program, which enables network operators to subsequently minimise particle based water quality impairments.

PARTICULATE MATTER IN DISTRIBUTION SYSTEMS

The main reasons for particle motion in typical pipe flow beside weight/buoyancy are hydraulic forces and weight. In principle, two states can be described for a particle in a pipe:

- Moved by pipe flow, including sedimentation, attachment on surfaces and re-suspension or
- Attached on surfaces or as immobile deposit on pipe bottom.

Particles enter drinking water distribution systems at outlet of water treatment plants or are formed due to corrosion in unlined steel pipe sections. Further sources are amongst others biofilms, chemical precipitation and impurities due to construction works.

In a first step, particulate matter in distribution systems was analysed, focusing on iron oxide particles from a corroding steel pipe. Using Stokes equation, sedimentation experiments in quiescent water yielded a mean wet density of 1430 kg/m³, including influence of particle form. With light microscopy, the sphericity ψ of primary particles could be calculated to 0.859 and the according shape factor f_{shape} for the Stokes equation to 0.945. This denotes that the settling velocity of these iron oxide particles is reduced by roughly five percent due to shape. As the particle density $\rho_{P,pykno}$ calculated with pyknometer was roughly 3300 kg/m³, the settling of these particles was predominantly influenced by particle structure respectively (mean) particle porosity, which could be identified to 77 percent. As the observed particles form stable aggregates in mixed fluids, this value describes the mean aggregate porosity including particle porosity. The real mean wet density ρ_P

of the particles respectively aggregates, including wetted pores but not form influence, is 1539 kg/m³ (at 20 °C water temperature). This is close to the values of Grainger (2002), who got a mean density for mixed samples of suspended particles in distribution systems of 1620 kg/m³. His measuring values for different sampling locations varied from 1180 – 2040 kg/m³.

NETWORK TOPOLOGY AND HYDRAULICS

Water quality modelling in distribution systems is based on network structure and hydraulic conditions. As software for modelling of network structure as well as hydraulics of drinking water distribution systems is provided by several software producers, quality models use the possibilities given by such software packages. Distribution systems are simplified for modelling procedure as links (pipe sections) and nodes.

The quality modelling software described here is bundled with STANET in a first step. STANET, developed by Fischer-Uhrig Engineering in Berlin, is a common commercial software package for modelling of several supply networks (gas, drinking water, power, …). After simulation, results can be saved in structured text files (CSV), which contain network topology, e.g. pipe length, diameter, roughness and so on, as well as hydraulics, e.g. mean flow velocity in the individual pipes, system pressure and water temperature.

Information in text files are imported previous to quality modelling and are prepared respectively stored in PC memory while software is running. For daily consumption patterns, currently used hydraulic data is replaced by new data, when leaving the current hydraulic time step and launching a new one. More details are explained in a later chapter.

TRANSPORT OF MATTER IN DISTRIBUTION SYSTEMS

Particles in pipe flow are exposed to hydraulic induced forces, which results in a motion analogue to fluid motion. In larger time scales of several seconds or even minutes, occurring inertia of particles may be neglected and a simplification is acceptable: inertia due to longitudinal fluctuation resulting from turbulences and varying flow rates are negligible. Therefore, particles move with fluid’s flow velocity in longitudinal direction.

Rossman (1996) describes four methods for the linking of quality models with hydraulic models. The Eulerian discrete volume method (DVM) is one of several methods described. DVM discretise the water body in each individual pipe section (“link”) between two nodes in packages of same size (see figure 1).

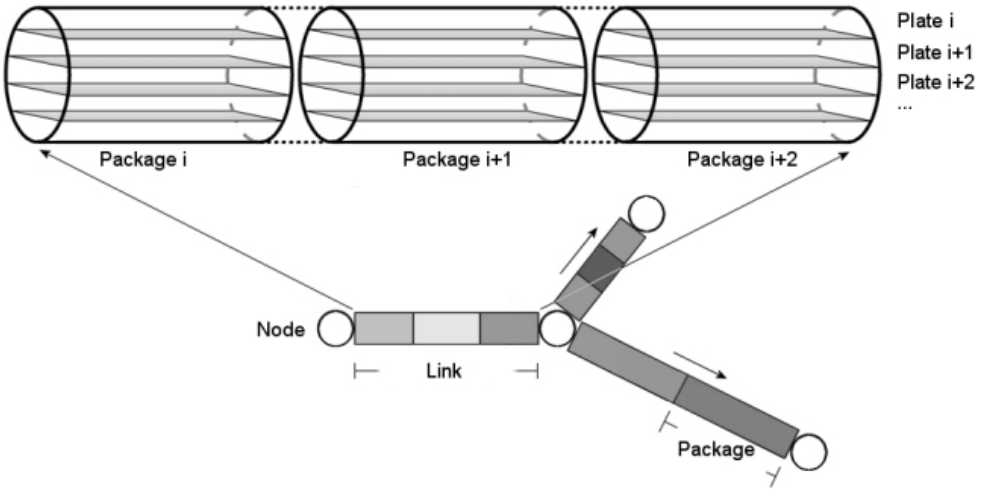

Figure 1. Spatial discretisation of the water body in a distribution system.

Each package is fully mixed, has constant hydraulic conditions (flow velocity) and own water quality parameters (e.g. solid load). Longitudinal, vertical, two-dimensional cuts of all pipes are observed to consider variations of flow velocity in the pipe cross section and therewith varying particle motion velocities.

To reproduce dispersion caused by the typical velocity profile of water in circular tubes, the longitudinal aligned water packages are also vertically segmented in plates with own local flow velocities. All vertically aligned plates of a water package have the same (package) length. This results in dispersion problems, as the length of the water package and the contained plates is adjusted based on the maximum flow velocity in the package and the quality time step length. That means, artificial (numerical) dispersion occurs in plates closer to the bottom respectively top of the pipe, when the content of a plate is assigned to the next package respectively plate downstream.

Beside mobile particulate matter also immobile deposits are modelled and are localised in the pipe by water package boundaries. These deposits do not influence the pipe hydraulics and have no direct influence on particle transport in pipe flow due to reduction of inner pipe diameter in the quality modelling software. However, radial motion of particles in pipe flow is influenced by forces, which are based or influenced on solid concentrations, what is considered in the software.

PARTICLE RELATED PROCESSES IN WATER SUPPLY SYSTEMS

When talking about particle related water quality in drinking water distribution systems, occurring overall measurable effects are the formation of particles as well as changes in particle concentration in bulk water and particle mass in deposits. A breakdown to individual reactions shows figure 2.

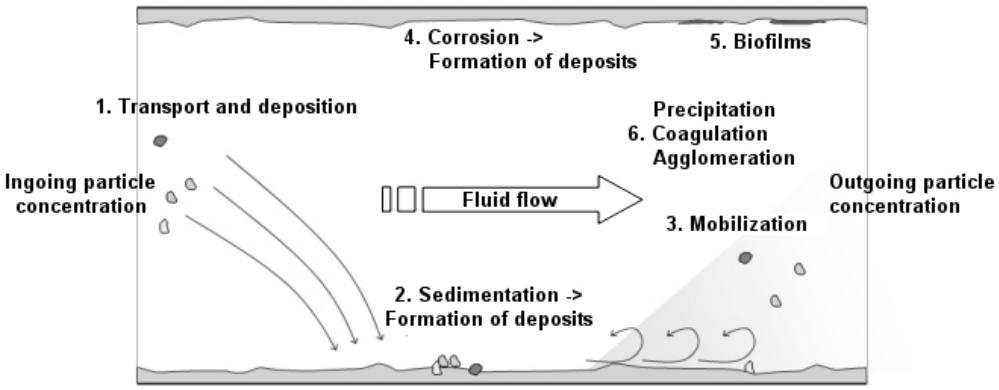

Figure 2. Processes, which affect particle related water quality and fouling of pipes in water supply systems.

A particle in bulk water is carried by fluid flow (1) and may be deposited by sedimentation and attachment on pipe walls. Particulate, soft, water-rich deposits may also result from corrosion (4) of unlined steel and cast iron pipes as well as microbial activity in biofilms (5). Beside mentioned sources, a chemical unstable water can release particles (6), e.g. by precipitation and coagulation of dissolved matter (chemicals used in drinking water treatment). Immobile, deposited particles (2) are exposed to fluid flow and may be re-suspended (3). This hydraulic stress may be described as wall shear stress.

Biofilms and effects of chemical unstable water are not described in the present particle model for drinking water distribution systems.

EXPERIMENTAL INVESTIGATION ON PARTICLE DEPOSITION IN PIPE FLOW

Two identical pipe loops, each with a length of 195 metres and 83 mm inner diameter, were installed for transport and mobilisation experiments. One pipe cycle consists of unlined steel pipes, which allows the formation of particulate corrosion products in a corrosion film under constant flow velocities and their mobilisation due to defined changed hydraulic conditions after a given developmental period for the corrosion film.

The second, identical, system is a PE pipe loop, where the settling and transport behaviour of suspended plastic particles (PVC, Vinnolit E 2078, density 1,400 kg/m³, rounded, solid) and the above described iron oxide particles (wet density 1,539 kg/m³, unshaped, porous) are observed. The pipe water circulates in the pipe loops. Turbidity, particle size distribution and pressure are continuously measured at inlet and outlet of the pipe loops. Furthermore, flow rate and temperature are continuously logged over the duration of the experiments. Differences between ingoing and outgoing particle concentrations result from sedimentation and may be quantified for different particle sizes and flow conditions. Results for the experiments with PVC powder and iron oxide particles are shown in figure 3.

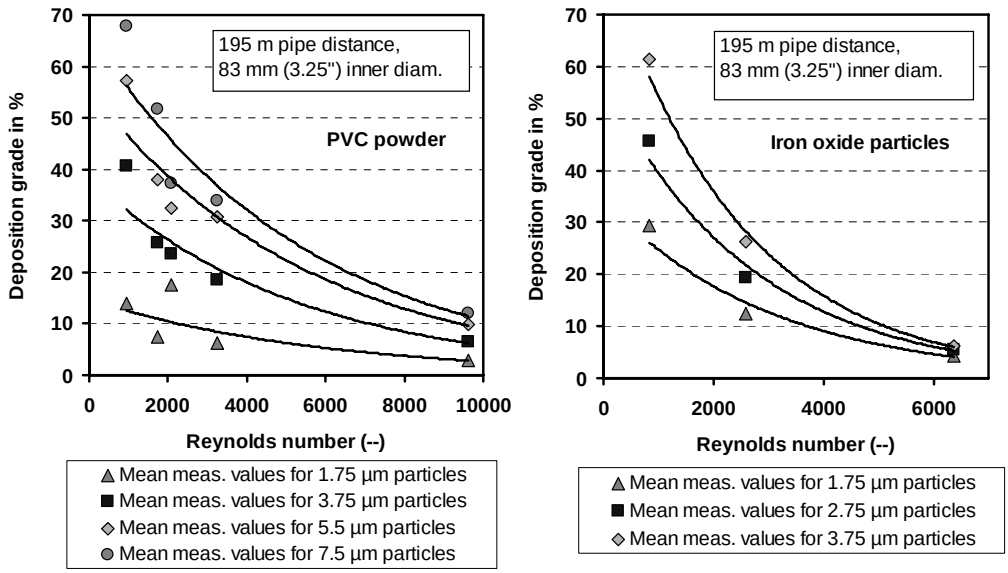

Figure 3. Deposition grade of particles from a PVC powder (LHS) and iron oxide particles (RHS) when transported through a pipe distance of 195 m (83 mm inner diameter).

The diagram on the left-hand side shows, as expected, that with decreasing flow velocity respectively Reynolds number the deposition grade of particulate matter increases, while at higher Reynolds numbers and turbulent flow only less suspended particles settle. This is also noticeable in the diagram on the right-hand side of figure 3. When comparing both diagrams (consider the different x-axes!), it can additionally be reasoned that the iron oxide particles settle „better“, but this observation fits with the particle properties of both particle systems: Even with porosity, the iron oxide particles are more heavy and additionally have surface properties which may possibly advance interaction mechanisms (adhesion) with pipe surfaces. This question is under further investigation.

EXPERIMENTAL INVESTIGATION ON PARTICLE MOBILISATION IN PIPE FLOW

Sediment is stressed by given pipe flow. That is often described as wall shear stress. Slaats et al. (2003) list several values for sediments in water supply systems available from literature, but it is not clearly stated, which type of particulate matter was available and furthermore, situation of sediment resp. pipe (particulate matter, incrustations, …) can’t be defined.

Therefore, mobilisation was experimentally investigated in the steel pipe loop of the pilot plant as described above. After a defined time period for the growth of the corrosion layer, which is situated over the whole pipe perimeter, mean flow velocity was increased by a defined value. Thus, turbidity in the pipe increases and with known relationship between turbidity and solid load, the amount of mobilised

sediment can be determined. After such an experiment, the pipe was flushed and the experiment started again. The result of two series of measurements, each with a constant mean flow velocity v0 for the formation of corrosion layers (=particulate deposit), is shown in the left diagram in figure 4.

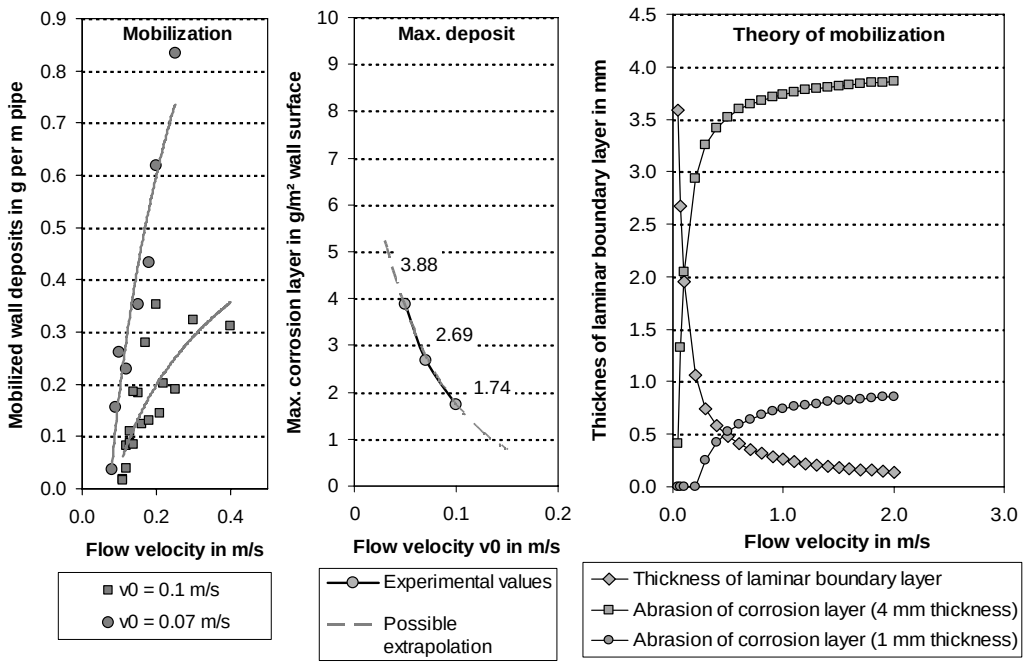

Figure 4. From left to right: Mobilisation of particulate iron oxide wall attachments dependent on mean flow velocity; maximum deposit in a pipe at given constant mean flow velocity; relationship between thickness of laminar boundary layer and mean flow velocity (all diagrams for 83 mm (3.25") inner pipe diameter).

As can be seen, higher flow velocities (the new adjusted velocity higher than v0) result in more mobilised sediments. With long-term experiments, where large amounts of particulate corrosion products could be formed, the maximum amount of attached particulate matter could be determined as can be seen in the middle diagram in figure 4. With increasing flow velocity, the maximum amount of immobile deposits at 80 mm (3.25") inner pipe diameter shows of course a tendency to zero, while at decreasing flow rates the amount of deposits reaches a maximum.

As explained before, the acting wall shear stress is a common value to interpret mobilisation of sediment. However, for particulate deposits in drinking water distribution systems it is important to look at the thickness of the laminar boundary layer, which covers pipe surfaces and attachments. The thickness of this layer δ_{lam} depends on Reynolds number Re and inner pipe diameter D_{pipe} (Bollrich, 2000):

$$\delta_{lam} = 34.2 \cdot D_{pipe} \cdot (0.5 \cdot Re)^{-7/8} \quad (1)$$

The relationship between thickness of the laminar boundary layer and thickness of sediments is illustrated in the right diagram in figure 4. Compared with a thick corrosion layer (here 4 mm), a thin corrosion layer (here 1 mm) is mobilised at higher velocities. If adopted that mobilisation is only possible at turbulent flow conditions with adequate (wall) shear stress on sediments, thickness of the laminar boundary layer decreases with increasing flow velocity and parts of the covered corrosion film may extend into the turbulent core zone of the pipe flow. There, shear stress may abrade this particulate matter. With higher flow, a rapid increase of mobilisation can be noticed at beginning of the mobilisation process, but this development is limited by the maximum available amount of sediment (see the right diagram in figure (4)).

If turbulent flow conditions periodically occur, the typical thickness respectively volume of the laminar boundary layer also describes the amount of maximum settleable matter. As incrustations in unlined pipes may clearly influence the velocity field, the approach described here may be only a first estimation for such pipes.

MODELLING OF PARTICLE MOTION IN PIPE FLOW

The plastic pipe loop of the pilot plant is hydraulically modelled as vertical 2D longitudinal section along the pipe axis in the CFD software package Comsol in full length under single-phase fluid conditions. CFD is the generic term for numerical methods to solve the Navier-Stokes equations. The physical conditions (fluid viscosity, flow velocity) are the same as in the experiments. Also in later descriptions, the x-axis is equal to the pipe bottom and the y-axis is normal to the pipe axis and in the direction of the top of the pipe.

Suspended particles subjected to pipe flow are influenced by various hydraulic induced forces. Lerch (2008) mathematically describes these and additional occurring forces for particles in capillaries of ultrafiltration membranes in detail. These acting forces are described by force balances and are based on the (hydraulic) simulation results of the Navier-Stokes equations. As conditions in pipes are different from capillaries, a simplification of the force model is used to describe particle transport in pipe flow. Table 1 lists the forces, which are required for description of particle motion in y-direction and gives some additional information. The particle motion in x-direction is equal to local flow velocity of the water

Table 1. Forces considered in the model for motion of suspended particles in y-direction transported in pipe flow (adopted from Lerch, 2008).

Force	Equation	#
Sedimentation force	$F_{sed} = f_{shape} \cdot (\rho_P - \rho_F) \cdot \frac{4}{3} \cdot \pi \cdot R_P^3 \cdot g$	(2)
Brownian diffusion	$F_{brown} = -D_{brown} \cdot \frac{dc_P}{dR_{pipe}} \cdot 6 \cdot \pi \cdot \eta_F \cdot R_P$	(3)
Shear induced diffusion	$F_{shear} = -D_{shear} \cdot \frac{dc_P}{dR_{pipe}} \cdot 6 \cdot \pi \cdot \eta_F \cdot R_P \cdot f_{conc}$	(4)
Lateral migration	$F_{lat} = 6 \cdot \pi \cdot \eta_F \cdot R_P \cdot v_{lat} \cdot f_{wall} \cdot f_{conc}$	(5)
Drag force	$F_{drag} = 6 \cdot \pi \cdot \eta_F \cdot v_P \cdot R_P \cdot f_{wall} \cdot f_{conc}$	(6)

According to eq. (2) to (6), the simplified force balance in y-direction for particles in fluid flow is

$$F_{sed} + F_{brown} + F_{shear} + F_{lat} + F_{drag} = 0. \quad (7)$$

Eq. (7) can be solved for the particle velocity v_P in y-direction, which is included in the drag force (see eq. (6)):

$$v_P = k_{correction} \cdot \frac{(F_{sed} + F_{lat} + F_{brown} + F_{shear})}{6 \cdot \pi \cdot \eta_F \cdot R_P \cdot f_{wall} \cdot f_{conc}}. \quad (8)$$

The detailed model with more aspects especially for membrane particularities and the mathematics behind the used equations are described by Lerch (2008).

The modelling results for particle deposition in pipe flow were compared with experimental results (see the according upper chapter “deposition experiments”.) Differences are described as correction factor $k_{correction}$ and used to correct eq. (8) for the particle velocity. With this equation, an individual settling velocity is calculated for particle size classes in all vertically aligned plates in all water packages.

With this force balance (eq. 7/8) it is not possible to model wall attachments, especially on the top of the pipe. However, as the calibration of the model is done with experimental values, also deposition due to attachment on pipe walls is indirectly considered in the modelling results.

INITIAL DESCRIPTION OF THE PARTICLE SOURCE “CORROSION”

An also considered reaction beside deposition and mobilisation is the release of particulate matter due to corrosion. Corroding steel and cast iron pipes may be an

important source for particulate matter in drinking water distribution systems. As there were no sufficient corrosion models available during development of the transport model, which may predict intensity and location of corrosion, a first, simple approach was implemented.

With systematic pipe flushing in present water supply systems, particulate sediments were investigated to determine a mean value for the release of iron (Fe^0) from corrosion in this particulate matter. This work was done by TZW Dresden (yet unpublished results). A small net was flushed with clean water front and after a defined time period, flushing was performed again to investigate the development of the deposits since last flushing and then calculate an "iron formation rate". The mean value 0.0025 g Fe^0/m pipe *day for three supply systems is used to calculate the amount of particulate matter, which is formed due to corrosion. This value can be used, to calculate a mean value for the iron oxide formation rate, when assuming that iron species like Fe_20_3 or FeO(OH) are formed.

All formed particles are attached on the pipe wall over the whole pipe perimeter after formation. It is assumed that no particles are released to bulk water during the formation process. The particle volume concentration of the corrosion layer in the steel pipe loop of the pilot plant was calculated from mobilisation experiments with 0.0415 %. In a first step, this value may also be used for the actual mixed sediment in present distribution systems. This low value indicates the large share of water in the deposits but includes also the irregular distribution and thickness of a natural corrosion layer. Mobilisation is based on this value, which is used to calculate the sediment volume respectively thickness. Thickness of deposits and laminar boundary layer are compared to determine the mobilised amount of particulate matter.

STRUCTURE OF THE SOFTWARE MODULE

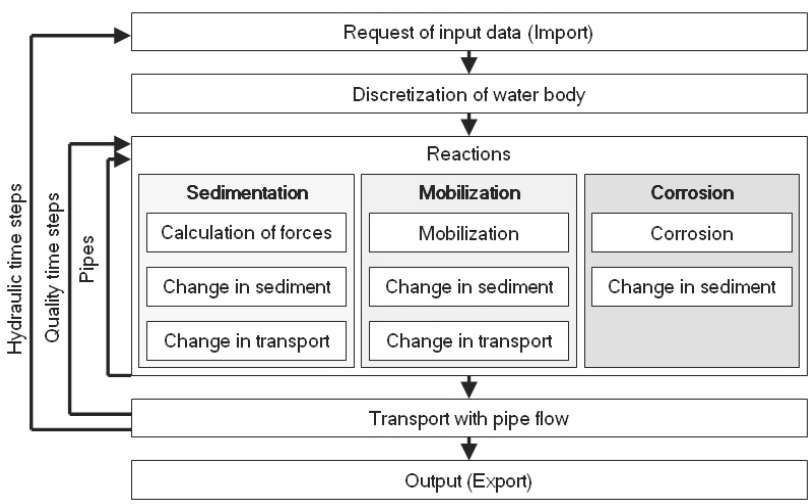

Figure 5. Structure of the software module.

The software module is written in Matlab 7.7 and optimised for Matlab's multiprocessing features. The module structure is shown in figure (5), the GUI in figure (6).

After receiving of input data (net topology and hydraulics) at the beginning of each hydraulic time step, the water body in all pipes is discretised. The hydraulic time step loop only occurs in case of used daily consumption patterns and then is described as a discretisation step of these patterns. As numerical dispersion will occur at each rearrangement of the water packages, it is currently not decided, if, with respect to the sediment, a change in discretisation for each hydraulic time step makes sense.

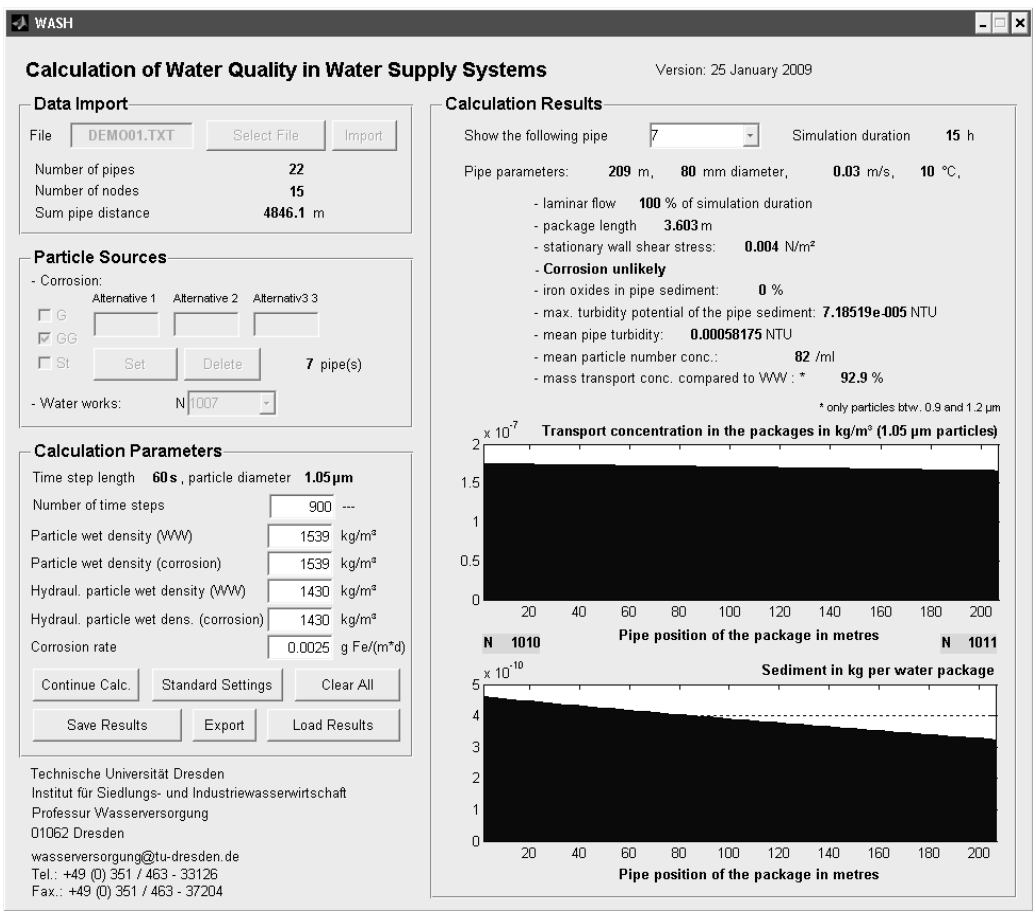

Figure 6. GUI of the software for quality modelling in drinking water distribution systems.

After all reactions and the resulted changes in transport mass concentration and sediment mass, transport with pipe flow is calculated according to Rossman (1996) and EPANET MSX (2008) manual: Initially, transport in the pipes and from the pipes into the nodes is performed. Then, mixing in the nodes is done for all plates and the node content is transported to the downstream pipes. This calculation step,

described in figure 5 as “quality time step” is also implemented as loop and encloses the pipe loop. This inner loop calculates for all pipes in the system the reactions in each quality time step.

The calculation results are stored in the original export file, which is imported to STANET to graphically show the results in whose GUI.

In the current state of the software, the user is guided through the GUI by three steps: import of data from STANET, definition of particle sources and setting up of the simulation parameters as well as handling of simulation results.

EXAMPLE FOR THE TRANSPORT PREDICTION

STANET contains a demo network (demo01), which is used for some first simulations and tests with the developed software. It consists of 22 links (furthermore named as pipes) and 15 nodes (figure (7)).

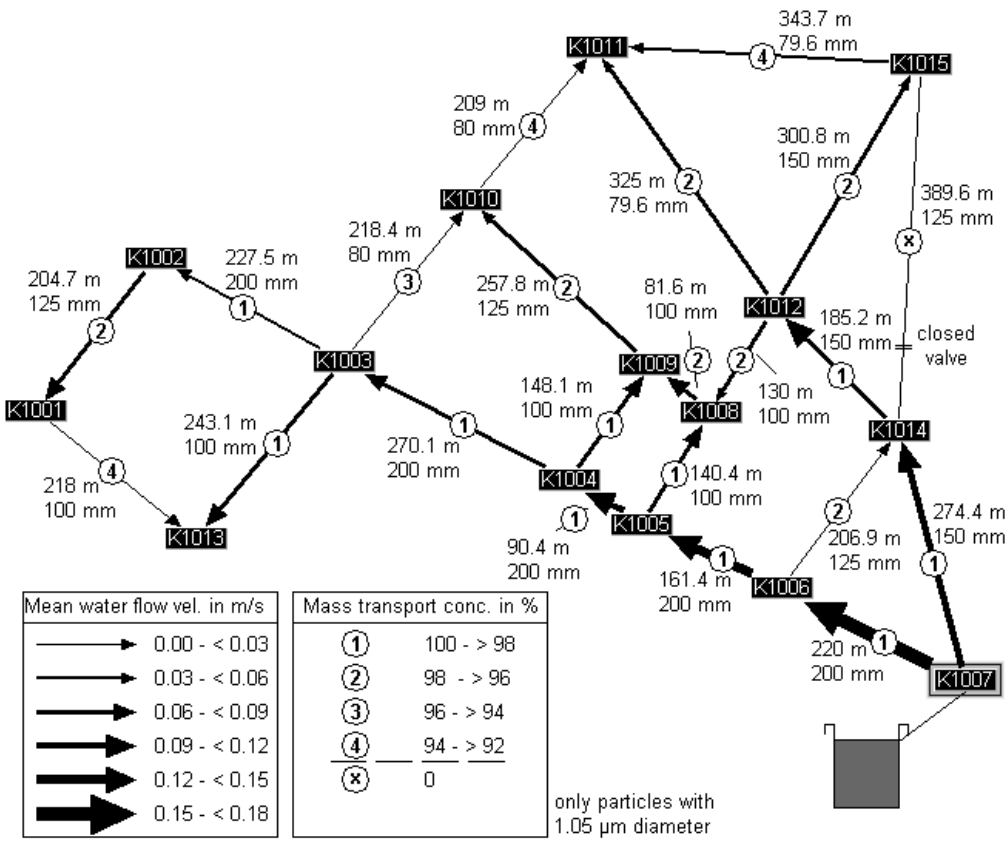

Figure 7. Comparison between particle mass concentration at storage tank outlet (node 1007) and in the pipes as percentage; the storage tank has 100 % (“demo01” from STANET).

This simple network is supplied by a storage tank at node 1007 (K1007). All other nodes are consumers. In this case, only constant consumption was used, as the support for daily consumption pattern in the software is currently in development.

The thickness of the pipe arrows show the mean flow velocities and the symbols on the arrows the mean (steady state) particle concentrations in the pipes compared with the quality in the storage tank. Only transport of particles with 1.05 µm (projection equivalent) diameter is calculated here. The transport simulation results are subsequently manually added to the figure, as file import into STANET isn't finished yet.

A decrease in particle concentration indicates a decrease in turbidity and therewith a better particle related water quality. Hence, it may be reasoned for this simple example that particles settle during water distribution and form deposits. These deposits have a so called "turbidity potential", which may be activated at given hydraulic conditions (Boxall, 2005). When calculating the Reynolds number for the pipes, which indicates turbulent flow conditions, it may also be seen that flow velocity isn't in every case the best choice to predict deposition of particles. For example, the pipe between the nodes 1003 and 1002 has a relatively low flow velocity of 0.05 m/s, but the large inner pipe diameter causes sufficient turbulent flow conditions with Reynolds number 7634, which prevent particles from sedimentation compared with laminar flow conditions (e.g., the pipe between the nodes 1010 and 1011 has RE = 1221 at v_F = 0.02 m/s).

SUMMARY, CONCLUSIONS AND OUTLOOK

A software module is developed for modelling of particle related water quality in drinking water distribution systems. Processes like sedimentation and mobilisation are described as well as required basics for the description of the particle sources "water works" and "corrosion" for a comprehensive approach. As all reactions are based on hydraulics and network topology, the software module was bundled with the pipe modelling software STANET.

Further works will focus on implementation of new, more detailed modelling approaches for the particle related processes corrosion, microbial activity and adsorption. In the mean time, the present model is tested with several hydraulically calibrated distribution systems. The investigation of these systems was done by TZW Dresden.

WDS Water Quality Parameter Estimation and Uncertainty

M.F.K Pasha[1] and K. Lansey[2]

[1]Water Resources Engineer, Tetra Tech Inc., Tucson, AZ 85711; email: fayzul.pasha@tetratech.com
[2]Professor and Head, Department of Civil Engineering and Engineering Mechanics, The University of Arizona, Tucson, AZ 85721; Ph (520)-621-2512; Fax (520)-621-2550; email: lansey@engr.arizona.edu.

ABSTRACT

During model development and calibration, errors in field measurements propagate to uncertainties in parameter uncertainty. Water distribution water quality models are typically calibrated using tracer test data. Here, we evaluate the uncertainty resulting from the test assuming demands are known exactly and only the wall coefficients are to be estimated.

A meta-heuristic search engine, Shuffled Frog Leaping Algorithm (SFLA) is linked with hydraulic and water quality simulation software EPANET to estimate the pipe wall decay coefficients. A first-order approximation is applied then to estimate the parameter uncertainty. This methodology is applied on a mid sized example network. Results show that with tracer injection parameter can be accurately estimated. It is also found that parameter estimation can be more accurate if the magnitude of the wall decay coefficients is higher.

INTRODUCTION

Chlorine, an oxidizing agent that decays with time, is the most popular water treatment disinfectant in municipal water distribution system. A minimum level of chlorine residual is always desired to be maintained in the distribution system to preserve both chemical and microbial quality of treated water (Vasconcelos et al. 1997, Munavalli and Mohan Kumar 2003). Chlorine reacts with different materials inside the pipe while it travels with water through the distribution system.

Reactants are present in the bulk water and on the surface of the pipe. After a certain age of the systems organic carbon or bio materials deposited on the surface of pipes or tank walls producing a biofilm. Thus, the wall component of reaction may play an important role in chlorine reaction kinetics.

Pasha and Lansey (2005) conducted a thorough study on water quality parameters uncertainty. All the hydraulic and water quality parameters such as pipe diameter and demand, spatial and temporal variation of nodal demand and decay parameters are considered in their uncertainty analysis to observe their impact on

nodal chlorine concentration. The study concluded that chlorine decay and residuals are significantly affected by the decay parameters (bulk and wall). Wall decay parameters are particularly important when the turbulence in the flow is higher.
Although bulk decay coefficient can be determined in a laboratory jar test, there is no direct method to determine the wall decay parameters. A field test is required to estimate wall decay parameters. Several studies have been conducted to estimate the wall decay parameters. A popular way of estimating wall decay parameters is automated calibration in which a water quality simulation model is connected with a search algorithm to estimate their value by minimizing the deviation between measured and simulated chlorine concentrations. However, proper calibration is not an easy task because of various reasons; such as (a) data collection is expensive and requires great effort; (b) most calibration procedures are deterministically based (Lansey et. al. 2001). Measurement error and poor calibration procedure cause uncertainties in the estimated parameters.

The objective of this paper is to estimate parameters and their uncertainty for various field measurement conditions to determine the accuracy that can be expected and the value of alternative measurement and tracer test campaigns.

BACKGROUND

Hydraulic model calibration in water distribution systems analysis was the main focus in the past. A range of optimization methods have been applied (Ormsbee 1989, Lansey and Basnet 1991, Todini 1999, Wu et al. 2000) to solve the hydraulic calibration problem.

Little work, however, has been conducted on water quality model calibration. Clark et al. (1995) estimated wall decay parameter by trial and error approach to simulate chlorine residual. Vasconcelos et al. (1997) calibrated a water quality model by sequentially adjusting the wall decay parameter to give the best fit between simulated and filed measurement. Islam et al. (1997) developed an inverse approach to determine the source concentrations required to meet the specified concentrations at selected nodes. However, no attempts were made in their study to estimate the wall decay parameters.

Munavalli and Mohan Kumar (2003) developed an inverse approach model to estimate reaction parameters in steady state distribution systems and later extended the model to dynamic conditions (Munavalli and Kumar 2005). They applied a weighted least squares method to estimate at most three wall decay parameters for a constant source chlorine injection. Boccelli et al (2004) conducted a network-wide dual-tracer field-scale study and model calibration. They used observed data for manual calibration of the system. No systemic approach was taken to estimate the distribution system parameters. Wall or bulk decay coefficients were not estimated in their studied. Very recently, Pasha and Lansey (2008) estimated best fit wall decay parameters by linking a hydraulic and water quality simulation model with a search engine known as Shuffled Frog Leaping Algorithm (SFLA). Up to six wall decay parameters have been considered with different field conditions. However, parameters uncertainties were not assessed.

METHODOLOGY

The methodology applied here involves two steps. The first is to estimate the parameters and the second step is to evaluate the uncertainties in the estimated parameters.

Parameter estimation. Field data collection is the first step. Due to lack of real world data a simulation model was run to generate data. To create field type condition a random error was added with the exact data. Following calculations can be made to generate the measurement error assuming that the error is normally distributed.

$$CV = \frac{\sigma}{\bar{x}} \tag{1}$$

where σ is the standard deviation and $\bar{x}$ is the mean of the concentrations at specific time and location. Therefore,

$$\sigma = CV * \bar{x} \tag{2}$$

According to normal distribution the measured concentrations can be written as

$$x = \bar{x} + \sigma * Z$$
$$x = \bar{x}(1 + CV * Z) \tag{3}$$

where, Z is the standard normal deviate.

The next step is to estimate the model parameters. The water quality calibration model objective in this paper is to determine the wall decay parameters ($\boldsymbol{k_w}$) so that the difference between the field measured concentration and the simulated values are minimized. Mathematically, the problem can be stated as:

Minimize $f(\boldsymbol{k_w})$ (4)

subject to:

$$\boldsymbol{G_H(H, q) = 0} \tag{5}$$

$$\boldsymbol{G_Q(H, q) = 0} \tag{6}$$

$$\boldsymbol{k_{wlower} \le k_w \le k_{wupper}} \tag{7}$$

where Eq.4 is the objective function that sums the square differences between computed and measured concentrations at selected locations and times. $\boldsymbol{H}$ and $\boldsymbol{q}$ are the vectors of pressure and flow demands for all nodes and demand pattern. $\boldsymbol{G_H}$ and $\boldsymbol{G_Q}$ are the conservation of energy and mass respectively. $\boldsymbol{k_w}$ is decision variable with upper ($\boldsymbol{k_{wupper)}}$ and lower ($\boldsymbol{k_{wlower}}$) bounds.

Equation 4 can be written as:

$$f(\boldsymbol{k_w}) = J = \sum_{l}^{L} \left(CC_l - MC_l\right)^2 \tag{8}$$

where CC_l and MC_l are the computed and measured concentrations at location l for all times considered and L is the total measurement locations. J is optimal objective value.

EPANET version 2.0 (Rossman (2002) is used as the hydraulic and water quality simulation model. Shuffled Frog Leaping Algorithm (SFLA), a meta-heuristic search algorithm (Eusuff and Lansey 2003 and Eusuff et al. 2005) has been linked with EPANET. An initial population (in this case frogs) is randomly generated first.

EPANET then simulates the water quality conditions and the objective function (Eq. 8) is then computed for each frog. New points (frogs) are then generated following the optimization procedure. This iterative process continues until a stopping criterion is reached.

Parameter Uncertainty Evaluation. The next step is to quantify the magnitude of the uncertainty involved with the estimated parameters since the measurement errors are involved. Yeh and Yoon (1981), Mallick and Lansey (1994), Bush and Uber (1998), and Lansey et al. (2001) applied first-order approximation to estimate uncertainties in the hydraulic parameters. This study applies same technique to evaluate the covariance matrix of the estimated parameters in this case the wall decay parameters (Cov($\boldsymbol{k_w}$)) using the concentration sensitivity matrix relative to the parameter ($\frac{\partial C}{\partial k_w}$) and the variance in measured concentrations ($\sigma_C^{\,2}$).

$$\text{Cov}(\boldsymbol{k_w}) = \left[\left(\frac{\partial C}{\partial k_w} \right) \left(\frac{\partial C}{\partial k_w} \right)^T \right]^{-1} \sigma_C^{\,2} \tag{9}$$

The diagonal elements of the Cov($\boldsymbol{k_w}$) are the variances of the individual wall decay parameters and the off diagonal terms are the covariances between the decay parameters. The $\sigma_C^{\,2}$ can be approximated by (Bard 1974)

$$\sigma_C^{\,2} = \frac{J}{M - L} \tag{10}$$

where J = optimal calibration objective (eq. 8); M = total number of field measurements; and L = number of calibrated parameters. The matrix of the sensitivities of the concentrations relative to the wall decay parameters can be estimated analytically or by a numerical approximation (Lansey et al. 2001). The numerical approximation method is used to calculate the sensitivity matrix.

$$\left[\frac{\partial C}{\partial k_w} \right] = \left[\frac{C_\Delta - C}{(k_w + \Delta k_w) - k_w} \right] \tag{11}$$

where C_Δ = concentrations computed by simulation using the perturbed wall decay parameter values; C = simulated concentrations with the best estimate of the wall decay parameters, k_w; and Δk_w = perturbation introduced to k_w. For this study a perturbation of 0.0001 is used.

EXAMPLE NETWORK

The network analyzed in this study is network NET2A from the EPANET with minor modifications (Figure 1). The network consists of 32 pipes, 28 nodes, one source (node 29), one tank (node 30) and three identical pumps at the source. The 24 hour average demand pattern listed in Table 1 was repeated for a 48 hour simulation period.

The source concentration was 3 mg/l. Disinfectants were injected as a pulse injection for the first 2 hours (3 mg/l) simultaneously with the continuous injection of

3 mg/l. The initial concentrations were determined by running the model for a month and then the taking the last hour's concentrations.

Alternative field conditions were examined including different measurement errors, tracer injection times, data collection times, and true wall decay parameter values. In all experiments the number of wall decay parameters (k_w) used is three and hourly data are collected at six locations. k_w is always constrained by upper value of 0.0 day^{-1} and lower value of -1.0 day^{-1}.

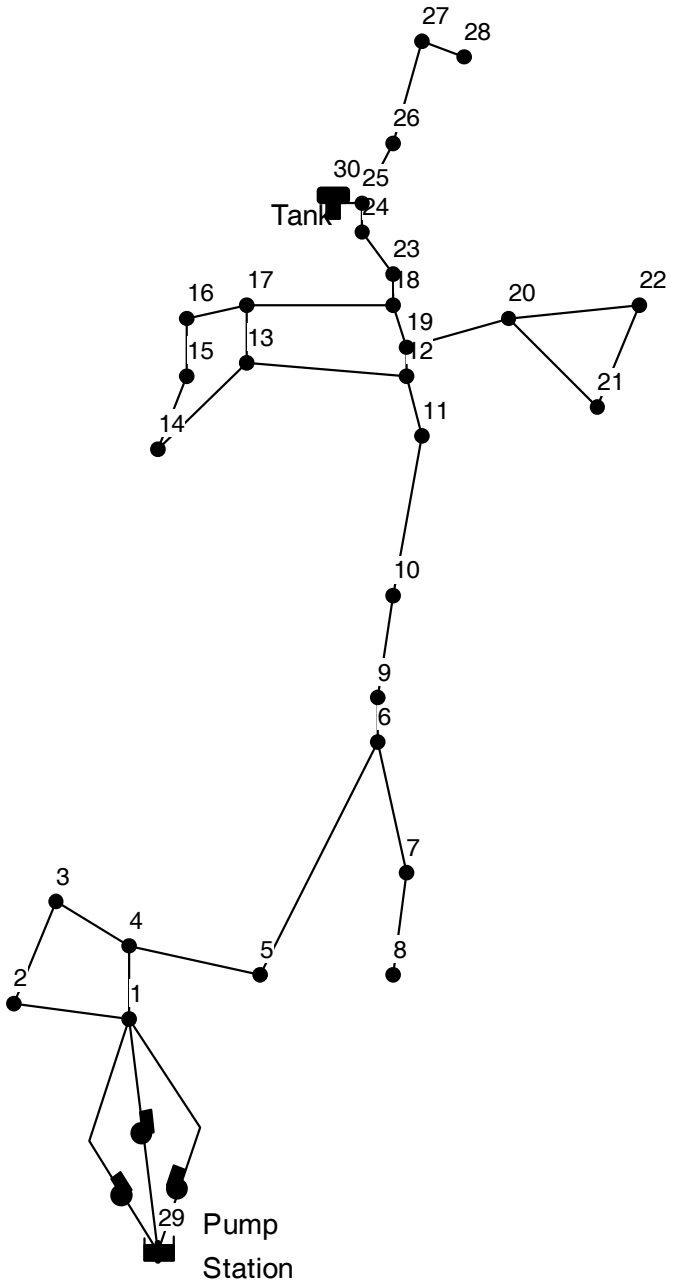

Figure 1. Example Net2A

SFLA parameters values that are used to search the best wall decay coefficients for this network are the number of memeplexes (m) = 50, the number of frogs in a memeplex (n) = 70, the number of frogs in a sub-memeplex (q) =5, the number of evolution or infection steps in a memeplex between two successive shuffling (N) =10, and the maximum step size allowed during an evolutionary step (S_{max}) = 100%. Different experiments are described below with their results.

Tracer injection timing. Four estimation uncertainty analyses are completed by varying the tracer injections timing. The time used are slected to determine the benefit of flow conditions: 12:00 am, 6:00 am, 12:00 pm, and 6:00 pm. A disinfection spike concentration of 3 mg/l is injected for two hours over the continuous injection of 3 mg/l. The measurement errors are introduced using a coefficient of variation of 0.0324.

Results are tabulated in Tables 2 and 3 and show that the impact of the different injection time is not pronounced. However, a closer inspection can find that for the injection at 6 am, the optimal objective value is the highest (Table 2) and that for the injection at 6 pm is the lowest.

Measurement errors can influence the parameter estimation process. As a result, uncertainty may be observed in the parameters. The parameters uncertainties (standard deviations) are calculated for each injection and are tabulated in Table 3. It is found that the parameter standard deviations are highest for the tracer injection at 6am and lowest for a 6 pm injection though the difference is not very significant.

Measurement error magnitude. The purpose of this experiment is to confirm whether the findings in the previous experiment are true for different levels of measurement errors. The previous experiment is repeated here for a coefficient of variation of 0.1 to generate the measurement errors.

It is found that parameters are estimated with highest accuracy at 12 am and lowest accuracy at 6 pm (Table 4). Parameter uncertainties are measured for each injection. Parameter uncertainties show that higher uncertainties (standard deviation of the parameters values) occurred when the parameter estimation accuracy is lower or the lower uncertainties occur when the parameter estimation accuracy is higher (Table 5). In general, uncertainty in the latter case (measurement error coefficient of variation 0.1) is 3 to 3 .5 times higher than the former case (measurement error coefficient of variation 0.0324).

Value of tracer injections and the impacts of the magnitude of wall decay coefficients. Several additional runs were complete to examine the benefits of a tracer injection and to observe the impact of different magnitudes of wall decay coefficients and data collection time. The tracer tests may provide more sensitivity in parameter estimates. This added sensitivity can justify the time of conducing the tracer test. The impact of the wall decay coefficient magnitude should be understood since larger values result in larger decay and higher disinfectant demands. The ability to accurately predict decay under these conditions is especially important.

Results from this experiment are compared with the results performed in the previous experiment (experiment 2). Therefore, previous experiment for the tracer

injection at 12 am is referred as base condition (Tables 6 and 7). To examine the benefit of the tracer, the injection rate is held constant and the process repeated. The result is compared with the base condition in which tracer is injected at 12 am. Parameter estimates are poorer when no chlorine spike is injected (Table 6). However, the relative parameter uncertainty is similar. Thus, the spike condition does benefit the model calibration.

To observe the impact of different magnitudes of wall decay coefficients, the true values k_w's are tripled. The parameter estimation/uncertainty process is repeated and results are compared with the base condition. The first k_w is very poorly estimates (Table 6) but its uncertainty was nearly equal to the previous cases. The other parameters were closer to the true values but the uncertainties increased. One would anticipate that the accuracy might increase because the decay is more significant, thus the parameter would be more sensitive. However, if the measured concentrations are in the slowly changing portion of the decay curve, this may not be the case. The low parameter uncertainty suggests that this may be the case here. This tradeoff between model precision and accuracy should be investigated further, perhaps in a multi-objective formulation.

Table 1. Temporal demand factors at different times in a day

Time	Average demand factors	Time	Average demand factors
12 am	0.50	12 pm	1.16
1 am	0.48	1 pm	1.17
2 am	0.45	2 pm	1.21
3 am	0.40	3 pm	1.23

CONCLUSIONS

The impacts of a tracer test on parameter estimations and uncertainty are analyzed in this paper. Analyses include varying tracer test conditions including tracer injection timing, magnitudes of measurement errors and a sensitivity of the tracer test has also been performed. Results show that without tracer injection, parameter can be estimated with less accuracy which can result higher prediction uncertainty.

ABSTRACT

The rapid discovery of the contaminant source and its mass loading characteristics in a water distribution system (WDS) is vital for generating an efficient control strategy during a contamination event. Previous work on the Adaptive Dynamic OPtimization Technique (ADOPT), which was developed as an Evolution Strategy (ES) based procedure, presents an approach to estimate the source characteristics adaptively, given dynamically updated observation data. Although this simulation-optimization approach is promising, it is computationally expensive, which poses challenges in the context of real-time solutions. This paper reports the findings of an investigation that builds upon the prior work by introducing a hybrid heuristic search method for the real-time characterization of a contaminant source. This new method integrates the ES-based ADOPT with a logistic regression (LR) analysis and a local improvement method to expedite the convergence and possibly solve the problem quickly. As a prescreening technique, a LR analysis step is performed prior to ADOPT; this step reduces the search space by eliminating unnecessary source nodes as potential source locations. Then, a local search (LS) approach is embedded into some of the algorithmic steps in ADOPT to serve as a postscreening step that potentially speeds up the convergence in localized regions in the solution space. Numerical experiments for the proposed hybrid approach are performed on an example water distribution network, and the results are compared with those of the standard implementation of ADOPT.

INTRODUCTION

Water distribution systems (WDSs) are highly susceptible to various threat attempts, including physical attack, cyber-disruption, and biochemical contamination (Clark and Deininger, 2000). Intentional biochemical contamination has become a major concern recently due to its inherent complexities and the potential hazard to human health. To enhance the response capability in the case of a contamination event, one protective step that should be taken is the installation of monitoring stations within the WDS to measure abnormal water quality resulting from the pollutants. While real-time measurements are collected at these stations, the contaminant source must be determined swiftly to facilitate appropriate decisions in response to the threat. Contaminant sources are typically characterized by the

injection location, starting time, duration, and mass injection rates that correspond to different time intervals.

