Monitor for corticosteroid side effects, and taper the dose depending on muscle condition and function.

PROGNOSIS AND OUTCOME 

Variable, depending on the underlying etiology. Process is reversible provided the muscles have not yet undergone extensive fibrosis.

PEARLS & CONSIDERATIONS 

COMMENTS

- Facial muscle atrophy is a common feature of many emaciating conditions in which there is also accompanying generalized loss of lean body mass.
- Generalized muscle atrophy is often first noticed in the facial muscles, especially in long-haired breeds.
- Of all the differentials discussed in this section, only trigeminal nerve abnormalities, MM, and anomalies of the TMJs are strictly confined to facial muscle atrophy.

CLIENT EDUCATION

Encourage clients to present patients early in the disease process

SUGGESTED READING

AUTHOR: JOHAN P. SCHOEMAN

EDITOR: ETIENNE CÔTÉ

Gunshot Wounds

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

A type of projectile injury involving handguns, air-powered weapons, shotguns, or rifles

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats of any age
- Male dogs may be overrepresented

RISK FACTORS

- Unsupervised roaming, notably intact male dogs
- Night and early morning hours
- Stray dogs in rural areas (e.g., deliberately shot if considered a nuisance or potential threat to livestock)
- During hunting season, dogs may be mistakenly shot as game or maliciously for sport.
- Guard dogs, police dogs, and hunting dogs are at risk of being shot during work.

GEOGRAPHY AND SEASONALITY

- Higher-crime urban neighborhoods
- In rural areas, shotgun and rifle injuries are more common.
- Air-powered weapons: more likely discharged in residential or rural areas

CLINICAL PRESENTATION

Subtypes:

- Pellet guns and BB guns (air-powered projectiles)
- Handguns
- Rifles
- Shotguns

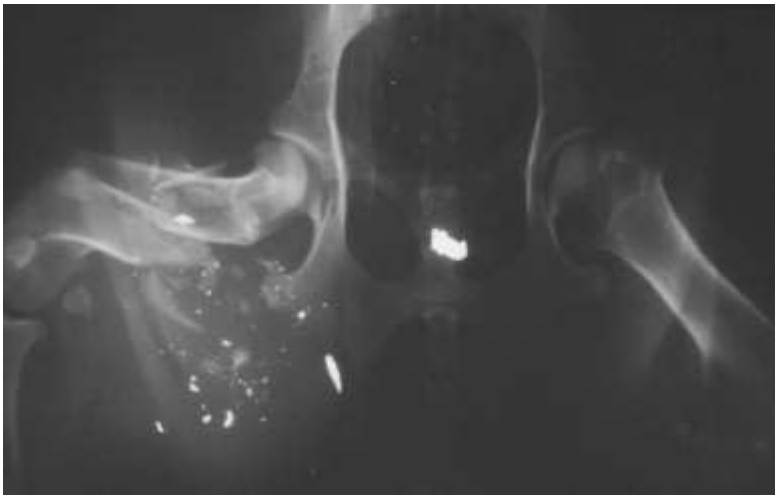
HISTORY, CHIEF COMPLAINT

- Pets may present with respiratory distress, internal hemorrhage, neurologic injury, or musculoskeletal injuries (fracture).
- Wound may escape notice, especially if event was not witnessed
- Dogs and cats with extensive blood loss will present in shock, with pale mucous membranes and tachycardia.
- Patient may present in pain; in minor cases, the patient may show little evidence of overt discomfort.

PHYSICAL EXAM FINDINGS

- Open wounds:
  - Circular, oval, or angular cutaneous entry wounds with solitary projectiles, often smaller than the projectile
  - Cutaneous burns/lesions if firearm was at close range
  - There may be no exit wound if the projectile is retained: low-velocity projectiles are more likely to be retained than high velocity projectiles.
  - Exit wounds are frequently larger and irregular in shape; shards of bone form secondary projectiles, increasing exit wound size.
  - At close range, shotgun injuries can cause extensive destruction of the skin and underlying tissues.
  - Low-velocity BBs and pellets (air-powered) create small entry wounds. Because of their low mass and comparatively low velocity, many of these projectiles will be retained (no exit wound).
- Internal injuries:
  - Clinical signs are commensurate with tissues impacted and the severity of trauma (orthopedic, spinal, ocular,

gastrointestinal, pulmonary involvement).
- Elastic tissues (lung, muscle) are capable of stretching, thereby partially dissipating the kinetic energy of the projectile. Inelastic organs, such as the liver (low collagen content), may show massive tissue destruction from the high-velocity rifle round compared to a low-velocity bullet.
- Abdominal gunshot wounds have a high probability for peritonitis (gastrointestinal tract penetration).



GUNSHOT WOUNDS Hunting rifle round, shattering the patient's femur. Note the bone and projectile fragments, creating secondary projectiles within the wound, enhancing soft tissue trauma.

ETIOLOGY AND PATHOPHYSIOLOGY

- The destructive potential of a projectile can be assessed in part by the formula:

$$\frac{\text{Mass} \times \text{Velocity}^2}{2}$$

- Bullets may have an outer metallic jacket to control the shape or expansion of the bullet as it impacts a target.
  - Hollow points are designed to mushroom on impact.
  - Frangible bullets are designed to break apart on impact.
  - Military-style full metal jacket bullets are designed to minimize deformation.
- Projectiles are capable of lodging and then migrating through the respiratory tract, urogenital tract, gastrointestinal tract, cardiovascular system, and fascial planes.
- Shotgun pellets expand in a conical pattern; they are very destructive in the first 20 yards or less.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Bullets, BBs, and pellets may be found as an incidental finding on radiographs. This may cause confusion when evaluating an acutely sick or injured patient. It is important to remember that acute gunshot wounds will have an entry wound.
- Gunshot wounds are most commonly mistaken for bite wounds and vehicular trauma.
- Because most animals are shot while wandering, radiographs are an important tool in looking for evidence of a retained projectile.

DIFFERENTIAL DIAGNOSIS

Other penetrating objects can create a skin opening that may mimic a bullet wound, including sticks, pointed metallic objects, and the like.

INITIAL DATABASE

- CBC, serum chemistry profile, and urinalysis as indicated by likely organs injured
- Radiographs (two-view minimum) for the body region shot, based on bullet retention or entry/exit wound locations. In a gunshot wound with no evidence of exit, additional views may be needed to locate a retained projectile.

ADVANCED TESTING OR CONFIRMATORY TESTING

- Abdominocentesis (see p. 1194), fluid analysis, cytology, and gram stains may be used to confirm the possible presence of peritonitis.
- Thoracocentesis can be both life saving and diagnostic for patients with pneumothorax or hemothorax; aerobic and anaerobic cultures if infection is suspected.

TREATMENT

TREATMENT OVERVIEW

- A team effort by doctors and technical support is necessary to efficiently stabilize critically injured patients.
- Control visible blood loss.
- Maintain an established airway, and assure patient is breathing satisfactorily.
- Placement of one or more intravenous lines for fluid support.
- Address life-threatening injuries and overlapping medical crises.
- Initiate pain therapy to reduce patient discomfort and stress.
- Initiate wound care and a plan for long-term management of the injuries.

ACUTE GENERAL TREATMENT

- Control external hemorrhage by external compression, tourniquets, ligatures, vascular clips. Attendants should wear gloves to prevent bacterial contamination and protect individuals from bloodborne disease.
- Intravenous fluid support (crystalloids, colloids, hypertonic saline, whole blood products)
- Establish and maintain respiratory system: intubation, emergency tracheotomy, thoracic tube insertion (hemo-thorax, pneumothorax, etc.) if indicated.
- Initiate pain medications that will not mask or compromise the patient's status. Consider a pure opioid agonist such as morphine, 0.1-1 mg/kg IV or IM q 2-6 h, for good analgesic activity and the ability for reversal as needed. Partial agonists (buprenorphine) and agonist/antagonists (butorphanol) acceptable for minor gunshot wounds.
- A muzzle or Elizabethan collar may be used to protect health care providers from being bitten by the anxious or painful patient.
- The external gunshot wound can be clipped, cleansed, and pressure lavaged (35-mL syringe and an 18-G needle); the wound may require enlargement to prevent entrapment of lavage fluids. A protective dressing may then be applied to the individual wounds.
- Broad-spectrum intravenous antibiotics (e.g., cefazolin, 22 mg/kg IV q 6 h) can be initiated in the seriously injured patient.
- Not all critical patients can be fully stabilized prior to surgery. For example, following initial attempts to support the hypovolemic patient, surgical intervention may be needed to control massive hemorrhage.
- Wound exploration is best performed under general anesthesia for detailed wound examination, débridement, and definitive wound repair.
- All acute abdominal gunshot wounds should be explored because of the high risk of peritonitis secondary to bowel penetration/perforation. All organs must be inspected closely for concomitant trauma.

CHRONIC TREATMENT

- Prolonged open wound management (serial débridement, multiple dressing applications, etc.) may be needed for contaminated or necrotic injuries.
- Peritonitis may require prolonged wound drainage (open abdomen, vacuum drain systems, sump drains), abdominal lavage, and possible reexploration (see p. 1250).
- Problematic soft-tissue wounds, including extensive skin loss, may require reconstructive surgery.
- With extensive orthopedic trauma (reparable), vacuum drains and lidocaine infusion catheters can be used for controlling dead space and reduce tissue pain. Lidocaine also may be temporarily infused using the tubing in a vacuum drain system (Jackson-Pratt drains).

POSSIBLE COMPLICATIONS

- The eyes are especially vulnerable to projectile wounds. Blindness and loss of the eye may result from extensive trauma.
- Paresis or paralysis may result from spinal cord trauma.
- Infection is a primary concern in gunshot wounds highlighted by extensive tissue destruction.
- Patients generally are at low risk for lead poisoning, except for lead in joints (should be removed).
- Delayed or nonhealing wounds

RECOMMENDED MONITORING

Vital signs in critical injuries

PROGNOSIS AND OUTCOME

- Determined by extent of injury and subsequent treatment
- Prompt stabilization of the patient and definitive medical/surgical intervention can improve the rate of survival and positive long-term outcome of the patient.
- Gunshot wounds to the brain, spinal cord, and abdomen normally carry a worse prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Due to potential legal ramifications of gunshot wounds, records must be detailed and accurate; all conversations should be detailed, complete, and noted in the medical record. Photographs of the injuries (entry, exit, tissue trauma inflicted) are useful evidence in court, along with supporting radiographs.
- A board-certified veterinary pathologist is best utilized to conduct detailed postmortem examination of deceased animals.
- It is critically important to transfer bullets and bullet fragments only to a qualified law enforcement officer, handling bullets gently (no metal forceps; wrap in tissue paper, and place in labeled, sealed container) should they be used as evidence in court.

EDITOR: RICHARD WALSHAW

Grapes and Raisins Toxicosis

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

Acute renal failure (ARF) following ingestion of grapes *(Vitis* spp.) or raisins

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Documented in dogs only
- Anecdotally reported in cats, ferrets
- No known age or sex predisposition; all breeds susceptible
- Ingestion of grapes or raisins does not consistently cause acute renal failure in all dogs.

RISK FACTORS

Animals with preexisting kidney disease may be at increased risk of developing ARF.

GEOGRAPHY AND SEASONALITY

Intoxication can occur any time of the year.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Ingestion suspected or directly observed
- Evidence of grapes/raisins in vomitus or stool
- Most common signs are manifestations of acute renal failure: vomiting, lethargy, anorexia, diarrhea, decreased urine output, signs of abdominal pain, ataxia, and weakness
- Vomiting, lethargy, anorexia within 24 hours; vomiting is usually seen within 12 hours after ingestion.

PHYSICAL EXAM FINDINGS

- Dehydration
- Signs of abdominal pain in some dogs
- Lethargy

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology unknown
- Renal tubular necrosis is a consistent histopathologic finding.
- Tubular basement membrane often remains intact, providing possibility for recovery. Evidence of tubular regeneration may be present in some dogs.
- Mineralization of kidneys, gastric mucosa, myocardium, lungs, and blood vessels

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of grape or raisin toxicosis is suspected based on possibility or certainty of exposure, presence of grapes/raisins in the vomitus/stool, and if several hours have passed, possibly the onset of vomiting, anorexia, lethargy, diarrhea, decreased urine output, ataxia or weakness, or a combination of these. Azotemia and other serum chemistry changes consistent with ARF are seen in 1-3 days, but supportive treatment is warranted as soon as possible.

DIFFERENTIAL DIAGNOSIS

Rule out other causes of ARF:

- Ethylene glycol toxicosis
- Leptospirosis
- Bacterial pyelonephritis
- Lily toxicosis in cats
- Iatrogenic/medication nephrotoxicosis (e.g., aminoglycoside antibiotics)
- Renal thromboembolism (usually accompanied by thromboembolism of other aortic branches)

INITIAL DATABASE

- Serum chemistry profile, CBC, calcium × phosphorus product (Ca × P):
  - Azotemia, hyperphosphatemia, elevated Ca × P (>60 when both are measured in mg/dL) almost always present if enough time has passed and ingestion was substantial; hypercalcemia frequent
  - Serum creatinine, phosphorus, and Ca × P can be elevated in less than 24 hours.
  - Blood urea nitrogen and calcium may be slower to rise (1-3 days).
- Urinalysis before giving fluids:
  - Urine specific gravity <1.030
  - Glucosuria, proteinuria
  - Cylindruria (casts)
- Abdominal radiographs; abnormalities uncommon:
  - Increased renal size
  - Metastatic mineralization

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonography to assess kidneys and pancreas
- Renal biopsy may help determine prognosis

TREATMENT

TREATMENT OVERVIEW

If any reasonable possibility exists of a patient having eaten a significant quantity of grapes (e.g., >10-12 grapes in an 8-kg dog) or raisins (>0.1 oz/kg [>3 g/kg]), treatment is justified to reduce the risk of permanent renal lesions. Treatment aims to decrease absorption (induction of vomiting and administration of activated charcoal) in early/mild ingestions when no clinical signs are apparent. When clinical signs are present, treatment consists of fluid diuresis, nutritional support, vomiting, seizure control, and management of acute renal failure (see p. 31) as needed.

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Emesis: useful 6-12 hours after exposure (see p. 1364)
  - Activated charcoal (1-2 g/kg PO): useful up to 12-24 hours after exposure
- Fluid diuresis:
  - Intravenous fluid diuresis for 48 hours in patients not yet showing clinical signs may prevent ARF.
  - Treat signs of ARF as needed (see p. 31). Currently no unique treatment identified. If concurrent hypercalcemia, consider using 0.9% normal saline.
- Manage vomiting:
  - Metoclopramide: 0.2-0.4 mg/kg q 6 h PO, SQ or IM or 1-2 mg/kg/d constant rate infusion (CRI); *or*
  - Maropitant: 1 mg/kg SQ (or 2 mg/kg PO) q 24 h up to 5 consecutive days
- Treat anuria/oliguria:
  - Correct dehydration first.
  - Mannitol: 0.25-0.5 g/kg IV over 3-5 minutes or CRI of 2-5 mL/min of 5%-10% mannitol in lactated Ringer's solution
  - Furosemide: 2-4 mg/kg IV up to 6 mg/kg if needed (if subnormal urine production persists) q 8 h; or combine 1 mg/kg/h furosemide (CRI or IV boluses) with dopamine CRI
  - Dopamine: 2-5 mcg/kg/min IV CRI. Efficacy in ARF questioned, and may cause nausea
  - Hemodialysis or peritoneal dialysis may be useful in some cases.

CHRONIC TREATMENT

Ongoing supportive care based on initial severity, response to treatments, individual's intrinsic ability to compensate, and extent of permanent renal injury

POSSIBLE COMPLICATIONS

- Uremia-related neurologic signs (seizures, ataxia)
- Metastatic mineralization (renal, cardiac, vascular, pulmonary)
- Pancreatitis

RECOMMENDED MONITORING

- Baseline blood urea nitrogen, creatinine, calcium, phosphorus, Ca × P, potassium, total protein, hematocrit, daily at first then as needed
- Urine output
- Signs of overhydration (respiratory character/effort, body weight)
- Acidosis

PROGNOSIS AND OUTCOME

- Of 43 dogs with grape/raisin toxicosis, 53% recovered with treatment, 12% died, and 35% were euthanized.
- Oliguria/anuria, ataxia, and weakness indicate poor prognosis.
- Higher serum [calcium] and Ca × P indicate poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Raisins at 0.1 oz/kg (3 g/kg) and grapes (10 to 12 grapes in an 8-kg dog) have led to ARF.
- Not all dogs that ingest raisins or grapes develop ARF.
- Raisins are 4.5 times more concentrated than grapes on an ounce-per-ounce basis.
- Treatment may be required for days to weeks.

PREVENTION

Keep raisins and grapes out of dogs' reach.

TECHNICIAN TIPS

- Decontamination with induction of vomiting can be effective up to 6-12 hours after exposure, and administration of charcoal up to 24 hours after exposure.
- Oliguria is defined as <0.25 mL/kg/h urine production, and treatment should aim to ensure that urine production remains greater than this level.

CLIENT EDUCATION

- Do not feed grapes or raisins to dogs.
- Treatment may be extensive and expensive and may be associated with a guarded prognosis.

SUGGESTED READING

1ST EDITION AUTHOR: PAUL EUBIG

Granulomatous Meningoencephalomyelitis (GME)

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A common, idiopathic, inflammatory, noninfectious meningoencephalomyelitis of dogs, the definitive diagnosis of which is dependent on characteristic histopathologic features

EPIDEMIOLOGY

SPECIES, AGE, SEX

Any age and either sex can be affected by granulomatous meningoencephalomyelitis (GME). This is a canine disease, being virtually nonexistent in cats. The median age is 5 years, and there appears to be a female predominance.

GENETICS AND BREED PREDISPOSITION

The genetics of GME are unknown. Small-breed dogs (e.g., poodles, terriers) are predisposed, although larger breeds are occasionally affected.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Three forms of GME have been described:

- Multifocal (disseminated)
- Focal
- Ocular (uncommon)

HISTORY, CHIEF COMPLAINT

- The history and chief complaint are reflective of the form of GME and the particular region or regions of the central nervous system involved.
- Central vestibular dysfunction is a common presentation for dogs with GME.
- Other common complaints include seizures, abnormal mental status, neck pain, and nonambulatory status.
- Dogs with multifocal and ocular forms of GME tend to have acute onset of clinical signs.
- Multifocal GME is usually rapidly progressive.

PHYSICAL EXAM FINDINGS

- Patients with GME are occasionally febrile on presentation.
- There are usually no other abnormalities on general physical examination.
- Neurologic abnormalities (see p. 1311) depend on the form of GME affecting the patient. Clinical evidence of fore-brain, brainstem, cerebellar, and cervical spinal cord dysfunction are prominent, either alone or in combination.

ETIOLOGY AND PATHOPHYSIOLOGY

The etiology of GME is unknown. However, there is strong evidence that this is an autoimmune disorder, most likely a T-cell mediated, delayed-type (type IV) hypersensitivity reaction.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A working clinical diagnosis of GME is dependent on compatible history, neurologic exam findings, diagnostic imaging, and

cerebrospinal fluid [CSF] analysis.

DIFFERENTIAL DIAGNOSIS

- Necrotizing encephalitis
- Infectious meningoencephalitis
- Neoplasia
- Caudal occipital malformation syndrome
- Intracranial intra-arachnoid cyst (quadrigeminal cyst)

INITIAL DATABASE

- CT, MRI: most cases exhibit contrast-enhancing lesions with white matter predominance.
- Characteristic CSF findings are a sterile, mixed-cell (primarily mononuclear) pleocytosis with elevated protein levels.

ADVANCED OR CONFIRMATORY TESTING

Definitive diagnosis of GME is dependent on histopathologic examination of brain and/or spinal cord parenchymal lesions, which are uncommonly obtained in the clinical setting.

TREATMENT

TREATMENT OVERVIEW

Treatment goals are:

- Suppression of the inflammatory process
- Recovery of functional neurologic status
- Pain management
- Seizure control, if seizures are part of the clinical picture

ACUTE GENERAL TREATMENT

- The standard treatment for GME has traditionally been immunosuppressive doses of glucocorticoids (e.g., prednisolone, 1-2 mg/kg PO q 12 h).
- Current treatment protocols include cyclosporine (3-5 mg/kg PO q 12 h), procarbazine (25 mg/m^2 PO q 24 h), and cytosine arabinoside (50 mg/m^2 SQ q 12 h for 2 days, then repeated initially q 3 wk), in addition to prednisone therapy. These drugs are reported to be used as single agents in combination with prednisone. The author typically administers these drugs concurrently.
- If the patient is seizuring, intravenous diazepam or levetiracetam can be administered while starting a maintenance anticonvulsant drug (see p. 1009).

CHRONIC TREATMENT

- One or more of the previously mentioned drugs is/are continued indefinitely. Coincident with clinical improvement, one or more drugs can be slowly weaned to lowest possible levels.
- A maintenance anticonvulsant without sedative tendencies and without the side effects of polyuria and polydipsia is recommended for seizure control (e.g., zonisamide, levetiracetam).
- Radiation therapy has been shown to be beneficial in cases of focal GME.

POSSIBLE COMPLICATIONS

- Typical glucocorticoid side effects are to be expected.
- Procarbazine may cause hemorrhagic gastroenteritis.
- Procarbazine and cytosine arabinoside may cause bone marrow suppression. The author has witnessed bone marrow suppression with the former but not the latter drug.
- Potential adverse effects of cyclosporine (infrequently observed) include vomiting, diarrhea, systemic hypertension, weight loss, anorexia, gingival hyperplasia, and excessive shedding.

RECOMMENDED MONITORING

CBCs should be evaluated for dogs receiving immunosuppressive/chemo-therapeutic agents (e.g., cytosine arabinoside, procarbazine) every week for the initial month of therapy, then monthly thereafter.

PROGNOSIS AND OUTCOME

- The prognosis for GME has improved dramatically coincident with the addition of new treatment protocols (i.e., cyclosporine, procarbazine, cytosine arabinoside).
- With the use of prednisone alone, the overall median survival is 14 days.
- With the use of prednisone alone, the median survival for focal GME is 114 days and for multifocal GME, 8 days.
- With procarbazine use, the overall median survival is 14 months.
- With the use of cytosine arabinoside, the overall median survival is approximately 18 months.
- Cyclosporine therapy is associated with an overall median survival of approximately 2.5 years.
- Dogs with focal GME treated with radiation therapy have a median survival of more than 400 days.

PEARLS & CONSIDERATIONS

COMMENTS

- The author routinely uses multiple drug therapy to achieve clinical remission in GME cases, often using cyclosporine, procarbazine, and cytosine arabinoside in addition to prednisone. In most cases, an obvious response to therapy is observed within 1 week. After 1-2 months of combination therapy, one drug is weaned at a time, usually starting with prednisone.
- Procarbazine is often weaned to every other day after several months to avoid adverse drug effects.
- In many GME cases, prednisone can be weaned to a very low dose (minimizing adverse effects) but not entirely discontinued.
- It is the author's clinical experience that most GME dogs improve dramatically or achieve clinical remission with multi drug therapy and often survive for more than 2 years.

AUTHOR & EDITOR: CURTIS W. DEWEY

Granulomatous Enteritis/Colitis

BASIC INFORMATION

DEFINITION

Uncommon cause for persistent (>3 weeks) signs of small-intestinal/colonic inflammation associated with mucosal infiltration of macrophages. Affected animals have large-bowel diarrhea and will also show systemic signs of fever, anorexia, and weight loss.

SYNONYMS

"Boxer colitis" when referring to the inflammatory bowel disease (IBD) variant, histiocytic ulcerative colitis (HUC). Histiocytic ulcerative colitis is characterized by mucosal infiltrates of PAS-positive histiocytes.

EPIDEMIOLOGY

SPECIES, AGE, SEX

HUC appears to be more prevalent in young male dogs. Granulomatous colitis of any cause is much less common in cats than in dogs. Granulomatous enteritis associated with primary gastrointestinal histoplasmosis may be seen in both the dog (common) and cat (rare).

GENETICS & BREED PREDISPOSITION

Boxers are predisposed to HUC. Large-breed dogs are more commonly affected with systemic fungal infections.

GEOGRAPHY AND SEASONALITY

Midwestern and southern United States for gastrointestinal (GI) histoplasmosis

ASSOCIATED CONDITIONS & DISORDERS

HUC is often recognized as an IBD variant that is much less common than lymphocytic plasmacytic colitis. Note than HUC may not be IBD but rather a unique and specific form of infectious (e.g., enteroinvasive *E. coli*) colitis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Histiocytic ulcerative colitis: IBD variant characterized by mucosal infiltration with PAS-positive histiocytes
- Infectious causes for granulomatous colitis: includes both systemic fungal infections caused by *Histoplasma capsulatum* and *Pythium insidiosum*, and algal infection caused by *Prototheca* spp. Gastrointestinal histoplasmosis is the most common form of infectious enteropathy.

HISTORY, CHIEF COMPLAINT

- Persistent large-bowel diarrhea: tenesmus (straining to defecate), increased frequency of defecation, mucoid feces, and fresh (red) blood
- Cachexia, anorexia, and weight loss are frequently observed with granulomatous colitis, which is in sharp contrast to other causes of colonic inflammation.

PHYSICAL EXAM FINDINGS

Fever, cachexia, weight loss, and peripheral/mesenteric lymphadenopathy are observed with infectious causes. Dogs with HUC may not have mesenteric lymphadenopathy. Ocular signs (uveitis) and/or neurologic abnormalities (e.g., paresis, head tilt, ataxia) are often reported with *Prototheca* spp. infection.

ETIOLOGY AND PATHOPHYSIOLOGY

- HUC: a severe but uncommon IBD variant
- Infiltrative mucosal disease caused by fungal or algal agents, resulting in granulomatous colonic inflammation. Dissemination to other organ systems is common with systemic mycotic and algal infections.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis may be suspected based on history of signs of chronic GI disturbance, prompting endoscopic or full-thickness intestinal biopsies (definitive confirmation).

DIFFERENTIAL DIAGNOSIS

- Specific causes: see Etiology and Pathophysiology above
- Other differential diagnoses: severe colonic IBD, neoplasia

INITIAL DATABASE

- CBC, serum biochemistry, urinalysis, and fecal tests are indicated to evaluate involvement of diverse organ systems.
- Exfoliative cytology (e.g., rectal scrape; see p. 1334) is a useful tool for confirming the presence of *Histoplasma* organisms contained within colonic macrophages. An easy and inexpensive screen which should be performed in endemic regions.
- Urinary excretion of histoplasmosis antigen is a highly sensitive and specific assay. This is a simple noninvasive diagnostic test for gastrointestinal histoplasmosis.
- Abdominal imaging (survey radiographs, contrast radiography, and/or ultrasonography) will identify diffuse colonic wall thickening, loss of wall layering, and/or mesenteric lymphadenopathy indicative of infiltrative mural disease.

ADVANCED OR CONFIRMATORY TESTING

- PCR or ELISA techniques on serum or tissues will confirm *Pythium* spp. infection.
- Oculocentesis may detect *Prototheca* spp. organisms in animals with ocular lesions.
- Urinary excretion of histoplasmosis antigen
- Mucosal biopsy obtained endoscopically or surgically will demonstrate the presence of PAS-positive histiocytes or granulomatous inflammation with infectious organisms.
- Fluorescence in situ hybridization (FISH) performed on tissue sections confirms the presence of adherent/invasive *E. coli* organisms in boxer dogs.

TREATMENT

TREATMENT OVERVIEW

- Treatment requires a specific definitive diagnosis determined by mucosal biopsy.
- Surgical excision of diseased tissues (if possible) is required for pythiosis.

NUTRITION/DIET

- Dogs with protein-losing enteropathy due to gastrointestinal histoplasmosis are generally protein-caloric malnourished and may benefit from low-fat rations. Assess cobalamin status in these patients and correct if present.
- Dietary management includes supplementation with sources of soluble fiber, which bind colonic irritants, normalize dysmotility, and promote colonic epithelial repair and renewal.

CHRONIC TREATMENT

- Treat HUC with enrofloxacin (5 mg/kg PO q 24 h for 14-21 days) alone or in combination with metronidazole or amoxicillin. Some dogs may respond to single drug therapy, but others may require combination therapy. Extend treatment 14 days past resolution of signs, owing to severity of most *E. coli* infections.
- Nutrition: low-fat, fiber-enriched, and highly digestible commercial ration. In some instances, a restricted-antigen (e.g., elimination) diet may also be helpful, since dogs may develop dietary sensitivity.
- Supplementation with increased n-3: n-6 fatty acids to reduce mucosal inflammation
- If the animal will not eat a commercial fiber-containing diet, addition of fiber (small to moderate amounts of soluble fiber [Metamucil sprinkled on the food at a dosage of 1-2 teaspoons/10 kg body weight per feeding]) to the regular diet.

- Infection with *Histoplasma* spp. requires antifungal therapy (see p. 538).
- Aggressive surgical resection will be required for animals infected with *Pythium* spp.
- There is no effective therapy for protothecosis.

POSSIBLE COMPLICATIONS

- Cure is often not possible in animals with pythiosis or protothecosis. These animals will likely die regardless of therapy.
- Animals having GI histoplasmosis and treated with amphotericin B are at risk for drug-induced renal disease.
- Boxers with HUC may require repeated intermittent or long-term therapy for remission of signs. If dogs fail to respond to enrofloxacin therapy, consider antibiotic resistance to this drug a strong possibility for treatment failure. A second-choice drug to consider would be ciprofloxacin; however, clinical trials attesting to efficacy with this medication in therapy of HUC have not been published.

RECOMMENDED MONITORING

- Rechecks are required at 2-to 4-week intervals initially in animals with HUC. Gradual drug reduction may occur as clinical signs lessen.
- Monitor renal function in animals treated with amphotericin B.

PROGNOSIS AND OUTCOME

- HUC carries a good prognosis short term, although long-term studies addressing the maintenance of a positive outcome (e.g., full remission) are lacking.
- GI histoplasmosis carries a guarded prognosis; however, most animals respond favorably to antifungal therapy (itraconazole) in spite of disease burden.
- Granulomatous colitis caused by *Pythium* spp. and *Prototheca* spp. carries a poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Major causes for granulomatous colitis include infectious and infiltrative disorders.
- A thorough diagnostic evaluation is warranted to rule out the varied causes for colonic inflammation.
- Colonoscopy with targeted mucosal biopsy is imperative for diagnosis.

TECHNICIAN TIPS

- Many patients with GI histoplasmosis will require fastidious nursing care to remain hydrated and maintain adequate nutritional status.
- Clients should be apprised that antifungal therapy may be expensive and require long-term (6-9 months) treatment.

CLIENT EDUCATION

- Dietary modification to a diet suitable for colonic disease may be required for the life of the pet.
- Educate clients about treatment costs and duration of therapy in dogs with GI histoplasmosis.

Glyphosate Herbicide Toxicosis

BASIC INFORMATION

DEFINITION

Glyphosate is a phosphanoglycine herbicide. It is currently the most commonly used broad-spectrum, systemic, nonselective postemergence herbicide. Toxicosis occurs when pets accidentally walk through the sprayed area and groom themselves, or lick a sprayed plant, or puncture the glyphosate container. Clinical signs of toxicosis are seen usually within 4 hours of exposure and are limited to mild signs of gastrointestinal upset such as hypersalivation, vomiting, or diarrhea.

SYNONYMS

N-(phosphonomethyl) glycine. Some common brand names are Accord, Bio-active, Bronco, Kleen-up, Landmaster, Rodeo, Roundup, RoundupPro, Round-upUltra, Roundup plus, Network, Spark, Vision.

EPIDEMIOLOGY

SPECIES, AGE, SEX

There are no known increases in risks based on species, age, or sex. Dogs are more commonly exposed owing to indiscriminate eating habits, compared to cats.

RISK FACTORS

Toxicosis more frequent during spring or summer months when herbicides are more frequently available and used.

GEOGRAPHY AND SEASONALITY

Exposure is more common in warm growing months when lawns are commonly treated with herbicides.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Observed licking or ingestion of a glyphosate-treated plant
- Evidence that the pet chewed a container of the product
- Recent use of a glyphosate product in the animal's environment and possible exposure
- Spontaneous hypersalivation, vomiting, and diarrhea may be present and noted by the owner. After exposure, vomiting may occur within the first 4 hours and diarrhea within 24 hours.

PHYSICAL EXAM FINDINGS

Drooling or licking motions may be evident, but otherwise the physical exam findings should be unremarkable.

ETIOLOGY AND PATHOPHYSIOLOGY

Glyphosate herbicides are primarily available as water-soluble liquids (ready-to-use spray) or concentrated solutions.

- Glyphosate herbicidal mechanism. Absorbed through the leaves or roots of the plant and transported throughout the plant. Interferes with phenylalanine, tyrosine, and tryptophan synthesis (inhibits a plant-only biochemical pathway, the shikimic acid pathway).
- Surfactant blends are used in varying concentrations as carriers in some formulations.
    - Surfactants account for the majority of signs of toxicosis.
- Different formulations may also contain other herbicides such as diquat or triclopyr.

DIAGNOSIS

OVERVIEW STATEMENT

Since clinical signs are nonspecific, an exact diagnosis of intoxication relies on observation or suspicion of exposure. A tentative diagnosis is sufficient to initiate treatment.

DIFFERENTIAL DIAGNOSIS

Any other etiology that can cause nausea, vomiting, and diarrhea (dietary indiscretion, garbage toxicosis, inflammatory bowel disease, intestinal neoplasia, intestinal obstruction, viral or bacterial gastroenteritis, pancreatitis)

INITIAL DATABASE

Since toxicosis is usually mild and self-limiting, no significant laboratory abnormalities are expected.

- In most cases, laboratory work (CBC, serum biochemistry profile) is not indicated.
- If severe signs, monitor hydration status and electrolytes.

ADVANCED OR CONFIRMATORY TESTING

Advanced confirmatory testing not needed or required. Glyphosates can be analyzed by HPLC or gas chromatography/mass spectrometry. However, no method is readily available for clinical use.

TREATMENT 

TREATMENT OVERVIEW

If no clinical signs are present after oral exposure, treatment centers on dilution (milk or water). Rarely, severe signs are present, warranting antiemetics and supportive care (rarely needed). Dermal exposures require topical decontamination.

ACUTE GENERAL TREATMENT

- Dermal exposure: bathe with a dilute solution of a mild dishwashing liquid and monitor for gastrointestinal (GI) signs at home.
- Oral exposure without clinical signs:
  - Dilution: give milk or water (45 mL PO syringe fed or via orogastric tube for 10-15 kg/dog) and monitor for GI signs at home for 4 hours.
- If clinical signs (vomiting, other) are present:
  - Nothing by mouth × 2-4 hours if mild vomiting
  - Antiemetics (rarely needed) only if severe vomiting:
    - Maropitant, 1 mg/kg SQ (or 2 mg/kg PO) SID up to 5 days, *or*
    - Metoclopramide, dog/cat: 0.1-0.4 mg/kg q 6 hours PO, SQ, or IM *or*
    - Dolasetron, dog/cat: 0.6-1 mg/kg PO q 12 h
  - Intravenous fluids (rarely needed) if severe signs are present

NUTRITION/DIET

Bland diet may be indicated if diarrhea develops.

PROGNOSIS AND OUTCOME 

Excellent; most cases can be treated at home by the owner and do not require veterinary care.

PEARLS & CONSIDERATIONS 

COMMENTS

- Glyphosates have very low oral toxicity in mammals. Oral LD50 in most animals is >5000 mg/kg. NOEL (no observable effect level) for 1 year in dogs is 500/mg/kg/day.
- Clinical signs of toxicosis (hypersalivation, vomiting, and diarrhea) are more related to the surfactant in the formulation than the active-ingredient glyphosate.

- Certain surfactants in the formulation are more toxic to fish and invertebrates; therefore, some formulations are not for aquatic applications.
- Structurally, glyphosate is classified as an organophosphate herbicide. However, this agent does not inhibit cholinesterase like organophosphate pesticides (see p. 792). Therefore, no cholinergic signs of toxicosis are seen in animals.

PREVENTION

Keep pets out of the sprayed area until it has completely dried.

CLIENT EDUCATION

Use products per label directions. Keep animals away from treated area until the product is dried on the plants. Store pesticides out of reach of pets.

Gluten-Sensitive Enteropathy

BASIC INFORMATION

DEFINITION

A chronic small-intestinal disease triggered in susceptible animals by the ingestion of gluten, a protein found in wheat

SYNONYMS

Celiac disease (humans), gliadin enteropathy, gluten enteropathy, GSE, wheat-sensitive enteropathy

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Uncommon disorder in dogs
- Can potentially occur in cats but poorly documented
- Disease is first seen in young dogs (4-7 months old) after weaning.
- No gender predisposition described

GENETICS & BREED PREDISPOSITION

Irish setter, Samoyed, soft-coated Wheaten terrier (SCWT), but potentially any breed. In SCWT, gluten-sensitive enteropathy may be part of a spectrum of small-intestinal disease, as resolution of clinical signs does not occur with dietary restriction.

RISK FACTORS

- Exposure to gluten-containing cereal grains after weaning
- Inflammatory small-bowel disease may lead to secondary gluten sensitivity.

ASSOCIATED CONDITIONS & DISORDERS

Humans with gluten-sensitive enteropathy may also suffer from gluten-sensitive skin disease (dermatitis herpetiformis) and are predisposed to alimentary lymphoma.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Chronic intermittent gastrointestinal signs (diarrhea is most common)
- Ill thrift but lack of overt gastrointestinal signs sometimes seen

HISTORY, CHIEF COMPLAINT

- Chronic intermittent or persistent small-bowel diarrhea, with weight loss or failure to thrive.

PHYSICAL EXAM FINDINGS

- Thin and/or stunted dog
- Poor body and coat condition

ETIOLOGY AND PATHOPHYSIOLOGY

- Gliadins are antigenic proteins that make up part of gluten, the main protein of wheat.
- Other proteins of flour from various grains have different degrees of crossreactivity: secalins (rye), hordeins (barley), and avenins (oats) are also implicated in gluten-sensitive enteropathy, whereas oryzenins (rice) and zeins (corn) do not exacerbate this disorder.
- These peptides cause intestinal damage, probably by an immune-mediated mechanism.

- An underlying defect in the intestinal mucosal barrier of Irish setters is reported and may predispose to this disease. This predisposition may be related to MHC gene expression.
- Serum antibody reactivity to gluten and serum immune complexes was not demonstrated in affected setters but has been seen in intestinal inflammation.
- The age of exposure to and dose of gluten may modulate expression of the disease.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Chronic gastrointestinal signs in dogs of susceptible breeds that fail to thrive are typical. Confirmation comes from resolution of clinical signs after withdrawal of gluten from the diet, followed by recurrence of signs with reintroduction of gluten.

DIFFERENTIAL DIAGNOSIS

- Other dietary sensitivities/hypersensitivities
- Idiopathic inflammatory bowel disease (IBD)
- Antibiotic-responsive diarrhea (small-intestinal bacterial overgrowth)
- Exocrine pancreatic insufficiency (EPI)
- Intestinal parasitism (e.g., giardiasis)
- Atypical hypoadrenocorticism
- Chronic intussusception
- Any cause of malabsorption (e.g., lymphangiectasia)

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: usually unremarkable
- Fecal parasite examination
- Normal trypsin-like immunoreactivity: rule out EPI
- Abdominal radiographs and ultrasound are typically unremarkable.

ADVANCED OR CONFIRMATORY TESTING

- Serum folate and cobalamin levels are variable; often normal, but decreased serum folate is the most common abnormality (see p. 220).
- Intestinal biopsy shows nonspecific changes of villous atrophy and intraepithelial lymphocyte infiltration, but similar changes are seen in other dietary sensitivities and idiopathic IBD.
- Serologic tests cannot reliably diagnose this condition, although reductions in fecal IgE excretion during a gluten-free diet trial have been reported in SCWT.
- Conclusive diagnosis: proof of gluten sensitivity depends on demonstration of resolution of signs and histologic changes on a gluten-free diet (typically 2-4 weeks) and relapse when challenged with gluten.

TREATMENT

TREATMENT OVERVIEW

All clinical signs should resolve when the patient is treated with a gluten-free diet. The therapeutic goal is complete resolution of clinical signs through elimination of gluten-containing grains (wheat, rye, barley, oats, buckwheat) from diet, treats, supplements, and chewable/flavored medications.

ACUTE GENERAL TREATMENT

Feed a diet lacking wheat and other gluten-containing related cereals.

CHRONIC TREATMENT

Evaluate for other causes of small-bowel diarrhea if response to dietary modification is suboptimal.

NUTRITION/DIET

Feed a diet lacking wheat gluten and related cereals (cornerstone of diagnosis and treatment).

BEHAVIOR/EXERCISE

No specific recommendations required

POSSIBLE COMPLICATIONS

Potential for nutritional deficiencies with homemade diets (see p. 868)

RECOMMENDED MONITORING

Centered on response to treatment (resolution of clinical signs) and physical exam (body weight, quality of coat, etc.)

PROGNOSIS AND OUTCOME

Good to excellent in dogs that respond to strict gluten-free diet

PEARLS & CONSIDERATIONS

COMMENTS

- This is predominantly a disease of young Irish setter dogs/puppies.
- Consider the development of gluten-sensitive enteropathy as a potential complication to underlying inflammatory small-bowel disease (IBD, protein-losing enteropathy).
- Gluten sensitivity has not been recorded in cats and is probably quite rare in dogs.
- Be aware that owner noncompliance may be a cause of treatment failure.

PREVENTION

- Selective breeding, as condition is probably familial
- Feeding a gluten-free diet will prevent disease.

CLIENT EDUCATION

- Awareness of gluten content of various foodstuffs
- Awareness of cross-reactivity to rye, barley, and possibly oats
- Monitor for recurrence of clinical signs
- Lifetime careful attention to diet may be required, although some affected dogs may develop tolerance over time.

AUTHOR: EDWARD J. HALL

EDITOR: DEBRA L. ZORAN

Glomerulonephritis

BASIC INFORMATION

DEFINITION

Glomerulonephritis is a common disorder characterized by proteinuria due to immune complex deposition in the glomeruli and resultant inflammation. The condition is often idiopathic, but it can result from inflammatory, infectious, or neoplastic disease processes.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs affected more often than cats, with no gender predilection. While animals of any age may be affected, most are middle-aged or older at diagnosis.

GENETICS & BREED PREDISPOSITION

Membranoproliferative glomerulonephritis

- Bernese mountain dogs
- Labrador retrievers and golden retrievers with positive *Borrelia* titers

RISK FACTORS

- Chronic bacterial infections (e.g., pyoderma, endocarditis, pyelonephritis, borreliosis, mycoplasmal polyarthritis)
- Fungal infection (e.g., coccidioidomycosis)
- Parasitic (e.g., heartworm disease)
- Rickettsial disease (e.g., ehrlichiosis)
- Protozoal infection (e.g., babesiosis, hepatozoonosis, leishmaniasis)
- Viral disease (e.g., feline immunodeficiency virus, feline leukemia virus, canine adenovirus)
- Neoplasia (e.g., mastocytosis, leukemia, lymphoma, systemic histiocytosis)
- Immune-mediated disease (e.g., polyarthritis, pemphigus, systemic lupus erythematosus)
- Chronic inflammatory disease (e.g., inflammatory bowel disease, pancreatitis, cholangiohepatitis, granulomatous meningoencephalitis, thyroiditis)
- Corticosteroid excess
- Trimethoprim-sulfa therapy
- Congenital C3 deficiency
- Genetic predisposition

See p. 1391.

CONTAGION & ZOONOSIS

Some causes of secondary glomerulonephritis are zoonotic (e.g., leptospirosis, leishmaniasis).

GEOGRAPHY AND SEASONALITY

Several causes of secondary glomerulonephritis have specific geographic distributions (e.g., borreliosis in the northeastern and north central United States).

ASSOCIATED CONDITIONS & DISORDERS

- Protein-losing nephropathy
- Nephrotic syndrome
- Chronic kidney disease
- Hypertension
- Hyperlipidemia

- Thromboembolic disease, including pulmonary thromboembolism
- Sideroblastic anemia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Morphologic classification: histopathologic (clinical correlates to therapy and prognosis not as well developed as in human nephrology)

- Membranoproliferative glomerulonephritis: most common
  - Type I: mesangiocapillary glomerulonephritis associated with infectious disease; most common type
  - Type II: dense deposit disease
- Proliferative glomerulonephritis: relatively rare

HISTORY, CHIEF COMPLAINT

Clinical signs may be absent. When signs are present, they may be due to uremia (see p. 207), nephrotic syndrome (see p. 762), or to the underlying disease responsible for glomerulonephritis:

- Vomiting (uremia or underlying disease)
- Lethargy (uremia or underlying disease)
- Anorexia (uremia or underlying disease)
- Weight loss (uremia, proteinuria, or underlying disease)
- Peripheral edema (hypoalbuminemia)
- Pendulous abdomen/ascites (hypoalbuminemia)
- Polyuria/polydipsia (chronic kidney disease)
- Halitosis (uremia)
- Dyspnea/panting (pulmonary thromboembolism events, ascites)
- Blindness (systemic hypertension)
- Signs associated with underlying infectious, inflammatory, or neoplastic disease

PHYSICAL EXAM FINDINGS

Clinical findings may be absent or may include:

- Poor body condition
- Dehydration
- Poor haircoat
- Signs associated with hypoalbuminemia:
  - Peripheral edema
  - Ascites (pure transudate)
  - Pleural effusion (rare)
- Signs associated with uremia:
  - Oral ulceration
  - Halitosis (uremia)
- Pallor (either due to anemia [chronic disease, renal failure] or poor perfusion [severe illness])
- Lipid corneal deposits
- Retinal hemorrhage/detachment (systemic hypertension)
- Kidneys may be normal sized or small.
- Other findings related to underlying disease

ETIOLOGY AND PATHOPHYSIOLOGY

- Immune complexes form or are trapped in the glomeruli. While it is often a primary process (idiopathic), there are many infectious, inflammatory, endocrine, or neoplastic conditions that can provide the antigen to which antibody is produced, resulting in secondary immune complex formation.
- Glomerular immune complexes initiate an inflammatory cascade. Inflammation directly damages the glomerulus, neutralizes glomerular endothelial electrical charge, and results in vasoconstriction and decreased glomerular filtration. The glomerulus responds to these insults with cellular proliferation.
- Albumin and similarly sized proteins are lost in the urine and may result in hypoalbuminemia and the nephrotic syndrome (see p. 762). Eventually, tubular function is lost as well, resulting in azotemia and uremia.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the identification of proteinuria, an elevated urine protein/creatinine ratio, and characteristic blood and imaging findings. Confirmation requires renal biopsy.

DIFFERENTIAL DIAGNOSIS

Proteinuria:

- Preglomerular (e.g., Bence Jones proteinuria, exercise, hemolysis, fever, seizure)
- Glomerular
  - Glomerulonephritis
  - Amyloidosis
  - Glomerulosclerosis, including chronic kidney disease
  - Familial renal disease
- Postglomerular (e.g., urinary tract infection, neoplasia, urolithiasis)

INITIAL DATABASE

- Retinal exam: tortuous retinal vessels, retinal hemorrhages (acute or chronic), or retinal detachments are possible (a result of systemic hypertension).
- Blood pressure: systemic hypertension (repeatable systolic readings > 180 mm Hg in calm environment) is commonly noted.
- CBC: often unremarkable; nonregenerative anemia (due to chronic kidney disease), leukocytosis (if inflammatory disease is present)
- Serum biochemical profile:
  - Hypoalbuminemia with normal globulin level
  - Hypercholesterolemia
  - Hypocalcemia (relative, owing to hypoalbuminemia)
  - Azotemia, hyperphosphatemia, hyperamylasemia, metabolic acidosis (in advanced disease)
- Urinalysis: proteinuria, variable urine concentration, sometimes hematuria
  - Proteinuria must be interpreted in light of urine concentration and urine sediment examination.
  - Dipstick measure of proteinuria should be confirmed by sulfosalicylic acid test (SSA) method or quantitative measures (e.g., urine protein: creatinine ratio).
  - Significant proteinuria may often precede loss of urine concentration or azotemia.
- Urine culture: indicated in all cases
- Thoracic radiographs: unremarkable. Evidence of underlying disease (neoplasia, chronic infectious or inflammatory disease) or pulmonary thromboembolism occasionally identified.
- Abdominal radiographs: often unremarkable. Kidneys may be small. May identify evidence of underlying disease (neoplasia, chronic infectious or inflammatory disease) or be unremarkable.
- Abdominal ultrasound: hyperechoic, small kidneys, decreased corticomedullary distinction, evidence of underlying disease (neoplasia, chronic infectious or inflammatory disease), or unremarkable.

ADVANCED OR CONFIRMATORY TESTING

- Urine protein/creatinine ratio:
  - Concurrent culture and sensitivity must be negative to rule out bacterial infection as cause of elevated ratio.
  - Normal for dogs, <0.5; cats, <0.4. Most animals with glomerulonephritis or amyloidosis have ratios >2.
- Microalbuminuria testing:
  - Assay for the presence of microalbuminuria does not provide additional benefit in animals with elevated protein/creatinine ratio. These assays detect very small quantities of urine albumin that would be missed on routine dipstick and are thus redundant when proteinuria has been identified.
- Renal biopsy is the only definitive means of diagnosis of glomerulonephritis, allowing morphologic classification of disease, and identifying type and location of immunoglobulin. Cortical tissue examined by light microscopy, immunofluorescence, and electron microscopy.
- Determining serum antithrombin concentrations may help quantify risk of thromboembolic disease (<80% suggests increased risk).
- A variety of other tests may be indicated in a search for an underlying cause of glomerulonephritis. The choice of tests depends on history and physical exam, results of initial evaluation (CBC, serum biochemistry, imaging studies), geographic region, and environmental exposures. Common examples include:
  - Serologic tests for heartworm, borreliosis, feline leukemia virus, feline immunodeficiency virus, *E. canis*,

coccidioidomycosis
- Antinuclear antibody test
- Arthrocentesis, echocardiography, bone marrow aspirates, thoracic radiographs
- Adrenocorticotropic hormone stimulation or low-dose dexamethasone suppression tests
- Species-specific pancreatic lipase, trypsin-like immunoreactivity

TREATMENT

TREATMENT OVERVIEW

Treatment mainly consists of medications to decrease the degree of proteinuria. When appropriate, medications for the management of hypertension and thromboembolic disease are indicated. If the patient is in renal failure, supportive management is advised.

ACUTE AND CHRONIC TREATMENT

- Address underlying disease conditions directly.
- If respirations are compromised by large-volume pleural effusion or severe ascites, thoracocentesis and/or abdominocentesis is indicated. Diuretic drug are largely ineffective for rapid mobilization of body-cavity fluid (see pp. 1338, p. 1192).
- Oxygen support may be required for animals with pulmonary thromboembolism.
- Proteinuria may be diminished through the use of angiotensin-converting enzyme (ACE) inhibitors; for dogs, enalapril, 0.5 mg/kg PO q 12-24 h; or benazepril, 0.25 mg/kg PO q 24 h.
- If hypertension persists despite ACE inhibitors, calcium channel blockers are indicated (amlodipine, 0.05-0.5 mg/kg PO q 24 h for dogs; 0.625 mg/cat PO q 12-24 h).
- Anticoagulant therapy to reduce the risk of thromboembolic disease. Unfractionated heparin is not effective because of loss of antithrombin.
  - Aspirin, 0.5 mg/kg q 12 h PO in the dog
  - Coumadin initial dose is 0.1-0.2 mg/kg PO q 24 h.
    - With coumadin, the prothrombin time should be monitored and dose adjusted until 1.5 to 2.5 times normal.
    - Protein-bound drug; therefore very difficult to titrate the dose effectively in patients with hypoalbuminemia, and not generally recommended unless benefit outweighs risk (e.g., prior embolic event while on aspirin)
- Uremic animals may require fluid therapy (see p. 207). Hypoalbuminemia may result in edema, in which case colloidal support may be necessary.
  - Hetastarch, 10-20 mL/kg/day IV
  - Dextrans; use with caution because of reported link to renal failure.
  - Large volumes of species-specific plasma or human albumin; expensive and short-lived effect
- Glucocorticoids and cyclosporine are ineffective in the treatment of idiopathic glomerulonephritis and may increase thromboembolic potential (glucocorticoids) or worsen renal protein loss (cyclosporine). Therefore they should be used only when documented autoimmune disease is present (e.g., systemic lupus erythematosus).
- Clinical signs of uremia and electrolyte and acid-base disorders are addressed as for overt chronic kidney disease (see pp. 205 and p. 207).

NUTRITION/DIET

- Moderate dietary restriction of protein (2-3 g/kg/d for dog; 4 g/kg/d for cat), phosphorus, and sodium are recommended. A variety of commercial or homemade diets can be used (e.g., Hill's k/d, Iams Veterinary Formula Renal Purina NF). To avoid food aversions, diet changes are best made when animal is not uremic.
- Omega-3 fatty acid supplementation may be renoprotective, decrease inflammation and proteinuria, and decrease cholesterol. Many commercial renal diets are so supplemented.

DRUG INTERACTIONS

- ACE inhibitors may cause hypotension when combined with diuretics or other vasodilators.
- ACE inhibitors may reduce proteinuria and ameliorate hypertension but may worsen azotemia, requiring that blood urea nitrogen (BUN) and creatinine be monitored during therapy.
- Nonsteroidal antiinflammatory agents may reduce efficacy of ACE inhibitors.

POSSIBLE COMPLICATIONS

- Third-space retention of fluids
- Worsening renal azotemia as a result of ACE inhibitor use (uncommon)
- Hypotension secondary to ACE inhibitor and calcium channel blocker
- Worsening of renal azotemia with dextran use

- Thromboembolic disease as a result of antithrombin and protein C level abnormalities
- Bleeding tendency from aspirin, warfarin use
- Gastrointestinal ulceration as a result of azotemia or aspirin therapy

RECOMMENDED MONITORING

Stable animals are monitored every 3-4 months. Rechecks should be more frequent if changes are made in therapy or when indicated by changing clinical signs.

- Physical examination
- Urine protein/creatinine ratio
- Serum BUN/creatinine/phosphorus
- Serum albumin
- Blood pressure
- Urinalysis/culture

PROGNOSIS AND OUTCOME

- Prognosis is best when an underlying disease can be identified and eliminated.
- When elimination of an underlying disease is not possible, survival is variable, but disease is usually progressive over months to 1-2 years.
- In dogs, prognosis for glomerulonephritis in general is better than for renal amyloidosis.
- Prognosis is worse when azotemia/uremia is/are present at diagnosis.
- Prognosis is worse for cats than dogs.
- Prognosis is poor for dogs where glomerulonephritis is associated with borreliosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Investigation of potential underlying diseases can become expensive. Clinical judgment should guide the choice of ancillary tests for each animal.
- Once protein-losing nephropathy is identified, renal biopsy is useful primarily as a prognostic tool. Although biopsy is required to distinguish the type of glomerular disease, therapy is often similar for each type.

PREVENTION

- Ectoparasite prophylaxis
- Heartworm prophylaxis

CLIENT EDUCATION

- Diligent rechecks are very important for adjusting medications and identifying complications early.
- Finding an underlying disease process may mean a better prognosis for the pet.

Glaucoma

Additional Images Available on Website

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- The glaucomas are a group of diseases characterized by visual impairment and blindness from damage to the retina and optic nerve caused by increased intraocular pressure (IOP).
- Glaucoma may be the result of primary eye disease (i.e., abnormalities of the drainage/iridocorneal angle; *primary glaucoma),* secondary to other eye diseases *(secondary glaucoma),* or less commonly, the result of anomalies of the anterior segment of the eye *(congenital glaucoma).*
- In dogs in North America, the prevalence of primary glaucoma is 0.9%, while it is 0.8% for secondary glaucomas.

SYNONYMS

Ocular hypertension. Buphthalmos: megaloglobus (enlargement of the globe secondary to elevated IOP)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats: variable age of onset depending on underlying cause
- Primary glaucoma:
  - Typically middle-aged to older dogs (3-12 years; average 8 years); rare in cats
  - In some breeds of dogs, primary glaucoma occurs more frequently in females.
- Secondary glaucoma due to:
  - Lens luxation: usually affects young to middle-aged dogs (3-7 years); older cats
  - Intraocular neoplasia: usually older animals (>7 years)
- Congenital glaucoma:
  - Young animals; elevation in IOP develops soon after birth.

GENETICS & BREED PREDISPOSITION

- Primary glaucoma:
  - Top breeds of dogs affected between 1994 and 2002 include American cocker spaniel, basset hound, chow chow, shar-pei, Boston terrier, wire fox terrier, Norwegian elkhound, Siberian husky, Cairn terrier, and miniature poodle.
  - Primary open-angle glaucoma is inherited in the beagle as an autosomal recessive trait.
  - Primary closed-angle glaucoma in the Welsh springer spaniel and Great Dane appears inherited as an autosomal dominant trait with variable expression.
  - Cats: Siamese breed may have inherited primary glaucoma.
- Secondary glaucoma:
  - Lens luxation: terrier breeds
  - Pigmentary uveitis: golden retrievers

RISK FACTORS

- Primary glaucoma:
  - Abnormalities of the iridocorneal angle (often termed *pectinate ligament dysplasia)* may narrow the opening to the sclerociliary cleft and increase the probability of glaucoma (dogs).
- Secondary glaucoma:
  - Anterior uveitis due to:
    - Cataract formation (common in dogs)
    - Systemic bacterial and mycotic diseases (dogs and cats)
    - Feline leukemia and feline immunodeficiency viruses (cats)
  - Lens luxation (see p. 644)
  - Intraocular neoplasia (see p. 620)
  - Hyphema (see p. 571).
  - Uveal cysts (see p. 1149).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Glaucoma may be classified based on:

- Cause: primary, secondary, or congenital
- Duration: acute (vision potential) versus chronic (typically blind, buphthalmic eye)

HISTORY, CHIEF COMPLAINT

Transient or constant red or cloudy eye with any or all of the following:

- Variable ocular pain (usually present when IOP >40 mm Hg) manifesting as unwillingness to be handled around the face or head, or blepharospasm.
- Bumping into objects or other manifestations of visual impairment or blindness
- Increased green reflection from eye (i.e., tapetal reflection from dilated pupil)
- Enlargement of the globe (buphthalmos)

PHYSICAL EXAM FINDINGS

Unilateral or bilateral ocular changes; initially unilateral with primary glaucoma:

- Corneal edema (typically diffuse)
- Episcleral hyperemia (tortuous episcleral vessels)
- Dilated pupil and sluggish to absent pupillary light reflexes
- Possible lens subluxation/luxation
- Variable optic nerve and retinal degeneration (see p. 983)
- Corneal stria (breaks in Descemet's membrane appearing as white lines within cornea; rare)

ETIOLOGY AND PATHOPHYSIOLOGY

- Impediment to aqueous humor outflow, causing elevated IOP
- Elevated IOP can damage the retina (retinal ganglion cells) and optic nerve head by reducing retinal, choroidal, and optic nerve head blood flow and axoplasmic flow in the optic nerve head.
- Onset and severity of these glaucomatous changes appear influenced by the duration and extent of the IOP elevation.
- About 50% of first eyes of dogs presented with the primary glaucomas are blind at initial ophthalmic examination.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A diagnosis of glaucoma should be considered for any case that presents for evaluation of (a) red eye(s), particularly if the ocular hyperemia is accompanied by mydriasis and corneal edema and especially if it occurs in a predisposed breed. Elevated IOP on tonometric evaluation is confirmatory.

DIFFERENTIAL DIAGNOSIS

Glaucoma must be differentiated from other causes of red eye (see p. 967)

INITIAL DATABASE

Complete ophthalmic examination (see p. 1313) including:

- Tonometry (the measurement of IOP): the most important diagnostic test
  - Schiøtz indentation tonometry (requires conversion of value from instrument to mm Hg using human calibration chart accompanying instrument or dog/cat calibration chart)
  - Applanation tonometry (e.g., TonoPen)
  - Rebound tonometry (e.g., TonoVet)
  - Normal IOP values range from 15-25 mm Hg; >30 mm Hg = glaucoma (dogs and cats).

ADVANCED OR CONFIRMATORY TESTING

- Referral to veterinary ophthalmologist for:
  - Additional or multiple tonometric measurements
  - Gonioscopy (direct observation of the iridocorneal angle)
  - Ophthalmoscopy of the ocular fundus (posterior segment of the eye including retina and optic nerve)
- Ocular ultrasound if ocular media are opaque and prevent evaluation of deeper ocular structures; helps rule out concurrent ocular abnormalities (i.e., lens luxation; lens capsule rupture; retinal detachment; intraocular masses)

TREATMENT 

TREATMENT OVERVIEW

In acute cases, it is critical that the IOP be lowered as soon as possible to maintain or restore vision (topical and oral medications). If tonometry is unavailable, glaucoma suspects should be referred to a veterinary ophthalmologist (as an emergency) for IOP measurement. Early surgical intervention may permit better and longer control of IOP; the clinician is urged to consider early referral, especially when vision in one eye has already been lost. Long-term treatment of glaucoma can be a frustrating endeavor, since the disease tends to progress despite medical therapy, particularly with primary glaucoma. Diligent monitoring, regular reassessment of therapeutic success, and client education are critical. Therapeutic goals are to lower IOP of affected eye to maintain vision for as long as possible, eliminate ocular pain, and treat contralateral eye prophylactically with IOP-lowering drugs to delay onset of glaucoma from ~*6* months (untreated) to 30 months (with prophylactic treatment) (primary glaucoma).

ACUTE GENERAL TREATMENT

Medical:

- Regardless of the type of glaucoma, the following may be administered initially and then long term if indicated:
  - Topical β-adrenergic antagonists or blockers (0.5% timolol or 0.5% betaxolol, usually q 8 h) *and*
  - Topical or systemic carbonic anhydrase inhibitors (CAI; topical: 2% dorzolamide or 1% brinzolamide q 8 h; oral: methazolamide, 5 mg/kg q 12 h)
- Mannitol (1-2 g/kg IV over 20 minutes) to rapidly lower IOP (first effects in 1-2 hours; maximum effect in 4-6 hours; duration ~8-10 hours) when there is a chance for return of vision (e.g., acute primary glaucoma)
- Topical (1% q 6 h) and/or systemic (1-2 mg/kg PO q 24 h) prednisolone is indicated when anterior uveitis is also present, unless an infectious cause for the uveitis is documented or strongly suspected (see p. 1151)

CHRONIC TREATMENT

Medical:

- Topical prostaglandins (PGF analogs, 0.005% latanoprost, 0.03% bimatoprost, or 0.004% travoprost q 12-24 h): used for primary glaucoma in dogs; not effective in the feline glaucomas)
- ± Topical and/or systemic prednisolone (when anterior uveitis also present; taper to lowest effective dose)
- In all of the breed-related *primary glaucomas,* the disease continues to progress (even though IOP may be controlled), and often combinations of several topical and systemic IOP-lowering drugs or surgery (see below) are eventually necessary.

Surgical:

- Anterior chamber shunts and laser cyclophotocoagulation are procedures offered by most veterinary ophthalmologists to prolong vision and prevent ocular pain. Laser cyclophotocoagulation may be performed with either a transscleral approach or with the assistance of a microendoscope.
- Removal of the lens (referable procedure; glaucoma secondary to lens luxation, see p. 644). This should be performed as soon as possible in cases of anterior lens displacement.
- End-stage blind and buphthalmic glaucomatous globes may be treated by:
  - Enucleation
  - Evisceration and intrascleral prosthesis
  - Intravitreal gentamicin injection (dogs)
  - Enucleation or evisceration and implant surgeries should be followed with histopathologic examination of the removed tissue to help determine cause of glaucoma (i.e., primary versus secondary) and prognosis for fellow eye.