Contaminant source characterization can be deemed as an inverse problem, the solutions of which are typically ill-posed (e.g., non-existence, instability, or non-uniqueness). Non-existence occurs when no solution exists, given available observations. Instability is caused by the sensitivity of inverse solutions to the observations. Non-uniqueness can be caused by insufficient data when different solutions yield similar explanations for the observations. These ill-posed solutions create challenges, especially in the context of system uncertainties and the need for rapid identification.

One way to address these issues is to formulate the problem as an optimization problem by making use of currently available observation data to inversely seek the best source characteristics. This approach may yield a good explanation for the obtained water quality samples. Most efforts that have been made to solve such a problem use optimization methods to discover the true source information by minimizing the deviation between the observed output from the sensors and the calculated concentration values. Such efforts include direct methods (e.g., Van Bloemen Wannders et al., 2003; Laird et al., 2005) and heuristic-based simulation-optimization approaches (Guan, 2006) that constitute the focus of this research due to their flexibility and robustness. In Liu et al. (2006), the ES-based ADOPT is employed to search for a set of contaminant source characteristics that may result in similar sensor observations. Although ADOPT has shown promise for its dynamically adaptive capability, the simulation-optimization approach suffers because it requires numerous computationally expensive simulations to adaptively recover the contaminant characteristics. The significant computational costs would unavoidably impact not only the identification time but also the resultant solution quality. Thus, to minimize the number of simulations and maintain acceptable accuracy, ADOPT has been enhanced by incorporating techniques that can expedite the solution.

In this paper, an algorithmic framework is introduced for solving a WDS contaminant source characterization problem by integrating ES-based ADOPT with one prescreening and one postscreening technique. The objective of a prescreening technique is to narrow the solution space. While the search is gradually converging to local regions, a postscreening technique is embedded into ADOPT to promote its local convergence capability.

PROBLEM STATEMENT

Given increasingly available observations, a contaminant source characterization can be constructed as a dynamic optimization problem. The objective function is calculated by minimizing the difference between the estimated concentration values and the currently available data, which are time-dependent. The primary goal is to quickly estimate the source characteristics that best explain the observed data at hand. The following mathematical formulation is defined to determine the source location, starting time, and corresponding mass loading history

at any time after the first detection of contamination. Although this definition assumes that the contamination is introduced at only one node in the network, the same model can be extended to consider multiple contamination source locations.

Find $\{L,\ M_{t_c}\ ,\ T_0\}$

$$\text{Minimize } F = \sqrt{\frac{\sum_{t=t_0}^{t_c}\sum_{i=1}^{N_s}(C_{it}^{obs} - C_{it}(L, M_{t_c}, T_0))^2}{N_s * t_c}} \tag{1}$$

where

F = prediction error;
L = contaminant source location;
T_0 = starting time of the contamination event;
t_0 = time of the first detection of the contamination at the sensors;
t_c = current time step;
$M_{t_c} = \{m_{T_0}, m_{T_0+1}, \cdots, m_{t_c}\}$, represented as a vector of mass injected at the source from time T_0 to t_c;
C_{it}^{obs} = the observed concentration at sensor i at time step t;
$C_{it}(L, M_{t_c}, T_0)$ = model (i.e., EPANET)-estimated concentration value at sensor i at time step t;
i = sensor location;
t = time step of observation; and
N_s = total number of sensors.

SOLUTION APPROACH

ES-based ADOPT. Two major challenges that must be faced when addressing a contaminant source characterization problem are: 1) continuously tracking the optimal solutions in dynamic environments, and 2) capturing the potential non-unique solutions that could provide similar explanations to the observations over time. To tackle these challenges, ES-based ADOPT was developed to search for potential solutions that are as different as possible from each other by exploring the decision space through multiple subpopulations. To set a benchmark for the best possible solution, one of the subpopulations searches independently for the solution that best fits the observations. The remaining subpopulations use that benchmark to find other possible solutions that fit the observations equally or nearly as well as the best solution. This procedure is executed for each observation time step. When new information becomes available, the solutions from the previous time step can be adapted to the new environment, if it is assumed that the observation data resulting from one contamination event. Therefore, the number of remaining subpopulations can be adapted according to the dynamic environments. The algorithm terminates when no more available information or only one subpopulation remains. The key steps of this approach are outlined as follows (Liu et al., 2006):

Step 1. Create an initial set of random solutions, equally divided among N subpopulations.

Step 2. Increment time step as t ← t + 1. Set generation index as g = 0. Update monitoring data with additional measurements and construct the prediction error function.

Step 2.1. Increment generation index as g ← g + 1. In the first subpopulation (p = 1), evaluate the fitness based on the prediction error. In other subpopulations (p = 2, 3,…N), evaluate the fitness based on the prediction error and its distance from all other subpopulations.

Step 2.2. In each subpopulation, apply selection and mutation operators, and create a new set of solutions.

Step 2.3. If stopping criterion (i.e., g < max no. of generations) is not met, then go to Step 2.1; otherwise, go to Step 3.

Step 3. Eliminate subpopulations that represent duplicate solutions. If only one subpopulation remains or the current set of solutions is acceptable, then stop.

Step 4. If no more observations are available, then stop; otherwise, return to Step 2.

The efficiency of ES-based ADOPT in characterizing a contaminant source can be improved by eliminating unnecessary nodes as potential source locations. In Liu et al. (2008), a predictive model based on logistic regression (LR) analysis was examined to determine the likelihood that any given node is a source. The resulting location-specific probability values could then be used to reduce the solution space for the optimization search, thus yielding a faster convergence. In addition, as a global optimizer, the ES typically becomes less efficient when the search concentrates on a local region. To further enhance the algorithm's efficiency, a local search (LS) operation is incorporated into ADOPT, which allows the advantage of local fine-tuning.

Logistic Regression Model (LRM). The numerous potential contamination scenarios and system uncertainties collectively contribute to the complexity of source characterization in a contamination event. To offer a fast probabilistic estimation of potential source locations, a linear LRM-based approach was presented in Liu et al. (2008) to model the likelihood of a node as a source, given the sensor observations. The LRM, constructed as follows, describes the relationship between the probability that node i is a source and the observations at time t after the contamination is detected at one or more sensors.

$$\log\left(\frac{p(A_i \mid C_{1t},\cdots,C_{Nt})}{1-p(A_i \mid C_{1t},\cdots,C_{Nt})}\right) = b_{0t} + b_{1t}C_{1t} + \ldots + b_{jt}C_{jt} + \ldots b_{Nt}C_{Nt}\,, \tag{2}$$

where $p(A_i \mid C_{1t},\cdots,C_{Nt})$ denotes the likelihood of the contaminant introduced at node i, given the observations at time t; A_i represents the contaminant entering through node i; (b_{0t}, …, b_{Nt}) are the regression coefficients obtained by the maximum likelihood procedure; and (C_{1t}, …, C_{Nt}) denotes the sensor observations at time t.

While knowledge of an existing WDS and its sensor placements allows simulations of contamination events, the LRMs that correspond to each node at each time interval can be pre-identified through a large number of hypothetical contamination events. Once a contamination is detected, the models can rapidly

return the probability estimation. Thus, the strength of a LRM is that it offers a simple and direct way to make a fast prediction of a small set of nodes that are likely candidates to be a source. In this study, the resulting solutions from the LRMs are used to reduce the search space in ADOPT by eliminating unnecessary nodes, which typically have zero probability as calculated by the LRMs.

Heuristic Search Methods. Heuristic search algorithms have received increasing attention due to their potential in tackling complex optimization problems. In addition to the effectiveness of such algorithms, the objective function evaluation is the only information required to direct the search during the iterative process. This advantage allows wider applications to a variety of complicated problems by coupling search algorithms to simulation models. Evolutionary algorithms (EAs) (Holland, 1975), as one class of heuristic methods, present a global search (GS) mechanism and are of great benefit for solving large nonlinear optimization problems. Making use of a population-based scheme and particular operators (e.g., crossover, mutation), EAs can discover global optima independently of initial guesswork as well as offer easy parallel implementation (Xu et al., 2001). However, as the population gradually moves towards optimal solutions, the efficiency of EAs typically decreases due to the stochastic property of the search process. In the early stages, and because the large search space inherent to early stages contains potentially better solutions, the EAs are more likely to discover improved solutions. As the search approaches the vicinity of local optima, the chance of finding better solutions decreases, and the search yields a slow local convergence (Xu et al., 2001; Gen & Chen, 1997). In contrast, LS approaches, such as the Hooke-Jeeves pattern search and the Nelder-Mead Simplex (NMS) method, focus mainly on locating locally better solutions by using a deterministic strategy, even though these methods are somewhat sensitive to the initial starting points.

Recently, some researchers have investigated hybrid heuristic approaches (i.e., the hybridization of a LS and a GS procedure) that are more likely to be efficient because they take advantage of both capabilities. The methods reported previously can be classified into three categories. The first one employs a GS procedure followed by a LS process (Partheepan, 2003; Espinoza et al., 2005; Mahinthakumar & Sayeed, 2005; and Yeh et al., 2007), where the GS discovers globally promising regions, the subsequent LS continually moves the resulting good solutions towards the optimum. An enhanced solution thus can be acquired through increased computational efforts associated with the LS procedure. The LS does not benefit the GS in this case, however. The second category alternately applies GS and LS procedures (e.g., Espinoza et al., 2005; Hart, 1994; and Land, 1998) whereby the two search procedures support each other. Although this category has the potential to achieve a high solution quality and computational efficiency, the parallel implementation of such an approach is inefficient. The third category of methods embeds a local optimizer into a GS as a genetic operator. One such approach, introduced by Xu et al. (2001), couples a micro genetic algorithm (GA) with the LS to generate two new solutions in place of the two worst solutions using the pattern move operator. Another approach, proposed by Partheepan (2003) links the GA with the NMS method by performing the reflection step as a new operator during the GA evolution process.

Overall, the embedment of the LS into the GS does not yield additional fitness evaluations. This factor is valuable, particularly in the context of complex real-world optimization problems that require time-consuming simulation runs.

Most discussions associated with the hybrid heuristic search methods focus on ways to maximally improve the solution quality with low computational costs. This problem introduces several questions, such as which LS procedure to use, the frequency of the LS, the time that the LS is performed, the way of selecting individuals to conduct the LS, etc. Different LS procedures may bring about quite different solutions. If too many LS procedures are incorporated into a GS, local convergence may result. In addition, it is worth noting that selecting inappropriate solutions or conducting a LS at an improper time can bias the direction of the GS (Hart, 1994; Land, 1998). This paper investigates a hybrid model by embedding a local optimizer into the ES-based ADOPT for characterizing a WDS contaminant source.

Algorithm Framework. Figure 1 shows the framework of the hybrid LRM-ADOPT-LS, starting with the LR analysis. At time step t, when the initial detection occurs, the LRMs input the concentration data collected by the sensors and output the probability of each node as a possible source. This process screens the candidate set, which is composed of nodes with non-zero probability values, for potential source locations. Specifically, the candidate set is employed in the subsequent initialization and mutation operations.

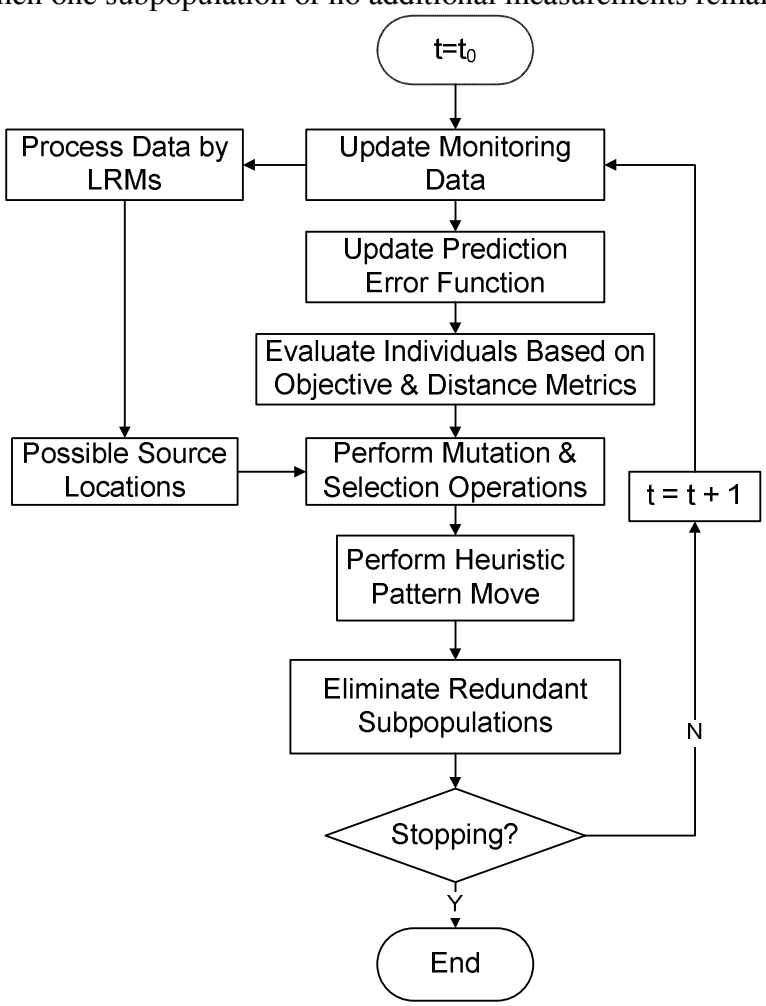
The combination of the ES-based ADOPT with a LS procedure is then applied to determine the source characteristics (i.e., contamination location, start time, duration and mass loading profile). In this phase, the ES-based ADOPT focuses on exploring promising regions, while the LS exploits local characteristics to expedite the convergence in localized regions. In addition to achieving a faster convergence without the expense of additional fitness evaluations, this hybrid search is expected to avoid premature convergence by embedding the pattern move simultaneously within multiple subpopulations. The incorporation of a LS operator into ES-based ADOPT is described in two steps as follows:

Step 1. Assess the need for the LS operator in each subpopulation. Subsequent to the selection operation, assess the necessity of the local optimizer. This process relies on the extent of the convergence of individuals. LS operations that are too numerous or performed too early may lead to premature convergence. Therefore, the LS operator is applied in a subpopulation when the following two conditions are met: 1) The proportion of individuals located at the same node exceeds a specified threshold (denoted as α); 2) The best individual locates at a different node from those in other subpopulations or is better than those in other subpopulations if they are at the same location.

Step 2. Perform the heuristic pattern move. In a subpopulation, the heuristic pattern move is carried out when the current convergence of individuals suggests its necessity. Based on the approach introduced by Xu et al. (2001), the pattern move operates around the current optimum to search for improved solutions.

Step 2.1. Sort individuals according to the prediction error function.
Step 2.2. Record the indices of the best, second best, worst, second worst, and third worst individuals for the same location.
Step 2.3. Generate three new individuals through the linear combination of the best and second best individuals. If I_b represents the optimum, and I_{sb} corresponds to the second best individual with a slightly worse objective value, the new individual $I_{new} = I_b + \beta(I_b - I_{sb})$ is constructed. β is the pattern move step size. (0.2, 0.5, and 1.0 are used in this study.)
Step 2.4. Replace the three worst individuals with the newly generated individuals.

Finally, this hybridization process is repeated over time. At each time step, this procedure leads to a set of possible solutions that is able to match the sensor observations within a specified range of prediction error. With increasingly available measurements, the set of alternatives reduces in number, and eventually reaches a single solution when sufficient sensor information is available. The identified single solution or a set of alternatives is expected to contain the true source. The algorithm terminates when one subpopulation or no additional measurements remain.



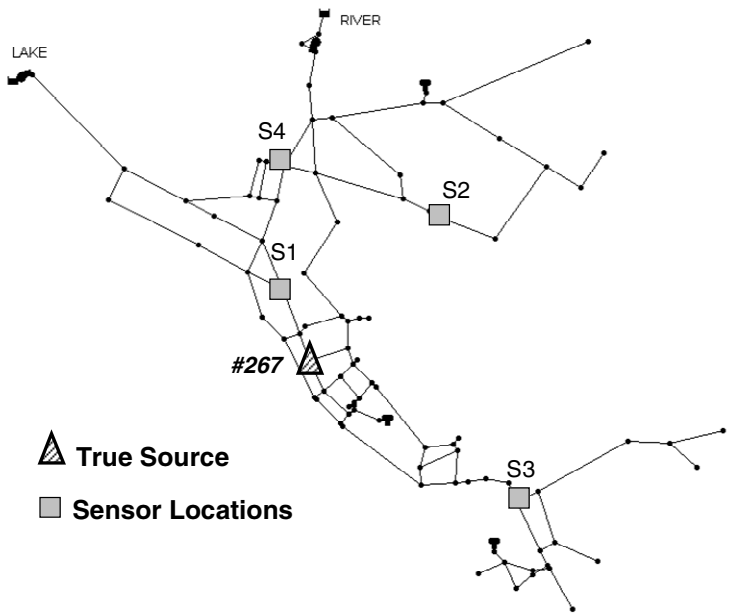


Figure 1. LRM-ADOPT-LS optimization framework.

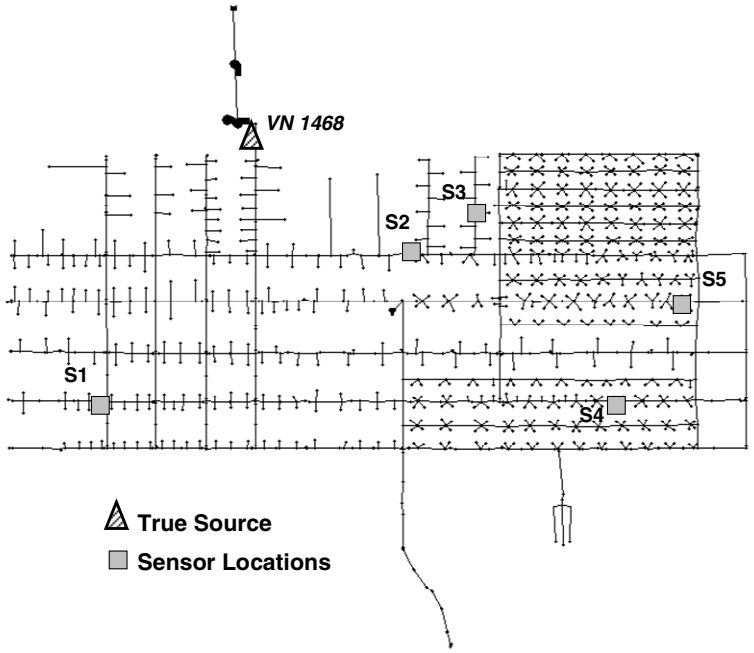

APPLICATIONS

To test the improvements provided by the LRM and LS, several contamination scenarios in two different WDS networks work studied. In this paper, the results of only two illustrative scenarios are presented. Scenario 1 assumes the intentional intrusion of the contaminant into a small water network. This network is one of the problem scenarios in the EPANET software (Rossman, 2000) and is comprised of 2 sources, 3 tanks, 97 nodes, and 117 pipes. The configuration of this network is depicted in Figure 2(a). Four ideal sensors are randomly placed within the network. A conservative contaminant enters the system through node #267 (denoted as a triangle in Figure 2(a)) at 10:00 a.m., and the event lasts one hour at the time-varying injection rates of 50, 60, 90, 80, 70, 40 g/min, each of which corresponds to a 10-minute interval. The first detection occurred at 12:20 p.m. by sensor S3. No non-zero concentration data were obtained at the other sensors during the observation period. This scenario is used as the baseline in the following discussions.

Scenario 2 represents a contamination event in a large network. This network contains 1574 junctions, 1415 pipes, 8 pumps, 2 reservoirs, and 1 tank. This network was developed for the micropolis virtual city with 5,000 residents, further details of which can be found in Brumbelow et al. (2007). The locations of five ideal sensors are chosen at random within the entire network (see Figure 2(b)). The contaminant entered the network through node VN1468 at the rates of 80, 70, 60 g/min for a duration of 0.5 hour. The contamination was initially detected at sensor S2 after 6.5 hours had elapsed since the first release of contamination. In addition to sensor S2, non-zero concentration data were observed at sensors S2 and S3 during the monitoring period.

SUMMARY

To help better understand the enhancements associated with the LRMs and the LS, a set of experiments were carried out with different enhancements added to ADOPT on the basis of the two scenarios described. The algorithm performance was evaluated in terms of the solution quality as well as the computational costs. In addition to yielding a better understanding of these enhancements, the case studies investigated the performance sensitivity to the coupling strategies along with the mutation sizes. Different strategies of LS selection were investigated to determine the optimal approach to enable the function of the LS. Also, the analysis by looking at the effect of mutation sizes was performed on the solutions when ADOPT is coupled with the LRM and LS. Results from these investigations indicate that the proposed method is able to identify consistently a set of nodes that includes the true source location, and reach this solution state in a computationally more efficient manner compared to the use of just ADOPT.

ABSTRACT

There are a number of sources of uncertainty in drinking water distribution system modeling. Uncertain parameters include pipe diameters, consumer demands, hydraulic energy loss coefficients, reaction coefficients and others. Understanding the relative importance of these sources of uncertainty can improve the allocation of resources for model refinement and calibration, as well as, aid knowledge inference from monitoring data. This paper presents an analysis of uncertainty and model sensitivity for chlorine transport and decay in a water distribution system. A clustering and global variance-based sensitivity methodology is proposed to account for spatial inconsistencies found in the results of previous studies of this problem. Results are presented from small and large scale case studies.

This methodology is then used to explore the occurrence of intrusion events in a water distribution system, and the potential to detect such events through online monitoring of chlorine residual concentrations. Noise present in the chlorine monitoring signal has the potential to overwhelm the detection of an upstream intrusion and its associated chlorine demand. Results are presented from simulated intrusion events of varying magnitude and duration.

INTRODUCTION

There are a number of sources of uncertainty in drinking water distribution system modeling. These include, pipe diameters, consumer demands, hydraulic energy loss coefficients, solute reaction coefficients, and others. These parameters can be grouped into two categories. Aleatory uncertainty is inherent to stochastic processes such as rainfall in Hydrology or in this case, consumer demands on a drinking water system. Epistemic uncertainty occurs when processes are unknown or poorly represented by mathematical models. An example of epistemic uncertainty is the variability that occurs in bulk first-order decay coefficients for free within a water distribution system. In this case, a single species first-order decay model does not accurately represent interactions with other species and pipe walls. Thus, the

analysis of uncertainty in any system is highly dependent on the model form and sophistication. Understanding of model uncertainty can be useful in allocating resources to model calibration and exploring novel approaches to modeling.

The objective of this paper is to better understand the sources of uncertainty in water distribution system modeling so that better modeling and monitoring methodologies can be developed. One potential monitoring approach is to use chlorine residual as an indicator of intrusion events. Through the introduction of chlorine demanding species, intrusion events can change the residual chlorine profile in a pipe network. If such a change were detected by a monitoring system, then appropriate response actions could be taken by water system operators to protect public health and restore network integrity. However, variability in network hydraulics and chlorine decay could obscure the detection of such a chlorine demand event. Previous studies have not fully characterized the relative importance of the various sources of uncertainty in this modeling problem.

A methodology is proposed for evaluating the relative effects of uncertain inputs on residual chlorine concentration at a monitoring node. Nodes are divided into upstream and downstream observational pairs that are then clustered into experimental units by mean travel time and node location. These experimental units define spatially and hydraulically similar regions of the network. Latin hypercube sampling and simulation of network hydraulics and chlorine transport using EPANET are proposed for both the undisturbed model condition and a chlorine demand event condition. Simulations are performed for a set of randomly sampled node pairs within each experimental unit. Independent uncertain inputs include nodal demand, pipe diameter, roughness, bulk chlorine reaction coefficient, and wall reaction coefficient. The first step of the sensitivity analysis is to screen input parameters using the Morris method (Saltelli, 2004) to eliminate those that negligibly influence output uncertainty and identify potential interaction effects. The second step is to apply a variance-based sensitivity analysis to determine the sensitivity indices for each input parameter. First-order indices and total sensitivity indices are calculated for each parameter. Higher order indices representing interactions between multiple parameters are calculated as suggested by the results of the Morris screening test. Indices are determined for each experimental unit and aggregated to characterize the total system sensitivity. The chlorine demand event simulations will explore a range of different magnitude chlorine reductions and the effect on downstream monitoring nodes relative to other uncertainties.

BACKGROUND

Uncertainty in water distribution system modeling has for the most part been a secondary topic of study in the research literature. There are several studies that utilize one or two uncertain inputs in developing models of hydraulic reliability (Wagner et al. 1988a and 1988b), optimal design (Lansey et al, 1989), solute fate and transport (Khamal, 2006), optimal monitoring (Jankovic et al., 2007), and to evaluate sensitivity methodologies (Kang et al. 2007). These studies contain some information about the output response to uncertainty in the selected input(s). However, there are very few studies that attempt to quantify the relative importance of multiple uncertain

inputs, and only one Pasha and Lansey (2005) attempt to do so for the case of fate and transport.

Table 1 presents a matrix of model characteristics and the relevant research literature. It is evident from this table that most of the studies have investigated uncertainty in hydraulic input parameters including nodal demand and pipe roughness coefficient. Simulation techniques such as Monte Carlo sampling and analytical approaches such as first order second moment (FOSM) are equally represented in the literature. There are a limited number of papers that have investigated uncertainty in water distribution systems water quality.

Wagner et al (1988a) and Wagner et al. (1988b) present a simulation and an analytical methodology, respectively, for modeling distribution system reliability subject to randomized mechanical failures of network components. Lansey et al. (1989) proposed a chance constrained model to minimize design cost taking into account uncertainties in pipe roughness, demand, and mechanical failure. Xu and Goulter (1999) also proposed a model to optimize design cost and reliability using the same uncertain inputs. Both of these papers utilized first order analytical methods for approximating model output response to input uncertainties. Neither paper makes assertions about the relative importance of input uncertainties.

Bao and Mays (1990) utilized Monte Carlo simulations to determine the effects of uncertainty in demand, pipe roughness, and pressure heads on reliability. Nodal reliability was defined as the probability that flow at a node will meet demand flows at a minimum pressure. The authors found that the choice of probability distribution for input parameters had a significant effect on nodal reliability, and that demand exerted a greater influence on outputs than did pipe roughness (Bao and Mays, 1990). Kapelan (2005) compared a sampling method with a deterministic integral approximation of the uncertain model response for the least-cost design problem. Demand was the only uncertain input for this study. Babayan (2005) proposed a cross entropy approach for multiobjective optimization of distribution system design with uncertain demand and roughness parameters. Babayan (2006) compared an integration based method with Latin hypercube sampling for solving the stochastic optimization design problem for water distribution systems. Again, demand and roughness were uncertain input parameters.

Kang et al. (2007) compared Monte Carlo and Latin hypercube sampling methods with a first order second moment analytical approach for estimating chlorine response to uncertain demand inputs. Sampling methods were found to be more accurate for unsteady flow conditions and the nonlinearities that occur due to flow reversals. First order methods were unable to approximate such nonlinear behavior. Demand was the only uncertain input parameter for this paper. Branisavljevic and Ivetic (2006) proposed a fuzzy approach for uncertainty analysis in a water distribution system. This method does not require the specification of an exact input probability distribution, but rather uncertainty is represented by fuzzy set mapping of input parameters. Outputs were found to be sensitive to the interval over which the fuzzy input set was specified. Pipe roughness was the only uncertain input parameter, and pressure head was the output.

Jankovic et al. (2007) describe a stochastic model for estimating network flows and heads from uncertain demand inputs in order to identify locations for

leakage monitoring. Monte Carlo simulations were used with EPANET to determine output response. Kapelan et al. (2007) proposed a novel analytical method for mapping uncertain input parameters to a set of output calibration data. The probability distributions for a set of input parameters were approximated using Bayesian recursive algorithm. The only uncertain inputs considered by Kapelan et al. (2007) were roughness coefficients.

Two papers in the water distribution system research literature have considered uncertainty analysis for water quality parameters. Khamal et al. (2006) modeled the injection and transport of a conservative solute and introduced an exposure index to quantify the downstream effects for consumers. A generalized sensitivity analysis was performed to determine system response to uncertainty in base demand, storage capacity, injection mass and injection duration. Base demand and injection mass were identified as the input parameters with the greatest influence on exposure index. Latin hypercube sampling coupled to EPANET simulation were used to evaluate system response. Lansey et al. (2005) modeled decay and transport in a water distribution system subject to uncertain demands, bulk decay coefficient, wall decay coefficient, pipe roughness, and pipe diameter. Monte Carlo sampling and EPANET simulation were used to determine the output pressure and chlorine concentration at each node. Results shown at three monitoring nodes suggest that wall decay coefficient, bulk decay coefficient, demand and pipe roughness all exhibit a large influence on output values, with each input taking precedence at different monitoring locations.

The following system of equations is utilized by the EPANET model for hydraulics and water quality in water distribution systems. Additional details may be found in Rossman (2002). Continuity and conservation of energy in a pipe network require that,

$$\sum_j Q_{ij} = D_i \tag{1}$$

and,

$$H_i - H_j = h_{ij} \tag{2}$$

where,
Q_{ij} = pipe flow between nodes *i* and *j*,
D_i = demand at node *i*,
H_i and H_j = total head at nodes *i* and *j* respectively, and
h_{ij} = head loss in the pipe between nodes *i* and *j*.

The head loss may be estimated using the Hazen-Williams equation (US customary units),

$$h_{ij} = K\left(\frac{Q_{ij}}{C}\right)^{1.852} \frac{L_{ij}}{D_{ij}^{4.87}} \tag{3}$$

where,
K = constant,
C = Hazen-Williams roughness coefficient,
L_{ij} = length of pipe between i and j, and
D_{ij} = diameter of pipe between i and j.

Solute fate and transport in the distribution system model can be represented by the following set of relationships for a first order decay model with bulk and wall reaction components (Rossman, 1994).

$$\frac{\partial C_i}{\partial t} = -u_i \frac{\partial C_i}{\partial x} + r(C_i) \tag{4}$$

where,
C = concentration
u = average flow velocity
x = longitudinal direction of pipe
t = time

i = pipe index
$r\ (C_i)$ = reaction rate ($M \cdot L^{-3} \cdot T^{-1}$) as a function of concentration, sum of wall and bulk reactions

$$r_{wall} = -\frac{k_w k_f C_i}{R_h\left(k_w + k_f\right)} \tag{5}$$

where,
k_w = wall decay constant ($L \cdot T^{-1}$)
k_f = fluid mass transfer coefficient ($L \cdot T^{-1}$)
R_h = hydraulic radius, pipe volume/area, or 2/radius

$$r_{bulk} = -\ k_b C_i \tag{6}$$

where,
k_b = bulk decay constant ($L \cdot T^{-1}$)

METHODOLOGY

The approach presented here proposes to accomplish two objectives: 1. extend the results from Lansey et al. (2005) to better understand model sensitivity for the fate and transport problem , and 2. model the occurrence of a chlorine demand event and system response within the context of other sources of uncertainty, a problem that has not been addressed previously in the research literature.

Sensitivity analysis (SA) and uncertainty analysis (UA) are terms that are often confused in the research literature. UA is a forward process to quantify the effect of uncertain inputs on output uncertainty, while SA works backward to ascribe uncertainty in the output to the different sources of uncertainties among the inputs. SA attempts to identify the hierarchy of influence that inputs exert on output variability.

There are a large number of sensitivity analysis methodologies (Saltelli, 2000) that have been applied to varying degrees in the Environmental Engineering domain. Variance-based approaches have been shown to be robust for non-monotonic and non-linear problems such as distribution system modeling (Saltelli, 2000). Storage tanks can create pipe flow reversals in nearby regions of a system, thereby causing abrupt nonlinear changes in the chemical profile of water at affected nodes. Variance-based sensitivity analysis is global in that it characterizes model sensitivity over the entire input parameter space.

Lansey et al. (2005) reported that the relative influence of uncertain input parameters varied with choice of monitoring node, and a different parameter was identified as the most important for the three cases shown. This result suggests that an additional spatially heterogeneous parameter may exist that would allow this source of variance to be separated and explained. In addition, Lansey et al. (2005) performed single fixed and single uncertain parameter simulations for each input, and made inferences about input parameter influence based on the standard deviation of chlorine concentration at monitoring nodes. Using the standard deviation is similar to

variance-based methods, however, first or higher order sensitivity indices that are normalized by the output variance were not calculated.

For this study, input probability distributions are consistent with those from Lansey (2005). Pipe diameter will be sampled from a uniform distribution with an interval range of 0.5 - inches, and all other input parameters will be normally distributed with a coefficient of variation equal to 0.1 (Lansey, 2005). The initial case study will be example network 2 from Rossman (2002). This network has been used extensively in the water distribution system research literature for developing novel methodologies.

Spatial Clustering and Sampling

In order to efficiently characterize the spatial variability of the system, a randomized sample of chlorine injection node and downstream monitoring node pairs is proposed. In the language of experimental design, each node pair is considered to be an observational unit. These node pairs are then clustered using the following characteristics:

t_t , mean travel time between the pair of nodes,
(x_1, y_1), coordinate location of node 1,
(x_2, y_2), coordinate location of node 2, and
r_{ud}, upstream-downstream relationship between nodes.

Upstream-downstream relationship refers to the set of three possible flow states that may occur between nodes: 1. no relationship – flow does not pass between nodes, 2. one node is always downstream throughout the simulation period, and 3. upstream and downstream node switch caused by a reversal of flow between the nodes. A schematic is shown in Figure 1 to demonstrate this idea.

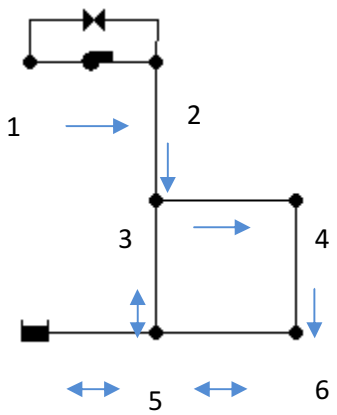

Figure 1. Example network schematic

The matrix shown in Table 2 demonstrates the full set of relationships between nodes in Figure 1. The reason for grouping observational pairs using this criteria is that pairs containing intermediate pathways with flow reversal may exhibit non-monotonic relationships between input and output parameters. Clusters of these six parameters define regions of the node pair space that are hydraulically and

spatially similar. These regions define experimental units that are randomly sampled in order to efficiently characterize the effects of spatial heterogeneity on the results.

Table 2. Matrix of monitoring node pair relationships

	1	2	3	4	5	6
1	n	c	s	c	s	s
2	n	n	s	c	s	s
3	n	n	n	c	s	s
4	n	n	n	n	s	s
5	n	n	s	s	n	s
6	n	n	s	s	s	n

where,
n = no relationship,
c = consistent downstream node
s = switching upstream and downstream node

Morris Screening Method

Screening methods are used to reduce model complexity prior to running exhaustive simulations over uncertain parameters. The Morris method is a means of initially evaluating the influence of inputs to determine if they exert negligible influence, exhibit linearity, or combine to form interaction effects (Saltelli, 2004). The elementary effect for the *i*th input is defined to be:

$$d_i(x) = \frac{\left[y(x_1,...,x_{i-1},x_i+\Delta,x_{i+1},...,x_k)-y(x)\right]}{\Delta} \quad (7)$$

where

y = output
$x = (x_1, x_2,\ldots,x_k)$ set of values selected from set {0, 1/(p-1), 2/(p-1), …, 1},
Δ = a constant value equal to a multiple of 1/(p-1), and
p = the number of input space divisions

The set x is randomly sampled and evaluated until the distribution of elementary effects for input i is found (F_i). The mean and standard deviation of F_i are used to evaluate the relative importance of an input value. The absolute value of d_i may be used in the generation of this distribution for non-monotonic models such as water distribution systems. The mean of F_i is a measure of the input's importance, and the standard deviation indicates non-linearity and interaction effects. These measures are used to refine the model prior to more exhaustive variance-based methods.

Variance-based Sensitivity Analysis

Variance-based sensitivity analysis presumes that variance is a suitable measure of uncertainty in an output. The total variance of the output is attributed to different sources within the set of uncertain input parameters, similar to Analysis of

Variance (ANOVA) techniques in the experimental design literature. The reduction in output variance that occurs if a single input parameter is fixed to its 'true' value is a measure of that parameter's first-order influence. The variance of an output given a single fixed input is,

$$V(Y|P_x = p^t{}_x) \tag{8}$$

where P_x is an uncertain input parameter, Y is the output, $p^t{}_x$ is the true fixed value of the input, V is the variance taken over all input parameters $\neg x$. The true value $p^t{}_x$ is unknown, however, it can be approximated by taking the expected value over P_x:

$$E(V(Y|P_x) \tag{9}$$

The law of total variance states that:

$$V_t = E(V(Y|P_x) + V(E(Y|P_x) \tag{10}$$

where V_t is the total variance of Y over all uncertain parameters. Thus the reduction in the total variance caused by fixing a single input is given by

$$V(E(Y|P_x) = V_t - E(V(Y|P_x) \tag{11}$$

The first order sensitivity index is found by normalizing over the total variance:

$$S_x = \frac{V\left(E\left(Y \mid P_x\right)\right)}{V_y} \tag{12}$$

For water distribution systems, S_x can be determined through Latin Hypercube simulations over all uncertain parameters save the single fixed input. Higher order sensitivity indices represent the interaction effects of multiple parameters. For orthogonal inputs, second order effects are:

$$S_{x1,x2} = \frac{V\left(E\left(Y \mid P_{x1}, P_{x2}\right)\right) - V\left(E\left(Y \mid P_{x1}\right)\right) - V\left(E\left(Y \mid P_{x2}\right)\right)}{V_y} \tag{13}$$

Higher orders are similarly calculated. The total effect ($S_{T,x}$) can be calculated which represents the total contribution of P_x for all orders. A relatively complete picture of a parameter's influence is given by S_x and $S_{T,x}$ and neglecting intermediate orders of interaction (Saltelli, 2004).

Chlorine Demand Simulation

The results of the sensitivity analysis will be used to refine the model and reduce the number of uncertain inputs. The refined model will then be used to estimate the effect of a chlorine demand event on downstream monitoring nodes. Again, monitoring node pairs clustered into similar hydraulic and locational experimental units will be used to characterize the spatial heterogeneity of the model. Random sampling within these units replaces an exhaustive simulation over all nodes.

A chlorine reduction will be simulated at each sampled upstream node. The distribution of chlorine concentration at the downstream node for the chlorine demand scenario will be compared to that of a non-demand scenario at each time step. The statistical difference between these distributions will be estimated. Different magnitudes of chlorine reduction and demand event duration will be simulated in order to determine the severity of event that may be detected. As with

the sensitivity analysis, results will be determined for each experimental unit and aggregated over the full system.

CONCLUSIONS AND NEXT STEPS

This paper presents a methodology to determine a water distribution system model response to uncertain inputs for the chlorine fate and transport problem. It also proposes to model the occurrence of chlorine demand events within the context of other sources of uncertainty. Results from this study will help better understand the potential for chlorine monitoring as an indicator of upstream intrusion events. Results from the methodology presented here also may explain the inconsistent influence that uncertain inputs exhibited on chlorine response shown by Lansey et al. (2005). A clustering and sampling approach for characterizing spatial heterogeneity in water distributions is proposed. The next steps for this study will be to implement conservative solute tracer simulations over the set of uncertain inputs to identify the monitoring pair classifications shown in Table 2 and the mean travel time between pairs. These will be used to cluster pairs into the appropriate experimental blocks.

Characterizing reactive contaminant sources in a water distribution system

Abstract

Accurate knowledge of the characteristics of the contamination source during a contamination event is necessary for development of any mitigation and control strategy. Contaminant injected in a system is most likely to be reactive with chlorine; however, it is impractical for water quality monitoring systems to be able to monitor for the presence of all possible contaminants. In any distribution system, chlorine levels and other water quality parameters (pH, conductance, etc.) are routinely monitored to maintain the prescribed disinfection capacity. Any reactive contaminant would affect the chlorine levels resulting in deviations in the expected chlorine levels from those expected under normal operating conditions. Anomalies in the chlorine concentration from that of the expected value can be used as a surrogate to characterize the contaminant source in the system. In the absence of knowing the reactive characteristics of the contaminants, the location of injection, and injection pattern, source identification becomes a difficult problem to solve. Source identification can be posed as an inverse problem. In earlier work authors investigated the effect of the order of reaction kinetics of the contaminant with chlorine and its impact on source identification problem assuming the reaction kinetics to be known. That work is extended to investigate a methodology to address the source identification problem based on chlorine measurements, and the effects of different uncertain contamination conditions. Findings from a range of scenarios will be presented and discussed.

Introduction

Water distribution systems are vital for the supply of safe drinking water to the public. They are prone to accidental or intentional contamination which can endanger the public health. A robust drinking water monitoring program should be able to provide early indication of contamination and minimize the public heath consequences (USEPA, 2005). Also, an early warning system should be able to reliably identify chemical, biological, or radioactive contamination events in source water or distribution systems in time to allow an effective local response to reduce or avoid the potential adverse impacts (ILSI, 1999).

Water distribution system contamination source identification problem has traditionally been approached as an inverse problem. Waanders et al. (2003) used a standard successive quadratic programming approach. An origin-tracking algorithm based on a Lagrangian non-linear programming approach was proposed Laird et al. (2005). Laird et al. (2006) proposed a mixed integer programming-based method for the identification of unique injection scenarios. Zechman et al. (2006) studied the issues related to non-uniqueness in source identification problem, which arises due to the limited availability of the observed water quality data from the sensors in the network. Most of the studies for source identification reported in the literature assume the pollutants to be conservative and a dedicated probe is available to sense that specific contaminant.

In the event of a reactive chemical or biological contamination event, surrogate water quality measurements could be used to source identification. In an earlier work authors (Kumar et al., 2008) used chlorine measurements to characterize the contaminant source location, and examined the effect of the kinetics of contaminant-chlorine reaction on the solution to the source identification problem was investigated. That approach is extended here to investigate the methodology to address the source identification problem using chlorine measurements obtained under uncertain contamination conditions.

Reactive Contaminants

Chlorine is a very commonly used disinfectant in most municipal water distribution systems. Doses of free chlorine are injected in the source water and at other injection nodes to maintain a minimum level of chlorine concentration required as per guidelines to maintain the disinfection capability of water distribution system. Chlorine concentration is routinely monitored in any water distribution system. When a contaminant that is reactive with the chlorine enters the water distribution system, the chlorine concentration in the system would respond according to the contaminant concentration present. Anomaly in the chlorine concentration in the system can be statistically analyzed to issue contamination event alarm (McKenna et al., 2007) and can be used to identify the source characteristics (Kumar et al., 2008). However, the kinetics of reaction between contaminant and chlorine in the water remains unknown during an event. Flow and hydraulic conditions in a water distribution network are highly dynamic, introducing further uncertainties about the interaction of the contaminant with chlorine. Kumar et al. (2008) studied the effect of the order of reaction between arsenic and chlorine on the chlorine concentration level in the system. First and second order reaction kinetics were studied. However, the order of the reaction remains unknown during an event as the type and reactive properties of the contaminant are unknown. This study extends the previous work (Kumar et al., 2008) to develop a methodology for identification of source characteristics for reactive contaminants using chlorine measurements under uncertain conditions.

For the purpose of this study, contamination of water with arsenic (As) is considered. Chlorine is assumed to be present in the form of monochloramine residuals. Arsenic may react with monochloramine leading to the decay of monocloramine as follows.

$$As^{+3} + NH_2Cl \rightarrow AsCl_3 + 3NH_2^+ \tag{1}$$

The reaction system can be solved using the following differential equations:

$$\frac{dAs^{+3}}{dt} = -K_a (As^{+3})^x (NH_2Cl)^y \tag{2}$$

$$\frac{dNH_2Cl}{dt} = -K_b (As^{+3})^x (NH_2Cl)^y - K_c (NH_2Cl)^z \tag{3}$$

where K_a is the decay rate of arsenic (As^{+3}), K_b is the decay rate of monochloramine when arsenic reacts with chlorine in water, K_c is the self decay rate of chlorine, and x, y, and z are the order of reaction of arsenic, monochloramine and self decay of monochloramine in the assumed reaction system. Self decay of monochloramine was assumed to be of first order in the current analysis while the reaction between arsenic and monochloramine was considered to be under first and second order conditions.

Formulation of source identification problem

Anomaly in the chlorine concentration levels in the system can be utilized for the characterization of contamination source. Optimization problem can formulated so as to find solution source with characteristics to match the observed chlorine measurements as accurately as possible. Several different scenarios of optimization problem would be studied using the anomalies in chlorine concentration as observation data. The mathematical problem is defined as:

$$\text{Minimize Error} = \sum_{t=0}^{Ts} \sum_{k=1}^{N_s} \left\{ C_{k,o}(t) - C_{k,p}(t) \right\}^2 \tag{4}$$

The objective function represents the sum squared deviation in the predicted chlorine concentration over chlorine observations at all the sensors over the monitoring period. $C_{k,o}(t)$ is the observed chlorine concentration at sensor k at time t, $C_{k,p}(t)$ is the predicted chlorine concentration at sensor k at time t, T_s is the total time for which the network is being simulated, and N_s is the total number of chlorine measurement locations in the distribution system. The objective is to identify the source characteristics (represented by the junction node where the source is introduced, the reaction order of the contaminant, the start time of the contamination, and the contaminant mass loading profile) that minimizes the prediction error by closely matching the time series of anomalous drop in chlorine concentration in the network.

Methodology

Source identification in water distribution system can be posed as inverse problem and solved using a simulation-optimization method. Evolutionary algorithms (EAs) (Holland, 1975) are a class of heuristic methods that provide a global search mechanism to identify efficiently near-optimal solutions for large optimization problems. Dandy et al., (1996) and Savic and Walters (1997) used genetic algorithms for the optimal design of water distribution systems. Vitkosvsky et al., (2000), and Lingireddy and Ormsbee (2002) solved using EAs the inverse problem associated with calibration of water distribution networks. In the present study, an EA-based procedure is employed for the source identification problem.

Evolution strategies (ES) (Schwefel, 1995) is an EA-based search method that is being explored as a solution approach for the source determination problem. ES works with a population of solutions. The first generation starts with a random population of μ individuals. A set of λ new solutions are created in each generation using a random mutation process. From the combined array of parent and offspring solutions (denoted as (μ + λ)-selection) or from the set of offspring alone ((μ, λ)-selection), the set of λ individuals are selected for the next generation. Zechman et al., (2006) used an ES-based search approach to solve the source identification problem in water distribution systems. The inverse problem was defined in terms of continuous concentration observations assuming the availability of perfect sensors for the specific contaminant. In the present study an ES based methodology will be used for addressing the source identification problem using chlorine observations.

Illustrative case studies

The proposed study is demonstrated through illustrative case studies involving two test networks. First is an example network (Network 1, Figure 1) that is included with the standard EPANET distribution. This network consists of 97 nodes including two sources, three tanks and 117 pipes, and the water distribution system is simulated using EPANET. The second network used in the study is the virtual city of Micropolis (Figure 2) that was developed by Brumbello et al., (2007). It consists of 1236 nodes, 575 mains, 486 service and hydrant connections, 197 valves, 28 hydrants, 8 pumps, 2 reservoirs, and 1 tank. Multiple-species extension toolkit (MSX) for EPANET provides the capability to model the chemical interaction among multiple reactive species.

Synthetic scenarios of contamination events in the example networks have been considered to study the performance of the proposed method. The Network 1 and Micropolis network are simulated for 24 hours and 72 hours, respectively. Hydraulics in network was simulated every hour while the water quality transport was simulated every 5 minutes. A sample network of sensors/monitoring stations was chosen in each network to uniformly cover the entire network. Water quality observations were recorded every 10 minutes at all the monitoring stations.

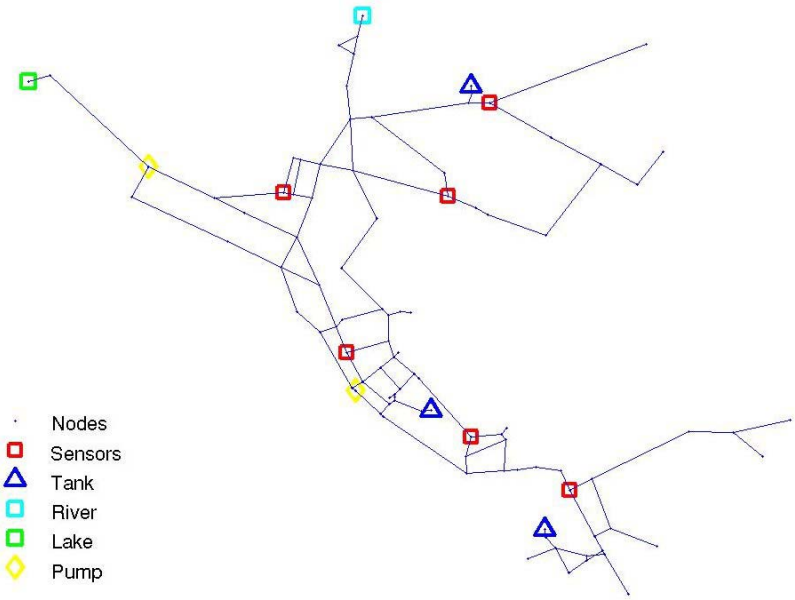

Figure 1. Test Network 1

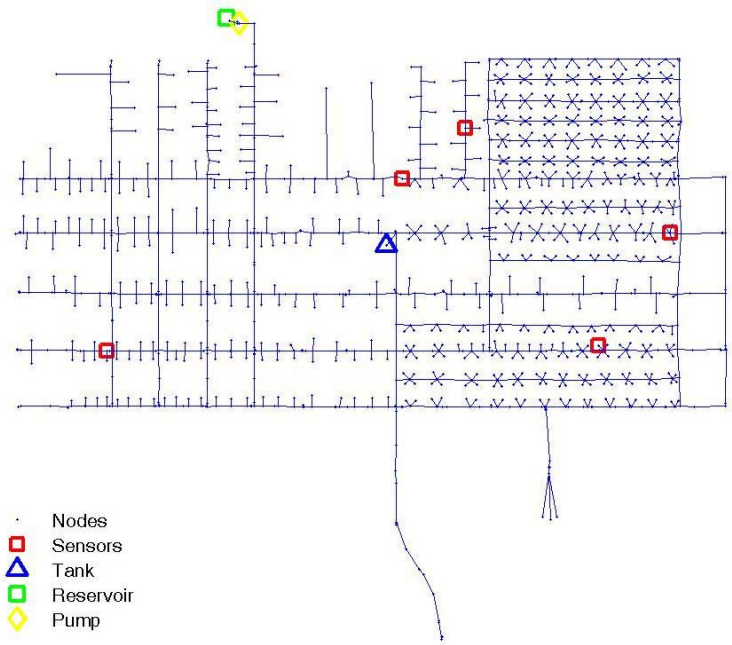

Figure 2. Micropolis network

Arsenic was assumed to undergo a first order or a second order reaction with monochloramine. A part of the source characterization problems is to identify the reaction order, which was assumed to be unknown. Problem was analyzed for two different nodes as contaminant injection location in Network 1. First and second order contamination scenarios were considered in the study, while source identification problem was solved under the conditions of unknown order of reaction. The study was conducted for two different sensor placements scenarios. The methodology was applied to Micropolis network for first and second order contamination scenario. Table 1 summarizes the scenarios studied in this work.

Table 1: Summary of scenarios investigated

Scenario	Network	No. of sensors	True injection source		Order of reaction for solution
			Location	Order of reaction	
1	Network 1	6	12	1st order	1st order / 2nd order
2	Network 1	6	12	2nd order	1st order / 2nd order
3	Network 1	3	12	1st order	1st order / 2nd order
4	Network 1	3	12	2nd order	1st order / 2nd order
5	Network 1	6	54	1st order	1st order / 2nd order
6	Network 1	6	54	2nd order	1st order / 2nd order
7	Network 1	3	54	1st order	1st order / 2nd order
8	Network 1	3	54	2nd order	1st order / 2nd order
9	Micropolis	5	653	1st order	1st order / 2nd order
10	Micropolis	5	653	2nd order	1st order / 2nd order

Summary
This study describes the development and investigation of a simulation-optimization methodology for the identification of source characteristics for contamination events involving reactive contaminants. In this study, the unknown source characteristics are described by the source location, the start time of contamination, the order of the reaction of the contaminant, and the contaminant loading profile. The residual chlorine signature in the system in response to the reactive contaminant is expected to capture the contaminant characteristics. The source characteristics are recreated based on the residual chlorine measurements in the network where the injected contaminant is assumed to undergo reactions with the disinfectant chlorine in the system. The effectiveness of this source characterization procedure under conditions of variability and uncertainty are also investigated. Further, the effect of limited information and data and observation errors on the ability of the method to uniquely identify the source location is investigated by extending the procedure to address non-uniqueness in the solutions. These investigations are conducted for an array of scenarios involving two different water distribution network examples. The preliminary results indicate that the proposed approach is effective in identifying a small set of potential nodes that includes the true contamination source.

ABSTRACT

There is copious evidence indicating intrusion of contaminants into the drinking water pipes through the leaking sections due to low pressure events associated with water hammer phenomenon. In this study, an experimental plumbing rig was designed and implemented that replicates the range of pressures encountered in actual service lines and the plumbing systems. This research addresses how a pressure transient triggered within a house and from municipal systems can impact the service lines with a possible suction effect. This experiment also enabled visualization of the various pressure transient phenomena including gaseous cavitation. It is demonstrated that hydraulic transients triggered from water mains result in low pressures events in service lines which can allow possible intrusion of microbial and chemical contaminants at service lines. Structural integrity of service line and hydraulic integrity at water mains should be maintained to minimize any public health risks.

INTRODUCTION

The growth in bottled water consumption, point of use water treatment (including various kinds of filters, distillation, ion exchange, and reverse osmosis) indicates citizens' concern regarding the quality of distributed water at the tap. Cost advantages of public water supply, higher maintenance problems related to the point of use devices and relative marginal improvement in water quality result in the municipal drinking water remaining as the top-ranked water supplier for maintaining established drinking water standards. It is widely believed that because a drinking water distribution system is pressurized, the water can only come out of the system. However, there is evidence that pump trips, opening and closing of fire hydrants, valve closures or malfunctioning, pipe break, and sudden change in demand and resonance can induce significant transients leading to low pressure events within a drinking water system. During such events a greater external pressure can lead to contamination intrusion through available openings. Tests of surrounding soil and pipe specimens from repair locations show the presence of pathogens. In 2000 alone 6,988 water systems affecting about 10.5 million people violated microbial drinking water standards in the US.

Le Chevallier et al. (2003) define intrusion as the specialized backflow situation in which nonpotable/contaminated water from the environment outside of the distribution piping flows into the pipe through leaking sections. Kirmeyer et al. (2001) and Friedman et al. (2004) provided comprehensive reviews and detailed discussions on the pathogen intrusion problems into the municipal drinking water systems. Any breakthrough is considered high risk and probability of occurrence is also considered high. They also point out physical mechanisms grouped as *transitory contamination* due to low pressure propagation in the system drawing in contaminants from the exterior surroundings with a higher pressure; *cross connection* between potable water system and a source that can potentially introduce contaminants into the potable water; *pipe break, repair and installation* that expose the distribution system to the externalities as routes of entries. Storage facilities both covered and uncovered, purposeful contamination, growth and resuspension serve as additional sources for pathogen intrusion.

Friedman et al. (2004) focused on transitory low pressure propagation in the municipal system that typically uses 4 inch to 10 inch pipes. They documented intrusions of contaminants and low pressures of the order of negative 10 psi (gage). They also emphasize that the intruded contaminant is not re-extruded out of the pipe but a portion of it is carried downstream. Distribution mains downstream of pumps, high elevation areas, low static pressure zones, areas far away from overhead tanks, and segments of pipes upstream and downstream of active valves in high flow areas are the most susceptible for low or negative pressures. Locations with frequent leaks and breaks, high water table regions, flooded air vacuum valve vaults, and high risk cross connections have the highest potential for intrusion. Gullick et al. (2004) observed most surge events as the result of pump operations and outages. Novak (2005) provided experimental evidence for a 90 degree bent pipe with a pressure range of less than 10 psi and with a velocity of about 6 ft/sec contamination can be sucked into downstream of the 90 deg bent region of the pipe.

Since the terrorist events of September 11, 2001, water security at water infrastructure has received more attention than before. NRC (2006) categorized drinking water distribution system's integrity into the following components: i) *physical integrity* indicating the physical barrier between pipe externalities and inside the piping, ii) *hydraulic integrity* controlling right pressure, flow, water age, and capacity for providing fire flow, and iii) *water quality integrity* keeping high standard of water quality without any degradation. If any of the components fails to keep the good level of integrity, this will result in serious public health risk. This indicates that drinking water infrastructure bears significant operational and managerial responsibilities towards public health.

Service lines

America's water distribution infrastructure system is old and deteriorating. A water system with its myriad of appurtenances (including pumps, valves, and tanks) is susceptible to hydraulic transients resulting in high and low pressure waves alternatively passing through the network. While the major municipal system is readily recognized as a vast infrastructure system of nearly 1,409,800 km of piping within the United States, the plumbing systems including service lines (minor systems) which are at least 5 to 10 times larger is generally not well addressed.

Leakage rates (water loss while transporting water from treatment plant to minor systems) in drinking water systems reaches 32 percent in some utilities which indicates high potential of

contamination intrusion (Kirmeyer et al., 2001). It is emphasized that 6 billion gallons of treated water is disappearing during distribution (AWWARF, 2007). According to NRC (2006), the majority of water leaks occur at service lines, service fittings, and connections. It is emphasized that the lower total chlorine residuals, lack of dilution, and short detention time before potential consumption might increase the potential health threat to individual consumers if intrusions were to occur at service lines. Also, service line's failure records are not readily available (as they belong to private property) so future prediction of failure is difficult.

To the author's knowledge, no study has been conducted to examine hydraulic impacts at service lines as a result of transients triggered from water mains (major) and plumbing (minor) systems. Also, while it is known water hammer is common inside a home, what pressures exist (when water hammer hits) within the plumbing system is not clearly understood. As plumbing systems and service lines are passive recipients from the water mains; if there is a contamination intrusion event at the service line, it is bound to enter into our tap water which poses health risk issues. The objectives of this research are to design, construct, and implement an experimental plumbing system that replicates the range of pressures encountered in actual minor water distribution systems. The experimental plumbing system is used to i) assess low pressure behavior at the service lines to predict the potential for contamination intrusion from the surrounding soil or water and ii) evaluate the cavitation phenomenon through clear plastic pipe for steady and transient state.

EXPERIMENTAL PLUMBING RIGS

Typical single-story residential house connections to a municipal water main are shown in Figure 1. The average pressure in the main system is 70~ 80 psi and it dictates the pressure at each house level. Cold water plumbing systems are usually branched-type systems that are typically comprised of 'one source, one or more intermediate nodes, and one or more plumbing fixtures' (Bhave, 1991).

In our experiment, we are simulating real plumbing systems by directly connecting to water mains. Three scenarios, referred to as Transient I, II, and III (see Figure 1) that can trigger a transient in a service line are considered. Transient I: In this case, transients are triggered due to actions initiated from inside of the house (e.g., by shutting off the valve, shower heads, or automatic on/off of solenoid valve from laundry room). Transient II and III: In these cases, transient causing actions are initiated from the municipal water systems (e.g., pump trips, opening and closing of fire hydrants, valve closures, pipe break, sudden change in demand and resonance, and malfunctioning of valves). Depending on the flow direction in the system, there are two transients (i.e. transients II and III) which influence the pressure variation at the service line (see Figure 1).

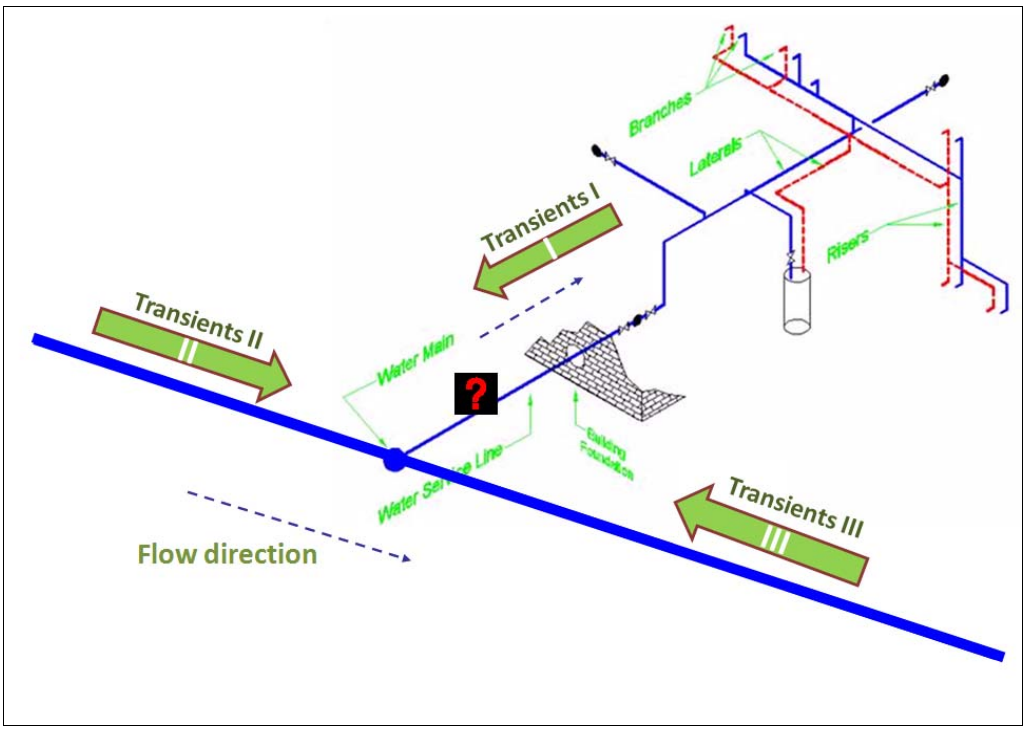

Figure 1 Scenarios of transients that can occur in drinking water distribution systems (modified from Ladd, 2005 with permission)

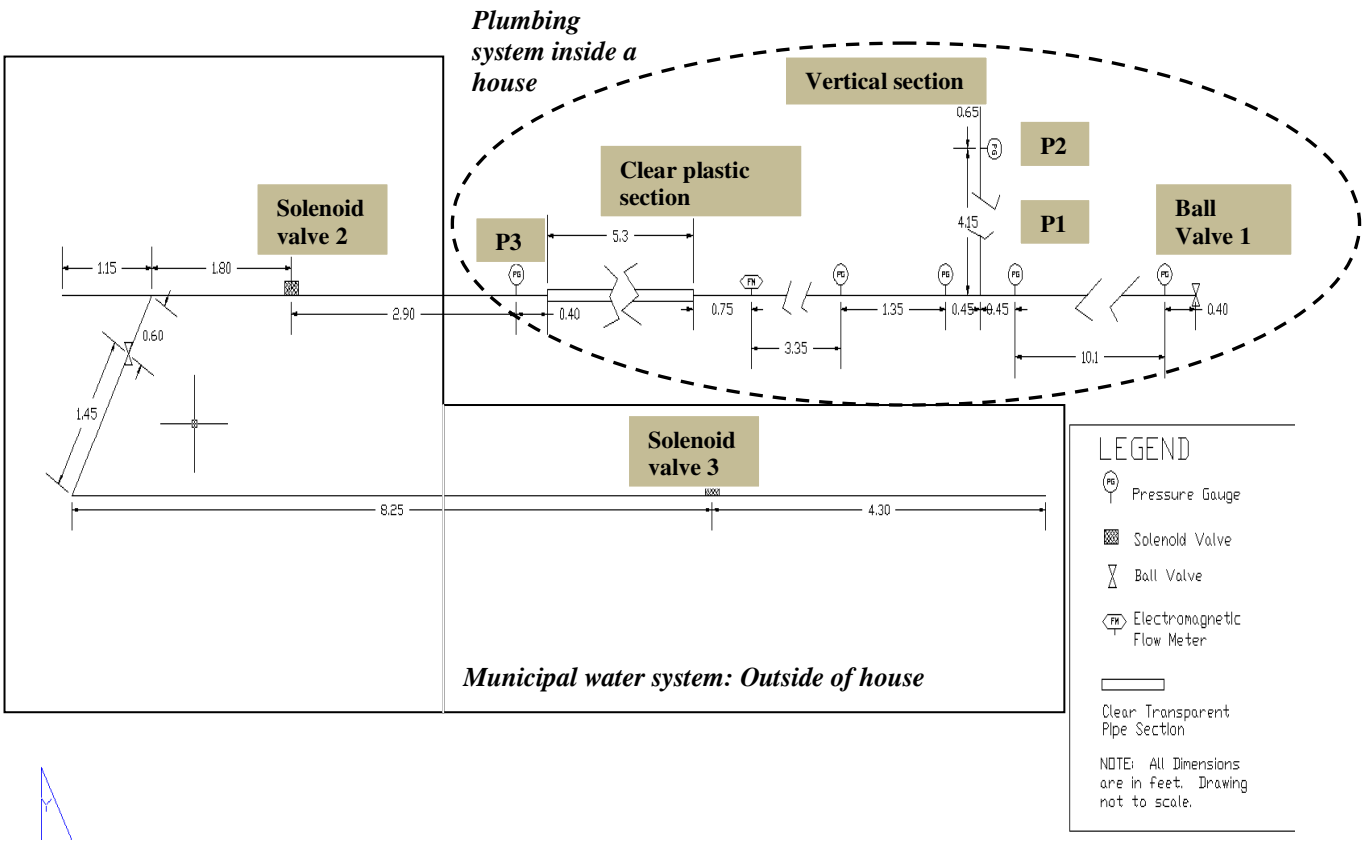

Figure 2 Schematic of the experimental plumbing system

An experimental plumbing rig is built in the hydraulics lab of CEE department at Virginia Tech to simulate these proposed three scenarios. Detailed configuration of the rig is guided by current plumbing code and advice from the plumbers. Main line has 0.75" diameter and we used soldering instead of threaded appurtenances to mimic real home plumbing more closely. Dotted oval shape indicates the plumbing system inside house and solid line is for municipal water system outside of a house (see Figure 2). High sensitive sensors such as pressure transducers and insertion type magnetic flowmeter were adopted to observe the spatial and temporal variation of the flow patterns. Three pressure transducers (P1, P2, and P3) and one flowmeter were installed at locations of interest (see Figure 2). The signals from the sensors were collected by LabVIEW based DAQ (Data Acquisition System) systems using sample and hold technique every 0.01 second so the data from multiple signals are acquired simultaneously. To visualize the phenomenon and study the specific nature of gaseous cavitation inside the piping system, a 5.3' section of clear plastic pipe was installed. We employed a high definition Video camera to capture the cavitation phenomenon for steady state and when water hammer hits.

This experiment involves pressure varying continuously over time over a range of -14.7 to over 250 psig (temperature range is 50 to 90 F [room temperature]). Water hammer occurs if a valve is suddenly closed (ball valve or solenoid valve) in a pipe system, and there is a sudden change in the velocity and pressure. As water hammer passes through the pipe, pressure measurements of the order of hundred readings per second capturing the maximum and minimum are required to visualize the pressure variation. The pressure continuously fluctuates until the transients die out. It was necessary to measure the pressures as they fluctuate continuously with time. To meet these requirements, we chose dynamic application sensors which means sudden change of properties. Water hammer shocks, acceleration, and vibration are examples of dynamic signals. For dynamic applications, piezoelectric pressure sensors are known to be ideal as they are able to measure very high frequencies compared to strain gauge technology due to their stiffness. Stiffness also leads to fast response time. Piezo sensors offer a response time of less than 1 micro-second so there is no trouble making several hundred readings per second as long as sampling rate on the DAQ is high enough (Our DAQ system is able to collect maximum of 1M readings per second).

However, piezoelectric sensors ignore the static pressure component. As such referencing the output to atmosphere or absolute is not possible. The sensor will show the pressure changes in relation to static pressure in the rig. In our application, the baseline pressure is the water line's steady state pressure. So, for the piezoelectric pressure sensor, instead of calling it gage pressure, it is really called a relative pressure measurement; relative to the water line's steady state pressure. For example, water line pressure is 30 psi; the 30 psig static water line pressure will read zero on a piezoelectric pressure sensor. A regular static sensor would read 30 psig. Then, when the water hammer hits, there will be a spike to 250 psi 'relative to 30 psig' and then a reflected pressure wave possibly down to -14.7 psi 'relative to 30 psig.' This -14.7 psi is relative to the static line pressure of 30 psig.

EXPERIMENTAL RESULTS

The experiment plumbing rig was connected to the water main in hydraulics lab to simulate a real household water supply situation (see Figure 2). The average static pressure was 80 ± 5 psig when all the valves were closed. It is opined that this fluctuation comes from water usage in nearby faucets or weak transients from the municipal systems. When the faucets were fully opened (flow rate is (37±5) liter/minute), however, the residual pressure was reduced to 40-45 psig within the experimental system. The level of residual pressure could be controlled by maneuvering the valve at the water main. Initially, the system is set in a steady state of 40 psig (residual pressure). Then the solenoid/ball valves were suddenly closed/ opened following three scenarios. The solenoid valve closing/opening time was known to be less than 0.3 seconds according to the manufacturer. The ball valve closing/opening time is believed to be less than 0.1 seconds after many times of operator's training.

Pressure Variation at Location P3: Representing Service Lines

The relative pressure variations at location P3 (which represents service lines) are explained in this section. Scenario I refers to the open/close at valve1; scenario II refers to open/close at valve 2; and scenario III is open/close at valve 3. When the valve 1 is suddenly closed, the pressure goes up to 70 psi (gage) from the steady state. So, within fraction of a second, service line is going through (40+70=110) psig of pressure. This may result in repetitive fatigue impact on service lines due to constant on/off from inside the house. But when opened, it is causing -30 psig so 80 psig (static pressure) – 30 (instantaneous pressure change) = 50 psig; which is not creating low enough pressure to cause suction.

Transient II scenario results are shown in Figure 3. After sudden closure, the pressure goes below 0 psig (around -10 psig) for a fraction of a second. It is seen that transient II is causing negative pressures (40 (steady state) – 50 (pressure variation) = -10 psig inside the system). When suddenly opened, the pressure goes up to 70 psig. Transient III scenario also showed pressure changes but the magnitudes are not so noticeable compared to scenarios I and II.

Gaseous Cavitation

When the pressure drops to -10 psig (above vaporous pressure values), gaseous bubbles forming inside the clear plastic pipe section was observed; then the bubble disappeared within less than 1 second when pressure goes above gas saturation pressure (see Figure 4). The bubble formation time was very quick (less than 1 second) and this is contrary to traditional theory of gaseous cavitation formation timing (2-3 seconds, Novak (2005)). Pre-existing gas nuclei that was existing on particles in the bulk solution seemed to grow to be the observed bubbles. Using HD video, consecutive phenomenon was captured every 0.033 second (30 frames per second). It is observed that created bubble shape and numbers are near random but gas evolution and dissolution timing seem to be almost consistent (less than 1 second) as long as we control the water hammer triggering mechanism (valve closing time). As the clear plastic's diameter is ¾", rough size of the gaseous cavitation bubbles can be estimated. Observed gaseous cavitation due to water hammer may have implications of noise problems within plumbing systems which bears further research.

CONCLUSIONS

Pressure variations at the service line corresponding to typical street level pressures encountered in a real water supply system are examined in this research. This study was specifically developed for a typical one story house (1800-2200 square foot; water hammer impacts from inside house applies *only to cold water line*) plumbing system which includes 150- 250 feet of pipes. Major findings of this research are following.

1. As a result of a street level transient, low pressure wave (up to -10 psig for fraction of a second) can propagate to the experimental service line. This pressure drop would be sufficient to induce potential contamination intrusion at service line.

2. Gaseous cavitation was observed due to water hammer induced low pressure (as a result of street level transient); also found that bubble formation timing due to gaseous cavitation can be less than 1 second. This phenomenon may have practical implications of implosion or gaseous impingement that is known to erode protective scales on the wall.

To minimize any public health effects, structural integrity of service lines and hydraulic integrity at water mains should be maintained in good condition. Also, this line of research results should be disseminated to the public so they are well aware of these important issues.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the support provided by the National Science Foundation under the grant DMI-0329474 and DLR-0431779. The authors greatly appreciate Late Mr. Juan Ortiz, and Late Mr. Waleed Shaalan for their founding work. The authors extend their sincere thanks to Drs. Marc Edwards, Paolo Scardina, and Steven Cox for their insightful advice on the experiment. Thanks also go to Mr. Seth Williamson for his physical help on the experiment.

DRINKING WATER INFRASTRUCTURE ASSESSMENT: THE NATIONAL RESEARCH COUNCIL OF CANADA PERSPECTIVE

Yehuda Kleiner, Balvant Rajani and Rehan Sadiq, National Research Council of Canada

Abstract

The essence of infrastructure asset management and decision-making on its renewal/ rehabilitation is a trade-off between system performance and cost. System performance criteria for water networks include quality, quantity and reliability, i.e., the water should be safe, with acceptable aesthetics, taste and odour; regular and peak demand (including fire flows) should be met with acceptable pressure and with minimal interruptions. Costs comprise capital investment in system design, installation and renewal, operation and maintenance (energy, materials, labour, monitoring, inspection, testing, repair), and indirect and social costs incurred due to failure (property damage, disruption, illness, etc.).

Several challenges need to be overcome in the development of an integrated decision framework for water distribution network. Mechanisms affecting system performance criteria are not all well understood. It is difficult to define and measure performance (which inherently comprises several non-commensurate and often conflicting criteria), let alone decide what level of performance is acceptable. It is also difficult to calculate the costs involved to achieve a specific level of performance. Substantial spatial and temporal variability is inherent in even a moderate-size network, and the collection of data on the performance and condition of these buried assets is often difficult and costly.

At the National Research Council of Canada we have identified the need to address these issues in a holistic way, and in the last 15 years have been involved in a continual effort, both independently and in collaboration with others, to put the pieces of the puzzle together. Although the state of knowledge has advanced significantly since we started, a lot still needs to be achieved. This paper describes our past and current research activities, views and vision for future activities in the field.

Overview

A trade-off between system performance and cost is the essence of decision making on the renewal of infrastructure systems. The general objectives of a water distribution network can be stated as the supply of water that is safe, with acceptable aesthetics, taste and odour; and regular and peak demand (including fire flows) should be met with acceptable pressure and with minimal interruptions. These general objectives are easy enough to understand but their quantification poses a significant challenge because it cannot be done directly but rather through indicators. There are literally hundreds of different performance/condition indicators that have been proposed in the literature by prominent institutions such as the USEPA (2002), the British Office of Water (OFWAT, 1998), the World Bank (Yepes and Dianders, 1996), the International Water Services Association (IWSA) (Alegre, 1999), and many others. This multitude of performance indicators is testament to the complexity involved. Mechanisms affecting the performance criteria are not well understood. It is difficult to define and measure performance, let alone decide what level of performance is acceptable. Furthermore, the costs involved comprise capital investment in system design, installation and renewal, operation and maintenance (energy, materials, labour, monitoring,

inspection, repair) and indirect and social costs resulting from failure (property damage, disruption, illness, etc.). It is difficult to calculate the costs involved to achieve a specific level of performance; and the collection of data on the performance and condition of these buried assets is difficult and costly. All these challenges and difficulties are exacerbated by substantial spatial and temporal variabilities inherent in even a moderate-size system.

The failure of a system is broadly defined as the inability to meet one or more of its performance criteria. The risk of failure can be defined as the expected magnitude of the consequences of failure, i.e.

Risk of failure = E(failure consequence) = f(probability of failure, costs of failure) (1)

Figure 1 illustrates a general, high-level view of the framework within which a water distribution network is managed. In the following sections we shall provide details about NRC's efforts to address the various pieces in this holistic puzzle.

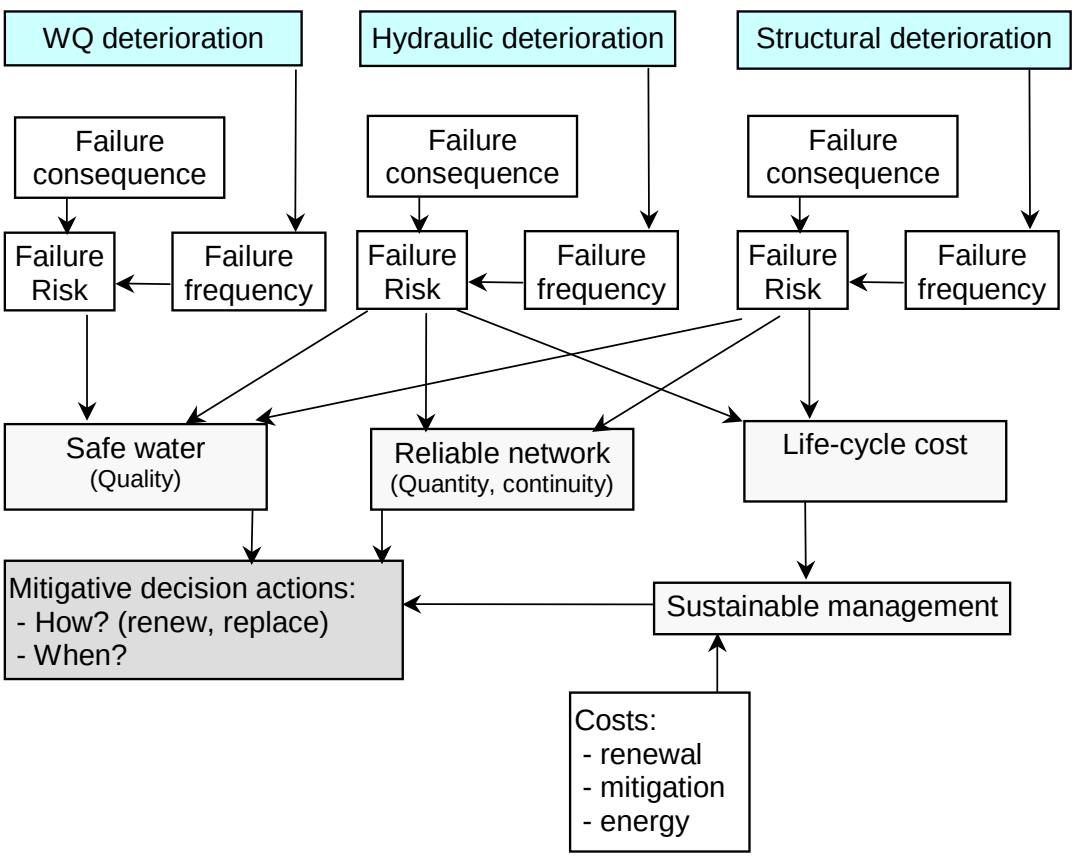

Figure 1. Holistic view of water distribution asset management

Structural deterioration of water mains and failure risk

As water mains age they deteriorate. This deterioration may be classified into two categories: (i) structural deterioration, which diminishes the pipes structural resiliency and

their ability to withstand the various types of stresses; and (ii) deterioration of pipe inner surfaces, resulting in diminished hydraulic capacity, degradation of water quality and even diminishing structural resiliency in cases of severe internal corrosion.

The probability of a water main failure due to structural deterioration can be estimated using physical (mechanistic) models (Rajani and Kleiner, 2001b) and/or statistical (empirical) models (Kleiner and Rajani, 2001a). Statistical models develop empirical relationships between the pipe, its exposure to the external and operational environments and its observed failure frequency while physical models endeavour to mimic realistic field conditions as well as external and operational environments. Empirical models typically over-simplify a complex reality in order to (hopefully) achieve "80% of the answer with 20% of the effort". In contrast, physical models are more general but require a substantial amount of data to represent specific conditions and environments. These data are either unavailable or very costly to obtain for even a modest portion of a distribution network.

The costs of a water main failure event may be classified into three categories: (a) direct, (b) indirect, and (c) social costs. While direct costs are relatively easy to quantify in monetary terms, indirect costs may require much more effort, and social costs are often the most difficult to describe and assess. The magnitude of failure consequence is, strictly speaking, a random value because no two failures have the same consequences. Failures in small distribution mains are usually repaired with little effort and typically collateral damage is relatively small. Failures of large transmission mains are relatively rare, and because only few water utilities attempt to assess total failure damage there are currently insufficient data to assign probability distributions to failure costs.

Figure 2 illustrates qualitatively how these differences between small distribution mains and large transmission mains translate into different forms of management. As a pipe ages and deteriorates (without renewal), its probability of failure (or failure frequency) increases and the risk increases as well. Note that the risk is expressed as the present value (PV) of expected cost. At the same time, the discounted (or PV of) the renewal cost declines as pipe renewal is deferred. The total expected life-cycle cost typically forms a convex shape, whose minimum point depicts the optimal time of renewal (t^*). The top part of Figure 2 illustrates a typical case of small distribution mains, where the optimal time of renewal corresponds to a relatively higher failure frequency. In contrast, due to higher failure cost, the bottom part of Figure 2 illustrates that for large distribution mains the optimal strategy is to avoid failure altogether, i.e., *failure prevention*, rather than tolerate some acceptable frequency, i.e., *failure management*.

Note that Figure 2 illustrates idealized cases, where the minimum point on the convex curve is quite clear. There are cases where this curve is not as well behaved. When the ageing rate (i.e., the rate at which failure frequency increases) is similar in magnitude to the discounting factor, the convexity of this curve can become quite flat, and the point of minimum cost becomes less crisp. When the cost of failure is relatively low compared to the cost of renewal and the discounting factor relatively high, the curve can take the shape

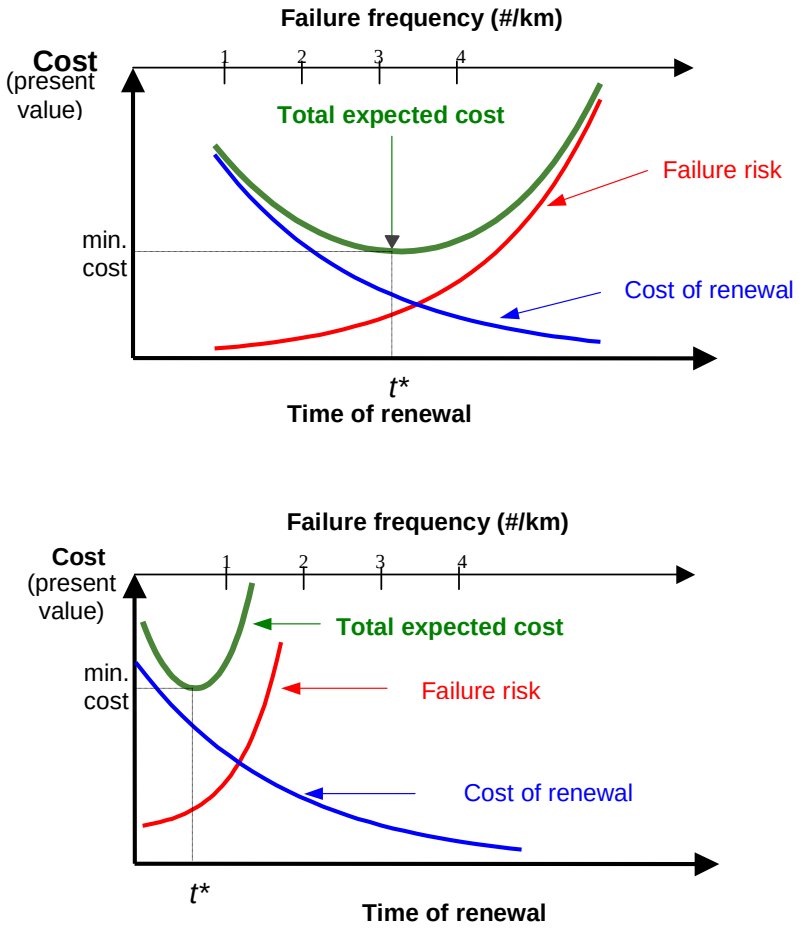

Figure 2. Optimal renewal frequency for distribution mains (top) vs. transmission mains (bottom). Time scale not necessarily same in both graphs.

of the "hammock-chair" as described by Herz (1999), with no definite minimum, indicating that renewal could perhaps be postponed indefinitely.

Asset management of small-diameter distribution mains

At the NRC, we have focused on several aspects of asset management of small-diameter distribution mains, namely investigation of the mechanics of pipe failure, development of statistical/empirical methods to model historical breakage frequency and forecast it in the future, development of leak-detection technologies and investigation of other nondestructive testing (NDT) technologies for the efficient assessment of the condition of pipes.

Numerous approaches have been proposed to decipher historical failure patterns. Kleiner and Rajani (2001b) provided a comprehensive review of the major ones, and more have been published since. Through the investigations of different aspects of the mechanical processes leading to pipe failure (e.g., Rajani and Tesfamariam, 2004; Tesfamariam *et al.*

2006.) we have developed an understanding of what factors need to be considered in asset management models for small distribution mains, which are based on empirical observations. Consequently, we have developed D-WARP (Distribution – Water Main Renewal Planner) and later I-WARP (Individual – Water Main Renewal Planner). Both D-WARP and I-WARP allow the consideration of time-dependent factors, such as climate effects, cathodic protection practices, etc. to be considered in the analysis of failure patterns. While D-WARP deals with high-level planning of groups (or cohorts) of water mains, I-WARP uses a nonhomogeneous Poisson process to model and forecast breakage frequency of individual water mains.

Climatic covariates that are used by both D-WARP and I-WARP are freezing index and rainfall deficit. Freezing index *(FI)* is a surrogate measure for the severity of winter, and rain deficit (*RD)* is a surrogate measure for soil moisture. *RD* can be considered in two separate forms. Cumulative *RD*, which is a measure of the average soil moisture over a given time period, corresponds to the effects described by Rajani *et al*. (1996). Snapshot *RD*, which is a measure of the soil moisture during winter, when the soil is mostly frozen, corresponds to the effects described by Rajani and Zhan (1996).

Cathodic protection can be defined as "… the reduction or elimination of corrosion by making the metal a cathode by means of an impressed direct current or attachment to a sacrificial anode (usually magnesium, aluminium or zinc)" (NACE, 1984). In practice, water utilities can implement two cathodic protection strategies, namely, hotspot and retrofit CP. Hotspot CP (HSCP) is the practice of opportunistically installing a protective (sacrificial) anode at the location of a pipe repair. These anodes are typically installed without any monitoring and stay in the ground until total depletion, usually without replacement. Retrofit CP refers to the practice of systematically protecting existing pipes with galvanic cathodic protection. If the existing water main is electrically discontinuous (e.g., bell and spigot with elastomeric gaskets and no bridging) then an anode is attached to each pipe segment (typically 6 m or 20' length). If the water main is electrically continuous then usually a bank of anodes in a single anode bed can protect several contiguous pipe segments. Figure 3 illustrates, using D-WARP, how an HSCP program that was implemented in 1990 by an East Ontario (Canada) municipality affected the breakage rate in one of its pipe cohorts.

In addition to the aforementioned climate and cathodic protection covariates, I-WARP allows the consideration of user-defined time series that may have impacted historical breakage rates. For example, pumping station failures have been observed to impact failure rates (due to high transient pressures) in a municipality in Western Canada. The inclusion of an appropriate (qualitative) time series helped to 'explain' the resulting outlier breakage rates. Other time series that may impact breakage (or repair) rates are leak detection campaigns, changes in pressure regimes, etc.

D-WARP is available for free download at the NRC-IRC website (NRC-IRC, 2007). A detailed user manual as well as select publications provide detailed information about the model and its application. A complete technical report, as well as a prototype computer application of I-WARP will be available later in 2009 from WRF (Water Research

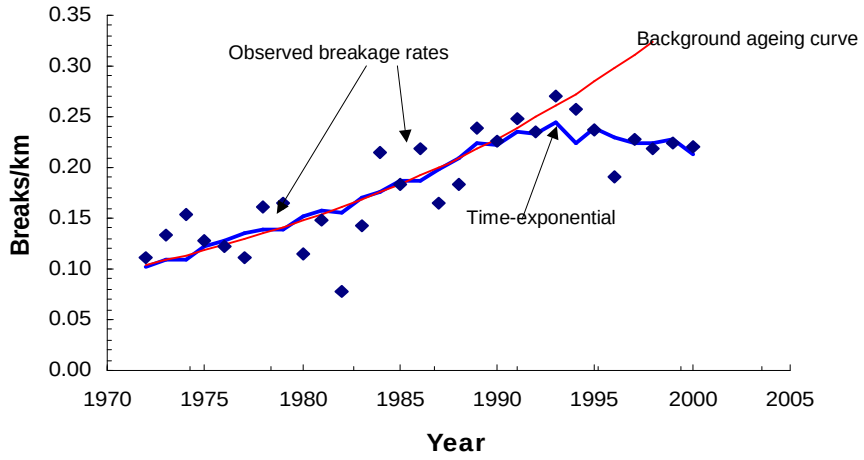

Figure 3 Effect of hotspot CP program on a cohort of cast iron mains.

Foundation – formerly known as the American Water Works Association Research Foundation – AwwaRF), which co-funded the research.

In the area of leak detection we have developed LeakFinderRT, which is a PC based system for locating leaks in all types of water pipes using the leak noise correlation method. It incorporates several new developments, most importantly an "enhanced" correlation function. LeakFinderRT is fully realized in software for PC running under Microsoft Windows. Leak noise is recorded using the PC's soundcard and then correlated via the Fast Fourier Transform (FFT). LeakfinderRT is now a fully commercialised technology, which provides affordable leak detection solutions for small and medium sized municipalities. Based on knowledge generated from leak detection work, a new acoustics-based method is currently in development to discern the average remaining wall thickness of buried pipes. This method has the potential to serve as a screening tool to prioritise some types of water mains for inspection.

In the area of NDT, we are in the early stages of developing a robotic underwater vehicle capable of carrying and manipulating multiple NDT sensors for inspection and early detection of defects in large pipes while in service.

Asset management of large-diameter transmission mains

As discussed earlier, large transmission mains typically have low failure rates but when they fail the consequences can be quite severe. This low rate of failure, coupled with the limitations of currently available inspection tools and high cost of inspection, have contributed to the current situation where most municipalities lack the necessary data to estimate directly or indirectly the deterioration rates of these assets and subsequently to make rational decisions regarding their renewal.

The condition assessment of a large transmission main comprises two steps. The first step involves the inspection of the main using direct observation (visual, video) and/or NDT techniques (radar, sonar, ultrasound, sound emissions, eddy currents, etc.), which reveal distress indicators. The second step involves the interpretation of these distress indicators to determine the condition of the main. This interpretation process is dependent upon the

inspection technique. Interpretation of the visual inspection results, although based on strict guidelines, can often be influenced by subjective judgment. The interpretation of NDT results on the other hand, is often complex (at times proprietary) and can be imprecise.

Managing the failure risk of large transmission mains requires a deterioration model to enable the forecast of the asset condition as well as its possibility of failure in the future. Significant research effort has been carried out in the last two decades to model infrastructure deterioration. The Markov deterioration process (MDP) is one approach that has gained prominence as exemplified by Madanat *et al*. (1997), Kleiner (2001) and others. Examples of other types of statistical models include Lu and Madanat (1994), Ramia and Ali (1997), Flourentzou *et al*. (1999), Ariaratnam *et al*. (2001) and others.

In recent years, increased research effort has been dedicated to the application of soft computing methods to assess infrastructure deterioration. Soft computing methods include techniques such as artificial neural network (ANN), genetic algorithms (GA), belief networks (BN), fuzzy sets and fuzzy techniques. Fuzzy techniques seem to be particularly suited to model the deterioration of buried infrastructure assets where data are scarce and cause-effect knowledge is imprecise. Consequently, we have developed the T-WARP (Transmission – Water Main Renewal Planner) to assess risk of transmission pipelines combining the advantages of both the Markov deterioration process and fuzzy logic.

A fuzzy set describes the relationship between an uncertain quantity x and a membership function which ranges between 0 and 1. A fuzzy set is an extension of the traditional set theory (in which x is either a member of set A or not) in that an x can be a member of set A with a certain degree of membership. Fuzzy techniques help address deficiencies inherent in binary logic and are useful in propagating uncertainties through models.

Membership functions are often represented by triangular fuzzy numbers (TFN), which permit the use of linguistic variables. To illustrate the concept, suppose that the age of a pipe is defined by five fuzzy subsets (or numbers), each representing an age grade; A_1 = "*new*", A_2 = "*young*", A_3 "*medium*", A_4 = "*old*" and A_5 = "*very old*", as illustrated in Figure 4. The fuzzy subset A_3 "*medium*" for example, has a membership function such that for age x below 20 years or above 60 years the membership to "*medium*" is zero, and for age between 20 and 60 years the membership follows straight lines that form a triangle. Fuzzy set A comprises the collection of the five subsets (or numbers) A_i. Further, a crisp (exact) pipe age can be mapped onto the fuzzy set A so that it has memberships of 0.52 and 0.4 to age grades *medium* and *old*, respectively (Figure 4).

In our so-called fuzzy –Markov deterioration approach we use the concept of fuzzy rules that define relationships between variables by means of fuzzy *if-then* propositions. For example: "If 'pipe' *is old* and 'pipe condition' is *good* then 'deterioration' *is slow*", where *old* and *good* and *slow* are linguistic constants represented by fuzzy sets (as in the age example above). An inference can be made, using the Mamdani (1977) algorithm, about how fast deterioration is if the pipe is only partially *old* (say 50% *old* and 50% *medium*) and its condition is only partially *good*. This method has the capacity to capture qualitative and highly uncertain knowledge. To describe the condition of the pipe we used a seven-grade fuzzy set: *excellent, good, adequate, fair, poor, bad,* and *failing.* The fuzzy Markov deterioration process is illustrated in Figure 5.

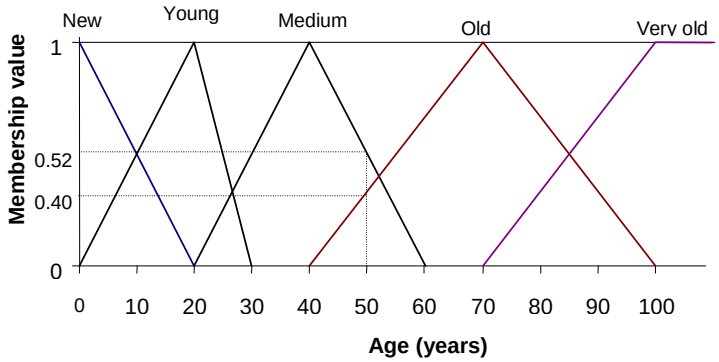

Figure 4. Example of fuzzy sub-sets (numbers).

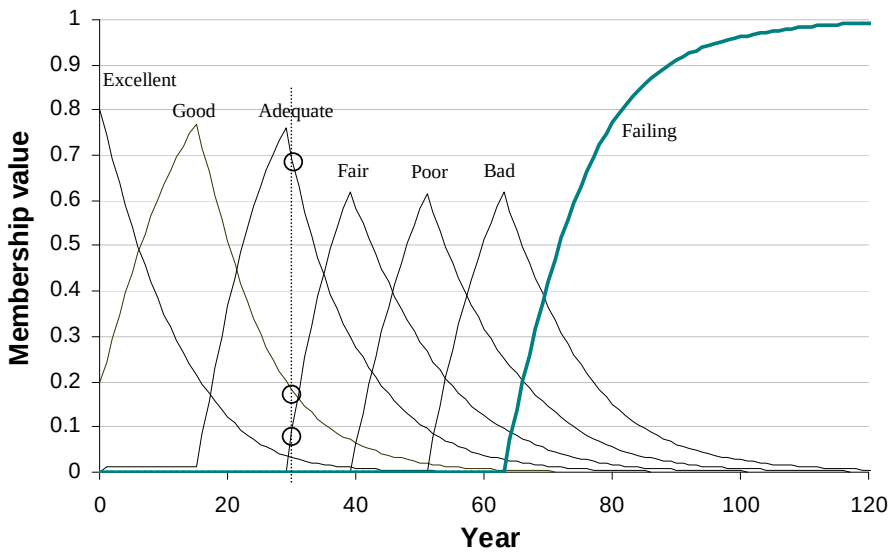

Figure 5. Fuzzy Markov deterioration curves.

As the pipe deteriorates, memberships "flow" from a given condition state to a worse one. The transition process is governed by a set of fuzzy rules (rather than transition probabilities as in the traditional Markov process), which is constructed based on expert opinion. Once deterioration curves are determined they are used to estimate the time in the future when the pipe is expected to approach the *failing* state. The deterioration model can be re-calibrated with each additional inspection and condition assessment. Any pipe inspection, whether visual, NDE or other reveals evidence about the existence and extent of distress indicators on the pipe. These distress indicators have to be interpreted and translated into the fuzzy condition states space described earlier. A condition assessment framework for translating the distress indicators into fuzzy condition states is described in detail by Rajani *et al*. (2006). Kleiner *et al*. (2006a) provide details on fuzzy Markov deterioration. Kleiner *et al*. (2006b), provide details on how to combine fuzzy deterioration

with fuzzy consequences into a life-cycle fuzzy risk of failure. A prototype software application of T-WARP is available from WRF, which co-funded the research.

Water quality deterioration in distribution pipes

Numerous factors affect water quality in the distribution network and interactions amongst them are complex and often not well understood. Water quality failures in distribution networks are scarce, which make it difficult to establish statistically significant generalizations. In such data-sparse circumstances, expert knowledge and judgment can serve as a supplement or even as alternative source(s) of information. Q-WARP (water Quality – Water Main Renewal Planner) is a proof-of-concept model to predict water quality changes in distribution pipe networks, developed at the NRC with co-funding from WRF (Sadiq *et al.*, 2009).

Several mechanisms can compromise water quality within a distribution network. These include (Kleiner, 1998): (1) Intrusion of contaminants into the distribution network through system components whose integrity is compromised or through misuse or cross-connection or intentional introduction of harmful substances in the water distribution network. (2) Formation of corrosion byproducts and leaching of chemicals from the internal pipe surface. (3) Regrowth of microorganisms in the distribution network. (4) Formation of disinfection byproducts (DBPs) and loss of residual disinfectants; and (5) Permeation of organic compounds from the soil through plastic components into the distribution network.

Q-WARP uses a soft computing technique called 'fuzzy cognitive maps' (FCM) to model causal relationship between the numerous factors influencing water quality in the distribution network. FCM is a cyclical graph comprising nodes and arcs (edges), as illustrated in Figure 6. Influencing factors are represented by nodes C_i and causal relationships are represented by directed arches. $w_{ij} \in [-1, 1]$ represents the nature and strength of the relationship between 'causal factor' i and 'effect factor' j and the sign

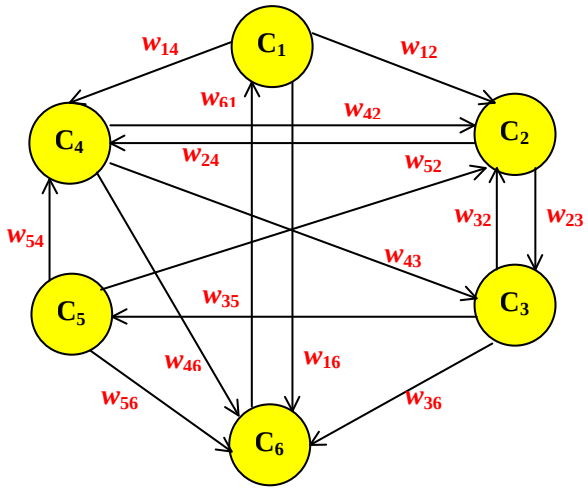

Figure 6. An example of a fuzzy cognitive map (FCM)

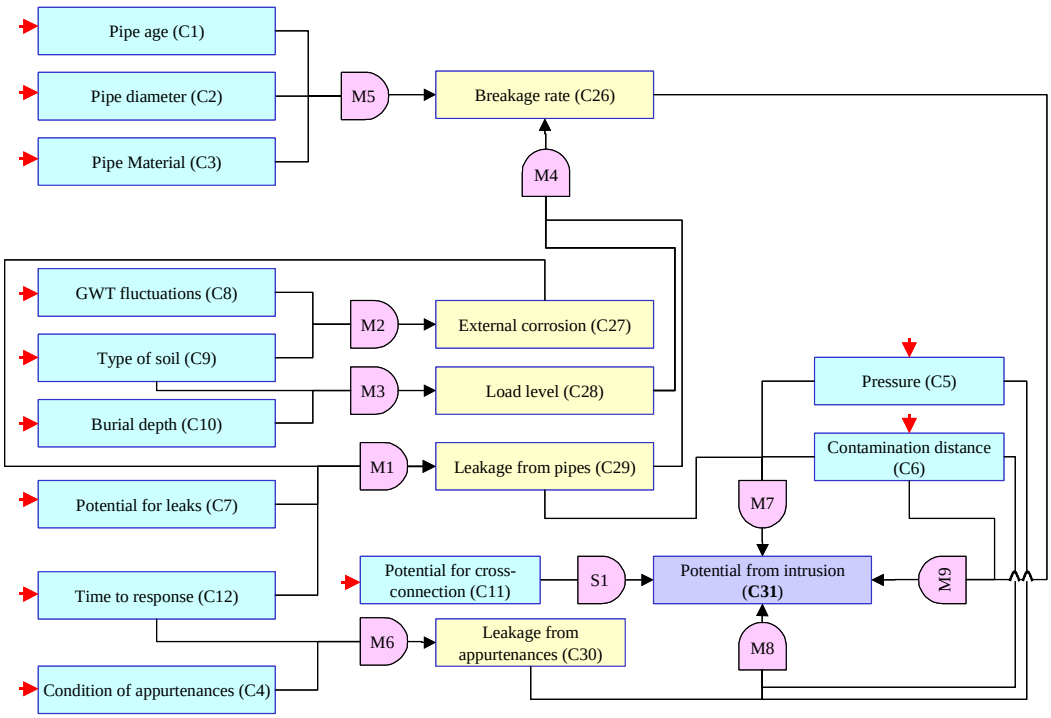

Figure 7. Modular FCM for predicting 'potential for contaminant intrusion'

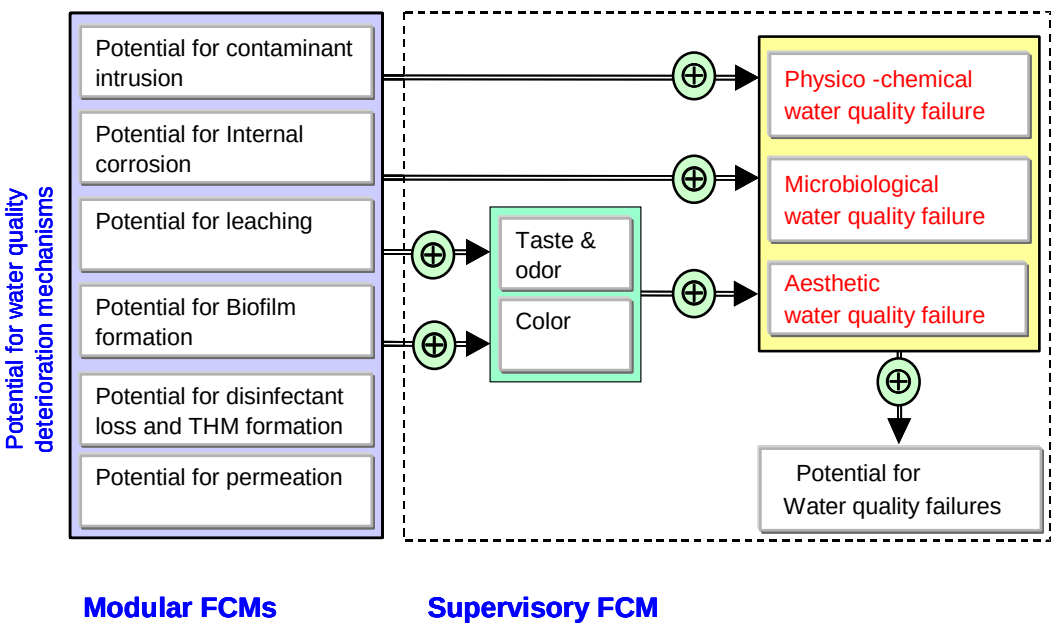

Figure 8. Two-tier (modular and supervisory FCM) framework

represents the type of causation. A positive causality is implied when $w_{ij} > 0$, where an increase in the value of *i* causes an increase in the value of *j* and vice versa. A negative causality is implied when $w_{ij} < 0$, where an increase in the value of *i* causes a decrease in the value of *j* and vice versa; and $w_{ij} = 0$ implies no causal relationship between *i* and *j*. Q-WARP is in fact a rule-base FCM, where causal relationships are defined by rules (e.g., 'if C_1 is high then C_2 is medium) similar to the rules described in the previous section.