DRUG INTERACTIONS

- Topical β-adrenergic blockers may lower heart rate and blood pressure and may cause bronchoconstriction in small-breed

dogs and in cats.
- Systemic CAIs in dogs and cats may cause metabolic acidosis and electrolyte imbalances as evidenced by depression (perhaps related to hypokalemia), and in dogs, vomiting and diarrhea that require drug cessation. Topical CAI preparations are not associated with these side effects.
- Topical prostaglandins often cause conjunctival hyperemia within minutes after instillation that gradually declines over an hour or so, and miosis that persists with the IOP reduction.
- Mannitol, an osmotic diuretic, should be avoided in patients with heart disease (risk of fluid overload/iatrogenic pulmonary edema) or oliguric/anuric renal failure (rarely concurrent with acute glaucoma).

POSSIBLE COMPLICATIONS

With poor or inadequate control of IOP, any or all of the following may occur:

- Buphthalmos (see Ocular Size Abnormalities,) causing increased corneal exposure ± recurrent corneal ulceration/corneal vascularization/corneal pigmentation
- Lens luxation/subluxation
- Optic nerve and retinal degeneration
- Ocular, head pain
- Blindness

RECOMMENDED MONITORING

- Regular reexaminations with tonometry (e.g., monthly once IOP control initially achieved) are necessary to control IOP (should be maintained at <20 mm Hg) and maintain vision for as long as possible.
- As the glaucoma progresses, increased frequency and/or additional topical and systemic drugs to lower IOP are usually necessary.

PROGNOSIS AND OUTCOME

- Prognosis is usually poor for the first eye presented with the primary glaucomas in dogs, because the disease is often advanced and refractory to medical therapy.
- Prognosis for the fellow eye is better, and prophylactic therapy with a β-adrenergic blocker or prostaglandin can significantly delay the onset of glaucoma for up to about 30 months.

PEARLS & CONSIDERATIONS

COMMENTS

- Patients with dilated pupils, corneal edema, and conjunctival hyperemia require tonometry to estimate IOP.
- Clinical management of the glaucomas is often difficult; therefore referral of these cases to a veterinary ophthalmologist is advised.
- Medical therapy of the glaucomas is expensive and is often required long term.
- Buphthalmos indicates chronic glaucoma, whereas acute glaucoma, with its potentially better prognosis for vision, presents episcleral injection and almost never buphthalmos.
- Even in a permanently blind, persistently glaucomatous eye, treatment (e.g., evisceration and implant, or enucleation) is generally indicated to remove the source of chronic intense pain.
- Digital pressure (pressing on the eyes through closed eyelids) cannot be used for accurately assessing IOP.

PREVENTION

The benefits of periodic tonometry in breeds and/or eyes at risk are unknown but should be considered. Anterior uveitis that is unrecognized or inadequately treated and controlled will predispose an eye to the development of secondary glaucoma. Cataractous eyes should be examined regularly for evidence of lens-induced uveitis, and treatment should be initiated when signs appear so as to prevent or delay the development of glaucoma.

TECHNICIAN TIPS

- Veterinary nurses and technicians should encourage clients to bring their pets in for evaluation promptly to rule out glaucoma if they complain of a “bloodshot” eye or acute visual disturbance.
- Restraint for animals undergoing tonometry is important. Care should be taken not to place any pressure on the jugular veins

or eyelids, as excessive pressure in these areas may result in falsely elevated IOP estimates. Excessive struggling should be avoided as well, as this may alter IOP readings.

CLIENT EDUCATION

- Glaucoma is a chronic disease that requires regular and diligent therapy. Missed medication will result in inadequate control of IOP, loss of sight, and pain.
- The primary glaucomas in the dog are concentrated in about 20 breeds.
- Dogs with cataracts that are not surgical candidates require periodic eye examinations and tonometry indefinitely because they are at increased risk of developing glaucoma.

Giardiasis

Additional Images Available on Website

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Giardia duodenalis is a flagellate protozoan parasite that can be found in the intestinal tract of humans and most domestic animals. Clinical disease usually appears as acute small-bowel diarrhea but can vary, with some animals, showing chronic small-bowel or acute or chronic large-bowel diarrhea.

SYNONYM

Giardia duodenalis; Giardia lamblia; Giardia intestinalis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Can affect humans and most domestic animals. Infection is most common in younger animals.

RISK FACTORS

Immunodeficient adults, young animals, and animals confined in large crowded groups are at increased risk.

CONTAGION & ZOONOSIS

Various genotypes differing in host range occur. Species-specific genotypes are the most commonly encountered in dogs and cats. Of the genotypes found in dogs (A, B, C, D) and cats (A, F), several (A, B) also infect humans, and therefore the potential for zoonotic exposure to people from pets exists.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

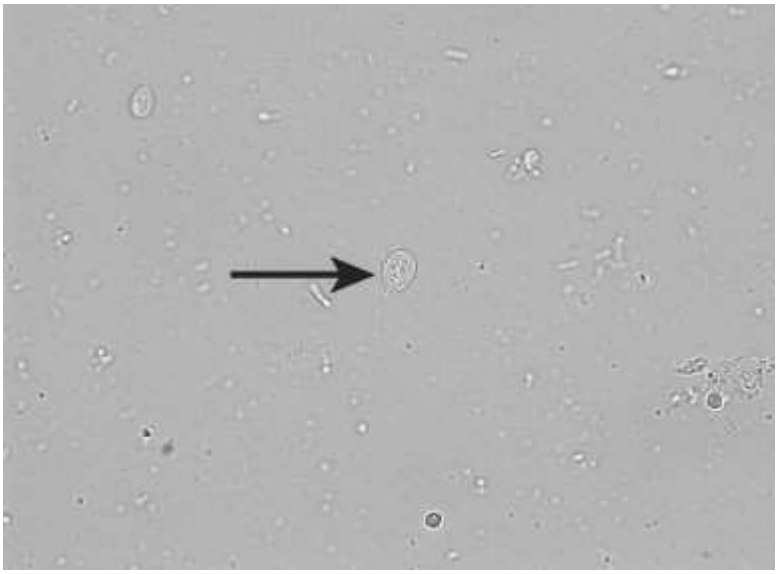
- Infections are usually subclinical.
- If diarrhea results, it can be acute and short lived, intermittent, or chronic.
- Steatorrhea or weight loss may be observed.
- Excessive fecal mucus is often observed in clinically affected cats.
- Emesis, fever, and anorexia may occur but are not typical.

PHYSICAL EXAM FINDINGS

No specific abnormalities

ETIOLOGY AND PATHOPHYSIOLOGY

- The *Giardia* life cycle is direct (no intermediate host). Cysts are ingested and exist in the duodenum, each cyst producing two motile trophozoites that replicate within the lumen of the small intestine. Before being shed in feces, the trophozoite encysts. On excretion, the cysts are immediately infective to another host. Cysts can survive for days to weeks in a cool, moist environment.
- Autoinfection from fecal material adhered to the haircoat or cysts in drinking water/environment is possible. Reinfection is probable in catteries and kennels, owing to environmental contamination.
- Trophozoites cause sloughing of intestinal epithelial cells and blunting of intestinal villi, resulting in a reduction in absorptive surface area, causing malabsorption.
- Abnormalities in cellular and humoral immune system function likely predispose individuals to clinical infection.



GIARDIASIS A *Giardia duodenalis* trophozoite *(arrow)* detected on a direct saline smear of feces from a dog, viewed under the high-dry objective. Trophozoites are teardrop shaped with 2 nuclei, 2 comma-shaped median bodies, and 8 flagella. They are 12-17 × 7-10 microns in size, slightly larger than a red blood cell by comparison (not seen here). Motile trophozoites have a typical "falling-leaf" movement and are easily kept in the microscopic field of view.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other intestinal parasitoses
- Idiopathic inflammatory bowel disease
- Maldigestion secondary to pancreatic exocrine insufficiency
- Neoplastic intestinal disease (i.e., lymphoma)
- Infectious intestinal disease (viral, bacterial, fungal)
- Food intolerance or dietary indiscretion (acute cases)

INITIAL DATABASE

- Direct fecal smear in saline: observation of viable, motile trophozoites
  - Trophozoites may predominate in diarrheic feces but due to their fragile nature are usually only detected in fresh samples (feces examined within 20 minutes of defecation).
  - Positive result is definitive; negative result does not rule out infection.
- Zinc sulfate centrifugal fecal flotation (ZSCF): detection of cysts. Due to intermittent fecal cyst shedding, sensitivity is increased by examining 2-3 fecal samples obtained over 3-5 days. If samples are shipped for testing, they should be maintained at 4°C. Lack of centrifugation and/or use of sugar or one of the other salts as flotation media will greatly decrease the detection sensitivity for *Giardia* cysts.

ADVANCED OR CONFIRMATORY TESTING

- ELISA kits to identify fecal *Giardia* antigens. Fresh, frozen, or formalin-preserved feces suitable. Sensitivity of one ELISA is similar to that of 2 or 3 fecal samples tested using ZSCF.
- Direct immunofluorescent testing for *Giardia* cysts in feces. Samples should be preserved in 10% formalin before being shipped to the laboratory.

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to eliminate clinical signs of *Giardia* infection, including diarrhea and weight loss, and eliminate shedding of infective cysts.

ACUTE GENERAL TREATMENT

- Fenbendazole, 50 mg/kg PO q 24 h for 3-5 days (dogs and cats) *or*
- Febantel-pyrantel-praziquantel, 37.8 mg/kg febantel PO q 24 h for 3 days (dogs) *or*
- Febantel-pyrantel-praziquantel, 56 mg/kg febantel PO q 24 h for 5 days (cats) *or*
- Metronidazole, 15-25 mg/kg PO q 12-24 h for 5-7 days (dogs and cats). Use as second choice; less effective than fenbendazole.
- *Giardia* vaccination has not been shown to be an effective treatment.

CHRONIC TREATMENT

- Allowing the environment to dry, cleaning contaminated surfaces with disinfectants containing quaternary ammonium, bathing animals, and treating animals again before returning to the clean environment are important in preventing reinfection.

POSSIBLE COMPLICATIONS

- Albendazole (alternative to fenbendazole): myelosuppression, hepatotoxicity (especially in cats) and suspected teratogen. Not recommended.

PROGNOSIS AND OUTCOME

Prognosis is usually good; clinical signs resolve in most individuals, but recurrent clinical signs due to persistent infection may occur in some animals.

PEARLS & CONSIDERATIONS

COMMENTS

- Empirical fenbendazole treatment is recommended in dogs with diarrhea, to address both *Giardia* and occult whipworm infection as possible underlying causes.
- The *Giardia* vaccine may be effective in reducing fecal shedding of cysts in dogs but is ineffective in prevention of infection. In a study of cats, the vaccine was ineffective for both.
- *Giardia-ELISA* kits have limited usefulness for posttreatment diagnostic surveillance because of prolonged persistent antigen shedding even in animals where clinical signs have resolved and no cysts can be detected on ZSCF.

1ST EDITION AUTHOR: LAURA J. SMALLWOOD

Gastrointestinal Obstruction: Foreign Body or Mass Lesion

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

Common disorder caused by a foreign object or mass that partially or completely occludes the intestinal lumen

SYNONYMS

Intraluminal obstruction, intestinal blockage

EPIDEMIOLOGY

RISK FACTORS

- Younger animals are at greater risk for dietary indiscretion and therefore foreign body ingestion.
- Some animals are more prone to ingesting foreign objects than others (individual behavior) irrespective of age.
- Older animals are at greater risk for development of neoplasia.

ASSOCIATED CONDITIONS & DISORDERS

Animals with diseases that cause pica may be more at risk for foreign-object ingestion.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Vomiting, anorexia, and depression are common primary complaints.
- Severity of clinical signs varies depending on duration and location of obstruction.
- Proximal and complete obstructions are generally associated with more severe clinical signs of illness.
- Distal or partial obstructions may be associated with vague and chronic signs such as intermittent vomiting, anorexia, weight loss, or diarrhea. When associated with gastrointestinal (GI) obstruction, diarrhea is usually scant and not profuse.

PHYSICAL EXAM FINDINGS

- Abdominal splinting or signs of pain on palpation may be noted.
- Mass or foreign object may be identified with careful palpation.
- Dehydration, depression, or shock; severe in proximal and complete obstructions

ETIOLOGY AND PATHOPHYSIOLOGY

- Mechanical obstruction of the intestinal lumen causes fluid and gas accumulation proximal to the foreign object or mass.
- Duodenal and proximal jejunal obstruction is often associated with acute and severe signs.
- Persistent vomiting and loss of gastric secretions associated with proximal obstructions may lead to electrolyte imbalances (hypochloremic metabolic alkalosis).
- Lymphatic and capillary stasis cause intestinal wall edema.
- Impaired intestinal mucosal barrier allows bacterial translocation, potentially resulting in endotoxemia and sepsis.
- High intraluminal pressure causes intestinal wall ischemia that may progress to necrosis and peritonitis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on history and physical examination, is supported by imaging (radiographic and/or ultrasonographic) findings, and is confirmed surgically. Diagnostic imaging should be considered in any young animal that presents with vomiting, anorexia, a painful abdomen, or has a history of foreign-body ingestion.

DIFFERENTIAL DIAGNOSIS

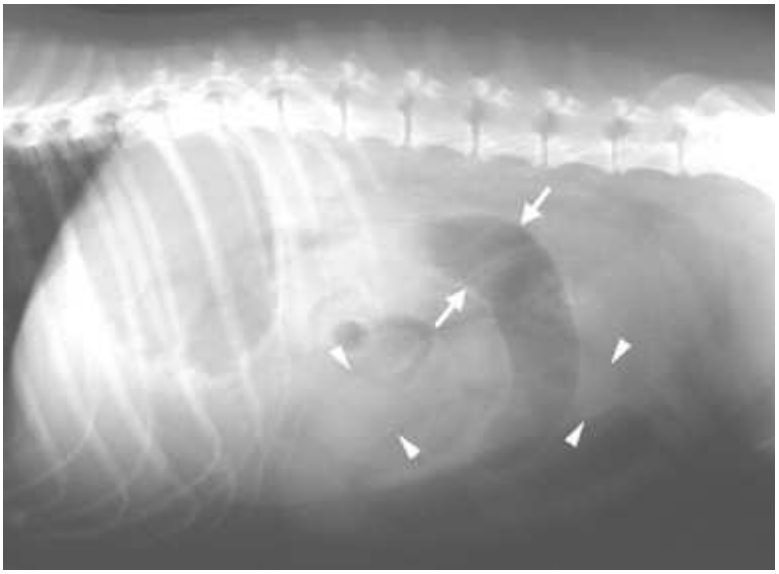
- Foreign body
- Mass
- Intussusception
- Linear foreign body
- Trichobezoar
- Intestinal volvulus or torsion
- Stricture or adhesions
- Functional obstruction (i.e., ileus)
- Infectious disease of the GI tract (e.g., parvoviral or coronaviral enteritis)
- Intoxication

INITIAL DATABASE

- CBC, serum biochemistry profile, and urinalysis
  - Evidence of dehydration (e.g., blood urea nitrogen, creatinine elevations with urine specific gravity > 1.030; hemoconcentration/elevated packed cell volume)
  - Electrolyte imbalances
    - Hypochloremia occurs in 51% of cases and is the most common abnormality.
    - Hypokalemia: 25%
    - Hyponatremia: 20% (occurs more commonly with linear rather than discrete foreign bodies)
  - Metabolic alkalosis with proximal obstruction; metabolic acidosis with hypoperfusion, sepsis secondary to peritonitis, or other systemic effects
- Abdominal radiographs: often the most informative test. Urgent consultation with a radiologist may be very helpful.
  - Radiopaque foreign objects may be visualized.
  - Fluid-or gas-distended intestinal loops
  - Pathologic dilation of intestinal loops: bowel lumen should not exceed the diameter of twice the width of a rib or be greater than 1.6 times the height of the fifth lumbar vertebra.
  - Radiographs that demonstrate a foreign body must be recent (minutes or hours before induction of general anesthesia, or better still, retaken just after induction) if surgery is planned. A gastric or duodenal foreign body can be displaced into the esophagus during anesthetic induction, while an intestinal foreign body may have been defecated since the original radiographs were taken.

ADVANCED OR CONFIRMATORY TESTING

- Contrast radiographs
  - Barium sulfate suspension for upper GI study unless perforation suspected (see p. 1351)
    - If perforation suspected, consider using nonionic iodinated contrast medium or other diagnostic techniques (centesis, lavage).
  - Barium enema (see p. 1204)
    - For assessing an obstructive pattern in the distal intestine
    - For differentiating small bowel from large bowel if it is not clear whether a gas-filled viscus is a pathologically distended segment of small intestine or the normal colon
- Abdominocentesis (see p. 1194) and fluid analysis if perforation/peritonitis suspected
- Abdominal ultrasound
  - Site of obstruction may be visualized.
  - Identification of small amounts of free abdominal fluid
  - Localization of free fluid for accurate centesis
- Diagnostic peritoneal lavage (see p.1250)
  - If peritonitis is suspected but centesis is unrewarding
  - Limited efficacy
- Thoracic radiographs in older animals with suspected neoplasia



GASTROINTESTINAL OBSTRUCTION: FOREIGN BODY OR NEOPLASIA Radiographic appearance of the abdomen of a dog with small-intestinal obstruction, lateral view. A small-intestinal segment is markedly distended with gas *(arrows)*, and another is markedly distended with fluid/soft tissue *(arrowheads)*.

(Courtesy Dr. Richard Walshaw.)

TREATMENT

TREATMENT OVERVIEW

Rehydration and rapid surgical intervention are recommended in any patient with intestinal obstruction. Correct dehydration and electrolyte abnormalities with intravenous fluid administration. Exploratory laparotomy is indicated to relieve the obstruction.

ACUTE GENERAL TREATMENT

- Exploratory laparotomy for foreign-body retrieval or mass resection
- An enterotomy may suffice for acute foreign body removal; if intestinal viability is questionable, resection and anastomosis are warranted.
- Wide margin (4-8 cm) resection and anastomosis should be performed if neoplastic disease is suspected based on the gross appearance of the lesion. In this case, also perform lymph node and liver biopsies.
- Omentum or serosal patch may be placed to reinforce suture line.
- Change gloves and surgical instruments before abdominal lavage and closure to minimize contamination.
- Administer prophylactic antibiotics.
    - Cefazolin, 22 mg/kg IV q 2 h during the perioperative period
- Obtain gastric, small-intestinal, and liver biopsies, even if all appear grossly normal. Biopsy any abnormal-looking organ. Future course of illness may evolve in such a way as to make these specimens essential for diagnosis.

CHRONIC TREATMENT

Postoperative considerations:

- Continue rehydration and daily electrolyte monitoring. Treat accordingly (especially hypokalemia arising from dilution [IV fluids] and anorexia).
- Nothing by mouth (NPO) 6-12 hours post enterotomy, 12 hours post resection and anastomosis
- Administer GI protectants as needed.
    - Famotidine, 0.5-1 mg/kg IV, IM, SQ, or PO q 12-24 h; *or*
    - Ranitidine, 0.5-2 mg/kg slow IV, IM, SQ, or PO q 8-12 h
        - Ranitidine also has promotility properties similar to those of metoclopramide.
- Administer antiemetics as needed.
    - Contraindicated before resolution of obstruction
    - Metoclopramide, 0.2-0.4 mg/kg PO, SQ, or IM q 6 h; *or*
    - Cisapride, 0.1-0.5 mg/kg PO q 8 h

POSSIBLE COMPLICATIONS

- Dehiscence: animals should be monitored in hospital for 48-72 hours in the postoperative period for signs of peritonitis. Risk factors include presence of preoperative peritonitis, serum albumin concentration <2.5 g/dL, and presence of a foreign body (versus neoplastic disease).
- Ileus
- Short bowel syndrome: unlikely if less than 70% of small intestine resected
- Stricture
- Recurrence

RECOMMENDED MONITORING

- The following parameters should be monitored daily until discharge from hospital: body temperature, blood glucose, electrolytes, abdominal pain.
- The patient should be eating and not vomiting. If anorexia or vomiting persists after surgery, consider performing abdominocentesis and CBC to valuate for possible development of peritonitis.

NUTRITION/DIET

Feeding tube placement (see pp. 1267, p. 1269, p. 1270, and p. 1273) at the time of surgery should be considered in animals with marked weight loss, hypoalbuminemia, or in those patients with evidence of peritonitis (esophageal in the latter case). If anorexia persists post operatively, syringe feeding, feeding tubes or total parenteral nutrition may be considered.

PROGNOSIS AND OUTCOME

- A good prognosis may be expected for acute disease, while those animals with preoperative debilitation or shock should be given a more guarded prognosis.
- Prognosis for neoplastic disease depends on histopathologic grade, evidence of metastasis, and completeness of surgical excision. Lymphosarcoma and adenocarcinoma are the most frequently encountered intestinal tumors.

PEARLS & CONSIDERATIONS

COMMENTS

Consider placing an intraoperative feeding tube (esophagostomy, gastrostomy, or gastrojejunostomy tube) in these patients based on preoperative nutritional status, degree of patient debilitation, or anticipated postoperative anorexia.

TECHNICIAN TIPS

Intestinal obstruction patients may be in a critical state and require intensive care. Technicians treating and caring for these patients should be familiar with and competent in:

- Fluid therapy
- Intensive patient monitoring including blood pressure, CBC and serum biochemistry profile, blood gases, urine output
- Nutritional support (see above)
- Analgesia

AUTHOR: JANET KOVAK MCCLARAN

EDITOR: RICHARD WALSHAW

Gastrointestinal Endocrine Disease

BASIC INFORMATION

DEFINITION

Gastrointestinal (GI) endocrine disease occurs as a result of a tumor of one or more hormone-secreting cells in the GI tract. Insulinoma (p. 613) and gastrinoma (p. 442) are discussed in detail elsewhere.

SYNONYMS

- General: amine precursor uptake and decarboxylation (APUD) tumors; APUDoma
- Specific: gastrinoma (Zollinger-Ellison syndrome, delta cell tumor), glucagonoma (alpha cell tumor), VIPoma (Verner-Morrison syndrome), carcinoid tumors (Thorson-Bioerck syndrome, argentaffinoma syndrome)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Gastrinoma: rare; middle-aged to old dogs and cats
- Glucagonoma: rare; middle-aged to old dogs; not reported in cats
- Carcinoid syndrome: rare; middle-aged to old dogs and cats

ASSOCIATED CONDITIONS & DISORDERS

Superficial necrolytic dermatitis and diabetes mellitus: glucagonoma

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Gastrinoma: gastrin
- Glucagonoma: glucagon
- Carcinoid syndrome: serotonin (primary substance)
- Somatostatinomas*: somatostatin
- Pancreatic polypeptideoma*: pancreatic polypeptide
- VIPoma*: vasoactive intestinal polypeptide

Legend:- *Documented in human but not veterinary medicine

HISTORY, CHIEF COMPLAINT

- Gastrinoma: vomiting, weight loss, anorexia, diarrhea, gastric hemorrhage
- Glucagonoma: ulcerative dermatitis, diarrhea, lethargy, weight loss, inappetence, possible polyuria and polydipsia
- Carcinoid tumors: often no overt clinical signs; possible abdominal pain, diarrhea, vomiting, weight loss, anorexia, or other signs of gastrointestinal obstruction or metastasis; carcinoid syndrome not reported in dogs or cats

PHYSICAL EXAM FINDINGS

- Gastrinoma: weight loss, lethargy, abdominal pain, pale mucous membranes, melena, and/or collapse and shock as a result of GI ulceration
- Glucagonoma: ulcerative dermatitis, lethargy
- Carcinoid tumor: no specific findings; possible anorexia, weight loss, acute abdomen due to obstruction

ETIOLOGY AND PATHOPHYSIOLOGY

- Specialized endocrine cells that secrete peptides are found throughout the GI tract.
- Neoplasia of these cells results in excess secretion of the hormone(s).

- Clinical signs occur as a result of the specific hormone oversecretion.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Nonspecific clinical signs in the history often lead to the passage of a protracted period of time prior to establishment of the diagnosis. A combination of clinical signs that become more obvious with clinical progression and ruling out of disorders that are more likely leads to diagnosis.

DIFFERENTIAL DIAGNOSIS

See Vomiting, ; Weight Loss, ; Diarrhea (Acute), 303; Acute Abdomen, 28; Ulcerative and Erosive Skin Disorders, ; Superficial Necrolytic Dermatitis, 1061

INITIAL DATABASE

- The diagnosis is made based on appropriate clinical signs and immunohistochemical staining of the tumor.
- A CBC, serum biochemical profile, and urinalysis should be evaluated to help rule out other diagnoses.
    - Mild hyperglycemia, increased liver enzymes, hypoalbuminemia, and possible glucosuria may be seen with glucagonoma.
    - A regenerative or iron-deficiency anemia, possible leukocytosis, hypoproteinemia, and increased liver enzymes may be seen with gastrinoma.
    - Results are usually normal with carcinoid syndrome.
- Radiographs and ultrasound results are usually normal but may help identify the primary tumor or metastatic lesions.

ADVANCED OR CONFIRMATORY TESTING

- Confirmation requires exploratory laparotomy and histopathology (immunohistochemical staining) of the tumor.
- Glucagonoma: increased plasma glucagon concentrations (in the absence of other diseases causing hyperglucagonemia), histopathologic evaluation of skin lesions, and hypoaminoacidemia are supportive. Results of liver function tests are normal (versus abnormal function with superficial necrolytic dermatitis).
- Gastrinoma: increased fasting serum gastrin concentration (in the absence of other diseases causing hypergastrinemia) and gastric hyperacidity; GI ulceration and/or increased prominence of gastric rugal folds seen with endoscopy, contrast radiography, or ultrasound; and excessive response to a gastrin secretagogue (secretin or calcium) are supportive.
- Carcinoid syndrome: increased serotonin metabolites (5-hydroxyindoleacetic acid) in urine are supportive.
- Indium-labeled somatostatin analogs (octreotide) are used in scintigraphy for detecting tumors expressing somatostatin receptors. CT scan and MRI can also be useful.

TREATMENT

TREATMENT OVERVIEW

Goals of treatment consist of:

- Removal of tumor
- Management of associated clinical signs

ACUTE GENERAL TREATMENT

- Fluid and electrolyte abnormalities should be corrected if present.
- Gastrinoma: treat hyperacidity and GI ulceration (see 440).
- Surgical removal of the primary tumor and any visible metastasis if possible. With gastrinoma, ulcer excision may also be needed.
- If the pancreas is manipulated during surgery, treat postoperatively for pancreatitis.

CHRONIC TREATMENT

- Because of the high incidence of metastasis at the time of diagnosis, surgery is not often curative, and subsequent medical management is needed.

- Gastrinoma: treat hyperacidity and GI ulcerations (see above); somatostatin analog treatment (octreotide, 5-20 mcg SQ q 8 h) can be tried.
- Glucagonoma: amino acid supplementation (eggs, prescription diets, possible IV amino acid infusion) has been suggested but is unproven; manage skin lesions (see pp. 1061 and p. 1122); octreotide (6 mcg SQ q 8 h) can be tried.
- Carcinoid syndrome: octreotide and cyproheptadine have been used. Methysergide maleate (antiserotonin agent) is not used because of serious side effect of retroperitoneal fibrosis.
- Effective chemotherapy for these tumors has not been reported in the dog and cat. Streptozotocin, doxorubicin, and 5-fluorouracil have been used in humans, with limited success.

POSSIBLE COMPLICATIONS

The most common postoperative complication is pancreatitis in dogs.

RECOMMENDED MONITORING

Monitor recurrence of clinical signs.

PROGNOSIS AND OUTCOME

- Glucagonoma: poor if concurrent advanced liver disease (mean 5 months) or metastasis
- Gastrinoma: poor long-term prognosis because metastasis is present in 70% of cases at time of diagnosis (mean 8 months)
- Carcinoid syndrome: many are clinically silent and found postmortem. Prognosis is guarded if metastatic disease is present.

PEARLS & CONSIDERATIONS

COMMENTS

These are complex tumors and very difficult to diagnose; referral to a specialist center is advised.

AUTHOR: NINETTE KELLER

EDITOR: SHERRI IHLE

Gastroenteritis: Acute, Nonspecific

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Sudden onset of vomiting and/or diarrhea; may be accompanied by anorexia and evidence of abdominal discomfort. Generally self-limiting, although supportive care may be necessary in severe cases.

SYNONYMS

Acute gastritis, dietary indiscretion, acute enteritis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs are more ofteffected owing to less discriminatorigestive behaviors.

RISK FACTORS: Poor supervision, access to garbage or other inappropriattems

ASSOCIATED CONDITIONS & DISORDERS: In severe cases: dehydration, hypokalemia, metabolic acidosis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acute onset of vomiting and/or diarrhea.
- Vomitus may contain food or foreign material.
- Diarrhea may be accompanied by mucus, urgency, tenesmus.
- Anorexia, lethargy, and mild abdominal discomfort may be noted in some cases.
- Owner may report recent dietary indiscretion.

PHYSICAL EXAM FINDINGS

- Normal vital parameters (temperature, heart rate, respiratory rate, pulse quality, blood pressure) in most cases
- Possible dehydration in more severe cases
- Mild nonlocalized abdominal discomfort may be noted.
- Mucoid stool may be noted on rectal examination.

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology is often not determined.
- Vomiting is likely due to direct gastric irritation or dysmotility.
- Diarrhea is likely due to irritation, dysmotility, or dysregulation of normal microbial populations within small and/or large intestine.
- Diagnosis usually based on history, absence of an identifiable cause, and prompt response to supportive therapy
- Often associated with dietary indiscretion (e.g., ingestion of garbage, nontoxic plants, spoiled food)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

This is a diagnosis of exclusion; pursue other differentials only if the patient's condition does not support this diagnosis or if the clinical signs persist for more than 48 hours.

DIFFERENTIAL DIAGNOSIS

- Infection: parasitic, bacterial, viral, protozoal
- Gastrointestinal (GI) obstruction

- Systemic diseases: acute hepatic injury, renal failure, pancreatitis, hypoadrenocorticism
- Drugs or toxin ingestion
- All causes of acute vomiting or diarrhea

INITIAL DATABASE

- Extensive diagnostics usually not necessary if clinical examination and hydration status are within normal limits
- CBC: stress leukogram is expected in canine patients; polycythemia may be noted if the patient is dehydrated.
- Serum biochemistry profile: hypokalemia commonly noted; metabolic acidosis; mild increase in BUN and creatinine may be evident if patient is substantially dehydrated.
- Urinalysis: no abnormalities expected; specific gravity may be increased depending on patient's hydration status.
- Fecal evaluation (centrifuged flotation and saline preparation): no pathogens noted
- Radiographs: generally unremarkable; ileus may be apparent.
- +/− Pancreatic lipase immunoreactivity (if high-risk breed, other risk factors): within normal range
- +/− Fecal ELISA for parvovirus (if neonate, questionable vaccination status): negative

TREATMENT

TREATMENT OVERVIEW

- Provide supportive therapy until normal GI tract function resumes.
- Select appropriate therapies based on physical examination and clinical evaluation.

ACUTE GENERAL TREATMENT

- Small quantities of water or an oral electrolyte solution may be offered if vomiting is infrequent.
- Subcutaneous crystalloids may be used for small animals with mild dehydration deficits.
- Intravenous fluids are required if patient is moderately dehydrated or has any evidence of hypovolemia.
- Antiemetics should be administered if vomiting is unremitting, provided GI obstruction has been ruled out.
    - Maropitant (1 mg/kg SQ q 24 h) is an effective first choice (only licensed for dogs; patient must be >16 weeks old).
    - Metoclopramide (0.2-0.4 mg/kg SQ q 6-8 h) must be given frequently to manage vomiting or provided as a constant rate infusion.
- Gastric acid–reducing drugs may reduce the risk of esophagitis; are always appropriate if hematemesis is noted.
    - Famotidine (0.5 mg/kg PO, IV, or SQ q 12-24 h) has a longer duration of effect than other drugs in this class.
- Protectants/adsorbents provide little clinical benefit and may be aspirated in vomiting animals. Products containing salicylate should be avoided in cats.
- Anticholinergics (e.g., aminopentamide) are not recommended; GI motility can be substantially compromised. Other side effects include dry mouth and tachycardia.
- Antibiotics are generally not indicated and may contribute to intestinal microbial disturbances and prolongation of diarrhea.

NUTRITION/DIET

- Food should be provided as soon as the patient is interested in eating. Easily digestible diets may be beneficial (e.g., boiled white rice with cottage cheese, boiled chicken, commercially available highly digestible enteric diets) because gastric emptying times are shorter, and fecal volume is minimized.
- Probiotics +/− prebiotics should be considered in patients with diarrhea, as disruption of the normal intestinal flora is both a likely cause and consequence of acute nonspecific gastroenteritis.

DRUG INTERACTIONS

- Maropitant is protein bound and may affect metabolism of other highly protein-bound drugs such as nonsteroidal antiinflammatories and anticonvulsants.
- Metoclopramide may increase absorption of drugs absorbed primarily in the small intestine; the adverse CNS effects of metoclopramide may be enhanced by concurrent use of sedatives (such as phenothiazines), tranquilizers, and narcotics.

RECOMMENDED MONITORING

- Hydration status
- Temperature, pulse, respiratory rate
- Volume of fluid losses

PROGNOSIS AND OUTCOME

Prognosis is excellent; this disorder usually resolves within 48 hours of onset.

PEARLS & CONSIDERATIONS

COMMENTS

- Animals with marked dehydration, hypovolemia, depression, or abdominal pain require a prompt and detailed diagnostic evaluation.
- Melena or substantial hematemesis are not consistent with a diagnosis of acute nonspecific gastroenteritis. Patients with these signs may require more investigation and aggressive management.

CLIENT EDUCATION

- This disorder should resolve within 48 hours. Further veterinary care should be sought if vomiting or diarrhea are persistent.
- Neonates, geriatric animals, and those with preexisting disorders are more prone to dehydration and may need more aggressive fluid support.

AUTHOR: AUDREY K. COOK

EDITOR: DEBRA L. ZORAN

Gastrinoma

BASIC INFORMATION

DEFINITION

Uncommon malignant amine precursor uptake and decarboxylation (APUD) cell tumors that secrete excessive amount of gastrin, resulting in gastric acid hypersecretion

SYNONYM

Zollinger-Ellison syndrome

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: average age 8.2 years (range 3.5-12 years). Cats: average age 10-12 years
- Female dogs and cats may be at a slightly higher risk than males.

GENETICS & BREED PREDISPOSITION: No breed predisposition is known.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Associated with gastrointestinal ulceration:
  - Chronic vomiting (most common)
  - Anorexia or ravenous appetite
  - Weight loss
  - Depression
  - Lethargy
  - Diarrhea
  - Polydipsia
  - Obstipation
  - Hematemesis
  - Melena
  - Pale mucous membranes
  - Abdominal pain
- Associated with perforating ulcer and peritonitis:
  - Collapse
  - Acute abdomen (pain)
  - Shock

PHYSICAL EXAM FINDINGS

- Nonspecific findings: lethargy, depression, poor body condition
- Pale mucous membranes
- Melena on rectal exam or apparent on rectal thermometer
- Palpable abdominal mass reported in one cat
- May be unremarkable

ETIOLOGY AND PATHOPHYSIOLOGY

APUD-cell tumors secrete excessive gastrin, resulting in hypersecretion of gastric acid by the stomach wall parietal cells. Gastric mucosal hypertrophy, gastrointestinal ulceration, esophagitis, and malassimilation secondary to enzyme inactivation and bile salt precipitation follow.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the presence of vomiting, anorexia, weight loss, and diarrhea or a combination of these, typically in a middle-aged to older dog/cat. Confirmation requires the presence of hypergastrinemia in fasted patients, in conjunction with histopathologic and immunohistochemical evaluation of excised pancreatic or duodenal neoplasms.

DIFFERENTIAL DIAGNOSIS

- Refractory gastritis/gastric ulcer disease
- Inflammatory bowel disease
- Gastrointestinal tract neoplasia
- Chronic pancreatitis
- Common bile duct obstruction

INITIAL DATABASE

- CBC: regenerative anemia due to gastrointestinal bleeding; neutrophilia associated with gastrointestinal ulceration.
- Serum chemistry panel and electrolytes: hypoalbuminemia and hypoproteinemia due to protein loss through gastroduodenal ulcerations. Chronic vomiting may result in hypokalemia, hyponatremia, and hypochloremia. Metabolic alkalosis, with or without aciduria, is consistent with a gastric outflow obstruction, which may be present in some cases. Metastasis to the liver may result in bilirubinemia and elevated liver enzymes.
- Abdominal radiographs: loss of abdominal detail if gastrointestinal perforation has occurred; otherwise, they are generally unremarkable. Contrast radiographs may reveal deep ulcers, prominent gastric rugae, or gastric outflow obstruction in some cases.
- Three-view thoracic radiographs: usually are within normal limits. Metastatic lesions usually occur late in the course of the disease.
- Abdominal ultrasound: thickened gastric wall or pylorus; evidence of metastatic disease to the liver or lymph nodes; diffuse increased echogenicity of the liver with severe gallbladder dilation and marked dilation of the cystic duct, common bile duct, and extrahepatic ducts.

ADVANCED OR CONFIRMATORY TESTING

- Endoscopy: esophagitis, gastric or duodenal ulceration, hypertrophy of gastric mucosa are evident on visual inspection. Histopathologic evaluation: rugae often appear normal, suggesting submucosal or muscular hypertrophy; duodenal villous blunting and ulceration is supportive of chronic hyperacidity but not diagnostic of gastrinoma.
- Basal gastric acid secretion: increased in more than 80% of human gastrinoma patients. Of the four reported dogs tested, all values were low.
- Basal serum gastrin concentration: best survey test in humans (increased in 98% of human gastrinoma patients). Correlates with dog and cat disease but can also be elevated in nonfasting sample, renal failure, gastric outflow obstruction, hypochlorhydria, pyloric stenosis, gastric dilatation and volvulus, atrophic gastritis, chronic gastritis, small intestine resection, hepatic disease, drug administration (H2 blockers, proton pump inhibitors, or glucocorticoids), immunoproliferative enteropathy of basenji dogs, and possibly *Helicobacter* spp. infection.
- Secretin stimulation test (2-4 U/kg IV, samples at 0.2, 5, 10, and 20 minutes postinjection): preferred provocative test for the diagnosis of gastrinoma in humans (gastrin levels greater than 200 pm/mL diagnostic in humans). Data regarding the procedure and its interpretation are limited in dogs and cats.
- Calcium stimulation test: data regarding the procedure and its interpretation are limited in dogs and cats (may be risky).
- ^{111}Iridium-octreotide or pentetreotide: somatostatin analogs bind to receptors expressed on gastrinomas and have facilitated localizing metastatic lesions in one dog.
- Histopathologic evaluation with immunohistochemistries or radioimmunoassay of extracts from the gastrinoma allow for a definitive diagnosis.
- Electron microscopy may also be used for detecting pancreatic Langerhans D cell intracytoplasmic secretory granules that are found in gastrinomas.

TREATMENT

TREATMENT OVERVIEW

Treatment mainly includes medical therapy to control clinical signs associated with gastric acid hypersecretion. Surgical reduction of

gastrinoma and metastatic lesions is palliative.

ACUTE GENERAL TREATMENT

- Intravenous fluids and electrolyte therapy to correct abnormalities associated with vomiting
- Control gastric hyperacidity:
  - H2 receptor antagonists (cimetidine, 10 mg/kg IV, IM, SQ, or PO q 8 h; ranitidine, 0.5-2 mg/kg IM, SQ, PO [minimal efficacy in the dog; IV may cause vomiting] q 8-12 h; famotidine, 0.2-1 mg/kg IV, IM, SQ, or PO q 12-24 h; or nizatidine, 2.5-5 mg/kg PO q 24 h)
  - H^+/K^+-ATPase (proton pump) inhibitors (omeprazole, 0.7-1 mg/kg PO q 12-24 h)
  - Somatostatin analog (octreotide, 10-40 mg [per dog] q 8-12 h)
- Promote healing:
  - Sucralfate, 0.25-1 g per dog PO q 6-12 h
  - Misoprostol, 1-5 mcg/kg PO q 8 h
- Surgical and medical management for gastrointestinal ulceration/perforation

CHRONIC TREATMENT

- Acute treatment management, along with antiemetics
- Surgical debulking of the primary and metastatic lesions decreases clinical signs associated with gastrinomas.
- Chemotherapy, receptor-mediated radiotherapy, and long-acting somatostatin analogs (+/− alpha-interferon) yield mixed responses.

POSSIBLE COMPLICATIONS

Gastrointestinal ulceration/perforation if hyperacidity is not controlled; common bile duct obstruction if due to a duodenal gastrinoma

RECOMMENDED MONITORING

According to clinical signs

PROGNOSIS AND OUTCOME

- Poor due to high rate of metastasis
- Animals that are managed medically and surgically live 1 week to 18 months (mean, 4.8 months).

PEARLS & CONSIDERATIONS

COMMENTS

A palpable abdominal mass or one that is visualized either at ultrasound or at surgery is uncommon with gastrinoma.

CLIENT EDUCATION

- Monitor for recurrence of clinical signs.
- Rapid deterioration is possible if gastrointestinal perforation occurs.

AUTHOR: M. RAQUEL BROWN

EDITOR: DEBRA L. ZORAN

Gastric Ulcer

BASIC INFORMATION

DEFINITION

Disruption of the gastric mucosa as a result of coagulative necrosis that breeches the muscularis layer and exposes the submucosa or deeper layers of the stomach wall

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats; no age, sex, or breed predisposition

RISK FACTORS

- Iatrogenic: administration of cyclooxygenase (COX) inhibitors, other nonsteroidal antiinflammatory drugs (NSAIDs), or corticosteroids
- Hypergastrinemia due to any number of causes
- Severe hypovolemia or ischemia (shock) leads to reduced gastrointestinal (GI) blood flow and increased risk of gastritis/ulcer.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Vomiting, hematemesis, melena are common complaints.
- Inappetence or anorexia and hyper-salivation are variably seen.
- Acute encephalopathic signs (e.g., stupor, seizures, or drooling in cats) may be observed in patients with concurrent severe liver disease.

PHYSICAL EXAM FINDINGS

- Generally nonspecific
- Abdominal pain, either on palpation or manifested as a “praying” position, is possible.
- Pale mucous membranes and circulatory shock possible with severe bleeding or gastric perforation

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary gastroduodenal diseases (e.g., toxins or foreign bodies, chronic gastritis, *Helicobacter* spp. infection, inflammatory bowel disease, neoplasia [mastocytosis, lymphoma, adenocarcinoma, or gastrinoma], pyloric outflow obstruction)
- Gastric hyperacidity disorders (e.g., gastrinomas, hypergastrinemia due to drugs)
- Drug-induced ulcers (e.g., COX inhibitors, other NSAIDs, corticosteroids)
- Other metabolic, endocrine, or systemic causes (e.g., pancreatitis, disseminated intravascular coagulation, hypoadrenocorticism, chronic kidney disease, liver failure, hypovolemic/septic shock, neurologic diseases, especially intervertebral disk disease or stress)
- The causes of ulceration are similar to those of gastritis and erosion, but for unknown reasons the reparative mechanisms of the mucosa are overwhelmed, resulting in deep indolent lesions.
- The process of ulcer healing starts as the necrotic mucosa sloughs and granulation tissue fills the ulcer. Mucus and bicarbonate are actively secreted by the neighboring mucosa to protect the ulcer. Granulation tissue eventually organizes, a connective-tissue bed develops, and epithelial tissues finally slide across the surface to reepithelialize it. Glandular structures are the last to repopulate the denuded area.
- Reduced gastric acid secretion facilitates this process, both by decreasing tissue damage from acid and by decreasing further damage from pepsin, which is less active at higher pH.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Gastric ulceration typically should be suspected in patients with any signs of GI disturbance that persist or worsen beyond the

degree expected for the primary diagnosis. A history of receiving ulcerogenic medications is suggestive but not essential. In many mild cases, clinical confirmation is only presumptive (response to antiulcer medications); a definitive clinical diagnosis requires endoscopy or laparotomy, particularly if severe/associated with gastric perforation and peritonitis.

DIFFERENTIAL DIAGNOSIS

- Acute vomiting:
  - Dietary indiscretion
  - Parasites
  - *Helicobacter* gastritis
  - Foreign bodies
  - Pancreatitis
  - Other acute metabolic conditions (renal failure, hypercalcemia, etc.)
- Hematemesis:
  - Coagulopathies or lack of platelets (number or function)
  - Ingested blood (nasopharyngeal, oral, esophageal, or pulmonary bleeding)
  - Hemorrhagic gastroenteritis (all causes of severe gastrointestinal erosion)
- Melena:
  - All causes of hematemesis ○ Intestinal neoplasia
  - Intestinal parasites (hookworm)
  - Intestinal ischemia
  - Inflammatory bowel disease or other infiltrative enteropathies
- Abdominal pain:
  - Hepatitis
  - Splenomegaly/splenic rupture/torsion
  - Intestinal obstruction
  - Acute renal failure
  - Intussusception/mesenteric torsion
  - Peritonitis
  - Pancreatitis

INITIAL DATABASE

- Rectal examination should be performed to assess presence of melena.
- CBC, serum biochemistry profile, urinalysis: important to identify underlying cause of gastric ulceration, and are especially needed if hematemesis or melena is present.
  - CBC may show anemia (variably regenerative if acute, depending on the time between onset of bleeding and time of testing; nonregenerative in the presence of underlying chronic disease; and microcytic, hypochromic, and regenerative [dogs] if associated with iron deficiency from chronic blood loss), neutrophilia (± left shift if associated with perforation), hypoproteinemia, or mild thrombocytopenia (rarely less than 75,000/µL).
  - Serum biochemistry profile may show an elevated blood urea nitrogen (BUN)/creatinine ratio or identify conditions associated with ulcers (renal failure, etc.). Not all cases will demonstrate an elevated BUN, however.
  - Urinalysis: essential for differentiating BUN elevation due to kidney disease (urine specific gravity 1.008-1.020) from BUN elevation due to prerenal causes (urine specific gravity > 1.035)
- Fecal occult blood test has limited utility.
  - *O*-tolidine-based tests are significantly more specific (0/108 false-positive results in healthy dogs) than guaiac-based tests (64/108 false-positive results in same dogs).
- Imaging studies:
  - Plain radiographs cannot confirm gastric ulceration. However, if perforation has occurred, loss of detail (suggesting peritonitis or free abdominal fluid) or free peritoneal gas may be present.
  - Contrast radiographs may identify a mucosal filling defect.
  - Ultrasonography may show local gastric wall thickening, loss of normal layering, the presence of a wall defect or "crater," fluid accumulation in the stomach, and diminished gastric motility. In animals with perforation due to the ulcer, there may be evidence of free fluid in the abdomen.

ADVANCED OR CONFIRMATORY TESTING

- Serum gastrin levels may help diagnose gastrinoma (see p. 442), but the animal must not have been on histamine-2 receptor blockers or proton pump inhibitors before testing.
- If a gastrointestinal perforation is suspected, abdominocentesis (see p. 1194) is indicated. If free fluid can be obtained during the ultrasound examination, that is often sufficient. However, a diagnostic peritoneal lavage may be needed to obtain samples if the perforation is relatively recent and the fluid accumulation is minimal.
- Gastroscopy: preferred for confirmation of gastric ulcer and tissue sampling; however, if a perforation is suspected, endoscopic examination is contraindicated, as it will increase abdominal contamination.

- A solitary ulcer in an otherwise normal stomach should raise the suspicion of gastric neoplasia, especially if the edges and surrounding mucosa are thickened.
- NSAID-induced ulcers can be solitary, but the surrounding mucosa is usually not normal, owing to generalized mucosal disease (gastritis and other erosions are common).
- Multiple diffuse small ulcers can be seen with NSAIDs, uremia, liver disease, mastocytosis, gastrinoma, and possibly *Helicobacter* gastritis.
- Biopsies should be obtained from the ulcer periphery to avoid perforation. Repeated biopsies from the same site may improve the likelihood of identifying neoplasia. However, in some cases, endoscopic biopsies will be inadequate for diagnosis (neoplastic tissue is deeper than superficial mucosal tissues sampled with endoscopic biopsies), and laparotomy is required for full-thickness biopsies.

TREATMENT

TREATMENT OVERVIEW

- Remove primary cause
- Promote healing
- Stabilization of patient with circulatory collapse from massive bleed or perforation

ACUTE GENERAL TREATMENT

- Supportive care:
  - Intravenous fluids, antibiotics, antiemetics, and opioid analgesics may be required for the patient with severe vomiting that has resulted in dehydration and electrolyte disturbances.
  - Blood transfusion for the patient with severe anemia as a result of massive bleeding
- Surgery:
  - Surgical resection is indicated when the ulcer appears deeply penetrating (volcano crater appearance), is bleeding continuously, has perforated, or is very large and fails to heal.
  - Surgical exploration may identify the etiology (neoplasia) and allow resection of the mass/ulcer.
- Medical:
  - H2 blockers. Options include:
    - Famotidine: 0.5-1 mg/kg PO, IV, or SQ q 12-24 h
    - Ranitidine: 1-4 mg/kg PO, IV, or SQ q 8-12 h
    - Cimetidine: 5-10 mg/kg PO, IV, or SQ q 6-8 h
  - Proton pump inhibitor: reduces gastric acid by >90% (not for use in cats). Options include:
    - Omeprazole: 0.7 mg/kg PO q 24 h (alternately 20 mg/dog)
    - Esomeprazole (Nexium): 1 mg/kg PO q 24 h
    - Lansoprazole (Prevacid): 1 mg/kg IV q 24 h
  - Prostaglandin E2-inhibitor: drug of choice for prevention/treatment of NSAID-induced ulcers; not for use in cats or pregnant females:
    - Misoprostol: 3-5 mcg/kg PO q 8 h
  - Sucralfate: mucosal protectant. As oral suspension, or dissolved in 6-10 mL tap water if tablet; is most effective if administered in an acidic environment (give 1-2 hours before acid-blocking drugs):
    - Dogs: 0.5-1 g PO q 8 h
    - Cats: 0.25 g PO q 8 h
  - Antiemetics: use as needed to control emesis:
    - Metoclopramide: 0.2-0.4 mg/kg PO or SQ q 8 h
    - Dolasetron: 0.3 mg/kg IV q 12-24 h

CHRONIC TREATMENT

Misoprostol is indicated for preventing ulcers in dogs that need to be on NSAIDs (e.g., arthritis) but are prone to developing ulcers.

DRUG INTERACTIONS

- Cimetidine and ranitidine inhibit a subset of the cytochrome P450 enzyme systems and may delay metabolism of some drugs.
- The dose of ranitidine must be altered (reduced) in dogs with kidney disease.

POSSIBLE COMPLICATIONS

The most important complications of gastric ulceration are blood-loss anemia (can be severe, requiring transfusions) and perforation, resulting in septic peritonitis and shock.

RECOMMENDED MONITORING

In dogs or cats with acute hematemesis, the packed cell volume/total protein must be monitored to determine if a blood transfusion or surgical intervention is needed.

PROGNOSIS AND OUTCOME

The prognosis for most gastric ulcers is good unless the underlying etiology is not identified or cannot be corrected.

PEARLS & CONSIDERATIONS

COMMENTS

- Careful endoscopic evaluation of the lesser curvature of the stomach is critical for identification of gastric adenocarcinoma.
- Patients with GI bleeding often have BUN elevations with normal creatinine, concentrated urine, and normal renal function.
- The combination of an H2 blocker with sucralfate is frequently used in the belief that healing is improved with the combination. A study in people comparing ranitidine to ranitidine-sucralfate showed no benefit from using the combination.
- Proton pump inhibitors (e.g., omeprazole) are the only effective means of completely reducing acid secretion. H2 blockers are much less potent, and of the group, only famotidine has been shown in dogs to adequately decrease gastric acid levels.

PREVENTION

Careful administration of NSAIDs, or use of NSAIDs with COX-2 selective properties, to minimize the risk of ulceration

CLIENT EDUCATION

- Advise clients of the dangers of consistent NSAID use, and provide them with signs to watch for that may indicate gastritis or ulcer formation.
- Advise clients about the potential dangers of over-the-counter NSAIDs in dogs and cats, as some of the most potent ulcerogenic drugs in dogs are ibuprofen, regular aspirin, and naproxen.
- Advise clients about the risk of potentially life-threatening complications from any over-the-counter NSAID given to cats.

AUTHOR: KENNETH R. HARKIN

EDITOR: DEBRA L. ZORAN

Gastric Parasites

BASIC INFORMATION

DEFINITION

Nematode parasites of the stomach affecting dogs and cats

EPIDEMIOLOGY

SPECIES, AGE, SEX: *Physaloptera* spp. infect dogs and cats. *Ollulanus tricuspis* is found exclusively in the cat. There is no age or sex predisposition.

RISK FACTORS

- Dogs and cats that habitually ingest the intermediate host (crickets, beetles, cockroaches) or transport hosts (e.g., rodents and snakes) for *Physaloptera* spp. are at greater risk of infection.
- Multicat households are a risk factor for *Ollulanus* spp. infection.

CONTAGION & ZOONOSIS: These are not zoonotic diseases. *Ollulanus* spp. is spread from cat to cat in the vomitus.

GEOGRAPHY AND SEASONALITY: Worldwide

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Chronic vomiting is the chief complaint for both parasitic infections. A good appetite is usually retained, and weight loss is usually insignificant, particularly for *Physaloptera* spp. infections. Cats with *Ollulanus* spp. infection may have chronic weight loss. The duration of signs may be from a few days to many months.

PHYSICAL EXAM FINDINGS: Typically there are no significant abnormal findings on physical examination. Emaciation may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Physaloptera* spp., most commonly *P. rara*. They range in length from 1 to 6 cm, although most are 1 to 2 cm.
  - Subclinical infections are believed to occur in many animals, but chronic vomiting due to gastritis or penetration of parasite into the gastric wall is the typical pathophysiologic presentation.
  - Intermediate hosts: beetles and crickets
- *O. tricuspis*. Size range is 0.7-1 mm long.
  - Presence *of Ollulanus* may induce gastric irritation and inflammation or in severe cases, a chronic fibrosing gastritis; however, infections with the parasite can also be inapparent.
  - Life cycle is direct: infection from eating vomitus containing larvae.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Affected individuals are identified by a chief complaint of vomiting that resolves with anthelmintic treatment (presumptive diagnosis based on response to treatment); alternatively, confirmation may come from demonstration of the parasites (endoscopic or microscopic).

DIFFERENTIAL DIAGNOSIS

- Dietary indiscretion
- Food intolerance or hypersensitivity/allergy
- Gastric foreign body
- *Helicobacter* gastritis
- Drugs or toxins (nonsteroidal antiinflammatory drugs, antibiotics, plants, lead)

- Idiopathic gastritis (lymphoplasmacytic, eosinophilic)
- Pyloric antral hypertrophy
- Pythiosis

INITIAL DATABASE

- CBC, serum biochemistry profile, and urinalysis are usually normal, although a rare dog or cat may have peripheral eosinophilia.
- Fecal flotation is usually negative. On rare occasions, the translucent eggs of *Physaloptera* spp. may be identified.
- Abdominal radiographs are normal.
- Abdominal ultrasound is normal.
- Microscopic examination of the vomitus may yield the presence of *Ollulanus* spp.

ADVANCED OR CONFIRMATORY TESTING

- In many cases of unconfirmed *Physaloptera*- or *Ollulanus*-associated gastritis, empirical anthelminthic treatment is highly effective, and advanced testing may be unnecessary.
- Gastroscopy is the only method to reliably identify the presence of *Physaloptera* spp. in the stomach.
- *Ollulanus* spp. can be identified from microscopic examination of vomitus, squash preps, or touch preps of gastric mucosal biopsies (endoscopy or surgery), or on histologic evaluation of the biopsies (less reliable).

TREATMENT

TREATMENT OVERVIEW

Removal of the parasite rapidly resolves vomiting.

ACUTE GENERAL TREATMENT

- Mechanical removal of *Physaloptera* spp. resolves clinical signs.
- Anthelminthics for *Physaloptera* spp.:
  - Pyrantel: 5 mg/kg PO (dog), 20 mg/kg PO (cat). Using a higher dose in dogs (10-15 mg/kg) and repeating in 2-3 weeks may yield a higher response rate.
  - Fenbendazole: 50 mg/kg/d PO for 3 days is reportedly effective (dog, cat). This author uses 75 mg/kg/d PO for 5 days in dogs.
  - Ivermectin: may be effective at 0.2 mg/kg PO (dog, cat). Not for use in ivermectin-sensitive breeds.
- Anthelminthics for *O. tricuspis*:
  - Fenbendazole: 50 mg/kg/d PO for 3 days
  - Pyrantel: 20 mg/kg PO, repeat in 2-3 weeks

POSSIBLE COMPLICATIONS

Fenbendazole is not labeled for use in cats and may be associated with idiosyncratic hepatotoxicosis with high doses or prolonged use.

PROGNOSIS AND OUTCOME

The prognosis for complete resolution of chronic vomiting is excellent. Reinfection with *Physaloptera* spp. is likely in most cases, as repeated ingestion of intermediate and transport hosts occurs. Treatment of all cats in a household for *O. tricuspis* should eliminate the parasite.

PEARLS & CONSIDERATIONS

COMMENTS

- At gastroscopy, the presence of small erosions or pinpoint hemorrhages on the gastric mucosa should prompt a careful inspection for *Physaloptera* spp.
- The elusive nature of the parasites, minimal severity of clinical signs, and expense of endoscopy all warrant a therapeutic trial

with an anthelminthic before advanced diagnostic testing. Gastric parasites may still be found after a failed therapeutic trial.

PREVENTION

- Block access to intermediate hosts or transport hosts.
- Administration of a monthly heartworm preventive that contains pyrantel may be beneficial in management of dogs with continued access to intermediate or transport hosts.

AUTHOR: KENNETH R. HARKIN

EDITOR: DEBRA L. ZORAN

Gastric Neoplasia

BASIC INFORMATION

DEFINITION

Benign or malignant tumors of epithelial, lymphoid, or mesenchymal origin. These tumors affect gastric function, are often painful, and may cause secondary systemic effects such as electrolyte disturbances, anemia, and weight loss.

SYNONYMS

Gastric adenocarcinoma, gastric adenoma, gastric polyps (benign), gastric carcinoma, gastric extramedullary plasmacytoma, gastric lymphoma (see p. 678), gastrointestinal stromal tumor (GIST), leiomyoma, leiomyosarcoma, scirrhous carcinoma of the stomach.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- In dogs, gastric tumors account for<1% of all malignancies:
  - Median age for adenocarcinoma is 10 years.
  - Median age for leiomyomas and GIST is 11 years.
- In cats, gastric tumors are most commonly lymphoma, which occurs in cats > 7 years old.

GENETICS & BREED PREDISPOSITION

- Gastric adenocarcinomas: rough collies, Staffordshire terriers, Belgian shepherds, and chow chows (may be familial)
- Leiomyoma and GIST: German shepherds

RISK FACTORS

Gastric adenocarcinomas:

- Chronic nitrosamine exposure experimentally
- Association of gastric carcinoma and lymphoma with chronic inflammation from *Helicobacter pylori* infection in people; unproven in companion animals

CONTAGION & ZOONOSIS

- *Helicobacter* spp. organisms may be frequently found in normal dogs and cats, but significance is undetermined.
- Zoonotic potential exists for *H. pylori,* but the prevalence of infection in animals is low.

ASSOCIATED CONDITIONS & DISORDERS: Gastric lymphoma in cats is generally not associated with retroviral infection (feline leukemia virus, feline immunodeficiency virus).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Chronic vomiting
- Hematemesis/melena
- Anorexia, weight loss
- Depression and lethargy, pain or restlessness

PHYSICAL EXAM FINDINGS

May include some or all of the following:

- Physical exam may be normal
- Poor body condition score (e.g., body condition score 1/9-2/9)

- Pale mucous membranes, signs of anemia
- Abdominal mass
- Abdominal pain

ETIOLOGY AND PATHOPHYSIOLOGY

- Chronic vomiting may result in weight loss, electrolyte imbalance.
- Anemia secondary to chronic gastrointestinal (GI) bleeding may be hypochromic, microcytic due to iron depletion.
- Panhypoproteinemia due to GI blood loss
- Hypoglycemia may occur secondary to insulin-like growth factor II release from smooth muscle tumors.
- GISTs are associated with activating mutation of the c-kit receptor tyrosine kinase oncogene.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is typically reached when nonspecific signs of gastrointestinal disturbance fail to respond to conservative management and/or are accompanied by systemic disturbances (e.g., weight loss). Radiographs and ultrasound may help to localize the lesion; confirmation requires a biopsy.

DIFFERENTIAL DIAGNOSIS

Any gastrointestinal or systemic cause of chronic vomiting may mimic gastric neoplasia:

- Gastric foreign body
- Gastric ulceration
- Granulomatous gastritis
- Chronic pancreatitis
- Systemic disease associated with chronic vomiting (renal, hepatic, diabetic ketoacidosis)

INITIAL DATABASE

CBC, serum chemistry panel with electrolytes, urinalysis: frequently normal or changes are nonspecific and secondary to GI electrolyte or blood losses (nonregenerative anemia, increased blood urea nitrogen, normal creatinine, normal urine specific gravity).

- Three-view thoracic staging radiographs (metastasis)
- Abdominal ultrasound evaluation: to assess gastric wall changes often not seen on routine radiographs and to rule out other causes of vomiting (pancreatitis, liver disease, etc.)
- Positive contrast gastrogram: assessment for outflow obstruction; does not differentiate neoplasia from other infiltrative diseases such as pythiosis
- Ultrasound-guided fine-needle aspiration cytology: if a gastric wall abnormality or lymphadenopathy is present. Lymphoma exfoliates most readily; GIST or gastric muscle tumors do not.
- Endoscopic biopsy: histopathologic diagnosis is essential for treatment and prognosis. Endoscopy rapidly and effectively provides mucosal tissue specimens, but if the tumor is in the gastric muscular or serosal layers, results may be inadequate, requiring surgical biopsy.
- Surgical biopsy: exploratory surgery provides opportunity for both diagnosis and treatment (surgical removal of the affected region).

ADVANCED OR CONFIRMATORY TESTING

Diagnosis is confirmed by biopsy with histopathology:

- Immunohistochemical stains for c-kit in GIST
- Cytokeratin, vimentin immunohistochemistry for undifferentiated tumors
- Immunophenotyping for lymphoma

TREATMENT

TREATMENT OVERVIEW

Benign gastric lesions may be cured surgically, as can early-diagnosed low-grade malignancy. Other surgical goals might be to relieve gastric obstruction or remove tumors that are painful or bleeding for palliation. Chemotherapy is potentially helpful in prolonging survival, although malignant gastric tumors are typically incurable.

ACUTE GENERAL TREATMENT

- Antiemetics (maropitant, 1 mg/kg PO, SQ; or dolasetron, 0.3 mg/kg q 12-24 h IV, SQ; or metoclopramide, 0.2-0.4 mg/kg q 8 h, PO, or IV if no obstruction present), gastroprotectants (famotidine, 0.5 mg/kg IV, PO q 12 h).
- Rehydration with intravenous fluids
- Antibiotics for *Helicobacter* infection if indicated
- Blood transfusion and hematinic therapy as indicated for nonregenerative iron-deficiency anemia
- Analgesic management as indicated by clinical signs
- Diet modification to easily digested, high-energy content food
- Parenteral alimentation as indicated (if the patient has not eaten for > 3 days or will not be able or willing to eat after surgery)

CHRONIC TREATMENT

- Gastric tumor resection often results in motility disorders.
  - May require motility modifiers (metoclopramide, 0.2-0.4 mg/kg IV, PO q 8 h; or cisapride, 0.25 mg/kg q 24 h PO)
- Chronic antiemetic therapy may be required.
- Chemotherapy with doxorubicin, platinum agents, or antimetabolites may prove helpful.
- Systemic chemotherapy for gastric lymphoma provides remission and prolonged survival (see p. 678).