Figure 7 illustrates the FCM representing processes leading to contaminant intrusion. The M_i gates represent rule sets that govern relationships between the various factors. Experience shows that if FCM are very large and 'democratic' (every node can be connected to every other node) they become insensitive to perturbations in inputs. Consequently, Q-WARP is designed as a two-tier framework, as is illustrated in Figure 8. Each of the six modular FCMs in tier 1 (representing six different WQ failure mechanisms) is in fact a FCM similar to the one illustrated in Figure 7 for contaminant intrusion. The outputs of the six modular FCMs flows into the supervisory FCM, whose output in turn yield the over potential for water quality failure. A full report on Q-WARP as well as a prototype software application is available from the WRF (Sadiq *et al.*, 2009).

Final remarks

In general, the industry seems to be progressing in the right direction despite many challenges and inherent complexities in the management and operations of water supply and distribution systems. Much progress has been made in the understanding of deterioration processes and failure modes. At the same time, as practices change and new materials are used, the knowledge gap, while decreasing from one end is increasing from the other. However, despite all these advances, too many water utilities still are not aware of the benefits of collecting and organising data that can be used in the various deterioration and decision support models.

As NDT techniques evolve, including the development of various sensors and robots, it appears that failure anticipation and prevention is likely to become technologically feasible as well as affordable. Currently, it seems that only mains prone to high-cost failure (namely transmission mains) can justify the use of these techniques, but this situation is likely to change over time. In the meantime, while the bulk of water distribution networks are comprised of small mains with relatively low failure consequences, NDT techniques can, in some circumstances, be used as complementary means to the empirical models, which rely on historical break records.

National Mains Failure Database Project

Neil S. Grigg[1]

[1]Department of Civil and Environmental Engineering, Colorado State University, Fort Collins, Colorado 80523-1372; PH (970) 491-3369; FAX (970) 491-7727; email: neilg@engr.colostate.edu

ABSTRACT

Water main breaks are a serious problem to utilities, and involve high cost as well as social disruption. Mitigating risk of breaks requires utilities to assess data on past failures and predict which mains are most likely to fail. The UK Water Industry Research has developed a National Mains Failure Database and the US Water Research Foundation has arranged for US utilities to participate. The database is being modified for use by US utilities and a pilot effort is scheduled for 2009. After experience with the database is gained, the Water Research Foundation will work with utility participants to modify and facilitate use of the database.

INTRODUCTION

Breaks in transmission and distribution mains are a serious problem for water utilities because buried pipes are their most costly capital assets and the condition of mains is a major risk factor. Main breaks are an indicator of infrastructure condition, and utilities in the US suffer about 250,000 to 300,000 of them every year. The cost to the nation for these main breaks cannot be quantified exactly, but is on the order of several billion dollars per year. For example, Gaewski and Blaha (2007) analyzed 30 breaks of mains 20-inches and larger and found that the cost of each failure was about $500,000, based on the geometric mean of the data. While many breaks are much smaller and less expensive, the total cost to the nation is high.

Mitigating risk of water main breaks requires utilities to assess which mains are most likely to fail. When utilities prepare business cases for pipe replacement in their capital budgets, they must estimate this risk so they can compute rates of return of remediation projects. While surveys show that utilities are aware that they should undertake pipe renewal programs, it is difficult to decide which pipes to renew because utilities cannot predict probability of failure for individual pipes, although they may be able to estimate the expected number of system-wide failures to expect. Utilities are aware of the need to manage main break data, and guidance is available to establish databases (Wood and Lence, 2007).

To confront this issue, the Water Research Foundation (formerly the AWWA Research Foundation or AwwaRF) has sponsored several projects about main breaks. These include projects on research needs, condition assessment, unique attributes of different pipe types, and modeling of break rates. These projects have provided

valuable information, but many individual utilities are unable to use the information because they lack organized data of their pipe inventories and break rates.

Utility plans to mitigate main break risk must be based on asset data, condition assessment, planning and prioritization, and action plans. While many utilities have basic databases of their water mains, no national register of these exists. Also, no national study of water main breaks across utilities has been conducted.

The UK experiences some 70,000 main failures per year, or roughly one-fourth those in the U.S. In the UK, main break rates are assessed at the national level through water utility regulatory reports. Through the UK Water Industry Research (UKWIR) organization, utilities in the UK have organized a National Mains Failure Database (NMFD) to help them study main breaks and prepare reports. UKWIR is a collaborative water industry research organization based in London which facilitates research projects of common interest to member water companies.

The US Water Research Foundation has decided to sponsor an effort to join the UK effort and organize a US national database. Australia has made the same decision through the Water Services Association of Australia (WSAA). This paper explains the structure and organization of the NMFD and the schedule by which it will be developed. Uses of the database will be explained, with an emphasis on the differences between US and UK conditions and reporting requirements.

OVERVIEW OF THE NMFD

The history of the NMFD has been summarized by MacKellar (2005), one of the developers of the software. The work includes a database of water main failures in the UK, along with a protocol for data collection of mains and failure information.

UKWIR works with twenty-three principal water companies in the UK (England, Wales, Scotland, Northern Ireland), and are regulated by the Office of Water Services (OFWAT). The NMFD managed by UKWIR contains data on known main failures from the water companies presented in the same format and classified by variables that include pipe materials, diameters, dates, land use and failure modes. The database also includes data on pipe stock, and can be viewed as a national asset register of water mains. Sewer failures are also included in the UK NMFD, but are not addressed in this paper.

The goal of UKWIR's NMFD for water mains is to provide "robust, validated data on which deterioration modelling and asset investment strategies can be based." The database includes records of water mains by material, age, diameter and length, along with other attributes such as geographical location. The length of mains covered is about 350,000 km and some 470,000 failures, mostly from 1994 to 2002, are included (UKWIR, 2006).

The planning for the NMFD was explained in (UKWIR, 2003). It includes the principles of the protocol for data management and explains how widespread

reporting differences made comparisons difficult. The protocol proposes best practices to overcome the differences and provide a practical way to manage data.

The UK water companies upload their asset and failure data to the NMFD software, which manages the data and provides tools to generate reports. Anonymity of the data providers is preserved in that companies can get reports of their own data and national reports of all data, which preserve the anonymity of the individual companies. Reports that are currently available include failure rate, number of failures and pipe length involved, failure rate area report, and statistical reports.

UK utilities work with the NMFD through its website, which enables them to upload their pipe and failure data using a "Compilation Tool."[1] This tool enables companies to organize their data in comma-separated-value (.CSV) files, which facilitate the upload. The NMFD software takes over from there to organize and catalog the data.

Examples of pipe data attributes that are included in the UK version are: identification number, diameter, material type, location, lining, ground surface type, installation year, and whether the main has pumped or gravity flow. Failure data items include type of failure, whether third-party damage was involved, location, and other related information.

The Water Research Foundation is working with UKWIR to add and/or change data items to correspond to US conditions and practices, which vary widely among utilities. The challenges to face include how to include geographic information, how to import soils data, and how to coordinate the many different practices for collecting and managing pipe data among US utilities.

US UTILITY PARTICIPATION

The Water Research Foundation is working with a group of utilities for an initial trial of the database. The initial effort to establish the US part of the NMFD is taking place during 2008 and 2009, and is planned to involve around 10 utilities. Plans are to begin data upload in the first half of 2009 and then to assess needed changes. Following completion of this phase, plans will be made to extend and improve the database and its applications.

A US utility participant in the NMFD will upload its water main and break data to the database in the same way as UK water companies do. Utility commitments are limited to uploading and management of their own data. By loading their data into the national database, utilities gain organization and analysis insights for their asset data.

Data will be kept anonymous so that no one other than the utility can see its individual characteristics, while displaying the overall statistics of all utilities to all

[1]The website address is: http://sewersandwatermains.ukwir.org/site/mains/home.

participants. This combined anonymity of individual utilities and transparency of all statistics taken together gives utilities a chance to compare their data with others so they can sharpen their investment planning.

A utility participant will prepare its data for uploading in CSV files in the same way that UK water companies will. The Water Research Foundation will work with the utility's key contact and provide advice for data organization, cleaning, and uploading. Technical support will be provided through UKWIR's existing service desk.

The initial planning by the Water Research Foundation resulted in a few changes to the data formats specified by UKWIR. One important difference is the geographical referencing of pipe and failure locations, which still must be worked out for US utilities. In the UK, a national grid provides a single coordinate system for the nation and is a basis to geo-reference pipe data. The US has a state plan coordinate system, but it does not provide a unified national grid system. Utilities with effective GIS systems are able to use latitude and longitude data for location, but they are not always able to locate pipes and failures using this information. A wide range of practices is in effect, and it is anticipated that initial work with the NMFD may offer a path to more standard approaches.

Looking ahead to the possibility of using the US NMFD as a tool to improve understanding of the causes of main failures, the Water Research Foundation has added attributes to the database that relate to historical US pipe failures. These include several data items that have been identified in reports such as (Kirmeyer et. al., 1994), which reported that the most common causes of main breaks were materials and deterioration, weak joints, earth movement, freezing, internal corrosion, corrosive soils, construction or utility digging, stray DC current, seasonal changes in water temperature, and heavy traffic load.

After the US version of the database is populated, utilities will be able to use models and other predictive methods to assess risk of failure based on their own data or on national experience. A number of mathematical models have been published, and these are summarized in (Grigg, 2005).

MANAGEMENT QUESTIONS FOR US UTILITIES

The general concept of the NMFD is that US utilities will upload water main break data to the US national database, managed by UKWIR. Data will be kept anonymous so that no one other than the utility can see its individual characteristics, but US utilities can obtain the overall statistics of breaks for all US utilities without knowing the sources of the data. This combined anonymity of individual utilities and transparency of all statistics taken together gives utilities a chance to compare their data with others so they can sharpen their investment planning.

A US utility participant will prepare its data for uploading by organizing it in a format supplied by the Water Research Foundation, which will work with the utility's key contact and provide technical advice for data organization, cleaning, and uploading.

Utilities will not have to pay for access to the national database as their commitments are limited to uploading and management of their own data. By loading their data into the national database, utilities gain organization and insights for their asset data. US utility participants who are Water Research Foundation subscribers will be able to generate reports from their data uploaded into the UKWIR database.

Agreements and licenses are needed between the Water Research Foundation and UKWIR and with participating utilities. Currently, UKWIR and each participating company in the UK sign a license agreement to use the software. Details on how these would work in the US are still to be developed. Provisions that will be important to US utilities will include: ownership of data, assurance of anonymity, rights of use, agreement by the water research foundation to finance the database, and access by researchers, among others.

CONCLUSIONS

Main breaks are an important problem for utilities, and are poised to worsen as infrastructure ages. While utilities know of the problem, they are often stymied in their attempts to invest in renewal because they do not know the probable rates of failure of individual pipes. Knowing these rates will always involve some uncertainty, but empirical data through an organized NMFD will improve knowledge of actual conditions in a utility's asset base and offer utilities a good way to organize and manage their pipe failure data.

As UKWIR has already invested in development of the software and website for the NMFD, US water utilities have a good opportunity to take advantage of this emerging tool to manage their pipe failure data. The Water Research Foundation has made arrangements to work with a limited number of US utilities to upload their data and participate in the NMFD. Once a trial period has been completed, additional US utilities may participate and further details on how the database will be managed can be prepared.

A number of management questions must also be answered, including ownership, assurance of anonymity, how to facilitate upgrades to the software, and how to train users and coordinate utility participation in the future. These questions will be faced in cooperation with UKWIR and the Australian utility organizations.

The NMFD offers an excellent opportunity for US utilities to work together to share knowledge about water main failures and their causes. The new knowledge developed will help them to upgrade engineering, construction, and maintenance procedures to reduce the incidence and consequences of water main failures in the US.

Abstract

*Widespread changes in the climate, demographics, population and economics are expected to impact the quantity, quality and timing of water resources across the globe in the 21st century. Some of these impacts may affect the performance and sustainability of the Nation's urban water resources infrastructure. In anticipation of these imminent global changes and their impact on the Nation's water infrastructure, the U.S. Environmental Protection Agency is implementing the **W**ater **R**esources **A**daptation **P**rogram for Infrastructure (**WRAP-Infrastructure**). **WRAP** seeks to identify and evaluate innovative approaches to improve the planning, design, operation and maintenance of the Nation's water resources infrastructure in the 21st century. A key question to be addressed by the **WRAP** program is, "How can the functionality of the Nation's aging water infrastructure be maintained and sustained to protect human health and preserve the environment for future generations in the face of profound global changes?" To help answer this question, a national data collection effort was conducted with water utilities to identify key factors affecting the current and future performance and sustainability of the water resources infrastructure across the US. Over 60 public and private water and wastewater utilities responded to a detailed web-based questionnaire. Data from this national reconnaissance are reported here.*

Key Words: **water resources, aging infrastructure, climate change.**

BACKGROUND

ASCE President, D. Wayne Klotz, refers to the global infrastructure as the "cathedral of modern civilization" (Klotz 2008). The portion of the national infrastructure responsible for supplying drinking water and disposing of wastewater is ranked among the top five engineering achievements of the 20th century (National Academy of Engineering 2008). These engineering accomplishments have led to an unprecedented standard of living in developed countries around the globe.

Can this standard be sustained? The national inventory of pipes, pumps, plants, and tanks has a high premium. Maintenance of the U.S. water infrastructure has been largely neglected for the past 50 years (Levin *et al* 2002). This lack of attention is reflected in recent ASCE Report Cards on America's Infrastructure which assign "D-" grades to the water and the wastewater areas (ASCE 2005, ASCE 2009).

Clearly, the United States faces an unprecedented challenge in the 21st century: Can the Nation's aging water infrastructure be repaired and restored in a manner that promotes economic and environmental sustainability while protecting human health and preserving the environment for future generations? This daunting assignment is exacerbated by the convergence of national and global trends involving changing climate, evolving institutions, growing population, regulatory issues, and uncertain economics.

In anticipation of these imminent global changes and their impact on the Nation's water infrastructure, the U.S. Environmental Protection Agency has implemented the **W**ater **R**esources **A**daptation **P**rogram for Infrastructure (**WRAP-Infrastructure**). **WRAP** seeks to identify and evaluate innovative approaches to improve the planning, design, operation and maintenance of the Nation's water resources infrastructure in the 21st century (Buchberger *et al* 2008).

A key question considered under the **WRAP** initiative is: How does the Nation's water industry view these impending challenges? To help answer this question, a 40+ question web-based survey was distributed on-line via several national water organizations (AMWA, NACWA, NAWC) to a select subset of the nation's drinking water and wastewater utilities during the summer of 2008. The main objective of the questionnaire was to identify, through the eyes of the Nation's water industry, the most important factors likely to affect the performance and sustainability of the public and private water resources infrastructure across the United States over the next 50 years.

This paper provides a brief overview of some of the key findings from this national survey of the water infrastructure.

METHOD

The research team partnered with three national drinking water and wastewater industry organizations to collect information on utility perceptions of key issues that they will be facing in the future. In each case, the research team worked closely with the organizations to develop a vehicle to collect information from member utilities. Data collection was performed using the Survey Monkey (www.surveymonkey.com) website. The participating water organizations are:

- **AMWA** - The Association of Metropolitan Water Agencies (AMWA) is an organization of the largest publicly owned drinking water systems in the United States. AMWA's membership serves more than 130 million Americans with drinking water from Alaska to Puerto Rico. http://www.amwa.net/

- **NACWA** – The National Association of Clean Water Agencies (NACWA) represents the interests of the country's wastewater treatment agencies, true environmental practitioners that serve the majority of the sewered population in the United States, and collectively treat and reclaim more than 18 billion gallons of wastewater each day. http://www.nacwa.org/

- **NAWC** - The National Association of Water Companies (NAWC) represents all aspects of the private water service industry. The range of members' business includes ownership of regulated drinking water and wastewater utilities and the many forms of public-private partnerships and management contract arrangements. NAWC's membership ranges in size from large companies owning and/or operating many hundreds of utilities in multiple states to individual utilities with only a few hundred customers. http://www.nawc.org/index.html

The on-line survey contained 42 questions and was designed to be completed at one sitting within an hour. The main topics covered in the questionnaire are summarized in Table 1.

Table 1. Main sections of the on-line questionnaire.

Section Number	Number of Questions	Survey Topic
1	0	Motivation
2	9	Utility Profile
3	18	Infrastructure and Operation
4	5	Agents of Change
5	8	Master Plan
6	2	Contact Information (optional)
Total	42	

RESULTS

A total of 55 water utilities responded representing nearly 43 million customers with infrastructure assets that included 91 water treatment plants, over 520 storage tanks, nearly 1200 pumping stations and over 73,000 miles of pipeline. A profile of participating utilities is given in Table 2; the geographic distribution is shown in Figure 1.

Table 2. Participant profile of utilities completing the on-line questionnaire.

Feature	Drinking Water	Wastewater	Total
Number of Utilities	31	24	55
Customers (million)	16.83	25.83	42.7
Summer Flow (mgd)	3,450	2,686	6,136
Water Use (gpcd)	135	160	295
20-yr Projected Growth	24%	17%	~1% per yr
Miles of Pipeline	47,135	26,117	73,252
Pumping Stations	426	735	1,161
Storage Tanks	526	0	526
Treatment Plants	43	48	91

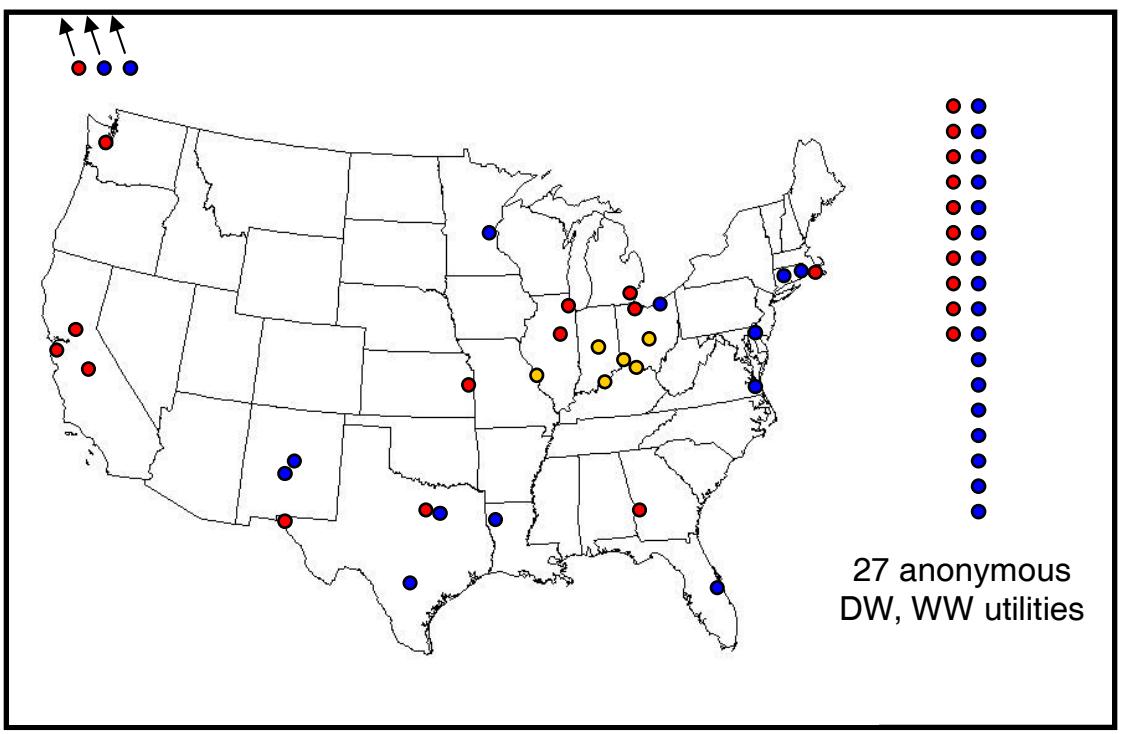

Figure 1. Participants in National Water Infrastructure Survey (red, yellow = wastewater; blue = drinking water)

Projected Growth, Master Plan, Asset Management

Four out of five utility respondents expected demand for water service to increase over the next 20 years with an average annual growth rate of about one percent (see Figure 2). This is consistent with population projections for the United States which forecast the number of U.S. residents to grow from 280 million to 420 million during the period 2000 to 2050 (Hobbs and Stoops 2002). About one in five water utilities expected to maintain the status quo, while one utility in each sector (i.e., drinking water and wastewater, representing less than five percent of the total respondents) anticipated a net decrease in utility size and service over the next 20 years.

Most water agencies had developed a formal master plan (see Figure 3). The master plan response closely mirrors the picture of anticipated growth (e.g., compare to Figure 2). It seems that water utilities who expect growth have a formal mechanism in place to help plan for it. Planning horizons ranged from 5 to 40 years with a median of about 20 years. Surprisingly, however, a significant percentage of water utilities (nearly 40%) have not implemented a formal asset management program (see Figure 4). A recent survey by the U.S. Conference of Mayors found that cities employing asset management practices are "gaining the information and knowledge they seek to determine the level of user rates that can lead to system sustainability" (Anderson 2007). Encouraging widespread adoption of asset management practices holds promise as a relatively simple but practical tool for helping the water industry better cope with anticipated challenges that will confront future utility operation.

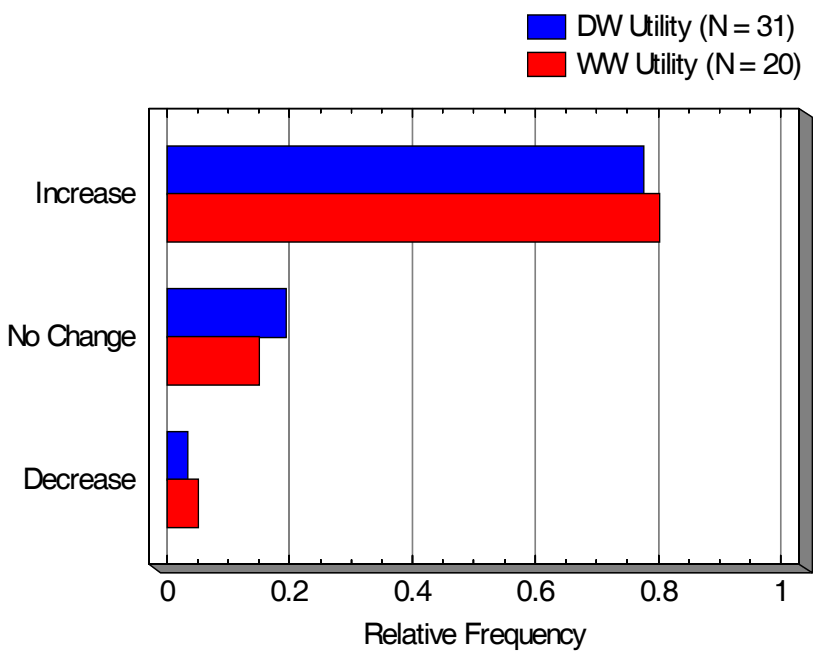

Figure 2. Projected water utility growth over the next 20 years.

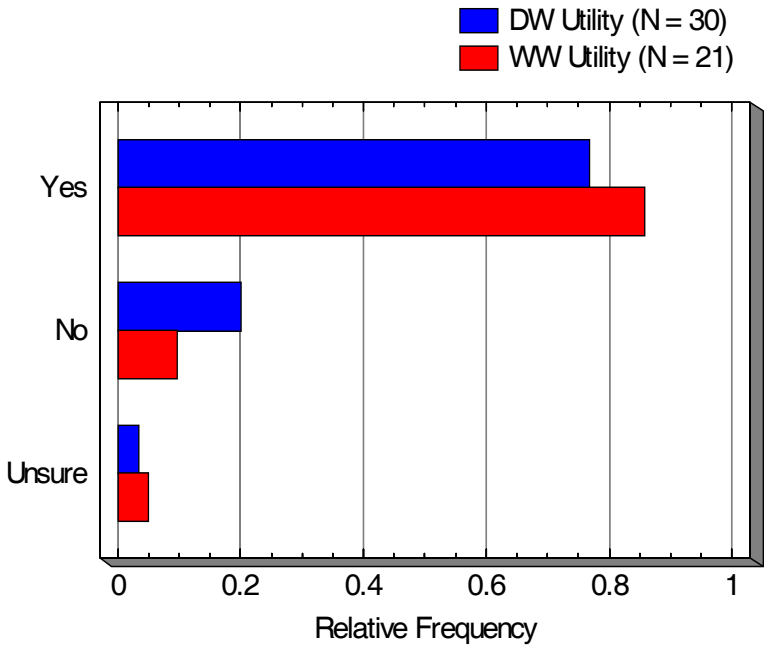

Figure 3. Water utilities with a master plan in place for future growth.

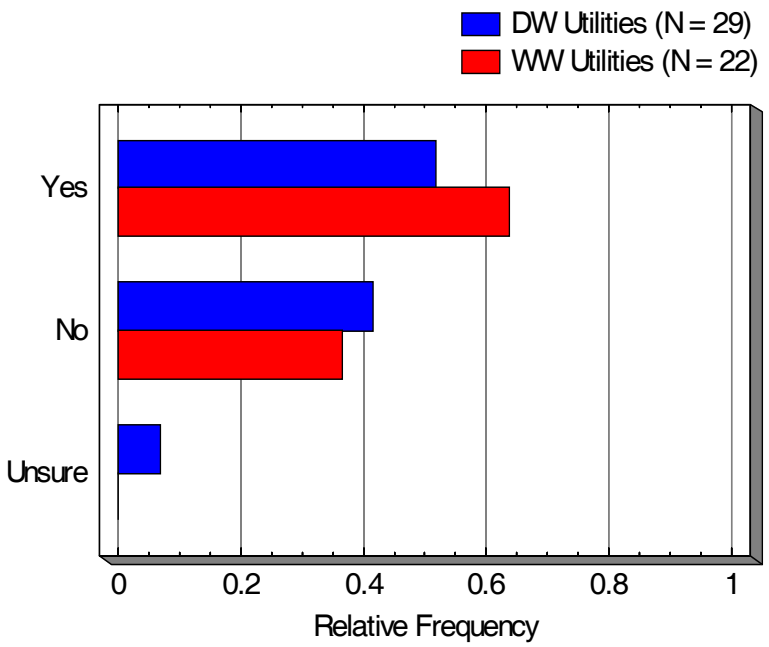

Figure 4. Water utilities with an asset management program.

Water Infrastructure Components

Of the four primary water-related infrastructure categories (pipes, pumps, tanks, plants), the pipeline systems used to distribute drinking water and collect wastewater were judged by the water utilities to be in the worst condition (see Figure 5). The generally poor self-assessment of existing urban water piping systems is consistent with the overall low grade assigned to the drinking water and wastewater sectors in recent ASCE report cards on the Nation's infrastructure (ASCE 2005, ASCE 2009). While the piping network is the portion of the national water infrastructure that is least in the public eye, it often represents the single largest collective capital investment for most water utilities. In comparison to the pipe network, pumping stations, storage tanks and treatment plants tended to fare slightly better in the self-assessment of infrastructure performance and condition.

Critical Future Issues

From a list of ten potential issues, the top three challenges perceived by the water industry to have the greatest impact on the operation and performance of the Nation's water utilities over the next 50 years were identified as: [i] aging infrastructure, [ii] government regulations and [iii] funding shortfalls (see Figure 6). These issues are consistent with the drinking water and wastewater sectors and reinforce key points of the recent infrastructure gap analysis (US EPA 2002). While climate change was recognized as an impending issue, it was viewed as a more distant concern in comparison to the immediate operational needs of the water utility.

SUMMARY

The Nation's water infrastructure ranks among the top engineering achievements of modern society. Public health benefits of this national infrastructure are enormous. Waterborne infectious diseases have been virtually eliminated from the United States. However, this triumph of the 20th century may be in jeopardy. Several major global changes, each with potentially serious consequences for the water industry, loom on the horizon. In the eyes of the engineers and executives from 55 utilities, the three most critical issues facing the water industry at the dawn of the 21st century are: [i] infrastructure decay [ii] federal regulations and [iii] funding sources. Other key concerns include: population growth, institutional evolution and climate change. On an individual basis, any of these issues poses a stiff challenge to the industry-wide mission of producing safe water to protect public health. Taken collectively, the combined impact of these critical factors could catalyze synergistic stresses that exceed the worst-case operating conditions envisioned during design and construction of the original water infrastructure. Fortunately, the national water industry is proactive (Means *et al* 2005; Daigger 2007; Freas *et al* 2008). The industry-wide practice of developing and updating a master plan provides a ready opportunity for incorporating flexible mitigation and adaptation strategies to help water utilities cope with anticipated impacts from aging infrastructure, global climate changes and other impending challenges. The key is recognizing which battle to fight.

ABSTRACT

In this paper a method is proposed for combined energy and pressure management via integration and coordination of pump scheduling with pressure control aspects. The proposed solution involves: formulation of an optimisation problem with the cost function being the total cost of water treatment and pumps energy usage, utilisation of an hydraulic model of the network with pressure dependent leakage, and inclusion of a PRV model with the PRV set-points included as a set of decision variables. Such problem formulation led to the optimizer attempting to reduce both energy usage and leakage. The developed algorithm has been integrated into a modelling, simulation and optimisation environment called FINESSE. The case study selected is a major water supply network, being part of Yorkshire Water Services, with a total average demand of 400 l/s.

1. INTRODUCTION

Water distribution systems, despite operational improvements introduced over the last 10-15 years, still lose a considerable amount of potable water from their networks due to leakage, whilst using a significant amount of energy for water treatment and pumping. Due to increasing energy prices, research aimed at the reduction of energy usage via the optimisation of pumps' operation (pump scheduling) has received significant interest in recent years, see e.g. (Bounds et al 2006; Ulanicki et al 2007; Ormsbee et al 2007). Minimisation of leakage, hence reduced losses of clean water and energy used for pumping and treatment, can be achieved by introducing pressure control algorithms (Ulanicki et al 2005). Whilst pump scheduling and pressure control are traditionally considered separately, if the pressure reducing valve (PRV) inlet pressure is higher than required, in many networks it could be reduced by adjusting pumping schedules in the upstream part of the network. Since many modern pumps are equipped with variable speed drives, manipulating their speed can be employed to control the pressure, thus reduce leakage and energy use.

In this paper a method is proposed for combined energy and pressure management via integration and coordination of pump scheduling with pressure control aspects. The developed algorithm has been integrated into a modelling,

simulation and optimisation environment called FINESSE, which utilises GAMS modelling language and CONOPT non-linear programming solver. The research forms a part of the Neptune project (Neptune 2006) and aims to minimize the leakage and the energy usage whilst supplying good service to customers. In Section 2 general description of the proposed method is provided. Section 3 considers formulation of an optimal network scheduling problem. Section 4 briefly describes implementation and in Section 5 case study is presented.

2. GENERAL METHODOLOGY DESCRIPTION

The proposed method for combined energy and pressure management, based on formulating and solving an optimisation problem, is an extension of the pump scheduling algorithms described in (Ulanicki et al 1999; Bounds et al 2006). The main differences between these methods and the one proposed in this paper are in the network model and in the decision variables set.

The proposed method involves utilisation of an hydraulic model of the network with pressure dependent leakage and inclusion of a PRV model with the PRV set-points included as a set of decision variables. The cost function remains as in (Ulanicki et al 1999; Bounds et al 2006), i.e. represents the total cost of water treatment and pumping. Figure 1 illustrates that, with such approach, an excessive pumping contributes to a high total cost in two ways. Firstly, it leads to high energy usage. Secondly, it induces high pressure, hence increased leakage, which means that more water needs to be pumped and taken from sources. Therefore the optimizer, by minimising the total cost, attempts to reduce both energy usage and leakage.

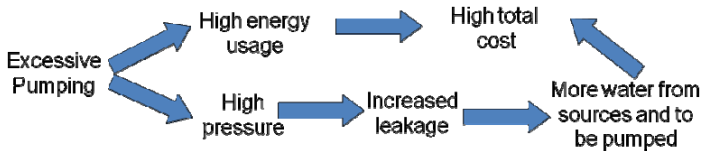

Figure 1. Illustrating how excessive pumping contributes to high total cost when network model with pressure dependent leakage is used.

In the optimisation problem considered some of the decision variables are continuous (e.g. water production, pump speed, and valve position) and some are integer (e.g. number of pumps switched on). Problems containing both continuous and integer variables are called mixed-integer problems and are hard to solve numerically. Continuous relaxation of integer variables (e.g. allowing 2.5 pumps on) enables network scheduling to be treated initially as a continuous optimisation problem solved by a non-linear programming algorithm. Subsequently, the continuous solution can be transformed into an integer solution by manual post-processing, or by further optimisation, see (Bounds et al 2006). For example, the result "2.5 pumps on" can be realised by a combination of 2 and 3 pumps switched over the time step. In this paper only continuous optimisation problem is considered, with the continuous solution of case studies (described in Section 5) being discretised by manual post-processing.

3. OPTIMAL NETWORK SCHEDULING PROBLEM

Network scheduling calculates least-cost operational schedules for pumps, valves and treatment works for a given period of time, typically 24 hours. The decision variables are the operational schedules for control components, such as pumps, valves (including PRVs) and water works outputs. The problem has the following three elements:

1. objective function,
2. hydraulic model of the network,
3. constraints.

The scheduling problem is succinctly expressed as: minimise (pumping cost + treatment cost), subject to the network equations and operational constraints. The three elements of the problem are discussed in the following subsections. The problem is expressed in discrete-time, as in (Ulanicki et al 1999; Bounds et al 2006).

3.1. Objective function. The objective function to be minimised is the total energy cost for water treatment and pumping. Pumping cost depends on the efficiency of the pumps used and the electricity power tariff over the pumping duration. The tariff is usually a function of time with cheaper and more expensive periods. Note that other costs (such as pump switching cost) could be included in the objective function. However, the switching cost is rarely considered due to insufficient data available to formulate it within the objective function (Ormsbee and Lansey 1994). For given time step Δt, the objective function considered over a given time horizon $[k_0, k_f]$ is given by the following equation:

$$\phi = \left(\sum_{j \in J_p} \sum_{k=k_0}^{k_f} \gamma_p^j(k)\, f_j(q^j(k), c^j(k)) + \sum_{j \in J_s} \sum_{k=k_0}^{k_f} \gamma_s^j(k) \times q_s^j(k) \right) \Delta t \qquad (1)$$

where J_p is the set of indices for pump stations and J_s is the set of indices for treatment works. The $c^j(k)$ vector represents the number of pumps on, denoted $u^j(k)$, and pump speed (for variable speed pumps) denoted $s^j(k)$. The function $\gamma_p^j(k)$ represents the electrical tariff. The treatment cost for each treatment works is proportional to the flow output with the unit price of $\gamma_s^j(k)$. The term $f_j(q^j(k), c^j(k))$ represents the electrical power consumed by pump station *j*. The mechanical power of water is obtained by multiplying the flow $q^j(k)$ and the head increase Δh^j across the pump station. The head increase Δh^j can be expressed in terms of flow in the pump hydraulic equation, so that the cost term depends only on the pump station flow $q^j(k)$ and the control variable $c^j(k)$. From mechanical power of water, the electrical power consumed by the pump can be calculated using the pump efficiency or using pump power characteristics (Ulanicki et al 2008).

3.2. Model of water distribution system. Each network component has a hydraulic equation. The fundamental requirement in an optimal scheduling problem is that all calculated variables satisfy the hydraulic model equations. The network equations are non-linear and play the role of equality constraints in the optimisation problem.

The network equations used in this paper to describe reservoir dynamics, components hydraulics and mass balance at reservoirs are those described in (Ulanicki et al 2007). Since leakage is assumed to be at connection nodes, the equation to describe mass balance at connection nodes is modified to include the leakage term:

$$\mathbf{\Lambda}_c \mathbf{q}(k) + \mathbf{d}_c(k) + \mathbf{l}_c(k) = \mathbf{0} \tag{2}$$

where $\mathbf{\Lambda}_c$ is node branch incidence matrix, $\mathbf{q}$ is vector of branch flows, $\mathbf{d}_c$ denotes vector of demands and $\mathbf{l}_c$ denotes vector of leakages calculated as:

$$\mathbf{l}_c = \mathbf{p}^{\alpha} \kappa \tag{3}$$

with $\mathbf{p}$ denoting vector of node pressures, $\alpha \in \langle 0.5,\ 1.5 \rangle$ denoting leakage exponent and κ denoting vector of leakage coefficients, see (Ulanicki et al 2000). Note that $\mathbf{p}^{\alpha}$ denotes each element of vector $\mathbf{p}$ raised to the power of α.

3.3. Constraints. In addition to equality constraints described by the hydraulic model equations, operational constraints are applied to keep the system-state within its feasible range. Practical requirements are translated from the linguistic statements into mathematical inequalities. The typical requirements of network scheduling are concerned with reservoir levels in order to prevent emptying or overflowing, and to maintain adequate storage for emergency purposes:

$$h_f^{\min} \le h_f(k) \le h_f^{\max} \quad for \quad k \in [k_0, k_f]$$

Similar constraints must be applied to the heads at critical connection nodes in order to maintain required pressures throughout the water network. Another constraint is on the final level of reservoirs, such that the final level is not smaller than the initial level. The control variables such as the number of pumps switched on, pump speeds or valve positions, are also constrained by lower and upper constraints determined by the features of the control components.

4. IMPLEMENTATION

Developed energy and pressure management scheduler was integrated into a modelling environment, called FINESSE. The scheduler, as with all tools in FINESSE, is general purpose in that it takes any data model of a network, simulates the network to initialise its decision variables for the network scheduler, and if the model is feasible it calculates the optimal schedules. Using model of a network FINESSE automatically generates optimal network scheduling problem written in a

mathematical modelling language called GAMS (Brooke et al. 1998), which calls up a non-linear programming solver called CONOPT (Drud 1985) to calculate a continuous optimisation solution. CONOPT is a non-linear programming solver, which uses a generalised reduced gradient algorithm (Drud 1985). An optimal solution is fed back from CONOPT into FINESSE for analysis and/or further processing. For further details on using GAMS and CONOPT for optimal network scheduling see (Ulanicki et al 1999).

5. CASE STUDY

5.1. Network description. The case study selected is a major water supply network, being part of Yorkshire Water Services (YWS). The network is fed by two major sources and has two major exports. The network consists of 2074 nodes, 2212 pipes, 4 reservoirs, 12 pumps and 56 valves (including one PRV) with a total average demand of 400 l/s. However, only 8 out of 12 pumps were actually used for scheduling, since other 4 pumps are in standby mode and should not be used unless in an emergency situation such as failure of other pumps. It was also found that only 8 out of 56 valves could be scheduled, while others are to remain fully closed. Schematic of the case study network is illustrated in Figure 2. Description of current operation of the network follows.

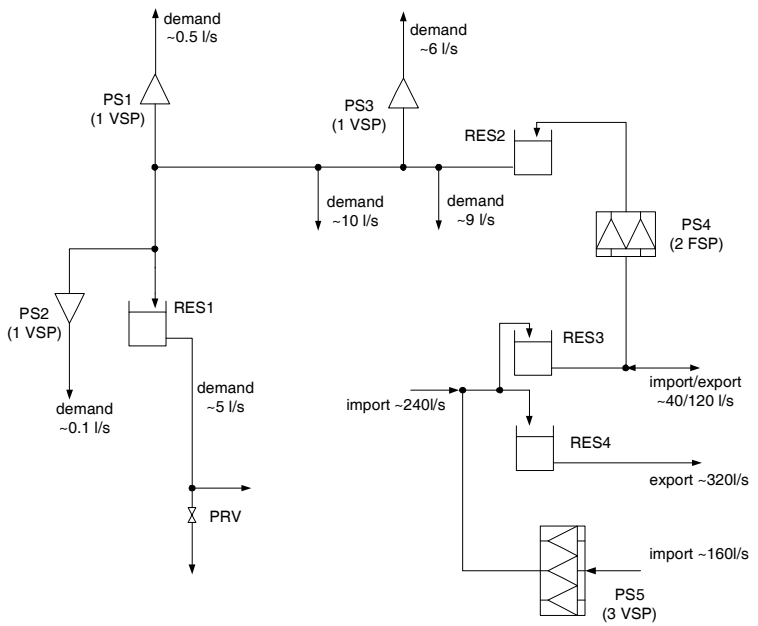

Figure 2. Illustrating schematic of the case study network. Abbreviations denote: PS – pumping station, FSP – fixed speed pump, VSP – variable speed pump, RES – reservoir. Demands and average import/exports are also depicted.

PS1, PS2 and PS3 consist of small pumps that operate to maintain given outlet pressure. Their speed, therefore, changes together with demand. PS4 is

controlled by water level in reservoir RES2 (on/off control with 20 cm water level margin); typically only one pump is used. Due to tight margin (20 cm) the pump in PS4 is switched on/off frequently, every 7 to 30 minutes. PS5 consists of three large pumps with variable speed drives. They operate to number of preset flow bands; typically only one or two pumps are on. Opening of the top-feed valve for RES1 is controlled by water level in RES1. The top-feed valves for RES2-5 are fully open.

Information about the electrical tariffs in the considered water network was not available at the time this work was carried out. For this reason the tariffs were assumed to represent a typical scheme of cheap at night and expensive during day. Assumed tariffs were: 0.1 £/kWh between 22.00 – 07.00 and 0.2 £/kWh between 07.00 – 22.00.

5.2. Modelling and simplification. A model of the network was provided in Aquis format. Structure of nodes and pipes was automatically converted into EPANET format and subsequently imported into FINESSE. Other network element, i.e. reservoirs, pumps and valves, were added manually to the FINESSE model. Pumps, valves and reservoirs parameters were described in FINESSE using data from Aquis model and additional information provided by YWS.

Once the FINESSE model was completed, it was simplified using FINESSE model reduction module (Ulanicki et al 1996) to reduce the size of the optimisation problem. In the simplified model all control elements remained unchanged, but the number of pipes and nodes was reduced to 45 and 43, respectively. Both full and simplified FINESSE models were simulated and compared, with respect to pump flow and reservoir trajectories, against the reference Aquis model. It was found that in Aquis model, which allows variable simulation step, the pump in PS4 was switching at intervals as small as 7 minutes. To represent such irregular switching and model similar operation of the PS4 pump in FINESSE, where minimal time step is 15 minutes, it was assumed that e.g. 0.5 pump is on during a single time step. Both FINESSE models showed satisfactory agreement, see reservoir trajectories illustrated in Figure 3. Since RES3 and RES4 are directly connected, it is considered sufficient to compare average levels for these two reservoirs. Note that for the purpose of comparison of FINESSE models with Aquis model local control rules, such as control of RES1 top-feed valve, were kept. Subsequently, these local rules were removed to enable scheduling of all control elements.

Only limited information about leakage in the considered network was available at the time this work was carried out. For this reason the network optimiser was run for several scenarios, assuming different leakages levels. According to YWS there is a considerable leakage on the connection between PS5 and reservoirs RES3 and RES4, due to significant distance and elevation difference which require high pressure at PS5 outlet. Therefore, in the scenarios described in next subsections the leakage was assumed to be on this connection.

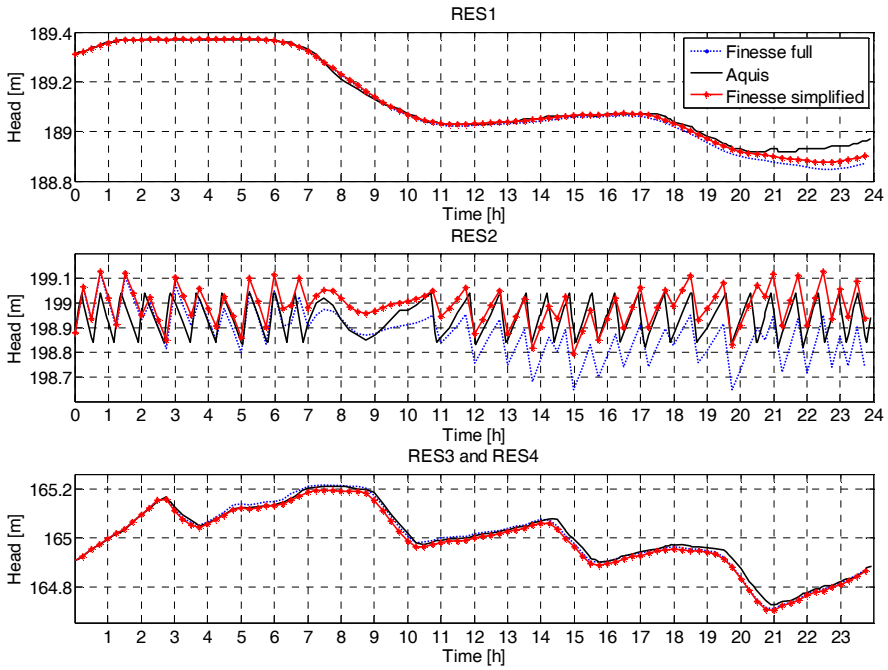

Figure 3. Illustrating reservoir level trajectories for full FINESSE model, simplified FINESSE model and reference Aquis model.

5.3. Network scheduling: no leakage. First, a case with no pressure-dependent leakage was considered, i.e. κ in Equation (3) was zero for all nodes. Time step Δt=1 hour was chosen. The optimisation ran for 2 minutes on a Pentium 4 3GHz PC. Obtained continuous solution was transformed into an integer solution by manual post-processing. Pump schedules for PS4 and PS5 are illustrated in Figure 4 and Figure 5, respectively. Daily cost of electrical energy was as follows: £799 for current network operation, £491 for optimised continuous solution and £494 for integer solution.

5.4. Network scheduling: with leakage term. Three scenarios were considered for different leakage levels. Parameter κ in Equation (3) was chosen such that the leakage at a node close to the outlet of PS5 was approximately 10%, 20% or 30% of the flow for scenarios 1, 2 and 3, respectively. Leakage was assumed to be zero at other nodes. Only continuous solution was considered for simplicity. Obtained pump schedules for PS5 for different scenarios are illustrated in Figure 6. Daily cost of electrical energy was £534, £547 and £562 for scenarios 1, 2 and 3, respectively.

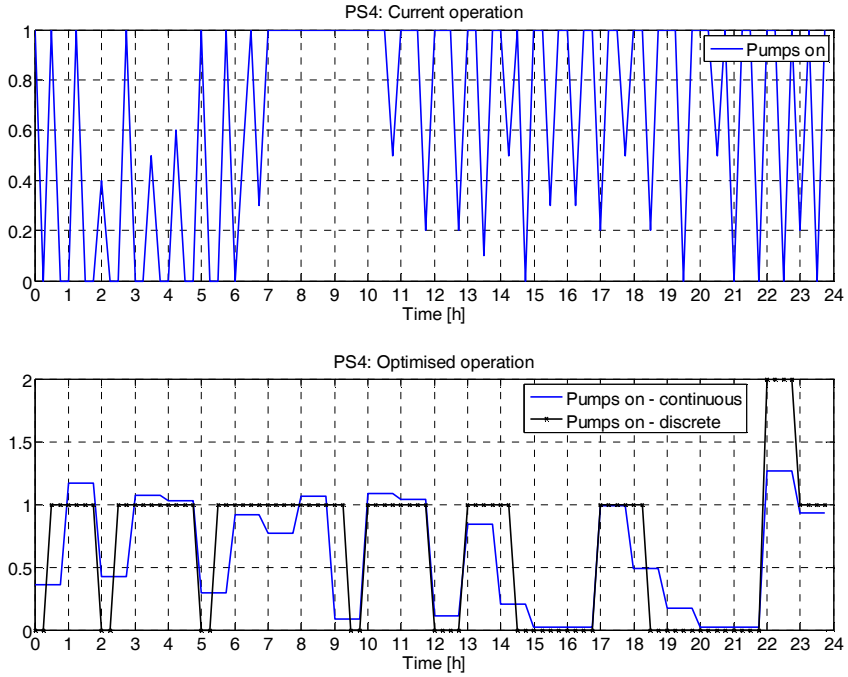

Figure 4. Comparison of current and optimised network operation for PS4.

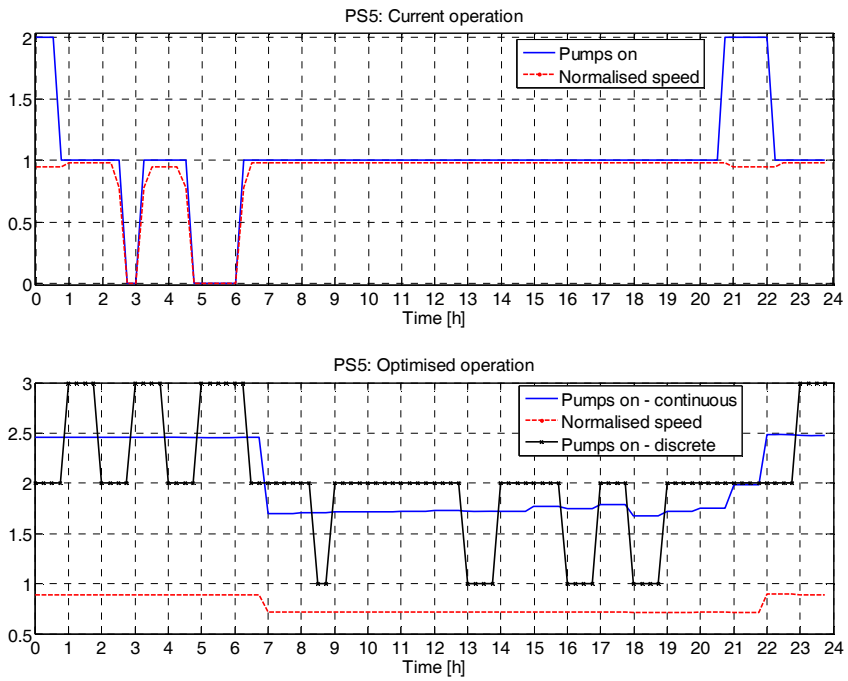

Figure 5. Comparison of current and optimised network operation for PS5.

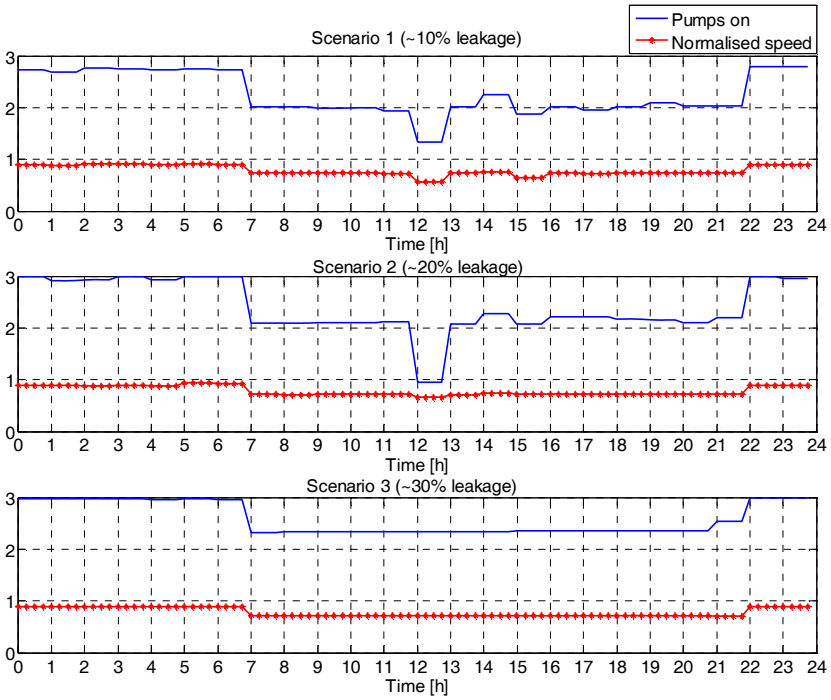

Figure 6. Comparison of PS5 pump schedules for three different leakage levels.

5.5. Discussion. It can be observed in Figure 4 that due to operational constraints not much savings can be achieved for PS4, since current and optimal schedules are similar, i.e. both exhibit switching 0-1 pumps on throughout the 24h period. However, recall from Section 5.1 that PS4 switches frequently due to tight margin (20 cm) for reservoir level controlling the pump operation. Optimal schedules resulted in less frequent switching which is beneficial for pump durability.

In Figure 5 it can be observed that optimal schedules for PS5 cause an intensive pumping during the cheap tariff period to fill RES3 and RES4, which subsequently supply water during the expensive tariff period. The operational speed of PS5 pumps is lower, compared to current operation, during the expensive tariff period, which also contributes to reduced cost. The total cost was reduced by 38%. It should, however, be noticed that these results were obtained for an assumed electrical tariff, which could significantly differ from the actual tariff, and did not take into account standing charge and other costs.

It was found that increased leakage coefficient, not surprisingly, led to increased cost, since harder pumping is required due to increased pump flow. Nevertheless, the pump schedules are similar to the 'no leakage' case, with intensive pumping during the cheap tariff period; compare Figures 5 and 6. It was observed that, despite indirect penalisation of high pressure in the cost function (see Figure 1), increased leakage coefficient did not result in lower PS5 outlet pressure. Analysis of CONOPT logs revealed that this was a result of hydraulic equation constraints: PS5 outlet pressure cannot be decreased, due to significant distance and elevation difference between PS5 and RES3.

6. CONCLUSIONS

In this paper a method was proposed for combined energy and pressure management via integration and coordination of pump scheduling with pressure control aspects. The proposed solution is an extension of the pump scheduling method based on formulation and solving of an optimisation problem. Proposed method utilises an hydraulic model of the network with pressure dependent leakage and takes into account PRV model with the PRV set-points included as a set of decision variables. Such formulation leads to the optimiser attempting to reduce both energy usage and leakage. The developed algorithm has been integrated into a modelling, simulation and optimisation environment called FINESSE, which utilises GAMS modelling language and CONOPT non-linear programming solver.

The method was applied to optimise the operation of a major water supply network, being part of Yorkshire Water Services. A network model provided in Aquis format was converted to Epanet format, imported to Finesse, simplified and validated against original Aquis model. Optimised network schedules resulted in the total cost of electrical energy reduced by 38%, albeit for an assumed electrical tariff, which could significantly differ from the actual tariff. The developed algorithm is currently further investigated using other case studies.

Introduction

Water scarcity is causing major concerns throughout the world, especially in arid regions where cities are growing rapidly and are depleting groundwater reserves faster than they can be recharged. The southwestern U.S., Arizona and Nevada in particular, are experiencing the large growth rates with limited water resources and no new sources available. In effort to reduce the amount of water being consumed by people, new engineering technologies are being explored. Water reuse is becoming recognized as the last untapped water resource. However, little research has been conducted on effectively distributing that water to user. In particular, distribution of reclaimed water through a parallel pipe networks system to homes or dual water supply system has not been considered.

Existing distribution systems deliver water via a single system. Meeting flow and pressure requirements for fire conditions are driving factors in designing water distribution systems. Minimum regulatory pipe diameters of six to eight inches are common in most systems and can lead to reduced water quality. The goal of a parallel system is to maximize the usage of reclaimed water. By distributing non-potable water through a separate line to meet non-sanitary uses (i.e., outdoor, fireflow, and toilet flushing), the need for potable water can be greatly reduced. Separating these demands from the potable system can reduce the potable system pipe sizes, improve water quality and reduce the overall cost of the water distribution system.

Some cities in the southwestern U.S. have already implemented this new system in some residential areas through a non-potable "purple pipe" system. However, the efficiency of these new systems has not been thoroughly examined. This paper will

focuses on the design of dual systems by using an optimization algorithm linked to EPANET (USEPA, 2000) via the EPANET toolkit to determine the optimal least-cost design of dual piping systems.

Previous Studies

Optimization of water distribution systems have been under research for some time. A number of optimization algorithms have been applied to water distribution systems with minimizing cost as the objective function and pipe size diameters as the decision variable. Eusuff and Lansey (2003) applied a Shuffled Frog Leaping Algorithm (SFLA) to optimize water distribution systems by minimizing cost. Other works have been done by trying to minimize cost using Genetic Algorithms - Hadji and Murphy (1990), Murphy and Simpson (1992), Walters and Cembrowiez (1993), and Simson et. al. (1994). This paper applies this technique to the least cost optimization of dual supply systems.

Methodology

Implementation of dual supply systems requires designing and optimizing two separate systems for the same network layout in order to analyze the effectiveness of the dual supply system. The objective is to minimize overall piping costs while still meeting the demands and minimum head requirements in the system.

A significant issue from engineering, public perception and regulatory perspectives is the demands that will be supplied in each pipe system. Here, we consider water demands to be composed of four different uses; outdoor, toilet, fire, and drinking/potable. The effectiveness of the dual supply system will be analyzed by determining the least-cost design of four different system configurations:

- Design 1 – (Single System) Outdoor, toilet, fire and drinking use are all distributed via a fully potable system (representative of almost all existing water distribution systems).
- Design 2 – (Dual System) Outdoor use will be distributed via a non-potable system. Toilet, fire, and drinking are delivered in the potable system.
- Design 3 – (Dual System) Outdoor and toilet use will be delivered via a non-potable system. Fire and drinking use is delivered via a potable system.
- Design 4 – (Dual System) Outdoor, toilet and fire use will be delivered via a non-potable system. Drinking use will be delivered via a potable system.

The derivation and proportion of the total demand for each uses is described in detail in the Network Development section. The least cost design, as determined by the optimization program for each of the configurations mentioned above will be compared to the fully potable system. A cost comparison based on pipe sizes will determine cost/benefit of the dual supply systems in terms of pipe construction cost.

Problem Formulation

In this paper, the design of dual water supply systems is formulated as a least-cost optimization problem. The goal is to minimize the pipe cost of the two systems that are composed of commercially available pipes. The layout of the water distribution network, as well as the nodal demands and minimum head requirements in the system are known. The following conditions must be satisfied:

- Conservation of mass: The inflows and outflows must be balanced at each node in the system.
- Conservation of energy: The head loss around a closed loop must equal zero.
- The head loss in each pipe is determined by Hazen-Williams pipe loss equation.
- The minimum pressure in the network must be given as well as the demand(s) in the system,
- Acceptable pipe sizes: Pipe diameters are selected from commercially available pipe sizes (with the exception of small sizes 1 in – 4 in).

The problem formulation subject to these conditions can be represented mathematically by:

$$\min f(D_1,....,D_{npipe}) = \sum_{k \in npipe} C_k(D_k, L_k) \tag{1}$$

Subject to

$$\sum Q_{in} - \sum Q_{in} = Q_e \tag{2}$$

$$\sum_{k \in Loopl} \Delta H_k = 0, \forall l \in nloop \tag{3}$$

$$\Delta H_k = H_{u/snode,k} - H_{d/snode,k} = \omega \frac{L_k}{C W_k^{\beta} D_k^{\gamma}} Q_k \left|Q_k\right|^{\beta-1}, \ \forall k \in npipe \tag{4}$$

$$H_{iN} \geq H_{\min iN}, \forall iN \in nnodes \tag{5}$$

$$D_k \in \{D\}, \forall k \in npipe \tag{6}$$

where (D_1….D_{npipe}) is the discrete pipe diameters selected from commercially available pipe sizes. $C_k(D_kL_k)$ is the cost of pipe with diameter D_k and length L_k. Q_{in} is the flow rate in and Q_{out} is the flow rate out of each node. ΔH_k is the headloss in pipe k and $nloop$ is the number of loops in the system. The headloss equation used is the Hazen-Williams equation with CW as the roughness coefficient which will be 130 for all pipes in the system. $nloop$ and $npipe$ is the number of loops and pipes in the system respectively. H_{iN} is the head in each node must satisfy the minimum head pressure requirement in the system H_{min}. For all designs the minimum head required throughout the system will be 40 psi.

This problem is solved by linking a genetic algorithm (GA) with EPANET as shown in the Figure 1. The GA generates solutions of pipe diameters that are passed to EPANET. The total cost is then calculated. If the pressure requirements (40 psi min.) are not met a penalty term will be added to the objective making the alternative not preferable. The optimization scheme will run until the least-cost of each design is determined or meets the stopping criteria as specified in the GA parameters.

Network Development

A fictitious network was developed that will be designed and analyzed for the dual supply systems. The network was created from a typical residential neighborhood layout in Tucson, Arizona The area chosen for consideration is approximately one square mile and is relatively flat (all nodes assigned zero elevation). (Figure 2).

The source head was modeled as a reservoir with a constant head of 138 feet. This is equivalent to connecting to an existing water main with a pressure of 60 psi. For purposes of this paper the source head was kept constant for each of the designs under consideration. The minimum pressure requirement for each node was 40 psi. Pipe cost for each pipe size is listed in Table 1.

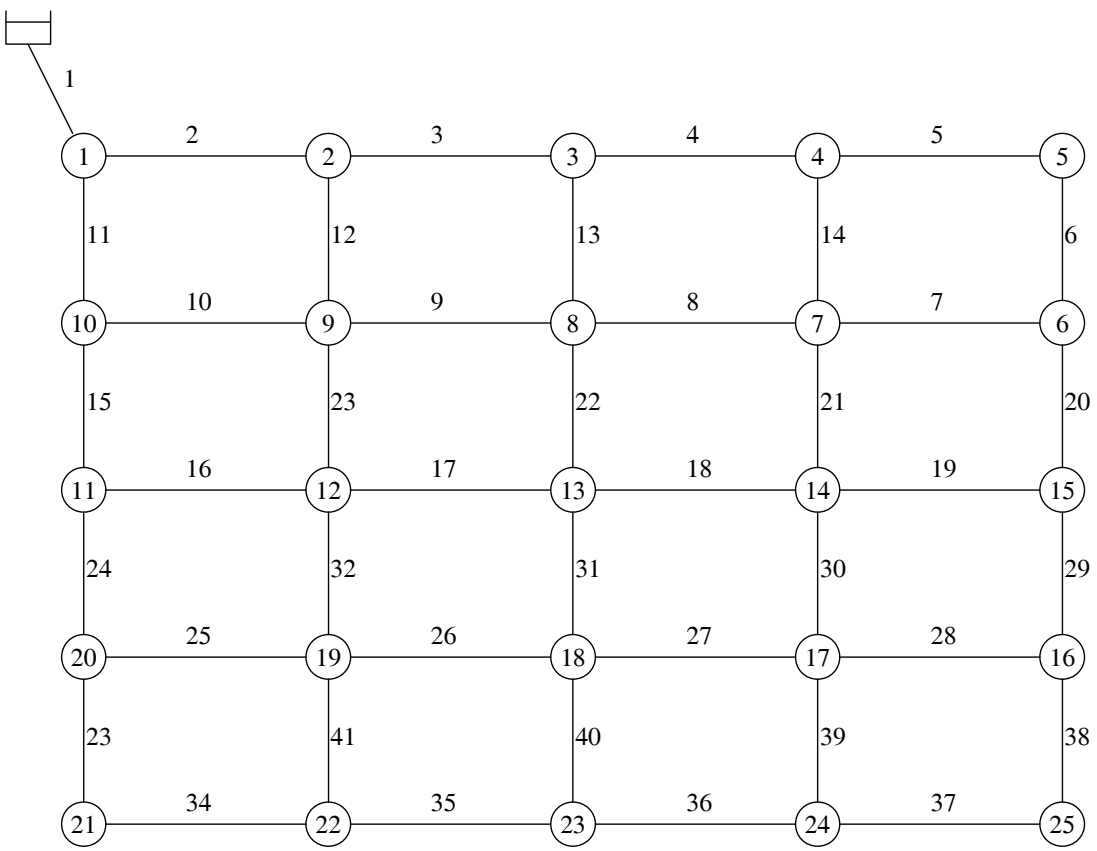

Figure 2 - Network Layout

Nodal Demand Development

Nodes were placed to represent approximately 9 square residential blocks with pipes representing street water mains. Twenty homes per block with 2.5 persons per home consuming 150 gallons/day/per person was used to get a base demand. A peak factor of 2 resulted in a demand of 94 gpm for each node and a simulated fire flow of 2000 gpm at node 25 (furthest from the source) was used for design considerations.

Demand Breakdown

The design demand was divided into outdoor use, toilet use and drinking use with proportions of 47 gpm, 13 gpm, and 34 gpm respectively, for each node. The fire flow will be applied only to node 25. Each of the four designs under consideration requires different combinations of each "type of use" as described above.

Results

Multiple runs were performed for each design to assure that the global minimum is identified. Table 2 shows the best solutions for each of the designs. Some generalization can be made about the design of dual supply systems. As expected, the systems with lower demands require smaller pipes and have lower costs. The fire flow controlled the overall water supply system cost. The system that provided the fire flow required significantly larger pipes and higher cost. Design 1 was the least expensive followed by Design 4, Design 3 and Design 2.

In general, if only pipe costs are considered and the source head is fixed, dual supply systems are more expensive than conventional system on the order of 6% to 14%. However, in this example, only material and construction cost associated with the design are considered. Many other cost factors come into play in distribution systems. Out of the three dual systems considered, the cheapest cost was Design 4, in which only drinking water was delivered via the potable system. This design was 6% more expensive than conventional designs. In theory, this design would be the ideal system if implementation of dual systems was desirable. This system configuration makes the most use of reclaimed water which is the ultimate goal of dual supply systems.

Discussion

In this paper a GA was used to determine optimal designs of dual water supply systems considering construction costs only. With this limitation, dual systems are somewhat more expensive than a single potable system. This results from the economies of scale of pipe diameter and flow relationships. However, considering dual systems functioning as a whole may prove to be more economical in the long run if pumping, source heads and energy costs are taken into account. Benefits of reducing potable demands, and other factors such as system reliability and water quality may also change this conclusion.

A number of factors affect dual water supply system design. Some of those factors are listed in Table 3. For example, here, the source energy was fixed at a constant pressure for the potable and non-potable systems. Additional runs suggest that the network design is sensitive to the source head. Further studies will add the source head as a decision variable to represent pump energy and pump station costs. Further head requirements for alternative systems may not require the same source head and pressure provided. For example, 40 psi may not be necessary for a non-potable system in which outdoor use and toilet flushing are the only uses. Reliability of the

dual systems that must be considered as the two networks may serve as backup systems for each other. Lastly, the type of waters that are socially acceptable to deliver to households must be evaluated. Thus, this study of dual system design must be considered an initial assessment and significantly more effort is necessary to address the value and cost benefits of these networks.

Table 3 – Factors affecting dual water supply system design

Regulatory	*System characteristics*	*Social*
Minimum pipe size	Topography	Water quality by use
Pressure requirements	Demand distribution by use	Reliability
Water quality requirements	Population density	Acceptance of alternative
Reliability	Service area size	waters for different uses
	Demand magnitude	Demands for waste water
	(ex, indoor, outdoor, etc)	Demands conservative
	Water source location/energy	practices
	available	· grey water use
		· rainwater harvesting
		· consumptive use
		reduction
		· indoor use conservation

Modeling Domestic Water Demand On A Suburb Level

M.L. Griffioen, J.E. van Zyl and A.S. le Roux

Department of Civil Engineering Science, University of Johannesburg, PO Box 524, Auckland Park, 2006, South Africa; PH (+2711 559-2540); email: mlgriffioen@uj.ac.za

ABSTRACT

In this study it was assumed that a suburb provides a good basis for grouping water demands, and that it is adequate to design for the average suburb AAD (annual average demand). A database on measured domestic water demands was used to determine the average AAD for a large number of suburbs in South Africa, and this data was further linked to sensus and climate data. The combined data set was then subjected to various regression analyses, and a method was developed to compare these models. This method may assist with determining suitable design guidelines for suburb AAD in future.

INTRODUCTION

Domestic water demand is influenced by a large number of factors, including socio-economic (household size, income, stand size, social status, number of household appliances, social patterns, public and school holidays, tourism and water price), climatic (temperature, rainfall, humidity, time since last rainfall and the number of preceding hot days) and structural (number of users, water metering, plumbing fitting properties, pressure and network capacity) (Van Zyl et al 2008). As a result it is impossible to predict water demand with certainty and any prediction model will invariably include significant errors.

The design water demand of a new area is normally determined by first estimating the annual average demand (AAD) and then multiplying this demand by peak factors to determine the design hydraulic load on the distribution network. The AAD may be estimated from measured demands of similar areas, or from design guidelines.

The South African design guideline for AAD provides an upper and lower bound based on stand size. The design engineer estimates the AAD for a particular area between these bounds by taking factors such as climate, income and local conditions into account.

In the last decade, a South African consulting engineering company (GLS) developed a software product called Swift that extracts water meter readings from a municipal treasury system and makes it available for engineering analysis. The product has been

implemented in a large number of municipalities throughout South Africa, and this data was used as the basis for an analysis of domestic water demands.

The data showed that individual water demands have large variations, even when important parameters such as climate, stand size and income are the same. However, if situated in the same geographical area, these extremes will balance each other out, and the designer only needs to consider the average demand for the area.

In this study it was assumed that a suburb provides a good basis for grouping water demands, and that it is adequate to design for the average suburb AAD. The demand database was used to determine the average AAD for a large number of suburbs in South Africa, and this data was further linked to socio-economic and climatic data for each suburb. The combined data set was then subjected to various regression analyses, and a method was developed for using these regression models to propose a new design guideline for AAD in South Africa.

DATA

The data used in this study was obtained from municipal meter readings entered into treasury databases for billing purposes and then extracted using a software package called Swift (GLS, 2007). The data was subjected to a number of verification and cleaning processes to ensure that errors are eliminated in an objective manner.

In the first data verification and cleaning stage, errors in the database were identified and corrected (where possible) or the records removed. Various types of errors were addressed, including missing meter readings, inconsistent reading dates, reading errors, meters that were replaced and duplicate records. After the first phase, the database consisted of 1 353 794 records of monthly water demand for at least a year, as well as other information for each record, such as the stand size and municipal stand valuation.

In the next phase, only residential stands were extracted and then grouped by suburb. The number of suburbs identified was 1 442. To eliminate outlyers in the data, the highest and lowest 2 % of water demands, stand sizes and stand values were removed in each suburb. In addition, filters were applied and records with AAD, stand sizes or stand values outside a reasonable range were removed. The ranges for these parameters were set as follows:

- AAD: between 0.05 and 10 kl/day.
- Stand size: between 50 and 5 000 m.
- Municipal stand valuation: between ZAR 1 000 and 3 500 000.

Climatic and sensus data were obtained from various sources and linked to the demand data. In the final step, all suburbs with no sensus data, or that contained less than 100 records were also removed from the data set.

The final data set consisted of 654 014 residential users in 739 suburbs. For each suburb, the following data was available:

- Location (municipality and suburb)
- Average AAD
- Average stand size
- Average stand value
- Type of water supply (piped water, borehole, spring, etc.)
- Type of sanitation (sewer line, septic tank, chemical toilet, etc.)
- Type of building (house, flat, traditional dwelling, etc.)
- Type of area (urban, smallholding, farm, etc.)
- Income
- Racial distribution
- No of rooms per house
- Mean annual precipitation
- Average maximum daily temperature
- Average minimum daily temperature
- Mean annual evaporation

The current South African design guideline for AAD provides upper and lower guideline values based on stand size. The suburb data was plotted on these guidelines as shown in Figure 1.

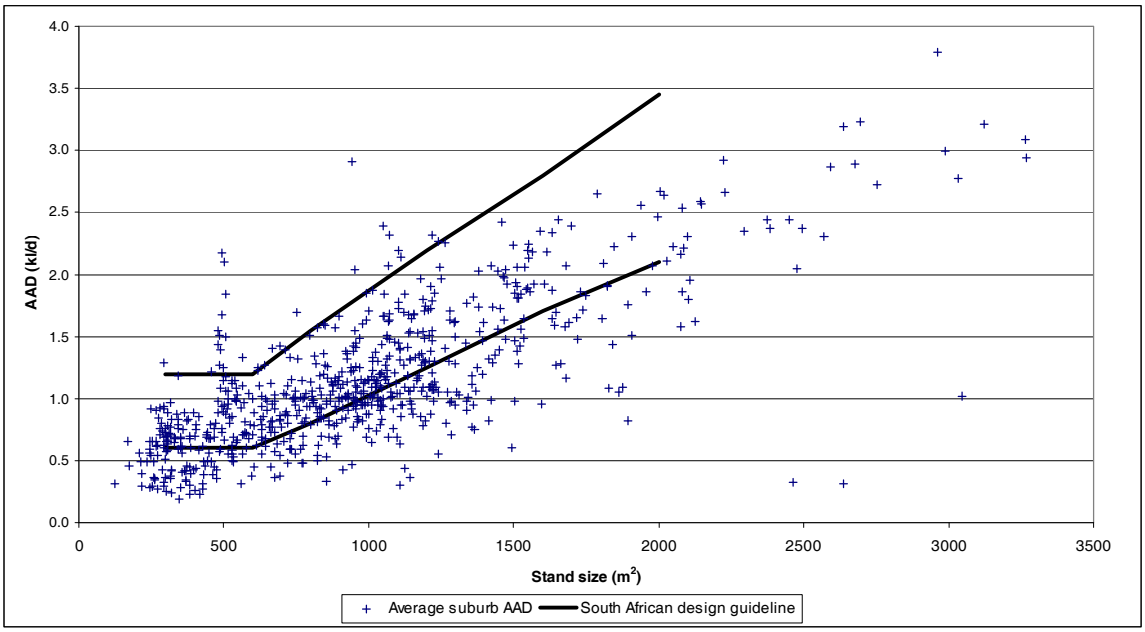

Figure 1 Average suburb AAD compared to the South African design guideline

It is clear that, while the guidelines replicate the general trend, a large fraction of the AAD values fall outside the proposed design envelope, especially on the lower side.

REGRESSION ANALYSES

The data set was then analysed through a number of regression analyses. In the first analysis, a step-wise multiple regression analysis was conducted, which identified the following significant parameters to predict Ln(AAD):

- Ln(fraction of cluster housing)
- Ln(average stand size)
- Mean annual evaporation
- Fraction of houses with piped water
- Fraction of stand-alone houses
- Stand value
- Fraction of African population
- Average number of rooms per house
- Average minimum daily temperature
- Mean annual precipitation
- Fraction of houses with flush toilets

The Adjusted R^2 value for the model was 0.73, which represents a reasonably good prediction for something as variable as water demand.

The step-wise multiple regression identified stand size as the most important predicter of AAD, followed by stand value. To explore these variables further, single regression models were developed for AAD as a function of stand size and value. The logs of the various parameters were also investigated in these models. The results of the single variable regression analyses are summarized in Table 1.

Table 1 Results of single variable regression analyses

Dependent Variable	Independent variable	Adjusted R^2
AADD	Stand size	0.58
AADD	Ln(Stand size)	0.50
Ln(AAD)	Stand size	0.48
Ln(AAD)	Ln(Stand size)	0.51
Ln(AAD)	Stand value	0.50

The model for AADD as a function of stand size produced the best results of all the single regression models with an adjusted R^2 value of 0.58. This model is shown in Figure 2.

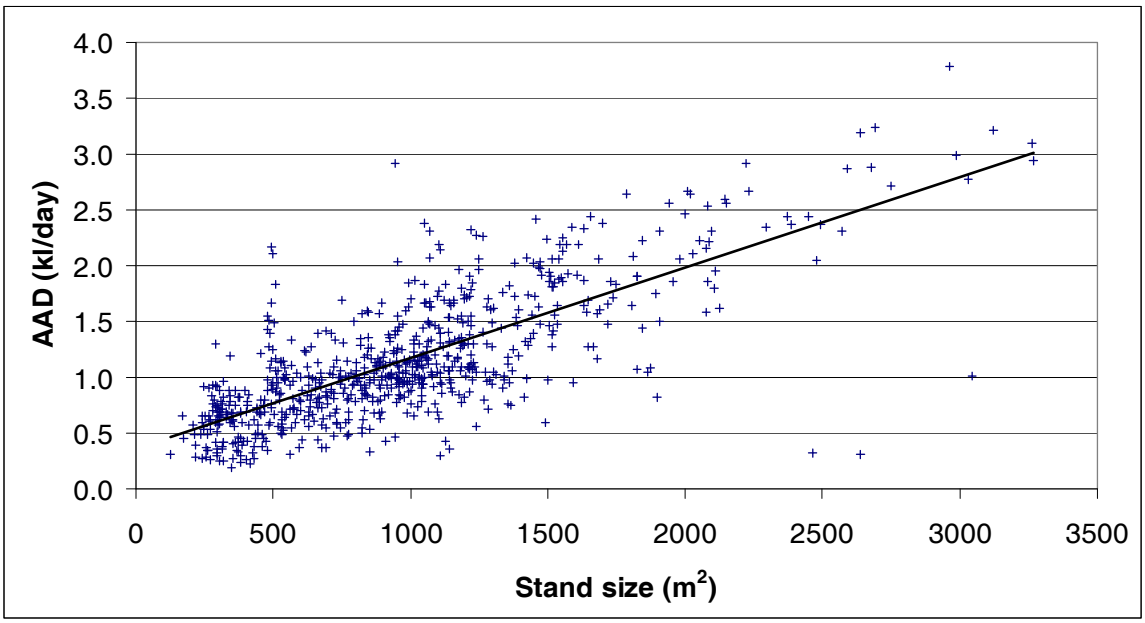

Figure 2 Single regression model for suburb AAD as a function of stand size

COMPARING THE MODELS

The regression analyses showed that the multiple regression model is able to predict suburb AAD significantly better than any of the single regression models. However, this improved accuracy requires data for 11 parameters to be estimated. Single regression equations have the advantage of being much simpler to apply, while still providing reasonable accuracy.

Even the multiple regression model is not perfect, and will underestimate the AAD in roughly half the cases. It is thus necessary to adjust this model to provide a more conservative estimate that will avoid underestimates of AAD, while at the same time not providing excessive over-estimates.

To evaluate and compare the regression models, a trade-off curve was developed by plotting the fraction of data points where the AAD is under-estimated against the average over-estimation error. Each of the regression models was then varied by adjusting its intercept, and the results plotted as shown in Figure 3. The current upper envelope of the South African design guidelines is also shown on the graph.

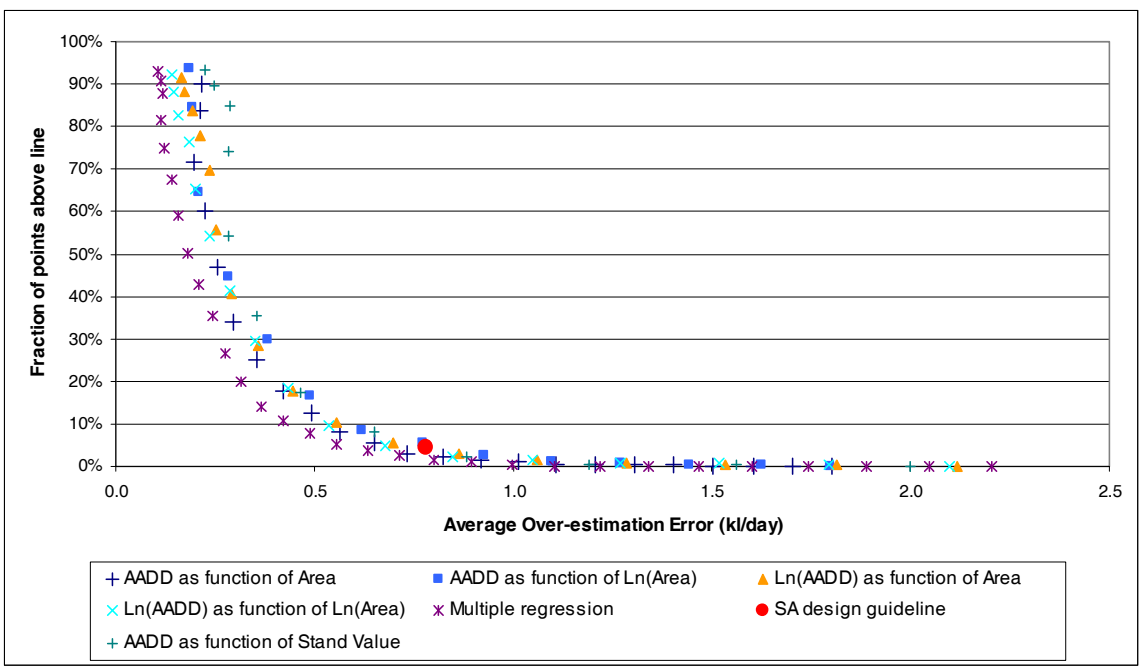

Figure 3 Comparison of different models

Figure 3 shows a that the multiple regression model provides the best prediction for the AAD for any level of safety.

The graph shown in Figure 3 is proposed as a basis for establishing an upper design curve for suburb AAD. It allowes different models to be compared, and allowes the user to pick the optimal curve for a given factor of safety. It is also possible to use the inverse of this method to determine a lower curve for a design envelope.

CONCLUSIONS

This study analysed residential water demand based on the assumption that a suburb provides a suitable grouping to base the design AAD on. A database of AAD values in South Africa was analysed and combined with climate and sensus data. Single and multiple regression models were developed for the data. The multiple regression model was able to predict water demand the best, but is much more complicated and cumbersome than the single regression models, where stand size proved to be the best predictor of AAD.

The different regression models were adjusted to provide better margins of safety for design purposes, and a way to compare the different models was proposed. This may provide a good basis for determining a suitable design envelope for AAD prediction in future.

Abstract

A methodology for modeling time series of hourly urban water use is presented based on separating the data into three components: trend, seasonality, and autocorrelation. Each component is represented by a model whose parameters are estimated. The series is transformed by removing each of the three components and the last transformation produces only a random error series. In the process of identifying the most suitable model for the autocorrelation component of the series, a large number of alternative autoregressive moving average (ARMA) models are assessed in terms of statistics that measure accuracy, parsimony, and randomness of the residuals. Hourly spatially aggregated water use in Cincinnati, Ohio, during the month of October, 2008 is modeled as an example. The model explains approximately 50% of the variance of this series, divided as trend (8.28%), seasonality (11.51%), and autocorrelation (29.94%). The methodology will be applied in a future study of a large data set of individual service connection hourly demand series, spatially aggregated under different schemes.

Introduction

Network hydraulic models are indispensable in sizing and operating water distribution systems (WDSs), and they may also become essential tools in assessing water quality dynamics at different levels of skeletonization. Increasingly, network water quality models are being used to assess water quality impacts due to intentional or accidental contamination sources, and USEPA regulations even allow the use of such models for assisting in selecting sampling locations, in lieu of more intensive field sampling. Nonetheless, uncertainty in key model parameters is looming as a significant factor

that may limit the promises assigned to network water quality models, especially as the models are applied at finer spatial and temporal resolutions. For many of these current or project applications, it is important to question the accuracy of network hydraulic modeling that is rooted in deterministic assumptions, where evidence and logic suggests a stochastic approach is required.

A sensitivity analysis of a WDS clearly shows that water demands are the parameters that most influence the hydraulic response of a water distribution network. This has been motivating efforts to characterize water demands at finer spatial and temporal resolutions, to support the need for accurate stochastic simulation models. Urban water demand models, which were historically used to quantify systemwide aggregate demand, and determine appropriate price structures, need to evolve toward finer temporal and spatial aggregation scales.

The spatial-temporal variability of urban water demands is assumed to be significant, and it seems natural to rely on the theory of stochastic processes and random fields as the mathematical framework for the development of a demand model that bridges a variety of spatial-temporal resolution scales, from highly aggregated daily demand models applied to entire service areas, to sub-hourly demands assigned to small groups of service connections. It may also be useful to adopt a flexible structure for the model, which at some degree of aggregation can be purely statistical, and at some other can attempt to represent the physical underlying processes. The ultimate goal will thus be to develop a model that adequately represents the statistical properties of water demands at different levels of spatial and temporal aggregation, by giving a reasonably close fit to selected features of data, while allowing a minimum number of parameters to be estimated from commonly available field data

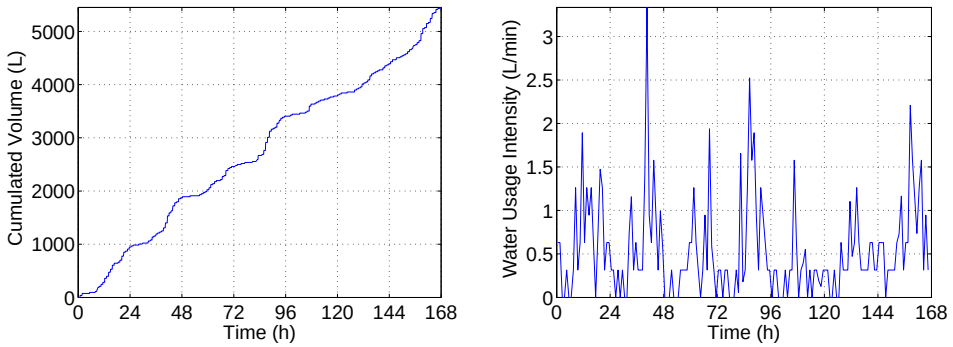
The construction of such a modeling framework requires a stepwise progression. This paper discusses the first preliminary stage, which involves the collection of a large data set of hourly water usage by individual service accounts (ISAs) and an exploratory analysis of such data under different schemes of spatial aggregation. Time series of hourly ISA demands show a predominant random component and several periods of inactivity throughout the day, suggesting an underlying point process as the generating mechanism (Cox and Isham, 1980). As such individual demands are aggregated in space, their temporal variation describes characteristics that may be modeled using time series techniques (Salas and Yevjevich, 1972; Maidment and Parzen, 1984; Maidment and Miaou, 1985), taking benefit from the rich available literature, in particular that relates to Auto Regressive Moving Average (ARMA) models (Box and Jenkins, 1976).

This paper discusses the process of data acquisition and Preprocessing employed to establish a significant demand data set for future model building and testing. Furthermore, it investigates the suitability of different ARMA model structures to spatially-aggregated demand data at hourly resolution. The objectives are to develop a methodology for time series analysis of the aggregated data and to analyze the order of models that can be fitted to residual stationary time series of hourly water usage rates. From a complete analysis using the entire data set (in process, and to be completed at a later date), we expect to better understand the statistical features of urban water usage as a function of various ways to classify them, and the modeling framework that would be required to bridge the various useful scales of demand analysis.

Data Acquisition and Management

For the purpose of this study, water demands are being continuously monitored at approximately 2500 accounts using 4 massive data collectors, with the data being transferred to a centralized database for data processing. The monitored areas were selected through a geographic and demographic study of Hamilton County, Ohio, to include a mixture of single and multi family residences, commercial and industrial establishments.

The system for data collection has three main components. First, at the ISA level, a water meter continuously measures the water inflow, encodes the current cumulated volume, and transmits its value to a radio Meter Interface Unit (MIU) once per hour. The second component is the data collector which is a stand alone unit able to receive the radio signals from the MIUs enclosed in its area of coverage. Also, the unit has the capability of compiling the records into daily binary files that are downloaded through public communication networks. Finally, data is merged into the third component, a centralized database, that can be queried for data retrieval.



The measuring and recording instruments allow a volumetric resolution of 5 gallons (18.93 Liters) and a temporal resolution of 1 hour. The implications are that if less than 5 gal is used, no increment will be recorded. However, the meter does accumulate demand continuously, so the long-term total demand is accurate within a 5-gal increment. On the contrary, for high water usage rates, the limiting resolution will be the temporal, obscuring the actual time at which 5-gal increments occurred between one hour and the next.

For a particular ISA or MIU, the raw data retrieved from the database contains records showing a cumulated water volume and the two times of the day, first and last, at which such volume was registered. For a given period of time, there will be a set of records that needs to be preprocessed to obtain a time series of hourly water usage rates. The preprocessing task includes several operations such as eliminating anomalous records, correcting time sequences, and re-sampling to determine the hourly rates at equal hourly intervals from the cumulated series at uneven time intervals. Figure 1 illustrates the two main steps in preprocessing the raw data for a sample MIU and during the first week of October 2008.

The cumulated series of Figure 1(a) is sampled at uneven intervals as it is generated from the raw data. The time series of Figure 1(b) is created through interpolation using the raw data of the cumulated series, in order to produce water usage time intervals equally spaced by one hour.

Methodology

The study of urban water use based on total system demand has been extensively addressed (Salas and Yevjevich, 1972; Yamauchi and Huang, 1977; Maidment and Parzen, 1984; Maidment and Miaou, 1985; Zhou et al., 2002). As a result, it is well known that spatially aggregated water use can be expressed as the sum of a long-memory or deterministic component and a short-memory or stochastic component. Maidment and

(a) Cumulated volumes (b) Hourly intensities

Figure 1: Sample plots of cumulated volumes and hourly water use rates.

Parzen (1984) define a long-memory time series as one with trends, or periodicities, or very slowly decaying correlations, or very low frequency cycles, or spectral densities with very large dynamic range. The authors also define a short-memory time series as being stationary with an invertible infinite autoregressive scheme representation.

A time series of aggregated water demand is the sequence $X_t = \{X_1, X_2, \ldots\}$ where X represents an aggregated water usage rate and the subscript represents hourly time intervals. The series of observations $x_t = \{x_1, x_2, \ldots, x_n\}$ is regarded as a measured sample realization of the time series X_t or, for simplicity, the data set. The long-memory component of X_t consists of a trend T_t and a seasonal component S_t. On the other hand, the short-memory constituent of X_t can be represented by a residual series Y_t. Thus, the time series X_t is given by

$$X_t = T_t + S_t + Y_t \tag{1}$$

A methodology to find the estimates $\hat{T}_t$, $\hat{S}_t$ and $\hat{Y}_t$, given the availability of the hourly water usage data x_t, is presented in this paper as detailed by the algorithm of Figure 2. The tasks involved and the methods used in every step are explained below.

Trend

The trend in water use time series is caused by several factors, such as household income, water price, number of water connections, and population. Long time series of monthly water demand are likely to show a growing trend that can be modeled by regressing mean annual water use against trend-causing variables (Maidment and Parzen, 1984). Such approach cannot be applied in this study due to the small temporal scale used. Therefore, the trend is considered as the fluctuation of the mean in the data series, produced mainly by sudden changes in population; it is thus estimated by applying the moving average filter (Brockwell and Davis, 2002):

$$\hat{T}_t = \frac{1}{2a+1} \sum_{i=-a}^{a} x_{t+i} \tag{2}$$

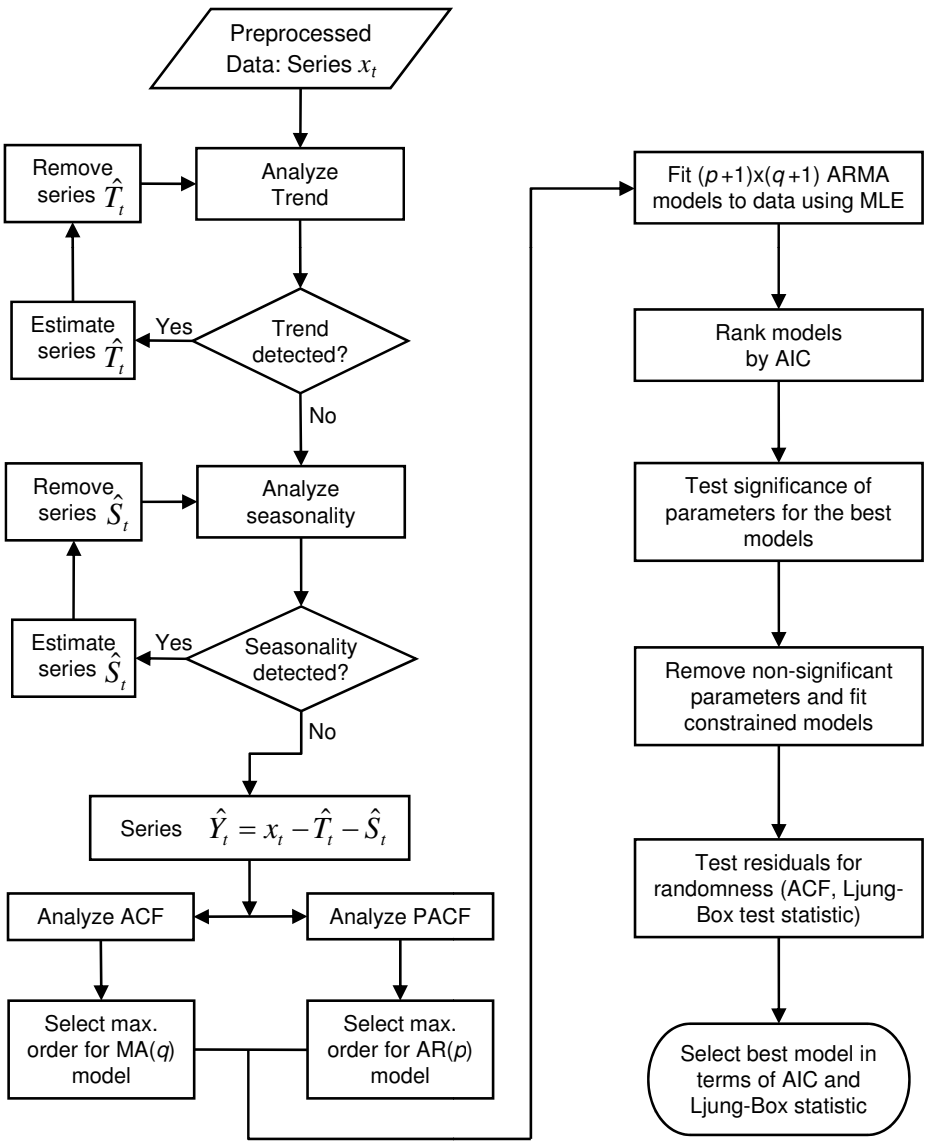


Figure 2: Algorithm for modeling hourly water demand time series.

where $\hat{T}_t$ is the estimated trend at time $t = 1, \ldots, n$, a is a nonnegative integer, and n is the sample size. Therefore, the trend in a time series at a given period τ is represented by its average over the period $t = \tau - a$ to $t = \tau + a$. The larger a the more data values are averaged and the smoother the trend.

Seasonality

Four methods are available for eliminating a seasonal cycle in a detrended water use series: form d-th differences of data (Box and Jenkins, 1976), where d is the estimated period; form an autoregressive model of the detrended series whose coefficients reflect seasonality; regress the series against a seasonal variable such as maximum air temperature; subtract the arithmetic or Fourier-fitted seasonal means. The last method is generally more effective in removing the seasonal cycle in water use and, specifically, the subtraction of Fourier-fitted means produces results that are more physically interpretable and offers an objective basis for determining the significance of seasonal cycles (Maidment and Parzen, 1984). The estimated seasonal series $\hat{S}_t$ expressed as a Fourier series is

$$\hat{S}_t = \alpha_0 + \sum_{m=1}^{M} \left[\alpha_m \cos \frac{2\pi m}{d_m} t + \beta_m \sin \frac{2\pi m}{d_m} t \right] \tag{3}$$

where M is the number of significant harmonics in the series, α_0, α_m and β_m are unknown parameters, and d_m is the period of the mth harmonic. The periods d_m are estimated by inverting the frequency values of the significant peaks in the periodogram (Brockwell and Davis, 2002)

$$I_n(w_k) = \frac{1}{n} \left| \sum_{t=1}^{n} (x_t - \hat{T}_t) e^{-itw_k} \right|^2 \tag{4}$$

where $w_k = 2\pi k/n$, $k = -[(n-1)/2], \ldots, [n/2]$ ($[y]$ denotes the largest integer less than or equal to y), $i = \sqrt{-1}$.

Stationary Model

The detrended and deseasonalized data series is assumed to be a stationary series $\hat{Y}_t$ that can be modeled as an ARMA(p, q) process of the form

$$\phi(B) Y_t = \theta(B) Z_t \tag{5}$$

where $\phi(B)$ and $\theta(B)$ are, respectively, the autoregressive and moving average polynomials of the model, given by

$$\begin{aligned} \phi(B) &= 1 - \phi_1 B - \ldots - \phi_p B^p, \\ \theta(B) &= 1 + \theta_1 B + \ldots + \theta_q B^q, \end{aligned}$$

p and q are, respectively, the autoregressive and moving average orders of the model, B is the backward shift operator ($B^jY_t = Y_{t-j}, B^jZ_t = Z_{t-j}$), $\phi_1, \ldots, \phi_p$ are the autoregressive parameters, $\theta_1, \ldots, \theta_q$ are the moving average parameters, and $\{Z_t\}$ is the white noise, i.e., a normally distributed random variable with mean of 0 and standard deviation σ^2.

The ARMA modeling stage starts by analyzing the Autocorrelation function (ACF) and Partial Autocorrelation Function (PACF) of the transformed data. Given the set of observations $\{x_1, \ldots, x_n\}$ of a time series, the sample autocovariance function is

$$\hat{\gamma}(h) = \frac{1}{n}\sum_{t=1}^{n-|h|}(x_{t+|h|} - \bar{x})(x_t - \bar{x}), \quad -n < h < n \tag{6}$$

where $\bar{x}$ is the sample mean of $x_1, \ldots, x_n$ and h is the time lag. The sample ACF is

$$\hat{\rho}(h) = \frac{\hat{\gamma}(h)}{\hat{\gamma}(0)}, \quad -n < h < n \tag{7}$$

The sample PACF of the same set of observations $\{x_1, \ldots, x_n\}$ with $x_i \neq x_j$, for some i and j, is given by

$$\begin{aligned} \hat{\alpha}(0) &= 1 \\ \hat{\alpha}(h) &= \hat{\phi}_{hh}, \quad h \geq 1, \end{aligned}$$

where $\hat{\phi}_{hh}$ is the last component of the vector of estimated autoregressive parameters

$$\hat{\boldsymbol{\phi}}_h = \hat{\boldsymbol{\Gamma}}_h^{-1}\hat{\boldsymbol{\gamma}}_h \tag{8}$$

where $\hat{\boldsymbol{\Gamma}}_h$ is the sample covariance matrix given by

$$\hat{\boldsymbol{\Gamma}}_h = \begin{bmatrix} \hat{\gamma}(0) & \hat{\gamma}(1) & \ldots & \hat{\gamma}(h-1) \\ \hat{\gamma}(1) & \hat{\gamma}(0) & \ldots & \hat{\gamma}(h-2) \\ \vdots & \vdots & & \vdots \\ \hat{\gamma}(h-1) & \hat{\gamma}(h-2) & \ldots & \hat{\gamma}(0) \end{bmatrix} \tag{9}$$

and $\hat{\boldsymbol{\gamma}}_h = [\hat{\gamma}(1), \hat{\gamma}(2), \ldots, \hat{\gamma}(h)]'$.

Information provided by the ACF and PACF will be used to select the maximum orders p_m and q_m for the autoregressive and moving average components of the ARMA models. The total number of alternative models to be estimated is given by the product $(p_m+1)\times(q_m+1)$. This provides a starting point from which a selection of appropriate values for orders p and q can be attempted.

It is not advantageous from a forecasting point of view to choose p and q arbitrarily large, because the mean squared error of the predictive demand model will depend not only on the white noise variance of the fitted model, but also on errors arising from estimation of the parameters of the model (Brockwell and Davis, 2002). It is therefore necessary to use a criterion based on penalty factors that discourage the fitting of models with too many parameters.

The criterion used here is the Akaike Information Criterion (AIC) (Akaike, 1973), defined as

$$\text{AIC}(\boldsymbol{\beta}) = -2\ln L_X(\boldsymbol{\beta}, S_X(\boldsymbol{\beta})/n) + 2(p+q+1) \tag{10}$$

where $\boldsymbol{\beta} = (\phi_1, \ldots, \phi_p, \theta_1, \ldots, \theta_q)'$, $L_X(\cdot)$ is the Gaussian Likelihood, and $S_X(\cdot)$ is a function of the mean squared errors of the forecasts.