POSSIBLE COMPLICATIONS

- Surgical wound dehiscence with secondary peritonitis, pneumoperitoneum
- Chemotherapy-induced leukopenia might predispose to infection.
- Chemotherapy-induced thrombocytopenia might increase gastric hemorrhage.
- Chemotherapy might result in gastric perforation of transmural lesions.

RECOMMENDED MONITORING

- Postoperative follow-up with chest radiographs and abdominal ultrasound for signs of recurrence or metastasis on a 1-to 2-month basis for 1 year
- Monitor CBC for recovery from nonregenerative anemia.
- Monitor for signs of dissemination of alimentary lymphoma.

PROGNOSIS AND OUTCOME

- Favorable for benign lesions (adenomas, leiomyomas), although complete resection of mesenchymal tumors is unlikely
- Poor for adenocarcinoma, carcinoma, GIST, especially when metastatic:
  - These dogs generally do not live beyond 6 months even with therapy.
- Guarded to fair for focal mass presentation of lymphoma
- Guarded for diffuse or multicentric alimentary lymphoma, as these lesions typically regress slowly and may have an indolent course but are ultimately incurable

PEARLS & CONSIDERATIONS

COMMENTS

- Gastric carcinoma is associated with early lymphatic spread. Lymph nodes detected on ultrasound can be used for diagnosis and prognosis.
- Gastric carcinomas may overexpress cyclooxygenase-2; nonsteroidal antiinflammatory drugs (piroxicam, 0.3 mg/kg PO q 24 h) may be palliative.
- Scirrhous carcinoma is rapidly fatal.

Gastric Dilatation/Volvulus

BASIC INFORMATION

DEFINITION

Rotation of the stomach on its mesenteric axis associated with gastric distention, well recognized in large-and giant-breed dogs

SYNONYMS

Bloat, gastric torsion, GDV

EPIDEMIOLOGY

SPECIES, AGE, SEX: Older dogs (>7 years) are at greatest risk; rarely reported in cats.

GENETICS & BREED PREDISPOSITION

- Large-and giant-breed dogs
- Purebred dogs at greater risk than mixed breeds
- Having a first-degree relative with gastric dilatation/volvulus (GDV) is associated with an increased risk.
- The most commonly affected breeds are the Great Dane, weimaraner, Saint Bernard, Gordon setter, Irish setter, Doberman pinscher, Old English sheepdog, and standard poodle. Bassett hound is at greatest risk among smaller breeds.

RISK FACTORS

Increased risk may be associated with:

- Narrow and deep thoracic cavity
- Long hepatogastric ligament
- Stress
- Fearful temperament
- Being underweight
- Nutritional risk factors including once-daily feeding, rapid ingestion of food, exercise after eating, consumption of large volumes of food or water, eating from a raised feeding bowl, and feeding dry dog food with oil or fat listed as one of the first four ingredients

GEOGRAPHY AND SEASONALITY: Possible increased incidence in the months of November, December, and January (United States)

ASSOCIATED CONDITIONS & DISORDERS

- Inflammatory bowel disease
- Previous splenectomy for splenic torsion or mass

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Abdominal distension
- Abdominal pain
- Ptyalism
- Retching or vomiting (may be nonproductive)
- Acute collapse

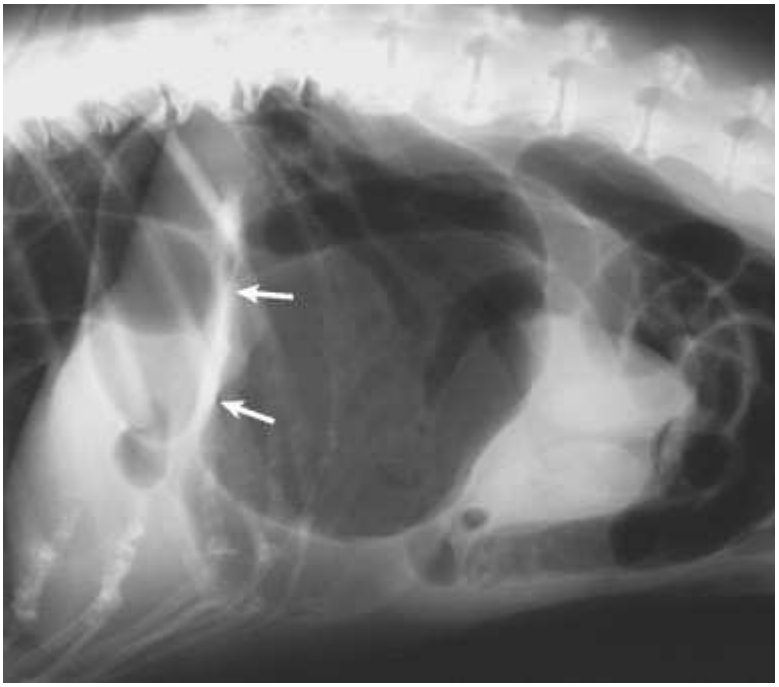
PHYSICAL EXAM FINDINGS

- Abdominal distension and tympany:
  - Simultaneous auscultation and percussion of the abdomen may reveal a tympanic sound, indicating the presence of a

taut, gas-filled viscus (stomach).
- Splenomegaly
- Clinical signs of hypovolemic shock: weak pulses, tachycardia, pale mucous membranes, prolonged capillary refill time, dyspnea

ETIOLOGY AND PATHOPHYSIOLOGY

- In most cases, the pylorus moves ventrally and from right to left; the rotation may be 90○-360○.
- Gastric dilation occurs secondary to failure of eructation and pyloric outflow obstruction. This occurs before or after gastric rotation.
- The distended stomach results in caudal vena cava and portal vein compression, causing decreased venous return to the heart.
- Decreased venous return results in decreased cardiac output, decreased arterial blood pressure, and myocardial ischemia.
- Myocardial ischemia causes cardiac arrhythmias.
- In the case of volvulus, increased intraluminal gastric pressure, portal hypertension, and avulsion of the short gastric vessels compromise blood flow to the gastric wall. Gastric necrosis and perforation can result.
- Portal vein compression/hypertension causes sequestration of splanchnic blood and decreased ability to clear gram-negative endotoxins.
- Endotoxemia further potentiates hypotension and decreased cardiac output.
- Pressure on the diaphragm, decreased lung perfusion, and decreased lung compliance cause respiratory dysfunction and exacerbate tissue hypoxia.



GASTRIC DILATATION/VOLVULUS Lateral abdominal radiograph of a dog with gastric dilatation/volvulus. Characteristic septation *(arrows)* of the gastric shadow is seen; displaced, gas-filled antrum is cranial to the arrows (to the left on this image), whereas gas-filled fundus is caudal (arrows are within it). A gas-filled esophagus and evidence of ileus in the form of distended, gas-filled small intestine are also present.

(Courtesy Dr. Richard Walshaw.)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

GDV should be suspected in large-or giant-breed dogs presenting with an acute history of a distended or painful abdomen, often with preceding or concurrent attempts at vomiting. Physical examination usually reveals a tympanic abdomen and often signs of shock. The diagnosis is confirmed with radiography, but treatment for shock is initiated beforehand based on clinical suspicion alone.

DIFFERENTIAL DIAGNOSIS

- Gastric bloat associated with overeating
- Mesenteric volvulus
- Splenic torsion
- Diaphragmatic hernia with stomach herniation

INITIAL DATABASE

- Abdominal radiographs:
  - Right lateral view is preferred.
  - Shows gas-filled pylorus cranial and dorsal to the fundus ("popeye sign," "C sign," or "double bubble")
  - Free abdominal air suggests gastric perforation.
- Quick assessment tests:
  - Packed cell volume/total solids (PCV/TS): often increased due to hypovolemia
  - Serum electrolyte and glucose concentrations: hypokalemia and hypoglycemia may be seen.
  - Acid-base analysis: metabolic acidosis due to lactic acidosis frequently seen
- Coagulation panel and platelet count: thrombocytopenia, increased prothrombin time/activated partial thromboplastin time/fibrinogen concentration and/or fibrin degradation product concentration associated with disseminated intravascular coagulation
- Electrocardiogram (ECG): ventricular arrhythmias are common

ADVANCED OR CONFIRMATORY TESTING

- Diagnosis confirmed at surgery
- Measurement of lactic acid concentration prior to surgery may assist in determining prognosis
  - Lactic acid (lactate) concentration >6.0 mmol/L associated with gastric necrosis and increased mortality

TREATMENT

TREATMENT OVERVIEW

The initial therapeutic goal is to manage hypovolemia with intravenous (IV) fluids and to decompress the stomach to reestablish systemic and gastric mural perfusion. Definitive treatment involves surgery to correct the position of the stomach, remove devitalized tissue, and perform a gastropexy to prevent recurrence.

ACUTE GENERAL TREATMENT

- Place large-bore IV catheters in both cephalic veins and infuse isotonic crystalloids at a rate of 90 mL/kg/h. Colloids can be administered in combination with crystalloids at 5-20 mL/kg over 15-30 minutes. For severe shock, hypertonic saline can be administered at 4 mL/kg over 5 minutes followed by crystalloids.
- Prophylactic antibiotic therapy
- Decompress the stomach by orogastric intubation (see p. 1281).
- If orogastric intubation is not possible and patient has visible abdominal distension with a radiographically confirmed GDV, perform percutaneous trocarization of the stomach:
  - Aseptically clip and prepare an area at least 4 × 4 in. (10 × 10 cm) on the left lateral or dorsolateral abdomen, just caudal to the last rib and over the region of most obvious distension.
  - Identify a point that is within the prepared area and ventral to the hypaxial muscles and caudal to the last rib.
  - Using a large-bore needle or needlestyleted catheter (e.g., 16 or 14 G) directed ventrally and slightly cranially, penetrate all layers of the body wall and stomach. When successful, the procedure should produce a hissing sound associated with a release of fetid-smelling gas through the needle.
- Immediate surgery to return stomach to a normal position:
  - Placing traction on the pylorus and elevating it while putting downward pressure on the fundus will aid derotation in a counterclockwise direction (most but not all cases will have rotated clockwise).
  - Evaluate stomach and spleen for irreversible vascular compromise and necrosis.
  - Perform partial or complete splenectomy if splenic necrosis, infarction, or torsion. Perform resection or invagination of necrotic areas of stomach.
  - Perform gastropexy of pyloric antrum to the right body wall.
- Medical treatment alone (repeated intubation, trocarization) has been uniformly disappointing.

CHRONIC TREATMENT

- Postoperative potassium supplementation if hypokalemic:
  - Do not exceed 0.5 mEq/kg/h IV.

- If ventricular arrhythmias are noted on the ECG:
  - Is hypokalemia present? If so, institute potassium replacement immediately.
    - Ventricular arrhythmias are caused by hypokalemia.
    - Ventricular arrhythmias are refractory to treatment with lidocaine, procainamide, and other antiarrhythmics when hypokalemia is present.
  - Is there anemia, hypoxemia, or acidosis? Many ventricular arrhythmias will resolve spontaneously if these systemic disturbances are corrected.
  - Is the rate rapid (>160 bpm), or is the pulse weak, despite addressing the systemic disturbances already mentioned? If so, consider treatment with lidocaine (see p. 1165).
- Treat peritonitis (see p. 865) if gastric perforation has occurred (fluids, antibiotics, abdominal lavage ± drainage).
- Treat gastric ulceration with H2 receptor antagonists:
  - Famotidine, 0.5-1 mg/kg IV, IM, SQ, or PO q 12-24 h; *or*
  - Ranitidine, 0.5-2 mg/kg IV, IM, SQ, or PO q 8-12 h
    - Ranitidine also has promotility properties similar to those of metoclopramide.
- Use drugs that increase gastric motility (i.e., metoclopramide, 0.2-0.4 mg/kg PO, SQ, or IM q 6 h, or 1-2 mg/kg/d IV as a continuous infusion; *or* cisapride, 0.1-0.5 mg/kg PO q 8 h) if recurrent bloating occurs after gastropexy, without evidence of gastric outflow obstruction.
- Pain management

NUTRITION/DIET

- Enteral/oral feeding can begin the day after surgery if the patient is not vomiting.
- Several recommendations are made to prevent gastric bloat after discharge or to prevent GDV in dogs that have not had a gastropexy:
  - Divide feedings into several small meals a day.
  - Do not feed dry foods that contain an oil or fat ingredient listed as one of the first four ingredients.
  - Avoid stress during feeding.
  - Do not elevate feeding bowl during eating.
  - Restrict exercise before and after meals.

POSSIBLE COMPLICATIONS

- Cardiac arrhythmias
- Reperfusion injury
- Gastric necrosis with peritonitis if devitalized tissue not removed
- Gastric ulceration
- Esophagitis and regurgitation
- Gastroparesis and ileus
- Disseminated intravascular coagulation
- Aspiration pneumonia
- Recurrence of dilation
- Recurrence of volvulus if inadequate gastropexy

RECOMMENDED MONITORING

- ECG: ventricular arrhythmias common within 36 hours of surgery
- Electrolyte concentrations: hypokalemia
- Blood glucose concentration: hypoglycemia
- PCV/TS: hemoconcentration indicates need for increased fluid therapy. Anemia can occur from bleeding of torn short gastric vessels.
- Physical parameters: mucous membrane color, capillary refill, pulse quality, temperature, respiratory effort, lung auscultation, abdominal distension, bruising

PROGNOSIS AND OUTCOME

- Approximately 15% mortality rate for patients with GDV treated surgically
- Gastric necrosis and need for gastric resection are associated with >30% mortality
- Increased risk of death if ≥5 hours time lag from onset of clinical signs to admission, hypothermic at admission, or if hypotension occurs at any time during hospitalization
- Serum lactate level in dogs with GDV:
  - 99% survival if <6 mmol/L
  - 58% survival if >6 mmol/L

PEARLS & CONSIDERATIONS

COMMENTS

- Begin fluid resuscitation before abdominal radiography.
- Do not assume the stomach is not rotated just because a stomach tube can be passed.
- Assess suspect areas of stomach for viability 10-15 minutes after derotation by palpation, evaluating blood flow and stomach wall color. If stomach wall is green or gray, this area will need to be resected.
- Ventricular arrhythmias have not been shown to worsen prognosis. Rather, they may identify arrhythmogenic disturbances (commonly in GDV: hypokalemia, anemia, or acidosis) that must be corrected for the arrhythmia to resolve.

PREVENTION

- See Nutrition/Diet
- Do not breed dogs if history of GDV
- Prophylactic gastropexy in breeds at high risk for GDV
    - Performed during ovariohysterectomy, during splenectomy, or as an elective procedure
    - Commonly performed with the aid of laparoscopy

EDITOR: RICHARD WALSHAW

Garbage Toxicosis

BASIC INFORMATION

DEFINITION

Gastroenteritis or hemorrhagic gastroenteritis caused by ingestion of food or garbage contaminated with bacteria or preformed bacterial toxins. Tremors or seizures can occur secondary to presence of tremorgenic mycotoxins. Garbage toxicosis is a common occurrence in dogs but less commonly seen in cats, owing to their more discriminating dietary habits.

SYNONYMS

Bacterial food poisoning, carrion toxicosis, garbage gut, songbird fever

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Potentially all animals; dogs are more likely to ingest spoiled foods.
- Cats that hunt and consume birds may develop this disorder.

RISK FACTORS

- Roaming animals
- Dogs fed food considered unfit for human consumption
- Raw food diets

CONTAGION & ZOONOSIS

- Disease is transmissible between animals because of habits of licking and sniffing.
- Dogs also might eat vomitus or feces containing bacteria or bacterial toxins.
- Zoonotic transmission possible, especially in young children or people with compromised immune systems.

GEOGRAPHY AND SEASONALITY: Disease common during warmer months, or year round in tropical and subtropical regions.

ASSOCIATED CONDITIONS & DISORDERS

- Botulism
- Tremorgenic mycotoxicosis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of exposure to carrion or garbage or raw food diets
- Clinical signs within 15 minutes to 6 hours post ingestion; diarrhea can be delayed for 48 hours
- Severe vomiting, diarrhea, lethargy, anorexia

PHYSICAL EXAM FINDINGS

- Signs of abdominal pain
- Abdominal distension from gas
- Foul smelling feces; watery or bloody diarrhea
- Fever
- Ataxia
- Weak pulse, muddy mucous membranes, increased capillary refill time, hypovolemic shock
- Hypothermia as the shock state progresses

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- *Streptococcus* spp., *Salmonella* spp., *Bacillus* spp., *Escherichia coli,* and *Clostridium perfringens* are the most common bacteria involved.
- Endotoxemia and enterotoxemia are possible.

Mechanism of Toxicosis

- Via different mechanisms; endotoxins produce hypovolemic shock, collapse, and death.
- Tremors, seizures, hyperthermia may occur from tremorgenic mycotoxins.
- Gastrointestinal (GI) epithelial cells irritated/eroded:
    - Permeability disturbed, initiating vomiting, GI hemorrhage, fluid and electrolyte loss
    - Normal absorptive capabilities of the GI tract may be disrupted.
    - Stasis and GI dilation with gas accumulation follows.
    - GI stasis encourages growth of gram-negative bacteria which liberate endotoxin.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on a history of ingesting garbage, spoiled food, carrion, songbirds (cats), and the like and typical clinical signs of gastroenteritis or tremors/seizures (with tremorgenic mycotoxins). The disorder is different from benign self-resolving gastroenteritis in the following ways: known ingestion of contaminated substances and/or presence of systemic signs (endotoxemia, neurologic dysfunction, other). In the absence of historical evidence of ingestion, other causes of gastroenteritis must be ruled out with appropriate testing.

DIFFERENTIAL DIAGNOSIS

Toxicologic:

- Plants: castor beans, sago palm, ornamental bulbs, autumn crocus, etc.
- Metals: arsenic, antimony, iron, etc.
- Others: disulfoton (an organophosphate pesticide), gastrointestinal-irritant mushrooms

Nontoxicologic, Spontaneous:

- Viral gastroenteritis
- Hemorrhagic gastroenteritis
- Acute pancreatitis
- Acute hepatopathies
- “Salmon poisoning”

INITIAL DATABASE

- CBC and serum biochemistry profile: nonspecific changes
- Abdominal radiographs: to identify abnormal ingesta or rule in/rule out other disorders
- Monitor blood glucose (hypoglycemia associated with endotoxemia)

ADVANCED OR CONFIRMATORY TESTING

- Bacterial fecal culture is of mixed value (healthy animals often have cultures that are positive for “pathogenic” bacteria).
- Blood culture if sepsis is suspected
- Serologic identification of staphylococcal or clostridial toxins
- Penitrem A or roquefortine (tremorgenic mycotoxins) can be analyzed in the contaminated food or stomach contents (through a diagnostic laboratory).

TREATMENT

TREATMENT OVERVIEW

Treatment is aimed at limiting absorption of bacterial toxins by inducing emesis and administering activated charcoal, controlling vomiting, correcting fluid and electrolyte disorders, and other supportive measures (preventing shock and preventing secondary infection). Initial approach is similar to any general intoxication, and specific treatments are indicated if systemic signs arise.

ACUTE GENERAL TREATMENT

- In animals with a known recent exposure but no clinical signs, induction of vomiting is indicated: hydrogen peroxide 3%: 1-2 mL/kg (maximum 45 mL total) PO once; *or* apomorphine, 0.04 mg/kg IV or instilled in conjunctival sac and rinsed out when vomiting begins (dogs); *or* xylazine, 0.44 mg/kg IM (cats).
- Activated charcoal, 1-3 g/kg PO (dose according to packaging label of product; e.g., 10 mL/kg of activated charcoal suspension PO made from 2 g/kg activated charcoal suspended in 10 mL/kg tap water)
- Appropriate fluid and electrolyte therapy
- Antibiotics
    - Injectable aminoglycosides generally contraindicated because of synergistic action with endotoxins in depressing the myocardium and risk of nephrotoxicosis in hypovolemia.
    - Oral aminoglycosides (streptomycin, 5-10 mg/kg PO q 12 h; *or* neomycin 10-20 mg/kg PO q 8-12 h) work well.
    - Metronidazole, 25 mg/kg PO q 12 h (for a maximum of 5 days at this dosage) can also be used.
    - If a cat has known songbird fever, routine antibiotics are not recommended, as this tends to alter normal GI flora, allowing colonization by *Salmonella*.
- Gastrointestinal protectants such as sucralfate ¼ to a whole 1-gram tablet PO q 8 h
- Treatment for shock as needed (see p. 585)
- Appropriate treatment if disseminated intravascular coagulation occurs (e.g., including heparin 75 IU SQ q 8 h (see p. 315)
- Control tremors and seizures with methocarbamol (55-220 mg/kg IV, repeat as needed; max dose 330 mg/kg/day) or diazepam (0.5-2 mg/kg IV, repeat as needed) in cases involving tremorgenic mycotoxins.
- Profuse, persistent vomiting after the toxin has been expelled may be controlled with maropitant, 1 mg/kg SQ q 24 h; dolasetron mesylate, 0.6 mg/kg IV q 24 h; or metoclopramide, 0.2-0.4 mg/kg IM or SQ q 8 h.

NUTRITION/DIET

- Bland diet
    - Canned prescription gastrointestinal therapeutic diets
    - Low-fat, low-spice homemade diet (e.g., boiled white rice with either boiled skinless/boneless chicken breast or 2% cottage cheese)

POSSIBLE COMPLICATIONS

- Chronic diarrhea with clostridial enteritis
- Pancreatitis, malabsorption syndromes with repeated episodes of garbage toxicosis

RECOMMENDED MONITORING

- Temperature
- Heart rate
- Blood pressure
- Glucose
- CBC

PROGNOSIS AND OUTCOME

- Prognosis good provided shock does not occur
- Poor or guarded if endotoxemic shock

PEARLS & CONSIDERATIONS

COMMENTS

- Clinical signs generally resolve in 3-5 days.
- The term *songbird fever* arises from the source of intoxication, namely the decayed carcasses of songbirds that cats hunt.
- Consumption of decomposing organic material, moldy refrigerated foods, cottage cheese, cream cheese, or moldy walnuts can cause tremors and seizures due to contamination with tremorgenic mycotoxins such as penitrem A and roquefortine.

PREVENTION

- Prevent roaming and scavenging.
- Feed fresh, high-quality food.

CLIENT EDUCATION

- Discuss nutrition.
- Discuss potentially zoonotic aspects of raw diets.

1ST EDITION AUTHOR: CHARLOTTE MEANS

Gallops and Other Extra Heart Sounds

BASIC INFORMATION

DEFINITION

Extra heart sounds are classified as sounds or vibrations other than the normally ausculted first and second heart sounds. They alter the sound of a heartbeat but not the rhythm of the heartbeat. Gallops and extra heart sounds are different from premature cardiac beats and arrhythmias.

SYNONYMS

Third heart sound, fourth heart sound, diastolic heart sound, protodiastolic heart sound, presystolic heart sound, summation diastolic heart sound

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats of any age and either sex, in the presence of heart disease/failure (gallop sounds)

RISK FACTORS

- Gallop sounds: congestive heart failure, systolic and diastolic ventricular dysfunction
- Systolic clicks: early mitral valvular insufficiency or flail leaflet
- Split heart sounds: increased ventricular pressures (causing splitting sounds due to delayed aortic or pulmonic valve closure under specific circumstances)
- Pericardial friction rubs: pericarditis, inflammation of the external pericardial lining

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Clinical signs relating to heart failure of virtually any etiology (see p. 468) are associated with gallop sounds. Splitting sounds may be normal or an indication of delay in valvular closure due to increased pressures on one or both sides of the heart or due to high pressure delaying valvular opening. Systolic clicks are not associated with clinical signs. Pericardial rubs are associated with pericardial diseases and their associated clinical signs.

PHYSICAL EXAM FINDINGS: A triple heart sound sequence with accentuated low-frequency sounds mimicking a cantering horse best describes a gallop sound. This sound is of low frequency, heard best with the bell of the stethoscope and usually over the mitral and or tricuspid valve area. The sound is likely to be associated with other signs of heart failure such as dyspnea, tachypnea, heart murmurs, and an increase in the heart rate.

ETIOLOGY AND PATHOPHYSIOLOGY

- Normally, only the S1 and S2 sounds are heard when auscultating the heart of the dog or cat.
- When the usually inaudible third or fourth sounds are so loud that they can be heard (gallops), they are an indication of the presence of ventricular systolic and/or diastolic dysfunction and are usually an indication of heart failure. By definition they occur during diastole and are generated by the vibration of ventricular walls during active ventricular filling (S3) or final ventricular filling by atrial contraction (S4) in a poorly compliant ventricle.
- Other additional sounds within the normal cardiac cycle can include:
    - Splitting of the normal heart sounds: either split S1, due to the asynchronous closure of AV valves, or split S2, due to asynchronous closure of aortic and pulmonic (semilunar) valves; caused by alterations in pressures within the heart and great vessels causing early or delayed valve closure
    - Extracardiac rubbing sounds
    - Systolic clicks: etiology unidentified, possibly caused by the warping/snapping of a diseased, prolapsed mitral valve. They are usually heard best with the diaphragm of the stethoscope, in contrast to the gallop sound which is a lower frequency sound heard better with the bell. The systolic click may be single or multiple. It also may come and go between consecutive cardiac cycles.
    - Opening snaps: heard in diastole and indicative of a calcified or hardened valve leaflet making a snapping sound when the valve opens during that phase of the cardiac cycle. These are unusually heard in dogs and cats, and they may be demonstrated by phonocardiography.

- Friction rubs: due to rubbing of a diseased pericardium against portions of the thorax

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Triple heart sounds occurring at a slow rate are not likely to be gallop rhythms and must be differentiated from extra beats, heart block, systolic clicks, split heart sounds, and opening snaps. Systolic clicks are higher-frequency sounds heard with the diaphragm of the stethoscope and usually are heard at the point of maximal intensity on the thorax. The sound may be consistent or variable and may be single or multiple. It can easily mimic a gallop sound except in the frequency of the ausculted sound. Split heart sounds are usually heard cranially and left over the aortic and pulmonic valve regions. They tend to be higher-frequency sounds heard best with the diaphragm of the stethoscope.

INITIAL DATABASE

Cardiac evaluation in the form of auscultation, radiography of the thorax, laboratory analyses, and echocardiographic examination usually are sufficient to identify the specific abnormality present.

TREATMENT

TREATMENT OVERVIEW

Extra heart sounds in and of themselves are NOT treated. Attention is directed to identifying the underlying cause and determining whether treatment is required for the primary etiology.

PROGNOSIS AND OUTCOME

Variable, depending on cause

PEARLS & CONSIDERATIONS

COMMENTS

The bell of the stethoscope is useful for differentiating low-frequency sounds such as gallop sounds (bell disproportionately enhances the third heart sound) from other heart sounds of higher frequency such as split heart sounds and systolic clicks (heard more clearly with the diaphram of the stethoscope).

EDITOR: ETIENNE CÔTÉ

Gallbladder Rupture

BASIC INFORMATION

DEFINITION

Loss of gallbladder wall integrity

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs:

- Associated with trauma: younger dogs (mean 2.8 years)
- Associated with intrinsic gallbladder disease: middle-aged dogs (mean 8.1 years)

GENETICS & BREED PREDISPOSITION

- Shetland sheepdogs and possibly cocker spaniels are overrepresented.

ASSOCIATED CONDITIONS & DISORDERS

Dogs:

- Cholelithiasis, cholecystitis, bile peritonitis, sepsis
- Associated with gallbladder mucocele
- Gallbladder infarction
- Hypothyroidism and hyperadrenocorticism may predispose a subset of dogs to gallbladder infarction/rupture.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Gallbladder infarction/necrotizing cholecystitis:
  - Without rupture
  - With hepatic and omental adhesions and possibly fistulae to other abdominal structures
  - With gallbladder perforation and diffuse peritonitis
- Gallbladder perforation associated with penetrating trauma and subsequent bile peritonitis

HISTORY, CHIEF COMPLAINT

- Nonspecific signs: vomiting, anorexia, weakness, polydipsia, polyuria, weight loss. Often chronic (duration from onset of signs to presentation: up to 1 month; mean = 12 days)
- Some owners may notice icterus, discolored urine (bilirubinuria).

PHYSICAL EXAM FINDINGS

- Icterus: very common (77% of bile peritonitis cases)
- Abdominal distension: common (65% of bile peritonitis cases), may be subtle
- Signs of abdominal pain
- Pyrexia
- Shock

ETIOLOGY AND PATHOPHYSIOLOGY

- Causes of gallbladder rupture:
  - Necrotizing cholecystitis

- Gallbladder infarction
- Penetrating trauma
- Inadequate choleresis due to excessively thick bile, defective gallbladder contractility, and/or altered outflow

- Gallbladder rupture may result in the development of septic or nonseptic peritonitis (see p. 865).
- Lack of bile secretion into the intestine results in:
  - Lack of digestion and absorption of fat and fat-soluble vitamins, most importantly vitamin K (coagulopathy)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on nonspecific history and physical examination finding of icterus +/− abdominal signs. Confirmation requires abdominal ultrasound examination and peritoneal fluid analysis.

DIFFERENTIAL DIAGNOSIS

- Icterus:
  - Hyperbilirubinemia due to hemolysis: immune-mediated hemolytic anemia and other diseases causing severe intravascular hemolysis
  - Hepatic diseases: cholangiohepatitis, cirrhotic/fibrosing liver disease, neoplasia, copper and other toxins
  - Extrahepatic biliary obstruction: choleliths, pancreatitis, cholangitis, neoplasia, stricture
  - Biliary leakage from other parts of the biliary system:
    - Traumatic rupture of the common or hepatic ducts
- Abdominal distension (if icterus not apparent):
  - Septic peritonitis: gastrointestinal perforation, penetrating trauma
  - Uroabdomen
  - Hemoabdomen: ruptured mass/viscus, bleeding disorder
  - Abdominal organ dilation/enlargement: gastric dilation/volvulus, mesenteric volvulus, splenic torsion, overeating, hyperadrenocorticism
  - Intraabdominal abscess: severe pancreatitis, hepatic abscess, ruptured prostatic abscess, ruptured pyometra
  - Portal hypertension
  - Congestive heart failure (right-sided)

INITIAL DATABASE

- CBC:
  - Inflammatory leukogram
  - Degenerative left shift with toxic changes:
    - Septic bile peritonitis
- Serum biochemistry profile:
  - Elevated bilirubin concentration (virtually all cases)
  - Elevated liver enzymes concentration (virtually all cases)
  - Hypokalemia
- Survey abdominal radiographs:
  - Increased opacity/loss of detail in anterior abdomen
  - Cholelithiasis (in dogs, 14%-48% are radiopaque)
  - Generalized loss of abdominal detail/fluid:
    - Bile peritonitis

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound examination:
  - Evaluate gallbladder wall thickness and integrity (cholecystitis); contents (choleliths, mucocele), presence of attached omentum, and surrounding fluid, suggesting either bile peritonitis or unrelated (e.g., other differential diagnoses)
- Peritoneal fluid analysis (obtained during abdominal ultrasound examination):
  - Bilirubin concentration: > twice that of serum bilirubin is diagnostic of bile peritonitis
  - Cytologic evaluation and bacterial culture and sensitivity testing (aerobic and anaerobic): septic peritonitis
- Coagulation profile (prothrombin time is first to be abnormal with vitamin K deficiency/malabsorption)

TREATMENT

TREATMENT OVERVIEW

Treatment consists of patient stabilization followed by surgical exploration of the abdomen, with removal of the ruptured gallbladder and treatment of associated bile peritonitis; adjunctive pain control is important.

ACUTE GENERAL TREATMENT

- Rehydration: intravenous administration of balanced electrolyte solution
  - Normalization of serum electrolyte concentrations
- Parenteral antibiotics effective against gram-negative bacteria and anaerobes
  - Empirical therapy:
    - Cefoxitin, 22 mg/kg IV q 2 h peri-operatively, then q 6 h; *or*
    - Metronidazole, 10-15 mg/kg IV q 12 h *with:*
    - Enrofloxacin, 2.5-5 mg/kg IV q 12 h (maximum 5 mg/kg q 24 h in cats)
  - Specific long-term therapy based on culture and sensitivity test results
- Possible administration of fresh frozen plasma: (see p. 1347)
  - Hypoproteinemia
  - Possible coagulopathy
- Vitamin K administration: 2.5 mg/kg SQ q 12 h × 3 days, then weekly
- Exploratory laparotomy once animal is stabilized:
  - Cholecystectomy
  - Ensure patency of biliary system
  - Aerobic and anaerobic microbiologic culture of peritoneal fluid
  - Treatment of bile peritonitis: consider open peritoneal drainage

CHRONIC TREATMENT

Maintenance of bile flow: ursodeoxycholic acid 10-15 mg/kg/day PO—only after biliary obstruction is definitively ruled out/corrected, because stimulates gallbladder contraction

NUTRITION/DIET

Nutritional support via placement of feeding tube if indicated (see pp. 1322 and p. 1267)

POSSIBLE COMPLICATIONS

- Ongoing/recurrent bile leakage
- Failure to resolve septic bile peritonitis:
  - Endotoxemia
  - Sepsis
- Biliary obstruction:
  - Recurrence of cholelithiasis
- Pancreatitis

RECOMMENDED MONITORING

- Clinical and laboratory parameters assessing perfusion, including capillary refill time, pulse rate and quality, blood pressure, urine output, arterial pH, and lactate concentrations
- Respiratory function
- Serum liver enzymes and bilirubin concentrations
- Coagulation profile

PROGNOSIS AND OUTCOME

- Guarded to fair in animals with aseptic bile peritonitis
- Poor to guarded in animals with septic bile peritonitis

PEARLS & CONSIDERATIONS

COMMENTS

In dogs and cats with bile peritonitis:

- Peripheral white blood cell count is significantly lower in survivors (mean = 20,608/µL) compared with nonsurvivors (mean = 35,715/µL).
- The immature neutrophil count is significantly lower in survivors (mean = 686/µL) than in nonsurvivors (mean = 4852/µL).

Gallbladder Mucocele

BASIC INFORMATION

DEFINITION

An abnormal accumulation of bile-laden mucus within the gallbladder (GB) lumen; the mucosa of the GB wall is characterized histologically by glandular hyperplasia. Once a rare condition, GB mucocele has recently been reported as the most common cause of canine extrahepatic biliary obstruction (EHBO).

SYNONYMS

Kiwi GB, cystic mucinous hyperplasia of the GB

EPIDEMIOLOGY

SPECIES, AGE, SEX: Older small or medium-size dogs usually affected, with no sex predilection reported. GB mucocele formation in humans is the result of cystic duct obstruction and not cystic mucinous hyperplasia.

GENETICS & BREED PREDISPOSITION: Cocker spaniels and Shetland sheepdogs are predisposed. In recent reports, miniature schnauzers are overrepresented.

ASSOCIATED CONDITIONS & DISORDERS: A weak association exists between hyperadrenocorticism and GB mucocele.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- GB mucocele can be an incidental finding or it can be responsible for the presenting complaint (approximately 75% of patients diagnosed with GB mucocele show overt signs of illness).
- Inflammation and necrosis of the GB wall can lead to rupture and peritonitis (focal or diffuse).

HISTORY, CHIEF COMPLIANT: Vomiting, inappetence, and lethargy are the most common presenting complaints. Other complaints include weight loss, diarrhea, ptyalism, and polyuria/polydipsia.

PHYSICAL EXAM FINDINGS: Abdominal pain, ascites, tachypnea, tachycardia, fever, hepatomegaly, and icterus

ETIOLOGY AND PATHOPHYSIOLOGY

- Abnormal accumulation of intraluminal mucus and inspissated bile
- Potential mechanisms for mucocele formation include progressive biliary sludging and alterations in water absorption across the GB mucosa.
- Histologic evidence of GB wall inflammation is not present in the majority of cases.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

GB mucocele diagnosis requires abdominal ultrasound. The stellate intraluminal pattern and non–gravity-dependent GB contents are considered pathognomonic. Less organized mucoceles can be more challenging to confirm.

DIFFERENTIAL DIAGNOSIS

- Cholecystitis (acute, chronic or necrotizing)
- Cholelithiasis
- Biliary sludge

INITIAL DATABASE

- CBC: most common abnormalities reported are leukocytosis characterized by a mature neutrophilia and monocytosis. In dogs, leukocytosis is significantly higher (21,200 cells/µL) with GB rupture than when the GB is intact (12,500 cells/µL).
- Serum biochemistry profile: common abnormalities include elevated serum alanine transaminase (ALT), alkaline phosphatase (ALP), aspartate transaminase (AST), and gammaglutamyl transpeptidase (GGT) activities. Increasing serum GGT activity may be associated with increased risk for mortality. Total bilirubin concentration is elevated in 63%-77% of cases. Hypercholesterolemia, hyperglobulinemia, and hypoalbuminemia are less common findings.
- Urinalysis: generally unremarkable; bilirubinuria may be noted.
- Abdominal radiography: generally unremarkable. In cases with GB rupture, decreased serosal detail may be noted if ascites is present.
- Abdominal ultrasonography: characteristic stellate/striated intraluminal GB contents. Increased GB volume/subjective distension can be noted. Other potential findings include common bile duct (BD) distension and ascites. The pancreas should be evaluated for ultrasonographic evidence of pancreatitis.

TREATMENT

TREATMENT OVERVIEW

Surgical intervention is indicated, with cholecystectomy generally considered the treatment of choice.

ACUTE GENERAL TREATMENT

- Emergency surgery is indicated for cases of suspected GB rupture. If present, ascitic fluid should be evaluated to determine whether the effusion is septic.
- GB rupture is suspected if (1) GB wall continuity can not be confirmed, (2) hyperechoic cranial abdominal fat is noted, (3) free abdominal fluid is present, and/or (4) stellate echogenic material is present within the peritoneal cavity.
- Patients with GB rupture are often hemodynamically unstable and require aggressive perioperative supportive care.
- Initial presurgical therapy generally includes fluid therapy, intravenous antibiotics (gram-negative anaerobes are the most common isolate), antiemetics, and analgesics.
- Cholecystectomy, cholecystoenterostomy, and cholecystotomy have been described for the treatment of GB mucoceles. Given that GB wall dysfunction appears to be associated with the etiopathogenesis of mucocele formation, the author believes that cholecystectomy is the treatment of choice.
- During surgery, confirmation of patency of the common BD is imperative. Gastrointestinal and hepatic biopsies should be considered.
- Samples of the GB wall and/or intraluminal contents should be collected for aerobic and anaerobic culture.
- Laparoscopic cholecystectomy has been reported for the treatment of uncomplicated cases of GB mucocele.

CHRONIC TREATMENT

- The nonsurgical resolution of GB mucocele has been reported in two dogs; however, the current literature is lacking adequate numbers to validate medical treatment.
- Patients with biliary sludge without mucocele formation generally do not require therapy unless clinical findings suggest GB disease. In these rare cases, medical management with antibiotic therapy, choleretics, and hepatoprotectants may prove helpful.

NUTRITION/DIET

- Esophagostomy, gastrostomy, or nasogastric tube placement should be encouraged, as postoperative inappetence is common in the author's experience (see pp. 1267, p. 1269, p. 1270).

POSSIBLE COMPLICATIONS

- The most commonly reported postoperative complications include pancreatitis and bile peritonitis. Aspiration pneumonia has also been reported.
- Postoperative common BD obstruction has been reported, emphasizing the need to confirm patency of the common BD at the time of cholecystectomy.

PROGNOSIS AND OUTCOME

- Perioperative mortality ranges from 21.7%-32%.
- The long-term prognosis for patients surviving to release from hospital is excellent.

- Mortality rates do not differ significantly between ruptured or intact mucoceles.
- If GB rupture results in diffuse bile peritonitis, mortality rates are as high as 68%-100%.

PEARLS & CONSIDERATIONS

COMMENTS

- Mucocele rupture does not preclude a successful outcome.
- Diffuse bile peritonitis with mucocele rupture is unlikely, owing to containment of bile salts within a solid mucinous matrix that limits exposure of bile salts to the peritoneal surface.
- To prevent reobstruction with mucocele material within the common BD and hepatic ducts, confirmation of patency of the common BD is imperative following cholecystectomy.
- Intestinal biopsies should be considered in patients with a history of chronic gastrointestinal disease.

AUTHOR: FRED S. PIKE

EDITOR: KEITH RICHTER

Hypothyroidism

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

The clinical syndrome that occurs as a result of decreased circulating levels of serum thyroid hormones (thyroxine [T4] and triiodothyronine [T3])

SYNONYM

Congenital hypothyroidism: cretinism

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs:

- Middle-aged at onset (2-9 years of age)
- No sex predilection

Cats

- Spontaneous hypothyroidism is very rare.
- Iatrogenic disease: middle-aged or older

GENETICS & BREED PREDISPOSITION

Dogs:

- Can occur in any breed, including mixed breeds
- Reported to be more prevalent in boxers, dachshunds, Doberman pinschers, golden retrievers, Great Danes, Irish setters, miniature schnauzers, poodles, and a number of other breeds

ASSOCIATED CONDITIONS & DISORDERS

Can occur as part of an autoimmune polyglandular syndrome (rare) along with hypoadrenocorticism or diabetes mellitus

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Congenital hypothyroidism (cretinism); rare
- Primary hypothyroidism (most common): disruption or atrophy of the thyroid glands
- Secondary hypothyroidism (rare): inadequate pituitary secretion of thyroid-stimulating hormone (TSH)

HISTORY, CHIEF COMPLAINT

- Acquired disease:
  - Signs are often nonspecific and gradual in onset.
  - Metabolic: weight gain, lethargy, mental dullness, exercise intolerance/inactivity, and cold intolerance are common.
  - Dermatologic: alopecia (bilaterally symmetric truncal) or thin hair, hyperkeratosis, seborrhea, hyper-pigmentation, otitis, “rat tail,” and pyoderma are often present, with alopecia or thin hair most common.
  - Reproductive (uncommon): persistent anestrus, infertility, and decreased libido
  - Neuromuscular: weakness/exercise intolerance are sometimes seen; other signs (ataxia, seizures, facial drooping/paralysis, head tilt/circling [vestibular signs], and stridor/change in bark [laryngeal paralysis]) are uncommon.
- Cretinism: disproportionate dwarfism, short limbs, persistent “puppy coat” or alopecia/thin dull hair, broad head, thick protruding tongue, mental dullness/retardation, delayed dental eruption, constipation

PHYSICAL EXAM FINDINGS

- Exam findings are similar to signs described by the owners.
- Additional findings (uncommon) may include ocular changes (corneal lipid deposits most common), bradycardia or other arrhythmias, constipation, decreased spinal reflexes, and decreased conscious proprioception.

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary hypothyroidism is the most common form and is usually due to lymphocytic thyroiditis or idiopathic thyroid gland atrophy. Less common causes include follicular cell hyperplasia and infiltrative neoplasia.
- Secondary hypothyroidism is rare. Decreased TSH secretion leads to atrophy of the follicular cells of the thyroid gland. Loss of normal TSH secretion can occur as a result of a congenital pituitary malformation, pituitary neoplasia, or suppression of pituitary thyrotropic cells (most commonly from excess glucocorticoids [exogenous or endogenous hyperadrenocorticism]). Reversibility is possible if glucocorticoid concentrations are returned to normal.
- Tertiary hypothyroidism (decreased secretion of thyrotropin-releasing hormone [TRH]) has not been reported in the dog.
- Iatrogenic hypothyroidism can occur as a result of antithyroid medications (e.g., methimazole), bilateral thyroidectomy, or 131 radioiodine therapy (see p. 562).
- Clinical signs reflect the widespread metabolic effects of thyroid hormones.
- Surgery or anesthesia, a wide range of concurrent illnesses, and various nonthyroidal medications (e.g., glucocorticoids, phenobarbital, sulfonamides, carprofen, clomipramine) also affect circulating thyroid hormone concentrations, but not to the extent of producing clinical hypothyroidism.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in a middle-aged dog presenting one or more of the common clinical signs. Confirmation is not always straightforward, but the presence of typical clinical signs in conjunction with a decreased serum FT4 ED value and an increased serum TSH value can be considered diagnostic.

DIFFERENTIAL DIAGNOSIS

- Alopecia (see p. 58)
- Seborrhea (see p. 255)
- Obesity/weight gain (see p. 773)

INITIAL DATABASE

- CBC, serum biochemical profile, urinalysis: hypercholesterolemia is most common and must be differentiated from normal postprandial hypercholesterolemia. A mild normocytic, normochromic, nonregenerative anemia; fasting hyperlipidemia/hypertriglyceridemia; mild increases in liver enzymes; and a mild increase in creatine kinase may also be seen.
- Basal serum total thyroxine concentration (T4):
  - Includes both free (<1%) and protein-bound (>99%) T4
  - Low levels in hypothyroid dogs: sensitivity: 89%-100%; specificity: 75%-82%; accuracy: 85%
  - If T4 is in the middle or upper end of the reference range, hypothyroidism is generally ruled out.
    - An exception is the presence of antithyroid antibodies that interfere with the assay.
    - If clinical signs strongly suggest hypothyroidism and T4 is normal, free thyroxine concentration by equilibrium dialysis (FT4ED), anti-T4 antibody, and thyroglobulin autoantibody concentrations should be measured.
  - If T4 is low or is at the low end of the reference range, it may be due to hypothyroidism, concurrent illness, medications, or may be normal (euthyroid).
- Basal serum free thyroxine concentration by equilibrium dialysis (FT4ED):
  - Measures just the free (i.e., metabolically available) T4
  - An assay based on equilibrium dialysis should be used; it is more time intensive and expensive than radio-immunoassay but much more accurate.
  - Low levels in hypothyroid dogs: sensitivity: 80%-98%; specificity 93%-94%; accuracy: 95%
  - Most accurate single hormone test for the diagnosis of hypothyroidism
- Basal serum TSH concentration:
  - A validated canine TSH assay should be used.
  - The test should not be evaluated alone but is best used in conjunction with T4 and/or FT4ED results.
    - High TSH with low T4: sensitivity: 63%-67%; specificity: 98%-100%; accuracy: 82%-88%
    - High TSH with low FT4ED: sensitivity: 74%; specificity: 98%; accuracy: 86%
    - Increased TSH with decreased T4 or FT4ED is strongly supportive of hypothyroidism.

        - A normal TSH in conjunction with decreased T4 or FT4ED does not rule out hypothyroidism.
- Also see the Hypothyroidism algorithm, .

ADVANCED OR CONFIRMATORY TESTING

If basal thyroid hormone concentrations do not rule in/out hypothyroidism, a few options exist:

- TSH stimulation test.
    - Protocol:
        - Many protocols reported; consult the laboratory performing the thyroid assays for the desired protocol and reference ranges for resting and poststimulation T4 concentrations.
        - 0.1 units/kg (maximum 5 units) medical-grade bovine TSH IV; evaluate serum T4 concentrations in preadministration and 6-hour postadministration samples.
        - Dogs <20 kg: 50 mcg recombinant human TSH IV; dogs >20 kg: 50 or 100 mcg recombinant human TSH IV; evaluate serum T4 concentrations in preadministration and 6-hour postadministration samples.
    - Interpretation:
        - If both results are below the reference range, hypothyroidism is present.
        - If post-TSH T4 concentration is >3 mcg/dL, the dog is not hypothyroid.
        - Results in between these parameters are equivocal; consider retesting 1-2 months later.
        - Medical-grade, bovine TSH is no longer available in most places.
- TRH stimulation test
    - Originally designed to identify secondary hypothyroidism. When the availability of bovine TSH became very limited, this test was used as a replacement. However, it is less reliable and so is uncommonly used.
- Response to therapy
- Serum thyroglobulin antibodies: increased levels suggest lymphocytic thyroiditis. However, lymphocytic thyroiditis does not always lead to or correlate with the presence of hypothyroidism.
- Serum thyroid hormone antibodies: if present, can interfere with testing and lead to spuriously high or low T4 results, depending on the T4 assay used.
- Thyroid scintigraphy may be useful for differentiation between hypothyroidism and nonthyroidal illness but is limited by cost and availability.
- Histopathologic evaluation of skin biopsies: vacuolated or hypertrophied erector pili muscles, increased dermal mucin, and a thickened dermis are consistent with hypothyroidism. A variety of other nonspecific changes supportive of an endocrinopathy may also be present.

TREATMENT

TREATMENT OVERVIEW

The mainstay of treatment is oral thyroid hormone replacement. Therapy should be designed to raise serum TT4 values to the normal range and eliminate clinical signs. Therapy is lifelong.

ACUTE GENERAL TREATMENT

- Hypothyroidism is generally a chronic condition that does not require acute therapy.
- Myxedema coma (rare): levothyroxine for injection 5 mcg/kg IV q 12 h until oral administration possible.

CHRONIC TREATMENT

Oral thyroid supplementation:

- Levothyroxine sodium (synthetic T4):
    - Initial dose (tablets): 0.02 mg/kg PO q 12 h. Maximum dose: 0.8 mg/dog q 12 h.
    - A novel liquid formulation of L-thyroxine available in Europe is often effective with once-daily dosing (0.02 mg/kg PO q 24 h).
    - If concurrent heart failure, renal failure, liver disease, hypoadrenocorticism, or diabetes is present, the initial dose should be decreased by 25%-50%, then slowly increased over the following 2-4 months. Also, hypothyroidism is rarely life threatening, so the concurrent disease should be controlled first before treatment of the hypothyroidism is pursued.
    - A brand-name preparation for animal use should be used, as bioavailability of generic forms can vary.
    - Adjust dose based on clinical response and serum T4 concentrations (see Recommended Monitoring below).
    - Absorption kinetics vary between brands, so serum concentrations should be reassessed if the levothyroxine brand is changed.

- Liothyronine sodium (synthetic T3):
  - Very rarely indicated
  - Consider only if a dog with confirmed hypothyroidism has failed to respond clinically, has normalized serum T4 concentrations, and at least two brands of levothyroxine have been tried.
  - Initial dosage is 4-6 mcg/kg PO q 8 h.
- Combination products (levothyroxine and liothyronine) are not recommended.

POSSIBLE COMPLICATIONS

Iatrogenic hyperthyroidism

RECOMMENDED MONITORING

- A physical examination and serum thyroxine concentration (4-6 hours post-pill) should be evaluated at 4 weeks, then q 6-8 weeks for 6-8 months, then q 6-12 months.
  - Serum T4 concentrations (4-6 hours post-pill) should be in the upper half of the normal range.
- Monitoring clinical signs: expected evolution of response.
  - An increase in alertness and activity commonly is seen within 1-2 weeks.
  - Neurologic improvement may begin within the first month, but several months may be needed for full resolution.
  - Dermatologic improvement often takes 1-4 months
  - Resolution of reproductive manifestations may take several months.
- If major clinical improvement is not seen in 3 months despite normal serum T4 concentrations, a concurrent as yet unidentified disease should be considered.

PROGNOSIS AND OUTCOME

- Primary hypothyroidism: long-term prognosis is good to excellent for return to function.
- Secondary hypothyroidism: long-term prognosis is usually guarded, since pituitary neoplasia is the most common underlying cause.

PEARLS & CONSIDERATIONS

COMMENTS

- The presence of nonthyroidal illness can make it difficult to obtain a definitive diagnosis of hypothyroidism. “Sick euthyroid syndrome” describes the condition that occurs when nonthyroidal illness results in a decrease in the basal T4 (and less commonly, FT4ED) concentrations.
- Subnormal T4 concentrations are not an immediate indication for supplementation with levothyroxine, which may at times be deleterious. The history and physical exam must be critically evaluated both for features supportive of hypothyroidism and for signs of other illness that could be causing the sick euthyroid syndrome. In the latter case, resolution/treatment of nonthyroidal illness returns T4 concentrations to normal.
- Obesity is much more prevalent (21%-40% of the North American pet dog population is or may become obese) than hypothyroidism (0.2% of dog population, possibly higher). Therefore, obese body condition can only be attributed to hypothyroidism in a small fraction of cases.

TECHNICIAN TIP

- Avoid lipemia and hemolysis when obtaining samples for diagnosis and therapeutic monitoring; fasted sample recommended.
- An artifactual increase in T4 and FT4ED occurs if the blood or serum sample is not kept cold.

Hypothermia

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Body temperature below 99.5°F (37.5°C) in the dog and 100°F (37.8°C) in the cat

EPIDEMIOLOGY

SPECIES, AGE, SEX

Any species, any age, and either sex can be affected.

RISK FACTORS

- Very old, very young animals
- Short-haired animals
- General anesthesia
- Cold environment
- Cardiac disease

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Mild hypothermia: 90°F-99.5°F (32.2°C-37.5°C)
- Moderate hypothermia: 82°F-90°F (27.8°C-32.2°C)
- Severe hypothermia: <82°F (27.8°C)

HISTORY, CHIEF COMPLAINT

- Weak or collapsed patient
- Exposure to cold environmental temperatures or general anesthesia

PHYSICAL EXAM FINDINGS

- Shivering
- Weakness
- Ataxia
- Cardiac arrhythmia
- Coma

ETIOLOGY AND PATHOPHYSIOLOGY

- Initial compensation for hypothermia: peripheral vasoconstriction, shivering, piloerection
- Respiratory rate and effort:
  - Increased with mild hypothermia
  - Decreased with moderate to severe hypothermia (central and reflex-mediated respiratory depression)
- Cardiovascular effects:
  - Mild hypothermia initially increases heart rate and cardiac output.
  - Moderate hypothermia may produce bradycardia and (rarely) Osborn waves (positive electrocardiographic [ECG] deflection after S wave).
  - Severe hypothermia can cause cardiac arrest from ventricular fibrillation.
- Central nervous system:
  - Muscle shivering, stupor, unconsciousness, and coma
- Gastrointestinal effects:
  - Ulceration
  - Mild to severe pancreatitis

- Renal effects:
  - Cold-induced diuresis can result in severe hypovolemia.
  - Severely decreased renal perfusion can lead to ischemic tubular necrosis.
- Clinicopathologic changes:
  - Lactic acidosis due to tissue ischemia
  - Leukopenia and thrombocytopenia (splenic sequestration)
  - Hyperglycemia
  - Glucosuria
  - Hyperkalemia
  - Disseminated intravascular coagulopathy

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is concluded by measuring body temperature. Historical features (e.g., exposure to cold weather, general anesthesia) can increase the index of suspicion and are important for early recognition and treatment.

DIFFERENTIAL DIAGNOSIS

- Exposure to cold environment
- Pathologic hypothermia:
  - Hypoglycemia (puppies and kittens, endocrine diseases)
  - Hypothyroidism
  - Anesthesia
  - Severe, advanced cardiac disease (malperfusion)
  - Head trauma, brain disease

INITIAL DATABASE

- Documentation of rectal temperature <99.5°F (37.5°C)
- Packed cell volume, total solids, serum electrolytes

ADVANCED OR CONFIRMATORY TESTING

ECG:

- Sinus bradycardia: common, usually not treated beyond rewarming
- Ventricular arrhythmias are common (see p. 1165).
- Mild changes (PR, QT, QRS prolongation). Osborn waves possible but less commonly observed.

TREATMENT

TREATMENT OVERVIEW

- Restoring of core body temperature to normal range
- Treatment of hypothermia varies with:
  - Degree of hypothermia
  - Underlying systemic diseases (cardiovascular, neurologic)

ACUTE GENERAL TREATMENT

- Place intravenous catheter.
- In the unconscious patient, endotracheal intubation and oxygen supplementation (reduce risk of aspiration pneumonia and arrhythmias)
- Monitor urine output.
- Continuous ECG: to monitor for ventricular arrhythmias
  - If unconscious patient and ventricular arrhythmias, prepare for ventricular fibrillation (requires defibrillation). The cold heart is relatively resistant to defibrillation. Rewarm patient and retry defibrillation.
  - The hypothermic heart does not respond well to antiarrhythmic drugs until a temperature of >86°F (30°C) is reached.

Lidocaine is generally ineffective, and procainamide is associated with increased ventricular fibrillation in humans.
    - Bradyarrhythmia does not respond reliably to atropine but resolves with rewarming.
- After addressing acute life-threatening problems, the patient needs to be assessed for the predisposing cause of hypothermia.
- Many hypothermic patients are dehydrated. Administer warm (body temperature) intravenous fluids. Fluid rate needs to be monitored closely owing to decreased heart function and severe peripheral vasoconstriction. Start as a bolus of 5-11 mL/kg and titrate up as needed. DO NOT administer fluids to cats with hypothermia due to severe heart failure.
- Rewarming:
    - Depending on severity of hypothermia, three methods are useful:
        - Passive external rewarming. Use in mild to moderate hypothermia. Animal is wrapped in blankets to prevent further loss of heat.
        - Active external rewarming. Use for moderate to severe hypothermia. Apply heat (warm water bags, heating pads, warm incubator, bair hugger) to patient's torso.
        - Active internal rewarming. Generally used in severe hypothermia with temperature <86°F (30°C) or for animals that did not respond to other treatments.
            - Gastric, colon, and urinary bladder lavage with 109°F (42.8°C) warm 0.9% NaCl
            - Peritoneal dialysis with warm 0.9% NaCl at a rate of 10-20 mL/ kg and an exchange rate of every 30 minutes
            - Increase inspired air temperature for animals on a ventilator.

POSSIBLE COMPLICATIONS

During the rewarming process, the extremities reduce vasoconstriction, and sequestered cold blood mixes with the central circulation. Relatively warm core blood now perfuses the cold peripheral tissues. These two mechanisms cause “afterdrop,” a decrease in body temperature during the rewarming process.

RECOMMENDED MONITORING

- ECG for ventricular arrhythmias during rewarming
- Serum potassium levels during rewarming
- Neurologic status during rewarming. Increased intracranial pressure may develop secondary to ischemic injury, cold-induced edema, or from osmotic gradients.
- Monitor fluid administration with urine output, blood pressure, central venous pressure, and respiratory effort.
- Monitor serum creatinine and blood urea nitrogen to ensure normal kidney function.

PROGNOSIS AND OUTCOME

Depending on severity of hypothermia, good to guarded prognosis

PEARLS & CONSIDERATIONS

COMMENTS

- Rewarming procedures should be tapered when the body temperature is still slightly below normal, to avoid overshooting (causing hyperthermia).
- Unconscious or debilitated patients are unable to move away from a heat source, so meticulous monitoring (e.g., body temperature q 15-60 min) is essential during initial rewarming of these individuals. Burns and hyperthermic deaths have been recorded as a result of inadequate monitoring.

PREVENTION

- Avoid exposure to low environmental temperature.
- Avoid prolonged general anesthesia.

TECHNICIAN TIPS

- Avoid prolonged anesthesia.
- Monitor rectal temperature closely in pets at risk.

CLIENT EDUCATION

Keep pets indoors or in a protected environment during cold weather.

AUTHOR: CARSTEN BANDT

EDITOR: ELIZABETH ROZANSKI

Hypotension, Systemic

BASIC INFORMATION

DEFINITION

A mean systemic arterial pressure <60 mm Hg and a systolic pressure <80-90 mm Hg

EPIDEMIOLOGY

SPECIES, AGE, SEX

Affects all species, ages, and sexes. The underlying disease may have a breed, sex, or age predilection.

RISK FACTORS

Hypotension is a clinical manifestation associated with numerous underlying disease processes (see Etiology and Pathophysiology below).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Signs of hypotension are typically vague and may include lethargy, depressed mentation, collapse, weakness, vomiting, and/or inappetence. Specific clinical signs related to the causative disorder may be present, such as cough and respiratory distress in a dog with hypotension due to primary cardiogenic causes, and overlap often occurs between signs of hypotension and signs due to its underlying cause.

PHYSICAL EXAM FINDINGS

- General: as above
- Circulatory: weak or thready pulses, pale mucous membranes, delayed capillary refill time
- Dogs will likely be tachycardic, whereas cats may display tachycardia or bradycardia.
- Findings related to an underlying disease, such as heart murmur, external/internal hemorrhage, or evidence of infection (fever or injected mucous membranes)

ETIOLOGY AND PATHOPHYSIOLOGY

There are numerous primary diseases that cause secondary hypotension:

- Cardiogenic:
  - Cardiomyopathies (dilated, hypertrophic, unclassified)
  - Pericardial effusion
  - Arrhythmias
  - Drug suppression of cardiac contractility (e.g., anesthetics, P-blockers)
- Hypovolemia:
  - Hemorrhage
  - Gastrointestinal fluid losses
  - Burns
  - Urinary loss
  - Hypoadrenocorticism
- Decreased vascular tone:
  - Sepsis
  - Anaphylaxis
  - Drugs (e.g., phenothiazines, angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers, nitroprusside)
- The body responds to a decrease in blood pressure in much the same way irrespective of cause.
- Decreased blood pressure causes the carotid sinus and aortic body receptors to respond, resulting in stimulation of the sympathetic nervous system, release of antidiuretic hormone (vasopressin) and adrenocorticotropic hormone from the pituitary, and release of catecholamines from the adrenal medulla.

- The renin-angiotensin-aldosterone system is stimulated: decreased arterial blood pressure elicits renin release from the juxtaglomerular cells of the kidney. In turn, renin transforms circulating angiotensinogen (α-2 macroglobulin from liver) to angiotensin I, which is activated to the powerful vasoconstrictor angiotensin II by the ACE in multiple tissues including the lung.
- These mechanisms lead to retention of sodium and water, vasoconstriction, and increased cardiac output, which all help to maintain blood pressure.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of systemic hypotension involves recognition of the clinical signs and physical exam findings consistent with hypotension and subsequent measurement of arterial blood pressure. Many clinicians have argued to make blood pressure measurement part of routine physical exams, which could be appropriate in severely ill patients but is not currently justified for outpatient or routine visits. A repeatable finding of systemic hypotension in a patient showing overt signs of illness justifies a full diagnostic workup to identify an underlying cause and initiate treatment to correct both the hypotension and the underlying disease.

DIFFERENTIAL DIAGNOSIS

See Etiology and Pathophysiology above. Also, need to rule out inaccurate measurement (recommend recheck measurement if reading does not fit the clinical picture).

INITIAL DATABASE

Indirect or direct arterial blood pressure: diagnostic test of choice for confirming and monitoring hypotension (see p. 1209). As part of evaluating patient for underlying disorders:

- CBC (e.g., high or low white cell count if patient has underlying sepsis)
- Serum biochemistry profile: azotemia is common and may be renal or prerenal. Other abnormalities (e.g., liver enzyme elevations) may similarly be related to the causes or may be the effects of hypotension.
- Urinalysis: evidence of primary renal disease (low specific gravity with azotemia or dehydration) or infection
- Thoracic and abdominal radiographs (evidence of pulmonary infiltrates [edema, hemorrhage, metastases], pneumonia, trauma, or effusions)
- Ultrasonography: to assess for effusions, cardiac function and chamber size, and assist in diagnostic paracentesis if indicated
- Paracentesis (abdominal, pleural, pericardial): to assess the nature of a patient's effusion (e.g., hemorrhage) if indicated

ADVANCED OR CONFIRMATORY TESTING

- Cytologic and microbiologic testing of effusions as needed
- Additional tests as mandated by results to date

TREATMENT

TREATMENT OVERVIEW

The primary goal is to treat the underlying disease. If this goal cannot be achieved promptly or if results of treatment may not be immediate, restoration of blood pressure using other intravenous fluids or vasoactive medications may be necessary. Prior to initiating these treatments, cardiogenic causes of hypotension must be ruled out, as the goal with cardiogenic shock may involve opposite targets relative to intravascular volume (e.g., diuretic and possibly positive inotrope administration if congestive heart failure is present). Treatment of hypotension is not justified when it is found incidentally in an otherwise well patient (rule out artifact or occult disorder needing to be identified first).