A subset of the total number of preliminary ARMA models will be thus selected using the AIC as the ranking criterion. From that, the significance of the parameters of the selected models is tested, and the nonsignificant parameters are removed. Then, the remaining parameters are "fine tuned" using constrained Maximum Likelihood Estimation.

Finally, the goodness of fit of the remaining models are assessed through the analysis of residuals, which are the rescaled one-step prediction errors,

$$\hat{W}_t = \frac{Y_t - \hat{Y}_t}{\sqrt{r_{t-1}}} \tag{11}$$

where $\hat{Y}_t$ is the best linear mean-square predictor of Y_t based on the observations up to time $t-1$, $r_{t-1} = E(Y_t - \hat{Y}_t)^2/\sigma^2$ and σ^2 is the white noise variance of the fitted model.

The randomness of the residuals $\hat{W}_t$ is tested using the residual ACF $\hat{\rho}_w$ (defined in Equation 7) and the Ljung-Box portmanteau test. By the former, if the sequence of estimated residuals $\hat{w}_1, \ldots, \hat{w}_n$ is a realization of an independent and identically distributed (iid) sequence, about 95% of the residual autocorrelations should fall between the bounds $\pm 1.96/\sqrt{n}$. By the latter, a single statistic is considered:

$$Q_{LB} = n(n+2)\sum_{j=1}^{h} \frac{\hat{\rho}_w^2(j)}{n-j} \tag{12}$$

If $\hat{w}_1, \ldots, \hat{w}_n$ is a finite variance iid sequence, then Q_{LB} is approximately distributed as the sum of squares of the independent N(0,1) random variables $\sqrt{n}\hat{\rho}_w(j), j = 1, \ldots, h$, i.e., as chi-squared with h degrees of freedom. A large value of Q_{LB} suggests that the residual autocorrelations are too large for the residuals to be a sample from an iid sequence. Therefore, the iid hypothesis is rejected at level α if $Q_{LB} > \chi^2_{1-\alpha}(h)$, where $\chi^2_{1-\alpha}(h)$ is the $1-\alpha$ quantile of the chi-squared distribution with h degrees of freedom.

Results and Discussion

This section presents the analysis of a sample data set by means of the methodology illustrated in Figure 2. The data comprises one month of hourly water usage rates from randomly selected ISAs located in one of the areas being monitored in Hamilton County, Ohio.

Sample Analysis

Figure 3 presents the data sample, which was obtained by aggregating hourly usage rates, in L/min, from 10 randomly selected ISAs monitored during the month of October 2008. As shown in Figure 4(a), the series does not exhibit a noticeable trend having

an approximately constant mean of 0.6679 L/min. The variance and the standard deviation of the series are, respectively, 0.1649 $(\text{L/min})^2$, and 0.4061 (L/min).

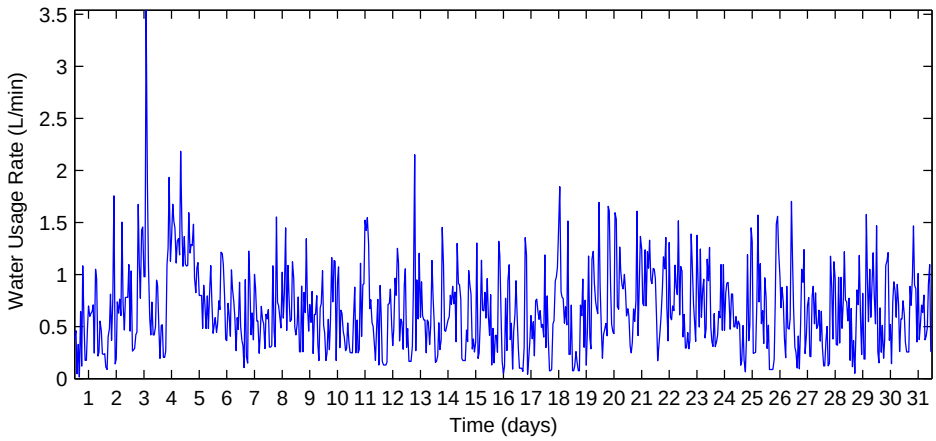

Figure 3: Data

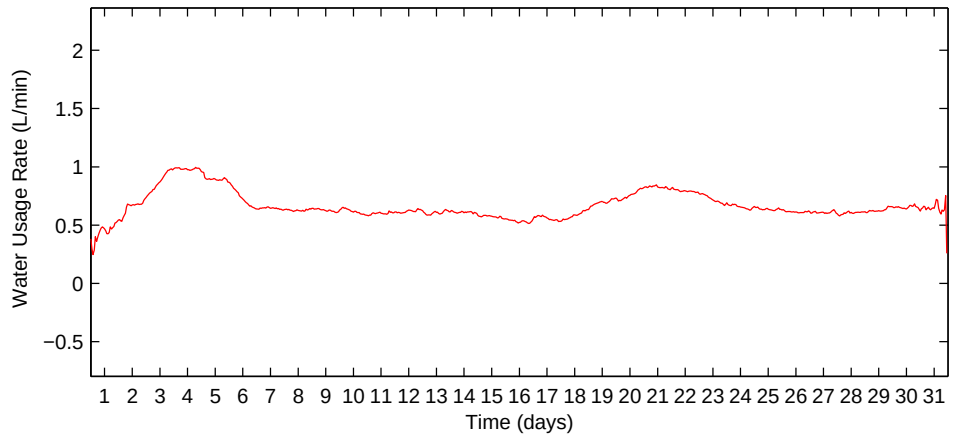
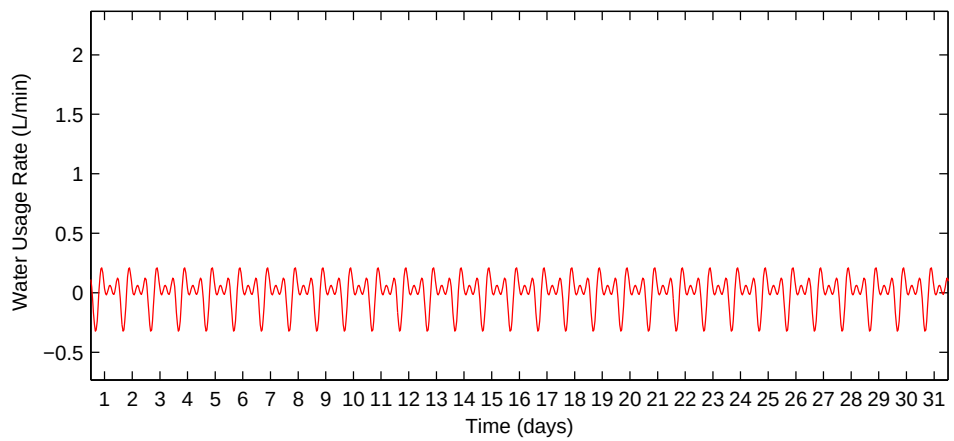


The selection of a in Equation 2 is based on obtaining a smooth series that shows the mean variation of the original series in time. Sudden changes in the level of the trend indicate events that affect the first-order stationarity of the series, such as a considerable increase or decrease in the number of water consumers in the sampled ISAs. A value $a = 36$ was adopted to estimate the moving average trend shown in Figure 4(a). It accounts for 8.28% of the total variance in the data.

To estimate the seasonal cycle in the detrended water use series, first, the periodicity in the series is determined through spectral analysis. Equation 4 is used to estimate the periodogram at frequencies w_k. The inversion of the frequencies of the periodogram allows the determination of periods of the dominant cycles in the series, as illustrated by Figure 5. It should be noted that long term seasonal variation is not being captured by the spectral analysis, given that only one month of data was used.



Three periods are dominant in Figure 5: $d_1 = 24$, $d_2 = 12$ and $d_3 = 8$, therefore three harmonics are considered in Equation 3. The values of parameters in the Fourier series are determined through least squares estimation, and the resulting seasonal model is

$$\begin{aligned} S_t &= 0.00048 - 0.06291\cos\frac{\pi}{12}t - 0.0665\sin\frac{\pi}{12}t \\ &\quad +0.07321\cos\frac{\pi}{6}t - 0.1117\sin\frac{\pi}{6}t \\ &\quad +0.1006\cos\frac{\pi}{4}t + 0.03963\sin\frac{\pi}{4}t \end{aligned} \tag{13}$$

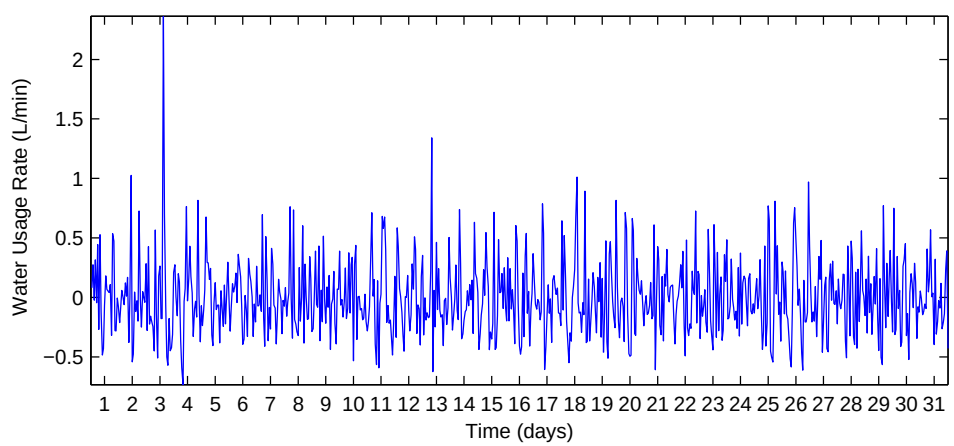


Figure 4(b) illustrates the seasonal model as given by Equation (13). It can be noted that a full cycle of three harmonics in the series is completed after 24 h. The detrended, deseasonalized time series $\hat{Y}_t$ is produced by subtracting $\hat{S}_t$ from the detrended series.

(a) Trend component.

(b) Seasonal series.

(c) Residual or short-memory series.

Figure 4: Different components of the data series.

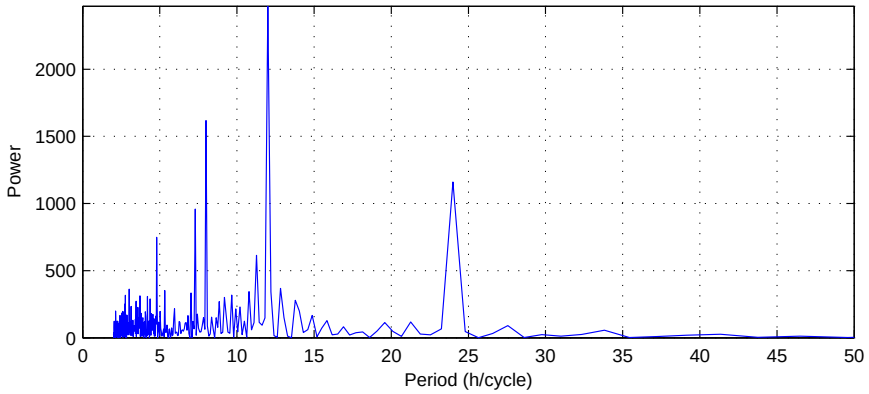

Figure 5: Plot of power of the series vs. period.

As shown in Figure 4(c), this short-memory series oscillates arbitrarily about a zero origin with no apparent trend or seasonal variation. The estimated seasonal component accounts for 11.51% of the original variance.

After transforming the data as described above, the fit of ARMA models to the residual series $\hat{Y}_t$ is attempted. The process starts by calculating and then observing the sample ACF and PACF of Figure 6, where the largest lags with PACF and ACF outside of the 95% confidence interval bounds are, respectively, 22 and 17. Therefore, those are the maximum orders of the autoregressive and moving average components, respectively, of the preliminary time series models to be compared. Thus, the procedure consists in fitting $23 \times 18 = 414$ models, and then selecting only those with the smallest AIC. Fitting is performed by a maximum likelihood estimation method that minimizes the model prediction errors when computing the parameter estimates. Several models were selected, ranked by AIC, and the 5 with the best AIC value were kept for the final selection stage, based on analysis of residuals. The AIC values computed for the 414 models had an average of -2.278, ranging between -2.403 and -1.171. Table 1 summarizes the information about the 5 preliminary models that were selected. The column named *significant lags* indicates the indexes of the model parameters that were found to be significant at 5% level. Values of AIC and estimated error variance presented in the table were computed for the models with all parameters, i.e., before setting the non-significant parameter values to zero.

The models in Table 1 were refined through constrained fitting and their estimated errors were analyzed by statistically testing the hypothesis that the residuals are independent and identically distributed. The tools used in this task are the ACF of the residuals and the Ljung-Box test statistic (Equation 12). This is the final stage in the algorithm of Figure 2 and is intended to lead to the selection of a single best ARMA model to fit the residual series $\hat{Y}_t$. Table 2 presents a comparison of the models in terms of the aforementioned statistics.

It can be noted in Table 2 that the models with largest number of parameters did not pass the test of randomness, having p-values smaller than 0.05. The remaining

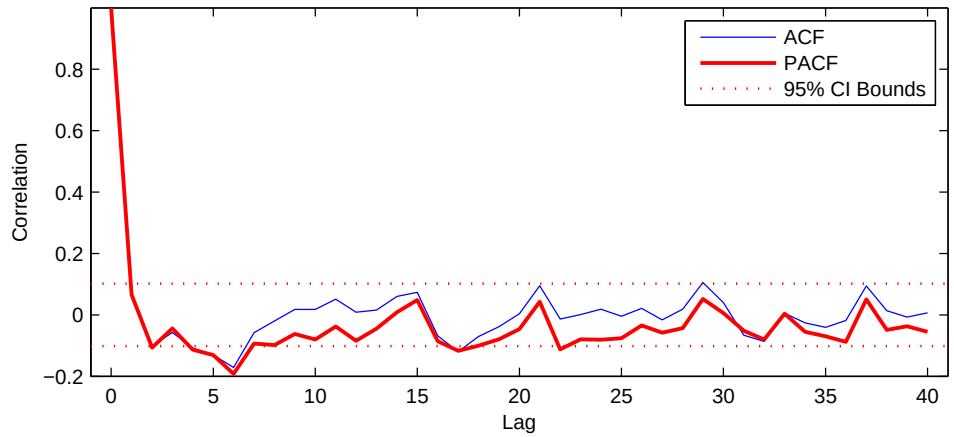

Figure 6: Sample ACF and PACF of the residual or short-memory series.

Table 1: Preliminary ARMA models

Model	Significant Lags		AIC	Error
	AR	MA		Variance
ARMA(22,15)	2, 5, 7, 9, 11, 13, 15, 16	6, 7, 8, 9, 10, 15	-2.403	0.0731
ARMA(12,7)	1, 2, 4, 5, 6, 12	1, 2, 3, 4, 5, 6	-2.385	0.0778
ARMA(8,12)	1, 2, 4, 5, 6, 7, 8	1, 2, 6, 7, 8, 9	-2.380	0.0787
ARMA(0,6)		2, 3, 4, 6	-2.380	0.0837
ARMA(11,11)	1, 4, 5, 7, 10, 11	1, 3, 4, 5, 7, 10	-2.370	0.0785

Table 2: Comparison of refined models

Model	AIC	Error	Analysis of Residuals		
		Variance	Uncorr.	Q_{LB}	p-value
ARMA(22,15)	-2.171	0.0898	90.32%	52.58	0.00009
ARMA(12,7)	-2.288	0.0821	93.55%	20.71	0.4144
ARMA(8,12)	-2.306	0.0806	93.55%	20.29	0.4399
ARMA(0,6)	-2.330	0.0829	93.55%	23.60	0.2603
ARMA(11,11)	-2.299	0.0875	91.13%	32.55	0.0377

models did not pass the criteria of uncorrelated residuals, having less than 95% of ACF values within the confidence interval bounds. This evidences the iterative nature of the selection process and poses a problem that may be solved by going one step backwards, i.e., restituting parameters in the models. The final selection is guided by the AIC, hence the model with smaller AIC, which is an ARMA(0,6), recovers its original parameters and is tested again for residual randomness. The final model passes all the criteria, having AIC, error variance, percentage of uncorrelated residuals, Q_{LB}, and p-value, equal to, respectively, -2.352, 0.0837, 95.16%, 17.61, 0.6129. The structure of the model, including parameter uncertainties is as follows

$$\begin{aligned} Y_t &= 1 - 0.06733(\pm 0.0519)Z_{t-1} - 0.2311(\pm 0.05173)Z_{t-2} \\ &\quad -0.1493(\pm 0.05228)Z_{t-3} - 0.1808(\pm 0.05234)Z_{t-4} \\ &\quad -0.1258(\pm 0.05194)Z_{t-5} - 0.1651(\pm 0.05232)Z_{t-6} \end{aligned} \tag{14}$$

where $Z \sim$ N(0,0.0837). As a result of the methodology used, an ARMA model, which accomplishes imposed statistical conditions was identified. As explained above, the trend and the seasonality account for, respectively, 8.28% and 11.51% of the variance in the original data set. On the other hand, the stochastic model accounts for 29.94% and the residuals represent the remaining 50.27% of the total variance. Such large value is not surprising in an aggregation of 10 hourly water usage series, given the large sources of uncertainty in demand behavior.

Conclusions

A modeling approach for hourly aggregated urban water demand data is presented which identifies the structure of a time series by passing it through a series of filters. Each filter estimates the parameters of an equation describing one property of the time series so that it can be transformed by removing that property. The final result of the transformations is a random error series. The properties identified are trend (related simply to the moving average of the time series), seasonality, and autocorrelation. In the future, the procedure is to be applied to a large ensemble of aggregated data from individual service accounts that are being monitored in Hamilton County, OH.

The concept of partitioning a time series into trend, seasonal, and short-memory components is classical. However, the determination of seasonal periods in the deterministic component of the data series as well as the selection of suitable ARMA models for the stochastic component of the series makes use of tools in a novel manner. The tool used in determining the periods in the series is the periodogram at inverted frequencies. For the stochastic component, the tools are statistics that assess accuracy and parsimony (AIC), as well as randomness in the residuals (ACF and Ljung-Box test statistic).

A sample dataset is analyzed using the methodology proposed and the different stages involved are explained along with the partial and final results. The main advantage of the methodology is that it allows one to explore the suitability of a large number of alternative stochastic models in a systematic fashion, and to select one or

more that best represent the residual (detrended and deseasonalized) series. A limitation of the methodology presented is that the filters which remove trend and seasonality ensure first-order stationarity, but not second-order stationarity. These two conditions are required to validate the assumption that the residual time series is generated by an ARMA process. Additional transformations can be introduced to address this limitation, but they require a comprehensible way to test when they need to be applied.

The advantage mentioned above is to be exploited in the future analysis of a large number of spatially aggregated water demand data sets. Thus, the methodology is to be applied in exploring the suitability of ARMA models to residual time series obtained from different schemes of aggregation. The authors expect to obtain relationships of model orders and levels of aggregation, by grouping ISAs either randomly or by geographic and demographic category. In the analysis of the complete data set, the main goal will therefore be to use the methodology to explore how the spatial aggregation schemes affect the variance in the water demand time series and thus understand how ISAs can be aggregated to reduce such variance.

Abstract
The adoption of a broadly stated sustainability framework as the basis for the Overflow Control Plan (OCP) in Kansas City, Missouri is both extraordinary, and reflective of the community's commitment to become America's Green Region. The plan positions the city's wet weather program as a tool to catalyze more integrated water resource management at the neighborhood and watershed scales, and as a strategic initiative that supports sustainable development efforts at the metropolitan scale.

Introduction

The adoption of a broadly stated sustainability framework as the basis for the Overflow Control Plan (OCP) in Kansas City, Missouri is both extraordinary, and reflective of the community's commitment to become America's Green Region. The plan positions the city's wet weather program as a tool to catalyze more integrated water resource management at the neighborhood and watershed scales, and as a strategic initiative that supports sustainable development efforts at the metropolitan scale.

In this plan, water resource management becomes embedded within a larger context of community (re-) development, such that public infrastructure investments support and reinforce achievement of broad community goals and visions. Many of these goals are articulated in related efforts associated with climate protection, growth and development, land use, transportation, housing, parks and greenways, energy, air quality, urban forestry and agriculture.

Metropolitan and Community vision

Seven leading governmental, civic and not-for-profit organizations jointly and formally adopted a goal for the greater Kansas City area to become America's Green Region. A broad community vision seeks to "*create and support a sustainable region that increases the vitality of our society, economy, and environment for current residents and future generations.*"

Similarly, the OCP is rooted in this strong vision, and in the following three guiding principles:

- *Water is a precious resource*. Recognition that water is an asset, not a liability, requires a transition from the conventional practice of collect, convey and discharge to one that manages water resources in ways that maximize community, environmental and economic benefits.
- *Integrated, systems thinking*. Understanding water resource management from a watershed perspective requires integrated, systems thinking. This means approaching problem-solving in a holistic manner, integrating not only multiple disciplines into the decision-making process, but also considering the

interconnectivity of built and natural systems, including energy and material efficiency, and by-product synergies.
- *Adaptive management*. Adaptive management integrates, design, implementation, management and monitoring to systematically test assumptions, learn from results and adapt future plans throughout implementation.

An Adaptive Management Approach

An adaptive management approach frames the Overflow Control Plan. This approach enables the city to minimize risk and uncertainty associated with the performance, acceptability and cost of the various plan components. The plan is founded upon a holistic, watershed perspective to controlling sewer overflows, which will result in more complete, cost-effective solutions that involve watershed stakeholders from various jurisdictions throughout the planning and management process.

As part of the adaptive approach, the OCP focuses on first repairing the existing system, reducing inflow and infiltration and measuring the potential of green infrastructure. Completing these activities early in the program allows for monitoring, modeling and measurement, focused evaluation of program results, and the flexibility to adapt the plan before constructing more expensive structural controls.

An adaptive management program requires rigorous evaluation metrics across the spectrum of social, economic, environmental and regulatory concerns. System-level metrics will address not only the number and volume of combined sewer overflows, but also co-benefits related to air quality, public health, community redevelopment, heat island abatement, education, and energy. Related program-level performance indicators, aligned with long term goals, will help guide shorter term program design and pilot project implementation efforts.

Similarly, appropriate organizational feedback mechanisms will be critical to review program effectiveness, and guide future activity. An organization that is open and receptive to change is necessary to learn from and adapt to changing circumstances.

Integrated planning and design

A sustainable vision for each neighborhood is rooted in an understanding that all aspects of community living will be served better in the future when infrastructure and community assets are integrated to optimize the efficiencies inherent in associated economies of scale and multiple-use programs.

Hawken, Lovins and Lovins characterized elements of sustainable systems in their work, *Natural Capitalism*:

- One is likely to make a system less efficient simply by not properly linking and synchronizing components or tactics
- Optimizing components or tactics in isolation can pessimize the effectiveness or efficiencies of others.

- If components or tactics are not designed to work with one another, they will tend to work against one another.

Broad thinking about sustainability and integrated planning and design suggests consideration of broader principles to guide the implementation of the OCP. These include aspirations to:

- integrate rainwater as a resource, where it falls, in the community.
- secure outdoor venues in which children can play and develop empathy for other living things; in which they can discover that almost all things in nature cannot ever be wholly understood, enhancing awe, wonder and humility.
- secure opportunities for all children to participate in an educational system that preserves their in-born love of learning.
- re-establish mechanisms for authentic, mature, wise elders to be available to children and young people, and to participate meaningfully in community life.
- reconnect with the love and appreciation for beauty in our built environments through a return to local craftsmanship and a renewed appreciation for quality and locally resourced materials. That which is well made is beautiful, that which is beautiful is loved and endures.
- Add beauty and vitality to the community. Sustainable design must be functional *and* beautiful.

The mechanics of an integrated approach

Implementation of a more integrated planning process in Kansas City will be tested through initial pilot projects. Planning processes will likely involve many different elements, from community education and engagement to design charettes or other community-based mechanisms. All relevant public and private stakeholders would be involved. Planning activities would be structured to:

- build neighborhood and community support and partnerships
- create the basis for integrative planning
- identify innovative sustainable design strategies, and
- demonstrate the effectiveness of a participatory planning process.

The institutionalization of green design will require heightened levels of interdepartmental collaboration. Standard engineering drawings and materials will be reviewed and adapted so that water is properly managed for every infrastructure project. Performance standards for water management will be applied to all projects with the goal of updating the city to meet modern water management standards. Even accounting and procurement standards and procedures may need to be adapted to properly account for life cycle benefits and multiple non-project purpose benefits such as social, community development and educational benefits.

From a process standpoint, integration among programs, departments, jurisdictions, and regulatory agencies is imperative. Two significant areas with substantial unrealized opportunity are the integration of stormwater and wastewater programs

in ways that also consider needs for water supply, and the integration of water resource planning with broader city capital investment programs. Opportunities for distributed management and treatment systems for wastewater as well as stormwater will be evaluated. In each area, strong opportunities appear to exist to achieve increased efficiency, impact and financial leverage.

At the regional scale, an integrated Blue River Watershed Management Plan will represent a bi-state, comprehensive effort to improve water quality in the 270 square mile watershed. It is exactly the kind of overarching approach that will be required to significantly reduce structural controls within the plan.

Green infrastructure pilots and partnerships

The plan includes substantial resources to develop large scale, green infrastructure pilots and partnerships in the combined sewer basins. Pilot projects will focus on incorporating and evaluating green infrastructure as part of the proposed basin specific solutions. Green infrastructure partnerships will concentrate on creating private sector participation in both the pilots and final basin solutions.

Pilots will facilitate establishment of standard design, cost, construction and maintenance criteria, as well as create the opportunity to measure the social, economic and environmental impacts of green infrastructure on the neighborhood and community.

The City's first pilot project will occur in the Marlborough neighborhood. The plan includes replacement of two previously proposed underground storage tanks with widespread green infrastructure throughout this 744 acre section of the Middle Blue River Basin. This project will include, in total, approximately 330 catch basin retrofits and nearly 25 acres of rain gardens, bioswales, green roofs and pervious pavement, representing an unprecedented commitment to green infrastructure.

Additional pilot projects will be identified for each primary land use/watershed condition. These projects will provide opportunities to model the full array of innovative, sustainability-oriented program elements that, if successful, may then be applied elsewhere over the long term. These elements would include:

i) development of strong community and public/private partnerships to support plan implementation;
ii) testing and evaluation of alternative incentive programs;
iii) social marketing and community education to support incorporation of water management (e.g. rain garden installation, downspout disconnects and incentives for private participation) on private properties;
iv) design, construction and evaluation of sustainable design strategies;
v) integrated, interdepartmental planning;
vi) creation of green collar jobs and training programs;
vii) development of effective sub-watershed scale models to assess the cumulative impacts of individual design strategies; and

viii) development of specific program and project level performance metrics related to performance goals to serve as a benchmark for future program evaluation.

Early pilot projects create extraordinary opportunities for the community to build new partnerships in support of the regulatory plan and the community vision. Every dollar spent by the city will strive to leverage additional resources. During the course of the proposed 25 year plan, one might expect private investment in re-development to outpace public infrastructure investment by orders of magnitude. Multiple opportunities exist to leverage private investment through creative partnerships with neighborhood, community, civic and development interests. A mix of regulatory approaches (e.g. green development standards), incentives (e.g. discounted utility rates), compliance assistance (e.g. technical assistance) and other mechanisms can facilitate the creation of durable partnerships. Further, contracts might be structured to maximize the creation of local green collar jobs to support planning, education, design, construction and maintenance responsibilities.

Green collar jobs and workforce development

The City's $2.4 billion investment in Kansas City's sewer infrastructure presents significant economic opportunities for local businesses and residents. The plan will support job creation and work force development organizations in the development and implementation of training programs, including a green collar jobs program.

Development of green collar jobs, embedded within community workforce development, job training and green economic development strategies, are strongly recommended as an implementation vehicle for green solutions in the Long Term Control Plan. This approach would simultaneously create jobs within economically distressed communities, build community support for neighborhood scale solutions, address ongoing concerns about green infrastructure maintenance, and catalyze ancillary aesthetic and community development benefits.

Public education and civic engagement

Opportunities for shared learning, whether within city hall or with community partners, will be integral to the overall program. Education may be formal or informal, professional or public, in person or virtual, primary or university level, classroom or field-based. This program will engage diverse constituencies through a range of formats. Greatest emphasis, however, will be placed on creation of experiential, outdoor learning opportunities for children at the primary and secondary levels. Such learning may take place in varied settings, such as green jobs program, summer, church or scout programs. Appropriate investment in the community's children will guarantee the long term program success. Emphasis also will be placed on building the local economy through opportunities such as urban agriculture, urban arts and craftsmanship, and distributed wastewater and stormwater systems management.

Civic engagement, public participation and community education will be married in general outreach efforts. The City will engage neighborhood associations, businesses, civic groups, non-profit entities, universities and citizens in a public dialogue designed to throughout the life of the plan. Extraordinary opportunities exist to expand Kansas City's award winning 10,000 Rain Gardens campaign as part of roust social marketing efforts designed to downspout disconnects and green infrastructure development on private land.

Conclusion

The Kansas City, Missouri effort is buoyed by high aspirations, broad community and political support, and growing scientific consensus about the effectiveness of green infrastructure in meeting prescribed regulatory goals. Substantial work has been undertaken to link community visions with program goals; to integrate community and regional planning efforts; and, to build institutional capacity to achieve an ambitious set of goals. Within that context, the city's adaptive approach is structured to begin implementation of a complex plan in ways that are both programmatic and strategic.

A Level Spreader - Vegetated Buffer System for Urban Stormwater Management

Ryan J. Winston, E.I.[1] and William F. Hunt, P.E., Ph.D.[2]

[1] Department of Biological and Agricultural Engineering, North Carolina State University, Box 7625, Raleigh, NC 27695, rjwinsto@ncsu.edu.
[2] Department of Biological and Agricultural Engineering, North Carolina State University, Box 7625, Raleigh, NC 27695, wfhunt@ncsu.edu.

Abstract. Vegetated filter strips (VFS) have been used to remove pollutants from contributing agricultural watersheds for decades. In order to improve effectiveness of vegetated buffers, level spreaders have been employed to distribute flow evenly across the length of the upstream end of the buffer. In North Carolina, level spreader- VFS systems are now gaining acceptance as a stormwater BMP for urbanized watersheds, as it promotes infiltration and reduces impervious surfaces, two tenets of Low Impact Development. A field study of four level spreader – vegetated filter strip systems was conducted at two urban watersheds in Louisburg and Apex, NC. At each site, stormwater was routed proportionately over two 13 ft long level spreaders, one draining to a 25 ft wide grassed buffer, the other to a 50 ft wide, half grassed, half forested buffer. Flow rates and flow volumes were measured at the inlet and outlets of the system. Composite, flow-weighted water quality samples were collected at the inlet and outlet of the system and analyzed for TKN, NO_3+NO_2, TN, NH_3, TP, Orthophosphate, and TSS. The buffers promoted infiltration, which resulted in a substantial decrease in flow volume and peak flow rate between the inlet and outlet of the system. To date, 46 storm events have been monitored for hydrology in Louisburg, NC. Flow volume was reduced by an average of 83% and 80% for the 25 ft and 50 ft wide buffers, respectively. These buffers also reduced peak flow rate by an average of 86% and 83%, respectively. These results show that a level spreader – vegetated filter strip system can effectively reduce the hydrologic impacts of impervious surfaces. Water quality monitoring has been ongoing since March, 2008, with 19 and 20 storms monitored for Apex and Louisburg, respectively. Reductions in event mean concentrations for all buffer treatments occurred for TKN, TN, and TSS, while the other pollutants studied had mixed results. Because of the large reduction in volume due to infiltration, these BMPs provide a large reduction in mass of pollutants. The median percent mass removal for the Louisburg buffers was greater than 74% for all but one water quality constituent studied. A level spreader is relatively (1) easy to install, (2) inexpensive, and (3) requires little maintenance. Carefully selected and designed level spreader – vegetated buffer systems can be an effective method of controlling stormwater flow and its associated pollutants in small urban watersheds.

Keywords. level spreader, buffer, filter strip, stormwater, LID, urban, bmps, best management practices

Introduction

Urbanization of agricultural and forested landscapes across the U.S. is occurring rapidly, often leading to environmental degradation. Construction leads to a large decrease in permeability. In turn, this causes a decrease in the ability of stormwater to infiltrate or evapotranspire, resulting in increased runoff volumes and peak flow rates. Flow enters water bodies and can cause impairment in water quality in urban streams, lakes, and estuaries. In order to ameliorate these issues, engineers and land use planners have designed and implemented Low Impact Development (LID) practices. Common LID practices include bioretention areas, cisterns (water harvesting), permeable pavement, vegetated swales, decentralized stormwater management, clustered site layouts, disconnected downspouts and reduction of impervious areas. LID practices employ a number of mechanisms to improve water quality and reduce runoff before it enters water bodies. The main purpose of these practices is to reduce runoff volumes to pre-development benchmarks. Ancillary goals of these practices include: removal of pollutants common to urban stormwater, including nitrogen, phosphorous, oil and grease, sediment, bacteria, heavy metals, and thermal pollution and improvements in urban hydrology, including mitigation of peak flows and time to peak.

An LID practice/stormwater BMP that is being used in the state of North Carolina is the level spreader - vegetated buffer system (LS-VBS). The term "level spreader" was first described by Smolen et al. (1988) as "a non-erosive outlet for concentrated runoff constructed to disperse flow uniformly across a slope." A level spreader is designed to receive upslope pipe flow, and create downslope diffuse flow through a vegetated buffer (Hathaway and Hunt, 2008). Design requirements for level spreaders have been produced in several states (IDEQ, 1998; MDEP, 2003; NC DENR, 2007), but past research on their effectiveness is inconclusive and inadequate.

Level spreaders were initially used to disperse runoff from drainage ditches through forested filter zones (FFZ). Runoff from these fields contains high concentrations of nitrogen and phosphorous derived from fertilizers. In an early study of a LS-FFZ system in Granville County, North Carolina (Franklin et al., 1992), stormwater was routed from a planted agricultural field through an unspecified length of wooden level spreader. Stormwater was recollected downslope of the forested filter zone in a wooden flume, with water quality and flow rate measured at the inlet and outlet of the LS-FFZ system. Twenty nine storm events were monitored between October 1989 and July 1990. It was determined that a level spreader-forested filter zone system was effective in reducing concentrations of NH_3-N (75%), TP (32%) and TSS (47%) between the inlet of the level spreader and the outlet of the forested filter zone. Another benefit was that a 36% reduction in flow volume was observed between the inlet and outlet of the LS-FFZ. So, on a mass basis, reduction in pollutants would have been much greater than reported above.

Two quantitative studies on urban water quality and the use of level spreaders can be readily obtained from the literature. The first was completed at a shopping center in Virginia. It involved studying a level spreader-grassed buffer system and its effects

on water quality (Yu et al., 1993). The level spreader in this study was 170 m long and was sized to convey 1.02 m^3/s over the spreader lip. Eight storm events during March-June of 1987 were sampled at three locations: the outlet of the watershed, at the level spreader, and at the outlet of the buffer. The removal efficiency of the level spreader-grassed buffer system was calculated using percent mass removal, with the following efficiencies: TSS, 54-84%; NO_3+NO_2, (27)-20%; TP, 25-40%; Pb, (16)-50%; and Zn, 47-55%, with terms in parentheses representing addition of pollutant. The authors concluded that the low removal efficiencies for NO_3+NO_2-N may be attributable to erosion downslope of the level spreader, and that dense grass cover was not established during the study. The authors also suggested that sedimentation and filtration were the primary methods for solids and metals removal in a vegetated filter strip, while adsorption, precipitation, and plant uptake were likely the means of nutrient removal. This study has three major conclusions: first, the LS-VBS was effective in removal of particulate pollutants such as TSS, but was not as effective at removal of soluble pollutants such as nitrate-nitrite N; second, removal efficiency for all pollutants increased as vegetated buffer width increases; finally, the LS-VBS was at least as cost effective at removal of common stormwater pollutants as a wet pond (Yu et al., 1993).

Another study of a level spreader-vegetated buffer system was conducted in Johnston County, North Carolina, near the intersection of NC 42 and I-40 (Line and Hunt, 2009). Stormwater runoff was collected primarily from the highway (0.35 ha watershed) and conveyed through a vegetated channel to a level spreader 7.3 m in length. Buffer width was 17 m. Reductions in flow volume of 49% were observed, which led to high rates of nutrient, metals, and solids removal. Mass removal efficiencies for the level spreader-grassed buffer system were as follows: 70% total suspended solids, 11% NO_3+NO_2, 36% ammonia nitrogen, 17% total Kjeldahl nitrogen, and an 11% increase in total phosphorous.

The three articles above offer a summary of level spreader-vegetated buffer system performance. For ease of comparison, the following two tables summarize experimental design and results for the three studies. The first table is a summary of level spreader and vegetated buffer characteristics, along with other experimental design parameters of importance to the water quality and hydrology results from each study (Table 1).

Table 1: Summary of LS Research
(Adapted from authors listed in table)

Author	Year Published	Level Spreader Material	Vegetated Buffer Type	Method of Removal Efficiency Calculation	Slope of Buffer (%)	# of Events	Land Use
Franklin et al.	1992	Wooden Trough	Forested (mixed pine-hardwood)	Concentration	4	29	Agricultural
Yu et al.	1993	Concrete	Kentucky 31 Grass	Concentration	6	8	Urban
Line and	In press	Concrete	Bermudagrass	Concentration and	5.2	14	Urban

Hunt				Summation of Loads			

An important note from Table 1 is that urban level spreader studies have been completed on grassed buffers only. Past research has not been documented on level spreader-wooded buffers in an urban setting. Table 2 summarizes the results for pollutant removal. For comparison, the buffer width and the percent of runoff volume reduction are included for each system:

Site Descriptions

Two level spreader research sites are currently being monitored in the Piedmont region of North Carolina, where soils are characterized by moderate clay contents. The sites are located in Apex and Louisburg, NC in two of the largest and most urbanized river basins in the state. Each site watershed is approximately 0.40 ha (1 ac) in drainage area, with 89% and 70% imperviousness, respectively, at the Apex and Louisburg sites. Prior to BMP construction, both watersheds drained to curb cuts. Stormwater was then allowed to flow into grassy areas, and eventually to ephemeral streams. Sites were surveyed extensively, and designs were created for two level spreaders at each site. Each level spreader is 3.96 m (13 ft) in length, and was constructed level across its length, in order to aid in dispersal of flow across the length of the buffer. Construction of the BMPs was completed in January 2008, and monitoring of the sites has been ongoing since March 2008.

At each site, incoming flow from the watershed is conveyed from the curb cuts into a forebay to settle out solids and remove trash and debris from the system. Two inlet pipes are used to convey flow proportionally from the forebay to two swales, constructed 9 inches deep. During a storm event, the stage of the water increases until the forebay and swales fill, at which point water flows over the level spreaders, and into one of the vegetated buffers. The buffers differ in width and vegetation type; the first is a 7.6 m wide grassed buffer, and the second is a 15.2 m wide buffer, which is one-half grassed and one-half wooded. This setup is repeated at both experimental sites. Figure 1 shows the level spreaders and associated monitoring equipment in Apex, North Carolina.

After the water passes through the buffer, the remaining surface flow is recollected in a trough downslope of the level spreader. Flow then passes from the trough to a weir box, and then discharges through a drainage pipe offsite. This setup can be seen in Figure 1, and is repeated four times, once for each of the level spreaders.

Figure 1. Level Spreader, Recollection Trough, and Weir Box.

Soil conditions contribute to the functioning of this LID practice, since it is almost solely dependent on infiltration as the volume reduction mechanism. The soils at both the Apex and Louisburg sites are classified as sandy loam. However, there is a tight clayey confining layer at a depth of 60 cm in Apex, which creates a saturated lens during wet periods.

Materials and Methods

Monitoring was conducted at both sites to effectively measure the impacts of a level spreader - vegetated buffer system on water quantity and quality. Hydrology monitoring occurred at four points at each site, using a total of eight ISCO 730 bubbler flow meters. At the inlet, stage measurements were taken in each of the 15 cm (6") diameter inlet pipes on a two minute interval, using ISCO 730 bubbler flow meters. Calculation of flow rates for the inlet was completed using Manning's equation for flow in round pipes, as given below in equation 1. A Manning's n value of 0.01 was used, as is typical for PVC pipes (Fangmeier et al., 2006).

$$Q=A*R^{2/3}*S^{1/2}/n \qquad [1]$$

Outlet hydrology was monitored downslope of the vegetated buffer. Following the initial abstraction, infiltration, and evapotranspiration in the buffer, the remaining flow was intercepted in a triangular cross section wooden trough. Flow was conveyed to one end of the trough, where it entered a weir box. A 30° V-notch weir was used in each weir box, in combination with an ISCO 730 bubbler flow module. The flow module recorded stage measurements at a two minute interval. Flow rates at the outlet were calculated using the standard stage discharge relationship for a 30° V-notch weir, given below in equation 2:

$$Q=0.676*H^{2.5} \quad [2]$$

Following the calculation of flow rates, inlet and outlet flow volumes were calculated by integration of the hydrograph.

Water quality samples were taken from three locations at each site, in order to quantify concentration reductions for each buffer width. During this study, samples were analyzed for the following parameters: Total Kjeldahl Nitrogen (TKN), nitrate-nitrite nitrogen (NO_3+NO_2), total nitrogen (TN), ammonia nitrogen (NH_3N), total phosphorous (TP), orthophosphate (ortho-P), and total suspended solids (TSS). A total of six ISCO 6712 water quality samplers were used to take composite, flow proportional water quality samples during storm events. The inlet sample intake at each site was located in the center of the forebay. The two outlet sample intakes at each site were located in the weir boxes, upstream of each 30° V-notch weir. The inlet water quality samples were used as a baseline for all comparisons, as they represented untreated stormwater runoff.

Hydrology Results

Monitoring has been ongoing at both the Louisburg and Apex, NC sites since March 2008. In Louisburg, forty-six storm events large enough to create inflow have been monitored. Due to minor equipment failures, all of those storm events were not captured for the two buffer lengths. Thirty-one storm events with precipitation depth <1.25 cm, seven events between 1.25 cm and 2.5 cm, and eight events >2.5 cm have been monitored. Median rainfall depth was 0.74 cm, with lower and upper extremes of 0.1 cm and 6.55 cm, respectively. Initial hydrologic results for this site are very promising (Figure 2). For both the 7.6 m buffer and the 15.2 m buffer, percent volume reduction and percent peak flow reduction appear to be correlated to the size of the rainfall event. As precipitation depth increases, the effectiveness of the level spreader - vegetated buffer system decreases. For storm events less than 1.25 cm, this system infiltrates most of the flow volume produced, resulting in >85% volume and peak flow reduction. However, general trends indicate that as rainfall depth increases, volume reduction and peak flow reduction decrease. Therefore, a level spreader - vegetated buffer system may prove more beneficial during events with smaller precipitation depths, similar to the conclusion of Li et al. (2009) for bioretention areas.

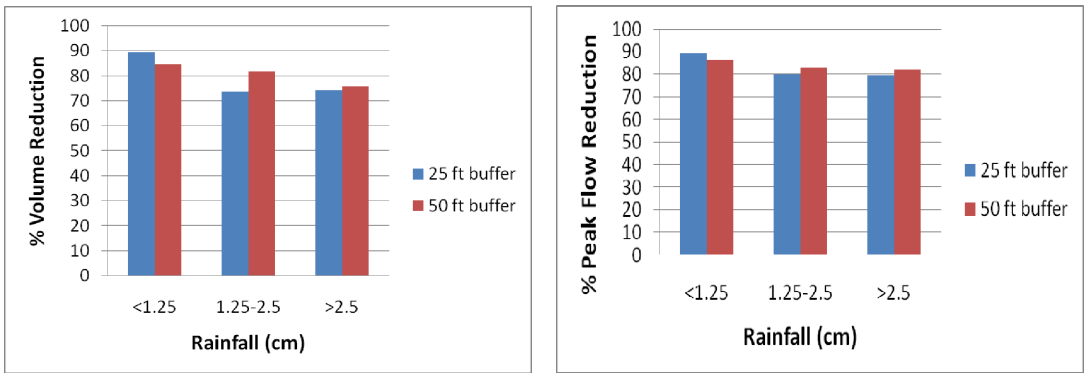

Figure 2. Preliminary Hydrology for Louisburg, NC Site.

At the Apex site, forty-three storm events large enough to create inflow have been monitored. However, accurate hydrology measurements at the site have been difficult to obtain. The slope from the inlet to the outlet of the system is very small (<4%), and this led to a small slope on the inlet pipes (where inlet hydrology is measured). During high intensity portions of the hydrograph, backwater is conveyed from the level spreaders up the inlet pipes, and stormwater is ponded above the bubbler. Because of this, the bubbler gives false readings, since Manning's equation assumes free flow in a pipe. Therefore, inlet hydrology results for the Apex site are not valid. An attempt at creating a rating curve of flow rate versus depth will be made by using area-velocity meters.

Water Quality Results

Monitoring for the water quality portion of this study has been ongoing since March 2008. For a water quality event to occur, a minimum of 0.5 cm of rainfall must occur. Therefore, many of the storm events analyzed above in the hydrology section were not large enough to be considered a "water quality event." In Apex, a total of 19 water quality events have been monitored, while 20 storms have been captured in Louisburg. Median concentration reductions between the inlet and outlet of each buffer can be seen in Figure 3:

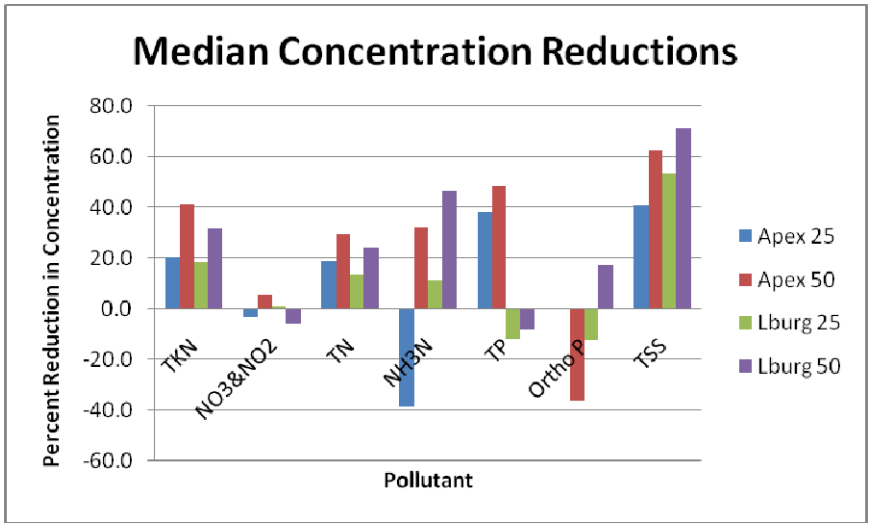

Figure 3. Percent Removal Results.

The terms "25" and "50" refer to the width of the buffer, that is, the 7.6 m (25 ft) buffer the 15.2 m (50 ft) buffer. TKN concentration reductions between 20-40% were seen in each of the buffers studied. However, these systems may be exporting organic nitrogen, since TKN removal rates are generally lower than those for NH_3-N. Nitrate-nitrite nitrogen is a highly soluble nutrient that does not adsorb to sediment due to its negative charge. Since the primary treatment in vegetated buffers is sedimentation, the lack of NO_3-NO_2 nitrogen removal in Figure 3 is logical. Total phosphorus results are mixed. This is disconcerting since TP is most often sediment sorbed, and TSS removal is observed in all four buffers. However, the median inlet TP concentration in Louisburg is 0.13 mg/L, well below the median TP concentration of 1.46 mg/L reported by Frink (1991) for urban runoff. The ortho-P results in Apex may be disregarded, as the inlet ortho-P concentrations are below laboratory detection limits. Removal of ortho-P in Louisburg is mixed, with an increasing width apparently producing greater removal. For TSS, all four buffers perform very well, removing 40-70% of TSS on a concentration basis. In both cases, the 15.2 m (50 ft) buffers removed 20% more sediment than the 7.6 m (25 ft) buffers. Similar results were reported in Robinson et al. (1996), where a 3 m buffer removed 70% of sediment and a 9.1 m buffer removed 85% of sediment.

As shown above, this LID practice is capable of removing sediment-sorbed pollutants on a concentration basis. As shown in Figure 4, this practice can have a large impact on water quality when mass removal of pollutants is considered. This is done by taking into account both the concentration of pollutant and flow volume removed from the system.

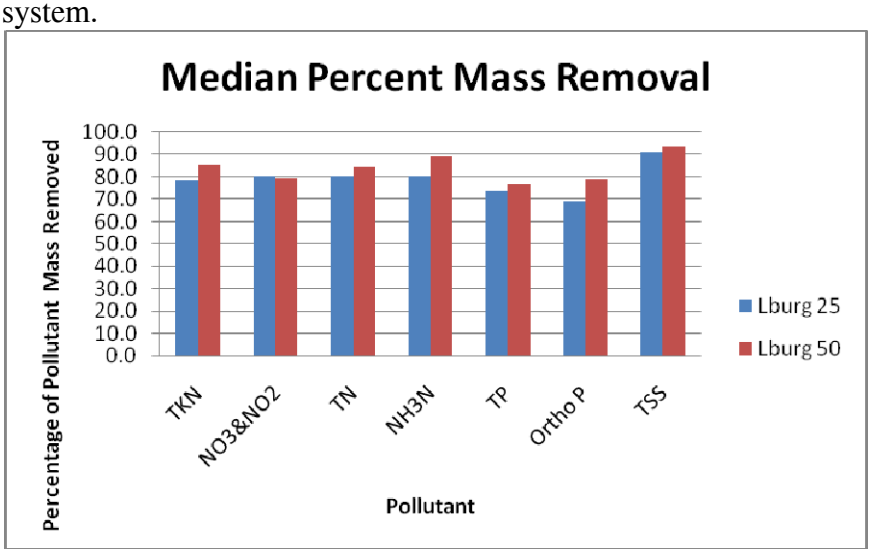

Figure 4. Median Percent Removal Results.

For all pollutants at the Louisburg site, reductions in mass of 68-90% were observed. This is due primarily to the large volume reductions in both buffers of >70%. In every case except $NO_{2\text{-}3}$-N, the wider buffer reduces the mass of pollutant to a greater extent. Overall, the results summarized above are very promising, and show that this system can be used to effectively remove pollutants on a mass basis before they enter downstream rivers, lakes, or estuaries.

Conclusion

Results indicate that level spreader - vegetated buffer systems may perform well in urbanized areas, allowing for greater infiltration, evapotranspiration, and groundwater recharge. Hydrology results show that this BMP performs better during storms with smaller rainfall depths. Water quality results also show promise for reduction in concentration of TKN, TN, TP, and TSS. Load basis calculation of water quality shows between 68-90% reduction in mass across the system.

Preliminary results show that a level spreader - vegetated buffer system can provide substantial peak flow reduction. During small storm events, peak flows were reduced by an order of magnitude. This shows another benefit of this LID practice beyond the traditional volume reductions.