ACUTE GENERAL TREATMENT

Volume replacement selected according to type of fluid lost:

- Crystalloids (lactated Ringer's solution, 0.9% NaCl): 40-90 mL/kg IV to effect
- Synthetic colloids: 5-20 mL/kg IV to effect
- Hypertonic saline: 4-6 mL/kg IV to effect (avoid if patient is dehydrated or hypernatremic)
- Blood, plasma transfusions (see p. 1347)
- Positive inotropic support (only after adequate volume resuscitation, if low cardiac contractility is documented or highly

suspected, and typically for short-term use only while underlying disease is addressed):
    - Dobutamine IV:
        - Dogs: 5-20 mcg/kg/min
        - Cats: 2.5-15 mcg/kg/min
- Vasopressors IV (only after adequate volume resuscitation and if hypotension is suspected to be due to systemic vasodilation; see):
    - Dopamine: 7-20 mcg/kg/min; *or*
    - Norepinephrine: 0.05-1 mcg/kg/min; *or*
    - Epinephrine: 0.1-1 mcg/kg/min; *or*
    - Vasopressin: 0.1-1 mU/kg/min
- Pericardiocentesis if pericardial effusion with tamponade is present.

CHRONIC TREATMENT

Treatment of the underlying cause (e.g., locate and stop source of hemorrhage, IV antibiotics for sepsis).

DRUG INTERACTIONS

- Use of high-dose or multiple vasopressors may lead to intense vasoconstriction that could result in organ ischemia.
- Catecholamines may precipitate cardiac arrhythmias.
- Cardiogenic causes of hypotension must be ruled out prior to IV fluid or vasopressor therapy, as these treatments may further decrease oxygen delivery and dramatically worsen patient condition.

POSSIBLE COMPLICATIONS

Complications related to severe or protracted hypotension include renal failure, loss of gastrointestinal integrity with absorption of bacteria and bacterial toxins, myocardial dysfunction, brain ischemia, and loss of vascular tone.

RECOMMENDED MONITORING

- Monitor blood pressure either indirectly (cuff) or directly (arterial line) until blood pressure has normalized. Direct monitoring is technically challenging and has possible minor complications, but it has the benefit of more accurate, continuous measurements and arterial blood sampling for acid-base and ventilation/perfusion analysis.
- Central venous pressure (CVP) can be utilized as an indicator of volume status (see p. 1227). If the CVP is low (<5 cm H2O), more fluids should be given. Adequate fluid resuscitation is present if the CVP is between 5 and 10 cm H2O. However, if left-sided heart disease is present, volume-overload pulmonary edema can occur despite normal CVP.
- Monitor for signs of end-organ damage (e.g., urine output, mentation).
- If hemorrhage is suspected, monitor hematocrit and total solids.
- Monitor ECG if arrhythmias are present.

PROGNOSIS AND OUTCOME

- Prognosis depends largely on the underlying cause, as well as initial response to supportive treatment.
- In most patients, hypotension will respond to intravenous fluid therapy.
- The need for high-dose or multiple vasoactive or inotropic medications may imply a worse overall prognosis.
- Nonresponsive hypotension implies a poor prognosis, with multiple organ dysfunction a likely outcome.

PEARLS & CONSIDERATIONS

COMMENTS

- Hypotension is a serious consequence of numerous disease processes.
- Prompt identification and treatment of the underlying cause is essential to a successful outcome.
- Persistent hypotension implies ongoing hemorrhage, systemic vasodilation, decreased cardiac function, or capillary leakage.

TECHNICIAN TIPS

- When any of the above historical or physical findings are present, obtaining a blood pressure measurement can identify systemic hypotension and greatly assist in determining the primary underlying cause.
- When using an indirect, cuffed technique, the width of the cuff should be approximately 40% of the circumference of the area

of the limb the cuff will be applied (see p. 1209).
- The Doppler technique only reliably measures the systolic arterial pressure.
- Most oscillometric machines measure systolic, mean, and diastolic pressures but are inaccurate on small patients or with significant vasoconstriction or arrhythmia.

1ST EDITION AUTHOR: BENJAMIN DAVIDSON

Hypospadias

BASIC INFORMATION

DEFINITION

A rare condition in which the penile urethra terminates proximal to the tip of the penis

SYNONYM

Pseudohermaphrodite

EPIDEMIOLOGY

SPECIES, AGE, SEX

Hypospadias has been reported in both dogs and cats. Affected animals can be genetically male (XY), female (XX), or some form of intersex (XX, XY, XX sry positive).

GENETICS & BREED PREDISPOSITION

Most commonly reported in Boston terriers; the genetic basis of the condition is unknown.

RISK FACTORS

Administration of progestins or androgens to pregnant dams prior to sexual differentiation of the external genitalia will result in partial masculinization (increased anogenital distance, elongation of the vulva, and clitoral hypertrophy).

ASSOCIATED CONDITIONS & DISORDERS

Urine dribbling and scalding, ascending urinary tract infection (cystitis)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Subtypes are based upon location of urethral opening: penile, scrotal, and perineal.

HISTORY, CHIEF COMPLAINT

Affected animals may show no clinical signs if the urethral orifice is located in the distal penis. Animals with the urethral orifice terminating at the scrotum or perineum may have urinary incontinence and inguinal dermatitis due to urine dribbling and scalding.

PHYSICAL EXAM FINDINGS

The severity of the lesion varies from a slight deviation of the urethral orifice in the distal glans penis to a ventral cleft along the entire length of the penis, prepuce, and scrotum, with the urethral orifice located in the perineum.

ETIOLOGY AND PATHOPHYSIOLOGY

Most likely due to a defect in masculinization and incomplete fusion of the ventral raphe of the penis. May be due to a defect in androgen receptors with the urogenital tubercle.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is made by physical examination.

DIFFERENTIAL DIAGNOSIS

This is a unique disorder.

INITIAL DATABASE

Physical examination

ADVANCED OR CONFIRMATORY TESTING

Urinalysis to identify cystitis if present (ascending infection)

TREATMENT

TREATMENT OVERVIEW

Treatment is necessary in severe cases to prevent urine dribbling due to proximal termination of the penile urethra.

ACUTE GENERAL TREATMENT

Depends on the location of the urethral termination. Surgical apposition of the ventral penile urethral mucosa and tunica around a urethral catheter may be sufficient in some cases. For those cases in which the urethra terminates at the scrotum or the perineum, a scrotal or perineal urethrostomy may be possible, with amputation of the distal penis.

HYPOSPADIAS Inguinal region of a male dog, cranial is to the left. A severe hypospadias lesion is seen with the urethral orifice opening as a ventral cleft along the entire length of the penis, prepuce, and scrotum.

PROGNOSIS AND OUTCOME

Good if a mild abnormality, fair for surgical repair

PEARLS & CONSIDERATIONS

COMMENTS

Examination of the penis (exteriorized from the prepuce) to identify defects such as hypospadias is essential in any case of urinary incontinence in puppies.

PREVENTION

Hypospadias is considered to be a form of male pseudohermaphroditism and may be heritable. However, hypospadias can be caused by administration of progestins or androgens and certain teratogens during pregnancy (resulting in female pseudohermaphroditism) as well as by feeding the dam a diet low in vitamin A. Castration is recommended unless known steroid administration to the dam during pregnancy can be confirmed.

AUTHOR: JAMES FLANDERS

EDITOR: MICHELLE A. KUTZLER

Hypopyon

BASIC INFORMATION

DEFINITION

The gross accumulation of leukocytes in the anterior chamber

SYNONYM

Pus in the anterior chamber

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats, either sex, all ages

RISK FACTORS

Anterior uveitis, endophthalmitis, panophthalmitis, and corneal ulceration

CONTAGION & ZOONOSIS

Some forms of uveitis may be due to infectious agents and also zoonotic (see p. 1151)

GEOGRAPHY AND SEASONALITY

In general none, although some forms of infectious uveitis may have geographic predispositions

ASSOCIATED CONDITIONS & DISORDERS

Anterior uveitis is usually present and may produce systemic signs. Ocular lymphoma, infected corneal ulcers, and post-surgical invasion of the anterior chamber may result in hypopyon.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Early forms of incipient hypopyon may be recognized by cells floating in the anterior chamber. Keratic precipitates are forms of leukocyte aggregation on the posterior cornea.

HISTORY, CHIEF COMPLAINT

White to yellow opacity noted in the ventral anterior chamber, conjunctival hyperemia and uveitis signs

PHYSICAL EXAM FINDINGS

- Varying degrees of a creamy white “keel boat” opacity in the anterior chamber. Most hypopyons do not occupy more than the ventral 20% of the anterior chamber. Easily overlooked when mild, as the third eyelid may hinder visualization.
- The eye usually has other signs of anterior uveitis such as conjunctival/episcleral vascular injection, aqueous flare (visible turbidity instead of transparency; suggests increased protein, cellularity, or both) in the anterior chamber, and a tonic (relatively or absolutely immobile) pupil that does not dilate readily.
- Corneal ulceration may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Hypopyon is produced by a strong leukotactic stimulus such as bacterial or fungal infection, but cultures from the anterior chamber often do not yield organisms. Negative cultures of the aqueous humor may indicate an absence of an infectious

agent, aqueous turnover diluting the organism, fastidious organisms that require special culturing techniques, or a toxin is responsible for stimulating leukotaxis.
- Corneal infections may produce inflammatory mediators that diffuse into the anterior chamber and result in hypopyon, even though the agent is not in the anterior chamber.
- Leukemias and ocular lymphoma may be associated with increased leukocytes in the anterior chamber to the point of producing hypopyon.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is made on observing a white to yellow opacity that settles ventrally within the anterior chamber. A bright focal light source and careful visualization of the ventral anterior chamber with the patient's head ventroflexed should help keep the third eyelid down and improve visualization of mild hypopyon.

DIFFERENTIAL DIAGNOSIS

- Lipids in the anterior chamber are creamy white but invariably diffuse.
- Fibrin clots in the anterior chamber. Both hypopyon and fibrin clots may occur concurrently. Fibrin clots are irregular in shape and frequently localized over the pupil. Hypopyon settles ventrally with a flat top.

INITIAL DATABASE

- History: recent intraocular surgery, systemic signs
- Thorough ocular and physical examinations (see p. 1313) to search for a source of sepsis or for a malignancy, either locally (in or on the eye) or systemically.
- If local ocular causes for the leukotaxis cannot be found, perform CBC, chemistry profile, urinalysis for evidence of systemic disease.
- If hypopyon or intraocular inflammation is so severe as to preclude posterior segment examination, ocular ultrasound is indicated for prognostic and diagnostic purposes to detect evidence of endophthalmitis, foreign bodies, neoplasia.
- Aqueous centesis with a 30-gauge needle for culture and cytology. Can be performed under topical anesthesia by an experienced examiner. In eyes with mild hypopyon or those associated with corneal disease, centesis is often not performed, as the signs often are improving by the time the culture results are known, or the cornea is a better source for culturing.

ADVANCED OR CONFIRMATORY TESTING

If the cause for hypopyon is anterior uveitis, and this is thought to originate from systemic disease, appropriate infectious disease titers, chest radiographs, and other tests may be indicated.

TREATMENT

TREATMENT OVERVIEW

The hypopyon itself is not treated (i.e., aspirated or surgically removed). The underlying disease (e.g., septic uveitis, keratitis, malignancy) is treated.

ACUTE GENERAL TREATMENT

- Frequent topical broad-spectrum antibiotic such as third- or fourth-generation fluoroquinolone q 4 h. Anterior chamber sepsis may not be present, but the risk is too great to delay initiation of antibiotics.
- Systemic broad-spectrum bactericidal antibiotics
- Topical 1% atropine sufficient to maintain pupil dilation
- Topical and/or systemic nonsteroidal antiinflammatory drugs for the uveitis.

CHRONIC TREATMENT

Therapy may be modified depending on results of culture and source of inflammation. Hypopyon usually resolves within several days when inflammation is controlled.

POSSIBLE COMPLICATIONS

Topical or systemic glucocorticoids may be contraindicated with bacterial or fungal infections but indicated with viral-or lymphoma-associated hypopyon.

RECOMMENDED MONITORING

If bacterial sepsis is suspected, initial monitoring should be either daily or more frequently if significant inflammation is present.

PROGNOSIS AND OUTCOME

The prognosis is variable, depending on the underlying disease. Hypopyon improves rapidly with successful therapy of the underlying stimulus.

PEARLS & CONSIDERATIONS

COMMENTS

- Bacterial culture results are negative in most cases of hypopyon, and the risk for rapid development of structural damage to the eye is too great to withhold antibiotics until culture results are known.
- Hypopyon itself is not treated and produces minimal sequela in most cases.

CLIENT EDUCATION

If hypopyon is due to sepsis, blindness is a potential sequela.

AUTHOR: CHARLES L. MARTIN

EDITOR: CHERYL L. CULLEN

Hypoplastic Trachea

BASIC INFORMATION

DEFINITION

Congenital abnormal narrowing of the tracheal lumen, well-recognized in brachycephalic breeds

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs <1 year old; 2:1 males/females. Not reported in cats.

GENETICS AND BREED PREDISPOSITION

Of reported dogs, 55% are bulldogs, and 15% are Boston terriers. Also reported as a recessive trait in Husky-mix puppies with blue eyes and partially white faces.

ASSOCIATED CONDITIONS AND DISORDERS

- Brachycephalic syndrome: elongated soft palate in 43% of affected dogs, stenotic nares in 22%
- Other congenital anomalies (pulmonic or aortic stenosis, megaesophagus) or respiratory abnormalities (bronchopneumonia, laryngeal paralysis, everted laryngeal saccules, laryngeal collapse) may be present.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Incidental finding in approximately 10% of affected dogs
- Recurrent respiratory infections with poor response to treatment
- Clinical signs associated with concurrent brachycephalic syndrome such as stertor, stridor, exercise intolerance, lethargy, coughing, gagging, syncope

PHYSICAL EXAM FINDINGS

- Physical examination can be unremarkable
- Abnormalities attributable to dyspnea or bronchopneumonia:
  - Cough
  - Stridor (inspiratory, may be high-pitched or gasping sounds) if laryngeal abnormalities
  - Stertor if elongated soft palate
  - Increased lung sounds
  - Fever
  - Lethargy
  - Increased respiratory rate and effort

ETIOLOGY AND PATHOPHYSIOLOGY

- Trachea develops with the ends/tips of cartilaginous rings apposed or overlapped and dorsal membrane narrow or absent, narrowing the tracheal lumen.
- With narrowed tracheal lumen, linear air velocity and tracheal resistance increase, increasing work of respiration.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of congenital tracheal hypoplasia is based on comparison of tracheal diameter to thoracic inlet diameter. Normal tracheal

diameter is smaller in bulldogs than in other breeds.

DIFFERENTIAL DIAGNOSIS

- Elongated soft palate
- Everted laryngeal saccules
- Stenotic nares
- Laryngeal paralysis or collapse
- Tracheal collapse
- Any cause of bronchopneumonia or tracheobronchitis

INITIAL DATABASE

- CBC: inflammatory leukogram with left shift possible if bronchopneumonia present
- Serum biochemistry panel and urinalysis: usually normal
- Thoracic radiographs:
  - Diffusely narrowed tracheal lumen
  - Bronchopneumonia in approximately 8% of cases

ADVANCED OR CONFIRMATORY TESTING

- Decrease in tracheal diameter on lateral thoracic radiograph:
  - TD:TI ratio is the ratio of tracheal diameter (TD) at the level of the thoracic inlet to the thoracic inlet diameter (TI, distance from the ventral aspect of the vertebral column at the midpoint of the first rib to the closest point on the inner surface of the manubrium).
  - For dogs older than 6 months, normal TD:TI = 0.2 for nonbrachycephalic breeds and non-bulldog brachycephalic breeds, and 0.14 for bulldogs.
  - Ratios lower than these indicate tracheal hypoplasia (assuming a diffuse, not focal, narrowing).
- Tracheoscopy/bronchoscopy or trans-tracheal wash for cytology, culture and sensitivity in dogs with nonresponsive bronchopneumonia.
- Histopathologic evaluation: generally not beneficial
  - Overlap or apposition of tips/ends of tracheal rings
  - Dorsal membrane folded, narrowed, or absent

TREATMENT

TREATMENT OVERVIEW

Since animals with tracheal hypoplasia usually present with signs caused by other abnormalities (e.g., elongated soft palate, stenotic nares, pneumonia), treatment is directed toward correction of the abnormality that is the primary cause of clinical signs and treatment of secondary infections when present. Surgery for stenotic nares and elongated soft palate should be delayed in animals with pneumonia until the lungs have improved radiographically.

ACUTE GENERAL TREATMENT

- Oxygen Supplementation (see p. 1318)
- Sedation
  - Acepromazine, 0.03-0.05 mg/kg IV (e.g., 0.25-0.5 mg total dose for medium-size dog) with butorphanol (0.2-0.4 mg/kg IV q 2-4 has needed) if dyspneic or hyperpneic
- If bronchopneumonia is present, broad-spectrum antibiotic treatment based ideally on results of culture and sensitivity

CHRONIC TREATMENT

- Reduce weight if obese.
- Limit exercise, reduce stress.
- Correct associated respiratory defects (see pp. 151 and p. 635)

POSSIBLE COMPLICATIONS

Death from severe respiratory distress or bronchopneumonia

RECOMMENDED MONITORING

Repeat thoracic films in 1-2 weeks in dogs with bronchopneumonia. Radiographic improvement of bronchopneumonia can lag several days behind clinical improvement.

PROGNOSIS AND OUTCOME

In the absence of concurrent respiratory disease, hypoplastic trachea is well tolerated. Mortality rate (death or euthanasia) of 50% reflects associated respiratory disease or other defects (megaesophagus, cardiac disease).

PEARLS & CONSIDERATIONS

COMMENTS

- Dyspnea is not related to the degree of tracheal lumen diameter narrowing but to presence of other diseases.
- Presence of hypoplastic trachea does not affect outcome of animals undergoing surgery for elongated soft palate or stenotic nares.
- Some degree of diffuse increase in tracheal diameter may be seen after clinical improvement; this increase in diameter is attributed to reduced tracheal mucosal edema.
- Of dogs with hypoplastic trachea, 60% are clinically normal at recheck >6 months after diagnosis.

PREVENTION

There are no means of preventing this disease. Affected animals should not be bred.

TECHNICIAN TIP

Normal bulldogs have a smaller-diameter trachea than other breeds and therefore will need smaller endotracheal tubes when undergoing general anesthesia.

CLIENT EDUCATION

- Consider thoracic radiographs of bulldogs, Boston terriers before breeding.
- Affected dogs have lifelong risk of respiratory infections and dyspnea.

AUTHOR: KAREN M. TOBIAS

EDITOR: RANCE K. SELLON

Hypoparathyroidism, Primary

BASIC INFORMATION

DEFINITION

An absolute or relative deficiency of parathyroid hormone (PTH) from parathyroid gland destruction or atrophy, causing hypocalcemia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Uncommon disorder in dogs and cats
- Dogs: any age, breed, or sex may be affected
- Cats: young to middle-aged, any breed; male predominance

CLINICAL PRESENTATION

HISTORY/CHIEF COMPLAINT

- Sporadic or episodic signs, all related to hypocalcemia (see p. 576)
- Most common:
  - Muscle tremors or twitching that may be focal or diffuse and may worsen with exercise or excitement
  - Seizures
  - Stiff gait, muscle pain/cramping
  - Weakness, decreased activity (more common in cats)
- Less common:
  - Facial rubbing
  - Biting or licking paws
  - Behavior changes (restless, nervous, anxious, aggressive, reluctant to be touched)
  - Excessive panting
  - Vomiting, diarrhea, weight loss

PHYSICAL EXAM FINDINGS

- Neuromuscular signs (see above); raised nictitating membranes possible (cats)
- Additional findings may include hyperthermia (from muscle fasciculations), tense abdomen, thin body condition, or cataracts.
- Physical examination may be normal.

ETIOLOGY AND PATHOPHYSIOLOGY

- Naturally occurring disease is suspected to be due to immune-mediated destruction or idiopathic atrophy of the parathyroid glands.
- In normal animals, PTH secretion is controlled by ionized calcium concentrations via negative feedback, but with hypoparathyroidism the parathyroid glands are unable to respond to hypocalcemia.
- Loss of PTH results in sustained, potentially severe hypocalcemia and hyperphosphatemia.
  - Hypocalcemia results from decreased resorption of calcium from bone, decreased intestinal absorption of calcium, and increased renal excretion of calcium.
  - Hyperphosphatemia occurs due to decreased renal phosphate excretion.
- Loss of the normal membrane-stabilizing effect of ionized calcium on nerve cells causes increased excitability of central and peripheral nervous tissue.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Concomitant hypocalcemia and hyperphosphatemia in a patient with normal renal function strongly suggests primary hypoparathyroidism. The diagnosis is confirmed by evaluating concurrent serum ionized calcium and PTH concentrations.

DIFFERENTIAL DIAGNOSIS

Hypocalcemia (see p. 576)

INITIAL DATABASE

- CBC: unremarkable. Serum biochemical profile, urinalysis: hypocalcemia and hyperphosphatemia, normal renal parameters
- Confirm hypocalcemia:
  - Repeat calcium measurement on a separate blood sample.
  - Measure serum ionized calcium concentration.
  - Formulas to "correct" serum calcium to account for changes in total calcium due to serum albumin values do not account for much of the variability in serum calcium and are no longer recommended.

ADVANCED OR CONFIRMATORY TESTING

- Primary hypoparathyroidism is confirmed by evaluating concurrent serum ionized calcium and PTH concentrations; both will usually be decreased.
- A low-normal serum PTH concentration is inappropriate if ionized calcium concentration is low; thus in a patient with low ionized calcium, a serum PTH concentration that is either decreased or low normal is compatible with a diagnosis of primary hypoparathyroidism.

TREATMENT

TREATMENT OVERVIEW

- The goal of therapy is to increase serum calcium concentration above the threshold for clinical signs and maintain it just below or at the low end of the reference range (i.e., 8-9.5 mg/ dL [2-2.4 mmol/L]). Lifelong therapy is required.
- Therapy must be individualized, and frequent monitoring for appropriate adjustment of drug dosages is required. "Overtreatment" resulting in hypercalcemia must be avoided.
- The need for acute emergency therapy will vary depending on the severity of presenting signs.
- Referral is indicated if 24-hour care and in-house serum calcium monitoring cannot be provided during the immediate posttetanic period.

ACUTE GENERAL TREATMENT

For hypocalcemic tetany: see p. 576.

CHRONIC TREATMENT

- Subacute/early chronic treatment:
  - Oral vitamin D (see table, below):
    - Calcitriol is preparation of choice
    - Quicker- and shorter-acting forms (and therefore easier to use for dosage adjustments) are more expensive.
  - Oral calcium:
    - Dose: 25 mg/kg elemental calcium q 8-12 h
    - The amount of elemental calcium per tablet varies with the preparation/salt.
    - Once the serum calcium concentration is stable and the dog or cat is eating well, oral calcium supplementation can be tapered over 2-3 weeks and then discontinued, as dietary calcium is adequate for most.
  - Parenteral calcium administration is usually needed during the time it takes for oral vitamin D and oral calcium supplementation to take effect:
    - Calcium gluconate IV via continuous rate infusion (60-90 mg/kg q 24 h; do not add to bicarbonate-containing fluids) or SQ q 6-8 h (see p. 576); dilute one part calcium to 2-4 parts saline). Do NOT give calcium chloride SQ, as perivascular administration can cause tissue necrosis and sloughing.
    - Monitor serum calcium concentrations q 12-24 h and adjust dose to maintain serum calcium concentration between 8-9.5 mg/dL (2.0-2.4 mmol/L). When serum calcium concentrations have been consistently above 8 mg/dL (2 mmol/L) for 48 hours, parenteral calcium can be tapered and discontinued over 3–7 days by increasing the dosing interval.

Vitamin D Preparations

Preparation	Daily Dose	Time to Maximal Effect	Time Required for Toxicity Relief

Calcitriol (1,25-dihydroxy-cholecalciferol, vitamin D3)	■ Initial: 0.01-0.015 mcg/kg PO q 12 h × 3-4 days (dog); 0.01-0.04 mcg/kg PO q 24 h (cat) ■ Maintenance: 0.005-0.015 mcg/kg PO q 24 h	1-4 days	1-14 days
Dihydrotachysterol	■ Initial: 0.02-0.03 mg/kg PO q 24 h × 2 days or to effect ■ Maintenance: 0.01-0.02 mg/kg PO q 24-48 h	1-7 days	1-3 weeks

- Maintenance/long-term chronic treatment:
  - Vitamin D should be slowly tapered to the lowest dose possible to maintain stable serum calcium concentrations. Lifelong therapy is required.

POSSIBLE COMPLICATIONS

- Overzealous treatment with vitamin D may result in hypercalcemia. Hypercalcemia in conjunction with hyperphosphatemia puts animals at risk for soft tissue (including renal) mineralization.
- Although SQ calcium gluconate is generally deemed safe, there are multiple case reports describing severe, extensive calcinosis cutis and epidermal necrosis following SQ administration of calcium gluconate for primary hypoparathyroidism in both dogs and a cat.

RECOMMENDED MONITORING

- During the immediate posttetanic phase, patients should be observed 24 hours/day for seizures and other clinical signs of hypocalcemia.
- Serum calcium and phosphorus concentrations should initially be measured at least q 12-24 h, then with decreasing frequency as serum calcium concentration stabilizes. When patients are stable with maintenance oral vitamin D therapy, evaluation of serum calcium and phosphorus concentrations is recommended q 3-6 months.

PROGNOSIS AND OUTCOME

With careful treatment and monitoring, prognosis is good.

PEARLS & CONSIDERATIONS

COMMENTS

- Treatment with synthetic human PTH is being evaluated in human patients and may be a future treatment option for veterinary patients.
- Because of the risk of induction of hypercalcemia, use of ergocalciferol (Vitamin D2) is not recommended.

SYNONYMS:

- Vitamin D1: lamisterol (forms calciferol); vitamin D2: ergocalciferol/viosterol/activated ergosterol; vitamin D3: cholecalciferol/ergosterol/activated 7-dehydrocholesterol; vitamin D4: dihydrotachysterol/22:23-dihydrovitamin D2; vitamin D5: irridated 7-dehydrositosterol; calcitriol: 1,25-dihydroxycholecalciferol/1,2 5-dihydroxyvitamin D

TECHNICIAN TIP

Hyperthermia in hypocalcemic patients generally results from muscle fasciculations, not true fever. Therefore, cooling measures (moistening paw pads, fan/air circulation) may be appropriate, but antipyrexic drugs (e.g., nonsteroidal antiinflammatories) are not.

CLIENT EDUCATION

- Appropriate therapy requires repeated evaluation of serum calcium concentrations. Monitoring will become less intensive as serum calcium concentrations stabilize, but clients should be prepared for frequent rechecks.
- Treatment must be lifelong for dogs with naturally occurring hypoparathyroidism.

AUTHOR: CARY L. M. BASSETT

EDITOR: SHERRI IHLE

Hyponatremia

BASIC INFORMATION

DEFINITION

Low serum sodium (<125 mEq/L) with plasma hypoosmolality; it may be associated with low, normal, or high plasma tonicity.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats: no breed or sex predilection

RISK FACTORS

- Renal insufficiency
- Excessive water intake
- Hypoadrenocorticism
- Severe liver disease or end-stage heart failure

ASSOCIATED CONDITIONS & DISORDERS

Osmotic demyelination syndrome (neurologic signs)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Clinical signs are related to the rapidity of onset rather than to severity of hyponatremia or hypoosmolality.
- Signs in humans are often seen with acute levels less than 120 mEq/L or a drop at a rate greater than 0.5 mEq/L/h
- Can lead to cerebral edema
- Clinical signs may be absent in chronic cases.

HISTORY, CHIEF COMPLAINT

- Mild lethargy
- Nausea and vomiting
- Abdominal distention
- Weight gain
- Seizures, incoordination, and coma

PHYSICAL EXAM FINDINGS

- Patient can exhibit signs of dehydration, including decreased skin turgor and tacky mucous membranes.
- Signs of third spacing such as ascites or edema
- Hypovolemia with weak pulses, tachycardia, prolonged capillary refill time

ETIOLOGY AND PATHOPHYSIOLOGY

- Hypotonic (dilutional) hyponatremia:
  - Excess of water relative to existing sodium stores
  - Most commonly due to impaired renal excretion of water
  - Other causes include congestive heart failure, severe liver disease, nephrotic syndrome.
  - Except for renal disease, characterized by high plasma concentrations of arginine vasopressin (antidiuretic hormone) despite hypotonicity
  - Ascites or edema is common.
  - Excessive water intake may also be a cause.
- Isotonic hyponatremia:

    - Associated with volume depletion (hypovolemia)
    - Causes include loss of fluid via gastrointestinal tract, loss into third spaces (peritoneal effusion, pleural effusion), and renal loss.
    - Hypotonicity with loss of hypotonic fluid results from:
        - A decrease in glomerular filtration rate increases isosmotic resorption of sodium and water in the proximal tubules and decreases delivery of tubular fluid to the distal diluting sites.
        - Volume depletion causes vasopressin release, which impairs water excretion.
        - Stimulation of thirst due to the volume depletion, which causes the animal to drink water.
- Hypertonic (translocational) hyponatremia:
    - Hyperglycemia
    - Retention of hypertonic mannitol in patients with renal insufficiency
- Pseudohyponatremia

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The clinical signs of hyponatremia are nonspecific, but a simple serum electrolyte measurement is confirmatory.

DIFFERENTIAL DIAGNOSIS

Pseudohyponatremia:

- Obtain plasma osmolality; hypernatremic patients with normal osmolality have pseudohyponatremia.
- Pseudohyponatremia is a laboratory artifact that may be seen with hyperlipidemia and severe hyperproteinemia.

INITIAL DATABASE

- CBC
- Serum biochemistry profile and urinalysis
- Abdominal and thoracic radiographs
- Abdominal ultrasound
- Calculated serum osmolality

ADVANCED OR CONFIRMATORY TESTING

- Thyroid panel
- Adrenocorticotropic hormone stimulation
- Abdominocentesis or thoracocentesis with fluid analysis

TREATMENT

TREATMENT OVERVIEW

Goals are to diagnose and manage underlying disease. If clinical signs are present, increase sodium concentration and osmolality gradually.

ACUTE GENERAL TREATMENT

- Aim to increase serum sodium concentrations by a maximum of 2-3 mEq/h.
- The use of conventional crystalloids such as lactated Ringer's solution or 0.9% saline is recommended.
- Restore volume if patient is hypovolemic.
- Treatment of underlying cause if systemic disorder

CHRONIC TREATMENT

- Aim to increase serum sodium concentration by 0.7 mEq/h.
- Management/resolution of systemic disorder if present
- Mild water restriction, with serum sodium concentration monitoring, can be effective.
- Edematous patients should be treated with a combination of sodium-restricted diet, saline, and diuretics.

- Do not correct at a rate of greater than 12-15 mEq/L/d.

POSSIBLE COMPLICATIONS

- Correcting a sodium deficit faster than the body can compensate by restoring organic osmolytes can lead to brain dehydration (rapid shifts in osmolality will cause disorders of the central nervous system secondary to dehydration of the brain).
- Brain injury causes osmotic demyelination syndrome, which leads to cerebral edema, seizures, and other neurologic signs.

RECOMMENDED MONITORING

Frequent monitoring of electrolytes including serum sodium and potassium concentrations

PROGNOSIS AND OUTCOME

Good, provided underlying problem can be reversed or eliminated and overly rapid correction is avoided

PEARLS & CONSIDERATIONS

COMMENTS

When treating acute hyponatremia, correction can be made as quickly as the hyponatremia developed (i.e., if the sodium dropped in 24 hours, it can be entirely corrected in 24 hours).

CLIENT EDUCATION

Related to underlying disease

Hypokalemia

BASIC INFORMATION

DEFINITION

Serum potassium concentration <3.5 mEq/L

EPIDEMIOLOGY

SPECIES, AGE, SEX

Cats are more likely to show clinical signs than dogs: signs may be seen when serum potassium is between 3 and 3.5 mEq/L. Dogs: signs may not be evident until serum potassium is <2.5 mEq/L.

GENETICS & BREED PREDISPOSITION

A familial inherited (assumed autosomal recessive) hypokalemic myopathy has been reported in 2- to 12-month-old Burmese kittens.

RISK FACTORS

Cats: dietary factors such as potassium-depleted, acidifying, magnesium-restricted, and/or high-protein diets. Canned feline diets have now been modified to reduce this risk.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Musculoskeletal:
  - Generalized muscle weakness
  - Polymyopathy: increased serum creatine kinase, electromyographic abnormalities (most notable in cats)
- Cardiovascular:
  - Variable clinical expression
- Renal:
  - Chronic tubulointerstitial nephritis, impaired renal function, azotemia (most notable in cats)
- Gastrointestinal (GI): paralytic ileus

HISTORY, CHIEF COMPLAINT

- Many dogs and cats have no obvious signs.
- Generalized skeletal muscle weakness: most common complaint
- Hypokalemic polymyopathy in cats: flaccid ventroflexion of neck (see online chapter: Neck Ventroflexion), forelimb hypermetria, broad-based stance in hind limbs
- Polyuria, polydipsia, decreased urine concentrating ability
- Vomiting; diarrhea, or constipation

PHYSICAL EXAM FINDINGS

- Musculoskeletal
  - Generalized skeletal muscle weakness
  - Cats with polymyopathy: flaccid ventroflexion of neck, forelimb hypermetria, broad-based stance in hind limbs
- Cardiovascular
  - Arrhythmias, especially premature ventricular complexes
  - Abnormalities often only detectable by electrocardiography
- GI (paralytic ileus)
  - Rare in dogs and cats
  - Abdominal distention
  - Constipation

ETIOLOGY AND PATHOPHYSIOLOGY

- Increased potassium loss in urine:
  - Chronic kidney disease (cats)
  - Diet-induced hypokalemic nephropathy (cats)
  - Renal tubular acidosis
  - Postobstructive diuresis (cats with urethral obstruction)
  - Diuretic administration
  - Dialysis
  - Hyperaldosteronism
  - Hyperadrenocorticism
- Increased potassium loss via GI tract:
  - Vomiting
  - Diarrhea
- Increased potassium sequestration into cells (translocation from extracellular to intracellular fluid) may occur with alkalemia, insulin release, catecholamine release:
  - Alkalemia: potassium ions enter cells in exchange for hydrogen ions.
  - Insulin: promotes uptake of glucose and potassium by hepatocytes and skeletal muscle cells.
  - Severe illness: stress leads to epinephrine release, which contributes to hypokalemia.
- Decreased potassium dietary intake:
  - Uncommon; may be a contributing factor
- Iatrogenic:
  - Fluid therapy, insulin therapy, bicarbonate therapy, loop and thiazide diuretics, enemas, parenteral nutrition
- Combinations of factors:
  - Diabetic ketoacidosis

DIAGNOSIS

OVERVIEW STATEMENT

A diagnosis of hypokalemia should be suspected when a patient presents with signs of profound muscle weakness. This is especially true if the patient has a history of predisposing risk factors, such as chronic kidney disease (primarily in cats) or diabetes mellitus.

INITIAL DATABASE

- CBC: no specific abnormality
- Serum biochemistry profile: establishes the diagnosis
- Urinalysis

ADVANCED OR CONFIRMATORY TESTING

- Do 24-hour urine potassium excretion (confirmation of excess renal potassium excretion). Rarely applied clinically.
- ACTH stimulation; low-dose dexamethasone suppression (hyperadrenocorticism)
- Serum aldosterone levels, abdominal ultrasound exam (hyperaldosteronism)
- Electrocardiography:
  - Hypokalemia delays ventricular repolarization, increases duration of action potential, increases automaticity.
  - Supraventricular and ventricular arrhythmias may be seen.
  - Decreased T-wave amplitude and ST-segment depression (often seen in human patients) are not consistent findings in dogs and cats.
- Echocardiography:
  - Decreased myocardial contractility
  - Decreased cardiac output

TREATMENT

TREATMENT OVERVIEW

The therapeutic goal is to reestablish normal serum potassium levels while avoiding hyperkalemia, as well as to maintain normal serum potassium levels long term. Therapy is indicated if serum potassium is <3 mEq/L, or if clinical signs of hypokalemia are evident, or if serum potassium loss is expected. Intravenous KCl is the drug of choice in the acute case; oral potassium gluconate is used for long-term maintenance therapy.

ACUTE GENERAL TREATMENT

- Potassium chloride (KCl) administered IV at a rate not to exceed 0.5 mEq/ kg/h
- In dogs and cats with normal renal function, maintenance potassium concentration should be approximately 20 mEq/L of fluids, given at a rate of 40 mL/kg/d IV.
- Concentration of potassium in IV fluids should not exceed 60 mEq/L (in most cases); higher concentrations can cause pain and sclerosis of peripheral veins.
- Although IV administration is preferred, KCl can be given subcutaneously so long as potassium concentration in fluids is less than 30 mEq/L.
- In mildly affected patients, oral potassium gluconate (Kaon Elixir, Tumil-K) may be the only therapy required; starting dose is 0.33 mEq/kg PO q 8 h.

CHRONIC TREATMENT

Once serum potassium is in normal range, oral potassium gluconate is continued at a maintenance dosage of 0.5 mEq/kg PO q 12 h until inciting cause is eliminated.

DRUG INTERACTIONS

Using potassium supplementation along with angiotensin-converting enzyme inhibitors, potassium-sparing diuretics (e.g., spironolactone), prostaglandin inhibitors, or β-blockers may result in hyperkalemia.

POSSIBLE COMPLICATIONS

Cardiac arrhythmias

RECOMMENDED MONITORING

During acute treatment phase, adjustments in IV potassium therapy should be based on serum potassium concentration measured once or twice a day.

PROGNOSIS AND OUTCOME

- Clinical signs usually resolve within 1-5 days after correction of hypokalemia.
- Depending on cause, long-term oral potassium supplementation may be required.

PEARLS & CONSIDERATIONS

COMMENTS

- Clinical signs associated with hypokalemia are seen more commonly in cats than in dogs.
- Chronic kidney disease is the most common condition associated with hypokalemia in cats; approximately 20%-30% of cats with chronic kidney disease are hypokalemic at presentation.
- Most dogs with chronic kidney disease have normal serum potassium concentrations.
- A common iatrogenic cause of hypokalemia is IV administration of potassium-deficient fluids to anorectic patients; solutions used for maintenance fluid therapy should contain 15-30 mEq potassium/L to avoid this complication.

EDITOR: ETIENNE CÔTÉ

Hypocalcemia

BASIC INFORMATION

DEFINITION

A reduction of blood calcium concentration below normal. Uncommon occurrence except in cats following thyroidectomy.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats of either sex and any age can be affected; exact predispositions depend on underlying causes.
- Hypoparathyroidism occurs mainly in female (65%), middle-aged dogs.
- Puerperal tetany (eclampsia) occurs in small lactating bitches.
- Older cats undergoing thyroidectomy are at risk of iatrogenic parathyroidectomy.

GENETICS & BREED PREDISPOSITION

Hypoparathyroidism in dogs: toy poodles, miniature schnauzers, Labrador retrievers, German shepherds, dachshunds, terriers

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Animal presented with signs relating to hypocalcemia
- Incidental finding on blood work, animal presented for another problem

HISTORY, CHIEF COMPLAINT

- Abrupt onset of neurologic and/or neuromuscular signs
- Signs may be intermittent despite persistent hypocalcemia:
  - Focal/generalized muscle tremors
  - Stiff, stilted, rigid gait
  - Nervousness, excessive panting
  - Generalized seizures, tetany
  - Facial rubbing
  - Ear twitching (common in cats)

PHYSICAL EXAM FINDINGS

- Muscle rigidity, tremors
- Tense abdomen
- Stiff gait
- Tachyarrhythmias, soft heart sounds, weak pulse
- Raised nictitating membranes (cats)
- Physical exam can be normal

ETIOLOGY AND PATHOPHYSIOLOGY

- Calcium homeostasis: 50% of total circulating calcium is ionized (biologically active form), 40% is bound to albumin (storage form), 10% is complexed to anions (storage form).
- Clinical signs of hypocalcemia will occur *only* when the ionized form is decreased.
- Serum calcium is tightly regulated by parathyroid hormone (PTH), vitamin D, and calcitonin.
- PTH increases serum calcium by:
  - Increasing osteoclastic bone resorption of calcium and phosphorus
  - Increasing calcium and decreasing phosphorus resorption from renal tubules
  - Stimulating conversion of vitamin D to its active form by the renal enzyme 1-a-hydroxylase
- Inactive vitamin D is absorbed in the intestine, transported to the liver where it is hydroxylated to 25-dihydroxy vitamin D, then

transported to the kidney where it is hydroxylated by 1-a-hydroxylase to the active metabolite 1,25-dihydroxy vitamin D (calcitriol).

- Vitamin D increases serum calcium and phosphorus by:
  - Increasing intestinal absorption of calcium, phosphorus and magnesium from the intestine
  - Facilitating PTH-induced bone resorption
  - Increasing renal tubular resorption of calcium and phosphorus
- Calcitonin decreases serum calcium and phosphorus by:
  - Blocking bone resorption
  - Decreasing renal tubular resorption of calcium and phosphorus

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The most common causes of clinical hypocalcemia are puerperal tetany in the lactating bitch and thyroidectomy in the cat. Hypoalbuminemia is a common cause of nonclinical hypocalcemia.

DIFFERENTIAL DIAGNOSIS

- Parathyroid-related:
  - Primary hypoparathyroidism (immune-mediated, idiopathic, surgical complication post thyroidectomy in cats)
- Acute renal failure/chronic kidney disease
- Puerperal tetany (eclampsia)
- Acute pancreatitis
- Ethylene glycol toxicity
- Hypomagnesemia
- Vitamin D deficiency
- Hypoalbuminemia (total serum [calcium] is low but ionized serum [calcium] is normal)
- Phosphate-containing enemas (especially in cats)
- Laboratory error

INITIAL DATABASE

- Complete serum biochemistry profile: identifies hypocalcemia
- Serum ionized calcium: differentiates between absolute hypocalcemia and relative (i.e., metabolically insignificant) hypocalcemia
- Serum magnesium: identifies hypomagnesemia
- Electrocardiogram

ADVANCED OR CONFIRMATORY TESTING

- Serum parathyroid hormone concentration: low in hypoparathyroidism
- Serum vitamin D concentration: low if the cause of the hypocalcemia

TREATMENT

TREATMENT OVERVIEW

In the patient presenting clinical signs, administration of calcium can be lifesaving. Increase serum calcium concentration above the threshold responsible for clinical signs:

- Total calcium above 6-7 mg/dL (1.5-1.75 mmol/L)
- Ionized calcium above 2.4-2.8 mg/dL (0.6-0.7 mmol/L)

ACUTE GENERAL TREATMENT

- Intravenous calcium infusion:
  - Administer 10% calcium gluconate IV at a dose of 0.5-1.5 mL/kg or 5-15 mg/kg slowly to effect over 15-30 minutes.
  - Electrographic monitoring is recommended during IV calcium administration.
  - The infusion should be slowed/discontinued if bradycardia, ventricular premature complexes, or shortening of the Q-T

interval is observed.
- Once clinical signs have improved, continue parenteral calcium administration. Calcium can be given as a continuous intravenous infusion at 60-90 mg/kg/d of elemental calcium (10% calcium gluconate contains 9.3 mg/mL of elemental calcium). Subcutaneous administration may be considered if venous access is not possible, but probably should be avoided in general (cases of severe, extensive calcinosis cutis and epidermal necrosis in some dogs and a cat treated with calcium gluconate).

CHRONIC TREATMENT

- Vitamin D: calcitriol is the form of vitamin D recommended for maintenance therapy (rapid onset of action, short half-life, does not require hepatic/renal transformation).
  - Loading dose: 0.01-0.015 mcg/kg q 12 h PO for 4 days
  - Maintenance dose: 0.0025-0.0075 mcg/kg q 12 h
  - Maximal effect is seen 1-4 days after initiation of treatment. Maintenance dose should be adjusted to obtain normocalcemia.
- Calcium supplementation: calcium carbonate (1 g = 20 mEq calcium) is recommended at a dose of 25 mg/kg q 8-12 h PO. Dose should be adjusted to obtain normocalcemia.
  - Once normocalcemia is achieved, the dose of oral calcium can be slowly decreased and stopped. Vitamin D must be continued until the underlying disorder is corrected.
- Therapy with synthetic PTH is not currently available.

POSSIBLE COMPLICATIONS

Subcutaneous calcium administration has been associated with the development of calcinosis cutis, and therefore the IV route may be preferable.

RECOMMENDED MONITORING

Monitor total serum calcium: target level 8-9.5 mg/dL (2-2.4 mmol/L; just below reference range).

PROGNOSIS AND OUTCOME

Dependent on the underlying disease

PEARLS & CONSIDERATIONS

COMMENTS

- Calcium must not be measured on EDTA blood. EDTA will chelate the calcium, falsely lowering its value, so avoid lavender-top tubes for serum calcium measurement.
- Avoid the use of calcium chloride for injections or infusions, as it is very caustic.
- Hypoalbuminemia may cause a mild decrease in the protein-bound fraction of calcium, thus resulting in a mildly decreased total serum calcium. Ionized calcium remains normal.
- Correcting the calcium value to compensate for albumin is not valid in dogs or cats; ionized calcium measurement is accurate.

CLIENT EDUCATION

The owner should be informed of clinical signs associated with hypocalcemia to ensure early and rapid detection.

Hypoadrenocorticism

Additional Images Available on Website

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

An endocrine disorder in dogs (rare in cats) caused by adrenocortical insufficiency

SYNONYM

Addison's disease

Glucocorticoid-deficient hypoadrenocorticism: “atypical” hypoadrenocorticism

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most common in young/middle-aged female dogs, but any age, gender, or breed may be affected
- “Atypical” hypoadrenocorticism: dogs tend to be older at time of diagnosis.
- Nova Scotia Duck Tolling Retrievers (NSDTR) tend to be younger at time of diagnosis
- Affected cats are typically young/middle-aged, although any age may be affected; no apparent sex predilection

GENETICS & BREED PREDISPOSITION

- Increased risk: Great Danes, Portuguese water dogs, West Highland white terriers, bearded collies, poodles, rottweilers, soft-coated wheaten terriers, NSDTR, and Leonbergers.
- Heritable disease in standard poodles, bearded collies, Portuguese water dogs, and NDSTR; no sex predilection in these breeds
    - Standard poodles, Portuguese water dogs, NSDTR; appears to be autosomal recessive mode of inheritance; mode of inheritance not clearly defined in bearded collies

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- “Typical” hypoadrenocorticism: signs of both glucocorticoid and mineralocorticoid deficiency
- “Atypical” hypoadrenocorticism: only signs of glucocorticoid deficiency are present.

HISTORY/CHIEF COMPLAINT

- Clinical signs classically are notoriously vague and often wax and wane over weeks or months (sometimes only apparent to owners in retrospect); worsening in stressful situations (e.g., travel, boarding) is possible. Severity of signs ranges from a mild, progressive, intermittent course to an acute, life-threatening crisis.
- Dogs:
    - Most common: weakness, lethargy, anorexia, vomiting
    - Less common: diarrhea (possibly with melena or hematochezia), weight loss, trembling, polyuria/polydipsia (PU/PD), regurgitation (due to megaesophagus), and collapse. Rarely, seizures may occur secondary to hypoglycemia.
- Cats: anorexia, weight loss, lethargy; vomiting and PU/PD are uncommon.

PHYSICAL EXAM FINDINGS

- As described (History/Chief Complaint, above)
- In crisis, aforementioned signs may be present and severe. Mental depression/moribund state, bradycardia (from hyperkalemia) and signs of hypovolemic shock are possible.

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary hypoadrenocorticism (typical and atypical): most commonly due to idiopathic or immune-mediated destruction of the

adrenal cortices. Other uncommon causes of adrenocortical destruction: granulomatous disease (histoplasmosis, blastomycosis, tuberculosis); infarction; neoplasia; adrenocortical amyloidosis; drugs (e.g., mitotane).

- Secondary hypoadrenocorticism (spontaneous): destructive lesions or congenital defects of the hypothalamus or pituitary result in decreased secretion of corticotropin-releasing factor or adrenocorticotropic hormone (ACTH), respectively. Very rare.
- Secondary hypoadrenocorticism (iatrogenic): administration of exogenous corticosteroids suppresses normal ACTH production, resulting in adrenal gland atrophy; sudden cessation of exogenous corticosteroid administration then produces hypoadrenocorticism.
- Clinical signs and laboratory findings reflect the absence of normal activities of glucocorticoids and mineralocorticoids.
- Hypoadrenocorticism affecting all layers of the adrenal cortex ("typical;" electrolytes are abnormal) is much more common than hypoadrenocorticism affecting only glucocorticoid synthesis ("atypical;" electrolytes are normal)
- Consequences of glucocorticoid deficiency:
  - Malaise, lethargy
  - Gastrointestinal (GI) signs (anorexia, vomiting, diarrhea, abdominal pain, melena, weight loss, regurgitation)
  - Hypoglycemia
  - Absence of a stress leukogram in an ill patient (failure of glucocorticoid-induced neutrophil release and lymphocyte reduction), mild anemia
- Consequences of mineralocorticoid (aldosterone) deficiency:
  - Decreased renal sodium, chloride (and consequently water) resorption, resulting in hyponatremia, hypochloremia, and volume depletion/dehydration
  - Hyponatremia (see p. 578) results in hypovolemia, hypotension, decreased cardiac output and poor tissue perfusion, solute diuresis and medullary solute washout. Consequences include prerenal azotemia, metabolic acidosis, weakness, microcardia, depression, decreased urine concentrating ability, and PU/PD.
  - Decreased renal potassium excretion resulting in hyperkalemia (see p. 556)
  - Metabolic acidosis due to decreased renal hydrogen ion excretion and poor tissue perfusion
- Additional reported findings for which a mechanism is not clearly defined include hypercalcemia (total and/or ionized calcium), hypoalbuminemia, hypocholesterolemia, and mega-esophagus.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

"Typical" hypoadrenocorticism is suspected based on compatible historical/ clinical findings in conjunction with hyponatremia and hyperkalemia. Bradycardia with concurrent hypovolemia and/or absence of a stress leukogram in an ill patient increase the likelihood of the diagnosis. "Atypical" hypoadrenocorticism should be considered in dogs with historical/clinical signs of nonspecific illness (particularly gastrointestinal signs) and compatible laboratory findings, including absence of a stress leukogram, anemia, hypoalbuminemia, hypoglycemia, or hypocholesterolemia. The diagnosis (typical or atypical) is confirmed with an ACTH stimulation test.

DIFFERENTIAL DIAGNOSIS

- History/chief complaint: primary gastrointestinal disease, intoxication, pancreatitis, renal disease, liver disease
  - The presence of prerenal azotemia and isosthenuria can make it difficult to distinguish between hypoadrenocorticism and acute renal failure. Differentiation is important because hypoadrenocorticism carries an excellent long-term prognosis. Initial treatment for both is similar, and the disorders can be distinguished using the ACTH stimulation test.
- Hyperkalemia (see p. 556)
- Hyponatremia (see p. 578)
- Hypercalcemia (see p. 553)
- Hypoglycemia (see p. 1401)

INITIAL DATABASE

- CBC, serum biochemical profile, urinalysis:
  - "Typical" hypoadrenocorticism: common findings include normocytic, normochromic nonregenerative anemia; absence of stress leukogram; hyponatremia; hypochloremia; hyperkalemia; metabolic acidosis; prerenal azotemia. Hypoglycemia, hypercalcemia, hypoalbuminemia, and isosthenuria are also possible. A decreased Na:K ratio (<27) supports a tentative diagnosis but is not pathognomonic and cannot be used for making a definitive diagnosis. Likewise, the diagnosis should not be excluded in dogs with a Na:K ratio of up to 30 in the presence of compatible clinical signs.
  - "Atypical" hypoadrenocorticism: normocytic, normochromic anemia; no stress leukogram, possible hypoglycemia hypoalbuminemia, hypocholesterolemia. Electrolyte levels are normal.
- In cats, a decreased Na:K ratio may be associated with many disorders other than hypoadrenocorticism.
- Electrocardiogram: changes consistent with hyperkalemia possible
- Thoracic radiographs: microcardia common; signs of megaesophagus ± aspiration pneumonia possible.

- Abdominal ultrasound: adrenal glands may be normal in size or slender; whereas slender adrenal glands are supportive of hypoadrenocorticism, normal adrenal gland size does not rule out the diagnosis.
- Basal serum cortisol level: if normal, hypoadrenocorticism is highly unlikely. If low, uncertainty persists.

ADVANCED OR CONFIRMATORY TESTING

- ACTH stimulation test is the definitive diagnostic test for hypoadrenocorticism. Basal serum cortisol concentration may be low-normal to low and fails to increase after ACTH administration.
- Dogs:
  - Protocol 1 (preferred): (a) Collect blood sample for pre-ACTH cortisol level; (b) Administer synthetic aqueous ACTH (cosyntropin) 5 mcg/ kg up to 250 mcg/dog IV; (c) Collect blood sample 60 minutes later (post-ACTH cortisol level).
  - Protocol 2: Collect blood sample for pre-ACTH cortisol level; (b) Administer ACTH gel 2.2 IU/kg IM; (c) Collect blood sample 2 hours later (post-ACTH cortisol level). Anecdotal reports indicate sporadic variability in ACTH gel efficacy.
- Cats:
  - (a) Collect blood sample for pre-ACTH cortisol level; (b) Administer synthetic aqueous ACTH 125 mcg/cat IV or IM; (c) Collect blood samples 30 and 60 minutes later (post-ACTH cortisol level).
- Endogenous ACTH can be measured to differentiate secondary (decreased ACTH) from early primary hypoadrenocorticism (increased ACTH) if atypical hypoadrenocorticism is present.

TREATMENT

TREATMENT OVERVIEW

Extent of initial therapy will depend on severity of clinical signs. For animals in an Addisonian crisis, initial therapy is directed toward correcting life-threatening conditions (hypotension, hypovolemia, hyperkalemia, acidosis, hypoglycemia). The cornerstone of therapy is IV fluid therapy. Patients with severe, typical clinical and laboratory abnormalities should be treated as if they have hypoadrenocorticism; delaying treatment until ACTH stimulation results are available may result in death of the patient. Chronic therapy involves physiologic replacement of deficient hormones. Lifelong hormone therapy is required.

ACUTE GENERAL TREATMENT

- Normal saline (0.9% NaCl) IV:
  - Critical component of therapy
  - Dogs: 40-80 mL/kg/h IV for ~1 to 2 hours, then 90-120 mL/kg/d for 1-2 days; switch to a balanced electrolyte solution (e.g., lactated Ringer's solution) when serum electrolyte levels are within reference ranges.
  - Cats: administer 40 mL/kg IV over 2-4 hours to rehydrate, then 65 mL/ kg/d
- Fluid therapy is the primary treatment for hyperkalemia and acidosis.
  - If hyperkalemia is life threatening (serum concentration >8 mEq/L and/or electrocardiographic findings), may need sodium bicarbonate, insulin/glucose or calcium gluconate (see p. 556).
  - If acidosis is severe (serum bicarbonate <12 mEq/L), consider bicarbonate therapy:
    - Base deficit (mEq/L) = 25 - patient's blood [$Hco3^{-}$]. If blood gas results are not available and patient is severely ill, assume base deficit = 10 mEq/L: Total dose NaHco3 (mEq/L) = body weight in kg × 0.3 × base deficit. Give 25% of total dose in IV fluids over first 6-8 hours, then reassess and repeat if blood $Hco3^{-}$ still <12 mEq/L.
- Glucocorticoid administration:
  - Dexamethasone sodium phosphate (preferred): rapid-acting and is not detected by cortisol assay (ACTH stimulation test). Initially administer 0.5-1 mg/kg IV once, then 0.05-0.1 mg/kg q 12 h in IV solution.
  - Alternatively, prednisone sodium succinate (4-20 mg/kg over 2-4 minutes initially, then q 2-6 h) can be administered but only after completion of the ACTH stimulation test.
- Hypoglycemia: add dextrose to IV fluids to make 2.5%-5% dextrose concentration.
- Once life-saving treatment has been initiated, perform ACTH stimulation test (as above).
- Monitor urine production.
- Monitor electrolytes and glucose q 8-12 h until normal.
- Maintain fluid therapy until patient is eating.
- Use injectable dexamethasone until oral prednisone can be instituted.
- Mineralocorticoid administration: can be initiated immediately *after* completion of ACTH stimulation test or following correction of electrolyte imbalances with fluid therapy.

CHRONIC TREATMENT

- Lifelong supplementation with glucocorticoids and mineralocorticoids (primary hypoadrenocorticism) or with glucocorticoids alone (secondary or atypical hypoadrenocorticism) is required.

- Glucocorticoid supplementation: prednisone, 0.22 mg/kg PO q 12 h initially then taper to 0.2-0.25 mg/kg PO q 24 h depending on individual needs
    - Increased prednisone (0.25-1 mg/kg PO q 12 h) may be required during times of stress (e.g., travel, new pet or child). Taper to usual maintenance dose once the event has resolved.
    - Patients receiving fludrocortisone acetate may not require additional daily glucocorticoid therapy, but those receiving deoxycorticosterone pivalate (DOCP) almost always do.
- Mineralocorticoid supplementation: either DOCP injection or oral fludrocortisone
    - DOCP
        - Initial dose is 2.2 mg/kg SQ or IM q ~25 days
        - Measure serum electrolytes on days 12 and 25 after treatment and adjust dosing based on results
        - If hyperkalemia and hyponatremia exist on day 12, increase the next dose by 5%-10%. If electrolytes are normal at 12 days but abnormal at 25 days, shorten the dosing interval by 48 hours.
        - Once dosage and dosing interval are determined, clients can be taught to give DOCP at home.
    - Fludrocortisone acetate
        - Dogs: 0.01 mg/kg PO q 12 h initially; dose often needs to be increased over first 6-18 months to maintain normal serum electrolyte concentrations.
        - Cats: 0.05-0.1 mg PO q 12 h initially; adjust based on serum electrolyte concentrations.
    - Salt supplementation: indicated if high fludrocortisone doses are required for normal serum sodium concentrations

POSSIBLE COMPLICATIONS

- With Addisonian crises, death can occur if treatment is not prompt and intensive.
- Overly rapid correction of hyponatremia can result in demyelinosis (see p. 559).
- Side effects of prolonged excessive prednisone and/or fludrocortisone treatment can include PU/PD and other mild signs of iatrogenic hyperadrenocorticism. In animals receiving fludrocortisone, if PU/PD cannot be resolved by eliminating salt supplementation and tapering prednisone (to lowest dose needed to prevent signs of hypocortisolism) then switching to DOCP should be considered.

RECOMMENDED MONITORING

- Serum electrolytes, BUN, glucose: 7 and 14 days after diagnosis (can coincide with day 12 after DOCP injection)
- Once electrolytes stabilize, recheck monthly for 3-6 months, then q 3-6 months.
- Once the treatment regimen is established and the dog is well, recheck electrolytes q 6-12 months for dose adjustments based on changing body weight.
- Subsequent ACTH stimulation testing is of no use (glucocorticoid interference).

PROGNOSIS AND OUTCOME 

- With treatment and monitoring, prognosis is excellent and a normal lifespan is expected.
- BUN and creatinine elevations with concurrent isosthenuria should not be taken to indicate renal failure and thus do not necessarily influence the prognosis (see Pearls & Considerations below).

PEARLS & CONSIDERATIONS 

COMMENTS

This disease can mimic others that are more common (acute renal failure, hepatic disease, GI disease), and the diagnosis of hypoadrenocorticism is commonly missed initially. The CBC can provide a valuable clue: absence of a stress leukogram in an ill animal is inappropriate and suggests hypoadrenocorticism.

TECHNICIAN TIP

A common cause of pseudohyperkalemia is normal in vitro blood clotting (platelet activation releases potassium); it is easily ruled out by remeasuring blood potassium on a sample drawn into a green-top tube (heparin).

CLIENT EDUCATION

It is important to educate clients that this disease requires lifelong treatment, and that failure to administer therapy may result in a life-threatening crisis.

AUTHOR: CARY L. M. BASSETT

EDITOR: SHERRI IHLE

Hyphema

BASIC INFORMATION

DEFINITION

Blood in the anterior chamber of the eye

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats; any age, either sex

GENETICS & BREED PREDISPOSITION

Dependent on the cause:

- Hereditary coagulopathies
- Breed predisposition to retinal detachments (see p. 985)
- Inherited congenital ocular defects (e.g., collie eye anomaly in rough and smooth collies, border collies, Australian shepherds, Lancashire heelers, and Shetland sheepdogs; persistent hyperplastic primary vitreous syndromes in Doberman pinschers, miniature schnauzers, and Staffordshire bull terriers)

RISK FACTORS

- Stimuli for ocular vascularization:
  - Chronic retinal detachments (see p. 985)
  - Intraocular neoplasia (see p. 620)
  - Glaucoma (see p. 448)
- Animals at increased risk of ocular trauma (e.g., blind animals, hunting dogs, exophthalmic dogs, puppies exposed to cats)
- Systemic diseases causing vasculopathies and/or coagulopathies:
  - Systemic hypertension (see p. 1068)
  - Leukemias
  - Hyperviscosity syndromes such as with multiple myeloma
  - Severe liver disease
  - Infectious diseases:
    - Feline leukemia virus (FeLV) infection and feline coronavirus/feline infectious peritonitis infection (FIP) in cats (see pp. 385 and p. 383)
    - Rickettsial diseases (see pp. 334 and p. 994)
  - Immune-mediated diseases:
    - Thrombocytopenia (see p. 1091)
    - Anemia (see p. 73)
  - Toxicosis:
    - Anticoagulant (see p. 83)
    - Complication of ciliary body cysts

CONTAGION & ZOONOSIS

Depends on underlying cause (e.g., FeLV and FIP transmitted cat to cat). *Brucella cants* infection with uveitis/hyphema: one of the few zoonotic diseases.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute:
  - Varying degrees of blood are present in the eye
  - When the blood is unclotted and the animal is quiet (often in the morning), blood settles ventrally producing a

meniscus.
    - Appearance may change rapidly. When activity level is increased during the day, settled blood may disperse and appear worse, or rebleeding may occur.
- Chronic:
    - Clot formation may become dark or black/brown (“eight ball hemorrhage”).
    - If glaucoma occurs, blood staining of the cornea may develop.

HISTORY, CHIEF COMPLAINT

- Reflective of underlying cause (see Risk Factors above)
- Blood or redness in the eye

PHYSICAL EXAM FINDINGS

- Ocular:
    - Varying degrees of blood in the anterior chamber
    - May see fibrin clots with erythrocyte entrapment +/−
    - Hypopyon +/−
    - Conjunctival injection is often present, indicating an associated anterior uveitis (see p. 1151)
    - Corneal edema +/−
    - Intraocular pressure (IOP):
        - May be reduced (<10 mm Hg) (i.e., acute; uveitis)
        - May be elevated (>30 mm Hg = glaucoma) (i.e., chronic; secondary glaucoma)
- General physical examination:
    - Search for evidence of systemic disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Neovascularization in the eye is fragile and often results in spontaneous hyphema.
- Blood in the anterior chamber is immediately diluted with aqueous humor and usually undergoes rapid fibrinolysis from tissue plasminogen activator that is produced by the iris. This may lyse the clot adjacent to the iris but leave a clot in the pupil.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

For all cases of hyphema, it is critical to determine whether the cause is strictly eye related (e.g., persistent hyperplastic primary vitreous, primary intraocular neoplasia) or systemic (bleeding disorder). Determining whether or not the affected globe has vision or the potential for vision is important for prognosis for vision.