Preliminary results show that a level spreader - vegetated buffer system is a viable LID practice for the management of urban stormwater runoff. In certain situations, level spreaders may be a cost effective method to reduce flow volumes, peak flow rates, and improve water quality in urbanized watersheds. The added green space required for the filter strip is an additional benefit of this practice. Maintenance and construction of these systems is very simple. Level spreader – vegetated filter strips are poised to become one of the most popular stormwater treatment devices in North Carolina.

A NEW METHODOLOGY TO EVALUATE POLLUTANT REMOVAL OF GROSS SOLIDS SEPARATION DEVICES

D. P. Smith[1]

[1]Applied Environmental Technology, 10809 Cedar Cove Drive, Tampa, FL 33592; PH (813) 864-5735; email: dpsmith_aet@verizon.net

ABSTRACT

Gross Solids are a set of stormwater components that includes large organic and inorganic materials, litter and trash, and relatively large suspended sediments. A common characteristic of *Gross Solids* is that they are not fully accounted for in BMP monitoring protocols that employ only automatic sampling devices for collection of water column samples. A methodology is presented that provides a quantitative framework for incorporating *Gross Solids* into estimates of the pollutant removal effectiveness of *Gross Solids Separation Devices*. Illustration of the methodology using monitoring data for a full scale Nutrient Separating Baffle Box demonstrates the significance of including *Gross Solids* in estimates of pollutant removal effectiveness. The resulting performance analysis would not be possible using traditional monitoring approaches.

BACKGROUND

Structural Best Management Practices are widely applied for stormwater treatment, but assessing their actual performance is a continuing challenge. Of particular concern is a set of materials that includes large organic and inorganic materials, litter and trash, and coarser stormwater solids. The term *Gross Solids* has been adopted to encompass these materials, which share a common characteristic of not being fully accounted for in typical BMP monitoring protocols that employ automatic sampling devices. A Technical Committee of the EWRI Urban Water Resources Research Council has developed monitoring guidance to assess the ability of treatment devices to remove *Gross Solids* pollutants in stormwater (EWRI, 2007). To rationally incorporate *Gross Solids* pollutants into stormwater and BMP monitoring, practical sampling and analyses protocols must be developed and applied.

METHODS

The Florida Department of Environmental Protection sponsored a monitoring study of a full scale "Nutrient Separating Baffle Box" (aka NSBB) located in Rockledge, Florida. The NSBB is a structural BMP made of concrete or fiberglass

that contains a series of settling chambers separated by baffles (Fig. 1). NSBB are generally deployed as an in-line device in the stormwater

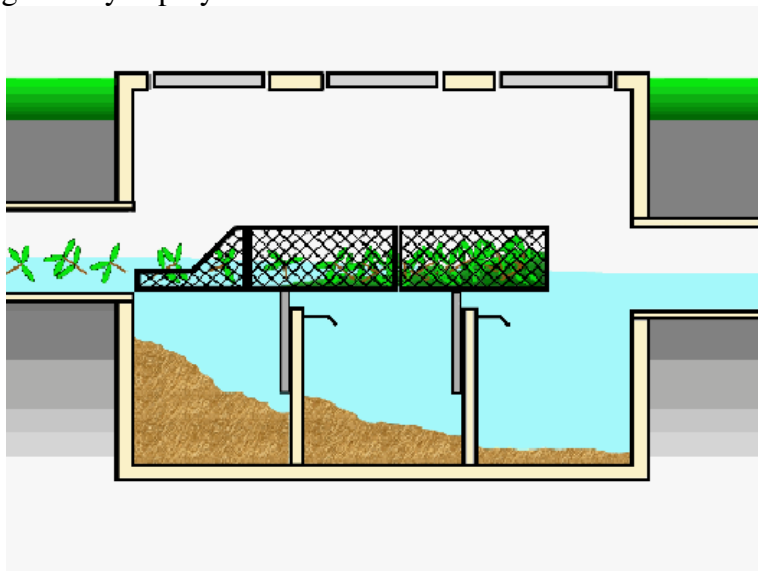

Fig. 1 Nutrient Separating Baffle Box schematic.

conveyance system. Baffle boxes remove stormwater solids that occur as sediment particles suspended in the water column and as larger solids that move by ablation along the bottom of stormwater pipes. The ability to remove suspended sediment solids is related to the settling velocity of solids and stormwater flowrate applied to the baffle box.

The NSBB-type baffle box contains a screen basket located above the bottom chamber baffles with ½ to ¾ in. openings that collect larger floating and suspended materials, including leaves, pine needles, and natural and human derived trash and debris (Fig. 2). Material captured in the NSBB screen is held above the surface of the water column in interevent periods, thus reducing the potential for leaching into the water column and enhancing the opportunity to dry. Material that is captured and retained by the screens can form a mat on the screen surface, which can then remove smaller stormwater particles that would otherwise pass through the screen openings.

Fig. 2 Nutrient Separating Baffle Box screen.

The Rockledge NSBB had a 49 ft^2 plan area (9.8 ft. x 5ft) with 3.5 ft. tall baffles. The NSBB treated stormwater runoff from a 10.6 acre area of predominantly single family residential land use before it discharged into the Indian River Lagoon. The Florida Department of Environmental Protection monitoring protocols for best management practices (BMPs) that require the collection of flow-composited influent and effluent samples for seven to ten storm events (Sutron et al. 2006). The accumulation of sediment in bottom chambers and gross solids in screen baskets occur during storm events, but monitoring of these *Gross Solids* components on a storm event basis would be problematic if not totally impractical. The Rockledge NSBB monitoring program was designed to facilitate a combination of water column and *Gross Solids* pollutant removals by maintaining a temporal linkage between the stormwater event measurements and the discreet Gross Solids cleanouts. Just prior to the start of the test period, the Lincoln baffle box was totally cleaned by removal of all materials deposited in the bottom chambers and all of the contents in the screen basket. The test period was started (t_{zero}) by activating the continuous flowrate acquisition and flowrate-based autosampler collection programs. A Doppler flowmeter provided instantaneous flowrate measurements which were recorded at 5 min. intervals throughout the project duration and used to initiate composite influent and effluent sampling. The methodology required that records be maintained for all removals of *Gross Solids* during the time period corresponding to that of the water column storm event measurements. Cleanout of bottom chambers and screen basket at the end of the operating period (t_{final}) would provide the cumulative removal for mass or volume of *Gross Solids* components.

REMOVAL EFFECTIVENESS

Monitoring of the Rockledge NSBB was initiated on 11/12/2006. All materials accumulated in the bottom chambers and screen basket were removed at the start of monitoring. This paper reports results for the period from start to 11/6/2007 when all accumulated materials were again removed from bottom chamber and screen basket. Continuous flowrate monitoring was conducted throughout the 359 time period, during which a total volume of 1.52 million gallons passed through the baffle box.

Water quality was monitored during seven individual storm events by autosampler collection of flow composited samples from influent and effluent pipes. The average TSS EMC reduction efficiency was moderate (range of -40 to 68%). Average EMC reductions were negative for nitrogen, phosphorus and fecal coliform, indicating net export during monitored storm events (Table 1).

For each bottom chamber the volume of accumulated material was quantified using the chamber cross sectional area and multiple depth measurements. A single sediment sample was assembled for physical and chemical testing characterization by combining sediment subsamples from each chamber in volume-weighted portions. Sediment data are shown in Table 2.

Table 1 Water column EMCs

Constituent	Average $EMC_{influent}$	Average $EMC_{effluent}$	Average % Reduction
Total Suspended Solids, mg/L	50.0	40.1	17.8
Total Nitrogen, mg/L	2.19	2.10	-11.5
Total Phosphorus, mg/L	0.58	0.58	-6.7
Fecal coliform, cfu/100 ml	39,320	89,800	-285

Table 2 Properties of material removed from bottom chambers

Sediment Property	Value
Dry mass removed, lbs.	1280
Bulk density (dry), g/cc	0.69
Water content, %	49.1
Organic matter, %	12.6
Total N, mg/kg	2,310
Total P, mg/kg	247

Material removed from the basket screen was collected, placed in plastic bags, and weighed in an as-received condition. The total mass of material removed from the basket screens was 2724 lbs. over the 359 day period. Screen basket

material collected in the last cleanout was subject to further analysis after weighing. The material was partially air dried and representative subsamples were assembled into a composite screen basket sample. The composite sample was size separated by sieving through a 1 mm nylon screen. Physical measurements and chemical analyses were conducted on each of the two size fractions (Table 3).

Table 3 Properties of material removed from basket screen

Property	Total	> 1 mm	< 1 mm
Wet mass removed, lbs.	**531**		
% Water	**51.6**		
Dry mass, lbs	257.3	106.2	151.0
% Organic Matter	47.88	73.30	30.00
Total N, mg/kg	593	482	670
Total P, mg/kg	834	755	890
Total N, mg/kg OM	1,584	658	2,235
Total P, mg/kg OM	2,167	1,030	2,967

Mass removals were calculated for water column storm events, chamber sediment, and basket screen material. Water column mass removal was estimated by summing mass removal for the monitored storm events and scaling up to the total volume that passed through the baffle box during the study period. The mass removal from each storm was calculated using the flow weighted pollutant concentrations (Event Mean Concentrations) in inlet and outlet and cumulative volume treated:

$$\text{Water Column Removal} = \sum_{i=1,n} \text{Volume}_i \, (\text{EMC}_{\text{inf}_i} - \text{EMC}_{\text{eff}_i})$$

Mass removals of stormwater pollutants in *Gross Solids* were calculated as the product of the accumulated bulk volume of the *Gross Solids* component times its

dry bulk density (i.e. mass *Gross Solids* removed over the study period), times the pollutant concentration (mass pollutant per dry weight solids):

$$\text{Sediment Removal} = \text{Volume}_{sediment} * p_{bulk,\ sediment} * C_{sediment}$$

$$\text{Screen Removal} = \text{Volume}_{screen} * p_{bulk,\ screen} * C_{screen}$$

Mass removal of solids, nitrogen and phosphorus are shown in Table 4. Solids removal in both chamber sediment and basket screen were much higher than in water column, and solids removal in the water column was only 3% of that in *Gross Solids* components. *Gross Solids* nutrient removals were greater than water column removals, which were negative for both nitrogen and phosphorus. Similar calculations are shown in Table 5 for four heavy metals. *Gross Solids* removals exceed those of water column for three of the four metals. The mass removal results using the calculation methodology illustrate that an overall assessment of pollutant removal effectiveness must include the contribution of *Gross Solids* accumulations within the NSBB. Traditional monitoring approaches that include only autosampler-based water column data would not include the *Gross Solids* contributions.

Table 4 Mass removals of solids and nutrients in water column and *Gross Solids* (lbs.)

Constituent	Chamber Sediment	Screen Material		Total Chamber + Screen	Water Column
		> 1 mm	< 1 mm		
Solids	1,280	841	1,196	3,317	98
Total Nitrogen	2.96	0.41	0.80	4.16	-0.77
Total Phosphorus	0.32	0.64	1.06	2.02	-0.08

Table 5 Mass removals of metals in water column and *Gross Solids* (gram)

Constituent	Chamber Sediment	Screen Material		Total Chamber + Screen	Water Column
		> 1 mm	< 1 mm		
Cadmium	0.02	0.25	0.26	0.53	2.04
Chromium	2.67	172	9.8	184	-0.47
Copper	4.75	16.0	19.6	40.3	-2.89
Zinc	34.0	81.4	100	215	58.2

CONCLUSIONS

A methodology was developed to quantify the removal of *Gross Solids* pollutants in stormwater and applied to a full scale Nutrient Separating Baffle Box. It was found that pollutant removal in *Gross Solids* components captured in the NSBB greatly exceeded water column removals calculated with autosampler-based EMCs. The results suggest that pollutant removal estimates for NSBB based solely on water column EMCs are scientifically inadequate. If anything, water column removal efficiencies should be relegated to a lesser status that *Gross Solids* accumulations in bottom chambers and screen basket. The results appear to reflect the inadequacy of water column autosamplers to capture influent pollutants that did in fact accumulate within the Rockledge NSBB. The evaluative framework and results of this study are applicable pollutant removal evaluations of other *Gross Solids Separation Devices*, which share with NSBB a limited water retention time and a primary function of *Gross Solids* removal. Attention should be directed to developing improved protocols for sampling, processing and analysis of *Gross Solids* that can lead to accepted quantitative estimates of pollutant load reduction.

ABSTRACT

Raw sewage discharges from Combined Sewer Overflows(CSO's) during rainfall can severely impact drinking water quality. Drinking water risk assessment studies in the past have not adequately captured the event driven temporal fluctuations in source water quality. This is despite the knowledge that fecal contamination of source waters is impacted by rainfall and long-term accumulated risks are affected by event driven concentration peaks. This paper presents a simple methodology to estimate the enteric pathogen loadings into the receiving water as a result of combined sewer overflows. The proposed methodology is more suitable for risk assessment studies to formulate policies for public health protection.

1 INTRODUCTION

Enteric viruses are widely reported to be a major cause of non bacterial gastroenteritis resulting in acute diarrhea. About 23 million cases of infection are reported every year in the US alone (Mead et al. (1999)). Enteric viruses, which are shed in faeces of infected individual are of concern in drinking water because of their resistance to environmental stress and disinfection. High concentrations of enteric viruses have been reported in raw and treated sewage (Lodder and de Roda Husman (2005); Lodder et al. (1999)). Some studies also indicated a relationship between a contaminated water source and disease outbreaks (Anderson et al. (2001); Brown et al. (2001)). Rainfall resulting in overflows in combined sewer networks increase the enteric pathogen loading into the receiving water used as drinking water sources. A portion of the public health risk from exposure to drinking water enteric pathogens is thus likely to be event-driven, episodic, and difficult to measure or assess.

Quantitative Microbial Risk Assessment (QMRA) has emerged as a tool to assess the impact of microbial contamination of drinking water on public health. Drinking water QMRA studies in the past (Masago et al. (2006); Westrell et al. (2003)) have not adequately captured the event driven temporal fluctuations in source water quality, despite the knowledge that fecal contamination of source waters is impacted by rainfall and long-term accumulated risks are affected by event driven concentration peaks (Westrell et al. (2006)). This work presents a methodology to estimate the enteric pathogen loadings to source water, incorporating events that are assumed to drive exposure variability.

2 PATHOGEN SOURCE MODELING

Combined sewers are designed to carry both sanitary sewage as well as runoff occurring in a watershed area. During the periods of low flow these deliver the sanitary sewage to the waste water treatment plants. In periods of rainfall, due to limited capacity of conveyance structures and treatment plants, some of the flow is directly discharged into the receiving water through combined sewer overflows(CSO's). These wet weather overflow discharges containing untreated sewage result in pathogen loading into receiving waters. Rodriguez (2007) reported that the concentration of enteric viruses was increased by almost 10 times during overflow events as compared to dry weather.

To model enteric pathogen loading into source water it is assumed that pathogen loading is entirely due to upstream contamination from treated and untreated sewage. Figure 1 illustrates the pathway for source water contamination by enteric viruses. To estimate the time series of pathogen concentrations in source waters a rainfall/runoff driven model is proposed. A simulation of sewer overflow discharges driven by historical precipitation data or synthetic design rain storms, superimposed on pathogen concentration in raw sewage, generates a time series of pathogen concentrations in source water. Detailed sewer network models can be used to predict overflow discharges in combined sewers resulting from rainfall events, using standard hydrodynamic calculations and software such as the EPA Storm Water Management Model (SWMM). Such an approach is, however, data and computationally intensive, particularly for long-term continuous simulation. This renders such an approach practically difficult for QMRA, and precluding useful computational statistics techniques such as Markov Chain Monte Carlo (MCMC) sampling, which can fuse exposure models with data. A simple, phenomenological, "grey-box" modeling approach is proposed here instead to translate precipitation into overflow volumes.

2.1 Combined Sewer Overflow (CSO) model

The simple grey box model to predict combined sewer overflows consists of a hydrological module and a sewer module (Figure 2), described below.

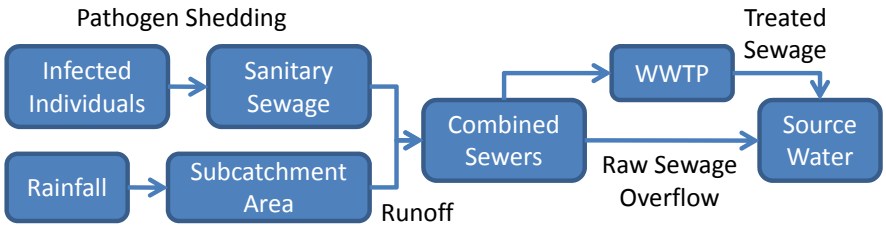

Figure 1: Source water contamination pathway.

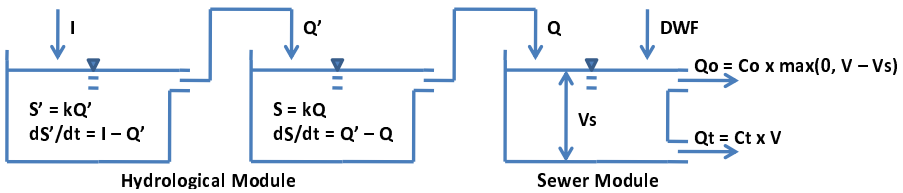

Figure 2: Simplified Grey-Box Model to estimate combined sewer overflows

2.1.1 Hydrological Module

The purpose of the hydrological module is to convert the rainfall falling over an urbanized catchment area into runoff that enters the combined sewer network through roof drain connections and catch basins.

Some amount of initial rainfall will be lost before the runoff occurs. This is accounted for by depression storage or loss potential parameter, L for subcatchment area i. Depression storage for impervious surfaces ranges between 0.05 - 0.1 inches (Rossman (2008)). The loss potential is assumed to recover during the dry period between rainfall events, with complete recovery after an elasped time, R^i with no rainfall. The amount of runoff generated depends on the subcatchment properties. Combining the continuity equations for two reservoirs in series, the subcatchment is conceptualized as a double linear reservoir by the following equation (Ruan and Wiggers (1998)).

$$k^2 \frac{dQ^2}{dt^2} + k\frac{dQ}{dt} + Q = I \times A_z \tag{1}$$

where, Q is runoff generated from the subcatchment area, I is effective rainfall intensity calculated from rain intensity after taking L and R into account, A_z is the impervious area of the subcatchment (assuming that only the impervious area contributes to runoff), and k is the lag coefficient or the concentration time of the subcatchment. The value of k depends upon the subcatchment properties and the storm characteristics. It represents the time lag between the peak rainfall intensity and the peak runoff discharge.
The above second degree ODE can be solved by using a two state space model (The Mathworks Inc. (2007)).

2.1.2 Sewer Module

Simplified sewer reservoir models have been used in the past to predict overflow discharges in large sewer networks. Ruan and Wiggers (1998) developed a model called Sewsim for predicting overflow discharges. Vaes and Berlamont (1999) used a physically based procedure to calibrate parameters for a multi linear sewer reservoir model. Runoff generated from the hydrological module plus the dry weather sanitary sewage flow is used as input into the sewer module. The sewer network is idealized as a reservoir (Figure 2) with an orifice regulating outflow to the treatment plant, Q_t. When the volume in the reservoir exceeds a threshold V_s, an overflow (Q_o) occurs with magnitude given by a weir relationship. Flow continuity for the sewer reservoir yields

$$\frac{dV}{dt} = Q - C_t \times V - C_o \times \max(0, V - V_s) \tag{2}$$

where V is volume in the reservoir, Q is the inflow into the sewer network, and C_t and C_o are lumped discharge coefficients for the fictitious orifice and weir, whose discharges have been simplified as linear functions of hydraulic head or volume.

The above sewer module is a gross simplification of the complex hydrodynamic processes occurring in a sewer network, but it is hoped that such a model can adequately represent the statistics of CSO events, while providing a flexible and more transparent approach for generating synthetic pathogen time series needed for QMRA methodology. The model was applied to a variety of test cases utilizing typical design rainfall storms as well as continuous rainfall input.

2.1.3 Model Calibration

The three parameters of the sewer module (C_t, C_o, V_s) are calibrated using the overflow discharge time series from a hydrodynamic SWMM simulation of a sewer network driven by a precipitation series. A direct search optimization procedure (Hooke and Jeeves (1961)), is used to obtain a least square estimate of the parameters. The objective function used in the calibration procedure is given by the following equation:

$$Z(C_t, C_o, V_s) = \alpha \times \sum_{i \in I_0} Q_i^2 + (1 - \alpha) \times \sum_{i \in I_1} (Q_i - Q_i^S)^2 \tag{3}$$

where, Q_i and Q_i^S are the discharges predicted at the time step i by the model and SWMM respectively, I_0 and I_1 are sets of time step indexes defined as $Q_i^S = 0 \; \forall \; i \in I_0$ and $Q_i^S \neq 0 \; \forall \; i \in I_1$, and α is a weighting coefficient : $0 < \alpha \leq 1$.

The optimization procedure has been tested using a grid optimization procedure to ensure that the least square estimates of the parameters are indeed the true estimates. The estimates of two parameters (keeping the third parameter constant) found using the Hookes-Jeeves algorithm have been found to be in agreement with those obtained from the grid optimization procedure.

2.2 Enteric Pathogen Concentration

The CSO model will be combined with simple statistical models of enteric pathogen concentrations in raw domestic sewage, and attenuation in a surface water environment to estimate the CSO enteric pathogen loadings to receiving waters and the enteric pathogen concentration at a drinking water intake. For estimating the raw sewage concentrations, environmental data on enteric pathogen occurrence in raw sewage from published sources will be used. The pathogen concentration will be adjusted for expected seasonal variability. Preliminary work in this regard has been done by Jeff Soller (Soller (2008)) as part of USEPA Star Grant Project under which the current work is being carried out. CSO enteric pathogen concentrations will be diluted from the dry weather flow concentrations using a simple dilution factor based on CSO overflow discharges.

$$C_s = \frac{Q_d \times C_d}{Q} \tag{4}$$

where, Q_d and C_d are the dry weather flow and pathogen concentration respectively, C_s is the diluted pathogen concentration in sewage after mixing with runoff.

For dilution calculations the overflow discharge Q_o will be assumed negligible in comparison to the discharge in the receiving water body, Q_R. The pathogen concentration in surface water due to overflow at the point of discharge (outfall) i, C_R can be calculated on the basis of mass continuity.

$$C_R = \frac{Q_o \times C_s}{Q_R + Q_o} = (\frac{Q_o}{Q_R}) \times (\frac{Q_d}{Q}) \times C_d \tag{5}$$

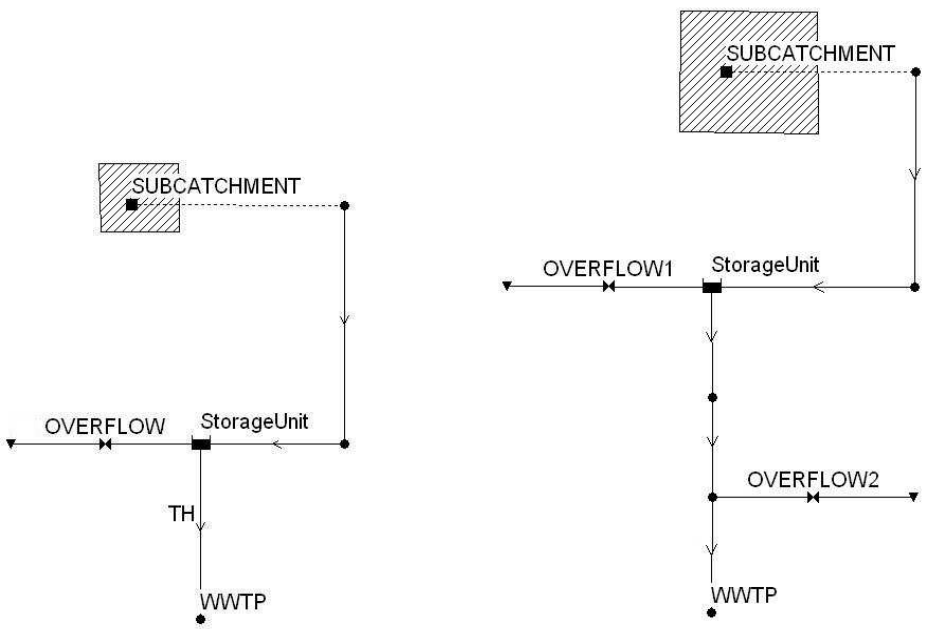
Assuming that the pathogen decay in the surface water environment follows first order kinetics, the pathogen concentration at the point of drinking water intake, C_I, can be estimated based on travel time from the overflow outfall i to intake.

$$C_I = C_R \times e^{-k \times t_i} \tag{6}$$

where, k is the decay rate constant, t_i is the travel time from the overflow outfall i to intake.

3 PRELIMINARY RESULTS FOR THE CSO MODEL

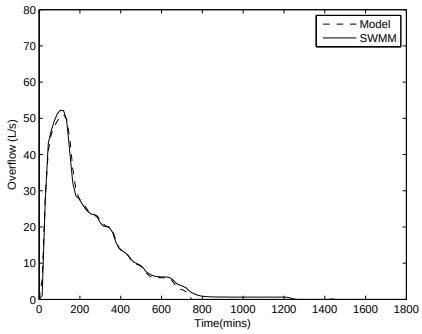
The above described modeling methodology has been applied to three preliminary test cases.



3.1 Test Case 1

The first test case consisted of a simple sewer network with one contributing subcatchment and one combined sewer overflow (Figure 3(a)). Initial condition of zero volume in the sewer network was assumed for simulation. For calibration a typical 24 hr design rainfall was used as input into the system. The value of alpha in the objective function was taken to be 0.5 (Equation (3)). Least square estimates of $0.0945\ s^{-1}$, $0.0567\ s^{-1}$,

$13.3812\ m^3$ were obtained for C_t, C_o and V_s respectively, with the optimal value of Z being 101.4154. Figure 4(a) shows the fit obtained as a result of calibration. The estimated set of optimal parameters were then used for the same system with another 24 hr design rainfall as input for validation. Figure 4(b) shows the overflow discharge time series predicted by the model in comparison to SWMM using the estimated set of optimal parameters.



3.2 Test Case 2

In the second test case, a sewer network with one contributing subcatchment area and two overflows (Figure 3(b)) was used. For modeling this system, the discharges from the two overflows were added together to calculate the total system overflow. The objective function was modified so that Q_i and Q_i^s corresponded to the total system overflow discharge. Using the same procedure as in Test Case 1 an optimal estimate of parameters was found to be $0.0395\ s^{-1}$, $0.0272\ s^{-1}$ and $108.6\ m^3$ for the fictitious reservoir system with corresponding optimal value of Z being $2.18E04$. Figure 5(a) shows the fit obtained for the total system overflow. The estimated set of model parameters was then validated using another 24 hr design rainfall as input (Figure 5(b)).

(a) Test Case 2 Calibration: Overflow discharge(L/sec) fit for Rainfall Input1

(b) Test Case 1 Validation: Overflow discharge (L/sec) for Rainfall Input2

Figure 5: Test Case 2

3.3 Test Case 3

The CSO model has been found to give promising results with simple sewer networks. A typical urbanized area however has several subcatchment areas and significantly more complex sewer network. The Metropolitan Sewer District (MSD) of Hamilton County is divided into three subdivisions. A portion of Little Miami subdivision was used as a test case. This portion of the Little Miami Subdivision consists of 1625 subcatchments and has four CSO's for discharge (Figure 6).

For the purpose of modeling, the overflows were assumed to be independent. Upstream contributing subcatchments to each overflow were assigned on the basis of network topology. A one year rainfall record for Lebanon, Ohio for year 2001 obtained from National Ocean and Atmospheric Agency (NOAA) database was used as rainfall input for calibration. The objective function used in calibration was obtained by adding the objective function given by equation (3) for each individual CSO location. For each

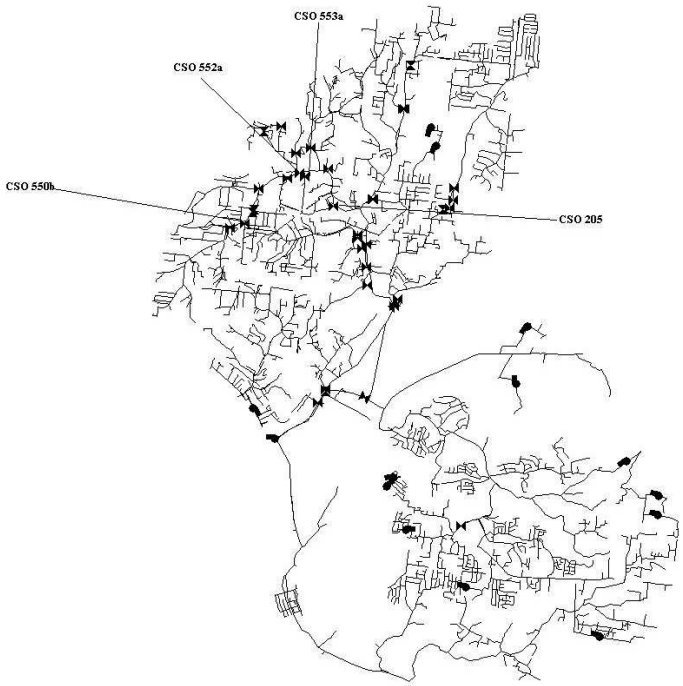

Figure 6: Little Miami Sewer Network

C_t (s^{-1})	C_o (s^{-1})	V_s (m^3)
0.017823	0.3353	54.1
0.00018	0.1991	500
0.001607	0.2417	387.6
0.003613	0.2006	207.2

Table 1: Optimal parameter estimate for Test Case 3

location an optimal set of parameters was thus obtained (Table 1) with $\alpha = 0.5$.

The time series of overflow discharges for total system sewer overflow predicted by model and SWMM are presented in Figure 7. Figure 8 compares the logarithm of non zero overflow discharge predicted by the simplified model to that computed by SWMM at a particular time step. As is clear from the graphs, the model in general tends to underestimate overflow discharge as compared to SWMM simulation. One of the probable reasons for this might be that the error metric compares the discharges at every time step of the continuous simulations, whereas it is likely more important to represent the total CSO loading for individual storm events. The value of optimization parameter, α, used might be another reason for the underestimation.

4 CONCLUSION

In order to assess the public health risk due to combined sewer overflows, a fundamentally different approach is required to incorporate event driven exposure variability. This paper presents a simple approach to model the complex urban sewer system to estimate the overflow discharge into receiving water. The time series of overflow discharges/volumes thus generated, superimposed on the pathogen concentration in the raw sewage, could be used to generate a time series of pathogen loading into source waters. This time series could be then used to drive the QMRA exposure models to assess the public health risk from enteric pathogens in drinking water. The flexibility and simplicity of the model may permit the usage of useful statistical techniques such as Markov Chain Monte Carlo sampling to fuse exposure models with data. The model has been found to give promising results with simple test cases. Further work is required for simulating complex realistic scenarios by calibrating with overflow data from public sewer utilities.

Source Control: The Solution to Stormwater Pollution

Michael A. Ports, PE, PH, D. WRE[1]

Introduction

Another name for source control is pollution prevention. In almost every case, it is easier and cheaper to prevent pollution from occurring in the first place than it is to collect and treat it after the fact. Municipal stormwater managers throughout the United States are coming to grips with the fact that municipal stormwater management requires significant effort and resources and raises numerous legal and financial issues and concerns. More emphasis on source control has the potential to improve system reliability, reduce costs, improve equity, reduce liabilities, as well as improve water quality.

When Phase II of the municipal separate storm sewer system permit program under the National Pollutant Discharge Elimination System began, most stormwater managers relied primarily on end of pipe treatment to meet their goals. Under the Clean Water Act, the United States learned that end of pipe treatments are effective in reducing pollutant loads discharging from municipal and industrial wastewater plants. For example, from 1968 through 1996, municipal wastewater treatment plants reduced BOD entering receiving waters by 45 percent in spite of a significant increase in population served (USEPA 2000). Thus it was no surprise that most municipalities formulated and began their stormwater programs based upon the assumption that, if end of pipe treatment worked so well with municipal sewage, then end of pipe treatment should work with urban stormwater.

Experience, unfortunately, has demonstrated that this is not the case. The flow and composition of municipal waste generally is well known and predictable. Thus, it is relatively easy to design and operate cost effective treatment systems. However, the flow and composition of urban stormwater is highly variable, both spatially and temporally. Municipal wastewater treatment plants are sophisticated, energy intensive operations equipped with elaborate control systems. On the other hand, end of pipe urban stormwater treatments are relatively simple structures with primitive, if any, operational control. At a modern municipal wastewater treatment plant, BOD removal usually reaches 95 percent or more and nutrient removal rates may exceed 85 percent. Removal rates for BOD at a typical structural stormwater BMP may vary by storm from as little as 16 to as much as 93 percent (Strecker, Quigly, and Urbonas 2000). Removal rates vary nearly as much from BMP to BMP regardless of type, size, location, and climate.

---

[1] Principal Water Resources Engineer, Bergmann Associates, 8653 Baypine Road, Suite 100, Jacksonville, Florida 32556. mports@bergmannpc.com

Another problem with structural BMPs is the ultimate fate of the pollutants removed. Stormwater pollutants include a wide variety of substances that build up on both pervious and impervious surfaces and later are transported by the next rainfall. These contaminants include heavy metals, petroleum hydrocarbons, pesticides, fertilizer, and a host of organic chemicals. Some pollutants naturally degrade and convert to harmless byproducts. Other pollutants are taken up by plants or microorganisms. But, many pollutants accumulate in the BMP and must be removed over time by dredging or other means. Some of these pollutants may accumulate to levels requiring classification as hazardous waste (Cox and Livingston, 1997).

In addition, construction costs for most structural stormwater BMPs are higher than for most source controls. Estimated total capital costs, not including land, for typical applications are summarized in Table 1. Total project costs may range from $27,000 to $37,000 per catchment acre. Depending upon the specific project, typical annual maintenance costs range from 5 to 10 percent of the total project cost.

Table 1
Capital Costs of Typical Applications of Structural BMPs

BMP TYPE	TYPICAL COST ($/BMP)	APPLICATION
Retention Basin	$130,000	50-acre residential site with 35 percent impervious cover
Wetland	$162,000	50-acre residential site with 35 percent impervious cover
Infiltration Trench	$58,000	5-acre commercial site with 65 percent impervious cover
Infiltration Basin	$19,000	5-acre commercial site with 65 percent impervious cover
Sand Filter	$45,000 to $91,000	5-acre commercial site with 65 percent impervious cover
Bioretention	$78,000	5-acre commercial site with 65 percent impervious cover
Grass Swale	$4,500	5-acre residential site with 35 percent impervious cover
Filter Strip	$0 to $11,000	5-acre residential site with 35 percent

		impervious cover

(EPA, 1999)

Based upon average removal rates for typical applications with different percentages of impervious cover, urban stormwater treatment costs may range from

- $2,000 to $3,000 per ton of total suspended sediment,
- $1,400 to $2,200 per pound of phosphorus,
- $1,000 to $3,000 per pound of nitrogen, and
- $1,200 to $3,000 per pound of metals.

Structural BMPs are a necessary and important element of any stormwater management program. However, relying solely upon end of pipe treatments is not necessarily the best approach. End of pipe treatments are not always effective. They are expensive. They accumulate pollutants and require diligent maintenance. The proper application of nonstructural, source control BMPs should be an integral part of comprehensive stormwater management programs.

Source Controls

The primary purpose of source control is to prevent pollutants from getting into the stormwater in the first place. By their very nature, source controls have certain advantages that all too often are not appreciated. For some pollutants, source control is more effective than end of pipe treatment. For example, the removal of soluble phosphorus is not effective in BMPs that rely on sedimentation. Because chloride is a soluble pollutant, no structural BMP is effective in removing or trapping chloride from road deicing operations. Hence, only source controls have the potential to reduce the discharge of such containments.

Source controls have the potential to reduce stormwater treatment unit costs. Composting grass cuttings, reducing fertilizer application rates, minimizing pesticide applications, and picking up pet waste can cost little or nothing, yet at the same time can be effective in reducing the discharge of stormwater containments.

Everyone pays for the costs of stormwater pollution through the loss of the use of the public resource. No one can go swimming when the beaches are closed due to stormwater pollution. No one can go angling when the fish are dead or driven away due to stormwater pollution. No one can enjoy the aesthetics of a beautiful water body when it is polluted by stormwater. The public pays the costs of dredging our receiving waters to remove sediments transported from urban construction sites. Source control transfers the cost of pollution control from the public to the polluter. The “polluter pays” philosophy is equitable. It is fair, for example, for the costs of on-site construction

erosion and sediment controls to be borne by the developer. It is not fair for the public to shoulder the burden of subsequent restoration and cleanup downstream. At least for some pollutants, the overall effectiveness and reliability of the stormwater management program may be improved when source controls are combined with end of pipe treatments.

Watershed Approach

When end of pipe treatments alone are implemented, it follows that the stormwater management program tends to be focused on the downstream end of the pipe. Often, stormwater engineers implicitly think that the drainage system consists only of the various constructed elements of the conveyance system, such as the gutters, inlets, pipes, etc. Impervious roadway and parking lot surfaces themselves do not contribute measurably to the overall pollutant loads, although various pollutants mostly from vehicular sources collect on the impervious surfaces. By far most pollutants entering the drainage conveyance system originate from such upstream sources as vehicular traffic, lawns, urban landscapes, tree canopies, and atmospheric deposition. Most impervious surfaces should be considered as part of the conveyance system rather than the source of pollution.

Comprehensive stormwater management should consider the watershed as a whole. Most often, pollutants are brought into the watershed from outside. For example, pet food is purchased at a store, brought home, and fed to the pet. Then the pet excretes the waste onto the lawn or other landscaped surface. When it rains, pollution from that pet waste runs off and enters the conveyance system downstream. For another example, polyphosphates added to municipal water systems for corrosion control may enter urban landscapes through irrigation. Significant pollutants enter the watershed through the streetscape. Copper, zinc, and other heavy metals come from wearing break pads and tires. Road salts and abrasives come from deicing and traction control operations. When considering stormwater pollution, the first question in mind should be "What is the source of the pollution?" The source may be the most effective and least costly place for control.

Characteristics of Stormwater Pollution

Typical pollutant concentrations in stormwater runoff are compared to wastewater and combined sewer overflows in Table 2. There is no apt description of "typical" combined sewer overflow or urban stormwater runoff for that matter. Both are a function of local conditions, including land use, geology, geomorphology, and the many vagaries of weather. Each situation should be evaluated individually, particularly with respect to the receiving water body in question.

Total suspended solids concentrations in typical urban stormwater runoff may be many times higher than found in untreated municipal wastewater or even combined sewer overflow. In addition, total nitrogen and total phosphorus concentrations in urban runoff may be higher than in the effluent from a secondary wastewater treatment plant. Urban

stormwater concentrations of metals also may be problematic. And finally, there is little difference between the fecal coli form concentration in urban stormwater runoff, untreated municipal wastewater, and combined sewer overflow. Other pathogen indicator organism counts, such as total coli form and *e. coli* and *enterococci*, are similar. Research is ongoing to determine the magnitude and characteristics of cryptosporidium and giardia in urban stormwater runoff.

Table 2

Comparison of Stormwater Pollutants to Wastewater

CONTAMINANT SOURCE	UNTREATED MUNICIPAL WASTEWATER	TREATED WASTEWATER (SECONDARY)	URBAN STORMWATER RUNOFF	COMBINED SEWER OVERFLOW
BOD_5 (mg/L)	100-400	<5-30	1-700	25-100
TSS (mg/L)	100-350	<5-30	2-11,300	150-400
Total N (mg/L)	20-85	15-25	0.4-5.0	3-24
Total P (mg/L)	4-15	<1-5	0.5-2.0	1-10
Lead (mg/L)	0.1	0.15	0-1.9	0.37
Zinc (mg/L)	0.28	0.08	0.02	0.17
Copper (mg/L)	0.22	0.03	0.05	0.03
Fecal Coli Form (ct/100ml)	10^7-10^9	<200	10^3-10^7	10^5-10^7

(APWA, 1969 and EPA, 2001)

Urban Forestry Management

Leaves, twigs, nuts, and other tree detritus may be a significant source of nutrients to streets and parking lots. Leaves contain significant amounts of soluble nutrients that can be washed downstream into the storm drainage system. Phosphorus, for example, can be leached out of a dead tree leaf and carried into the storm drainage system without the leaf ever having to move. Phosphorus loadings from streets that are lined with closely-spaced, mature trees with large canopies may be larger than loadings from lawns. An obvious source reduction practice is to sweep the streets more frequently during the autumn leaf dropping period. The potential phosphorus content of leaves and seeds may

range from 1.6 to 11 mg/g (Waller and Hart, 1986). The annual leaf production from trees typically found in urban landscaped environments ranges from approximately 14 to 26 kg per tree.

Pet Waste Management

Pet waste can be a source of fecal bacteria, nutrients, and oxygen-demanding compounds in urban stormwater runoff. Pet fecal matter especially is annoying and polluting in urban residential neighborhoods that are highly impervious. Some European city centers with significant residential populations often suffer from excessive pet waste. In contrast, downtown areas of most large U.S. cities often exclude residential inhabitation, which goes a long way toward solving the pet waste problem but makes the cities look deserted after regular business hours. To control pet waste accumulation, owners should pick up any material deposited by their pets and dispose of it in a clean and safe manner. Pet waste should be placed in the garbage, flushed down the toilet, or buried. To prevent the potential spread of disease, pet waste should not be incorporated into compost piles that will be used on vegetable gardens. Many communities have adopted laws or regulations that require owners to pick up the waste that their pets deposit. The typical pet dog is responsible for as much as 2.6 pounds of phosphate per year (RISE, 2004).

Lawn Management

Stormwater runoff from lawns generally is highly polluted, especially with nutrients, suspended solids, pesticides, and pathogens. Significant concentrations of pollutants are only part of the problem. In too many cases, lawns are compacted during or after construction, increasing the runoff coefficient and thereby the fraction of precipitation that becomes runoff. As the infiltration rate declines, the fraction of the applied fertilizer that enters the runoff increases. It is well documented in the hydrologic literature that the volume of runoff from lawns is an order of magnitude greater than runoff from natural prairie or forest lands. Elevated nutrient loadings coupled with elevated runoff volumes often make lawn runoff the primary source of nutrient pollution in watersheds with significant residential land use. Moreover, nutrients from applied fertilizers, grass clippings, leave mulching, and animal waste all contribute to lawn runoff pollution.

Improved lawn management certainly would reduce the export of pollutants to the runoff. First and foremost, during the initial construction of the lawn, care should be taken not to compact the lawn area. In fact, the soil should be loosened and improved so as to enhance its infiltration ability. Next, care should be taken to apply only low nutrient fertilizers with appropriate irrigation and avoid application on saturated soils prior to rain events. Pretesting soils to determine the optimum application rates should prevent excessive applications and decrease nutrient loads over time.

The comparative phosphorus contributions from different sources within a hypothetical, yet typical small residential catchment is shown in Figure 1. A tree-lined boulevard, one half mile long and 100 feet wide with adjoining residential lots 50 feet by 100 feet in size is assumed. Additional assumptions include:

- Boulevard is lined on both sides by mature trees at 75-foot intervals.
- Half of the households own dogs.
- No dog waste is scooped.
- Half of residential lots drain to boulevard.
- Average runoff coefficient is 0.5 for residential lots.
- Average annual rainfall is 48 inches.

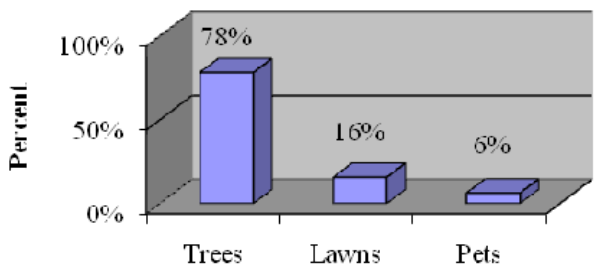

Figure 1
Comparitive P Source Contribution

In such a simplified hypothetical example, the total annual phosphorus contribution from the boulevard trees may exceed 3,000 pounds. But, assuming that half of the leaves fall on the lawns and some of the remainder get blown away, an annual phosphorus contribution of 1,000 pounds is a more reasonable estimate. From the residential lawns, as much as 200 pounds of phosphorus may be contributed annually. The neighborhood dogs may contribute another 80 pounds. Thus, in this hypothetical example, a total of 1,280 pounds of phosphorus is contributed annually to the stormwater runoff. A program to reduce the phosphorus loading should direct most, if not all, of its initial efforts at removing leaves from the public rights-of-way. More frequent street sweeping coupled with mulching and removing leaves from landscaped or grassed areas conceivably could reduce the phosphorus contribution to significantly lower levels, perhaps as low as 200 pounds per year.

Will Citizens Participate?

Many municipal stormwater managers assert that homeowners and other members of the general public will not participate in improved lawn management. Others, especially engineers, assert that they cannot guarantee public acceptance and adoption in the future. They collectively conclude that source reduction is futile and, thus, not worth pursuing.

Actual experience, however, with other environmental programs that include changing environmental behaviors suggests otherwise. For the same reasons, curbside recycling once was regarded as unrealistic. In the early 1970s, only 7 percent of municipal waste was recycled. By 1999, more than 32 percent was recycled nationwide (EPA, 2002).

From 1982 through 2003, soil erosion on U.S. cropland decreased by 43 percent (NRCS, 2007). This significant decline may be attributed to a combination of ongoing education and outreach efforts, incentive payments for adopting conservation practices, encouraging conservation tillage, and removing highly erodible lands from crop production. Farmers also are using fertilizers and pesticides more efficiently and more effectively due to both overall market forces, ongoing public education programs, and peer pressure. Residential water conservation also can be successful. Tampa Bay Water reports that residential water use has declined by more than 40 percent since 1989.

Thus, the historical evidence is clear that private citizens will change their environmental behaviors. The question is, "How should programs be formulated and implemented to result in those changed behaviors?" Anecdotal evidence indicates that successful programs which change environmental behaviors incorporate a mix of education, incentives, penalties, and social marketing. For example, the Tampa Bay Water conservation program includes extensive public education programs, incentives to adopt specific practices, increasing rates for increased consumption, and penalties for certain water uses during drought.

Programs to improve residential lawn management should be formulated differently for different audiences. A program targeted at commercial lawn service companies may be more specific and may be based upon more strict regulatory requirements. A program for avid gardeners and lawn growing homeowners probably should be quite different than a program for the more casual homeowner or renter. Differing program elements may be warranted in different neighborhoods based upon socio-economic indicators, neighborhood organizational context, prevalence and type of pets, population density, and type of housing.

Conclusion

Structural end of pipe treatments alone cannot reduce stormwater pollution sufficiently to meet appropriate water quality goals. Properly designed and implemented source controls should yield major reductions in pollutant loadings. While improved construction and landscaping is most cost-effective when implemented during initial development, significant improvements still are possible with smart retrofits. Significant additional research is needed to improve source control effectiveness and economics. Much may be learned from previous efforts to change environmental behaviors that could be applied to stormwater public outreach programs. More research in lawn ecology and residential lawn behaviors could lead to moving beyond generic, one-size-fits-all recommendations to carefully targeted messages accompanied by appropriate incentives and effective restrictions. Practical research is needed to understand how adaptive management algorithms could be applied to source controls such as road deicing.

Properly designed and implemented source controls offer more potential for reducing pollutant loadings more effectively, more cheaply, and more fairly than end of pipe treatments.

ABSTRACT

Potter Lake is a small water body on the University of Kansas campus. Eutrophication and sedimentation are both significant water quality issues for this system. As stormwater runoff provides as significant portion of the total inflow to this system, student-led efforts to develop a restoration and management plan for Potter Lake, have focused on assessing the quantity and quality of this runoff. A water balance model for the Potter Lake watershed was developed using climatological data and watershed characteristics. Runoff samples from four locations were collected for water quality analysis using passive collection bottles suspended in existing storm sewers. Water quality analysis indicates that runoff from Jayhawk Boulevard contributes a disproportionate amount of the total loading of suspended solids and phosphorus, particularly during heavy storms when soils are mobilized from open areas along this street. Improving the water quality in Potter Lake may require treatment of this stormwater prior to discharge into the lake.

INTRODUCTION

Potter Lake is a one and a half acre manmade water body located on the campus of the University of Kansas. Originally created in 1910 to provide a water source for fire protection, the lake became a popular campus feature. At various points in its history, it has been used for swimming, boating and other recreational activities. At present, it serves as a centerpiece for one of the largest remaining open spaces on the main campus, used by students as a place to study and relax. Potter Lake and the adjoining open space are listed as a signature campus feature, is designated for preservation in the current University Landscape Master Plan (Jeffrey L. Bruce and Company 2002), and is apart of a historical Marvin Grove district slated for the National Register of Historic Places. Preserving the aesthetic character of Potter Lake for the future requires addressing two related water quality issues: eutrophication and sedimentation.

Eutrophication is the primary ongoing cause of water quality impairment in Potter Lake. In 1999, the Kansas Department of Health and Environment placed the lake on its list of 120 polluted water bodies in the state due to the effects of repeated algal blooms and vegetation growth. In 2000, a TMDL was issued for nutrients and pH. This TMDL was based on results of a water quality survey conducted in September 1994 that showed the lake as hypereutrophic, with a Carlson trophic state index greater than 70 (Kansas Department of Health and Environment 2000). The report cited total phosphorus as the limiting nutrient for plant growth. Data taken during the survey listed the total phosphorus concentration at 30 ppb, although the report also states that this value was unusually low when compared to the simultaneously measured chlorophyll-a values of approximately 100 ppb. In order to improve lake water quality to acceptable levels, a load allocation of 2.6 lb phosphorus per year was recommended, an 88% reduction from the estimated total loading at that time. The TMDL also noted high pH levels in the lake, ranging from 8.82-9.01, during the September 1994 sampling. More recent sampling, in June of 2007, showed decreased levels of chlorophyll-a (< 10 ppb) and slightly lower phosphorus concentrations (20 ppb); however, excessive plant growth and decay remain a significant issue.

Sedimentation due to transport of suspended solids in stormwater runoff has also been a consistent issue with regard to water quality in Potter Lake. In addition to transporting phosphorus, sediments entrained in stormwater runoff contribute to reducing lake volume and depth. In turn, this increases the potential for growth of rooted aquatic plants, accelerating both eutrophication and further sedimentation. The lake was completely drained, dredged and then refilled in 1958 in a previous attempt to combat the effects of sedimentation. A bathymetric survey conducted in the summer of 2008 shows that most of the lake has once again been substantially filled in from the ~16 foot depth re-established at that time. The maximum lake depth is currently between 12 and 13 feet, while approximately two-thirds of the lake has a depth less than 6 feet. In the southwest quarter of the lake, the depth ranges from <1 to 4 ft. It is in this area that excessive vegetation growth of both rooted and floating plants is most severe.