DIFFERENTIAL DIAGNOSIS

- Intense corneal vascularization (see p. 254)
- Rubeosis iridis: new blood vessel growth on the surface of the iris (see p. 1151)

INITIAL DATABASE

- Ophthalmic examination (see p. 1313):
    - Examine periocular region for evidence of trauma; examine contralateral eye for lesions in both anterior and posterior segments.
    - Pupillary light and dazzle reflexes, menace response, for vision prognosis
    - Fluorescein stain and examine cornea/sclera for evidence of perforating injury.
    - If possible, examine iris for evidence of inflammation and assess pupil size.
    - Measure IOP to assess for signs of uveitis (i.e., hypotony or low IOP [IOP <10 mm Hg]) versus glaucoma (IOP >30 mm Hg).
- General physical examination:
    - Examine mucous membranes and skin for petechiae.
    - Palpate abdominal organs and lymph nodes for organomegaly and/ or lymphadenopathy suggestive of neoplastic and/or infectious diseases.
    - Auscult chest (pulmonary hemorrhage).
- Ocular ultrasound: for cause of bleeding such as retinal detachment, intraocular neoplasia, or intraocular foreign body
- Radiograph of head to detect metallic foreign body (pellet) in hunting dogs or if possibility of malicious cause

- CBC, chemistry profile, and urinalysis for evidence of systemic disease
- Systemic blood pressure to test for hypertension

ADVANCED OR CONFIRMATORY TESTING

- Coagulation profile
- Infectious disease titers or tests
- Fine-needle aspirates/biopsy of organomegaly or enlarged lymph nodes

TREATMENT 

TREATMENT OVERVIEW

While investigating the underlying cause, prompt initiation of therapy is recommended to begin resorption of erythrocytes and fibrin from the anterior chamber and help prevent secondary glaucoma. With systemic disorders, treatment centers on hemostasis and optimal blood volume and blood pressure. In cases of uncontrollable uveitis and/or secondary glaucoma, enucleation or evisceration and prosthesis (globe salvage) should be considered once the underlying cause has been determined and addressed.

ACUTE GENERAL TREATMENT

- Treat anterior uveitis with topical corticosteroids (e.g., prednisolone acetate 1% or dexamethasone 0.1% q 6-8 h).
  - *Only* if no lesions of the corneal surface
- If pupil is not dilated and IOP is normal or low (<15-20 mm Hg), topical atropine 1% solution q 12 h
- If IOP >20 mm Hg, topical or systemic carbonic anhydrase inhibitors (see p. 448)
- Trauma: surgery to repair corneal and/ or scleral defects (see p. 249)

CHRONIC TREATMENT

- Traumatic hyphema:
  - *Clotted* hyphema may be dissolved with injection of 25 mcg of tissue plasminogen activator into the anterior chamber (referable procedure) within 3-4 days of the hemorrhage; risk of rebleeding.
- Uncontrollable uveitis and/or secondary glaucoma:
  - Enucleation (globe removal) or evisceration and prosthesis (globe salvage)
- Surgical removal of blood from anterior chamber rarely indicated (referable procedure)

BEHAVIOR/EXERCISE

Restricted activity in acute cases of clotting disorders or trauma. In acute severe hyphema, cage rest with sedation if necessary to keep patient quiet.

DRUG INTERACTIONS

Nonsteroidal antiinflammatory drugs are usually avoided to prevent secondary bleeding.

POSSIBLE COMPLICATIONS

Rebleeding, glaucoma, vision loss, phthisis bulbi with ruptured globes, severe uveitis

RECOMMENDED MONITORING

Reexamine in 48-72 hours for resorption of blood and changes in IOP.

PROGNOSIS AND OUTCOME 

- Dependent on removal or control of underlying cause
- Traumatic hyphema < half of the anterior chamber typically improves spontaneously.
- Hyphemas > three-fourths of the chamber have guarded prognosis.
- Prognosis for vision in traumatic hyphema is usually determined by the initial trauma and the associated ocular injury.
- Globes with chronic uveitis and/or glaucoma require enucleation or evisceration and prosthesis.

PEARLS & CONSIDERATIONS

COMMENTS

- Almost every instance of hyphema is thought by the owner to be caused by trauma.
- Unless obvious abrasions and contusions exist around the eye, rule out other causes before confirming traumatic hyphema.

PREVENTION

- Avoid situations that predispose the animal to trauma (i.e., puppies interacting with feisty cats).
- Ensure toxins such as warfarin are out of reach of animals.
- Tick control.
- Avoid breeding dogs and cats with predisposing genetic diseases.

CLIENT EDUCATION

Resorption of hyphema is highly variable and difficult to predict.

Hyperviscosity Syndrome

BASIC INFORMATION

DEFINITION

An uncommon sequela of some disease processes that may result in elevated viscosity of the blood. A constellation of clinical signs can occur secondarily.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs more frequently than cats; middle-aged to older

ASSOCIATED CONDITIONS & DISORDERS

Hyperviscosity syndrome can cause several sequelae:

- Volume overload and congestive heart failure
- Azotemia from decreased renal perfusion, infiltrative renal lesions, or associated hypercalcemia
- Immune suppression and secondary infection
- Pathologic fractures from infiltrative bone lesions
- Neurologic signs from sludging of blood
- Bleeding disorder from platelet and coagulation factor inhibition

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Variable combinations and severity of nonspecific signs: lethargy, weakness, weight loss, polyuria/polydipsia, neurologic deficits, and blindness. Occasionally a patient will be noted to manifest a bleeding disorder, or blood is noted to be thick and difficult to draw via phlebotomy.

PHYSICAL EXAM FINDINGS

Ocular changes (retinal vessel engorgement/tortuosity, retinal hemorrhage or detachment, papilledema), neurologic deficits (blindness, dementia), epistaxis, mucosal hemorrhage or ecchymoses, or lymphadenopathy may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

Hyperviscosity syndrome may be caused by one of several hematologic conditions:

- Multiple myeloma (IgG or IgA)
- Waldenström's macroglobulinemia (IgM)
- Plasma cell leukemia
- Lymphoma
- Chronic lymphocytic leukemia
- Feline infectious peritonitis
- Amyloidosis
- Ehrlichiosis
- Primary polycythemia
- Secondary polycythemia:
  - Hypoxemia (right-to-left patent ductus arteriosus, elevated altitude, pulmonary disease)
  - Neoplasia (renal tumors, rarely sarcomas)
- Blood viscosity is a function of the concentration and composition of its components.
- A marked increase in plasma proteins or cellular constituents raises blood viscosity. This leads to sludging in the microcirculation, which is the mechanism for clinical manifestations.
- Hyperviscosity may present insidiously with vague, nonspecific signs or acutely with neurologic and/or ophthalmic deficits.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History and physical exam findings should trigger an index of suspicion for the diagnosis, which is further supported by routine CBC and serum biochemistry profile showing severe leukocytosis, erythrocytosis/polycythemia, or hyperglobulinemia. Identifying any of these lab test abnormalities warrants a complete diagnostic evaluation to identify the underlying condition. Establishing a diagnosis of the underlying cause (see list above) is essential for optimal treatment. Serum viscosity can occasionally be measured by a reference laboratory, but the clinical utility is low because treatment will still depend on the underlying cause.

DIFFERENTIAL DIAGNOSIS

- Lethargy, weakness, weight loss, polyuria/polydipsia: these nonspecific signs are generally investigated with at least a CBC, serum biochemical profile, and urinalysis, which are the screening tests of choice for identifying abnormalities responsible for hyperviscosity.
- Acute visual deficits: retinal detachment, retinal hemorrhage, sudden acquired retinal degeneration, other
- Acute neurologic deficit: encephalitis, intracranial hemorrhage, hepatic encephalopathy, other
- Difficult phlebotomy: hypovolemia, technical difficulties

INITIAL DATABASE

- CBC: markedly elevated hematocrit (i.e., >60%) suggests erythrocytosis/ polycythemia as cause of hyperviscosity; abnormal lymphocyte count and/ or morphology may be apparent with chronic lymphocytic leukemia.
- Serum biochemistry profile: hyperglobulinemia if hyperviscosity caused by Waldenström's macroglobulinemia, multiple myeloma, feline infectious peritonitis, amyloidosis, or ehrlichiosis; possibly present with chronic lymphocytic leukemia.
- Urinalysis: no specific findings. Bence Jones proteins are not detected on routine urinalysis.
- Retinal exam: retinal arteries may be enlarged or tortuous; signs of uveitis or chorioretinitis may be present in feline infectious peritonitis.

ADVANCED OR CONFIRMATORY TESTING

- Arterial blood pressure: systemic hypertension may be a sequela of hyperglobulinemia.
- Chest radiographs: lytic bone lesions can be observed with multiple myeloma or metastatic disease in lymphoma; heavy interstitial or bronchiolar patterns possible in secondary polycythemia.
- Abdominal ultrasound:
    - Diffuse hepatosplenomegaly or lymphadenopathy may be present with lymphoma, ehrlichiosis, multiple myeloma (mainly splenomegaly)
    - Renal neoplasm (source of excess erythropoietin) possibly identified as source of secondary polycythemia
- Serum protein electrophoresis: monoclonal protein spike common with chronic lymphocytic leukemia, Waldenström's macroglobulinemia, multiple myeloma or plasma cell leukemia. More often polyclonal with feline infectious peritonitis, amyloidosis, or ehrlichiosis but occasionally can be monoclonal. Urine electrophoresis may reveal monoclonal spike for the neoplastic disorders (less commonly used).
- Bence-Jones proteinuria expected if hyperglobulinemia is cause of hyperviscosity
    - Excessive immunoglobulin light chains excreted in urine
    - May be present with multiple myeloma, chronic lymphocytic leukemia, Waldenström's macroglobulinemia, or plasma cell leukemia
- Coagulation profile: bleeding disorder, especially platelet dysfunction (elevated buccal mucosal bleeding time; normal PT, APTT) may occur with hyperglobulinemia. Indicated in cases with signs of bleeding (e.g., hyphema).
- Bone marrow aspirate ± core biopsy: >20% plasma cells in multiple myeloma or plasma cell leukemia
- Echocardiogram (with microbubble contrast): to identify right ventricular hypertrophy and right-to-left cardiac shunt if present
- *Ehrlichia canis* titer, *Leishmania* direct agglutination test, others: as indicated by geographic exposure and other features of case

TREATMENT

TREATMENT OVERVIEW

As hyperviscosity syndrome is a secondary condition, it is imperative to recognize that patients may present with chief complaints that are actually sequelae (i.e., epistaxis, blindness, retinal hemorrhage) of the underlying condition. Identifying and treating the primary disease process is the cornerstone of long-term care. Acutely, the most important treatment interventions are to ensure the patient is adequately hydrated, oxygenated, and producing urine. Phlebotomy or other treatments to reduce circulating blood components may

be used immediately if clinical signs are severe and clinical improvement is needed prior to the onset of benefit of treating the underlying cause.

ACUTE GENERAL TREATMENT

Plasmapheresis or phlebotomy to decrease Hct to <60% (e.g., remove 10-20 mL/kg whole blood, with replacement of equivalent volume of isotonic crystalloid fluids) to decrease blood viscosity and alleviate neurologic or ophthalmic signs. When hyperglobulinemia is the cause of hyperviscosity, the withdrawn blood can be centrifuged, and autologous red cells may be autotransfused.

CHRONIC TREATMENT

- Treatment of the underlying disorder (e.g., chemotherapy for leukemias, lymphoma, multiple myeloma; doxy-cycline for ehrlichiosis)
- Repeated plasmapheresis for Waldenström's macroglobulinemia
- Polycythemia, two options:
    - Phlebotomy. A total of 10-20 mL/kg in one day, repeated on an as-needed basis as clinical signs and polycythemia recurrence dictate; *or*
    - Anti-RBC-precursor drugs. First decrease the Hct to <60% using phlebotomy, then hydroxyurea 30-50 mg/kg PO q 24 h initially for 7-10 days followed by 30-50 mg/kg 2 or 3 times weekly as needed to maintain Hct <60%. Monitor CBC for signs of myelotoxicity.

RECOMMENDED MONITORING

- For hyperviscosity caused by polycythemia: monitor hematocrit.
- For hyperviscosity caused by hyperglobulinemia, monitor total protein, albumin, and globulin; repeated serum electrophoresis can be used for monitoring multiple myeloma.

PROGNOSIS AND OUTCOME

Guarded, dependent on underlying disease process

PEARLS & CONSIDERATIONS

COMMENTS

- Use corticosteroids cautiously prior to establishing a diagnosis, as biopsy or bone marrow results may be affected.
- Patients with hyperglobulinemia are predisposed to infection, and corticosteroids suppress the immune system.

AUTHOR: JONATHAN BACH

EDITOR: SUSAN M. COTTER

Hypertrophic Osteopathy

BASIC INFORMATION

DEFINITION

A periosteal reaction in the distal extremities of the limbs secondary to a mass in the thorax or abdomen

SYNONYMS

HO, hypertrophic pulmonary osteoarthropathy (HPOA), hypertrophic pulmonary osteopathy, Marie's disease, pulmonary osteoarthropathy

EPIDEMIOLOGY

SPECIES, AGE, SEX

Mainly dogs, rare in cats. Older animals, since this disorder is often associated with neoplasia.

GENETICS & BREED PREDISPOSITION

Large breeds of dogs

RISK FACTORS

- Thoracic mass (e.g., primary pulmonary neoplasia, metastatic pulmonary neoplasia, pulmonary abscess, esophageal carcinoma, *Spirocerca lupi* granuloma)
- Heartworm disease
- Canine tuberculosis
- Abdominal mass (e.g., rhabdomyosarcoma of the bladder, liver adenocarcinoma, prostatic adenocarcinoma)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acute or gradual swelling of limbs, especially forelimbs
- Lethargy, low-grade lameness or reluctance to move
- Incidental finding secondary to a thoracic or abdominal mass

PHYSICAL EXAM FINDINGS

- Swollen, hard extremities (e.g., distal long bones)
- Occasional pitting edema
- Decreased movement in joints secondary to soft-tissue swelling

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology unknown
- Autonomic neurovascular reflex increasing peripheral blood flow and causing periosteal congestion and new bone formation is speculated.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The combination of a limb lesion and radiographic appearance of a lung or abdominal mass defines hypertrophic osteopathy.

DIFFERENTIAL DIAGNOSIS

Radiographic:

- Primary bone neoplasia
- Secondary bone neoplasia
- Fungal bone disease
- Panosteitis

INITIAL DATABASE

- CBC: thrombocytopenia occasionally seen, unknown cause
- Serum biochemistry profile and urinalysis unremarkable or related to thoracic or abdominal mass
- Plain radiographs of extremities: palisades of periosteal new bone on phalanges, metacarpi, metatarsi progressing to tibia/fibula, radius/ulna
- Thoracic radiographs
- Abdominal radiographs

ADVANCED OR CONFIRMATORY TESTING

- Thoracic ultrasonography
- Abdominal ultrasonography
- Biopsy of inciting (e.g., pulmonary) lesion for histologic diagnosis

TREATMENT

TREATMENT OVERVIEW

Treat the underlying thoracic or abdominal disease.

ACUTE GENERAL TREATMENT

Definitive thoracic or abdominal surgery to treat the primary disease

HYPERTROPHIC OSTEOPATHY Lateral radiograph of the radius and ulna of a 9-year-old female spayed Dachshund dog with pulmonary carcinoma. Note the exuberant periosteal reaction *(arrowheads)* typical of hypertrophic osteopathy.

RECOMMENDED MONITORING

Follow-up radiographs of extremities to evaluate bone remodeling

PROGNOSIS AND OUTCOME

- Determined by the underlying thoracic or abdominal mass
- After treatment of the primary disease, clinical signs may continue for 1-2 weeks. Bone lesions can take months to remodel, even with correction of the underlying disorder, and are not known to be fully reversible.

PEARLS & CONSIDERATIONS

COMMENTS

Swelling of the distal extremities of an older dog with radiographic evidence of characteristic palisading periosteal reaction calls for thoracic and abdominal radiographs in search of an underlying primary lesion.

SUGGESTED READING

Halliwell WH: Tumorlike lesions of bone. In Bojrab MJ, editor: Disease mechanisms in small animal surgery. Philadelphia, 1993, Lea & Febiger, pp 933–934.

AUTHOR: NICHOLAS J. TROUT

EDITOR: ETIENNE CÔTÉ

Hypertrophic Osteodystrophy

BASIC INFORMATION

DEFINITION

A disease of the long bones of young, rapidly growing dogs, causing disruption of metaphyseal trabeculae

SYNONYMS

Barlow's disease, canine skeletal scurvy, HOD, hypovitaminosis C, idiopathic osteodystrophy, metaphyseal osteopathy, Moeller-Barlow disease, osteodystrophy types I and II

EPIDEMIOLOGY

SPECIES, AGE, SEX

Canine, range 2-8 months; males more commonly affected

GENETICS & BREED PREDISPOSITION

Large breeds

RISK FACTORS

Rapid rate of growth

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute
- Occasionally peracute

HISTORY, CHIEF COMPLAINT

- An acute onset of soft-tissue swelling of the distal forelimbs or occasionally of the distal hind limbs
- Low-grade lameness of short duration
- Peracute refusal to stand, anorexia, signs of pain

PHYSICAL EXAM FINDINGS

- Febrile, 104°F (40°C) or higher
- Swollen, hot limb with moderate pain
- Peracute cases can show lethargy, dehydration, and severe pain on palpation of the swollen extremities.

ETIOLOGY AND PATHOPHYSIOLOGY

- Unknown
- Definitely not a deficiency of vitamin C or an excess of vitamin D, dietary minerals, or caloric intake
- Unproven link to canine distemper virus
- Disturbance of metaphyseal blood supply, causing delayed ossification of the physeal hypertrophic zone

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The presentation of acute warm diaphyseal regions of the long bone(s) in a growing dog is highly suggestive. Radiographs of the affected region are warranted because they may support the diagnosis and rule out other possible disorders.

DIFFERENTIAL DIAGNOSIS

Radiographic:

- Panosteitis
- Septic arthritis
- Rickets (failure to calcify the cartilaginous matrix of the growth plate)

INITIAL DATABASE

- Plain radiographs; pathognomonic pseudophyseal line adjacent to the physis on the metaphyseal side (“scorbutic line”)
- CBC, biochemistry profile, and urinalysis are invariably unremarkable.
- Rare hypocalcemia of unknown significance

HYPERTROPHIC OSTEODYSTROPHY Lateral radiographic view of the distal radius and ulna of a 4-month-old Great Dane puppy with hypertrophic osteodystrophy (HOD). Note the radiolucent lines (“scorbutic lines” *[arrows])* parallel to the epiphyseal growth plates and antebrachiocarpal joint, characteristic of HOD.

ADVANCED OR CONFIRMATORY TESTING

Arthrocentesis (usually performed if physical exam and/or radiographs suggest a different or concurrent diagnosis): increased volume of transparent, straw-colored fluid with normal viscosity and increased numbers of neutrophils; otherwise normal

TREATMENT

TREATMENT OVERVIEW

Pain relief and supportive care; the disorder self-resolves with time.

ACUTE GENERAL TREATMENT

- Nonsteroidal antiinflammatory medication (e.g., carprofen, meloxicam, or deracoxib)
- Rest, confinement, soft bedding, turning every 4-6 hours if nonambulatory
- Severe cases require more intensive management, including the use of intravenous glucocorticoids (rule out possibility of bacterial infection first), intravenous fluids, and nutritional support.

CHRONIC TREATMENT

- Do not supplement with vitamin C, D, or minerals.
- Correct the use of inappropriate diet:
  - Use a lower-calorie puppy food.
  - Feed an amount that will achieve a thin or lean body condition score so as to minimize load on the developing skeleton until the dog reaches skeletal maturity.

POSSIBLE COMPLICATIONS

Relapses can occur until the patient reaches skeletal maturity.

PROGNOSIS AND OUTCOME

- Good
- Despite expected complete resolution, some owners may elect euthanasia in severe cases or following multiple relapses.
- Diaphyseal deformities of the affected long bones may persist.

PEARLS & CONSIDERATIONS

COMMENTS

- Radiographic changes are pathognomonic.
- Relapses and permanent bone deformities can occur.

AUTHOR: NICHOLAS J. TROUT

EDITOR: ETIENNE CÔTÉ

Hypertrophic Cardiomyopathy

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Hypertrophic cardiomyopathy (HCM) is a common, primary myocardial disease characterized by presence of increased left ventricular wall thickness (concentric hypertrophy) in the absence of secondary causes of hypertrophy such as systemic hypertension, aortic stenosis, or hyperthyroidism.

SYNONYMS

Idiopathic hypertrophic cardiomyopathy (HCM). Hypertrophic obstructive cardiomyopathy (HOCM): if systolic anterior motion of the mitral valve is present, obstructing the left ventricular outflow tract

EPIDEMIOLOGY

SPECIES, AGE, SEX

Juvenile (4 months) to aged routinely recognized; average age ≈6 yrs. Purebred cats often younger: average age of diagnosis in Ragdoll cats is 15 months. Males tend to be more severely affected, but there is no sex-linked heritability.

GENETICS & BREED PREDISPOSITION

- Autosomal-dominant heritability with incomplete penetrance in Maine coon cats and Ragdoll cats. Two different missense mutations of the sarcomeric protein, myosin-binding protein C, are causative of HCM in these two breeds, although there is suspicion that there are additional mutations yet to be discovered in the Maine coon cat.
- Autosomal-dominant heritability in a family of American shorthair cats.
- Other breeds predisposed: British shorthair, Norwegian forest cat, Turkish van, Scottish fold, Sphynx, and Rex. However, domestic shorthair cats remain the most common type of cat diagnosed with HCM.

RISK FACTORS

Precipitating events commonly lead to congestive heart failure (CHF) in cats with previously compensated (“asymptomatic”) HCM. Intravenous fluid administration, recent corticosteroid administration (methylprednisolone acetate), or recent anesthesia/ surgery are common triggers.

ASSOCIATED CONDITIONS & DISORDERS

Congestive heart failure (CHF), aortic thromboembolism, sudden cardiac death

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Often, cats show no clinical signs, and HCM is discovered incidentally (e.g., murmur on physical exam).
- Respiratory abnormalities (CHF): tachypnea, dyspnea, orthopnea, open mouth breathing, uncommonly cough
- Nonspecific: lethargy, anorexia, vomiting
- Lameness or inability to move limb (aortic thromboembolism)
- Sudden death

PHYSICAL EXAM FINDINGS

- Systolic murmur (30%-80% of cases)
- Gallop heart sound (S4 heart sound) variably present (≈30%)
- Arrhythmia: premature beats, irregular rhythm (20%-70% of cats)
- Respiratory abnormalities common if heart failure: tachypnea, dyspnea, increased adventitious lung sounds, ventrally dampened lung sounds if pleural effusion
- If arterial thromboembolism: cyanotic nail beds and toe pads, absent pulses of that limb, contracted and painful muscles,

paresis or plegia of limb

ETIOLOGY AND PATHOPHYSIOLOGY

- Initial defect is myocyte dysfunction due to primary sarcomeric defect; remaining sarcomeres develop compensatory concentric hypertrophy. Myocardial fibrosis consists of replacement fibrosis of dead myocardial cells and interstitial fibrosis likely due to elevated angiotensin II and aldosterone levels.
- Diastolic dysfunction (impaired relaxation and increased myocardial stiffness) caused by altered calcium handling, concentric hypertrophy, myofiber disarray, and myocardial fibrosis.
- Elevated left ventricular filling pressure leads to elevated left atrial and pulmonary venous pressure and development of left sided CHF (pulmonary edema +/− pleural effusion).
- Left atrial thrombus may form secondary to sluggish blood flow in the dilated left atrium and can lead to arterial thromboembolism.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is made by echocardiographic measurement of increased left ventricular wall or interventricular wall thickness of 6 mm or greater in the absence of systemic causes such as hyperthyroidism or systemic hypertension. Thoracic radiographs are necessary to evaluate for presence of congestive heart failure but radiographs alone cannot specify the type of cardiac disease present.

DIFFERENTIAL DIAGNOSIS

Echocardiographically, hypertrophic cardiomyopathy is a diagnosis of exclusion after other causes of increased left ventricular wall thickness have been ruled out:

- Hyperthyroidism
- Systemic hypertension
- Subaortic stenosis
- Acromegaly

INITIAL DATABASE

- Echocardiogram: interventricular septum or left ventricular free wall end diastolic thickness 6 mm or greater. Papillary hypertrophy often present (subjective or quantitative). End-systolic cavity obliteration may be seen. Systolic anterior motion (SAM) of the mitral valve may be seen, confirming HOCM; with HOCM, color-flow Doppler shows left ventricular outflow tract/aortic turbulence and mitral regurgitation. Degree of obstruction caused by SAM is determined by continuous-wave Doppler measurement of the aortic blood flow velocity, using the left apical five-chamber view. Left atrial enlargement is determined by two-dimensional measurements of left atrial diameter and aortic diameter in diastole, using the right parasternal short-axis view at the level of the aortic valve. Left atrial to aortic ratio greater than 1.5 or left atrial diameter >16 mm in the cat denotes left atrial enlargement.
- Electrocardiogram (ECG): supra ventricular or ventricular premature complexes possible. Atrial fibrillation is rare but may be seen with severe left atrial dilation. Left axis deviation (mean electrical axis 0 to −90 degrees) or increased QRS amplitude >1 mV may indicate left ventricular hypertrophy.
- Clinicopathologic evaluation: CBC, serum biochemistry profile, urinalysis unremarkable unless arterial thromboembolism (see p. 88).
- Serum T4 and systolic blood pressure are important to evaluate for secondary causes of concentric left ventricular hypertrophy.
- Thoracic radiographs: Often normal if no left atrial enlargement. More severe cases may show left atrial enlargement, distended pulmonary veins, and if CHF is present, patchy interstitial to alveolar infiltrates often of caudal lung lobes and accessory lung lobe, although no pattern of distribution is typical; pleural effusion also is possible.

ADVANCED OR CONFIRMATORY TESTING

- Tissue Doppler imaging (TDI) echocardiography (pulsed-wave Doppler or color Doppler) to identify diastolic dysfunction and monitor therapeutic effects or progression of disease.
- Plasma brain natriuretic peptide (BNP) often is markedly elevated in cats with severe HCM and CHF and may be elevated in asymptomatic cats. The inactive fragment, NT-proBNP, may be measured using a commercially available test (Cardiocare [IDEXX Laboratories]), but no point-of-care test is yet available.

TREATMENT

TREATMENT OVERVIEW

- Treatment of CHF: reduce the accumulation of pleural effusion or pulmonary edema.
- Antihypertrophic treatment in attempts to reduce the concentric hypertrophy of the left ventricle and decrease myocardial stiffness; consider if wall thickness >7 mm; unproven efficacy.
- Reduce SAM if moderate or severe (pressure gradient >50 mm Hg), which will reduce the pressure overload of the left ventricle, reduce mitral regurgitation, and potentially reduce concentric hypertrophy in severe obstructions.
- Antiarrhythmic treatment if severe tachyarrhythmias such as ventricular tachycardia, supra ventricular tachycardia, or atrial fibrillation
- Anticoagulant therapy in animals with high risk of arterial thromboembolism (spontaneous contrast, severe left atrial dilation, or a left atrial thrombus present on echocardiogram) or in animals having suffered arterial thromboembolism

ACUTE GENERAL TREATMENT

Acute decompensated CHF (see p. 468):

- Thoracocentesis
- Oxygen therapy in oxygen cage, minimize stress
- Furosemide (1-4 mg/kg IV)
- Nitroglycerin
- Concurrent fluid therapy is contraindicated.
- Avoidance of β-blocker therapy during the initial decompensated stage (unless severe tachyarrhythmia also present), controversial whether to start once heart failure is resolved.

CHRONIC TREATMENT

- Reduce SAM if moderate or severe: atenolol or diltiazem
  - Atenolol, 6.25-12.5 mg per cat PO q 12 h. Start at the low dose (typically when asymptomatic), recheck heart rate (HR) and murmur intensity in 1-2 weeks, then increase to 12.5 mg PO q 12 h if HR remains >170 bpm or if SAM severity by continuous-wave Doppler echocardiography or murmur intensity not improved. Do not increase atenolol if HR< 130 bpm.
  - Diltiazem: less effective than atenolol in reducing SAM and preventing sinus tachycardia.
    - Diltiazem, 7.5 mg per cat PO q 8 h
    - Sustained release diltiazem:
  - Dilacor XR, 30 mg PO q 12 h (60-mg tablets)
  - Cardizem CD (180-mg capsules), 10 mg/kg PO q 24 h
  - Consider antihypertrophic treatment for moderate to severe left ventricular hypertrophy (wall thickness >7 mm).
    - Atenolol or diltiazem at doses written previously; may reduce hypertrophy in some cases; controversial.
    - Angiotensin-converting enzyme (ACE) inhibitors or aldosterone antagonist (spironolactone) not likely to be of benefit in early compensated HCM; controversial.
- Chronic CHF: see p. 470
- Chronic refractory CHF:
  - Addition of second diuretic: hydrochlorothiazide (1-4 mg/kg PO q 12 h) ± spironolactone (1-2 mg/kg PO q 12 h)
  - ± Potassium supplement if hypokalemic (2-4 mEq PO q 12 h)
  - Consider SQ administration (increased bioavailability compared to oral) of furosemide 1-2 times a week if maximized on 4 mg/kg PO q 8 h in the face of active heart failure.
- Anticoagulation for prevention of arterial thromboembolism:
  - One baby aspirin (81 mg ASA) or 5 mg PO q 3 d
  - Low-molecular-weight heparin (Enoxaparin): 1.5 mg/kg SQ q 12 h; pharmacokinetics and optimal dosing are still under investigation.
  - Clopidogrel as a potent platelet inhibitor (18.75 mg PO q 24 h)
  - Combination therapy is controversial but has been done in cats with persistent spontaneous contrast on echocardiography or recurrent arterial thromboembolism.
- Antiarrhythmic therapy if supraventricular tachycardia, ventricular tachycardia, or atrial fibrillation with rapid ventricular response rate (see pp. 1165 and p. 108)

NUTRITION/DIET

Sodium restriction only if palatable and only with congestive heart failure; diuretic administration is ongoing (sodium restriction may decrease required dosage of diuretic [s]).

BEHAVIOR/EXERCISE

Avoidance of eliciting intense physical activity (e.g., laser pointer, feather on end of string and wire), which increases heart rate and myocardial oxygen demand

DRUG INTERACTIONS

- Diuretics and ACE inhibitors may exacerbate renal dysfunction.
- Concurrent use of β-blockers and calcium channel blockers is generally contraindicated, as they may cause profound negative chronotropic ± negative inotropic effects.

POSSIBLE COMPLICATIONS

- Prerenal/renal azotemia and hypokalemia during treatment with diuretics
- Cats receiving high doses of diuretics are often mild to moderately azotemic but often maintain reasonable quality of life without requirement for concurrent fluid administration.
- ACE inhibitors occasionally may cause acute renal azotemia, which may reverse after discontinuation of the ACE inhibitor and supportive care.

RECOMMENDED MONITORING

- Baseline serum renal panel and urinalysis; repeat renal panel q 12 h during acute CHF treatment.
- Repeat renal panel 1-2 weeks after initiation of treatment with ACE inhibitor. If significant azotemia occurs, decrease or discontinue the ACE inhibitor, and if possible decrease the diuretic and recheck renal panel.
- Thoracic radiographs to assess therapeutic efficacy of diuretics in resolving the CHF; intermittent recheck radiographs q 2-4 months once stabilized.
- Echocardiogram: depending on severity of HCM q 3-12 months. If recent pulmonary edema or pleural effusion, recheck echocardiogram to assess for left atrial dilation to support the diagnosis of CHF. Monitor left atrial size as risk factor for development of CHF or arterial thromboembolism. Monitor left ventricular (LV) hypertrophy to assess possible progression of disease or assess potential antihypertrophic therapeutic effects. To evaluate for therapeutic reduction in SAM, repeat echocardiogram 1-2 weeks after therapy.
- If systemic hypertension or hyperthyroidism is present, a recheck echocardiogram 3-4 months after cat is normotensive or euthyroid should show regression of LV hypertrophy. If hypertrophy is still present, the cat has concurrent HCM or there is incomplete control of the systemic disorder.
- If arrhythmia is present, recheck ECG to assess response to antiarrhythmic therapy.

PROGNOSIS AND OUTCOME 

- Fair to good prognosis for cats with mild nonprogressive HCM. Cats with HCM and no clinical signs have a median survival >5 years.
- Young male cats and Ragdoll cats with significant left ventricular hypertrophy often progress more rapidly and die from their disease, and often die by 4 years of age.
- Severe HCM and CHF: poor long-term prognosis, median survival of 3 months, although highly variable with survival times over 2 years in some individuals.
- Severe HCM and arterial thromboembolism: poor prognosis, median survival of 2 months but highly variable.

PEARLS & CONSIDERATIONS 

COMMENTS

- Wide range of severity and progression of HCM in individual cats
- In a multicenter, prospective, randomized and blinded study, neither ACE inhibitors, atenolol, nor diltiazem were shown to improve survival over furosemide alone in cats with severe HCM and CHF or arterial thromboembolism.
- Avoidance of long-acting corticosteroid injections
- Anesthetic considerations: avoidance of high fluid rates and drugs that cause tachycardia. Consider induction with midazolam and propofol or with etomidate; maintenance with isoflurane or propofol.

PREVENTION

Genetic screening tests are available for Maine coon cats and Ragdolls, and breeding programs should be aimed at eliminating

genotypically affected cats. Echocardiograms are necessary to screen potential breeding candidates in all breeds, including Maine coon cats, since some Maine coon cats may have HCM despite a normal genotype.

TECHNICIAN TIPS

- Cats with HCM and heart failure tend to be very fragile and require careful handling to minimize stress. For thoracocentesis, cats may be maintained in a comfortable sternal position with gentle and as minimal as possible restraint.
- Blood pressure measurement should also be done prior to other diagnostic tests, with as minimal restraint or stress as possible

CLIENT EDUCATION

- In cats with CHF, teaching clients to monitor resting respiratory rate and respiratory effort is helpful, and to contact the doctor when rates are consistently >40 breaths per minute.
- Risk of sudden death and arterial thromboembolism. Difficulty in preventing arterial thromboembolism when severe underlying cardiac disease is present.

Hyperthyroidism

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

The clinical condition that results from continued excessive secretion of thyroid hormones (thyroxine and triiodothyronine) by the thyroid gland.

SYNONYM

Thyrotoxicosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Older cats; range is 4-20+ years, but 95% of cats diagnosed with hyperthyroidism are >8 years old.
- No sex predilection

GENETICS & BREED PREDISPOSITION

Purebred cats are significantly less likely to be hyperthyroid than domestic/mixed breeds.

RISK FACTORS

Possibly canned food or ectoparasiticide exposure

ASSOCIATED CONDITIONS & DISORDERS

- Concentric cardiac hypertrophy (ventricular thickening)
- Systemic hypertension
- Hyperthyroidism may mask underlying renal dysfunction

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Apathetic hyperthyroidism (10% of cases): cat has decreased appetite, lethargy, and occasionally weight gain.

HISTORY, CHIEF COMPLAINT

- Polydipsia and polyuria
- Polyphagia
- Weight loss despite good appetite
- Hyperactivity, nervousness
- Vomiting and/or diarrhea
- Tachypnea/panting
- Weakness, lethargy
- Decreased grooming activity
- Heat avoidance or seeking cool areas

PHYSICAL EXAM FINDINGS

- Poor body condition
- Unkempt haircoat
- Dehydration
- Cardiac changes
    - Sinus tachycardia

  - Systolic heart murmur
  - Arrhythmia
- Abnormal retinal examination (tortuous retinal blood vessels, retinal tears, retinal detachment)
- Palpable thyroid gland(s)

ETIOLOGY AND PATHOPHYSIOLOGY

- Benign thyroid neoplasia or adenomatous hyperplasia of one (30%) or both (70%) thyroid lobes is most common.
- Thyroid carcinoma is found in <2% of hyperthyroid cats.
- Although many theories have been proposed, no studies have adequately demonstrated an etiology for feline hyperthyroidism.
- Canine hyperthyroidism is the result of a functional thyroid carcinoma (see p. 1095).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in a middle-aged to older cat with clinical signs of weight loss, polyphagia, polyuria, polydipsia, and/or poor grooming habits. Confirmation is usually based on a high serum total thyroxine (T4) concentration. In rare cases when the serum T4 does not correlate with the clinical signs, further evaluation of the thyroid status is necessary.

DIFFERENTIAL DIAGNOSIS

- For polyphagia with weight loss in an adult/geriatric cat: diabetes mellitus, inflammatory bowel disease, gastrointestinal lymphoma. Rarely in cats: hyperadrenocorticism, glomerulonephritis/protein-losing nephropathy.
- For polyuria/polydipsia, see p. 902
- For polyphagia, see p. 899
- For weight loss, see p. 1181
- For vomiting, chronic, see p. 1175
- For diarrhea, chronic, see p. 305
- For arrhythmias/tachycardia/murmur:
  - Primary idiopathic hypertrophic cardiomyopathy (see p. 565)
  - Restrictive cardiomyopathy (see p. 981)

INITIAL DATABASE

- CBC, serum biochemical profile, urinalysis: possible stress leukogram and mild erythrocytosis; increase in liver enzymes common; increased blood urea nitrogen (BUN) and creatinine, phosphorus, and bilirubin less common; urine specific gravity results vary.
- Serum total thyroxine (T4) measurement: usually increased, although values are sometimes in the upper half of the reference range, especially if concurrent disease is present (“euthyroid sick”–like effect).
- Thoracic radiographs: cardiomegaly common; possible pulmonary edema, and/or pleural effusion
- Systemic blood pressure measurement (see p. 1209): hypertension (systolic blood pressure repeatedly >180 mm Hg in calm environment) is common.
- Electrocardiogram if an arrhythmia or other signs of heart disease are present: sinus tachycardia is most common; atrial or ventricular arrhythmias are possible but uncommon.

ADVANCED OR CONFIRMATORY TESTING

- Serum T4 (increased) alone is often diagnostic. If T4 is in the normal range, but the thyroid gland is palpable and/or signs suggestive of hyperthyroidism are present, one of the following tests can be considered:
  - Reevaluate the T4 in a few weeks (if clinical signs are mild).
  - Serum free T4 by equilibrium dialysis (FT4ED): increased FT4ED in conjunction with a high normal total T4 supports a diagnosis of hyperthyroidism.
- T3 suppression test: generally replaced by FT4ED
- Thyroid-stimulating hormone (TSH) and thyrotropin-releasing hormone (TRH) response tests have also been used but are of more limited diagnostic use owing to poor differentiation of hyperthyroid and euthyroid cats, especially if concurrent disease is present.
- Radionuclide (99m-technetium) thyroid scan can be used for determining whether one or both thyroid glands is/are involved, and whether ectopic functional thyroid tissue is present. These points are perhaps of greatest concern if surgical thyroidectomy is contemplated (completeness of excision).
- Echocardiography (cats): can identify left ventricular thickening. If it is symmetric (whole left ventricle is thickened), either

hyperthyroidism or unrelated idiopathic hypertrophic cardiomyopathy (HCM) may be the cause. If it is asymmetric (e.g., interventricular septum is thicker than left ventricular free wall), or hypertrophy is severe, then idiopathic HCM is contributory, and hyperthyroidism alone cannot be causative.

TREATMENT

TREATMENT OVERVIEW

- Three treatment options are available, including daily antithyroid medication, surgical thyroidectomy, and radioactive iodine therapy. The clinical status of the patient will dictate which treatment option is best for an individual. Therapy of concurrent medical conditions such as cardiac hypertrophy and systemic hypertension may be necessary, especially in the early stages of therapy.
- Ideally, therapy will restore serum T4 to normal levels and eliminate clinical signs.
- The clinical therapeutic goal is to encourage weight gain and improve body condition and haircoat, as well as decrease polyuria, polydipsia, and polyphagia, with the overall goal of maximizing quality of life. Depending on renal function, achieving this goal may or may not include returning the serum thyroid hormone levels to normal.

ACUTE GENERAL TREATMENT

- Hyperthyroidism is a chronic disease, so urgent acute treatment usually is not needed.
- Concurrent congestive heart failure may require immediate intervention (see p. 468).
- "Thyroid storm": intense sympathetic discharge usually in response to restraint or other stressful trigger.
    - Managed most effectively through prevention (calm environment, cautious/gentle restraint)
    - If thyroid storm occurs, immediately ensure as calm and quiet an environment as possible while initiating supportive management of complications that occur. May include any or all of the following: acute/decompensated heart failure, severe tachycardia (best treated through calming environment, possibly mild sedation but not with acepromazine), severe bradycardia (very conservative doses of atropine, e.g., 0.01-0.02 mg/kg IV once), severe systemic hypertension (calming environment).
    - Thyroid storm may be acutely fatal and must be prevented through gentle handling of hyperthyroid cats, who often are hyperesthetic and fractious.
    - Prevention through beta-blockade (atenolol, 6.25 mg PO q 12 h, provided medication administration can be accomplished with minimal stress to the cat) has been advocated.

CHRONIC TREATMENT

See Hyperthyroidism algorithm,

- Cats often have renal dysfunction that is not identifiable at the time of diagnosis of hyperthyroidism. Once antithyroid therapy is initiated, the renal dysfunction is unmasked. Therefore a trial of oral antithyroid medication (10-14 days or longer), with monitoring of renal parameters, is recommended before treatment with a more permanent and costly modality (i.e., surgery or radioactive iodine).
- Medical treatment:
    - Thioureylene antithyroid drugs suppress thyroid hormone production.
        - Methimazole (2.5-5 mg/cat PO q 8-12 h) or carbimazole (5 mg/cat PO q 8 h; currently not available in North America) are most commonly used.
        - Transdermal methimazole (methimazole in pluronic lecithin organogel (PLO) from a compounding pharmacy) (2.5-5 mg/cat applied inside the ear pinna q 12 h) has been used in cats that are not amenable to pill administration. Owners should wear an examination glove or a finger cot, and should clean any residual material from the pinna using a damp cotton ball prior to methimazole dosing. Remission may take longer with this formulation. This formulation is also more costly, and longer-term stability (>a few weeks to a few months) of the drug is unproven.
        - Regardless of the formulation used, the dosage is adjusted so that serum T4 concentrations are in the lower half of the reference range.
        - Therapy is expected to be lifelong.
    - Discontinuation of the medication will result in return of clinical signs, so client compliance is essential.
    - Potential side effects of methimazole include anorexia/vomiting, lethargy, pruritus of the head and neck (and self-induced trauma), hepatoxicity (uncommon), thrombocytopenia (uncommon), agranulocytosis (uncommon), and immune-mediated hemolytic anemia (rare). If hemorrhage, icterus, or severe neutropenia occurs, drug administration must be stopped and an alternative treatment initiated. Adverse effects are generally reversible.
    - Other medical treatments that have been used include potassium iodate and calcium ipodate, but these are considered only for short-term use before a more definitive treatment in patients who cannot tolerate methimazole or carbimazole.

- A β-blocker (e.g., atenolol, 6.25 mg/cat PO q 12 h) is used if severe sinus tachycardia (>260 beats/min) persists despite euthyroidism, or if antithyroid drugs need to be stopped (e.g., in preparation for radioiodine).

- Thyroidectomy:
  - Potentially curative
  - Eliminates grossly abnormal thyroid tissue, but ectopic tissue may remain if radionuclide imaging is bypassed.
  - Unilateral thyroidectomy: contralateral thyroid gland can eventually become hyperplastic or adenomatous (recurrent hyperthyroidism).
  - Medical treatment is recommended for several weeks before surgery (assess euthyroid renal function, improve metabolic and cardiac status before administering anesthetic).
  - Bilateral thyroidectomy: may involve loss of several or all parathyroids. Postoperative monitoring of serum calcium is required; if indicated, treat as for hypoparathyroidism (see p. 580).
  - Other possible postoperative complications include Horner's syndrome (see p. 543) and laryngeal paralysis (see p. 635).
- Radioactive iodine (^{131}I) therapy:
  - This is considered the best treatment option for long-term control and possible cure of hyperthyroidism, provided that during a trial of medical antithyroid therapy, serum BUN and creatinine are normal and/or urine specific gravity > 1.035.
  - Treatment renders all hyperfunctional thyroid tissue, including ectopic tissue, nonfunctional.
  - Disadvantages: special handling facilities and posttherapy isolation for several days to weeks are required. The length of isolation is dependent upon the facility. Prior to therapy, the cat must be eating and able to tolerate the required period of time in isolation.
  - The necessity of discontinuing medical antithyroid drugs before treatment is controversial. Consult the facility administering the radiotherapy.

RECOMMENDED MONITORING

- Medical therapy: exam including body weight, CBC, serum biochemical profile, urine specific gravity, T4 at 2 weeks; if normal, reassess q 6 months or if adverse effect or recurrent signs of hyperthyroidism occur.
- Thyroidectomy: exam including body weight, postoperative monitoring of serum calcium if bilateral thyroidectomy; CBC, serum biochemical profile, urinalysis and T4 at 2 weeks, then monitor T4 q 3-6 months.
- Radioactive iodine therapy: exam including body weight, CBC, serum biochemical profile, urinalysis, and T4 2 weeks after treatment, then monitor T4 q 3-6 months.

PROGNOSIS AND OUTCOME

- With successful radioactive iodine therapy or thyroidectomy the short-term prognosis is excellent and long-term prognosis is good. Cure may be obtained in many cases.
  - These patients are older at the time of diagnosis, and other conditions may be present or soon develop; length of survival has been documented to be approximately 2 years post diagnosis regardless of the type of therapy chosen.
- With the presence of renal dysfunction the short-term prognosis is good, but the long-term prognosis is guarded to poor, as both hyperthyroidism and renal dysfunction are progressive illnesses and treatments may be mutually antagonistic.

PEARLS & CONSIDERATIONS

COMMENTS

Concurrent hyperthyroidism and chronic kidney disease should be treated according to which disorder is predominantly responsible for clinical signs:

- Hyperthyroid cats with polyphagia, weight loss, and/or hyperactivity who are also incidentally found to be azotemic should be treated for hyperthyroidism. Chronic kidney disease (see p. 205) is monitored and managed secondarily.
- Cats with chronic kidney disease and overt anorexia, dehydration, uremic oral ulcers, and/or vomiting who are also incidentally found to be hyperthyroid should be treated for chronic kidney disease. In these cases, hyperthyroidism is monitored and generally not treated unless it is causing characteristic signs.
- Cats with no clinical signs attributable to either chronic kidney disease or hyperthyroidism but who are found to have both syndromes incidentally on routine laboratory testing should be monitored periodically (see Recommended Monitoring above) and not treated specifically for either disorder, other than preventive measures (e.g., nutrition).
- Cats with clinical signs of both chronic kidney disease and hyperthyroidism may require medical treatment for chronic kidney disease and “partial treatment” of hyperthyroidism (i.e., medical treatment to lower the T4 somewhat but still above the normal range).

TECHNICIAN TIPS

- Serum submitted for T4 should be free of hemolysis.
- Serum submitted for FT4 ED should be free of hemolysis and lipemia; a fasted sample is recommended.

Hyperparathyroidism, Primary

BASIC INFORMATION

DEFINITION

Primary hyperparathyroidism (PHPTH) is an uncommon disease of dogs caused by increased synthesis and secretion of parathyroid hormone (PTH). The source of increased PTH is autonomously functioning parathyroid cells due to parathyroid adenoma, hyperplasia, or carcinoma. For secondary causes of hyperparathyroidism, see pp. 976 and p. 770.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Older dogs predominantly; no gender predilection
- Rare in cats. Typically older cats are affected.

GENETICS & BREED PREDISPOSITION

- Any breed
- Keeshonden overrepresented. In Keeshonden, PHPTH is heritable (autosomal dominant). A genetic test is available to determine if a Keeshond patient has the affected form of the gene.
- Hereditary neonatal PHPTH has been reported in two German shepherd dogs.

CLINICAL PRESENTATION

HISTORY/CHIEF COMPLAINT

- Polyuria/polydipsia (≈50% dogs; ≈10% cats)
- Lower urinary tract signs (caused by infection or cystic calculi) including pollakiuria, stranguria, and hematuria (≈50% of dogs)
- Weakness, lethargy (≈40-50% of dogs and cats)
- Inappetence (≈25-30% of dogs; ≈40% of cats), vomiting (≈10% of dogs; ≈40% of cats)
- Some (≈30%) affected dogs have no clinical signs; hypercalcemia is an incidental finding.

PHYSICAL EXAM FINDINGS

- Physical examination is typically unremarkable.
- A parathyroid mass is not usually palpable in dogs. Parathyroid masses may be palpable in the ventral neck of cats.

ETIOLOGY AND PATHOPHYSIOLOGY

- PHPTH is most often due to a solitary parathyroid adenoma. Less common causes include hyperplasia of one or more glands or (rarely) parathyroid carcinoma.
- In normal animals, serum PTH concentration is controlled by ionized calcium via negative feedback. In PHPTH, the gland(s) function autonomously, and feedback inhibition is lost.
- Increased serum PTH concentrations cause hypercalcemia and hypophosphatemia.
- Clinical signs are due to hypercalcemia (see p. 553).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Concurrent hypercalcemia and low to low-normal serum phosphorus concentration suggest the possibility of PHPTH; however, these findings are also characteristic of humoral hypercalcemia of malignancy, a far more common disorder. The presence of cystic calculi and/or the absence of other historical or physical signs further increase suspicion for PHPTH.
- One or more parathyroid masses may be visible with ultrasonography; failure to visualize a parathyroid mass does not rule out the diagnosis.

- The diagnosis is established by measuring concurrent serum ionized calcium and PTH concentrations.

DIFFERENTIAL DIAGNOSIS

Hypercalcemia (see p. 553)

INITIAL DATABASE

- CBC, serum biochemical profile, urinalysis, urine culture: hypercalcemia, low or low-normal phosphorus concentration, and isosthenuria are typical. Urinary tract infection is relatively common.
- Confirm hypercalcemia by repeating the test on a new sample and/or measure serum ionized calcium concentration.
- Abdominal radiographs: possible cystic calculi
- Other tests to rule out more common of causes of hypercalcemia, particularly hypercalcemia of malignancy, may include thoracic and abdominal radiographs, abdominal ultrasound, aspiration of lymph nodes and/or bone marrow, and/or serum parathyroid hormone-related protein (PTHrP) concentration.

ADVANCED OR CONFIRMATORY TESTING

- Concurrent serum ionized calcium and PTH concentrations: A serum PTH concentration within the reference range is inappropriate with concurrent increased ionized calcium concentration; thus in a patient with increased ionized calcium, a serum PTH concentration that is either high or within the reference limits supports a diagnosis of PHPTH.
  - Elevated PTH: ≈one-fourth of cases
  - PTH within reference range: ≈three-fourths of cases; of these, over half reported in the lower half of the reference range.
- Ultrasonography of the neck to evaluate the parathyroid glands requires an experienced ultrasonographer and sensitive ultrasound equipment. Visualization of an enlarged parathyroid gland(s) in conjunction with compatible serum ionized calcium and PTH concentrations strongly supports the diagnosis of PHPTH.
- Diagnosis is confirmed by exploratory surgery of the neck or by response to ablation therapy.

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to remove or ablate affected parathyroid gland(s) and monitor/treat for postoperative hypocalcemia. Refenal is indicated if the attending clinician is unfamiliar with thyroid/parathyroid evaluation and surgery, or if 24-hour care and in-house serum calcium monitoring cannot be provided during the immediate postprocedural period. Treat urinary tract infections and remove cystic calculi.

ACUTE GENERAL TREATMENT

- +/-Nonspecific treatment of hypercalcemia (see p. 553) while awaiting a definitive diagnosis or surgery (see p. 553). Contrary to patients with other causes of hypercalcemia, animals with PHPTH rarely require treatment for hypercalcemia.
- Surgical exploration of the neck, with removal of the affected parathyroid gland(s). Most often a solitary parathyroid mass is easily identified and removed. Occasionally evaluation/identification of affected glands can be difficult. In rare instances, removal of all four parathyroid glands and both thyroid glands is considered.
- Newer therapies (percutaneous ultrasound-guided ethanol ablation or radiofrequency heat ablation) are effective and less invasive than surgery but technically challenging and still require general anesthesia (see p. 1263).

CHRONIC TREATMENT

- Surgical or ablation therapy is curative in most patients, so chronic therapy is not required.
- If all four parathyroid glands are removed, lifelong vitamin D and thyroid hormone replacement are indicated (see pp. 580 and 588).

POSSIBLE COMPLICATIONS

- The most important complication is postprocedural hypocalcemia, which may occur with parathyroidectomy or ablation.
- Unaffected glands often atrophy with prolonged increased serum PTH concentrations. After removal of the affected gland(s), serum PTH and calcium may decline more rapidly than normal glands can recover.
- Hospitalization is recommended for at least 5 days after surgery to minimize physical activity, monitor for signs of hypocalcemia, and monitor serum calcium concentrations (q 12-24 h).
- Treatment for hypocalcemia (vitamin D +/-calcium) must be individualized. The goal of therapy is to keep the serum calcium

concentration in the slightly low/low-normal range (8–9.5 mg/dL; 2-2.4 mmol/L) to prevent clinical signs of hypocalcemia while stimulating recovery of function in atrophied parathyroid glands (see p. 576 for vitamin D dosage).

- In general, if serum calcium concentration <14 mg/dL (3.5 mmol/L) before surgery, postoperative hypocalcemia is unlikely. Treatment is recommended only if total calcium falls below 8.5 mg/dL (2.1 mmol/L), if the rate of decline of calcium after surgery is very rapid (e.g., >25% in 1 day), or if clinical signs of hypocalcemia occur.
- If pretreatment serum calcium concentration >14 mg/dL (3.5 mmol/L), prophylactic treatment with vitamin D and calcium is begun the morning of surgery.
- If pretreatment serum calcium concentration >18 mg/dL (4.5 mmol/L), prophylactic treatment is begun 36 hours before surgery.
- If only 1-3 parathyroid glands were removed, vitamin D treatment can be tapered over 3-6 months based on serum calcium levels.
- Additional complications following ultrasound-guided heat or ethanol ablation occur uncommonly and include cough, voice change, and Horner's syndrome.

RECOMMENDED MONITORING

Although rare, PHPTH recurrences may be observed even longer than 12 months after successful treatment; evaluation of serum calcium is recommended every 3-6 months.

PROGNOSIS AND OUTCOME

Prognosis is excellent following successful surgery or ablation.

PEARLS & CONSIDERATIONS

COMMENTS

- Renal failure and associated azotemia occur uncommonly with PHPTH.
- A normal serum PTH level is consistent with PHPTH when there is concurrent hypercalcemia, because it should be low in response to calcium elevations.

TECHNICIAN TIP

Postoperative (parathyroid ablation/removal) patients should be monitored for the first signs of hypocalcemia (muscle fasciculations/twitching, stiff gait, eventually seizures) as immediate grounds for measuring serum calcium level.

AUTHOR: CARY L. M. BASSETT

EDITOR: SHERRI IHLE

Hypernatremia

BASIC INFORMATION

DEFINITION

A serum sodium concentration >158 mEq/L in dogs or >165 mEq/L in cats, which represents a deficit of water in relation to the body's sodium stores. Hypernatremia can result from a net water loss or a hypertonic sodium gain.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats of any age and either sex

GENETICS & BREED PREDISPOSITION

Primary hypodipsia in miniature schnauzers

RISK FACTORS

Inadequate access to water, fever, high ambient temperature, altered mental status

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- *Pure water deficit:* a net water loss in the absence of sodium deficit; majority of water loss is from the intracellular fluid compartment
- *Hypotonic fluid loss:* water loss along with sodium loss; most common form encountered in veterinary medicine
- Impermeant solute gain

HISTORY, CHIEF COMPLAINT

- Often discovered incidentally
- When present, signs of hypernatremia largely reflect central nervous system dysfunction.
- Severity of signs correlates positively with the degree of hypernatremia and rapidity of onset.

PHYSICAL EXAM FINDINGS

- Primarily neurologic signs: seen when plasma sodium is >170 mEq/L. Signs are due to movement of water out of brain cells.
- Tachypnea, muscular weakness, restlessness, ataxia, seizure, coma. Polydipsia may occur initially but dissipates as disease progresses.
- With hypotonic fluid loss, signs of volume depletion (hypotension, dehydration) may be present.
- With impermeant solute gain (rare), signs of volume overload (overhydration: serous nasal discharge, dyspnea from pulmonary edema) may be present.
- Other findings depend on underlying condition.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Pure water deficit:* a net water loss from the body in the absence of sodium deficit; majority of water loss is from the intracellular fluid compartment. Causes include:
  - Unreplaced insensible losses
  - Hypodipsia: primary hypodipsia in miniature schnauzers
  - Neurogenic (central) diabetes insipidus: posttraumatic, neoplastic, idiopathic, meningitis, encephalitis, hypoxic or ischemic encephalopathy
  - Nephrogenic diabetes insipidus: renal disease, hypercalcemia, hypokalemia
- *Hypotonic fluid loss:* water loss along with some degree of sodium loss. Causes include:
  - Renal: loop diuretics, osmotic diuretics, postobstructive diuresis

- Polyuric phase of acute tubular necrosis, intrinsic renal disease
- Gastrointestinal: vomiting, diarrhea, osmotic cathartics
- Cutaneous: burns

- *Impermeant solute gain.* Causes include:
  - Administration of hypertonic sodium bicarbonate, sodium chloride, or hypertonic fluid
  - Ingestion of table salt or salt water
  - Hyperaldosteronism or hyperadrenocorticism

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

See Etiology and Pathophysiology above.

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis. By definition, identifies hypernatremia. Provides further information regarding possible underlying causes (e.g., renal parameters)
- Serum osmolality (calculated or measured)
  - Elevated with hypernatremia of any cause; sodium is the main determinant of serum osmolality.
  - Serial measurement possible for monitoring response to treatment
  - Advantage of measured osmolality over calculated osmolality or serum sodium measurement alone: measurement of otherwise undetected high-osmolality molecules (e.g., ethylene glycol)

ADVANCED OR CONFIRMATORY TESTING

As dictated by history, physical exam findings, and preliminary tests. May include adrenocorticotropic hormone stimulation test, thyroid profile, imaging studies of the brain.

TREATMENT

TREATMENT OVERVIEW

- Replace water and electrolytes, restore effective circulating volume, and treat underlying cause. Rate of correction depends on whether hypernatremia was acute in onset (began within the previous 24 hours, as with recent administration of hypertonic saline) or chronic or unknown in time of onset (vast majority; hypernatremia is known or suspected to have begun >24 hours earlier, as with most naturally occurring hypernatremia).
  - Acute: replace at a rate such that the decrease in serum sodium does not exceed 1 mEq/L/h and does not exceed 24 mEq/L/day
  - Chronic or unknown: replace at a rate such that the decrease in serum sodium does not exceed 0.5 mEq/L/h and does not exceed 12 mEq/L/day
- The cornerstone of successful treatment is frequent monitoring of the patient's mentation and serum sodium concentration.

ACUTE GENERAL TREATMENT

- *Pure water loss:* calculate water deficit. Replace the deficit over 24-48 hours with 5% dextrose in water, not exceeding limit (see Pearls and Considerations below).
  - Water deficit (Liters) = body weight (kg) × 0.6 × ([present serum Na/desired serum Na]-1).
  - Administer calculated water deficit over the recommended time frame for acute or chronic hypernatremia.
  - Total body water is normally 60% of body weight. This value (0.6 in the equation) can be increased in pediatric/neonates or can be decreased in cachectic animals.
- *Hypotonic fluid loss:* replace with a limited amount of isotonic crystalloids to improve hemodynamic parameters. Once improved/stabilized, switch to a hypotonic solution and administer/titrate based on monitoring, not exceeding limit.
- *Gain of impermeant solute:* 5% dextrose diuresis and administer/titrate based on monitoring, not exceeding limit (see Pearls and Considerations below).
- Persistent hypernatremia despite fluid therapy adjustments:
  - Central diabetes insipidus: DDAVP, 1 mcg/kg SQ q 8-12 h; or aqueous vasopressin, 1-2 U/cat or 3-5 U/dog q 24-48 h (see p. 296)
  - Nephrogenic diabetes insipidus: thiazide diuretics (see p. 296)

CHRONIC TREATMENT

- Remove offending drugs.
- Treat underlying condition.

POSSIBLE COMPLICATIONS

Rapid correction of hypernatremia can lead to cerebral edema as excess water moves into brain cells. The signs of cerebral edema may not be seen for 2-3 days post correction of hypernatremia. Edema is more likely to occur in patients with prolonged hyperosmolality and aggressive hypotonic fluid replacement.

RECOMMENDED MONITORING

Check serum electrolytes q 4-8 h.

PROGNOSIS AND OUTCOME 

Mortality varies according to the severity of hypernatremia, rapidity of onset, and underlying condition

PEARLS & CONSIDERATIONS 

COMMENTS

When correcting hypernatremia, the rate of decrease of blood/serum sodium concentration must not exceed 0.5 mEq/L/h.

- Decreasing sodium concentration at a rate >0.5 mEq/L/h risks complications such as cerebral edema.
- Exception: up to 1 mEq/L/h is possible if hypernatremia is known to have begun within 24 hours (e.g., hypertonic saline administration).

PREVENTION

- Ensure adequate drinking water access. prevent excessive drinking of salt water or consumption of pure salt.
- Do not administer table salt as an emetic in cases of toxin ingestion. Use hydrogen peroxide or syrup of ipecac instead.

Hyperlipidemia

BASIC INFORMATION

DEFINITION

Increased fasting blood cholesterol and/or triglyceride (TG) concentrations; a well-recognized (dogs) to uncommon (cats) disorder in small animals.