A student-led group formed during the spring of 2008 has been developing plans for the restoration and long-term preservation of Potter Lake for the continued use and enjoyment of the Lawrence and KU community. The overall objectives of this group are to implement a plan for necessary remediation and restoration efforts (including dredging) that will address current water quality and aesthetics issues at Potter Lake and to develop a long-term strategy to minimize the re-establishment of eutrophic conditions in the lake. The primary focus of this long-term strategy is to evaluate the impact of stormwater runoff and contaminant transport on Potter Lake and to provide management alternatives that would mitigate the effects of this runoff of water quality. In addition to sheet runoff from the surrounding open space, Potter Lake receives channelized stormwater runoff from adjacent locations. The major contributors to this stormwater runoff are two roads (Jayhawk Boulevard and Memorial Drive) south and west of the Potter Lake drainage basin and a parking lot located on the northwest side. Storm sewers at all three of these locations feed runoff into concrete pipes that deposit directly into Potter Lake (from the parking lot and

Memorial Drive) or to an above ground outlet located approximately 15 ft from the lake (Jayhawk Boulevard storm sewers). While this runoff is a significant source of nutrients and sediments, it is also an important part of the water budget for Potter Lake, as the only other significant water source is direct precipitation.

In the current work, we present results of studies conducted during the fall of 2008 to evaluate the impact of stormwater runoff from each of these sources on the hydrology and water quality of Potter Lake. The purpose of this work was to assess the relative contributions of runoff from these locations to lake volume and to contaminant loading and to determine whether some or all of this runoff should be treated or diverted from the Potter Lake watershed in order to improve long-term surface water quality. In order to achieve these objectives, a hydrological model of Potter Lake was developed using available data. This model estimates the relative contributions of different runoff sources to the overall water budget. Model results were combined with runoff water quality data to determine the impact of runoff from each location on total loading of nutrients and suspended solids.

METHODS

Stormwater samples were collected between July and December, 2008 and analyzed for a range of water quality parameters, including total suspended solids, dissolved nitrate and phosphate, and total and dissolved reactive phosphorus. Samples were collected using one liter polycarbonate bottles equipped with a screen to reject large solid materials and a collection funnel with floating ball valve (I-CHEM) to seal the bottle after sample collection was complete. These bottles were suspended from storm grates at four locations: 1.) a storm sewer on the north side of Jayhawk Boulevard, 2.) a storm sewer in the southeast corner of a parking lot on the northwest side of the lake, 3.) one of two storm sewers on the north side of Memorial Drive, 4.) a storm grate collecting sheet runoff from the grassy hill located immediately south of Potter Lake. Sampling locations 1-3 drain primarily from paved surfaces, although locations 1 and 3 also drain from grassy open areas surrounding the roads. The grassy hill at location 4 forms a basin around two sides of Potter Lake. This open space is vegetated with a mixture of fescue grasses and drains directly to the lake. The current landscaping plan calls for minimal to no phosphorus application in this area.

Stormwater samples were transported back to the laboratory for analysis within 24 hours after each storm event. All analyses were conducted using standard procedures (American Public Health Association et al. 2005), with dissolved samples filtered through a 0.45 μm nylon filter prior to analysis . Total suspended solids tests were conducted on the same day as sample collection according to the 2540D procedure. Dissolved nitrate and phosphate concentrations were measured using an ion chromatograph (Dionex Corp.) with a hydroxide eluent. Total and total dissolved phosphorus were determined using the ascorbic acid procedure.

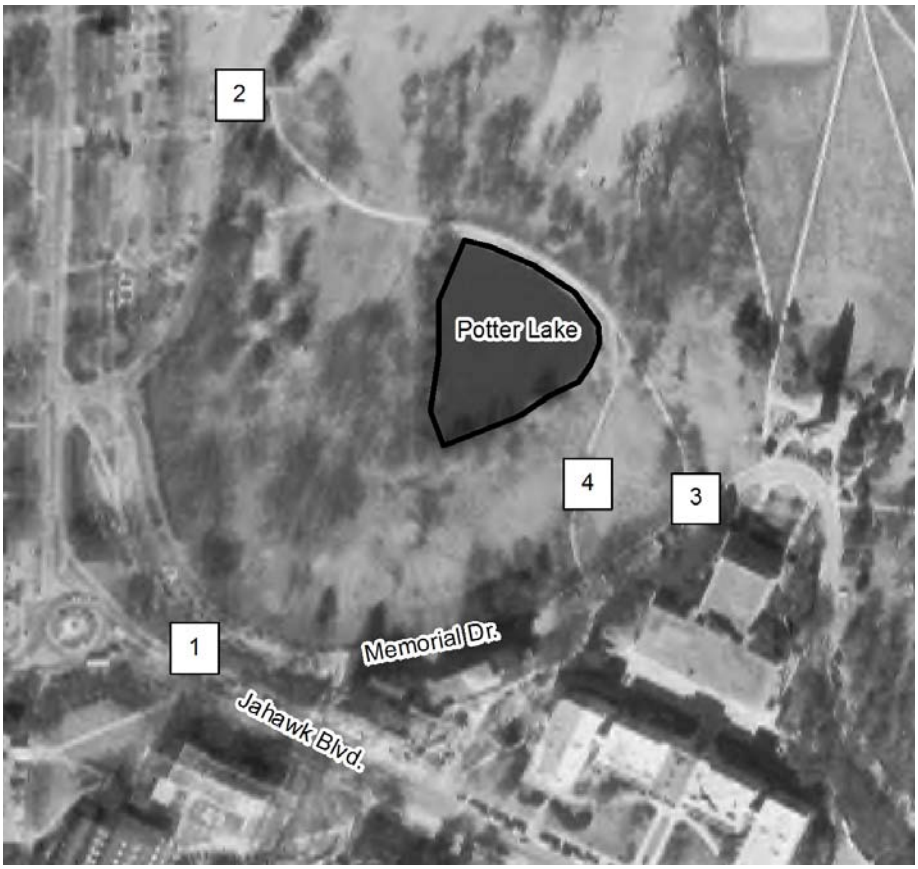

Figure 1. Map of Potter Lake Showing Stormwater Sampling Locations

A hydrological model was developed for the Potter Lake watershed that included two primary components: a water balance simulation for the volume of storage in the lake and simulations of stormwater runoff volumes from discrete regions of the watershed. This model is designed to aid in understanding the hydrologic behavior of the watershed and lake, not to simulate the response to any particular runoff event. Runoff into Potter Lake was simulated for the period March 1964-July 2008 using the NRCS Runoff Curve Number method. The model was driven by daily rainfall data for the NWS weather station in Topeka, Kansas. This gage represents a high quality record with very few missing rainfall values. Translation of the record from Topeka to Lawrence means that the model results are representative of the climate for NE Kansas, but do not simulate the actual daily conditions.

Runoff volumes were computed separately for four areas within the watershed based on the stormwater sampling locations and surrounding land use. The land use for each area was manually classified using aerial photography and field observations. The NRCS hydrologic soil type was determined using the NRCS soil survey for Douglas County, Kansas. The relative runoff contribution was computed for each land use area, making it possible to extrapolate water quality concentrations to annual mass loadings.

RESULTS

Stormwater samples were collected from 8 storm events occurring between July 3 and December 7, 2008. The majority of sampling events (6 of the 8) occurred between August 23 and November 15. The Jayhawk Boulevard site had the highest number of collected samples during this time period, with runoff collected during every storm event. At the Memorial Drive location, however, samples were only collected during higher rainfall events (> 0.4 inches). This is likely due to the smaller drainage area and flatter curbs at this site, which result in lower runoff collection. The sampling location in the open area surrounding Potter Lake had the fewest number of samples (3), a result both of the fact that less runoff is generated from this site and the difficulty of correctly placing the sampler to intercept sheet flow.

Table 1 provides average concentrations of measured pollutants for each of the four sampling locations. As expected, total suspended solids concentrations were substantially higher in the road and parking lot samples than in the sheet flow samples collected immediately around Potter Lake. The highest single TSS concentrations recorded were 594 and 843 mg/L at the Jayhawk Boulevard and Memorial Drive locations, respectively, during the same rainfall event in November, 2008. Since the sampling bottles capture the first liter of runoff, these values are most representative of first flush data for most of the storm events sampled.

Table 1. Water Quality Results from Stormwater Sampling

	Jayhawk Boulevard	Parking Lot	Memorial Drive	Hill
Samples	8	7	4	3
TSS (mg/L)	337	202	438	67
Total P (mg/L)	1.52	1.17	0.766	2.76
NO_3 (mg N/L)	0.37	0.63	0.30	0.64
PO_4 (mg P /L)	0.50	0.14	0.11	1.12

Phosphorus levels from all four sites are higher than values typically found in urban runoff (United States Environmental Protection Agency 1983), with the highest concentrations observed in the sheet runoff adjacent to the lake. The most likely source of this phosphorus is fertilizer application. The sheet runoff collected at location 4 recorded the highest concentrations of dissolved nitrate and phosphate along with very high total phosphorus concentrations, suggesting that fertilizer application may still be occurring in the open space surrounding Potter Lake. Dissolved phosphorus concentrations are much lower for two of the three locations which collect runoff from paved surfaces. The exception is the Jayhawk Boulevard sampling location, which has notably higher concentrations of both dissolved and total P. Total phosphorus and total suspended solids concentrations are strongly correlated at this location (Figure 2). This suggests that the highest loadings of both contaminants occur due to the release of soil from open spaces along the street, including several sets of flowerbeds located within the drainage area. The highest total phosphorus concentrations for this site were recorded after rainstorms totaling

more than 1 inch, allowing for greater washout of soil from the areas surrounding this road.

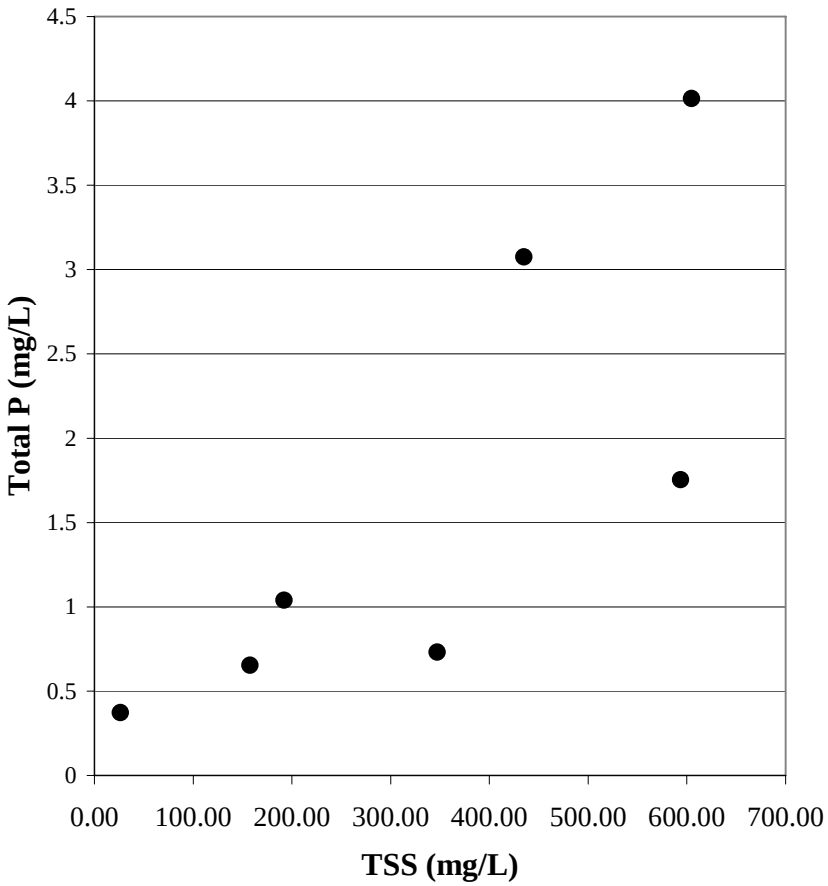

Figure 2. Relationship between TSS and Total P at Jayhawk Boulevard sampling location.

Contaminant Loadings to Potter Lake. The concentrations of total suspended solids and phosphorus found in the stormwater runoff are significantly higher than those found in the lake itself. This indicates that, under current conditions, stormwater runoff entering the lake will continue to impact lake water quality, particularly with respect to eutrophication and sedimentation. In order to better quantify the impact of this runoff and to assess the relative contributions of the different portions of the watershed to water quality degradation, contaminant loadings were calculated for a simulated rainfall event on a mass basis using the average contaminant concentrations reported above.

The relative runoff contributions for the four land use groups in the Potter Lake hydrological model are presented in Table 2. The total annual runoff volume to the lake is approximately 220 ac-ft, or a runoff depth of 9.6 in/yr. Overall, Jayhawk Boulevard (including surrounding areas that drain to the street) is the largest contributor of stormwater runoff to the lake, contributing approximately 37% of the total annual runoff from the watershed. The contributions from Memorial Drive and

from the hill surrounding the lake are approximately equal contributors, while the parking lot on the northwest side has the smallest annual contribution.

The remaining columns in Table 2 show the calculated runoff and contaminant loading to Potter Lake from each drainage region for a simulated 1.0 inch storm event. Estimated runoff volumes were multiplied by the average TSS and total phosphorus concentrations at each sampling location to determine the mass loading of pollutants to the lake as a result of this hypothetical storm event. The total loadings reported here are likely to be high-end estimates, as the concentrations of most contaminants in paved surface runoff will typically decrease in the latter portion of a storm event (Sansalone and Cristina 2004). The concentrations reported in our samples, by contrast, are weighted towards the earlier part of the storm. The calculations do indicate, however, that two of the four regions, Jayhawk Boulevard and the grassy open space, contribute the majority of the total phosphorus received by the lake. The drainage area around Jayhawk Boulevard has a particularly significant water quality impact, as it contributes the highest loading of both suspended solids and total phosphorus.

Table 2. Simulated Runoff and Contaminant Loadings for a 1.0 inch Storm Event

Area	Annual Contribution	Simulated Runoff (ac-ft)	TSS Loading (kg)	Phosphorus Loading (kg)
Jayhawk Blvd	37%	0.240	100	0.424
Hill	24%	0.125	10.4	0.402
JRP	14%	0.101	25.1	0.135
Memorial Drive	25%	0.171	92.4	0.150

CONCLUSION

The results presented here show that stormwater runoff from the watershed surrounding Potter Lake continues to transport a substantial amount of suspended solids and nutrients into the lake. In order to address current water quality and aesthetic problems in the lake resulting from eutrophication, and to preserve the improvements gained by future remediation or restoration actions, this contaminant loading must be significantly reduced. Since stormwater is a significant portion of the total influent to Potter Lake, diversion of these flows to other locations is probably inadvisable. Thus, source reduction and stormwater treatment become the best solutions. The sheet runoff from the gray hill surrounding the lake presents the most difficult challenge from a treatment standpoint. While it may be possible to further adjust fertilizer application strategies in this area to reduce the amount of transportable phosphorus, it would be difficult to intercept and treat this water. The runoff from Jayhawk Boulevard, however, could be more easily treated as it enters or exits the storm sewer that coveys it to the lake. Given the apparent association between suspended solids and total phosphorus in the runoff from this location, the installation of particle collection filter bags at storm sewer inlets could provide substantial reductions to contaminant loading to the lake from this source.

A Tool for the Performance Assessment of Hydrodynamic Separators

Omid Mohseni[1], Janna M. Kieffer[1], and Jennifer A. Koehler[1]
[1] Barr Engineering Company, 4700 West 77th St., Suite 200, Minneapolis, MN 55435

Abstract

Hydrodynamic separators are stormwater treatment devices with small footprints used for removing suspended sediments from stormwater runoff in urban areas. These devices have been tested by different laboratories under a set of specific conditions, e.g. a limited number of flow rates, under a specific water temperature (fluid viscosity), a specific particle size distribution and particle specific gravity. However, the question ahead of the primary users of these devices, i.e. cities, counties and other local government agencies and large retailers is: "How well do these devices remove suspended sediment from our stormwater runoff?"

To address this question a tool has been developed to simulate continuous loading from small drainage basins in urban areas and to simulate the response of these devices in removing the suspended load from stormwater runoff. The tool is comprised of a hydrologic model and a generic device response model. The hydrologic model utilizes the SCS curve number method and the SCS unit hydrograph to simulate runoff. The input data into the hydrologic model are the drainage basin characteristics and 10 years of 15-minute precipitation data. The generic device response model utilizes the removal efficiency performance functions developed from the laboratory testing conducted on hydrodynamic separators. The input data for the device response model are 10 years of daily air temperature data, the particle size distribution, specific gravity, and influent concentration of suspended sediments in stormwater runoff.

The tool has been applied to four small urban drainage basins in Minnetonka, MN using four hydrodynamic separators as stormwater treatment devices. The results of continuous simulation were compared to the performance assessment of the devices under 1-year and 2-year frequency storm events to determine if an event-based simulation is adequate to assess the performance of these devices.

Introduction

Hydrodynamic separators are underground proprietary devices which have been used as stormwater treatment devices for almost two decades. They are primarily used for removing floatables and coarser and heavier suspended sediments from stormwater runoff. They can function as stand-alone treatment devices or as a pre-treatment to other devices such as filters, ponds and infiltration basins to reduce maintenance costs.

Many hydrodynamic separators have been tested by manufacturers and laboratories and many have been monitored by researchers from universities and research institutes (e.g. Fassman, 2006; Roseen et al., 2005; ETV 2005a and 2005b). Subsequently, a number of protocols, e.g. TARP and TAPE, have been developed by different state agencies in the US to make the testing procedure more methodical with well defined parameters and suitable for the projected conditions of those states. Therefore, in most laboratory studies and monitoring programs, the removal efficiencies of these devices have been assessed for a certain flow condition, particle size distribution or a specific drainage basin in a certain climate condition (assuming the monitoring program was conducted for several years), i.e. the results of these studies cannot shed any light on how a tested device may remove the stormwater pollutants for a different location with different storm patterns and suspended loads. Therefore the question ahead of the primary users of these devices, i.e. cities, counties, department of transportations and other local government agencies and large retailers is: "How well do these tested devices remove suspended sediment from our stormwater runoff?"

Recently, Carlson et al. (2006) and then Wilson et al. (2009) introduced a performance function which describes removal efficiency of hydrodynamic separators as a function of a Peclet number. The Peclet number in this application is the ratio of settling of the suspended sediments to the turbulence induced in the sump of hydrodynamic separator and is defined as

$$Pe = \frac{V_s \; h \; d}{Q} \tag{1}$$

In equation 1, *P*e is the Peclet number, V_s is the settling velocity of particles, which is a function of the particles specific gravity and viscosity of water (a temperature dependent parameter), h and d are the height and diameter of the sump, respectively, and Q is the flow rate through the device. Wilson et al. (2009), Mohseni and Fyten (2008) and Fyten and Mohseni (2009) used the Peclet number defined in equation 1 to describe removal efficiency of seven hydrodynamic separators using the results of their field and laboratory tests. The Peclet number-based performance function is a useful tool for predicting the performance of a hydrodynamic separator over a range of storm events, sediment size and sediment density observed in stormwater. In this study, the functions introduced for these devices have been combined with a simple continuous runoff model and thus a computer program has been developed to predict the performance of these devices under a variety of conditions applicable to any location and climate condition.

General Description of the Tool

As stated above, a tool has been developed to predict the amount of suspended sediments removed from stormwater runoff by a given hydrodynamic separator over a period of time. The tool is comprised of a simple continuous runoff model and the performance function of the device. In the following sections, the components of this computer model are described.

Runoff Model

It is well known that the removal efficiency of hydrodynamic separators decreases as the flow rate through these devices increases. However, most storm events are low intensity storms, i.e. storms with high magnitude and intensity are less frequent. In addition, every storm event results in a runoff hydrograph with (a) a period of low flow conditions in its rising limb, i.e. the conditions which are favorable for these devices to remove a considerable amount of sediments from stormwater runoff, (b) a period with relatively higher flow conditions, when the devices are not that effective in treating stormwater, and (c) finally the storm receding period when again the devices are capable of effective treatment of stormwater. In order to accurately assess the performance of these devices, it is necessary to incorporate the entire storm runoff hydrograph as well as the concentration of suspended load throughout the runoff event. Unfortunately, there is not enough information regarding the concentration of suspended sediments in stormwater runoff. There are, however, several particle size distributions (PSDs) recommended by few organizations to estimate the total suspended loads in runoff events (e.g. NURP, and the NJDEP PSD) and so far there is no usable information available on the variability of the suspended sediment concentration throughout a storm event. Therefore, in this study only the variability of flow rate in every event and throughout the year have been incorporated to predict the performance of hydrodynamic separators.

In order to simulate runoff from small urban drainage areas, the SCS curve number method is used to estimate the excess rainfall. Using the SCS curve number method is not the best choice to simulate runoff continuously throughout the year, because the moisture content of the top soil cannot be well incorporated into calculation of runoff. However, since the SCS curve number method is a conventional method often used by city engineers to estimate runoff, it was decided to utilize the method with some minor modification.

Total excess rainfall at each time step is therefore the weighted average of rainfall over the impervious area and the excess rainfall calculated for the pervious area using the SCS curve number method. By default, the initial abstraction is set equal to 20% of the maximum potential retention, however, the amount of initial abstraction can be selected by the user. If there is no rainfall event for 12 hours, the initial abstraction recovers completely.

The SCS synthetic unit hydrograph is used to develop the runoff hydrograph. Each time step of the unit hydrograph is 15 minutes long. Since hydrodynamic separators are used for very small urban drainage basins, i.e. only a few acres, no routing through sewers or curb side is incorporated into the model.

Treatment Model

Wilson et al. (2009) proposed a three-parameter function to describe removal efficiency of hydrodynamic separators as a function of the Peclet number. The function is given in equation 2.

$$\eta = \left(\frac{1}{R^b} + \frac{1}{(aPe)^b} \right)^{-\frac{1}{b}} \quad (2)$$

In equation 2, η is removal efficiency, and a, b and R are the fitted parameters obtained from the non-linear regression analysis of the data obtained from laboratory and field tests.

Particle size distribution and specific gravity are input by the user, and at each time step the model calculates settling velocity of all particles using the equation proposed by Cheng (1997).

$$V_s = \frac{\nu}{D} \left(\sqrt{25 + 1.2 \left(D \left(\frac{g(SG-1)}{\nu^2} \right)^{1/3} \right)^2} - 5 \right)^{1.5} \quad (3)$$

In equation 3, ν is the kinematic viscosity of water, D is the particle size, and SG is the specific gravity of the particle. To estimate ν, it is necessary to know the temperature of water in the sump and runoff. Since the detention time of hydrodynamic separators is very small, runoff temperature is adequate to estimate ν. The runoff temperature is a function of rain temperature and the surface temperature of the ground before the rainfall event. Herb et al. (2008) showed that the rain temperature, dew point temperature and air temperature are very similar during rain storms. During hot summer months, the impacts of paved surfaces on runoff temperature can be very significant at the beginning of the storm events, but soon the surface temperature reaches the rainfall temperature. Since the time step of the model is set at 15 minutes, it was decided to use average daily air temperature to estimate the kinematic viscosity of water for each day. For very hot summer days, this method results in larger value of ν, thus smaller settling velocity and removal efficiency, i.e. using air temperature overall underestimates the performance of hydrodynamic separators.

At each time step, the model estimates the Peclet number of each particle size from equation 1 using the discharge obtained from the runoff hydrograph and the settling velocity of the particle and the total amount of each sediment size removed from equation 2. By utilizing the particle size distribution and the influent concentration, the model calculates the total amount of suspended sediments removed at each time step. In addition, the model updates the available height of the sump in equation 1 by subtracting the average height of the deposit from the height of the device. When the average depth of deposit reaches the maximum storage capacity of the device before cleaning, which is recommended by manufacturers, the model assumes that the device is cleaned and set the height in equation 1 equal to the original height of the device.

Model Input

The runoff model input data are the drainage basin area, the percent imperviousness of the drainage basin, the drainage basin average curve number, the hydraulic length

and average slope of the drainage basin and a time series of rainfall. Rainfall is input at 15-minute time intervals. The 15-minute rainfall data can be obtained from the NCDC web site for more than 3000 rain gages across the country. Since the model does not simulate snowmelt, for regions where air temperature drops below freezing point for an extended period, e.g. Minnesota, Wisconsin and North Dakota, the rainfall time series is for non-snowfall seasons. The weather data can be input for a number of years.

The input data for the treatment module of the model are: influent concentration, particle size distribution and the specific gravity of each particle size in the distribution, daily air temperature time series, the height and diameter of the hydrodynamic separator and the maximum storage capacity of the device before cleaning.

Model Application

The tool was used to estimate the performance of four devices if installed at the outlet of four urban drainage basins in Minnetonka, MN. The four devices selected were a Vortechs 2000, a Stormceptor 4800, a V2B1 Model 4 and an ecoStorm Model 3. The above hydrodynamic separators had already been tested and evaluated by Wilson et al. (2009) and Mohseni and Fyten (2008), therefore, their performance function parameters (a, b and R in equation 2) were available.

The characteristics of the four drainage basins are summarized in Table 1. The particle size distribution and specific gravity of the suspended sediments in stormwater runoff was provided by the City of Minnetonka and is given in Table 2.

Table 1. Characteristics of the urban drainage basins used in this study

Watersheds	Area (hectares)	% imperviousness	Average CN	Hydraulic Length (m)	Average slope
1	2.31	25	51.75	186	0.01
2	4.05	20	65	255	0.0075
3	4.25	77	72	272	0.005
4	2.02	80	61	143	0.0025

Table 2. Particle size distribution recommended by the City of Minnetonka, MN

Particle size (μm)	Percent finer	Specific gravity of the range
2000	100	2.65
400	80	2.65
130	60	2.2
60	40	1.8
20	20	1.3

The model was run for a 10-year period from 1998-2007. For every year of the simulation period, the model was used to estimate runoff at 15-minute time steps from the beginning of April to the end of November. The mean annual removal efficiencies of the four devices for the watersheds in Table 1 are summarized in Table 3. A sample of estimated runoff hydrograph and the sediment load from watershed no. 4, and the amount of sediments removed by Stormceptor SC4800 from that watershed is displayed in Figure 1. It is evident that Stormceptor SC4800 can remove more than 90% of the sediment load, as described in Table 2, from low intensity storm events and at the beginning of each storm event. However, when the flow rate is as large as 40 cfs, removal efficiency drops to 60% and as runoff exceeds 120 cfs, the removal efficiency drops below 50%. It is noteworthy that SC4800 is one of the larger models of Stormceptor and its sump has a 3 m (10 ft) diameter.

Assuming a maximum capacity of 0.6 m (2 ft) for SC4800, before cleaning is required, this device did not require cleaning more than once every two years for the given watershed characteristics. The Stormceptor tested for scour and washout at St. Anthony Falls Laboratory showed no scour (the effluent concentration was measured to be less than 4 mg/l) of the US Silica Sand F110 with a median particle size of about 120 microns. Therefore, it is very likely that the model estimate of removal efficiency for Stormceptor 4800 is a fair estimate, assuming that the particle size distribution given in Table 2 represents the average particle size distribution of the sediments in stormwater runoff in Minnetonka, MN. It is important to note that this tool does not include any function to estimate scouring at this point, because no such function has yet been developed for any hydrodynamic separators. Therefore, the estimates given for mean annual sediment removal efficiency of the other three devices are likely to be higher than what they should be.

To determine whether it is necessary to run a continuous runoff model or only a single storm event to estimate the performance of these four devices, the average annual removal efficiency of devices were compared with their removal efficiencies for 1-year and 2-year 24-hour storm events. The comparison with the 2-year, 24-hour storm events is summarized in Table 3. The removal efficiencies estimated from 2-year 24-hour storm events are within 3% of the 10-year average removal efficiencies. Therefore, it seems that an event based approach can provide a good estimate of the performance of these devices over long periods. However, the scour and washout of deposited sediments should be assessed using a continuous runoff model which is not yet part of this tool.

It is important to note the results summarized in Table 3 do not provide enough information regarding the advantage of one device over another one, because the four devices presented have different sizes. In order to make a fair comparison, the price of each device, and the cost of installation as well as maintenance should be included in the comparison.

Table 3. Estimated removal efficiencies of four hydrodynamic separators based on 10-year average and 2-year 24 storm events in Minneapolis, MN.

Device		ecoStorm31		V2B1-4		Stormceptor4800		Vortechs2000	
Watershed		10-yr Avg	2-yr, 24-hr Event	10-yr Avg	2-yr, 24-hr Event	10-yr Avg	2-yr, 24-hr Event	10-yr Avg	2-yr, 24-hr Event
1	2.31 acres, 25% impervious	56.9	57.4	58.1	57.8	61.7	61.5	52.0	51.8
2	4.05 acres, 20% impervious	53.8	52.4	55.0	52.0	59.3	56.8	48.7	45.4
3	4.25 acres, 77% impervious	44.2	42.5	42.2	40.3	47.0	45.8	35.3	33.1
4	2.02 acres, 80% impervious	49.8	49.0	49.1	47.9	52.6	51.9	42.7	41.2

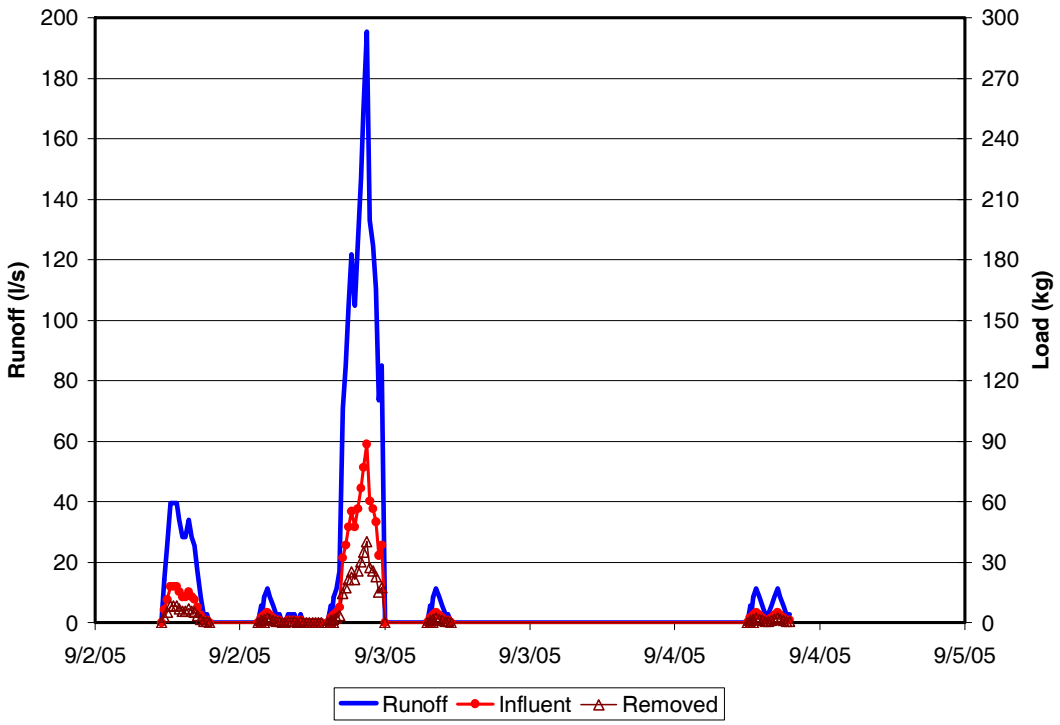

Figure 1. The estimated runoff hydrograph and the load from watershed no. 4, and the amount of sediments removed by a Stormceptor SC4800.

Summary

A tool has been developed to assess the performance of hydrodynamic separators in removing suspended sediments from stormwater runoff. The tool, which is a computer program, includes a continuous runoff model to simulate time variant discharge and a Peclet number-based treatment function to simulate removal efficiency of these devices in treating the suspended load. The continuous runoff model utilizes the SCS curve number method and the SCS synthetic unit hydrograph. The tool was used to estimate the 10-year average performance of four devices in four small drainage basins in Minnesota. The results of continuous simulation were compared to the performance assessment of the devices under 1-year and 2-year

frequency storm events. The removal efficiencies estimated from the 2-year, 24-hour storm events are within 3% of the 10-year average removal efficiencies.

Currently, the model does not include a scour function because no scour function has been developed for hydrodynamic separators. By incorporating scour functions in the model, the maintenance frequency of the devices can be determined with more confidence.

Accurate Sampling of Suspended Solids

Gregory P. DeGroot[1], John S. Gulliver[2] and Omid Mohseni[3]

Abstract

Automatic samplers have difficulty with sampling accuracy of inorganic particles larger than silt. The samples are generally at higher concentrations than the true mean concentration in the flow, because of the settling velocity of the particles and the sampling near the bottom of the flow. The vertical mixing is insufficient to overcome the settling of coarse silts and sands. A sampling methodology has been developed to accurately sample suspended solids in stormwater. This methodology is evaluated for its effectiveness, as well as its ability to be transferred to engineering and environmental practice. Emphasis is being placed on developing a methodology which is cost-effective, allowing a method of particle sampling which fits specific users and their projects.

Introduction

Water body impairment due to suspended solids pollution is a common water quality management issue. It is most common for a water body to be primarily or secondarily impaired due to suspended solids pollution (MPCA 2008). In addition, suspended solids are associated with additional pollutants including heavy metals, phosphorus, polycyclic aromatic hydrocarbons (PAHs), and pathogenic bacteria. Thus, removing suspended solids is one of the major water quality improvement objectives of stormwater treatment.

In response to the degraded water quality found in receiving waters due to urban stormwater runoff, the Clean Water Act requires the regulation of municipal separate storm sewer systems (MS4s) and the implementation of a two-phase Storm Water Pollution Prevention Program (SWPPP) (USEPA, 2007). The SWPPP requires discharge detection and elimination, construction and post construction runoff control, and pollution prevention measures. Key to pollution prevention efforts in urban areas are the installation and maintenance of stormwater best management practices (BMPs). Improving the design of best management practices (BMPs) requires more accurate information regarding stormwater particles. For BMPs which treat particles through settling, the particle settling velocity distribution is especially important. For BMPs which remove particles via filtration/infiltration, knowledge of particle size and composition is important. As always, better knowledge of what is coming down the pipe enables better distribution of resources to meet water quality goals.

Monitoring is one means of obtaining particle data. Portable automatic field samplers are common tools for monitoring watersheds – both for establishing baseline conditions and assessing the performance of management practices. Automatic samplers have been used frequently in studies with the goal of characterizing stormwater particles.

Particle Data: Size Distributions and Treatment by Settling

Particle size distribution data vary widely. Figure 1 compares two examples of stormwater particle data. Data produced by the Nationwide Urban Runoff Program (NURP) is compared with recent data gathered by Kim and Sansalone (2008) for highway runoff. One can see that the median particle size differs by nearly 1.5 orders of magnitude.

Note that when graphically comparing particle size distributions it is important to take note of the minimum and maximum particle sizes considered in the study and rescale all data to fit the narrowest study range. In Figure 1 below, Kim and Sansalone (2008) data has been rescaled to the NURP maximum particle size of 2mm.

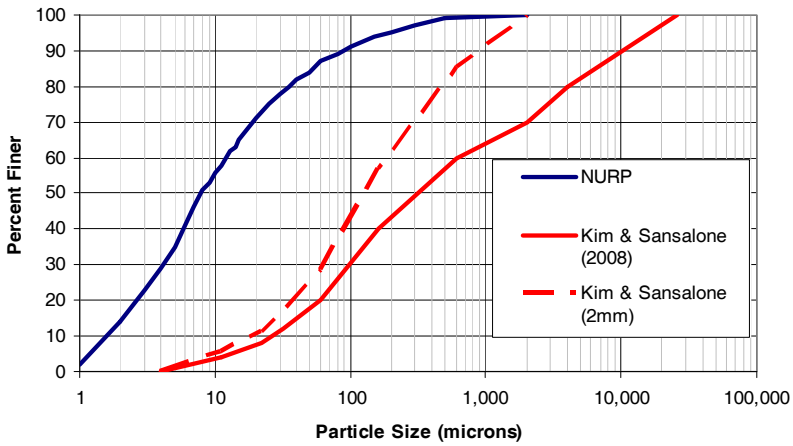

Figure 1. Comparison of Particle Size Distributions.

Particle Distribution in the Flow Column

The main difficulty in sampling suspended solids arises from the behavior of these particles in turbulent flow. Sediment particles are not uniformly distributed with depth in the water column. Suspended solids are composed of an organic portion and an inorganic portion, where the latter is considered to be suspended sediments. The difficulty with sampling suspended sediments has been known for some time. The analysis of Rouse (1937), for example, can be used to develop a suspended sediment concentration relative to the cross-sectional mean concentration based upon particle fall velocity in quiescent fluid, turbulence, and depth.

$$\frac{C}{C_{Ave}} = d\,\frac{(d/y-1)^{\frac{v_s}{\kappa u_*}}}{\int_{y_0}^{d}(d/y-1)^{\frac{v_s}{\kappa u_*}}\,dy} \qquad (1)$$

where C is suspended sediment concentration at depth y, measured from the bed, y_0 is a small distance above the channel bed, C_{Ave} is the cross-sectional mean suspended sediment concentration, v_s is settling velocity, u_* is channel shear velocity, d is channel depth and κ is von Karman's constant. Eq. (1) requires a numerical integration. Shear velocity can be determined from the relation, $u_* = (ghS)^{1/2}$, where S is water surface slope. The particle fall

velocity, in turn, depends upon particle size, density and viscosity of the water. Small particles (< 0.1 mm) have a settling velocity that is described by Stokes law (1851), given in Eq. (2).

$$v_s = \frac{gRd^2}{18\nu} \tag{2}$$

Where g is the acceleration of gravity, R is submerged specific gravity (1.65 for quartz), d is sediment equivalent diameter and v is kinematic viscosity of water. To incorporate larger particles, the empirical equation of Ferguson and Church (2004), with $C_1 = 18$ and $C_2 = 1$ will accurately describe settling velocity for larger sand particles and becomes Stokes Law for smaller particles:

$$v_s = \frac{gRd^2}{C_1\nu + \sqrt{0.75C_2 gRd^3}} \tag{3}$$

Equation (1) was integrated for typical storm sewer conditions of 0.25 m depth of flow and a water surface slope of 0.02. The results, shown in Fig. 2, indicate a substantial vertical variation for suspended sediments greater than 50 μm.

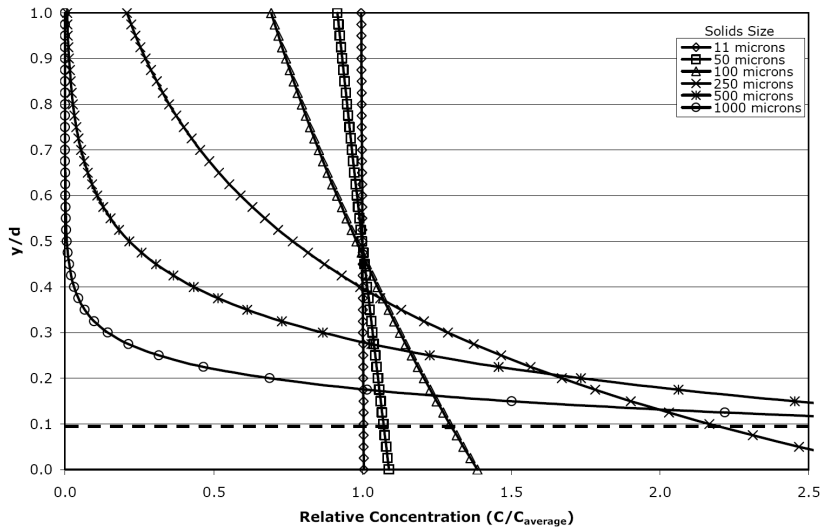

Figure 2. Distribution of suspended sediment concentration with distance from the bed for a depth of 0.25 m and water surface slope of 0.02. The horizontal dashed line indicates the region of sampling, where concentration can be much greater than the cross-sectional mean.

Evaluating Current Sampling Methods

Existing sampling methods were evaluated to establish sampling accuracy. The performance of an automatic sampler was evaluated in a controlled laboratory environment to determine its sampling accuracy for inorganic particles ranging from silt, with a median particle diameter of 20 μm, to medium sand up to 355 μm (Gettel, et al 2009). A laboratory setup was constructed to replicate sampling conditions in a storm sewer conduit. Sediment was fed into a 0.45 m diameter steel pipe at an upstream feed point. Samples were taken with an automatic sampler 10.6 meters downstream of the feed point. Baseline

samples were taken to establish background concentrations and samples were analyzed using the Suspended Sediment Concentration (SSC) method.

Samples were taken with different sediment size ranges and with multiple sampling intake configurations. Intake configurations included a tube oriented parallel to the flow – facing upstream and facing downstream. A manufacturer-recommended sampling manifold was also tested in configurations which included being fixed to the pipe, as well as being allowed to move freely within the flow.

Typical results are shown in Figs. 3 and 4. Results with the intake tube of the sampler indicate that although fine silts and clays (less than 44 μm) were sampled to within 127 percent of the fed concentration, coarse silts and sands were not sampled accurately. Coarse silts sampled at 153 percent of the fed concentration and some sands sampled as high as 6580 percent of the fed concentration. When the intake manifold was used, all silts and clays were sampled within 127 percent of the fed concentration, but fine sands between 180 and 250 μm were sampled at 303 percent of the fed concentration.

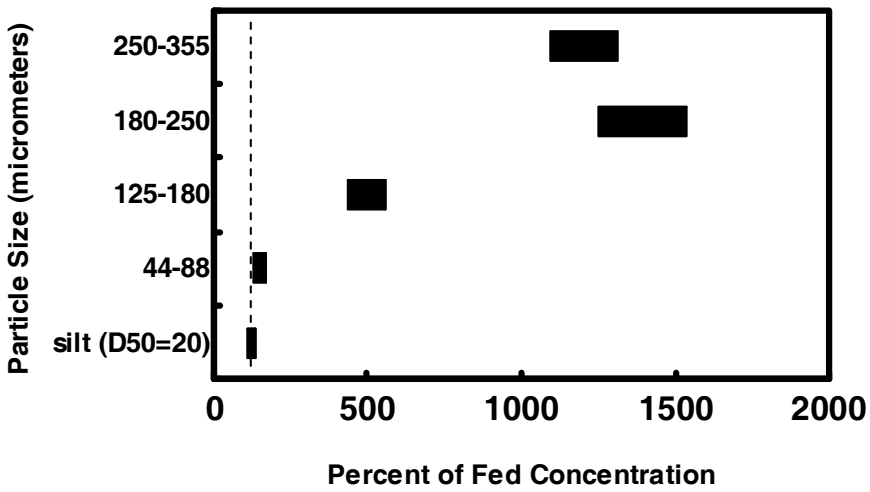

Figure 3. Percent of fed concentration versus particle size for sampling tube facing downstream. Each bar represents a ninety-five percent confidence interval of the mean.

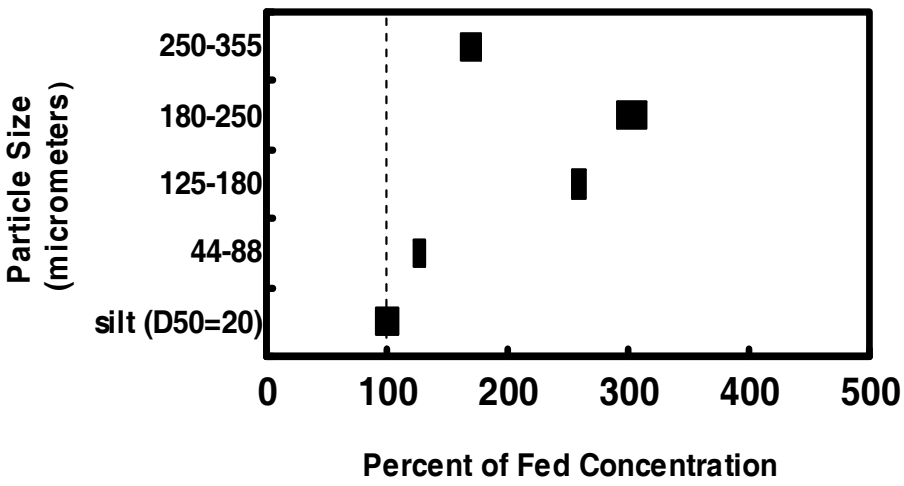

Figure 1. Percent of fed concentration versus particle size for sampling manifold in the fixed configuration. Each bar represents a ninety-five percent confidence interval of the mean.

It is seen that the current sampling technology overestimates most suspended sediment sizes with the sampling tube alone (Fig. 3) and overestimates sand concentration with the sampling manifold (Fig. 4).

Improving Current Sampling Methods

Improvements to sampling mechanisms address two major areas of concern: (1) obtaining an equal volume of sample from multiple regions in the flow column, and (2) ensuring that the lowest section of the flow column is sufficiently mixed. Equal-volume sampling across the flow column ensures the sample is representative of the mean concentration.

Current design iterations of the improved sampling mechanism utilize a passive mixing structure upstream of the intake manifold to ensure the lowest portion of the flow column is well-mixed. The intake manifold itself is hinged from the bottom of the pipe, and a fin is used to provide lift. The intake manifold thus adjusts itself to the depth of flow in the pipe. Equal-volume sampling is attained through variation in the size of the intake ports to account for pressure differences and head loss across the manifold. Figure 5 shows a sketch of the improved sampling mechanism.

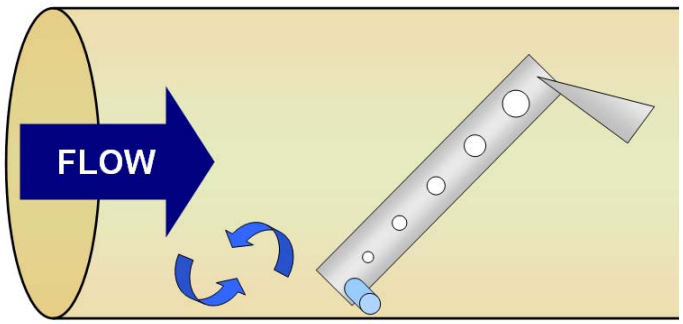

Figure 5. Conceptual Sketch of Improved Sampling Mechanism

Laboratory testing has yielded results as accurate as 119 percent of the fed concentration for fine sand (180 to 250 µm) with a standard sampler. A modified sampler with higher flow rates yielded results as accurate as 103 percent for medium sand (250 to 355 µm).

While this mechanism shows promise for smaller storm sewer pipes, an alternate mechanism is likely necessary for accurate sampling in pipes in excess of 24-inches in diameter.

Conclusions

Previous particle size distribution studies indicate a wide variation in particle size ranges. Taken in concert with the principles of particle settling, an even greater variability becomes apparent with respect to particle settling velocity. Accurate data for particle size and composition is necessary to improve BMP design. Sampling (accurately) with automatic samplers is one means to obtain such data.

Automatic sampling inaccuracy is primarily attributable to the distribution of particles in the flow column. Sampling with a single intake opening does not capture a sample which is representative of the mean concentration. Sampling with multiple intake openings also does not capture a representative sample unless equal-volumes are taken across the flow column and the lowest section of the flow column is well-mixed.

Improved sampling mechanisms have been developed which allow for the sampling of equal-volumes at multiple points in the flow column. These mechanisms are being evaluated for performance over a range of flow conditions, as well as for durability, and resistance to fouling. Future work will also consider methods to accurately sample suspended solids in pipes with very large flow depths.

An Evaluation of Stormwater Wetlands in Series

J.M. Hathaway[1] and W.F. Hunt[2]

[1] Graduate Research Assistant, [2] Assistant Professor and Extension Specialist, Department of Biological and Agricultural Engineering, North Carolina State University, Campus Box 7625, Raleigh, NC 27695; email: jon_hathaway@ncsu.edu

Abstract

Retrofit BMPs are an important tool for achieving water quality goals in urban watersheds, providing treatment to areas not originally developed with stormwater management practices. One such BMP was installed and monitored in Mooresville, N.C. The system includes three wetlands built "in-series" to treat runoff from a highly impervious 30 acre watershed. The configuration of the wetlands allowed monitoring of water quality parameters at the outlet of each of the three stormwater wetlands. The results of this study indicate that water quality improvement for a number of pollutants experiences diminishing returns as it passes through the three wetland cells. For total suspended solids (TSS), approximately 95% of the total concentration reduction took place in the first wetland cell despite it only comprising 60% of the total surface area of the system. Analysis of the effluent concentrations of the first wetland cell indicates that undersized wetlands (roughly 1.5% of the contributing watershed in this case) may still contribute to water quality improvements in urban watersheds. Thus, retrofit BMPs may be desirable even in circumstances when they cannot be sized appropriately for the contributing watershed.

Introduction

Retrofit stormwater Best Management Practices (BMPs) are installed in urbanized areas throughout the United States. These BMPs are designed to treat watersheds which were developed prior to the implementation of stomwater runoff control regulations. Retrofit BMPs are an important tool in watershed management; however, many questions remain regarding their feasibility and performance.

Design guidance for stormwater BMPs in newly developed areas of North Carolina requires the capture and treatment of the water quality volume, that is, the runoff volume associated with either the 2.54 or 3.81-cm (1 or 1.5-inch) storm depending on the physiographic region (NCDENR 2007). This is similar to water quality design criteria in several states, including Maryland (MDE 2000), New York (NYSDEC 2003), Virginia (VDCR 1999). However, in retrofit applications the surface area needed to capture the water quality volume is commonly not available. Thus, innovative designs may be required to maximize available land in urban areas and to optimally treat urban stormwater runoff. The effectiveness of retrofit designs, namely undersized BMPs, is not

well documented. Thus, cost-benefit analyses on urban retrofits are limited by a lack of knowledge as to how undersized BMPs perform.

As efforts continue to reach TMDLs in degraded surface waters, various innovative stormwater treatment designs have been promoted. In North Carolina's nutrient sensitive watersheds, where stormwater nutrient load reductions are required, designers are allowed to place BMPs in series. Each BMP is afforded a state regulated removal rate based on its type (NCDENR 2007). The standard removal rate is applied regardless of a BMP's position in the series (first, second, etc). For example, constructed stormwater wetlands are allotted 85% total suspended solids removal, 40% total nitrogen removal, and 35% total phosphorus removal. Although limited field study has been conducted on the performance of similar kind BMPs in series, most experts agree that this practice is not likely effective for BMPs which rely on similar pollutant removal mechanisms (USEPA 2002, ASCE – WEF 1998, NCDENR 2007). Therefore, NCDENR (2007) only allows two BMPs which rely on similar removal mechanisms to be placed in series. However, both BMPs placed in series are each given full pollutant removal credit, thereby assuming a BMP's location along the series will not significantly impact its performance.

Stormwater BMP efficiency has been shown to vary based on numerous factors including hydraulic loading rate, detention time, characteristics of the storms monitored, and the quality of the stormwater entering the wetland, resulting in a wide performance range when evaluations are based on percent removal calculations (Carleton et al. 2001, Clary et al. 2002, Strecker et al. 2001, Urbonas 1995). Strecker et al. (2001) examined multiple methods of determining stormwater BMP efficiency, concluding that analysis of effluent pollutant concentrations, along with a statistical analysis of influent and effluent pollutant concentrations, was a good measure of BMP performance. Such analysis infers that BMPs receiving relatively clean runoff may not perform as well from a percent removal perspective as BMPs receiving dirty runoff, thus biasing results. This was observed in wetlands studied by Lenhart and Hunt (in review) and Line et al. (2008), where low influent pollutant concentrations led to poor performance based on percent removal calculations despite low effluent concentrations. Various comparisons can be made in an attempt to determine how well a BMP functions, including comparison to effluent concentrations from similar BMPs.