SYNONYMS

Hyperlipoproteinemia, lipemia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Primary: middle-aged/older (dogs); variable age of onset (cats)
- Secondary: varies with primary cause

GENETICS & BREED PREDISPOSITION

- Idiopathic hypertriglyceridemia: miniature schnauzers, Burmese cats
- Idiopathic hypercholesterolemia: Doberman pinschers, rottweilers, briards, rough collies
- Feline familial hyperlipidemia: autosomal recessive trait in domestic short-haired cats

RISK FACTORS

- Obesity (dogs)
- Drugs: glucocorticoids, phenobarbital (dogs), megestrol acetate (cats)
- High-fat diets or parenteral nutrition
- Hypothyroidism
- Hyperadrenocorticism
- Pancreatitis
- Diabetes mellitus
- Protein-losing nephropathy
- Cholestasis

ASSOCIATED CONDITIONS & DISORDERS

- Pancreatitis
- Vacuolar hepatopathy
- Gallbladder mucocele
- Seizures
- Xanthomas (intraocular or cutaneous nodules/plaques composed of lipid-containing histiocytes)
- Peripheral neuropathy
- Behavior changes

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Primary hyperlipidemia:

- Dogs:
  - Idiopathic hyperlipidemia/idiopathic hypertriglyceridemia
    - Increased very low-density lipoproteins (VLDL)
    - ± Increased chylomicra (CM)
    - ± Mild hypercholesterolemia

    - Idiopathic hyperchylomicronemia
        - Increased TG and CM
    - Idiopathic hypercholesterolemia
        - Increased low-density lipoproteins (LDL)
- Cats:
    - Familial hyperlipidemia/hyperchylomicronemia:
        - Increased CM and VLDL
        - Inactive lipoprotein lipase Secondary Hyperlipidemia: *see Risk Factors above*

HISTORY, CHIEF COMPLAINT

- Clinical signs, when present, are the result of hypertriglyceridemia; hypercholesterolemia virtually never causes clinical signs.
- Dogs: vomiting, diarrhea, abdominal discomfort (pancreatitis), seizures, anorexia, lethargy
- Cats: cutaneous/subcutaneous masses (xanthomas), lameness (neuropathy)

PHYSICAL EXAM FINDINGS

- Hypertriglyceridemia
    - Dogs: signs of abdominal discomfort, hepatosplenomegaly, lipemia retinalis, lipemic aqueous humor, intraocular xanthogranuloma
    - Cats: xanthomas, decreased reflexes (peripheral neuropathy), pale mucous membranes, lipemia retinalis, lipid keratopathy, lipemic aqueous humor
- Hypercholesterolemia
    - Dogs: lipemia retinalis, lipid keratopathy, arcus lipoides corneae

ETIOLOGY AND PATHOPHYSIOLOGY

- Lipoproteins
    - Lipids (TG and cholesterol) do not circulate free in circulation; rather, they are complexed in varying proportions as circulating particles called *lipoproteins.*
    - Four major types (listed in decreasing order of TG concentration and increasing order of cholesterol concentration in the lipoprotein particle):
        - CM
        - VLDL
        - Low-density lipoproteins
        - High-density lipoproteins
- Hyperlipidemia
    - From excessive dietary lipid, excessive endogenous lipid production/mobilization, and/or impaired lipid clearance from blood. Types:
        - Postprandial hyperlipidemia:
            - CM in circulation 2-10 hours after fatty meal
        - Primary hyperlipidemia:
            - Inborn error in lipoprotein metabolism
                - Lack of lipoprotein lipase activity
                - Absence of surface apolipo-proteins (CII)
        - Secondary hyperlipidemia:
            - Underlying disease (see Risk Factors above) causing altered lipid metabolism
            - Secondary hyperlipidemias are more common than primary.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Lipemic serum suggests hypertriglyceridemia; hypercholesterolemia alone does not cause serum to appear lipemic. Persistent increases in triglycerides or cholesterol after a 12-hour fast indicate disease and should prompt investigation for secondary causes of hyperlipidemia.

DIFFERENTIAL DIAGNOSIS

Postprandial hyperlipidemia

INITIAL DATABASE

- CBC, serum biochemical profile (including serum cholesterol and TG concentrations), urinalysis:
  - Perform after > 12-hour fast
  - Identify causes of secondary hyperlipidemia
- Subsequently, consider:
  - Tests for hypothyroidism (see p. 588)
  - Tests for hyperadrenocorticism (see p. 548)
  - Urine protein/creatinine ratio
  - Abdominal ultrasound
  - Serum trypsinlike immunoreactivity
  - Pre- and postprandial bile acids

ADVANCED OR CONFIRMATORY TESTING

- If a cause of secondary hyperlipidemia is not found, additional tests may help define the primary hyperlipidemia.
- Chylomicron (CM) test: lipemic serum is left undisturbed for 12 hours at 4°C.
  - If CM are present they will form a surface "cream layer" over a clear infranatant of serum, suggesting a disorder of CM metabolism such as idiopathic hyperchylomicronemia. A nonfasting sample is an important differential.
  - If the sample remains turbid, VLDL retention (and therefore a secondary hyperlipidemia such as that due to diabetes mellitus) is likely.
  - Formation of a "cream layer" over turbid serum suggests a combined disorder.
- Lipoprotein electrophoresis, ultracentrifugation, and precipitation tests can be useful but are not routinely available.
- Lipoprotein lipase activity can be assessed by measuring TG (± lipoprotein) concentrations before and 15 minutes after heparin (dog: 90 IU/kg IV; cat: 40 IU/kg IV) administration. If no change, lipoprotein lipase inactivity is suspected.

TREATMENT

TREATMENT OVERVIEW

Treatment primarily consists of management of secondary causes and nutritional therapy. Medications are reserved for unresponsive severe cases of hyperlipidemia (TG > 500 mg/dL or cholesterol > 800 mg/dL). Goal of treatment is to reduce fasting TG or cholesterol concentrations to < 500 mg/dL. Treatment is lifelong.

ACUTE GENERAL TREATMENT

Treat underlying diseases.

CHRONIC TREATMENT

- Hypertriglyceridemia
  - Dietary management should be the mainstay of treatment (see Nutrition, below)
  - Menhaden fish oils: 200-330 mg/kg/d PO (dogs); *or*
  - Gemfibrozil: 200 mg/kg PO q 24 h (dogs); 7.5-10 mg/kg PO q 12 h (cats); *or*
  - Niacin 100 mg PO q 24 h (dogs)
- Hypercholesterolemia
  - A primary cause is often (almost always) present, and its control resolves the hypercholesterolemia.
  - Otherwise, dietary management should be the mainstay of treatment (see Nutrition, below).
  - Cholestyramine: 1-2 g PO q 12 h (dogs); *or*
  - Lovastatin: 10-20 mg PO q 24 h (dogs)

NUTRITION/DIET

- Hypertriglyceridemia
  - Dietary fat restriction (dog: <20% metabolizable energy [ME]; cat: <25% ME)
  - If the low-fat diet is unsuccessful, then an ultralow-fat (10-12% ME) homemade diet can be designed by a nutritionist.
- Hypercholesterolemia
  - Low-fat diet with increased amounts of soluble fiber

DRUG INTERACTIONS

- Cholestyramine can interfere with the absorption of other oral medications (digoxin, ursodiol, calcitriol, dihydrotachysterol)
- Lovastatin's metabolism may be inhibited by clarithromycin and cyclosporine, and lovastatin may increase the toxicity of cyclosporine.

POSSIBLE COMPLICATIONS

- Gemfibrozil may cause abdominal discomfort, vomiting, diarrhea, and hepatopathy.
- Niacin may cause vomiting, diarrhea, erythema, pruritus, and hepatopathy.
- Cholestyramine may cause constipation and hypertriglyceridemia.
- Lovastatin may cause lethargy, diarrhea, muscle pain, and hepatopathy.

RECOMMENDED MONITORING

- Monitor plasma triglycerides 1 month after initiation of low-fat diet, then every 6-12 months.
- Monitor hematologic/biochemical parameters with gemfibrozil, niacin, or lovastatin.
- Monitor plasma TG with cholestyramine.

PROGNOSIS AND OUTCOME

- Successful management depends on adequate control of underlying diseases and reduction of plasma lipid concentrations.
- Cats with peripheral neuropathies:
    - Clinical signs generally resolve within 4-12 weeks of instituting diet change.

PEARLS & CONSIDERATIONS

COMMENTS

- Hyperlipidemia in fasted patients (>12 hours) is abnormal.
- Hypertriglyceridemia often signals underlying disease.
- Lipemic plasma is an indication of hypertriglyceridemia, not hypercholesterolemia.
- Hypercholesterolemia may indicate the presence of an underlying disorder but rarely causes significant clinical disease.

TECHNICIAN TIP

If the supernatant in a hematocrit tube is cloudy, and the patient has not eaten in >12 hours, the most likely reason is hyperlipidemia (specifically, elevated triglycerides). This valuable clue should be mentioned to the attending veterinarian, as it may influence treatment and prognosis.

PREVENTION

- Treat predisposing disorders.
- Monitor TG concentrations in susceptible breeds.

Hyperkalemia

BASIC INFORMATION

DEFINITION

A serum potassium concentration in excess of 5.5 mEq/L. Amounts exceeding 7.5 mEq/L are potentially harmful.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Any patient can be affected.

GENETICS & BREED PREDISPOSITION

- Actual hyperkalemia: standard poodles with Addison's disease
- Pseudohyperkalemia: Akita, English springer spaniel with phosphofructokinase deficiency

RISK FACTORS

- Renal impairment
- Urinary obstruction
- Urinary bladder rupture
- Hypoadrenocorticism
- Mineral acid metabolic acidosis
- Excess intake

ASSOCIATED CONDITIONS & DISORDERS

Bradycardia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Acute and chronic

HISTORY, CHIEF COMPLAINT

- Acute: dramatic and life threatening; produces diffuse muscle weakness, mental depression, anorexia. Stranguria accompanies lower urinary outflow obstructions. Vomiting common with acute renal failure and hypoadrenocorticism.
- Chronic: slower in onset and not as dramatic. Decreased appetite, weight loss, intermittent vomiting and diarrhea can occur.

PHYSICAL EXAM FINDINGS

- Generalized muscle weakness
- Weak pulse
- Prolonged capillary refill time
- Bradycardia, especially in setting of dehydration (where heart rate would normally be increased)
- Irregular heart rate
- Body temperature normal or hypothermia

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology:

- Increased potassium intake
- Potassium translocation from intracellular to extracellular fluid space:

    - Mineral acid-caused metabolic acidosis
    - Insulin deficiency
    - Catecholamine increases
    - Hypertonicity
    - Massive tissue destruction (rare in dogs and cats)
- Decreased excretion:
    - Hypoaldosteronism
    - Acute renal failure
    - Urinary bladder rupture or outflow obstruction
    - Type 4 renal tubular acidosis
    - Certain drugs (uncommon)

Pathophysiology:

- Affects primarily skeletal and cardiac muscle tissues
- Life-threatening effects on heart:
    - Depressed excitability and conduction velocity
    - Secondary to persistent depolarization and inactivation of the sodium channels within the cell membranes, causing cardiac conduction abnormalities
- Skeletal muscle weakness occurs.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Presumptive with history, physical examination, and electrocardiogram (ECG). Confirmed with specific laboratory measurement.
- Traditionally, experimentally induced hyperkalemia has been reported to cause a pattern of electrocardiogram (ECG) abnormalities that worsened in parallel to the degree of the elevated serum potassium concentration. These included peaked or depressed T wave, decreased R-wave and P-wave amplitudes, prolongation of PR interval, eventual disappearance of P-wave, widening of QRS complexes, heart blocks, aberrant atrioventricular conduction, and eventually ventricular fibrillation or asystole.
- A recent clinical study by Tag and Day shows that sick dogs and cats do not follow the predicted pattern mentioned above. Some with considerably elevated serum potassium concentrations (>7.0 mEq/L) can have either normal ECG patterns or show minimal changes that would be expected only at lower serum levels. Some patients with serum potassium levels <7.0 mEq/L had more severe ECG patterns than would be expected at those lower serum levels. However, this same article did not attempt to correlate the ECG of any particular serum potassium concentration with simultaneous serum sodium measurements.
- Confirmed with laboratory serum potassium quantitation

HYPERKALEMIA ECG from a cat with urethral obstruction and hyperkalemia (serum K^+ = 7.1 mEq/L) showing atrial standstill. No P waves are seen, but the R-R rhythm is regular, typical of atrial standstill. The heart rate is 210/min, demonstrating that in cats, unlike dogs, a rapid heart rate is still consistent with hyperkalemia. There is mild ST-segment elevation, suggesting myocardial hypoxia. Lead V2, 25 mm/sec, 1 cm = 1 mV.

DIFFERENTIAL DIAGNOSIS

- Any cause of hypovolemic shock
- Primary underlying myocardial disease

INITIAL DATABASE

- Thorough history and physical examination
- CBC
- Serum biochemistry profile:
  - Serum electrolytes: elevated potassium (by definition); sodium may be concurrently low with hypoadrenocorticism, enteritis, renal disease, or pregnancy; chloride.
  - Blood urea nitrogen, creatinine: elevated with prerenal (e.g., hypoadrenocorticism), renal, or postrenal (e.g., urethral obstruction or urinary bladder rupture) azotemia.
  - Total CO2/Hco3¯decreased with metabolic acidosis
  - Glucose: may be decreased in hypoadrenocorticism, sepsis.
- Urinalysis: isosthenuria concurrent with azotemia in renal failure or in hypoadrenocorticism.
- Blood gas: pH, Hco3¯, or Tco2 helpful
- Abdominal imaging

TREATMENT

TREATMENT OVERVIEW

- Antagonize myocardiotoxicity.
- Treat the underlying cause.
- Stop drugs known to increase serum potassium concentration.

ACUTE TREATMENT

The main object is to either antagonize the effects or decrease the serum potassium concentration.

- Calcium gluconate 10% solution (0.5-1.5 mL/kg IV) immediately antagonizes myocardiotoxicity without actually lowering serum potassium concentration
- Lowering the serum potassium:
  - Sodium bicarbonate, 1-2 mEq/kg IV bolus (minimally effective)
  - Regular insulin and glucose, give 0.25-0.5 units of insulin/kg IV, covering each unit of insulin administered with 2 g dextrose (2 g =4 mL 50% dextrose)
- ECG monitoring
- Treat the underlying cause.
- Repeat serum potassium measurement.

CHRONIC TREATMENT

Treat any underlying disease:

- Hypoadrenocorticism (see p. 548): desoxycorticosterone pivalate and prednisone
- Renal tubular acidosis type 4: furosemide
- Chronic renal disease: fluid therapy or dialysis

DRUG INTERACTIONS

- Can impair potassium excretion
- Avoid ACE inhibitors and aldosterone antagonists during the hyperkalemia or if there is a predisposition for recurrence.

POSSIBLE COMPLICATIONS

Cardiac arrest, death

RECOMMENDED MONITORING

- Periodic serum sodium and potassium monitoring with hypoadrenocorticism
- Follow-up renal evaluations

PROGNOSIS AND OUTCOME

- Guarded for renal failure
- Good for hypoadrenocorticism

PEARLS & CONSIDERATIONS

- Do a lead II ECG on all patients that are suspect for having hyperkalemia.
- Bradycardia in a dehydrated patient is inappropriate; hyperkalemia should be considered as one of the causes.
- Calcium gluconate IV works within a few minutes, sodium bicarbonate IV works within 15 minutes, and regular insulin and dextrose work within 30 minutes.
- Other causes of pseudohyperkalemia: thrombocytosis, very high white blood cell counts, blood samples put in ethylenediamine tetraacetic acid (EDTA) tubes.
- In cats, hyperkalemia does not always cause bradycardia; hyperkalemic cats may be tachycardic even with severe hyperkalemia.
- On an ECG, peaked T waves are often normal; the transition from normal T wave to peaked T wave, however, is very suggestive of evolving hyperkalemia.

PREVENTION

Timely treatment of predisposing cause

CLIENT EDUCATION

Become acquainted with the early signs of the primary disorder.

Hyperemia

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

- Active hyperemia: an increased volume of blood in an affected tissue or area due to arterial and arteriolar dilation
- Passive hyperemia: increased volume of blood in an affected tissue or area due to obstruction of blood outflow

SYNONYMS

- Active hyperemia: arterial hyperemia, reactive hyperemia, engorgement, flushing, erythema, injected mucous membranes
- Passive hyperemia: venous hyperemia, congestion

EPIDEMIOLOGY

SPECIES, AGE, SEX

No species, age, or sex predilection except as dependent on underlying etiology

RISK FACTORS

- Increased tissue metabolic demand (e.g., fever, physical exertion)
- Vascular occlusion: extravascular or intravascular

GEOGRAPHY AND SEASONALITY

Vasodilatory cooling related to high environmental heat is a normal manifestation of hyperemia.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Primary complaint:
  - Obvious extravascular occlusion such as limb constriction
  - Gross tissue changes
- Secondary finding:
  - Clinical sign noted in addition to other associated abnormal findings
  - Incidental finding of no clinical significance (e.g., due to anxiety, physical activity, or hot weather)
- Hyperemia may also be classified as active or passive, or as regional or generalized.

HISTORY, CHIEF COMPLAINT

- Highly variable depending on underlying cause
- Examples (generalized hyperemia):
  - Recent exposure to allergen (insect bite, vaccine, food allergen, other)
  - Exposure to infectious agent
  - Exposure to high environmental temperature (enclosed in car during hot weather, other)
  - Anxiety, restlessness (e.g., pheochromocytoma, mast cell disease, polycythemia)
  - None (incidental finding during routine examination)

PHYSICAL EXAM FINDINGS

- Since hyperemia is a clinical sign and not a disease entity, specific physical findings are dependent on the underlying etiology.
- Generalized hyperemia:
  - Tachycardia, tachypnea, hyperthermia
  - Increased respiratory effort
  - Shortened capillary refill time

    - Weakness, collapse
    - Episodic increased levels of activity
- Localized hyperemia:
    - Regional dermal redness
    - Possible swelling and/or pain in the region

ETIOLOGY AND PATHOPHYSIOLOGY

Arteriolar dilation due to sympathetic neurogenic mechanisms or exposure to or release of local or systemic vasoactive substances such as adenosine or nitric oxide in response to altered blood flow.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

As hyperemia is a clinical sign associated with a wide variety of conditions, the first step is to rule out obvious causes via a careful history and physical examination and determine whether the presence of hyperemia is clinically significant.

DIFFERENTIAL DIAGNOSIS

- Any condition causing redness, swelling, or inflammation such as infectious, inflammatory, immune-mediated, neurogenic, toxic, allergic
- Any cause of hyperthermia such as environmental, exercise, infectious, inflammatory, immune-mediated, neurogenic, toxicity
- Rebound vasodilation after ischemic crisis such as external constriction (rubber band, collar), embolic occlusion
- Altered perfusion states such as severe hypertension and hypotensive crises such as cardiac arrest
- Decreased venous return states: cardiac, hepatic, venous occlusion
- Episodic hyperemia: mast cell tumor, pheochromocytoma
- Acute contact dermatitis
- Congenital: telangiectasis
- Vasculitis
- Carbon monoxide intoxication
- Polycythemia
- Acute allergic reaction, drug reaction

INITIAL DATABASE

- Temperature, heart rate, respiration rate
    - Hyperthermia warrants consideration of true fever (infectious, inflammatory, neoplastic causes; see p. 589) versus environmental hyperthermia (hot weather, thick haircoat, anxiety, etc.).
- Diascopy: superficial lesions blanch with external pressure, such as with a glass slide.
    - This maneuver helps confirm whether hyperemia is present versus a normal coloration for the animal.

ADVANCED OR CONFIRMATORY TESTING

Use of these tests depends on determination of need. For example, in animals that are otherwise clinically normal (routine exam), behavioral agitation/anxiety, benign environmental hyperthermia, and exercise are common causes of hyperemia that generally do not warrant further evaluation.

- Blood pressure measurements
    - Systemic
    - Localized (if suspect embolic occlusion)
- CBC (infectious, inflammatory, neoplastic, polycythemia)
- Serum biochemistry panel (hepatic, renal elevations)
- Radiographs: organomegaly, neoplasia
- Neurologic evaluation (in cases of suspected intoxication or other systemic disorders with neurologic effects): see p. 1311
- Abdominal ultrasound (neoplasm, infection/abscess, chronic passive congestion)
- Echocardiogram (endocarditis, other)
- CT or MRI for embolism evaluation
- Aspirates and/or biopsies: masses/lesions
- Tickborne disease titers
- Blood gas analysis
- Cooximetry: carbon monoxide intoxication

TREATMENT

TREATMENT OVERVIEW

Goal of treatment is resolution of the underlying etiology, with special attention paid to ensuring adequate tissue perfusion.

ACUTE GENERAL TREATMENT

Supportive as needed: analgesia, oxygen, restoration of perfusion, cooling of affected region.

CHRONIC TREATMENT

Treatment as appropriate for underlying etiology

POSSIBLE COMPLICATIONS

- Reperfusion injury
- Tissue necrosis

PROGNOSIS AND OUTCOME

Highly variable depending on underlying etiology

PEARLS & CONSIDERATIONS

COMMENTS

- Presenting signs (true chief complaint, versus routine visit for preventive/annual exam) are extremely valuable in determining the importance of a patient's hyperemia.
- Intermittent/episodic hyperemia associated with behavioral changes, cardiac arrhythmias, or other systemic signs should arouse the suspicion of mast cell tumor or pheochromocytoma.

AUTHORS: LISA M. ABBOTT, ADAM J. REISS

EDITOR: ETIENNE CÔTÉ

Hypercalcemia

BASIC INFORMATION

DEFINITION

Elevation in serum calcium concentration

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Hypercalcemia can occur in dogs or cats of either gender and any age; depends on the underlying cause.
- Normal young dogs, cats <6 months old: commonly show mild, incidental hypercalcemia

GENETICS & BREED PREDISPOSITION

Depends on etiology, but there is a definite inherited predisposition for primary hyperparathyroidism in the keeshond.

RISK FACTORS

Depends on etiology

CONTAGION & ZOONOSIS

Rarely relevant. Common-source infections possible with systemic mycoses.

GEOGRAPHY AND SEASONALITY

Granulomatous diseases (systemic mycoses, schistosomiasis): specific geographic distributions

ASSOCIATED CONDITIONS & DISORDERS

Renal failure (potentially irreversible)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Polyuria/polydipsia
- Malaise: lethargy, weakness, decrease in appetite. Each is mild in dogs and cats with hypercalcemia alone. Clinical signs are more worrisome if underlying cause is a condition other than primary hyperparathyroidism.
- Other signs depend on underlying problem.
- In reviewing the most common causes of hypercalcemia, the list includes: lymphosarcoma (15%-30% of lymphoma dogs), chronic renal failure (<5% of renal failure dogs), vitamin D toxicosis, hypoadrenocorticism, apocrine gland carcinoma of the anal sac, primary hyperparathyroidism, multiple myeloma, histoplasmosis (uncommon), blastomycosis (uncommon), various other malignancies (hypercalcemia uncommon in each). In general, all these conditions in dogs are associated with worrisome clinical signs, EXCEPT those dogs with primary hyperparathyroidism.

PHYSICAL EXAM FINDINGS

- Generally reflective of the underlying cause. For example, lymphadenopathy is possible with lymphoma, other malignancies, or granulomatous/fungal disease.
- No physical finding is pathognomonic for a specific cause of hypercalcemia.
- Rectal palpation: up to 30% of anal sac adenocarcinomas are found incidentally, emphasizing the importance of rectal palpation as a routine part of physical examination of dogs.

ETIOLOGY AND PATHOPHYSIOLOGY

- Normal range of serum total calcium concentration:
  - Dog: 9.5-11.5 mg/dL (2.32-3.06 mmol/L)
  - Cat: 9.0-11.5 mg/dL (2.20-3.04 mmol/L)
- Dystrophic, soft-tissue mineralization, specifically of nephrons) is more likely to occur if the product of calcium × phosphorus concentrations (in mg/dL) >60-80.
- Approximately 50% of circulating calcium is ionized, 40% is protein bound (mostly to albumin), and 10% is bound to other molecules (lactate, citrate, etc.).
- Mechanisms of causative disorders:
  - Primary hyperparathyroidism: elevated parathyroid hormone concentrations activate osteoclastic resorption of calcium from bone, renal conservation, and intestinal absorption
  - Hypercalcemia of malignancy: neoplastic cells elaborate parathyroid hormone-related protein (PTHrP: actions similar to parathyroid hormone [PTH]).
  - Granulomatous disease: elaboration of PTHrP-like substances
  - Idiopathic hypercalcemia of cats: this condition is poorly understood. Many hypercalcemic cats have underlying lymphoma. Some mildly hypercalcemic cats are predisposed to urolith formation. If uroliths are not present, there may be no reason to treat such cats.
  - Chronic renal failure: renal secondary hyperparathyroidism
  - Vitamin D toxicosis (rodenticide or human prescription medications, e. g., calcipotriene): heightened vitamin D-mediated intestinal calcium absorption, renal calcium conservation
  - Youth: normal bone growth

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Dogs: see Etiology and Pathophysiology and comments under Clinical Presentation, above.
- In hypercalcemic cats, malignancy (30%), renal failure (25%), and urolithiasis (15%) are recognized associations, in addition to idiopathic hypercalcemia and other less common disorders such as primary hyperparathyroidism.

INITIAL DATABASE

- CBC: changes depend on underlying cause
- Serum chemistry panel:
  - Blood urea nitrogen, creatinine, phosphorus: increases common; prerenal or renal
  - Potassium: increase suggests hypoadrenocorticism, acute renal failure, rupture in urinary tract, any illness associated with significant loss of appetite, vomiting, and diarrhea. Remember, in vitro hemolysis will result in dramatic increases in serum potassium, especially in the Akita and Japanese Tosa breeds. Other artifact hyperkalemia is rare.
  - Concomitant hypophosphatemia suggests primary hyperparathyroidism, hypercalcemia of malignancy.
  - Concomitant hyperphosphatemia suggests chronic renal failure, vitamin D toxicosis, hypoadrenocorticism.
- Urinalysis:
  - Hypercalcemia as the sole abnormality (as occurs with primary hyperparathyroidism) is associated with urine specific gravity <1.020 (mean -1.011), with values as low as 1.002. Dogs with this condition usually have low-normal or low BUN, creatinine, and phosphorus (increases in any of these parameters is rare).
  - Isosthenuria with concurrent azotemia and hypercalcemia suggests renal failure, hypoadrenocorticism, or blood and urine samples drawn at different times (no conclusions possible if blood and urine are not obtained simultaneously).
  - Dilute urine (specific gravity <1.020) is commonly associated with urinary tract infection.
  - Uroliths and calcium-containing crystalluria are common in hypercalcemia
- Thoracic radiographs:
  - Metastatic disease or sternal lymphadenopathy may suggest neoplasia (rule out fungal disease, if appropriate).
  - Cranial mediastinal mass (thymic?) is common in dogs that have hypercalcemia secondary to lymphosarcoma.
  - Radiographs should be assessed for any lytic bone lesion that might be suggestive of multiple myeloma (or other metastatic cancer), as well as for any pulmonary mass or masses consistent with neoplasia.
- Abdominal imaging (ultrasound ± radiographs):
  - Lesions suggesting malignancy (lymphadenopathy, hepatosplenomegaly, possible metastases)
  - Uroliths (calcium phosphate, calcium oxalate, or both) and bladder wall thickening due to chronic infection: common in canine hyperparathyroidism
  - Assess renal structure. Renal dystrophic mineralization due to chronic severe hypercalcemia usually is not apparent radiographically or ultraso-nographically.

ADVANCED OR CONFIRMATORY TESTING

- Ionized calcium: biologically active component of serum calcium. Elevated with primary hyperparathyroidism, hypercalcemia of

malignancy, and vitamin D toxicosis, but normal or low with chronic renal failure.
- Serum PTH and PTHrP concentrations: PTH should be undetectable in response to hypercalcemia of any cause. PTH values within reference range or higher (and ionized hypercalcemia) are consistent with primary hyperparathyroidism. Undetectable PTH and detectable PTHrP consistent with hypercalcemia of malignancy (lymphoma, apocrine gland carcinoma of the anal sac).
- Serum vitamin D concentrations: if suspect rodenticide intoxication
- Cervical ultrasound: ultrasound examination of the neck by a skilled ultrasonographer often allows visualization of a mass involving one or more parathyroid gland(s) (usually 4-8 mm in greatest diameter) in dogs with primary hyperparathyroidism. Dogs with renal secondary hyperparathyroidism have enlargement of 2, 3, or all 4 parathyroid glands.
- Confirmatory testing based on abnormalities identified (e.g., fine-needle aspiration of enlarged lymph node[s])

TREATMENT

THERAPEUTIC GOAL(S)

- Rapid lowering of serum calcium concentration is NOT necessary, even with extremely increased values (15-23 mg/dL) if the product of calcium × phosphorus (in mg/dL) is <60. This is often the case in dogs with primary hyperparathyroidism, whose product is usually <45. In contrast, dogs and cats with normal serum calcium and increased serum phosphorus, as with chronic renal failure, must have the phosphorus and calcium × phosphorus decreased to avoid nephron damage and worsening renal failure.
- Successful treatment of underlying cause will decrease the serum calcium.

ACUTE GENERAL TREATMENT

- *Primary:* most efficacious:
  - IV fluid therapy (calcium free; e.g., avoid lactated Ringer's solution).
    - Dilution of serum calcium and phosphorus concentrations, improvement in renal perfusion and glomerular filtration rate
    - Rate of 100-150 mL/kg/d (twice maintenance) plus any dehydration deficit (mL replacement = % dehydration [5 to 15] × body weight [kg] × 10) should be administered over the first 24 hours assuming no heart disease, oliguria, or other factor predisposing to intolerance of volume load: adjust according to clinical signs.
  - Furosemide: 2-3 mg/kg IV q 4-8 h. Calciuric diuretic (unlike thiazide diuretics or spironolactone, which do not promote calcium excretion). Prolonged use in hypercalcemic patients with renal insufficiency is not recommended, especially if the patient is anorexic and not receiving IV fluids.
  - Glucocorticoids: prednisone 1-2 mg/kg PO q 12 h or dexamethasone 0.1-0.2 mg/kg PO q 12 h. Decrease intestinal calcium absorption, increase renal calcium excretion. Since lymphoma is common cause of hypercalcemia, and glucocorticoids can interfere with a definitive diagnosis, diagnostic samples should be obtained before (e.g., lymph node aspirates) or within a maximum of 24 hours after the first dose of prednisone (e.g., for procedures requiring general anesthesia or refenal, such as bone marrow aspirate, liver or intestinal biopsy, etc.).
- *Secondary:* generally less efficacious:
  - Calcitonin: 4-6 IU/kg SQ q 8-12 h
  - Pamidronate: 1.3 mg/kg in 150 mL 0.9% NaCl, infused over 2 hours; may repeat in 1 week

CHRONIC TREATMENT

Treatment of the inciting cause

POSSIBLE COMPLICATIONS

- Renal failure is not caused by hypercalcemia. In a recent study, dogs with hypercalcemia secondary to primary hyperparathyroidism had a significantly lower incidence of renal failure than dogs that did not have primary hyperparathyroidism.
- Overcorrection (hypocalcemia)

RECOMMENDED MONITORING

- Serum total and ionized calcium
- Renal parameters
- Serum electrolytes

PROGNOSIS AND OUTCOME

- Variable; excellent with hyperparathyroidism if treated appropriately (secondary renal failure is rare) to poor with other disorders (e.g., end-stage chronic renal failure)
- Specific prognosis depends on ability to achieve normocalcemia rapidly and correct underlying cause.

PEARLS & CONSIDERATIONS

COMMENTS

- Correcting total calcium concentration for hypoalbuminemia or hyperalbuminemia is not reliable (measure serum ionized calcium instead).
- Oral consumption of calcium (e.g., calcium carbonate) alone can virtually never cause hypercalcemia.
- The more ill a dog with hypercalcemia, the more likely it has a condition other than primary hyperparathyroidism.

AUTHOR: EDWARD C. FELDMAN

EDITOR: ETIENNE CÔTÉ

Hyperaldosteronism, Primary

BASIC INFORMATION

DEFINITION

Autonomous secretion of aldosterone by abnormal zona glomerulosa tissue within the adrenal gland(s).

SYNONYM

Conn's syndrome

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Rare disease of dogs, with increasing recognition in cats
- Older animals (>8 years)
- No sex predilection

ASSOCIATED CONDITIONS & DISORDERS

Hypokalemia; occasionally systemic hyper-tension

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Adrenal tumor
- Bilateral adrenal hyperplasia

HISTORY, CHIEF COMPLAINT

Weakness (may be episodic), lethargy, polyuria/polydipsia, stiff gait, nocturia, loss of vision

PHYSICAL EXAM FINDINGS

Generalized muscular weakness, cervi-cal ventroflexion (cats), stiff gait,

muscle pain, retinal hemorrhages and/or detachment

ETIOLOGY AND PATHOPHYSIOLOGY

- Occurs as a result of an aldosterone-secreting adrenal tumor (adenoma or adenocarcinoma) or hyperplasia of the adrenal zona glomerulosa
- Circulating hyperaldosteronemia leads to increased renal potassium excretion (causing hypokalemia) and increased renal sodium and water resorption. Renin-angiotensin production is sup-pressed.
- Clinical signs result from serum hypokalemia and associated muscle weakness, and hypertension due to extracellular fluid volume expansion.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Hyperaldosteronism should be considered in all middle-aged to older dogs and cats with hypokalemic muscle weakness and/or systemic hypertension. Abdominal ultrasonography is indicated in all cases to rule out an adrenal mass, and diagnosis of hyperaldosteronism should be confirmed using plasma aldosterone and renin concentrations.

DIFFERENTIAL DIAGNOSIS

Adrenal enlargement or mass:

- Cortisol or sex hormone–secreting adrenal tumor
- Pheochromocytoma
- Nonsecretory adrenal mass (see p. 42)

For hyperaldosteronemia:

- Secondary to renal failure, heart failure, or severe hepatic dysfunction

For severe hypokalemia:

- Hypomagnesemia
- Polyuric renal failure
- Hyperthyroidism

INITIAL DATABASE

- CBC, serum biochemical profile, urinalysis, total thyroxine (T4): severe hypokalemia (often <3 mEq/L), normal or slightly increased sodium concentration, minimally concentrated urine, normal or low T4
- Abdominal ultrasound: possible unilateral adrenal mass ± intraabdominal metastasis. Cats with primary hyperaldosteronism secondary to micronodular adrenal hyperplasia may have grossly normal adrenal glands on abdominal imaging.
- Thoracic radiographs: possible metastasis from adrenal adenocarcinoma
- Systolic arterial blood pressure: usually increased >160-180 mm Hg
- Blood gas analysis: metabolic alkalosis

ADVANCED OR CONFIRMATORY TESTING

- Plasma aldosterone concentrations (PAC): usually markedly increased
- Plasma renin concentrations (PRC): may be decreased or within the normal reference range. In theory, an increased plasma renin concentration excludes a diagnosis of primary hyperaldosteronism.
- An increased PAC : PRC ratio may be useful in establishing the diagnosis in those animals without markedly elevated aldosterone concentrations.
- CT scan can be used for detecting subtle changes within the adrenal cortex and to better delineate in the preoperative phase the extent of the adrenal mass.

TREATMENT

TREATMENT OVERVIEW

Treatment is directed at resolving clinical signs associated with hypertension and hypokalemia by normalizing serum potassium and arterial blood pressure. Surgical excision is warranted if an adrenal tumor is identified.

ACUTE GENERAL TREATMENT

- Correct hypokalemia: oral supplementation of potassium (mild hypokalemia) or intravenous administration of potassium-supplemented fluids at a rate of potassium delivery not to exceed 0.5 mEq/L/h
- Manage hypertension (see p. 1068).
- Spironolactone, an aldosterone antagonist, may be effective alone for control of both hypokalemia and systemic hypertension at a dose of 1-2 mg/kg PO q 12 h.

CHRONIC TREATMENT

Surgical excision of the adrenal tumor is recommended if there is no evidence of abdominal or thoracic metastasis. Chronic medical management with spironolactone and oral potassium supplementation can be successful at managing clinical signs if surgery is not feasible.

DRUG INTERACTIONS

Hyperkalemia can occur if spironolactone is used concurrently with other potassium-sparing diuretics or with angiotensin-converting

enzyme inhibitors.

POSSIBLE COMPLICATIONS

- The major potential complication of unilateral adrenalectomy is perioperative hemorrhage.
- There are no reports of postoperative hypoaldosteronism occurring after excision of an aldosterone-secreting adrenal tumor.

RECOMMENDED MONITORING

- Successful surgical management of primary hyperaldosteronism should result in resolution of hypokalemia and hypertension and normalization of serum aldosterone concentrations.
- If chronic medical management is un-dertaken, serial electrolyte and blood pressure monitoring is recommended.

PROGNOSIS AND OUTCOME

- There are few reported cases of primary hyperaldosteronism in dogs, and two small case series in cats.
- Prognosis is fair to guarded in cases of adrenal adenocarcinoma, as metastasis can occur. Medical management of patients with inoperable disease may achieve good short-term control of hypokalemia and systemic hypertension.
- Animals with successfully removed adenomas or adrenal hyperplasia are likely to have a good outcome.
- Data concerning survival times are limited. Reported long-term survival times in cats and dogs with surgical management range from 1-5 years. There are reports of cats surviving from 1-2.7 years with medical management alone.

PEARLS & CONSIDERATIONS

COMMENTS

- In a series of cats with primary hyperaldosteronism secondary to adrenal micronodular hyperplasia, progressive renal insufficiency was observed despite medical management of the hyperaldosteronism and was thought to be a consequence of hyperaldosteronism. Serial monitoring of renal function in these cats is recom-mended.
- Hyperaldosteronism is an important differential diagnosis for highly refractory hypokalemia.

AUTHOR: SARAH L. NAIDOO

EDITOR: SHERRI IHLE

Hyperadrenocorticism

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Syndrome caused by an excess of one or more adrenal steroids (i.e., cortisol, mineralocorticoids, adrenal androgens) but most commonly cortisol. Other causes of altered adrenal function are discussed in greater detail under their respective headings (see pp. 43, p. 6, and 551).

SYNONYMS

HAC; canine Cushing's syndrome: hypercortisolemia; Cushing's disease: hypercortisolemia secondary to excessive adrenocorticotropic hormone (ACTH) secretion from the pituitary gland

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most common in dogs. Rare in cats.
- Dogs: middle-aged/old. Rare in dogs <6 years. Slight female predisposition.
- Cats: middle-aged/old (median 10.7 years); no sex predilection

GENETICS & BREED PREDISPOSITION

Dogs:

- Pituitary-dependent hyperadrenocorticism (PDH): small breeds predominate (75% weigh <20 kg). Beagles, boxers, dachshunds, German shepherds, poodles, and terriers are overrepresented.
- Adrenal tumor hyperadrenocorticism (ATH): medium to large breeds predominate (50% weigh >20 kg), dachshunds, German shepherds, Labrador retrievers, poodles, and terriers are overrepresented.

ASSOCIATED CONDITIONS & DISORDERS

- Urinary tract infections
- Urinary calculi
- Systemic hypertension
- Diabetes mellitus
- Sudden acquired retinal degeneration
- Glomerular disease
- Pancreatitis
- Neurologic signs with pituitary macroadenoma
- Thrombosis and pulmonary thromboembolism

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- PDH: 80%-85% of cases
- ATH: 15%-20% of cases
- Iatrogenic: due to glucocorticoid administration

HISTORY, CHIEF COMPLAINT

- Dogs: possibilities include varying combinations of polyuria, polydipsia, polyphagia, pendulous abdomen, excessive bruising, panting, alopecia, clitoral hypertrophy, testicular atrophy, anestrus, weakness/lethargy, exercise intolerance, muscle atrophy, obesity.
- Cats: polyuria, polydipsia, polyphagia, pendulous abdomen, unkempt haircoat, alopecia, fragile (easily torn) skin, lethargy, muscle wasting, obesity

PHYSICAL EXAM FINDINGS

- Dogs: thin skin, bilaterally symmetric alopecia, hepatomegaly, pyoderma, abdominal enlargement, clitoral hypertrophy, testicular atrophy, bruising, muscle wasting, seborrhea, calcinosis cutis, hyperpigmentation, comedones
- Cats: pendulous abdomen, unkempt haircoat, alopecia, fragile (easily torn) skin, muscle wasting, obesity

ETIOLOGY AND PATHOPHYSIOLOGY

- PDH:
  - 80%-90% caused by a pituitary microadenoma (<10 mm in diameter).
  - Pituitary carcinomas, macroadenomas, and corticotroph hyperplasia are rare.
  - Excessive ACTH secretion from the pituitary gland stimulates the adrenal glands (zonae fasciculata and reticularis of the adrenal cortex) to produce excessive amounts of cortisol, resulting in adrenal hypertrophy.
  - The abnormal pituitary cells become less sensitive to inhibition by cortisol, continuing to secrete ACTH despite hypercortisolemia.
- ATH: see p. 43
- Iatrogenic: Exogenous corticosteroids decrease pituitary ACTH secretion (with eventual adrenocortical atrophy), but clinical signs occur as a result of hypercortisolemia.
- Cortisol/glucocorticoids interfere with antidiuretic hormone release (causing polyuria with secondary polydipsia), stimulate protein catabolism (causing muscle loss, weakness, pendulous abdomen, polyphagia), cause hypertension (and secondary proteinuria, associated with low circulating levels of antithrombin III), and compromise normal processes of the skin (causing bilaterally symmetrical alopecia, pyoderma, and/or comedone formation).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

HAC is a clinical disease encompassing overt historical signs observed by the owner, physical examination findings, and biochemical abnormalities attributable to hypercortisolemia. To avoid misdiagnosis (common error), it is essential to interpret the hypothalamic/pituitary/adrenal function tests together with the physical and clinical signs.

DIFFERENTIAL DIAGNOSIS

- See Polyuria/Polydipsia,
- See Polyphagia,
- See Alopecia,

INITIAL DATABASE

- CBC: mature neutrophilia, monocytosis, lymphopenia, eosinopenia (“stress leukogram”), thrombocytosis
- Serum biochemical profile:
  - Dog: increased alkaline phosphatase (ALP), hypercholesterolemia, hyperglycemia (usually mild)
  - Cat: hyperglycemia (80% have concurrent diabetes mellitus), hypercholesterolemia, increased alanine aminotransferase (ALT), increased ALP (30% of cases)
- Urinalysis and bacterial culture: specific gravity <1.020; proteinuria common; infection in 40%-50% of cases regardless of urine sediment
- Abdominal radiographs: hepatomegaly, cystic calculi, mineralized adrenal gland, and/or osteopenia
- Thoracic radiographs (three views): possible metastasis (if adrenal tumor), hypovascular lungs and alveolar infiltrates (secondary thromboembolism), and airway mineralization
- Blood pressure: possible hypertension
- Fundic examination: possible retinal hemorrhage

ADVANCED OR CONFIRMATORY TESTING

- To identify HAC:
  - ACTH stimulation test:
    - Will not differentiate PDH from ATH
    - Sensitivity: dogs: PDH 87%, ATH 60%; cats: 81% for both PDH and ATH
    - Specificity: 85%-90% (dogs)
      - A 15% chance of false-positive exists with chronic nonadrenal illness, so adrenal testing should be postponed if other disease is present.
    - Only test that will identify iatrogenic HAC

        - Protocol: cortisol measured in blood collected before and 1 to 2 hours after administration of exogenous ACTH. Test times vary depending on the ACTH product used and laboratory (see p. 548 for general guidelines).
            - A poststimulation cortisol concentration greater than 25 mg/dL (690 mmol/L) is suspicious for HAC; >30 mg/dL (830 mmol/L) is usually diagnostic for HAC.
    - Low-dose dexamethasone suppression test (LDDS):
        - Can confirm HAC and in some cases discriminate between PDH and ATH
        - Sensitivity: dogs: 85%-95%; cats: 80%
        - Specificity 70%-75% (dogs)
        - A 50% chance of false-positive results with nonadrenal illness, so adrenal testing should be postponed if other disease is present.
        - Protocol:
            - Dogs: cortisol measured in blood collected before and 4 and 8 hours after administration of dexamethasone (0.01 mg/kg IV).
                - Normal: suppression of serum cortisol concentration (<1.4 mg/dL (40 mmol/L) at both 4 and 8 hours
                - Dogs with HAC: inadequate cortisol suppression (cortisol >1.4 mg/dL [40 mmol/L]) at 8 hours
                    - Dogs with ATH: inadequate cortisol suppression at either time point
                    - Dogs with PDH: 35% will not suppress at either time point; 65% will show one of three patterns of suppression:
                        - 8-hour cortisol concentration > reference range but <50% of basal value
                        - 4-hour cortisol concentration <50% of basal value or <reference range; 8-hour cortisol >1.4 mg/dL (40 mmol/L)
                        - 4-hour cortisol concentration <1.4 mg/dL, 8-hour cortisol >1.4 mg/dL (40 mmol/L)
            - Cats: protocol as for dogs except the dexamethasone dose is 0.1 mg/kg IV.
                - Between 65% and 90% of cats with PDH and 100% of ATH have inadequate cortisol suppression at this dose.
    - Low-dose dexamethasone test using oral dexamethasone:
        - Protocol, dog:
            - Owners collect urine from their dog on two consecutive mornings (8:00 am) for determination of baseline cortisol/creatinine ratios.
            - Immediately after collection of the second urine sample, owners administer dexamethasone (tablet form) 0.01 mg/kg PO.
            - Owners walk dog at 12:00 pm and 2:00 pm to ensure bladder emptying.
            - Owners collect a third urine sample for measurement of cortisol/creatinine ratio at 4:00 pm (8 hours after oral administration of dexamethasone).
            - Interpretation: a 50% suppression in the mean urinary cortisol/creatinine ratio is consistent with a normal response. Dogs with HAC would be expected to fail to show adequate suppression of the urine cortisol/creatinine 8 hours following oral dexamethasone administration.
    - Urine cortisol/creatinine ratio:
        - Between 90% and 100% sensitive for both dogs and cats; <10%-15% chance of dog having HAC if ratio is normal. False-positive results very common (75% of dogs with nonadrenal illness have ratio consistent with HAC).
        - Protocol: owner collects morning urine (at home), which is submitted for cortisol and creatinine measurement.
- To differentiate PDH from ATH once a diagnosis of HAC has been established:
    - In some cases, the LDDS results will identify PDH (see above).
        - High-dose dexamethasone suppression test (HDDS): often not performed if test results are consistent with HAC and an adrenal mass is present on ultrasound.
        - Protocol: cortisol measured in blood collected before and 4 and 8 hours after administration of dexamethasone (dogs: 0.1 mg/kg IV; cats: 1 mg/kg IV).
            - Dogs with PDH: suppression of cortisol concentrations (<50% of basal concentrations or <1.4 mg/dL [40 mmol/L]) at 4 or 8 hours. However, 24%-35% of dogs with PDH fail to suppress HDDS and need a further discriminating test.
            - Dogs with ATH: inadequate suppression, although random fluctuations in cortisol concentrations can be seen. Partial or unclear result warrants other test (e.g., ultrasonography).
    - Endogenous ACTH concentrations: (rarely assessed)
        - Low in dogs with ATH and high in dogs with PDH.
        - ACTH is very labile in plasma, and the hormone degrades rapidly if not handled correctly (risk of non-diagnostic result).
    - Abdominal ultrasonography: normal adrenal thickness: 3-7.5 mm
        - PDH: bilaterally symmetric enlargement of the adrenal glands; 5%-10% will have nodular hyperplasia.
        - ATH: unilateral adrenal enlargement with a small contralateral adrenal
    - CT or MRI: used for pituitary imaging (pituitary macroadenoma) or abdominal imaging (adrenal size, tumor invasion),

typically when central nervous system (CNS) deficits coexist with signs and test results indicating HAC.
    - Desmopressin stimulation test: preliminary results with this test are promising for the ability to differentiate PDH from ATH.

TREATMENT

TREATMENT OVERVIEW

- Resolution of clinical signs
- For medical therapy: cortisol concentrations within the basal reference range on both the pre- and post-ACTH stimulation samples

ACUTE GENERAL TREATMENT

By definition, hyperadrenocorticism is a chronic, slowly progressive disease. Therefore acute treatment is not indicated.

CHRONIC TREATMENT

- Medical therapy: mitotane, trilostane, ketoconazole, L-deprenyl:
    - Mitotane (o, p'-DDD, Lysodren):
        - Selectively destroys glucocorticoid-producing zones of the adrenal gland
        - Protocol:
            - PDH:
                - See treatment algorithm,
                - The owner should always have prednisone (0.2 mg/kg PO q 24 h) available for administration to the pet at home if needed.
            - ATH: see p. 43
        - Adverse effects: vomiting, hypocortisolism, complete hypoadrenocorticism (uncommon).
- Ketoconazole:
    - Inhibits adrenal synthesis of cortisol
    - Protocol: See treatment algorithm, .
    - Only effective in 50% of PDH and ATH cases
    - May be used short term to control signs of HAC before surgery for ATH
    - Adverse effects: anorexia, vomiting, diarrhea, lethargy, hepatopathy
- Trilostane (Vetoryl):
    - Inhibits cortisol synthesis
    - Dogs with PDH:
        - Protocol: See treatment algorithm, .
        - By the end of 6 months, doses can range from 4-16 mg/kg/d.
        - Some dogs require q 12 h therapy.
    - Adverse effects: hypocortisolism
- L-deprenyl (selegiline, Anipryl):
    - Decreases ACTH secretion by increasing dopaminergic tone to the hypothalamic-pituitary axis
    - Initial reports by Deprenyl Animal Health Inc. showed 75%-80% efficacy, but two independent studies showed poor efficacy.
    - Protocol: See treatment algorithm,
    - If no response is seen after 2-3 months, the diagnosis of hyperadrenocorticism should be reassessed; if confirmed, another treatment should be used.
- Medical treatment is inconsistent in cats. Mitotane, ketoconazole, and trilostane (30-60 mg/cat/d) are reported to have mixed results, but information is limited. Metyrapone (65 mg/kg PO q 12 h) and aminoglutethimide (6 mg/kg PO q 12 h) have also been tried.
- Surgical therapy:
    - Hypophysectomy has been described in both dogs and cats but is not widely available.
    - Bilateral adrenalectomy is the treatment of choice for PDH in cats.
    - Unilateral adrenalectomy is the treatment of choice for adrenal neoplasia in dogs and cats.
- Radiation therapy (cobalt teletherapy or linear accelerator) for pituitary macroadenomas

DRUG INTERACTIONS

- Mitotane: increases barbiturate and warfarin metabolism; additive depressive effects with CNS depressants; insulin requirements in diabetic dogs may decrease; spironolactone may block mitotane's actions.
- Ketoconazole: antacids and H2 bockers may decrease absorption; decreases theophylline and increases cyclosporine

concentrations; increases anticoagulant effects of warfarin.
- L-deprenyl: interacts with selective serotonin reuptake inhibitors, tricyclic antidepressants, meperidine.
- Trilostane: avoid concurrent use of other treatments for HAC.

POSSIBLE COMPLICATIONS

- Medical treatment: see adverse effects listed after each drug in Chronic Treatment above.
- Adrenalectomy: see p. 43

RECOMMENDED MONITORING

- See Chronic Treatment above and algorithm for treatment of hyperadrenocorticism, .
- At home: owner monitors clinical signs; treated patients may require short-term prednisone supplementation (0.2 mg/kg/d) during stressful situations.

PROGNOSIS AND OUTCOME

Dogs:

- PDH: mitotane therapy—median survival 23 months; average, 30 months,
- PDH: trilostane therapy—median survival 22 months
- PDH: ketoconazole therapy—median survival 25 months; range 2-61 months
- ATH: see p. 43

PEARLS & CONSIDERATIONS

COMMENTS

- For all endocrine tests, it is useful to consult the reference laboratory concerning specific test protocols and guidelines for interpretation.
- LDDS test requires very small volumes of dexamethasone; measure carefully and/or dilute for accurate dosing.
- Before medical therapy and during induction therapy, the owner must quantify water and food intake.
- No dog with a decreased appetite should receive mitotane.
- During induction therapy, have the owner feed one-third the normal food intake twice a day so that any reduction in appetite is obvious.
- Mitotane should be given after the dog's meal to enhance absorption and to confirm that all food is eaten.
- Never initiate antiadrenal therapy in hospital, as food and water intake is usually reduced.
- Daily phone contact with owners is recommended during induction therapy.

TECHNICIAN TIPS

- All dogs and cats having cortisol testing must be kept in a quiet, stress-free environment.
- Ensure samples for cortisol testing are not hemolyzed.

CLIENT EDUCATION

Clients must be educated as to the risks of medical therapy and be able to recognize clinical signs of hypoadrenocorticism.

EDITOR: SHERRI IHLE

Hyperadrenocorticism Suspect/Conflicting Results

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Some of the clinical signs of hyperadrenocorticism (Cushing's disease) are present and/or biochemical test results are suggestive of hyperadrenocorticism, but there are conflicting results with other clinical features or with cortisol testing.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Middle-aged or older dogs

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

One clinical sign (e.g., polyuria/polydipsia, endocrine alopecia, systemic hypertension), one biochemical abnormality (e.g., increased alkaline phosphatase concentration, proteinuria), or one other finding (e.g., vacuolar hepatopathy on biopsy) suggests hyperadrenocorticism, but other results are normal or contradictory.

HISTORY, CHIEF COMPLAINT

- The absence of any overt clinical signs of hyperadrenocorticism makes the diagnosis of hyperadrenocorticism extremely unlikely. Specifically, a dog showing no polyuria, no polydipsia, and no polyphagia almost certainly does not have hyperadrenocorticism.
    - Example: If hyperadrenocorticism is suspected only because of incidentally discovered elevated liver value(s) on a preanesthetic screen, a disease process other than hyperadrenocorticism is almost always the cause of the liver value elevation.
- If anorexia, vomiting, and/or diarrhea are present, a diagnosis other than hyperadrenocorticism is likely (exception: if undergoing treatment with o, p'-DDD).
- Polyphagia, one of the common signs of hyperadrenocorticism, also is very common in healthy, gluttonous dogs. The history therefore should assess whether appetite has increased in the preceding weeks to months despite no change in diet (more consistent with hyperadrenocorticism) or has always been voracious.
- Panting, which is noted in dogs with hyperadrenocorticism, is a common chief complaint in dogs with many disorders that occur more commonly than hyperadrenocorticism, including obesity, hyperthermia, anxiety, pain, and acid-base disorders.
- Seasonal, anxiety-related, or other environmental changes commonly increase water consumption in dogs, without producing true polydipsia. Normal daily water consumption: <70 mL/kg/d (dogs; higher in dogs <4 kg), <250 mL/d (average-size cat).
- Dogs first presented for evaluation of critical, severe clinical signs virtually never have hyperadrenocorticism (exception: severe complications of hyperadrenocorticism treatment or pulmonary thromboembolism).

PHYSICAL EXAM FINDINGS

- “Textbook” hyperadrenocorticism appearance (potbellied, thin-skinned, symmetrically alopecic dog with comedones) is not present in all patients with hyperadrenocorticism.
- Similarly, these typical features may be found in patients with diseases other than hyperadrenocorticism (see p. 6).
- Therefore, suggestive physical findings should be correlated to history, and if hyperadrenocorticism remains likely, testing to evaluate both hyperadrenocorticism and aberrant adrenocortical disease (see pp. 548 and p. 6) may be warranted.

ETIOLOGY AND PATHOPHYSIOLOGY

- Hyperadrenocorticism is a slowly progressive disease that produces clinical signs gradually and chronically.
- The prevalence of complications such as thromboembolic disease and systemic hypertension prior to the onset of overt clinical signs (polyuria/polydipsia, polyphagia) is not known.
- Other endocrine disorders, particularly aberrant adrenocortical disease may clinically mimic hyperadrenocorticism, so the diagnosis of hyperadrenocorticism and the decision to treat cannot be based on a single abnormality (be it historic, physical, or biochemical) alone.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Depends on the clinical signs and biochemical abnormalities seen:

- Polyuria/polydipsia (see p. 902)
- Polyphagia (see p. 899)
- Alopecia (see p. 58)
- Proteinuria (see pp. 926, p. 450, and p. 61) secondary to other systemic disease
- Hypertension (see p. 1068)
- Alkaline phosphatase elevation (see p. 1444)

INITIAL DATABASE

- Revisit a detailed history and physical examination to identify any previously missed signs or findings that would support hyperadrenocorticism or another disorder.
- CBC, serum biochemistry, urinalysis with urine culture, systemic blood pressure, fundic examination (see p. 548)

ADVANCED OR CONFIRMATORY TESTING

- Adrenocorticotropic hormone (ACTH) stimulation test with adrenal sex hormone panel (see p. 6)
  - ACTH stimulation test is abnormal in 60%-87% of dogs with hyperadrenocorticism.
- Low-dose dexamethasone suppression test (see p. 548).
  - Abnormal in 85%-95% of dogs with hyperadrenocorticism, provided dogs with signs of systemic illness such as anorexia or gastrointestinal signs are not tested (systemic illness falsifies results and precludes treatment for hyperadrenocorticism anyway).
- Urine cortisol/creatinine ratio (see p. 548)
  - Highly sensitive (90%-100% of dogs with hyperadrenocorticism have elevated result, and normal result means <15% likelihood of hyperadrenocorticism) but poorly specific (many other disorders elevate results).
- Abdominal ultrasound: see p. 548 for findings supportive of hyperadrenocorticism; with nonadrenal disease, findings will vary with the primary disease.
- Urine protein/creatinine ratio if proteinuria is present and urine culture is negative. Commonly elevated in hyperadrenocorticism.

TREATMENT

TREATMENT OVERVIEW

- Hyperadrenocorticism is a disease characterized by overt physical manifestations. Therefore:
  - Treatment for hyperadrenocorticism should ONLY be instituted when clinical signs consistent with the disease are present and should not be based solely on laboratory test results. None of the tests of the hypothalamic-pituitary-adrenal axis has 100% sensitivity or specificity, and all available information needs to be critically evaluated.
  - If cortisol testing is suggestive of hyperadrenocorticism but there are no clinical signs associated with the disease, either look for other underlying illnesses that could result in increased cortisol concentrations or have the owner monitor for signs of hyperadrenocorticism (e.g., increased water intake, polyphagia).
- Aberrant adrenocortical disease explains some cases of physically “typical” hyperadrenocorticism in which cortisol response is normal.
- If nonadrenal disease is identified, it should be treated and possible hyperadrenocorticism reassessed at a later time if clinical signs persist.

ACUTE GENERAL TREATMENT

- Virtually by definition, hyperadrenocorticism does not warrant acute treatment. Patients in whom the diagnosis is unclear may benefit from watchful waiting, given the potential negative effects of adrenal suppression (see p. 548).
- Proteinuria (see p. 926)
- Hypertension (see p. 1068)

CHRONIC TREATMENT

Treat for hyperadrenocorticism (see p. 548) if history, physical exam, and diagnostic testing together support the diagnosis

POSSIBLE COMPLICATIONS

Hypocortisolism, or full hypoadrenocorticism, if hyperadrenocorticism is mistakenly diagnosed and treated

RECOMMENDED MONITORING

- Home: owner to monitor clinical signs (e.g., polyuria/polydipsia, polyphagia)
- In-hospital:
  - Reevaluate a physical examination, history, and serum biochemical profile ± urinalysis and systolic blood pressure q 2-3 months to identify any new signs or abnormalities.
  - If proteinuria: assess UP: UC q 2-3 months.
- If/when clinical signs of hyperadrenocorticism develop, repeat a CBC, serum biochemical profile, urinalysis (±urine culture), and cortisol testing prior to instituting treatment.

PROGNOSIS AND OUTCOME

Dependent on the disease present

PEARLS & CONSIDERATIONS

COMMENTS

Because of the number of different combinations of signs and test results that can be seen, these can be challenging cases. Controversy exists even among specialists as to exactly which patients should be treated and when.

AUTHOR: KATE HILL

EDITOR: SHERRI IHLE

Hydronephrosis

BASIC INFORMATION

DEFINITION

Dilation of the renal pelvis and calices (pyelectasia) in one or both kidneys, typically as a result of ureteral (or rarely urethral) obstruction, resulting in atrophy of the renal parenchyma.

EPIDEMIOLOGY

SPECIES, AGE, SEX

More common in dogs than cats; no age or sex predilection

RISK FACTORS

Any cause of ureteral (or urethral) obstruction, whether mechanical or functional:

- Bladder atonia/hypotonia
- Blood clots
- Celiotomy (inadvertent ligation or fibrotic entrapment of ureter)
- Congenital ureteral stenosis or stricture
- Ectopic ureter (common cause)
- Prostatic carcinoma
- Reflex dyssynergia
- Retroperitoneal mass/fibrosis/infarction
- Trauma
- Ureteral fibroepithelial polyps
- Urinary tract neoplasia
- Urolithiasis

ASSOCIATED CONDITIONS & DISORDERS

- Renal failure +/− uremia
- Hypertension
- Urinary tract infection

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Reversible or irreversible
- Unilateral or bilateral

HISTORY, CHIEF COMPLAINT

Often clinically normal. Signs can include:

- Vague abdominal pain associated with renomegaly
- Polydipsia/polyuria associated with chronic kidney disease
- Anorexia and vomiting associated with uremia
- Pollakiuria, stranguria, dysuria, hematuria possible
- Urinary incontinence (if hydronephrosis due to ectopic ureter)
- Oliguria or anuria (urethral obstruction or, rarely, bilateral ureteral obstruction)

PHYSICAL EXAM FINDINGS

Often normal. Abnormalities may include:

- Abdominal discomfort (severity related to rate of onset of obstruction rather than degree of obstruction)
- Renomegaly
- Distended bladder (if urethral obstruction)
- Abdominal mass (kidney, bladder, prostate, granuloma)
- Urethral mass (via rectal palpation)
- Prostatomegaly
- Dehydration
- Halitosis (due to uremia)
- Oral ulcerations (due to uremia)

ETIOLOGY AND PATHOPHYSIOLOGY

- Illness varies depending on whether obstruction is unilateral or bilateral, completeness and duration of obstruction, and preexisting renal function.
- Clinical signs can be absent, chronic, or acute; acute signs are more likely when obstruction is complete.
- Obstruction results in increased hydrostatic pressure in renal pelvis, collecting ducts, and distal tubules causing tubular dilatation with flattening of the tubular cells.
- Concurrently, renal vasculature and blood supply are compromised. Renal blood flow progressively decreases, arterioles constrict, capillary pressure decreases, and many arterioles collapse resulting in parenchymal atrophy.
- Changes may become irreversible after 14-45 days.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Hydronephrosis is usually diagnosed via renal imaging studies, including ultrasound or contrast studies, in conjunction with recognition of a functional or physical reason for urinary obstruction.

DIFFERENTIAL DIAGNOSIS

- Pyelectasia: pyelonephritis, iatrogenic fluid diuresis (mild)
- Renomegaly: renal cyst(s), perinephric pseudocyst, neoplasia (e.g., renal adenocarcinoma, lymphoma), amyloidosis, granuloma, perinephric abscess, feline infectious peritonitis, hematoma, compensatory hypertrophy (unilateral)

INITIAL DATABASE

- Digital rectal examination: lesions of the urethra and bladder trigone may cause hydronephrosis.
- Urethral catheterization: can rule out or confirm urethral obstruction from urolithiasis
- CBC: unremarkable; neutrophilia possible if concurrent pyelonephritis
- Serum biochemical profile: depending on degree of obstruction and/or nephron loss, azotemia, hyperphosphatemia, hyperkalemia, metabolic acidosis, increased anion gap
- Urinalysis: isosthenuria (e.g., if *>66%* nephron loss), sometimes hematuria, pyuria
- Urine culture and sensitivity (C&S) to rule out infection
- Blood pressure to rule out hypertension
- Abdominal radiographs: often renomegaly; additional findings may include
  - Urolithiasis
  - Urinary bladder distension
  - Prostatomegaly
  - Abdominal mass effect
  - Loss of contrast in retroperitoneal space
  - Loss of abdominal detail
- Abdominal ultrasound: pyelectasia; additional findings may include
  - Renomegaly
  - Loss of medullary parenchyma
  - Hydroureter
  - Uroliths
  - Masses in ureter, bladder, prostate, or urethra

ADVANCED OR CONFIRMATORY TESTING

- Additional testing is not always required or beneficial.
- Excretory urography (EU)/intravenous pyelography (IVP) (see p. 1265) to assess perfusion of each kidney; percutaneous

nephropyelography to assess structure of renal pelvis and ureter
  - Pyelectasia
  - Ureteral dilatation or lack of filling (EU only)
  - May identify ectopic ureter
- Renal scintigraphy or CT with contrast
  - Affected kidney contributes little to glomerular filtration rate.
- Other testing is aimed at characterizing underlying cause of hydronephrosis (e.g., quantitative analysis of uroliths, imaging studies to localize neurologic lesions contributing to reflex dyssynergia, cystoscopy for bladder abnormalities or ectopic ureter).

TREATMENT

TREATMENT OVERVIEW

Hydronephrosis has no specific treatment. Instead, obstruction of urine flow should be corrected when possible and complications of renal failure addressed.

ACUTE GENERAL TREATMENT

- Relieve urinary obstruction (see pp. 1131 and p. 1129)
- Crystalloid fluid therapy for azotemia (see pp. 31 and p. 207):
  - Initial rate of 120 mL/kg IV q 24 h if no concurrent heart disease, hypoalbuminemia, or vasculitis; adjust as needed based on degree of dehydration/hypovolemia
  - Postobstructive diuresis may require “ins-and-outs” method of fluid therapy (rate adjustments based on measured urine output)
- Analgesia for abdominal pain (e.g., buprenorphine, 0.01 mg/kg IM, IV, or SQ q 6-8 h)
- Address electrolyte disorders, acidosis
- Address uremia (see pp. 31 and p. 207)

CHRONIC TREATMENT

- Antibiotics if indicated by results of urine C&S:
  - If infection cannot be cured medically, nephrectomy may be indicated to remove infected, poorly functioning kidney if function of contralateral kidney is adequate.
- Address underlying cause of structural or functional urinary obstruction (e.g., therapeutic or prophylactic/dietary measures for urolithiasis, pharmacologic therapy of bladder atonia, reflex dyssynergia)

POSSIBLE COMPLICATIONS

- Renal failure
- Urinary tract infection
- Urinary rupture and uroabdomen (septic peritonitis if urinary tract is infected)

RECOMMENDED MONITORING

- Ultrasound is repeated several weeks after urinary obstruction relieved. If hydronephrosis persists after 6 weeks, changes are likely to be permanent.
- Animals with permanent hydronephrosis are monitored as for chronic kidney disease (see pp. 205 and p. 207) with periodic urinalysis and culture, assessment of azotemia, electrolytes, and packed cell volume. Azotemic animals are monitored more intensively than nonazotemic animals.

PROGNOSIS AND OUTCOME

- Dependent on extent of renal damage, underlying cause and resolution of cause, duration, and concurrent infection. Hydronephrosis can be associated with severe renal failure or may be an incidental finding.
- Structural kidney changes may be irreversible.

PEARLS & CONSIDERATIONS

COMMENTS

- Hydronephrosis is a consequence of obstructive urinary tract disease rather than a primary disease.
- Hydronephrosis can lead to renal failure or may be manifest only as subclinical pyelectasia.

PREVENTION

Strategies that limit the formation of uroliths are important for patients that have already demonstrated a predisposition to urolithiasis or those with known risk factors.

CLIENT EDUCATION

Urinary tract obstruction is life threatening. Stranguria or signs of systemic illness should prompt immediate veterinary attention.

Hydrocephalus

BASIC INFORMATION

DEFINITION

An increase in volume of cerebrospinal fluid (CSF) within the ventricular system of the brain that causes signs of encephalopathy

EPIDEMIOLOGY

SPECIES, AGE, SEX

Congenital: dog, cat <6 months old. Acquired: any.

GENETICS & BREED PREDISPOSITION

- Toy breeds: Chihuahua, toy poodle, Pomeranian, Lhasa apso, pug, Pekingese, and Cairn, Yorkshire, Manchester, and Maltese terriers
- Brachycephalic breeds: Boston terrier, bulldog
- Autosomal-recessive inheritance in Siamese cats

RISK FACTORS

- Often represents a secondary manifestation of a developmental (Chiari malformation) or an acquired (neoplasia, inflammatory) disorder
- Vitamin A deficiency, toxicosis (cats: griseofulvin during pregnancy); infectious (cats: panleukopenia, feline infectious peritonitis; dogs: parainfluenza)

ASSOCIATED CONDITIONS & DISORDERS

Small birth size, short gestation periods, high stress at birth (dystocia)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Congenital: animal is born with clinical signs; usually associated with fusion of mesencephalic aqueduct.
- Acquired: caused by obstructive insults at any age (i.e., infection, trauma, neoplasia)

HISTORY, CHIEF COMPLAINT

- Changes in mentation: dullness, disorientation, stupor
- Behavioral abnormalities: inability to learn (e.g., litter box use), loss of housebreaking, compulsive activities, aggression
- Seizures

PHYSICAL EXAM FINDINGS

- Domed-shaped head and persistent fontanelle are possible
- Eye position typically will manifest ventrolateral deviation
- Neurologic examination: mentation changes; gait abnormalities may manifest as dysmetria, ataxia, circling, aimless wandering; central blindness; and seizure activity

ETIOLOGY AND PATHOPHYSIOLOGY

- Pathologic changes include focal destruction of the ependymal lining, compromise of cerebral vasculature, damage to periventricular white matter, and injury to neurons.
- Secondary calvarial abnormalities depend on the stage of ossification at onset of fluid accumulation.
- Ventriculomegaly results from obstruction within the ventricular system, overproduction of CSF, or insufficient absorption of CSF at the arachnoid villi.

- Congenital:
  - Fusion of the rostral colliculi, causing mesencephalic aqueductal stenosis. There is no other active disease process.
- Acquired:
  - Exposure to teratogenic drugs, chemicals, and viral diseases during gestation
  - Obstruction of ventricular system by neoplastic mass, hemorrhage, or inflammation
  - Hydrocephalus also may be a component of other anomalous disorders (i.e., Chiari malformation, Dandy-Walker syndrome, lissencephaly).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected based on the physical examination and signalment. Confirmation comes from diagnostic imaging (beginning with ultrasound and proceeding to CT/MRI if needed) and procedures assisting with determining underlying causes.

DIFFERENTIAL DIAGNOSIS

- Hydrocephalus usually will manifest signs of forebrain dysfunction.
- Encephalopathies:
  - Degenerative disorders: storage diseases, leukodystrophies, multisystem atrophy
  - Anomalies (congenital): malformations (e.g. caudal occipital malformation syndrome, Dandy-Walker syndrome, hydranencephaly)
  - Metabolic: hepatic encephalopathy, organic acid disorders
  - Neoplasia: causes secondary obstructive hydrocephalus
  - Inflammatory: infectious (feline panleukopenia, feline infectious peritonitis, parainfluenza, canine distemper), noninfectious (breed specific, meningoencephalomyelitis of unknown etiology)
  - Idiopathic: arachnoidal cysts
  - Trauma: hydrocephalus ex vacuo occurs with destruction of brain tissue (e.g., cerebrovascular accidents)
  - Toxin exposure: griseofulvin

INITIAL DATABASE

- Signalment
- Neurologic examination (see p. 1311)
- CBC, serum biochemistry profile, urinalysis: generally unremarkable
- Serologic titers: to rule out infectious causes if appropriate
- Skull radiography: decreased prominence of normal calvarial convolutions

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonography: through persistent fontanelles
- Advanced imaging: to confirm hydrocephalus but also rule out other contributing disorders and differentials that would mimic disease
  - CT: visualization of lateral ventricles
  - MRI: visualization of the ventricular system and the brain parenchyma
- CSF analysis: to rule out other disorders if appropriate
- Electroencephalography

TREATMENT

TREATMENT OVERVIEW

The treatment of hydrocephalus is guided by the underlying cause. Medical therapy offers temporary palliation of clinical signs. Surgical management using shunting procedures may offer a more permanent remedy.

ACUTE AND CHRONIC TREATMENT

- Medical:
  - Prednisone (↓ CSF production):
    - 0.25-0.5 mg/kg PO q 12-24 h, then tapered to lowest effective dose

- Furosemide (↓ CSF production; Na-K cotransport inhibition):
  - 0.5-2 mg/kg PO q 12-24 h
- Acetazolamide (↓ CSF production; carbonic anhydrase inhibition):
  - 10 mg/kg PO q 8 h
- Omeprazole (↓ CSF production; proton pump inhibition):
  - 0.7 mg/kg PO q 24 h
  - 10 mg q 24 h for dogs weighing <20 kg or 20 mg q 24 h for dogs weighing >20 kg
- Antiepileptic drug therapy for seizure control

- Surgical: advocated if clinical signs do not improve within 2-3 weeks:
  - Ventriculoperitoneal shunt
  - Ventriculoatrial shunt

DRUG INTERACTIONS

Prolonged use of glucocorticoids and acetazolamide may cause potassium depletion and other systemic disorders.

POSSIBLE COMPLICATIONS

- Generally, medical therapy may result in only transient improvement of clinical signs.
- Complications of shunt placement include mechanical and functional obstruction, infections, overshunting.

RECOMMENDED MONITORING

- Signs of acute decompensation: coma, seizures, behavior changes
- Seizure control

PROGNOSIS AND OUTCOME

- Congenital: guarded. Prognosis also is influenced by coexistence of other neural abnormalities.
- Acquired: prognosis depends on underlying cause.

PEARLS & CONSIDERATIONS

COMMENTS

- Every attempt is made to determine the underlying cause.
- Early shunt placement is advocated to lessen residual neurologic deficits and behavior abnormalities.

PREVENTION

Limit prenatal exposure to toxins, viral infections, and vaccines.

TECHNICIAN TIPS

- Avoid excessive holding and compression of the external jugular veins in these patients (can increase intracranial pressure).
- The owners need to be counseled on monitoring for gastrointestinal ulceration if the animal is being treated with glucocorticoids.
- After surgery for shunt placement, the skin over the shunt will need to be monitored for signs of pressure necrosis, especially in small-breed dogs with tendency for thin skin.

CLIENT EDUCATION

- Clinical signs of acute decompensation
- Guarded prognosis and likelihood of residual neurologic deficits with therapy
- Importance of maintaining the pet in a protective environment

EDITOR: CURTIS W. DEWEY

Horner's Syndrome

BASIC INFORMATION

DEFINITION

Manifestations of loss of sympathetic innervation to the eye. Signs are miosis (small pupil), ptosis (dropped upper eyelid, causing a smaller palpebral fissure), enophthalmos, and protrusion of the third eyelid.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats of any age and either sex

GENETICS & BREED PREDISPOSITION

Male golden retrievers may be overrepresented (of 155 dogs with Horner's syndrome in one study, 110 were golden retrievers; idiopathic Horner's syndrome was present in 100 of them, 95 were male).

HORNER'S SYNDROME Right-sided Horner's syndrome in a 9-year-old pointer-cross dog. Note right-sided ptosis, miosis, and protruding third eyelid caused by enophthalmos. The hematocrit was 75%, and pathologic proteinuria was present, leading to a suspicion of thromboembolic disease as the cause of the Horner's syndrome.

Modified from Collins BK, O'Brien D: Autonomic dysfunction of the eye. Semin Vet Med Surg Small Anim 5:24–36, 1990. Reprinted with permission.

FCE, Fibrocartilaginous emboli; *LMN,* lower motor neuron; *UMN,* upper motor neuron.*Most common.

Localizing Lesions in Horner's Syndrome

Location	Common Etiologies	Neuron Affected	Commonly Associated Signs
Brainstem	Neoplasia,* trauma, infection	UMN	Altered consciousness, thermoregulation, endocrine function, appetite, drinking, cranial nerve deficits, motor deficits, dyspnea

Location	Common Etiologies	Neuron Affected	Commonly Associated Signs
Cervical spinal cord	Trauma, neoplasia, FCE	UMN	Tetraparesis/plegia, hemiparesis/plegia, UMN signs in all four limbs if cranial lesion, LMN signs in thoracic limbs with UMN signs in pelvic limbs if caudal cervical lesion
T1-T3 spinal cord	Trauma,* neoplasia,* FCE	UMN	Thoracic limb paresis/paralysis with LMN thoracic limb signs, pelvic limb paresis/paralysis with UMN thoracic limb signs
T1-T3 ventral nerve roots	Brachial plexus avulsion,* neurofibroma	Preganglionic	Brachial plexus paresis/paralysis of ipsilateral limb
Cranial thoracic sympathetic trunk	Lymphoma, neurofibroma, thoracic disease	Preganglionic	Respiratory distress; no other signs if confined to trunk
Cervical sympathetic trunk	Trauma, iatrogenic, neoplasia	Preganglionic	May be none if unilateral; may interfere with laryngeal or esophageal function from vagal involvement
Middle ear	Otitis media,* neoplasia	Postganglionic	Head tilt, nystagmus, and/or facial paralysis
Cavernous sinus	Neoplasia, vascular disease	Postganglionic	Internal, external, or complete ophthalmoplegia (may produce mydriasis rather than miosis)
Orbital disease	Abscess, neoplasia, contusion, pseudotumor	Postganglionic	Exophthalmos, discomfort, optic nerve or oculomotor deficits

RISK FACTORS

Blunt trauma (e.g., hit by car), other cervical/thoracic spinal cord damage (fibrocartilaginous embolization, intervertebral disk disease) or infiltration (lymphoma), surgical trauma or neoplastic infiltration of the neck (affecting the sympathetic trunk), intracranial neoplasia, otitis media or other middle ear lesions, retrobulbar inflammation or mass

ASSOCIATED CONDITIONS & DISORDERS

Exposure keratitis. The inability to blink normally is mostly compensated for by the third eyelid, but a band of desiccated cornea may occur across the central cornea (lagophthalmos). Keratoconjunctivitis sicca and facial neuropathies have also been associated with Horner's syndrome.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Signs referable to the underlying cause
- Trauma (e.g., hit by car) to the head, neck, chest or brachial plexus is the most common historically identifiable cause in dogs and cats, followed by history of a recent or current ear infection.
- Ocular signs observed by the owner

PHYSICAL EXAM FINDINGS

- Enophthalmos (retracted/sunken globe)
- Ptosis
- Miosis
- Third eyelid protrusion
- Other associated signs may be present, depending on the location of the inciting lesion (see table).

ETIOLOGY AND PATHOPHYSIOLOGY

- Interference with the sympathetic innervation to the eye: brainstem. → cervical spinal cord → T1-T3 spinal cord segments → thoracic sympathetic truck → vagosympathetic trunk → cranial cervical ganglion (synapse; lesion preceding this point is preganglionic or UMN/central, and lesion after this point is postganglionic) → middle ear → ophthalmic branch of the trigeminal nerve → orbit → orbitalis muscle, ciliaris muscle, and smooth muscle of the pupil (see table)
- An immune-mediated mechanism has been speculated as a possible cause for idiopathic Horner's syndrome.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History and physical/neurologic examination are generally sufficient for differentiation.

DIFFERENTIAL DIAGNOSIS

Ocular trauma causing miosis (uveitis)

- Phthisis bulbi causing protrusion of the third eyelid and a small palpebral fissure
- Hypothyroidism

INITIAL DATABASE

- Minimum database
- Otoscopic examination
- Thoracic and cervical radiographs

ADVANCED OR CONFIRMATORY TESTING

- Thyroid testing
- MRI of brain and cervical spine
- Pharmacologic testing. Suggested protocol:
    - Topical 10% phenylephrine solution: 1 drop applied to affected eye
    - Mydriasis occurs in <20 minutes when lesion is postganglionic.
    - Mydriasis occurs in 20-45 minutes when lesion is preganglionic.
    - Mydriasis occurs in >45 minutes when lesion is central/UMN.
    - Results have been inconsistent; reliability of test is controversial.

TREATMENT

TREATMENT OVERVIEW

Horner's syndrome is not treated; it is a sign that may indicate an underlying lesion that may require treatment.

ACUTE GENERAL TREATMENT

Treat underlying cause, if any. Prevent/treat corneal ulcerations secondary to exposure keratitis.

PROGNOSIS AND OUTCOME

- The prognosis depends on resolution of the underlying cause. Patients with traumatic causes have quicker resolution (days/weeks) than patients with idiopathic or iatrogenic causes.
- In idiopathic Horner's syndrome, essentially all patients have resolution of the signs of Horner' syndrome within 6 months after diagnosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Approximately 50% of cases of Horner's syndrome in dogs are idiopathic, and the syndrome generally resolves without treatment in <6 months.
- In cats, a cause is virtually always found: idiopathic Horner's syndrome is very rare.
- Strictly speaking, Horner's syndrome also affects the surface of the face and neck (causing erythema/flushing of the skin) and the nasal mucosa (causing congestion), but these manifestations usually have no clinical significance.
- Pharmacologic testing to determine the site of the lesion has produced inconsistent results.

1ST EDITION AUTHOR: ETIENNE CÔTÉ

Hookworm Infection

BASIC INFORMATION

DEFINITION

Infection with nematode parasites of dogs and cats that colonize the gastrointestinal tract and cause blood loss anemia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cats: *Ancylostoma tubaeforme, Ancylostoma braziliense, Uncinaria stenocephala* (rare)
- Dogs: *Ancylostoma caninum;* less commonly *Uncinaria stenocephala, Ancylostoma braziliense*
- Young animals of both species are primarily affected.

RISK FACTORS

Small body size (smaller blood volumes such as in puppies, kittens) increases risk for disproportionately greater anemia with high worm burdens. Puppies born to bitches with poor husbandry are at increased risk, especially from 2-8 weeks old.

CONTAGION & ZOONOSIS

- Contagion: arrested larvae in the female dog become reactivated during pregnancy and migrate to the placenta and mammary glands, where they are transmitted to pups. No similar transplacental or transmammary transmission of *A. tubaeforme* in the cat.
- Zoonosis: *A. braziliense* and less commonly *A. caninum* can cause cutaneous larval migrans (CLM) in humans. Infective larvae penetrate and migrate through the skin, causing intensely pruritic elevated winding tracts. Adult *A. caninum* can parasitize the human intestine human.

GEOGRAPHY AND SEASONALITY

- *A. tubaeforme:* worldwide. *A. caninum:* worldwide subtropical and temperate regions. *A. braziliense:* tropical and subtropical climates in North and South America, Africa; near coastlines. *U. stenocephala:* temperate to cooler climates, North and Central America, Europe, Asia.
- Eggs only develop into infective third-stage larvae above 15°C, so infection occurs primarily in warmer months in temperate regions.

ASSOCIATED CONDITIONS & DISORDERS

Coinfection with other nematodes (particularly *Toxocara canis* and *Toxocara cati)* is common in young animals.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Weight loss
- Lethargy
- Polydipsia
- Poor growth and unthriftiness (puppies/kittens)
- Melena
- Diarrhea
- Ova may be found incidentally on fecal examination.

PHYSICAL EXAM FINDINGS

- Pale mucous membranes are the hallmark, owing to the bloodsucking activity of adult hookworms.
- Poor body condition and haircoat
- Melena on rectal examination

- Heart murmur due to anemia (systolic, left-sided, soft)
- Tachycardia, tachypnea, weakness or obtundation if in hemorrhagic shock
- Clinical signs vary based on degree of blood loss and chronicity of parasitism.
- Physical examination may be normal if worm burden is low.

ETIOLOGY AND PATHOPHYSIOLOGY

- Hookworms attach to the small-intestinal mucosa. Host blood travels through hookworm gut, providing oxygen and nutrients to the worm. Attached worms essentially mimic open blood vessels, causing persistent gastrointestinal hemorrhage. Hookworms are also known to change their attachment sites, moving from one site to another within the small intestine. The buccal cavity of hookworms naturally secretes a potent anticoagulant, so the former attachment sites continue to bleed after the detachment/reattachment.
- *A. caninum* consumes more of the host's blood than the other hookworms. *U. stenocephala* rarely causes clinical disease or significant anemia.
- Life cycles among species are similar. Prepatent periods (incubation period, from the time of ingestion to the appearance of ova in feces) vary from 12-28 days depending on species.
    - Inoculation occurs via oral ingestion or skin penetration from infective third-stage larvae in the environment. Puppies are infected via transmammary or transplacental transmission.
        - Oral: swallowed infective third-stage larvae penetrate stomach and intestinal wall, where they become arrested in submucosa or other tissues, are reactivated, and return to intestine to attach to mucosa.
        - Skin: third-stage larvae penetrate skin, migrate through lungs and up trachea, are swallowed, and ultimately attach to intestinal wall.

DIAGNOSIS

DIAGNOSIS OVERVIEW

A small, young animal with evidence of internal blood loss should trigger the consideration of hookworm infection, particularly in warm climates. Basic fecal flotation is the preferred diagnostic test, though empirical treatment without testing (subclinical infection) is also reasonable.

DIFFERENTIAL DIAGNOSIS

- Foreign body ingestion
- Canine parvovirus (puppies)
- Feline leukemia virus infection (kittens)
- Gastrointestinal ulceration
- Gastrointestinal neoplasia (older animals)
- Anemia due to hemolysis
- Anemia due to ectoparasites (e.g., fleas, ticks)

INITIAL DATABASE

- Fecal flotation: diagnostic test of choice:
    - Eggs of *Ancylostoma* species and *U. stenocephala* appear similar: characteristic ova are ellipsoidal and contain an 8-cell morula.

ADVANCED OR CONFIRMATORY TESTING

- CBC:
    - Regenerative anemia (most cases)
    - Nonregenerative anemia with microcytic hypochromic red cells may occur secondary to chronic gastrointestinal blood loss and subsequent iron deficiency.
    - Eosinophilia
- Serum biochemistry profile:
    - Hypoproteinemia/hypoalbuminemia
    - Hyponatremia/hypochloremia in polydipsic animals
- Urinalysis: generally unremarkable

TREATMENT

TREATMENT OVERVIEW

Rapid eradication is important in affected puppies and kittens (anthelmintics). Severe cases may require transfusion.

ACUTE GENERAL TREATMENT

- Transfuse severely anemic or compromised patients with blood products or oxygen-carrying fluids (20 mL/kg whole blood or polymerized bovine hemoglobin [Oxyglobin]). See p. 1347.
- Iron supplementation may be required in patients with prolonged or profound gastrointestinal blood loss (dam's/queen's milk is a poor source of iron).
    - For severe iron-deficiency anemia: iron dextran, 10-20 mg/kg IM once (dogs), 50 mg/animal IM once (cats), followed by oral supplementation.
    - Ferrous sulfate, 100-300 mg/animal PO once daily (dogs), 50-100 mg/animal PO once daily (cats). May cause gastric irritation; should be given with food.
- Anthelmintics should be administered once every 2 weeks to puppies and kittens until adolescence (6 months of age); 1-2 treatments usually adequate:
    - Pyrantel pamoate, 5-10 mg/kg PO; *or*
    - Febantel, 10-15 mg/kg PO (higher dose in younger animals); *or*
    - Fenbendazole, 50 mg/kg PO q 24 h for 3 days; *or*
    - Ivermectin, 0.2 mg/kg PO or SQ (beware risks; see p. 625)

CHRONIC TREATMENT

- Repeat dewormings necessary to prevent reinfection. Resistance to infection increases with age and exposure.
- Deworm every 2-3 weeks.
- To prevent passage of infective larvae from lactating bitches to puppies, treat with of fenbendazole 50 mg/kg PO q 24 h from day 40 of gestation to day 14 of lactation.

RECOMMENDED MONITORING

- Acute anemia: monitor hematocrit, reticulocyte counts
- Repeat fecal flotations

PROGNOSIS AND OUTCOME

Prognosis is excellent with removal of parasites in compensated infection but guarded in cases of acute severe anemia.

PEARLS & CONSIDERATIONS

COMMENTS

Peak blood loss from hookworm infestation occurs before eggs are shed in feces. Therefore, a negative fecal examination does not rule out hookworm disease, especially in very young puppies or kittens that present with evidence of anemia and shock.

PREVENTION

- Sodium borate applied to gravel or concrete will control hookworm larvae in the environment.
- Best prevention is regular administration of anthelmintics. Commercial heartworm preventives containing ivermectin/pyrantel pamoate, milbemycin, and selamectin have simultaneous anthelmintic properties for monthly control of hookworms in adult dogs and cats. Note that selamectin does not control hookworms in dogs but is efficacious in cats at heartworm preventive doses.

Hit by Car

BASIC INFORMATION

DEFINITION

Trauma sustained as a result of direct impact from a car, truck, or other motorized vehicle

SYNONYMS

HBC, vehicular trauma, motor vehicle accident

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats of any age, breed, or sex can be affected.

RISK FACTORS

Young, male dogs and cats may be at increased risk.

ASSOCIATED CONDITIONS & DISORDERS

Hypovolemic shock, hemorrhage, fractures, neurologic deficits, ocular lesions, skin abrasions/lacerations

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- The accident may be witnessed or not (e.g., the animal may be found near the side of the road).
- Primary complaints include acute collapse, difficulty breathing, lacerations, lameness, and suspected fractures.
- If the accident is witnessed, it is important to determine:
  - Primary location of impact on the animal's body
  - Whether the animal was seen walking after the accident
  - Other signs the owner has noticed since the accident

PHYSICAL EXAM FINDINGS

Dependent on site and extent of injuries:

- Altered mentation (dull, depressed, comatose), ocular injuries, and/or skull fractures with head trauma
- Tachycardia (usually sinus) reflecting pain, hypovolemia, hypotension, or combinations thereof:
  - Sinus tachycardia is essentially never treated with antitachycardic drugs (β-blockers, calcium channel blockers, etc.), because it almost always represents a physiologic response. Rather, the underlying cause needs to be identified and treated.
- Increased respiratory rate and effort (pulmonary contusions, pneumothorax, pain)
- Skin lacerations:
  - Often associated with incrusted debris or road/tire marking, increasing the suspicion of hit by car in an animal with an uncertain history
- Fractures
- Other specific injuries reflective of the site of the impact

ETIOLOGY AND PATHOPHYSIOLOGY

- Physiologic response to trauma is complex, involving catecholamine and hormone release.
- Goal of physiologic response is to maintain oxygen delivery to the heart and brain at expense of other tissues (e.g., skeletal muscle, abdominal viscera).
- Initial response results in clinical signs of early/compensatory shock:

    - Tachycardia
    - Tachypnea
    - Increased capillary refill time
    - Bounding femoral pulses
- Compensatory phase of shock has high energy demands and if untreated can rapidly progress to decompensatory (terminal) phase of shock.
- Continued reduction in oxygen delivery to tissues results in clinical signs of decompensatory (terminal) shock:
    - Bradycardia (less of a severe indicator in cats, who may have heart rates <150 beats/min without being in advanced shock states)
    - Pale mucous membranes
    - Weak femoral pulses
    - Hypotension
    - Cardiopulmonary arrest

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The history is conclusive if the event was witnessed; otherwise, a presumptive diagnosis can be made from cutaneous wounds and internal injuries. Diagnostic evaluation centers around assessing all body systems for traumatic injury.

DIFFERENTIAL DIAGNOSIS

- Metabolic causes of shock (e.g., sepsis, endocrine, heat stroke)
- Other causes of trauma (e.g., kicks, fall from height, bite wounds)

INITIAL DATABASE

- Triage: a wide spectrum of patient states can result when an animal is hit by a vehicle.
    - Rapid assessment of neurologic (mentation, ability to ambulate), cardiorespiratory (dyspnea, respiratory arrest, palpable heartbeat and pulse), skeletal (fractures), and pain parameters determines the immediate extent of diagnostic and treatment efforts.
    - An interim prognosis based on a brief but thorough physical examination may often dictate the extent to which an owner wishes to support the patient's diagnostic testing and treatment.
- Packed cell volume/total solids (PCV/TS):
    - Can be normal in a hit-by-car patient even with acute hemorrhage
    - Decrease may take hours but is more rapid if intravenous fluids are administered (dilution).
    - Serial monitoring of PCV/TS 1-2 hours after admission and every 4-6 hours is recommended to detect changes associated with hemorrhage.
- Blood glucose, electrolytes, venous or arterial blood gas, lactate measurement if available, CBC, serum chemistry profile, urinalysis
- Electrocardiogram:
    - Monitor arrhythmias (especially ventricular [see p. 1165]; occasionally premature atrial complexes, atrial fibrillation, or others).
    - Monitor heart rate during fluid resuscitation. Heart rate in dogs will often decrease with successful correction of hypovolemia through fluid resuscitation (e.g., initial heart rate 180-200 beats/min decreasing to 100-130 in a medium- to large-breed dog).
- Blood pressure
- Blood lactate concentration
    - Can determine if lactic acidosis is present (e.g., from prolonged hypo-perfusion associated with shock)
    - Blood lactate level should return to normal once adequate perfusion is restored with intravascular volume replacement.
- Survey radiographs of chest, abdomen, ± axial or appendicular skeletal system structures as dictated by physical findings
- Pulse oximetry:
    - Assess oxygenation (possibility of pulmonary contusions or pneumothorax if desaturation [i.e., if <90%-93% O2 saturation]).

ADVANCED OR CONFIRMATORY TESTING

- Radiographic contrast studies to assess integrity of urinary tract if indicated
- Ultrasound to assess abdominal structures
- Advanced neuroimaging modalities such as CT or MRI to better define skull and brain injuries

TREATMENT

TREATMENT OVERVIEW

- Rapid restoration of effective circulating volume with bolus intravenous fluid administration
- Stabilization of life-threatening respiratory compromise
- Identification of ongoing blood loss that may require surgical intervention
- Identification of internal injuries (e.g., organ rupture, diaphragmatic hernia)
- Pain management of musculoskeletal injuries, including appropriate bandaging of fractures

ACUTE GENERAL TREATMENT

- Bolus intravenous crystalloid fluid administration up to 90 mL/kg/h in dogs and up to 45 mL/kg/h in cats; may start with 25 mL/kg bolus over 5 minutes and repeat as necessary.
- Bolus intravenous colloid administration (dosages vary with different colloids) if crystalloids do not restore cardiovascular function
- Consider hypertonic fluid therapy (e.g., hypertonic saline [7% NaCl 2-6 mL/kg slow IV; acceptable to inject into peripheral or central IV catheter; follow with isotonic crystalloids such as lactated Ringer's]) in cases of head trauma and/or hemorrhagic shock.
- Packed red blood cells or fresh whole blood transfusion in cases of severe hemorrhagic shock (see p. 1347)
- Supplemental oxygen administration in cases of respiratory compromise or head trauma (see p. 1318)
- Use of sterile bandages to cover wounds, including appropriate bandaging of fractures (definitive wound and fracture repair often not possible until cardiovascular and respiratory systems are stabilized).
- Pain management with systemic narcotics when cardiovascular stability achieved
    - Options include:
        - Hydromorphone, 0.05-0.1 mg/kg IM, IV q 4-6 h; *or*
        - Morphine (dogs), 0.5-1 mg/kg SQ, IM q 4-6 h; *or*
        - Fentanyl, constant rate IV infusion 0.002-0.006 mg/kg/h; *or*
        - Morphine-ketamine combination, constant rate infusion; can mix together in syringe or bag diluted in 0.9% saline or lactated Ringer's solution:
            - Morphine, 0.5 mg/kg IM initial loading dose then 0.12-0.36 mg/kg/h IV
            - Ketamine, 0.25-0.5 mg/kg IV initial loading dose then 0.12-1.2 mg/kg/h IV
- Antibiotics (topical or systemic for superficial or deep wounds, respectively) as needed

POSSIBLE COMPLICATIONS

- Thoracic injuries including rib fractures, pneumothorax, hemothorax, pulmonary contusions, and diaphragmatic hernias
- Abdominal injuries including body wall hernias and hollow and solid organ rupture
- Musculoskeletal injuries (fractures, luxations, ligament injuries)
- Integument injuries (lacerations, degloving wounds, others)
- Traumatic brain or spinal cord injury
- Peripheral nerve damage (sciatic nerve injury, brachial plexus avulsion, others)

RECOMMENDED MONITORING

- Physical parameters including heart rate, respiratory rate/effort, mucous membrane color, body temperature, and blood pressure
- Oxygenation assessment using pulse oximetry and or arterial blood gas measurement as needed
- PCV/TS to assess for blood loss, recheck of other blood work indicated by baseline values and clinical course
- Urination:
    - Frequency, estimated amount and character
    - May need to place urinary catheter if concerned about urine output or integrity of urinary tract
    - Note that patients with ruptured urinary bladder may still pass urine and may also have a palpable bladder; suspect bladder rupture if ascites, abdominal distention, hematuria, pelvic fractures, or lethargy with hyperkalemia are present.

PROGNOSIS AND OUTCOME

- Reported survival rate in dogs is 82%-87%; reported survival rate in cats is 84%.
- In one study:
    - Death most commonly resulted from intrathoracic and intraabdominal injuries.

- Most of the dogs that were euthanized had central nervous system injury.

PEARLS & CONSIDERATIONS

COMMENTS

- Tachycardia, tachypnea, hyperemia/injected mucous membranes, and bounding femoral pulses are signs of early compensatory shock and require immediate treatment.
- Acute blood loss causes a decrease in the plasma TS before a drop in the PCV, because splenic and hepatic contraction replace lost red cells; if blood loss continues, the PCV will decrease rapidly.
- Thoracic radiographs are recommended in all cases, especially dogs requiring general anesthesia and surgical repair of fractures; prevalence of thoracic wall and pulmonary trauma was reported as 39% in one study.
- Uroabdomen may be predicted with an abnormal abdominal fluid creatinine concentration to peripheral blood creatinine ratio of >2:f or an abnormal potassium concentration to peripheral blood potassium concentration of >1.4:1.
- In rare cases, injuries to gastrointestinal tract or biliary tract are undetectable for several days.

PREVENTION

- Keep cats housed indoors.
- Walk dogs on a leash at all times.
- Frequently check fences and other enclosure systems for damage.
- Do not allow dogs to sleep or lie in driveways.

AUTHOR: JENNIFER L. HOLM

EDITOR: ELIZABETH ROZANSKI

Histoplasmosis

BASIC INFORMATION

DEFINITION

A systemic fungal disease caused by the soil-dwelling dimorphic fungus, *Histoplasma capsulatum;* affects both companion animals and humans.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats are equally likely to develop histoplasmosis once exposed.
- Young adult (<4 years) large-breed dogs; no apparent sex predilection
- Most cats with histoplasmosis are young (<4 years). Females may be more commonly affected.

GENETICS & BREED PREDISPOSITION

- Sporting (hunting) breeds may be overrepresented, likely due to greater environmental exposure.

RISK FACTORS

- Outdoor activities in endemic areas
- Contact with nitrogen-rich organic material such as moist soil containing bird (classically, starling, but many bird species are implicated) or bat excrement

CONTAGION & ZOONOSIS

Common-source exposure possible, but true zoonosis does not occur (exception: accidental laboratory inoculation/inhalation).

GEOGRAPHY AND SEASONALITY

H. capsulatum is endemic to many temperate and subtropical regions of the world. In the United States, histoplasmosis occurs most commonly in the Missouri, Mississippi, and Ohio River valleys. *H. capsulatum* may thrive in nonendemic regions, however, if soil conditions change to favor fungal growth.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Disease may remain confined to the lungs or gastrointestinal (GI) tract or may become disseminated (commonly with **GI** involvement).

HISTOPLASMOSIS Geographic area in which histoplasmosis is endemic. Areas of highest prevalence are cross-hatched.

(From Rippon JW: Medical mycology, ed 3, Philadelphia, 1988, Saunders. Reprinted with permission.)

HISTORY, CHIEF COMPLAINT

- Clinical signs are determined by the major organ system(s) affected. Clients should be carefully questioned about recent travel with their pets to endemic areas in the preceding 1-2 months.
- Nonspecific signs of disease are common (especially in cats), typically including depression, anorexia, and weight loss. Clients may notice labored breathing in dogs and cats with pulmonary histoplasmosis. Dogs with GI involvement may exhibit signs consistent with small- and/or large-bowel diarrhea, melena/hematochezia, tenesmus, and recent weight loss. Signs of GI involvement in cats are less readily identifiable versus those in dogs and may manifest merely as weight loss and anorexia.

PHYSICAL EXAM FINDINGS

- Dyspnea, tachypnea, coughing, abnormal lung sounds, pale mucous membranes
- Lymphadenopathy
- Poor body condition/emaciation
- Fever
- Hepatomegaly, splenomegaly (or both if disseminated disease)
- Ocular and dermal lesions (rare)

ETIOLOGY AND PATHOPHYSIOLOGY

- The mycelial stage (in soil; releases spores [microconidia and macroconidia]) of *H. capsulatum* is responsible for mammalian infections. Exposure probably most commonly occurs by inhaling microconidia, which are small enough to reach the lower airways. Oral exposure may result in disease, as evidenced by some animals developing only GI signs.
- After inhalation, microconidia convert to the yeast form in the small airways of the lower respiratory tract, where they reproduce by budding.
- The organisms are phagocytosed by host mononuclear cells, in which they undergo further replication. Disease at this point may remain limited to the respiratory system or become generalized via lymphatic and/or hematogenous dissemination.
- Dissemination to the GI tract, lymph nodes, spleen, liver, and bone marrow is common. The organism load in infected tissues is generally high, and affected tissues respond with granulomatous inflammation.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected based on the presence of a miliary or nodular pattern on thoracic radiographs in a dog with exposure to an endemic region; lymphadenopathy and hepatomegaly further support the diagnosis. Confirmation requires cytologic or histologic analysis.

DIFFERENTIAL DIAGNOSIS

- Other systemic mycoses (e.g., blastomycosis, cryptococcosis, coccidioido-mycosis)
- Neoplasia

INITIAL DATABASE

- CBC:
  - Nonregenerative anemia (the most consistent, albeit nonspecific, finding with histoplasmosis). Likely secondary to chronic disease, bone marrow infiltration, and/or GI blood loss.
  - Leukocyte parameters are variably affected, and thrombocytopenia may be present.
  - Intracellular organisms may be (very rarely) observed on blood smears.
- Serum chemistry profile: variable abnormalities; commonly hypoalbuminemia, elevated liver enzyme activity, and/or hypercalcemia
- Radiography:
  - Dogs and cats with active pulmonary histoplasmosis often exhibit a diffuse miliary interstitial or nodular pattern on thoracic radiographs consistent with mycotic pneumonia.
  - Tracheobronchial lymphadenopathy is commonly observed.
  - Pleural effusion may occasionally be present and obscure the aforementioned radiographic findings.
  - Osseous lesions are rarely observed, but when present, they consist of a mixed pattern of osteolysis and osteoproliferation.

ADVANCED OR CONFIRMATORY TESTING

- Fine-needle aspiration and cytologic evaluation:
  - Usually provides a definitive ante-mortem diagnosis
  - The organisms are usually observed within phagocytic cells and appear as single to multiple round bodies with a basophilic center and clear, thin outer rim.
  - Tissues most rewarding for obtaining a diagnostic sample in the dog include rectal scrapings (see p. 1334), colonic biopsy imprints, and aspirates of bone marrow (see p. 1212), liver, spleen (see p. 1275), and lung (see p. 1277), depending on the extent of disease. Organ enlargement and ease of access determine which organs are sampled.
  - In cats, tissues that may successfully be sampled include bone marrow, lung, and lymph nodes.
- Histologic analysis of biopsy specimens may be necessary if cytologic testing results are inconclusive.
- Serologic testing is not recommended owing to the unreliability of current immunodiagnostic tests.

TREATMENT

TREATMENT OVERVIEW

- Treatment has focused on clearing *H. capsulatum* infection with oral azole antifungal agents and in some cases controlling inflammation with antiinflammatory medication. Duration of treatment depends on severity of disease and the patient's response to therapy. Typically, animals are treated with oral antifungals for at least 4-6 months.
- Itraconazole is the treatment of choice for mild histoplasmosis infections. Fluconazole is not effective in treating histoplasmosis.
- Ketoconazole has lower potency and increased toxicity compared to itraconazole and is not generally recommended for treatment of histoplasmosis.

ACUTE GENERAL TREATMENT

- Azole drugs (mild cases):
  - For mild cases (local involvement only, no overt respiratory signs, patient is eating and is not debilitated).
  - Itraconazole capsules 10 mg/kg PO q 24 h (dogs), 10 mg/kg PO q 12 h (cats); *or*
  - Itraconazole oral solution (5 mg/kg PO q 24 h [cats, dogs])
  - Treatment should be initiated as early as possible in the disease process to improve the probability of preventing dissemination.
- Itraconazole + amphotericin B:
  - For severe disseminated histoplasmosis or fulrninant pulmonary or GI disease, combination therapy of an oral azole with parenteral amphotericin B should be considered (various protocols).
  - The drugs are started concomitantly, with the azole continued past cessation of amphotericin B therapy.
  - Sample protocol for amphotericin B: Dog, 0.5 mg/kg IV q 48-72 h up to 60 days or until signs of toxicosis, usually renal. Cat, 0.25 mg/kg IV q 48-72 h or until signs of toxicosis, usually renal.
  - Sample protocol for lipid-soluble amphotericin B (lower risk of nephrotoxicosis) for dogs and cats: 1 mg/kg IV q 48-72

h × 60 days or until signs of toxicosis.
- Amphotericin B is fungicidal (versus azoles, which are fungistatic) but is limited by its high risk of progressive nephrotoxicosis (ensure patient is well hydrated and undergoing diuresis during treatment; monitor daily blood urea nitrogen and creatinine during treatment, and stop treatment if >50% increase in either parameter), the potentially severe perivascular reaction or sloughing elicited by extravasation, and the possibility of anaphylaxis.
- Prednisone, 2 mg/kg PO q 24 h hastens resolution of dyspnea in dogs with histoplasmosis-induced tracheobronchial lymphadenomegaly (in the absence of systemic histoplasmosis). When used alone or with antifungals, clinical signs resolve faster (<2.6 weeks) compared to dogs treated with antifungals alone (8.8 weeks).
- Voriconazole: treatment of choice in human histoplasmosis; very costly

CHRONIC TREATMENT

Itraconazole or voriconazole PO for at least 4-6 months. The most difficult to treat tissues include ocular, central nervous system, bone, and epididymis. Orchiectomy is advised for epididymal histoplasmosis.

POSSIBLE COMPLICATIONS

Renal failure with amphotericin B

RECOMMENDED MONITORING

Response to treatment is monitored by periodically assessing CBC and serum chemistry values, observing for improvement in body condition, and monitoring for resolution of radiographic lesions.

PROGNOSIS AND OUTCOME

- Prognosis may vary from guarded to good depending on the extent of disease.
- Disease limited to the lungs typically carries a better prognosis compared to GI or disseminated histoplasmosis.
- Prognosis is guarded for return of vision with ocular involvement, depending on severity of retinal damage prior to treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- Depending on the degree of *H. capsulatum* infection, some patients may be successfully treated with oral antifungals alone. Alternatively, some patients may be critically ill and require more intense combination therapy and supportive care. The need for fluid and nutritional support should not be overlooked in these patients.
- Itraconazole capsules should always be administered with food; bioavailability is optimized in the presence of ingesta. Itraconazole liquid solution should be given on an empty stomach and has a greater bioavailability than capsules.
- Therapeutic drug monitoring (serum level measurement) is available for itraconazole.

PREVENTION

There is no effective vaccine against *H. capsulatum.* Disease is best prevented by avoiding contact with contaminated soil in endemic areas.

1ST EDITION AUTHOR: JODI SMITH

Histiocytic Diseases

BASIC INFORMATION

DEFINITION

A complex group of syndromes resulting from an accumulation of histiocytes, which are cells of macrophage or dendritic origin. These disease syndromes share many common features, though clinical and histologic aspects help differentiate each one. Most are shown to arise from dendritic cell (DC) origin, specifically interstitial DCs, and less commonly Langerhans DCs. Histiocytic diseases occur in both dogs and cats, though reports in cats are sparse. Syndromes overlap, diverge, and converge but can be simplified into the following groups:

- Benign tumors:
  - Histiocytoma: spontaneously regressing skin tumor common in young animals
  - Idiopathic periadnexal multinodular granulomatous dermatitis
- Reactive histiocytic disorders:
  - Cutaneous histiocytosis: a benign accumulation of histiocytes in the skin, with predilection for the nasal planum, head, and neck
  - Systemic histiocytosis: similar to cutaneous histiocytosis but characterized by lymph node and organ involvement
- Malignant histiocytic neoplasia:
  - Histiocytic sarcoma: focal or disseminated, the latter is commonly considered synonymous with malignant histiocytosis.
  - Malignant fibrous histiocytoma: despite its name, this focal lesion is a unique soft tissue sarcoma with three histologic subtypes: storiform-pleomorphic (mesenchymal tissue with histiocytic infiltrate, the most common form in dogs), inflammatory (most common in the spleen of dogs), and giant cell (the most common type in cats). The histiocytic infiltrate is not neoplastic and is of questionable importance (see p. 684).
  - Malignant fibrous histiocytoma: despite its name, this focal lesion is a unique soft tissue sarcoma with three histologic subtypes: storiform-pleomorphic (mesenchymal tissue with histiocytic infiltrate, the most common form in dogs), inflammatory (most common in the spleen of dogs), and giant cell (the most common type in cats). The histiocytic infiltrate is not neoplastic and is of questionable importance (see p. 684).

SYNONYM

Histiocytic sarcoma (disseminated): malignant histiocytosis (though some texts describe disseminated histiocytic sarcoma as having features of both malignant histiocytosis and malignant fibrous histiocytoma).

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Histiocytic diseases have predominantly been reported in dogs, but reports exist in cats (malignant histiocytosis), cattle (malignant histiocytosis), and people.
- Cutaneous histiocytosis can occur in younger dogs, with systemic histiocytosis and malignant histiocytosis in middle-aged dogs (median age 6 years).
- Equal prevalence in males and females

GENETICS & BREED PREDISPOSITION

Bernese mountain dogs (BMD) are predisposed to many types of histiocytic disease, though as a breed they are not as commonly affected with malignant fibrous histiocytoma. In BMD, heritability is oligogenic and almost certainly *not* autosomal or sex linked. Other breeds overrepresented in histiocytic diseases include golden retrievers, flat-coated retrievers (44% of all tumors), rottweilers, and Doberman pinschers. Flat-coated retrievers are predisposed to malignant fibrous histiocytoma. No breed predisposition has been reported in cats.

RISK FACTORS

For cats, vaccination may predispose to malignant fibrous histiocytoma.

GEOGRAPHY AND SEASONALITY

Initially, histiocytosis in BMD primarily affected dogs from Switzerland, where the breed originated. Many cases have now been reported in dogs born in the United States and the United Kingdom. There is no reported seasonality.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- As detailed above, histiocytic diseases can be divided in different ways but ultimately are either local or diffuse, reactive, benign, or malignant.
- A hemophagocytic variant occurs in both dogs and cats and leads to anemia and thrombocytopenia. This variant is very aggressive.

HISTORY, CHIEF COMPLAINT

- Most dogs are presented for signs referable to the primary tumor.
- Dogs with cutaneous histiocytosis and systemic histiocytosis are typically presented for evaluation of skin lesions.
- Systemic histiocytosis can have orbital involvement, and patients may be presented for evaluation of ocular signs.
- Dogs with malignant fibrous histiocytoma are usually presented for evaluation of a soft-tissue mass or lameness (if the joint tissues or bones are involved).
- Disseminated HS (MH) is a much more insidious disease, since masses are primarily visceral (spleen, liver, bone marrow, lymph nodes, lungs). Cutaneous and subcutaneous masses are uncommon with malignant histiocytosis. These dogs and cats are often presented for evaluation of nonspecific systemic signs such as lethargy and anorexia/weight loss. Skeletal tumors can also be of histiocytic origin, cause lameness, are usually associated with a soft-tissue mass, and usually associated with the disseminated form of the disease.

PHYSICAL EXAM FINDINGS

- Focal lesions typically involve a palpable mass, often on the extremities. If the mass is subarticular, lameness may be prominent, especially with bone involvement.
- A prominent spleen may be palpated with splenic malignant fibrous histiocytoma or with splenic involvement of malignant histiocytosis and can correlate with worse prognosis.
- Dogs with malignant histiocytosis often have significant pulmonary involvement and may be dyspneic with advanced disease. Cough is a common presenting complaint.
- With systemic histiocytosis, skin lesions may be seen on the nasal planum, muzzle, flank, and scrotum as well as the periocular tissues. Skin lesions in cutaneous histiocytosis and systemic histiocytosis are typically nodular to plaquelike.
- Generalized lymphadenopathy may be appreciated with systemic histiocytosis and malignant histiocytosis, and enlargement of the draining lymph node may be found with malignant fibrous histiocytoma.

ETIOLOGY AND PATHOPHYSIOLOGY

- Largely unknown in dogs, although oligogenic inheritance has been shown in BMD, and 25% of BMD are affected by clinical HS.
- Hemophagocytic HS is of macrophage origin and originates in the splenic red pulp or bone marrow.
- Malignant fibrous histiocytoma in cats possibly resulting from vaccination is covered elsewhere under injection-site sarcomas (see p. 610).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Histiocytic diseases occur in dogs and cats and have many forms which can be distinguished from each other based on clinical presentation, including site(s) of involvement, and immunohistochemistry.

DIFFERENTIAL DIAGNOSIS

- Granulomatous disease
- Lymphoma
- Poorly differentiated mast cell tumor
- Anaplastic sarcoma or carcinoma
- Synovial sarcoma (joint tumors)
- Other soft-tissue or bone sarcomas (for local disease)

INITIAL DATABASE

- CBC, serum chemistry profile, and urinalysis. No characteristic or specific findings with histiocytic diseases, except hemophagocytic syndrome results in Coombs-negative anemia and thrombocytopenia. Hypoalbuminemia may be present.
- Fine-needle aspiration of accessible masses and lymph nodes for cytologic examination (look for multinucleated giant cells and erythrophagocytosis by macrophages).
- Biopsy of affected tissue
- Radiography of affected area if bony involvement is suspected typically reveals a lesion that is permeative, punctate, or moth-eaten.
- Thoracic radiography to evaluate pulmonary parenchyma for nodules (often large)
- Abdominal ultrasound to screen for visceral involvement
- Bone marrow aspiration and cytology if suspect systemic disease

ADVANCED OR CONFIRMATORY TESTING

- CT scan of affected area if focal and considering resection
- Immunohistochemistry on biopsy tissue (see Pearls & Considerations below)

TREATMENT

TREATMENT OVERVIEW

For benign/reactive disease, immunosuppression may suppress disease, but lesions are often resistant to treatment. For malignant disease, if only local involvement is present, surgical removal should be followed by adjuvant CCNU. If disseminated disease is present, CCNU and palliative care may extend survival time, but long-term prognosis is poor.

ACUTE GENERAL TREATMENT

- Patients with malignant histiocytosis having significant erythrophagocytosis may require red blood cell transfusion, ideally in conjunction with initiation of therapy to abort red cell loss.
- Dyspneic patients with malignant histiocytosis may benefit temporarily from oxygen therapy, but the prognosis is grave when the disease has reached the point of producing respiratory compromise.

CHRONIC TREATMENT

- Reactive histiocytoses are typically treated with immunosuppressive therapy. Initially prednisone is used (2 mg/kg PO q 24 h until clinical response is noted, then a slow taper of 1 mg/kg PO q 24 h for 1 month, 0.5 mg/kg PO q 24 h for 1 month, 0.5 mg/kg PO q 48 h for 3 months, then stop or maintain at lowest effective dose). If no response is noted within 1 month of prednisone therapy, or if lesions relapse and no longer respond to prednisone, then azathioprine (at 2 mg/kg PO q 24 h, with the same taper schedule as prednisone) or cyclosporine may be added. Recent anecdotal evidence suggests efficacy of tetracycline and niacinamide (dogs under 10 kg: 250 mg of each drug q 8 h, and dogs over 10 kg: 500 mg of each drug q 8 h). All treatments can be used with or without antibiotics depending on appearance of skin lesions and at the discretion of the treating clinician.
- Systemic malignant histiocytic diseases are poorly responsive to therapy and remissions, if achieved, are typically short lived.
    - Therapies attempted include: chemotherapy (29%-46% response of macroscopic disease to 60-90 mg/m^2 CCNU, doxorubicin 30 mg/m^2 also suggested) and TALL104 therapy (cytotoxic T-lymphocytes; not commercially available)
- Focal malignant histiocytic diseases respond well to surgical resection (amputation if joint or bone affected or if complete resection with limb salvage impossible) ± irradiation.

RECOMMENDED MONITORING

- The involved site(s) should be monitored closely via regular observation and diagnostic imaging as appropriate.
- Three-view thoracic radiographs and physical examination including lymph node palpation and examination of the site should be performed every 3 months for the first year after diagnosis for malignant fibrous histiocytoma and every 4-6 months thereafter.

PROGNOSIS AND OUTCOME

- Cutaneous histiocytosis: good; may regress spontaneously or respond to immunosuppressive doses of prednisone.
- Systemic histiocytosis and disseminated HS (malignant histiocytosis): poor. For both dogs and cats, systemic histiocytosis

may wax and wane but is ultimately progressive, whereas malignant histiocytosis is rapidly progressive, with both leading to euthanasia. Disseminated HS (malignant histiocytosis) is considered uniformly fatal. Survival of dogs with systemic histiocytosis ranges from months to years. Survival for dogs with disseminated HS/malignant histiocytosis averages around 4 months, though chemotherapy in the adjuvant setting with CCNU may prolong survival to greater than f year in some dogs. Prognosis to date for cats with malignant histiocytosis is similarly grave, and response to therapy has been poor.

- Malignant fibrous histiocytoma or focal histiocytic sarcoma: good if low-grade and local control is achieved with surgery ± radiation.

PEARLS & CONSIDERATIONS 

COMMENTS

The following clinical and pathologic differences can help differentiate histiocytic syndromes:

- Clinical findings/behavior:
  - Disseminated HS (malignant histiocytosis) is a multiorgan disease typically arising from internal sites including viscera, whereas systemic histiocytosis involves skin and lymph nodes with occasional internal sites.
  - Systemic histiocytosis may wax and wane but ultimately progresses, whereas malignant histiocytosis is rapidly progressive.
  - Cutaneous histiocytosis is limited to the skin and does not lead to malignant histiocytosis.
  - When malignant fibrous histiocytoma occurs in the viscera, the spleen is the most common location.
  - Malignant fibrous histiocytoma can metastasize to the lymph nodes, especially the giant cell variant, which is unusual for sarcomas.
- Histopathology:
  - Malignant histiocytosis exhibits a greater degree of cellular atypia than systemic histiocytosis.
  - Malignant histiocytosis often exhibits erythrocytophagy and sometimes leukocytophagy.
  - Multinucleated giant cells can be seen in malignant histiocytosis and in MFH, but the neoplastic population in MFH is spindyloid.
- Immunohistochemistry for both dogs and cats:
  - CD 18+ (leukocyte marker), CD 3–, and CD 79a– are the three immunohistochemical stains and the pattern most useful for diagnosing dendritic cell origin and ruling out lymphoma. CD f8 positivity combined with stains negative for other lineages may confirm HS at other sites such as ocular HS.
  - Dendritic cells should be CD 1a or c+, CD 11c+, and MHC ll+ (Langerhans DCs are associated with E-cadherin positivity) and macrophages should be CD 1-, CD 11c- and CD 11d+ as well as lysozyme positive.
  - Malignant histiocytic diseases should be CD 4- and reactive syndromes, CD 4+.
  - Macrophage origin HS is associated with hemophagocytic syndrome.

PREVENTION

Because histiocytic diseases are often inherited, careful documentation of pedigrees for affected animals is crucial to the eventual control by selective breeding. Inheritance of histiocytosis in Bernese mountain dogs has been calculated at a moderate 0.298, suggesting that careful breeding could be effective at eliminating this disease. This means that 29.8% of the risk of developing histiocytosis in the population of Bernese mountain dogs is attributable to genetic differences among individuals. The remainder of the risk is environmental, though specific factors have not been identified.

CLIENT EDUCATION

- Owners should contact the breeder or source of affected animals.
- An overtly (phenotypically) normal breeding pair of Bernese mountain dogs with one affected offspring will produce on average one in seven puppies that will ultimately succumb to histiocytosis.

Hip Luxation

BASIC INFORMATION

DEFINITION

- Dislocation of the femoral head relative to the acetabulum, most frequently in a craniodorsal direction
- Luxation: complete displacement of the femoral head relative to the acetabulum
- Subluxation: partial or incomplete dislocation of the femoral head relative to the acetabulum (i.e., joint incongruity exists)

SYNONYMS

Coxofemoral luxation, dislocated hip

EPIDEMIOLOGY

RISK FACTORS

Dogs with hip dysplasia are at risk for luxation with even minor trauma.

ASSOCIATED CONDITIONS & DISORDERS

Pelvic and proximal femoral fractures

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Craniodorsal luxation most common; caudoventral is uncommon.

HISTORY, CHIEF COMPLAINT

- Trauma (falls, vehicular) causing acute non-weight-bearing lameness
- Intermittent lameness in chronic cases with unrecognized trauma

PHYSICAL EXAM FINDINGS

- Variable lameness
- With craniodorsal luxation, leg appears shortened, stifle rotated externally, and tarsus internally.
- Palpation of hip reveals swelling, pain, crepitus, and abnormal position of greater trochanter.

ETIOLOGY AND PATHOPHYSIOLOGY

Traumatic coxofemoral luxations comprise 90% of all luxations in small animals.

- With craniodorsal luxation, femoral head is driven dorsally over the acetabular rim:
  - Both femoral head ligament and joint capsule are torn.
  - Avulsion fracture associated with ligament can occur.
  - Gluteal muscle contractions exacerbate craniodorsal displacement of proximal femur.
- With ventral luxation, transverse acetabular ligament is ruptured.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Orthogonal view radiography is critical in establishing a diagnosis and delineating concomitant regional osseous injuries.

DIFFERENTIAL DIAGNOSIS

Subluxation due to hip dysplasia, femoral capital physeal fracture, femoral neck fracture, acetabular fracture

INITIAL DATABASE

- Physical examination: findings as described previously (see Physical Exam Findings above)
- CBC/serum chemistry panel/urinalysis and thoracic/abdominal radiographs based on patient stability and the American Society of Anesthesiologists' classification (see p. 1372)
- Limb and pelvis examinations plus orthogonal view radiography to confirm the diagnosis and determine concomitant or inciting disorders

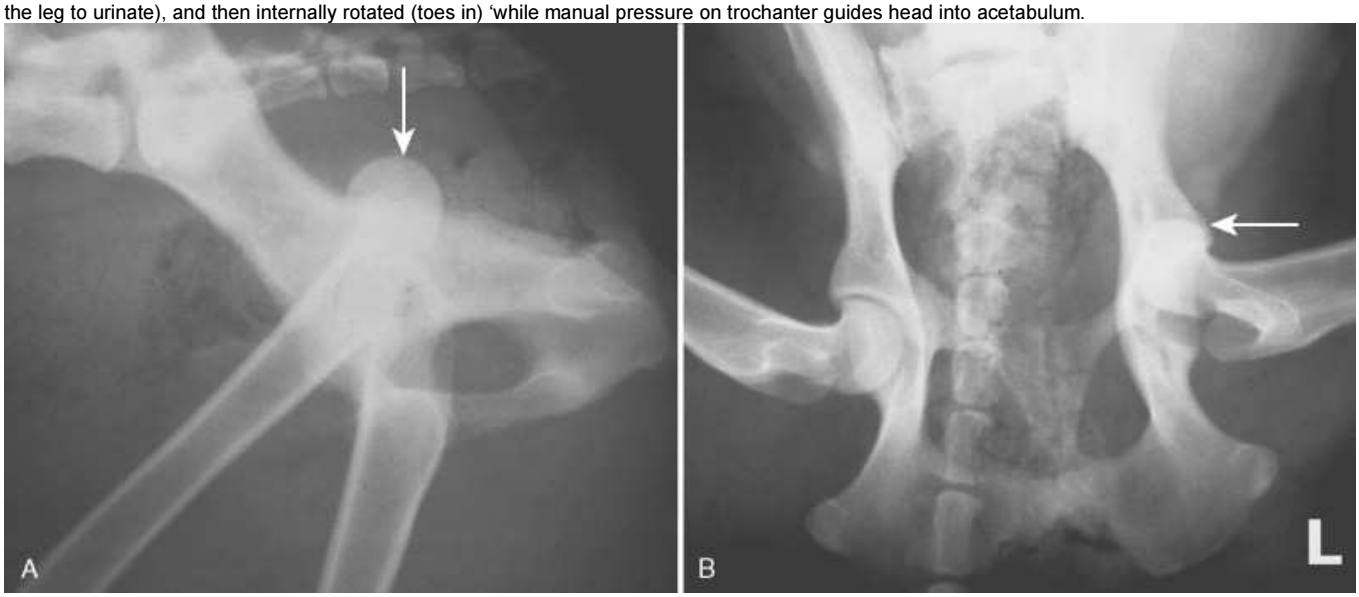
TREATMENT

TREATMENT OVERVIEW

- With acute injury of a normal hip joint, the goal is closed or open anatomic joint reduction/stabilization.
- With an abnormal or chronically luxated normal joint, goal is to save limb and treat joint by femoral head osteotomy (FHO), total hip replacement (THR), or triple pelvic osteotomy (TPO).

ACUTE GENERAL TREATMENT

- Closed reduction and Ehmer sling application if:
  - Duration of injury is <48 hours, *and*
  - Hip is otherwise structurally normal, *and*
  - Patient is sufficiently stable to undergo general anesthesia.
- With patient in lateral recumbency (unaffected side down), the upper (affected) limb is externally rotated (toes out), abducted (lifted, as a male dog lifts the leg to urinate), and then internally rotated (toes in) 'while manual pressure on trochanter guides head into acetabulum.



HIP LUXATION Lateral **(A)** and ventrodorsal **(B)** projections of a craniodorsal luxation of left hip joint. Note dorsal and cranial displacement of femoral head relative to acetabulum *(arrows).*

HIP LUXATION Postoperative ventrodorsal projection of hip joints of an obese 45-kg dog treated for traumatic bilateral hip luxation. Bilateral toggle pins and greater trochanter-to-ilium wires were used for stabilizing injuries.

- After reduction, extensive range-of-motion maneuvers are performed to force soft tissue out of acetabulum and test joint stability.
- Open reduction is performed in failed or unstable closed reductions in a patient 'with normal coxofemoral joint.
- Extraarticular techniques include suture between origin of greater trochanter and rectus femoris muscle, iliofemoral suture, synthetic sutures to replace capsule, capsulorrhaphy, or De Vita pinning (controversial).
- Intraarticular techniques: toggle pinning, fascia lata loop or sacrotuberal ligament transposition
- Triple pelvic osteotomy can be performed for mildly dysplastic immature dogs 'with no degenerative joint changes.
- For chronic injuries, open reduction is difficult owing to muscular contraction and tissue fibrosis; cartilage degeneration exists. FHO or THR may be required in place of primary repairs.

CHRONIC TREATMENT

- Physical rehabilitation to maintain muscle tone, joint health, and overall limb functions

- Controlled activity to avoid relaxation, implant failures
- Nonsteroidal antiinflammatory drugs (NSAIDs) as needed to reduce pain and inflammation:
  - Aspirin, 10-25 mg/kg PO q 8-24 h *or*
  - Carprofen, 2 mg/kg PO q 12 h; *or*
  - Etodolac, 10-15 mg/kg PO q 24 h *or*
  - Deracoxib, 1-2 mg/kg PO q 24 h (may use 3-4 mg/kg PO q 24 h for first 7 days only); *or*
  - Meloxicam, 0.1 mg/kg PO q 24 h; *or*
  - Firocoxib, 5 mg/kg PO q 24 h; *or*
  - Tepoxalin, 10 mg/kg PO q 24 h (new product, objective data pending); *or*
  - Others

POSSIBLE COMPLICATIONS

- Reluxation
- Implant failure
- Degenerative joint disease
- Infection

RECOMMENDED MONITORING

- For closed reduction:
  - Frequent sling evaluations and removal 7-10 days post application
  - Limited activity for 1 month
  - Radiography after sling application and if lameness recurs
- For open repairs:
  - Restricted ambulation 1-2 months
  - Radiography if lameness recurs and based on fixation method

PROGNOSIS AND OUTCOME

- Variable ‘with closed reduction: 50% fail due to technical error or unrecognized joint disease.
- Good to excellent ‘with most operative procedures of acute injuries (i.e., previously normal joint)
- Guarded for dysplastic hips unless TPO, FHO, THR performed

PEARLS & CONSIDERATIONS

COMMENTS

- With normal hips, reduction/stabilization is preferred over FHO for all patient sizes.
- Extensive joint capsule and ligament damage impede successful closed reduction.
- Femoral head ligament avulsion fractures are often not recognized radiographically.

Hip Dysplasia

Video Available on Website

BASIC INFORMATION

DEFINITION

A condition caused by abnormal development of the coxofemoral joint, characterized by joint laxity in young patients and degenerative joint disease (DJD) of variable severity in both young and adult patients

EPIDEMIOLOGY

SPECIES, AGE, SEX

- The condition is a developmental disease and occurs in young dogs. Clinical signs may be recognized in the immature or mature patient, or the condition may remain occult throughout life.
- Less frequent in cats

GENETICS & BREED PREDISPOSITION

- Most common in large and giant breeds (Labrador retriever, golden retriever, German shepherd dog, rottweiler, Newfoundland)
- May be more common in the Maine coon than other cat breeds

RISK FACTORS

- Rapid weight gain and growth associated with excessive caloric intake
- Factors causing synovial inflammation of the coxofemoral joint

ASSOCIATED CONDITIONS & DISORDERS

Affected animals may have other genetically predisposed or developmental conditions concurrently. These include:

- Elbow dysplasia
- Osteochondrosis
- Stifle disease
- Panosteitis
- Hypertrophic osteodystrophy

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Hip laxity is the main cause of juvenile and mature manifestations.
- Juvenile:
  - Hip laxity characterized by subluxation or luxation of the coxofemoral joint
    - Acetabular dysplasia
    - Femoral head/neck malformations
- Mature:
  - Degenerative joint disease

HISTORY, CHIEF COMPLAINT

- Juvenile patients typically have hindlimb lameness characterized by:
  - “Bunny-hopping” gait
  - Unilateral or bilateral pelvic limb lameness
  - Difficulty rising
  - Exercise intolerance
  - Description of an audible “clicking” when rising or walking
  - Shifting of weight to the thoracic limbs and extension of the hocks

- Mature patients have progressively worsening hindlimb lameness characterized by:
  - Weight-bearing lameness
  - Lameness following exercise
  - Pelvic musculature disuse atrophy

PHYSICAL EXAM FINDINGS

- Juvenile patient:
  - Pain during caudal extension, external rotation, and abduction of the coxofemoral joint
  - Hip joint laxity (positive Ortolani sign) characterized by dorsal subluxation of the femoral head with the limb adducted, followed by a palpable click with reduction of the femoral head when the limb is abducted
    - Angle of reduction is the measured point at which the femoral head slips back into the acetabulum as the limb is abducted.
    - Angle of subluxation is the measured point at which the femoral head slips out of the acetabulum as the limb is then adducted.
  - Poor pelvic limb musculature
  - Abnormal pelvic limb conformation (tarsal hyperextension)
  - Patient may appear to have an arched spine as weight is shifted forward to the forelimbs.
  - Narrow pelvic limb stance
- Mature patient:
  - Pain during extension, external rotation, and abduction of the hip
  - Decreased joint range of motion
  - Coxofemoral joint crepitus
  - Ortolani sign is lost as periarticular fibrosis limits femoral head movements
  - Hind limb muscle atrophy
  - Exaggerated hip movement at a walk (see online video clip)

ETIOLOGY AND PATHOPHYSIOLOGY

- A combination of genetic and environmental factors lead to hip joint laxity, resulting in joint instability and abnormal progression of endochondral ossification.
- Puppies with a genetic predisposition to canine hip dysplasia are born with hips that are grossly normal. Changes in the hip joint begin within the first few weeks after birth.
- Lameness and gait abnormalities appear during growth between 3 and 8 months old.
- Lameness may resolve over time as joint stability is gained through periarticular fibrosis (this process recently has been called into question). As degenerative changes accumulate, clinical signs of mature hip dysplasia will develop.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on clinical signs of lameness, hip joint laxity or degeneration, and radiographs delineating a malformed and/or arthritic joint

DIFFERENTIAL DIAGNOSIS

Any cause of hind limb lameness in the juvenile or adult dog, including:

- In the immature patient:
  - Panosteitis
  - Osteochondrosis
  - Physeal fractures of the femoral head
  - Hypertrophic osteodystrophy
  - Muscle injury (iliopsoas, gracilis, adductor, pectineus, and sartorius muscles)
  - Patella luxation
- In the mature patient:
  - Cranial cruciate ligament injury
  - Patella luxation
  - Lumbosacral disease
  - Polyarthritis
  - Bone neoplasia
  - Rickettsial and fungal disease (geographic)
  - Muscle injury

INITIAL DATABASE

In the young patient:

- Palpation of hip joints for Ortolani sign, in addition to calculation of angles of subluxation and reduction (may require sedation/anesthesia)
- Lateral and ventrodorsal pelvic radiographs

ADVANCED OR CONFIRMATORY TESTING

- Orthopedic Foundation for Animals (OFA) for radiographic protocol subjective evaluation
- PennHIP radiographic protocol or dorsolateral subluxation radiographic views for objective evaluation of joint laxity to aid in individual and familial prognostication
- Coxofemoral arthroscopy to identify ligament and cartilage damage

TREATMENT

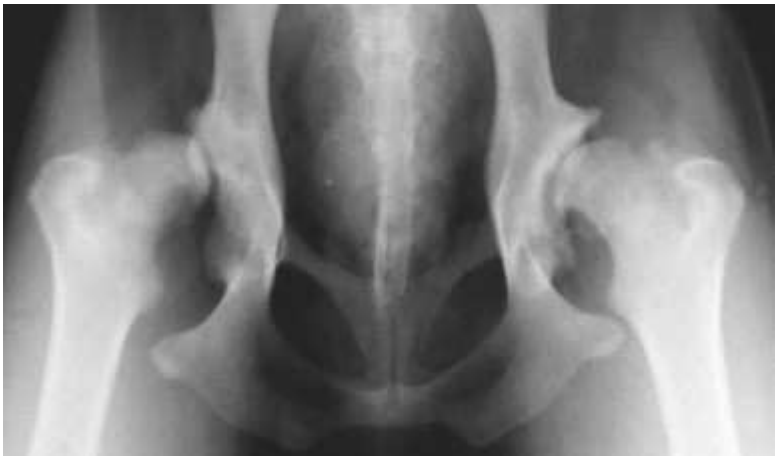
TREATMENT OVERVIEW

In cases without complete luxation of the coxofemoral joint, medical therapy is typically the initial recommended treatment. In general, medical management and progression of DJD will not encumber future surgical intervention with THR or FHO, as these surgical treatments are considered salvage procedures. Therapeutic goals are to:

- Reduce pain through decreasing inflammation and surgical improvement of malarticulation.
- Improve function through biomechanical stabilization of the hip joint or joint replacement.

ACUTE GENERAL TREATMENT

- Medical management (see p. 1565):
  - Nonsteroidal antiinflammatory drugs (NSAIDs):
    - Carprofen, 2 mg/kg PO q 12 h;*or*
    - Etodolac, 10-15 mg/kg PO q 24 h;*or*
    - Deracoxib, 1-2 mg/kg PO q 24 h;*or*
    - Meloxicam, 0.1 mg/kg PO q 24 h;*or*
    - Tepoxalin, 10 mg/kg PO q 24 h;*or*
    - Firocoxib, 5 mg/kg PO q 24 h
- Surgical management:
  - Juvenile pubic symphysiodesis (JPS):
    - In immature patients with joint laxity and without DJD (14-20 weeks of age)
    - To increase acetabular coverage of the femoral head; prevents osteoarthritis
    - Not recommended in cases with severe subluxation or luxation
  - Triple pelvic osteotomy (TPO):
    - In young dogs with joint laxity and ‘without DJD
    - To increase acetabular coverage of the femoral head and prevent osteoarthritis
    - Not recommended in cases with severe subluxation or luxation
  - Total hip replacement (THR): gold standard for restoration of normal joint function
    - In mature dogs
    - To replace degenerative joint structures with synthetic components
  - Femoral head and neck ostectomy (FHO):
    - Young to mature dogs
    - To reduce degenerative bone contact and form a pseudoarthrosis



HIP DYSPLASIA Ventrodorsal projection of severely dysplastic hips in a 16-month-old retriever cross dog. Radiographic abnormalities include subluxation of the femoral heads and remodeling of the shallow acetabula and femoral necks. This dog would be a candidate for total hip replacement or femoral head/neck ostectomies, based on clinical parameters described in the text.

        - Some surgeons do not recommend this procedure in giant-breed dogs.
        - Requires immediate and aggressive postoperative physical therapy to improve long-term outcome
        - Once a patient has undergone this procedure, future THR becomes exceptionally difficult and is typically accompanied by an unacceptable complication rate.
    - Acetabular denervation
        - Neurotomy of nerve fibers in the periarticular region to partially desensitize the hip joint
        - Only a palliative procedure
        - Objective (force plate) evaluations question efficacy of the procedure.

CHRONIC TREATMENT

- Medical management:
    - Prevention or elimination of overweight/obesity is the most important factor for long-term successful medical management (see p. 773).
    - PRN or daily NSAID administration as listed under Acute General Treatment above
    - Analgesia
        - Amantadine, 2-4 mg/kg PO q 24 h; *and/or*
        - Gabapentin, 3 mg/kg PO q 24 h; *and/or*
        - Tramadol, 2-4 mg/kg PO q 8-12 h; *or*
        - Codeine, 0.5-2 mg/kg PO q 8-12 h; *or*
        - Buprenorphine (cats), 0.01-0.03 mg/kg PO q 6 h
    - Joint fluid modifiers may be beneficial:
        - Polysulfated glycosaminoglycan 5 mg/kg IM twice weekly × 4-6 weeks; *or*
        - Pentosan polysulfate (from beech-wood hemicellulose) 3 mg/kg SQ once weekly; *or*
        - Oral formulations (glucosamine, chondroitin sulfate, hyaluronan): according to formulation/labeled instructions
    - Nutrition (energy restricted diet, as appropriate)
        - High omega-3 fatty acid diet
- Surgical management:
    - JPS or TPO are performed in some young animals with hip laxity.
    - FHO or THR are performed in mature animals with chronic disease (joint degeneration) unresponsive to medical therapies.

BEHAVIOR/EXERCISE

- Exercise moderation; limit high impact activities such as jogging and rough play
- Physical rehabilitation (see p. 1329); increase low impact activities to encourage muscular development-underwater treadmill, swimming and walking

POSSIBLE COMPLICATIONS

- Medical management:
    - Adverse reaction to NSAID
    - Continued progression of DJD necessitating surgical intervention

- Failure of medical management to control pain
- Surgical management:
  - Nerve and/or urinary tract damage from TPO or JPS surgery
  - Implant failure/pelvic canal narrowing with TPO
  - Osteomyelitis
  - Hip luxation or femoral fracture with THR
  - Poor limb usage after FHO due to patient obesity, muscular atony, or poor postoperative rehabilitation

RECOMMENDED MONITORING

- Basic laboratory monitoring of patients on NSAID therapy
- Weight, exercise level, clinical signs
- Radiographic monitoring if clinical signs progress and surgical intervention is warranted

PROGNOSIS AND OUTCOME

- The majority of patients will function at an improved level of activity with appropriate medical and surgical intervention.
- Postoperative rehabilitation (see p. 1329) is critical for good clinical recovery.

PEARLS & CONSIDERATIONS

COMMENTS

- Bilateral lameness may be difficult to recognize; musculature asymmetry between pelvic and thoracic limbs is suggestive of bilateral disease.
- Animals with a history of hip dysplasia that are acutely “down in the hind end” likely have concurrent bilateral cranial cruciate ligament rupture. A full orthopedic evaluation should be performed in these dogs prior to referral for surgical management of hip dysplasia.
- A total of 60%-75% of juvenile patients who are lame due to hip joint laxity and are treated with medical management may return to acceptable clinical function with maturity.
- Radiographic signs do not always correlate with clinical signs.
- FHO significantly complicates further surgical procedures such as THR. If THR is an option, then FHO should not be the first surgical intervention attempted.
- Routine radiographic monitoring of the clinically stable patient is generally not necessary, because further intervention is dictated by failure of medical management/progression of clinical signs.
- Editor's Note: Practitioners should consider consultation and referral with an orthopedic surgeon for management of this condition.

PREVENTION

- Screening and control of breeding animals for hip dysplasia:
  - Avoid breeding animals that have not been evaluated for hip conformation or hip laxity using either the OFA or the PennHIP methods.
  - Controversy exists regarding which of the two systems is “best;” OFA evaluation has been the traditional and simpler methodology, but evaluation is subjective and is performed on animals >2 years old. Only dogs receiving “excellent” or “good” evaluations should be bred. The PennHIP method is an objective measure of hip laxity performed as early as 16 weeks of age. Breeding just dogs that are in the top 50% (dogs with less joint laxity) of the breed will help to decrease laxity within the breed and decrease the incidence of hip dysplasia for that breed.
- Avoid high-energy diets in young, rapidly growing large-dog breeds.
- Based on equivalent human medical approaches, low-impact activities such as walking, swimming, and underwater treadmill therapy under the guidance of a trained canine rehabilitation specialist may provide benefit to affected individuals by increasing muscle mass and subsequently coxofemoral joint congruity (see p. 1329).

CLIENT EDUCATION

- Knowledge and careful screening of genetic history of the siblings and parents of potential pets
- Early sterilization of affected dogs and dogs treated with TPO or JPS
- Minimize the phenotypic expression of the disease in affected dogs through diet, low-impact exercise (see Prevention), and medical management.

1ST EDITION AUTHORS: JAMES BOULAY, BARBARA GORES

High-Rise Syndrome

BASIC INFORMATION

DEFINITION

A collection of traumatic injuries sustained by an animal that falls from a substantial height. The term was originally coined in reference to cats, associated with a triad of injuries (epistaxis, hard palate fracture and pneumothorax) sustained by falls from a height of two or more stories. The orofacial aspects of high-rise syndrome are discussed in detail separately (see online chapter: High-Rise Syndrome, Craniofacial).

SYNONYMS

High-flyer syndrome, jumper's syndrome (both in humans)

EPIDEMIOLOGY

SPECIES, AGE, SEX

Predominantly young animals; cats less than 3 years old (reported age range 2.5 months to 20 years) and dogs less than 5 years old (range 2.5 months to 13 years 8 months).

RISK FACTORS

- Urban areas
- Tall buildings, particularly high-rise apartment buildings
- Open windows and balcony doors; access to roof tops

GEOGRAPHY AND SEASONALITY

Falls occur more frequently in summer, followed by autumn, when windows and balcony doors are open, and outdoor play is a factor.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

A witnessed (most commonly in dogs) or suspected (more common in cats) fall from a height such as a window sill, balcony, or roof

PHYSICAL EXAM FINDINGS

- A substantial number of animals present in a life-threatening condition requiring emergency treatment (7.8%-57.6% of cats and 44% of dogs)
- Clinical signs consistent with shock/cardiovascular instability (seen in 10%-24% of cats; exact incidence not known in dogs) including:
    - Tachycardia or bradycardia
    - Poor pulse quality and/or low blood pressure
    - Pale mucous membranes
    - Prolonged capillary refill time
    - Decreased core body temperature
- Respiratory distress (e.g. dyspnea, tachypnea, paradoxical respiration, cyanosis, and open-mouth breathing) due to pulmonary contusion, pneumothorax, rib fractures, diaphragmatic hernia and/or pain
- Facial injuries (see p. 531)
- Orthopedic injuries:
- Limb fractures (39%-61% of cats; 80% of dogs)
- Femoral and tibial fractures most common in cats
- Dogs that jump tend to land on their thoracic limbs, resulting in a higher percentage of forelimb injuries, whereas dogs that fall accidentally are reported to land predominantly on their pelvic limbs, resulting in a higher percentage of hindlimb injuries.
- Open fractures occur commonly.
- Pelvic fractures

- Luxations (e.g. coxofemoral, elbow and tibiotarsal)
- Ligamentous injuries:
  - Rupture (e.g., cruciate ligament, Achilles tendon)
  - Carpal hyperextension (more prevalent in dogs than cats)
- Evidence of visceral injury due to blunt abdominal trauma:
  - Uroabdomen secondary to urinary tract rupture (most commonly bladder)
  - Hematuria secondary to urinary bladder contusion
  - Hemoabdomen (may be mild and self-limiting or require surgical intervention [e.g., secondary to splenic rupture])
  - Abdominal wall rupture/herniation
  - Prepubic tendon rupture
- Spinal injuries (e.g., fracture, luxation or traumatic intervertebral disk herniation resulting in caudal paresis/plegia, tetraparesis or brachial palsy (due to brachial plexus avulsion)
- Penetrating abdominal or thoracic wounds secondary to impalement. May be accompanied by subcutaneous emphysema, abdominal wall herniation, or flail chest. Reported predominantly in cats falling onto spiked wrought iron fences.
- Evidence of head trauma/traumatic brain injury including:
  - Cranial neurologic abnormalities (such as anisocoria, Horner's syndrome)
  - Depressed level of consciousness
- Soft-tissue abrasions

ETIOLOGY AND PATHOPHYSIOLOGY

- Jumping during play or while chasing a squirrel, bird, insect, other animal (e.g., dogs chasing cats or other dogs), intruders, owners driving away in the street below or objects thrown while playing. Most common in dogs.
- Slipping while walking on the edge of a balcony railing or window, including icy ledges; suspected to be most common in cats.
- Thunderstorms or fireworks may incite a dog to jump if phobic.
- Range of documented heights fallen by cats (1-32 stories) and humans (1-20 stories) is high compared to that by dogs (1-6 stories)
- Injuries result from extreme vertical deceleration trauma.
- Impact surface is usually concrete; less commonly grass, rocks, snow, rubble, or dirt. Rarely impalement on metal railings. Objects encountered during the fall (e.g., potted plants on balcony railings, metal structures for hanging laundry, fire escapes, awnings, and trees) may result in additional injury or could help reduce injury by breaking the fall.
- Height of the fall is thought to have the greatest effect on injury pattern. In cats, severity of injury has been reported to increase up to seven stories (each story is 12-15 feet), after which further increases in height do not exacerbate injury severity; however, not all case series are consistent with this theory.
- Cats are better able to withstand free falls than dogs or humans due to their:
  - Highly developed vestibular system and righting reflex resulting in a unique ability to fall in a feet-first position from heights up to −100 feet, thereby minimizing postural torque, tumbling and rotation
  - Rapid achievement of terminal velocity (60 mph after −5 stories) such that their vestibular system is no longer stimulated by acceleration, reflex limb extension resolves, and the cat adopts a horizontal position, favoring a wider distribution of energy on impact
- Dogs experience a higher proportion of limb injuries, suggested to be associated with the greater size and strength of their limbs absorbing more of the impact before their trunk. Spinal injuries increase with increasing height of fall, as dogs have a tendency to tumble, landing on their back or in a vertical position.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

High-rise syndrome is usually diagnosed via history and physical examination. Following stabilization, thorough orthopedic and neurologic examination is vital. Diagnostic imaging (radiography, ultrasonography and/or CT) is then used to further characterize injury.

DIFFERENTIAL DIAGNOSIS

- Hit-by-car trauma
- Hit by a blunt object
- Kicked by an ungulate animal
- Fights with other animals
- Foreign body penetration
- Gunshot trauma
- Malicious injury

INITIAL DATABASE

- Orthopedic and neurologic examination (following stabilization if necessary)
- CBC, serum biochemistry panel, urinalysis
- Abdominal and thoracic ultrasound (abdominal and thoracic focused assessment sonography for trauma [AFAST and TFAST, respectively]; description of the procedures has been published for dogs but can be applied in cats if tolerated).
- Radiographs of thorax, abdomen, spine, and limbs
- Abdominocentesis and fluid analysis
- Full mouth (intraoral) dental radiographs
- Radiographs of the head, temporomandibular joints, and bullae

ADVANCED OR CONFIRMATORY TESTING

CT of head and spine

TREATMENT

TREATMENT OVERVIEW

- Stabilize animal; priorities are to resolve/improve dyspnea and shock and minimize stress (especially in cats).
- Orthopedic manipulations, radiography, or surgical procedures may initially need to be delayed, with adjunctive pain control, if the patient is systemically unstable at the time of presentation.

ACUTE GENERAL TREATMENT

- Management of respiratory distress:
  - Oxygen supplementation
  - Thoracocentesis if respiratory pattern suggestive of pneumothorax
- Fluid resuscitation from shock:
  - Obtain IV access in an uninjured limb.
  - Administer isotonic crystalloid ± colloid fluids to effect.
  - Start with 20 mL/kg crystalloid bolus in dogs or 10 mL/kg in cats, and titrate to effect up to 80-90 mL/kg/h in dogs and 50-60 mL/kg/h in cats. Consider judicious fluid use, particularly in animals with evidence of pulmonary contusions.
  - Consider addition of colloids if cardiovascular instability persists; start with a 5 mL/kg bolus in dogs and 1-2 mL/kg in cats, and titrate to effect up to 20 mL/kg in dogs and 10 mL/kg in cats.
  - Consider hypertonic saline (3-5 mL/kg once) ± hetastarch if evidence of traumatic brain injury.
- Blood product transfusion (whole blood or packed red blood cells) may be necessary if severe hemorrhage has occurred.
- Provision of appropriate analgesia (opioid analgesia is recommended initially; nonsteroidal antiinflammatory drugs may be added following patient stabilization and assessment of suitability).
- Broad-spectrum antibiotic coverage in animals with penetrating body cavity wounds prior to exploratory surgery
- Further treatment, if sedation or general anesthesia is required, depends on the successful outcome of this initial stabilization.
- Surgical treatment of skeletal injuries
- Exploratory thoracotomy or celiotomy in patients with penetrating thoracic or abdominal wounds, respectively
- Oral/dental treatment (see p. 531)

CHRONIC TREATMENT

- If response to emergency treatment is poor, visceral injury (abdominal and thoracic) with possible hemorrhage should be considered and pursued diagnostically, even in the absence of penetrating body cavity wounds as blunt trauma can occur.
- Chronic oronasal communication: medially positioned double flaps with releasing incisions along dental arch or overlapping double flaps.
- Temporomandibular joint injury (chronic luxation or ankylosis): unilateral or bilateral condylectomy.
- Extraction or endodontic therapy of teeth with pulp exposure.

NUTRITION/DIET

- With dental injuries, soft food is usually adequate; esophagostomy tubes are rarely necessary.

POSSIBLE COMPLICATIONS

- Chronic oronasal communication

- Temporomandibular joint ankylosis in very young animals with difficulty or inability to open the mouth
- Chylothorax

RECOMMENDED MONITORING

- In-patient monitoring until discharge
- Reexamination and removal of skin sutures in 2 weeks
- Removal of cerclage wire around mandibles in 4-5 weeks
- Routine follow-up and radiography to ensure fracture healing following orthopedic surgery

PROGNOSIS AND OUTCOME 

- Good prognosis for survival for ~90% of cats and dogs
- Euthanasia due to client financial constraints is reported, given the high percentage of animals requiring surgery.
- Death, excluding euthanasia, is generally due to shock, stress, and respiratory distress due to thoracic trauma.
- Most deaths occur within 24-36 hours of admission or in the immediate postoperative period
- It is suspected that most dogs falling >6 stories do not survive and hence are not brought to the hospital and assessed in case series

PEARLS & CONSIDERATIONS 

COMMENTS

Number and severity of injuries increase with increasing height of fall; it has been reported that the association between injuries and height of fall follows a curvilinear pattern.

CLIENT EDUCATION

Close windows and balcony doors in the presence of animals

High-Rise Syndrome, Craniofacial

BASIC INFORMATION

DEFINITION

Triad of craniofacial, thoracic, and limb injuries sustained by an animal that falls from a height of one or more stories. The term was originally coined in reference to cats, associated primarily with falls from a height of two or more stories. For systemic effects of high-rise syndrome, see 529.

SYNONYMS

High-flyer syndrome (in humans), jumper's syndrome, extreme deceleration trauma

EPIDEMIOLOGY

SPECIES, AGE, SEX

Predominantly affects cats <3 years old and dogs <5 years old. There is no sex predilection in either species.

RISK FACTORS

- Urban areas
- Tall buildings
- Open windows and balcony doors; roofs

GEOGRAPHY AND SEASONALITY

Falls occur more frequently in summer, followed by autumn, when windows and balcony doors are open and outdoor play is a factor.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Triad of craniofacial, thorax and limb injuries; focus in this chapter is on craniofacial injury.

HISTORY, CHIEF COMPLAINT

Observed fall from window sills, narrow ledges, balconies, and roofs. Encounter of animal with typical injuries in location consistent with prior fall.

PHYSICAL EXAM FINDINGS

Typical craniofacial findings include:

- Mandibular symphysis separation and perisymphyseal fracture (malalignment in the mandibular incisor area)
- Split hard palate (with or without extension into soft palate and malalignment in the maxillary incisor area)
- Epistaxis
- Fractured maxillary canines (with or without pulp exposure), maxillary fourth premolars (traumatic hemisection between mesiobuccal and mesiopalatal crown-root segments), and mandibular first molars
- Temporomandibular joint luxation or fracture
- Zygomatic arch fracture
- Facial wounds
- Orofacial abrasion and hematoma

ETIOLOGY AND PATHOPHYSIOLOGY

- Jumping during play or while chasing a squirrel, bird, insect, or other animal
- Slipping while walking on the edge of a balcony railing or window

- Range of heights fallen by surviving cats (2-32 stories) is high compared to those fallen by dogs (1-6 stories), probably because most dogs do not survive falls from distances higher than 6 stories and thus are not brought to the veterinarian.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The combination of history and characteristic lesions on physical exam is diagnostic. The extent of diagnostic imaging performed on a case depends on the distribution and severity of lesions; most cases require a thoracic radiograph to assess for pneumothorax, pulmonary contusions, and chest wall injuries.

DIFFERENTIAL DIAGNOSIS

- Hit-by-car trauma
- Hit by a blunt object
- Kicked by an ungulate animal
- Fights with other animals
- Foreign-body penetration
- Gunshot trauma
- Animal abuse

INITIAL DATABASE

- Orthopedic and neurologic examination
- CBC, serum biochemistry panel, urinalysis
- Full mouth (intraoral) dental radiographs
- Radiographs of the head, temporomandibular joints, and tympanic bullae
- Radiographs of thorax, abdomen, spine, pelvis, and limbs

ADVANCED OR CONFIRMATORY TESTING

CT of head and spine

TREATMENT

TREATMENT OVERVIEW

- Stabilize animal, especially upper and lower airways and cardiovascular system (hypotension/blood loss).
- Preserve normal anatomic structure and function. Orthopedic manipulations or surgical procedures may initially need to be delayed, with adjunctive pain control, if the patient is unstable at the time of presentation.

ACUTE GENERAL TREATMENT

- Initial treatment for shock (fluid therapy) and thoracic injury (thoracocentesis if pneumothorax) followed by orthopedic/neurologic examination. Further treatment, if sedation or general anesthesia is required, depends on the successful outcome of this initial stabilization.
- Surgical treatment of skeletal injuries
- Cerclage wiring for perisymphyseal fracture/symphyseal separation
- Extraction of teeth with pulp exposure or displacement injury
- Fresh midline clefts of the hard palate: elevation of medially positioned flaps with full-thickness releasing incisions made into palatal mucoperiosteum 1 mm away from the teeth along the dental arches, followed by approximation of the displaced bony structures with digital pressure and suturing of the torn palatal soft tissues in a simple interrupted or mattress pattern. If the separation is extensive, interarcade fixation may be required. Very narrow and short clefts may sometimes heal spontaneously in 2-4 weeks with conservative management, but the benefit of initial surgical management outweighs the risk of developing a persistent oronasal communication.
- Temporomandibular joint luxation: conservative reduction with a wooden dowel (pencil in a cat; see p. 1078)

CHRONIC TREATMENT

- If response to emergency treatment is poor, visceral injury (abdominal and thoracic) with possible hemorrhage should be considered and pursued diagnostically.

- Chronic oronasal communication: medially positioned double flaps with releasing incisions along dental arch or overlapping double flaps
- Temporomandibular joint injury (chronic luxation or ankylosis): unilateral or bilateral condylectomy
- Extraction or endodontic therapy of teeth with pulp exposure

NUTRITION/DIET

Nutritional support: soft food is appropriate. An esophagostomy tube is rarely necessary (see p. 1267).

HIGH-RISE SYNDROME, CRANIOFACIAL A, Open-mouth clinical image of the dorsal aspect of the oral cavity; rostral is toward the bottom of the image. Traumatic cleft palate in a cat after falling from a height. Note separation of left and right incisive bones *(arrow)*, fractured left maxillary canine tooth *(asterisk)*, and midline defect in hard and soft palates. **B,** Postoperative image of the same patient. Repair of traumatic cleft palate was accomplished by means of approximation and suturing of medially positioned flaps after creation of bilateral releasing incisions *(arrows)* into palatal mucoperiosteum along dental arches. Note interarcade fixation (twisted wire reinforced with composite resin) between maxillary canine teeth. (Copyright Dr. Alexander M. Reiter, with permission.)

POSSIBLE COMPLICATIONS

- Chronic oronasal communication
- Malocclusion
- Temporomandibular joint ankylosis in very young animals with difficulty or inability to open the mouth
- Chylothorax

RECOMMENDED MONITORING

- In-patient monitoring until discharge
- Reexamination and removal of skin sutures in 2 weeks
- Removal of cerclage wire around mandibles in 4-5 weeks

PROGNOSIS AND OUTCOME

Good prognosis for survival and return to normal function for ~90% of cats

PEARLS & CONSIDERATIONS

COMMENTS

Number and severity of injuries increase with increasing height of fall; others reported that the association between injuries and height of fall follows a curvilinear pattern.

TECHNICIAN TIPS

Gently offering soft food during the healing period can be the cornerstone of nutritional support.

CLIENT EDUCATION

Close windows and balcony doors in the presence of animals.

Hiatal Hernia/Gastroesophageal Intussusception

BASIC INFORMATION

Hiatal hernia (HH) and gastroesophageal intussusception (GEI) are problems associated with the esophageal hiatus of the diaphragm. They represent very different conditions, in that HH is often subclinical and GEI is often an acute clinical and potentially fatal problem. This indicates the need for accurate diagnosis of caudal esophageal mass lesions.

DEFINITION

- Hiatal hernia:
  - An uncommon condition in dogs, rare in cats, representing protrusion of the abdominal esophagus, gastroesophageal junction, cardia, or gastric fundus through the esophageal hiatus of the diaphragm into the caudal mediastinum
- Gastroesophageal intussusception:
  - An extremely rare condition, seen more often in dogs than in cats
  - An imagination of the cardia into the terminal esophagus through the esophageal hiatus

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Congenital hiatal hernia: primarily dogs <1 year of age
- Acquired hiatal hernia: dogs or cats of any age

GENETICS & BREED PREDISPOSITION

Shar-pei and brachycephalic breeds (e.g., bulldog) may be predisposed to hiatal hernia.

German shepherd dogs may be overrepresented for gastroesophageal intussusception.

RISK FACTORS

Trauma (both)

ASSOCIATED CONDITIONS & DISORDERS

- Esophageal hypomotility or megaesophagus
- Gastroesophageal reflux/esophagitis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Sliding or axial hiatal hernia:
  - Longitudinal displacement of the abdominal esophagus, gastroesophageal junction, or stomach into the caudal mediastinum
- Paraesophageal hernia:
  - Gastroesophageal junction remains caudal to the hiatus, and the fundus of the stomach protrudes adjacent to and parallel to the gastroesophageal junction through the hiatus.
- Gastroesophageal intussusception (rare):
  - Cardia invaginates into the terminal esophagus and through the hiatus.
  - Associated with acute obstruction and severe clinical signs in dogs

HISTORY, CHIEF COMPLAINT

- Absence of clinical signs:
  - Incidental finding on thoracic radiograph (50% of hiatal hernia cases; smaller proportion of gastroesophageal intussusception cases)
- Intermittent signs with sliding HH; typically:

- Regurgitation, dysphagia, ptyalism, and weight loss or slow growth
- GEI
  - Acute vomiting or regurgitation, dyspnea, hematemesis, abdominal pain, and collapse
  - Chronic intermittent vomiting and regurgitation are far less common.

PHYSICAL EXAM FINDINGS

- May be unremarkable
- If clinical signs are present, they may include:
  - Thin body condition
  - Dehydration
- Ptyalism
- Fever, harsh lung sounds, cough, dyspnea
- Possible aspiration pneumonia

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology:

- Congenital hiatal hernia:
  - Abnormal diaphragmatic esophageal hiatus (abnormally large or abnormal laxity of phrenicoesophageal ligament)
- Trauma:
  - Esophageal hiatal enlargement and/or stretching of phrenicoesophageal ligament
- Severe respiratory disease:
  - Intense negative intrapleural pressure required for ventilation may be associated with hiatal hernia in dogs and cats.

Mechanism:

- Loss of normal anatomic relationship:
  - Adversely affects the normal high-pressure zone at the gastroesophageal junction, causing reflux esophagitis
- Primary or secondary esophageal motility disorders and megaesophagus can exacerbate signs.
- Upper airway obstruction (e.g. brachycephalic syndrome):
  - May result in significant negative intrapleural pressure required for inspiration, causing hiatal herniation/gastroesophageal reflux
- Large hernias may allow other abdominal organs to enter the caudal mediastinum.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected based on patient signalment, presenting history, physical examination findings, and above all, demonstration of a mass effect in the area of the terminal esophagus on thoracic radiographs. Elucidation of the diagnosis requires radiographic contrast studies and endoscopy.

DIFFERENTIAL DIAGNOSIS

- Megaesophagus
- Esophageal foreign body, stricture, or mass
- Mediastinal or pulmonary mass

INITIAL DATABASE

- CBC:
  - Neutrophilia with toxic changes and/or left shift, associated with inflammation/infection: suspect aspiration pneumonia
- Serum biochemistry profile:
  - Hypoproteinemia possible (malnutrition)
- Diagnostic imaging:
  - Survey thoracic radiographs
    - Increased density/mass lesion in the caudodorsal mediastinum. Highly characteristic of these disorders. Disappearance/reappearance on repeated radiographs is characteristic but not essential.
    - Can be within normal limits if sliding hernia

ADVANCED OR CONFIRMATORY TESTING

- Fluoroscopy with a positive contrast esophagram:
  - Evaluate esophageal size and motility.
  - Identify sliding hernia. Application of external abdominal pressure during fluoroscopy may aid in diagnosis of sliding hernia.
- Esophagoscopy:
  - Assess presence/severity of esophagitis.
  - Gastroesophageal intussusception: confirm diagnosis.

TREATMENT

TREATMENT OVERVIEW

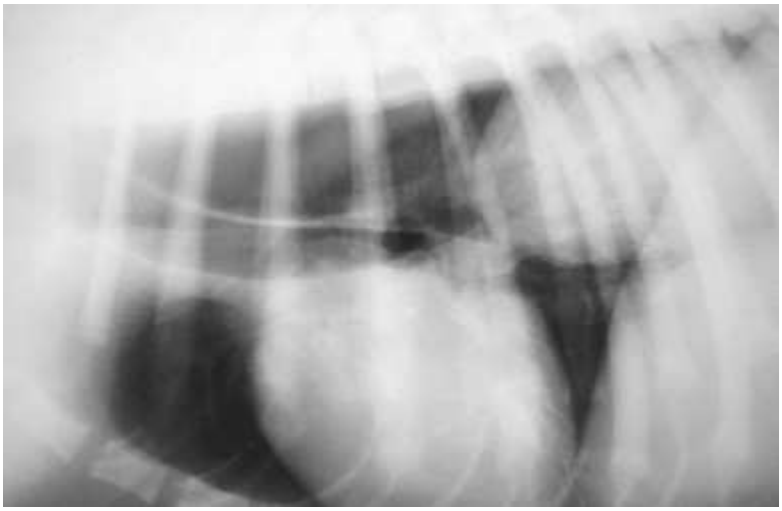
Treatment of hiatal hernia is aimed at diminishing gastroesophageal reflux, providing nutritional support, and managing aspiration pneumonia if present. Surgery is performed on cases that fail to respond to medical therapy. Treatment of paraesophageal hernia and GEI requires surgery to address the anatomic malpositioning of organs through the esophageal hiatus.

ACUTE GENERAL TREATMENT

- Medical management:
  - Correction of fluid and electrolyte deficits if present
  - Aggressive treatment of aspiration pneumonia (see p. 885)
  - Treatment of gastroesophageal reflux/esophagitis (see p. 367)
- Surgical management: patients showing clinical signs referable to hernia/intussusception:
  - Reduction of hiatal hernia/gastroesophageal intussusception
  - Closure of esophageal hiatus to a normal size
  - Left-fundic gastropexy to prevent recurrence

CHRONIC TREATMENT

- Continuation of treatment of gastroesophageal reflux/esophagitis
- Surgical correction of hiatal hernia in patients that do not respond to medical management within 30 days



HIATAL HERNIA/GASTROESOPHAGEAL INTUSSUSCEPTION Lateral thoracic radiograph of a dog, demonstrating a large soft-tissue mass due to gastroesophageal intussusception, located characteristically in the caudodorsal thorax. The dog suffered strangulation injury when it became caught in a snare. Also visible is an air-filled esophagus which demonstrates both sides of the dorsal tracheal membrane ("tracheal stripe sign"). A differential diagnosis for the radiographic appearance of the mass lesion is primary lung tumor.

(Courtesy Dr. Richard Walshaw.)

NUTRITION/DIET

Acute:

- Upright feeding of small, frequent meals to promote normal function of the esophagus/gastroesophageal junction
- Feeding (percutaneous endogastric) tube if oral intake inadequate (see p. 1270)

Chronic:

- Continuation of feeding regimen
- Upright feeding in cases of megaesophagus associated with GEI

POSSIBLE COMPLICATIONS

- Failure of medical management to adequately resolve problem
- Recurrence of hiatal hernia after surgical correction
- Development of esophageal stricture secondary to gastroesophageal reflux/esophagitis

RECOMMENDED MONITORING

Follow-up positive contrast esophagram (4-6 weeks):

- Demonstrate resolution of
  - Hiatal hernia/gastroesophageal intussusception
  - Gastroesophageal reflux
- Assess esophageal motility
- Determine whether continuation of feeding regimen and treatment of gastroesophageal reflux/esophagitis still necessary.

PROGNOSIS AND OUTCOME

- Good prognosis:
  - If the patient has no or mild clinical signs
  - With surgical intervention in the absence of aspiration pneumonia
- Poor prognosis associated with:
  - Resistant aspiration pneumonia
  - Severe esophagitis/stricture
  - Persistent megaesophagus

PEARLS & CONSIDERATIONS

COMMENTS

- Treatment for esophagitis should be continued postoperatively in any patient undergoing surgical correction of hiatal hernia.
- Aspiration pneumonia requires intensive treatment prior to considering surgical intervention.

Heterobilharzia americana Infection

BASIC INFORMATION

DEFINITION

Infection with trematodes (flukes) of the blood vasculature of the small intestine, primarily the mesenteric veins, of mammals

SYNONYMS

These parasites may be referred to as blood flukes or schistosomes. The syndrome may be referred to as canine heterobilharziasis, canine bilharziasis, or canine schistosomiasis.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Rare in dogs and very rare in cats. Definitive hosts include members of the Canidae and Felidae families. Raccoons may serve as reservoir hosts.

GENETICS & BREED PREDISPOSITION

Sporting/hunting breeds of dogs (environmental exposure)

RISK FACTORS

Hunting and exposure to/contact with large stationary or slow-moving bodies of water inhabited by molluscan (snail) intermediate hosts of the genera *Lymnaea*, *Pseudosuccinea*, and *Fossaria.*

CONTAGION & ZOONOSIS

Cercarial stages of the parasite emerge from aquatic snails, swim in the water, and directly penetrate the skin of the definitive host. Cercarial dermatitis, schistosome dermatitis, “swimmer's itch,” or “water dermatitis” due to *Heterobilharzia americana* has been reported in humans in Louisiana. This is due to the cercarial stages of the parasite repeatedly penetrating human skin following human contact with “infected water.”

GEOGRAPHY AND SEASONALITY

These blood flukes are found in definitive hosts in North America, particularly the states bordering the Gulf of Mexico (range extends from Texas to North Carolina).

ASSOCIATED CONDITIONS & DISORDERS

Granulomatous inflammation, hypercalcemia, rectal strictures, and bloody diarrhea have been reported.

CLINICAL PRESENTATION

Clinical signs of heterobilharziasis in dogs are poorly described but may include weight loss, hematochezia, melena, borborygmus, flatulence, and diarrhea. Severe cases may exhibit hepatomegaly and ascites. Cutaneous erythema and dermatitis may be seen, especially on the extremities.

HISTORY, CHIEF COMPLAINT

The dog or cat typically will have had a history of roaming freely and having had contact with fresh water. Infected dogs may demonstrate weight loss, diarrhea, hematochezia, and other clinical signs related to the gastrointestinal (GI) tract.

PHYSICAL EXAM FINDINGS

- Loss of weight

- Abdominal pain
- Dermatitis, redness, urticaria
- Afebrile
- Rectal examination may reveal melena, mucoid or hemorrhagic stool.

ETIOLOGY AND PATHOPHYSIOLOGY

- The parasites are also referred to as schistosomes or blood flukes (they are closely related to *Schistosoma* species, the number-one helminth parasite of humans throughout the world).
- The adult stages of this parasite (both male and female blood flukes) are found within the blood vasculature in copula; the female fluke resides within the gynecophoric (female-carrying) canal of the male fluke.
- The life cycle involves intermediate hosts, aquatic snails of the genera *Lymnaea*, *Pseudosuccinea*, and *Fossaria.*
- Fluke ova (eggs) exit the definitive (mammal) host in the feces. Eggs must make contact with fresh water inhabited by certain species of snails.
- Each ovum will hatch, releasing a motile larval stage, the miracidium. The miracidium actively penetrates the epithelium of an aquatic snail. Within the snail, the miracidium undergoes asexual (multiplicative) development, ultimately producing a larval stage known as a cercaria. Hundreds of cercariae may be produced from a single miracidium.
- The cercarial stage emerges from the aquatic snail and swims about in the water, ready to actively penetrate the skin of the definitive host.
- The cercariae transform into schistosomula which are transported to the host's lungs hematogenously.
- The schistosomula are then carried to the liver via the blood stream and are found in the portal vessels of the liver. The male and female flukes pair up in the portal veins before they leave the liver, reaching maturity in the mesenteric veins.
- Within the veins, the male and female worms are permanently in copula.
- The egg-laying female penetrates deeply into the small vessels of the mucosa or submucosa of the intestine, laying her eggs in the capillaries.
- From the capillaries, the eggs pass through the host intestinal wall into the small-intestinal lumen and pass out in the host feces.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in endemic areas when outdoor dogs show gastrointestinal signs and is most easily confirmed via fecal flotation. Cases that are more challenging require advanced diagnostic testing if other more likely causes have been ruled out.

DIFFERENTIAL DIAGNOSIS

Hemorrhagic gastroenteritis, clostridial diarrhea, hypoadrenocorticism, GI histoplasmosis, lymphosarcoma, apocrine gland adenocarcinoma

INITIAL DATABASE

- CBC and serum chemistry profile (often normal but may reveal anemia, eosinophilia, increased liver enzyme levels, hypercalcemia, hypoalbuminemia, hyperglobulinemia, and azotemia)
- Fecal smear to check for the characteristic ovum containing the miracidium. Should be preformed on multiple occasions because of intermittent shedding of ova in host feces.
    - Eggs can sometimes be seen on a direct fecal smear. They are thin walled with a single operculum.
    - An alternate method of diagnosis is to place a large amount of stool in water and obtain a sample from the top layer in 2 hours. Miracidia that hatch can be seen “swimming” under the microscope.
- Since eggs are difficult to observe on fecal flotation or sedimentation, the practitioner may have to resort to more invasive forms of diagnostics (liver or intestinal biopsies) or submission of feces to an outside diagnostic service for a PCR-based assay (www.cvm.tamu.edu/gilab)
    - Liver and/or intestinal biopsies with histopathologic examination revealing granulomatous lesions with helminth ova or trematode nidi

ADVANCED OR CONFIRMATORY TESTING

- A PCR-based assay for the detection of DNA from the ova in host feces
- Indirect hemagglutination may be useful.

TREATMENT

TREATMENT OVERVIEW

Eliminate adult male and female schistosomes within blood vasculature.

ACUTE AND CHRONIC TREATMENT

- Praziquantel (25 mg/kg PO q 8 h for 2 days); nausea and vomiting may be side effects.
- Fenbendazole (40 mg/kg PO q 24 h) SID for 10 days, repeat in 3 weeks.

NUTRITION/DIET

Bland, high-carbohydrate, low-fat diets that are easily digested are recommended until GI signs abate.

POSSIBLE COMPLICATIONS

Adult blood flukes may be killed en masse then embolize the portal system (large infections).

RECOMMENDED MONITORING

- Serum liver values +/- liver function tests
- May repeat PCR on feces to ensure that it is negative following treatment

PROGNOSIS AND OUTCOME

Generally good, barring complications of massive parasite kill

PEARLS & CONSIDERATIONS

COMMENTS

Since this larval cestode is rare, diagnosis can be challenging. A pathologist or parasitologist at a veterinary diagnostic laboratory may be called on to assist in the definitive diagnosis of the parasite.

PREVENTION

Prevent dogs and cats from roaming and coming into contact with freshwater aquatic environments (large stationary or slow-moving bodies of water) inhabited by the snail intermediate host.

TECHNICIAN TIPS

- Fecal smears should be performed on multiple occasions because of intermittent shedding of ova in host feces.
- Fecal flotation and sedimentation techniques may offer low/no yield because the thin-walled eggs burst.

CLIENT EDUCATION

To avoid infection in endemic areas, dogs should not be allowed to roam freely, thus avoiding contact with infested waters.

AUTHOR: CHARLES HENDRIX

EDITOR: DOUGLASS K. MACINTIRE

Herpesvirus, Dog

BASIC INFORMATION

DEFINITION

Viral infection of canids that can present one of four possible clinical scenarios: respiratory distress from upper airway infection; abortion; vaginitis; and neonatal puppy mortality up to 3 weeks of age.

SYNONYMS

Canine herpesvirus type 1 (CHV-1), CHV, dog herpes, neonatal herpes, fading puppy syndrome

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Domestic dogs; wild canids (coyotes, wolves, etc.)
- Immunologically naive pregnant dams are most susceptible to the reproductive effects of CHV-1, and their offspring are most susceptible to systemic disease, with high puppy mortality.

RISK FACTORS

There are nine major risk factors: immunologic status of dams (pups), age, mating experience, reproductive cycle, breeding kennel, kennel size, breeding management (use of nonresident males), kennel cough, and kennel hygiene.

CONTAGION & ZOONOSIS

- Highly contagious among canids only via saliva and vaginal secretions
- Fomites may contribute to spread.
- Direct contact (saliva, urogenital secretions) is the most efficient mode of transmission, especially from dogs with clinical signs but possibly from latent carriers also.
- The virus is readily inactivated outside the body by heat, drying, or disinfectants (diluted bleach 1:30).
- Not zoonotic

GEOGRAPHY AND SEASONALITY

The virus persists in carrier dogs worldwide as a latent infection and may be exacerbated with stress-induced or physiologic/hormone-related immune suppression.

ASSOCIATED CONDITIONS & DISORDERS

Surviving puppies may have deafness, neurologic dysfunction or renal damage.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Dogs, usually <2 years old; acute to chronic upper airway signs
- Dam aborts litter, usually with 100% puppy mortality if infection of dam occurs during last trimester.
- Dam infects her litter during whelping, usually 80%-100% puppy mortality if infection is a reexacerbation of latent infection.
- Naïve dam gives birth to naïve litter, and secondary contact with CHV-shed-ding dog carries virus back to litter. Mortality rate varies from 25%-80% depending on virus challenge dose, age of puppies, and body temperature of puppies.
- Dam or sire presented for evaluation of papulovesicular lesions of the external genital organs.

HISTORY, CHIEF COMPLAINT

As described above

PHYSICAL EXAM FINDINGS

Puppies appear lethargic, fail to nurse; decreased body weight; soft, yellow-green feces; no fever; rhinitis possible, with serous/mucopurulent/hemorrhagic nasal discharge; mucosal petechiae common. Puppies lose consciousness and may have opisthotonos and seizures before death.

ETIOLOGY AND PATHOPHYSIOLOGY

- CHV has a predilection for lymphoid and neural cells, both of which may become latently infected (no mature viral production), but a dog remains a potential shedder if the virus is reexacerbated due to stress (e.g., pregnancy, corticosteroids, irradiation).
- The optimal temperature for CHV replication is 33°C-35°C (i.e., the temperature of the outer genital and upper respiratory tracts).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Although a presumptive diagnosis of CHV-induced disease can be achieved by the observation of ill pups <3 weeks of age, confirmation of CHV can be obtained histopathologically on fixed liver and kidney tissue of affected pups, virus isolation from fresh/frozen tissues, and/or PCR on whole blood from pups. Carrier dogs can be identified by PCR on whole blood from adult dogs.

DIFFERENTIAL DIAGNOSIS

- Acute-onset respiratory signs/respiratory distress of upper airway origin: canine adenovirus type 2; canine parainfluenza; *Bordetella bronchiseptica;* upper airway foreign body
- Reproductive disease: *Brucella canis, Streptococcus* spp.; canine distemper virus; neosporosis; toxoplasmosis

INITIAL DATABASE

CBC, serum biochemistry profile, urinalysis: hematologic and biochemical values are usually nonspecific, but a marked thrombocytopenia may be observed. A marked increase in the alanine aminotransferase activity may be found in affected neonatal puppies.

ADVANCED OR CONFIRMATORY TESTING

- Antemortem testing:
  - Serologic titers from affected adult dogs (titers equal to or greater than 1:2 indicate exposure/infection). Antibody titers do not correlate with active viral shedding but are good indicators of prior infection and latency status.
  - Virus isolation from nasal/urogenital swabs indicates infection and active shedding.
  - PCR on whole blood indicates infection and either active viremia or latency.
- Postmortem testing (aborted/neonatal dead puppies):
  - Virus isolation from lung, bronchiolar lymph nodes, liver, kidney, and spleen
  - Histopathologic evaluation of lung, liver, kidney, spleen, small intestine, and brain. Depending on the stage of cellular infection and method of fixation, basophilic or acidophilic intranuclear inclusions may be noted. These intranuclear inclusion bodies are considered pathognomonic for CHV.
  - No CHV immunohistochemical test is commercially available.
  - PCR can also be done on the aforementioned selected tissues but is usually reserved for determining latency.

TREATMENT

TREATMENT OVERVIEW

Treatment of CHV-induced neonatal disease requires rapid response on the part of owner and veterinarian. Usually by the time clinical signs occur, individually affected pups have a poor prognosis. Unaffected litter mates may be treated with antiviral drugs and/or CHV-hyper-immune serum. The temperature of the puppy environment should be raised without the dam and surviving pups becoming dehydrated.

ACUTE GENERAL TREATMENT

- Treatment of neonatal puppies with CHV-induced disease is usually not recommended because of rapid progression, poor prognosis, and the potential for cerebellar and retinal dysplasias in surviving puppies.
- If only a portion of the litter demonstrates overt signs, the remaining littermates can be treated with immune serum (2 mL of serum from a dog with known anti-CHV titer, given intraperitoneally).
- Neonates can also be maintained in an environment with high humidity (up to 55%) and elevated ambient temperatures of 26.6°C-37.7°C (98°F-100&°F). Because CHV is naturally temperature sensitive, raising the pup's body temperature by artificial heating early in the course of the infection may have therapeutic value; caution and constant body temperature monitoring are essential to avoid iatrogenic hyperthermia.

CHRONIC TREATMENT

Owing to high incidence of life-threatening sequelae, treatment is not recommended if pup is presented already showing clinical signs.

BEHAVIOR/EXCERCISE

Puppies will be in pain and crying. Keep as comfortable as possible with warm cloths.

POSSIBLE COMPLICATIONS

Treatment of clinically ill puppies may result in associated conditions and disorders (see above).

RECOMMENDED MONITORING

Puppies presented while showing clinical signs should be monitored every few hours, as prognosis is poor. Dam can be monitored by checking CHV antibody titers and by PCR on urogenital secretions (swabs).

PROGNOSIS AND OUTCOME

- Unaffected neonatal puppies from an affected litter have a good prognosis.
- Dams that abort or have a naive litter that subsequently becomes infected by a secondary source of CHV commonly seroconvert and will subsequently have normal litter. CHV immunity will be passed onto litters via colostrum. Colostral immunity, which persists to 8 weeks, will prevent clinical signs in the puppies but will not prevent against primary infection and subsequent latency.

PEARLS & CONSIDERATIONS

COMMENTS

CHV is a manageable infection and a preventable disease (see Prevention and Client Education below).

PREVENTION

- Good hygiene: cleanliness of dam, rigorous handwashing or use of gloves by handlers, together with a warm and clean puppy environment
- No vaccine available in the United States. A European product has been licensed, with good results reported when used prebreeding.

TECHNICIAN TIPS

- Emphasize good prenatal and postnatal hygiene with clients.
- Incorporate kennel surveillance program for *Brucella cants* and CHV testing prebreeding.
- Identify first-time pregnant dogs as high risk, and quarantine from outside dogs/humans as much as possible.

CLIENT EDUCATION

- Planned exposure of young (>6 months) puppies to older dogs to “naturally immunize” them before breeding and whelping. This induced infection rarely becomes clinically overt, and if it does as a respiratory disease, a 2-week quarantine is advised.
- Maintenance of a strict quarantine period to work within the “6-week danger period” (3 weeks before and 3 weeks after whelping)

- Maintaining ambient body temperature to minimize risk of hypothermia. CHV is very heat sensitive.

Herpesviral Keratitis, Cats

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Corneal inflammation associated with feline herpesvirus type 1 (FHV-1) infection
- Sometimes divided into ulcerative and nonulcerative (or stromal) keratitis or into an overlapping pair of epidemiologically relevant categories: primary and recrudescent herpesviral keratitis

SYNONYMS

Herpetic keratitis

Feline viral rhinotracheitis: FHV-1, FVR

EPIDEMIOLOGY

SPECIES, AGE, SEX

- FHV-1 is highly species specific. Domestic and wild cats of any age may be affected (see p. 1127).
- Young kittens undergoing primary exposure usually display ulcerative disease, and older cats undergoing viral reactivation may experience ulcerative or nonulcerative recrudescent disease.

GENETICS & BREED PREDISPOSITION

- No breed predilection has been proven (prevalence in breeding catteries may give false impression of susceptibility).
- Individual variation in susceptibility to recrudescent herpetic keratitis suggests immunologic predisposition.

RISK FACTORS

- Stresses such as rehousing, intercurrent disease, or pregnancy/parturition/lactation; corticosteroid administration; multicat households or shelters; inadequate vaccination

CONTAGION & ZOONOSIS

- Highly contagious among cats
- Not zoonotic

GEOGRAPHY AND SEASONALITY

- Worldwide viral distribution without seasonality
- Because of susceptibility of kittens, trends in disease prevalence may be noted in association with feline breeding seasons.

ASSOCIATED CONDITIONS & DISORDERS

- FHV-1 also causes conjunctivitis, dermatitis, and may cause anterior uveitis.
- FHV-1 is associated with corneal sequestra and eosinophilic/proliferative keratitis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Ulcerative keratitis (seen most often upon initial exposure but also in recurrent forms)
- Nonulcerative keratitis (seen most often in chronic primary or recurrent forms)

HISTORY, CHIEF COMPLAINT

- Ocular discharge

- Blepharospasm (squinting)
- Corneal opacification
- Upper respiratory signs may be seen, including nasal congestion, sneezing, and serous or mucopurulent nasal discharge
- Ocular signs are typically bilateral in primary disease but often unilateral during recrudescences.

PHYSICAL EXAM FINDINGS

- Ocular discharge (serous, mucoid, purulent, sanguineous, or dry and crusty; sometimes dark red or black-stained)
- Blepharospasm
- Deep or superficial corneal vascularization, ulceration (dendritic early; usually geographic by time of presentation; often chronic nonhealing and sometimes with a lip of redundant epithelium)
- Corneal opacification due to white blood cell infiltration and/or corneal edema and/or scarring
- Conjunctival or episcleral injection
- Chemosis (conjunctival edema), blepharoedema
- Reflex uveitis (e.g., miotic pupil; aqueous flare and/or inflammatory cells in the anterior chamber); see p. 1151
- Eosinophilic/proliferative keratitis appears as raised pink, sometimes chalky plaques extending from the limbus often with a leading zone of ulceration.
- Corneal sequestration appears as a planar to sometimes raised amber to dark black region of axial to paraxial cornea often surrounded by corneal vascularization and sometimes stromal inflammatory cell infiltration.

ETIOLOGY AND PATHOPHYSIOLOGY

- FHV-1 is a ubiquitous virus.
- Infection causes usually self-limiting primary disease in essentially all cats infected with the virus.
- Approximately 80% of affected cats become latently infected for life.
- Periodic reactivation occurs in about half of these.
- Periodic recrudescent disease occurs in a minority of cats.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The frequency with which cats are vaccinated and the number of normal cats that shed virus at ocular sites make serologic and viral detection methods unhelpful. Inclusion bodies are rarely seen on cytologic specimens. Diagnosis is made based on visualization of dendritic ulcers, presence of supportive signs, and/or response to therapy.

DIFFERENTIAL DIAGNOSIS

- There are no other recognized primary feline corneal pathogens.
- *Chlamydophila felis* (formerly *Chlamydia psittaci)* causes conjunctivitis but is not known to cause keratitis.
- Feline calicivirus is not a primary corneoconjunctival pathogen but rather causes lesions of the oral and pharyngeal mucosa.
- Noninfectious corneal disease (immune-mediated, neoplastic, KCS, foreign body, traumatic) is uncommon in cats compared to dogs but should be considered.

INITIAL DATABASE

- Thorough ophthalmic examination (see p. 1313) including application of fluorescein and sometimes rose bengal stains
- Corneal or conjunctival cytologic evaluation will eliminate the possibility of eosinophilic/proliferative keratocon-junctivitis; however, herpesviral inclusions are seen extremely rarely.

ADVANCED OR CONFIRMATORY TESTING

- Serologic titers are not useful because of vaccination and widespread (97%) seroprevalence.
- Detection of virus (isolation) or its proteins (immunofluorescent antibody testing) or DNA (PCR) is of limited value because of the number of normal animals that may shed these.

TREATMENT

TREATMENT OVERVIEW

Cats with primary and many mild recrudescent forms of herpetic disease improve with supportive care only. Cats with severe or frequently recurrent keratitis require specific antiviral therapy. Due to toxicity and efficacy profiles, such treatment is largely limited to topical therapy (many systemic antiviral agents are of low efficacy and/or high toxicity). Lysine may limit recurrences in some cats.

ACUTE GENERAL TREATMENT

- Cats with respiratory signs may need supportive care.
- Cats with ulcerative keratitis require a topical broad-spectrum antibiotic.
- Consider a topical antiviral for chronic or severe signs. Topical antiviral agents (e.g., idoxuridine, trifluridine, vidarabine) are virostatic and must be administered at least 4-6 times daily. The exception is cidofovir, which because of tissue accumulation may be administered twice daily.
- Use systemic antiviral agents (e.g., acyclovir) with extreme care if at all, owing to toxicity.
- Consider mucinomimetic tear-replacement products (hyaluronic acid).
- Avoid topical or systemic corticosteroid administration.

CHRONIC TREATMENT

- Consider oral administration of lysine (500 mg/cat PO q 12 h: lifelong treatment) to reduce viral replication in cats with frequent recurrences.
- Avoid prolonged topical antiviral administration if possible.
- Avoid topical or systemic corticosteroid administration.

BEHAVIOR/EXERCISE

- Reduce known stresses.
- Reduce overcrowding in multicat situations.

POSSIBLE COMPLICATIONS

- Topical antiviral agents are epitheliotoxic.
- Valacyclovir is toxic to cats.

RECOMMENDED MONITORING

- Frequent ophthalmic examinations, especially of ulcerative keratitis
- Monitor CBC and serum biochemistry panels if systemic antiviral agents are used.

PROGNOSIS AND OUTCOME

- Primary disease is self-limiting in most cats.
- A minority experience chronic and/or recrudescent disease.
- Treat recurrences early and aggressively.
- Secondary bacterial invasion of corneal ulcers can cause globe perforation.
- Chronic stromal herpetic keratitis is painful and can be blinding secondary to corneal scarring.

PEARLS & CONSIDERATIONS

COMMENTS

- FHV-1 is the most common cause of ulcerative and nonulcerative keratitis in cats.
- Diagnostic testing is confounded by viral shedding in normal cats.
- Topical antiviral agents must be administered frequently to be effective.

PREVENTION

- Vaccination lessens signs but may not reduce recurrences or establishment of latency.

TECHNICIAN TIPS

- Minimize transfer of FHV-1 between cats by handwashing.
- Clean contaminated equipment with standard disinfectants.

CLIENT EDUCATION

- Minimize known stresses.
- Early recognition and therapy of recrudescent disease are important.

EDITOR: CHERYL L. CULLEN

Herbicide (Phenoxy, Others) Toxicosis

BASIC INFORMATION

DEFINITION

- Phenoxy-type herbicides include: *2, 4-D* (2, 4-dichlorophenoxyacetic acid), *MCPA* (2-methy1-4-chlorophenoxyacetic acid), *MCPP* (2-[4-chloro-2-methoxy] propionic acid), and *dicamba* (3,6-dichloro-2-methoxybenzoic acid).
- Commonly used in a residential setting (lawns, along fences) and available through lawn care professionals or local retail outlets
- Available as concentrates or ready-to-use products. Most exposures in animals occur from walking through a recently treated yard (dermal and oral exposure) or chewing and puncturing the container to produce a **spill** situation.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs most commonly involved; outdoor cats on occasion
- Younger, inquisitive or active dogs more likely to be exposed. Dogs lick or sometimes “graze” an herbicide-treated area.
- Cats exposed by running through a freshly treated area then ingesting the product through grooming

GENETICS & BREED PREDISPOSITION

Dogs eliminate chlorophenoxy compounds (e.g., 2,4-D, MCPA) slowly owing to saturation of the renal organic anion system, which can prolong urinary excretion and extend recovery times.

RISK FACTORS

- Preexisting debilitation or chronic kidney disease
- Exposures to concentrated products are typically of greater concern.

GEOGRAPHY AND SEASONALITY

Spring and summer provide greater opportunity for accidental exposure.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Most cases involve ready-to-use products, are acute in nature (onset of signs <1-4 hours after exposure), and are restricted to mild, self-limiting hypersalivation, excessive licking, hacking, retching, vomiting, diarrhea, anorexia within 4 hours of exposure. Systemic effects are not expected in these cases.
- Much less commonly, exposure to concentrated products in substantial amounts can cause systemic absorption and subsequent gastritis, myotonia, paresis, generalized muscle weakness, ataxia, and seizures.

HISTORY, CHIEF COMPLAINT

- Most common: patient was on a treated lawn; signs as listed above.
- Licking furniture or other inanimate objects (contact irritant nature of the product)

PHYSICAL EXAM FINDINGS

- Routine presentation: as above plus increased cough/gag reflex, soft abdomen; vital signs typically within normal limits
- With substantial ingestion of concentrate (rare): as described above

ETIOLOGY AND PATHOPHYSIOLOGY

- Local contact: physical irritant effect in most cases (due to normally low-end-use concentrations of active ingredients and

surfactants)
- Consumption of concentrates may lead to systemic absorption and in very large doses may uncouple oxidative phosphorylation, induce systemic metabolic acidosis, cause hepatic and renal toxicosis, and cause gastrointestinal ulceration and bleeding. Death is rarely encountered.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based entirely on history of exposure (walking through a treated lawn) and clinical signs (vomiting, gagging, muscle weakness), as timely clinical testing is not available.

DIFFERENTIAL DIAGNOSIS

- Lawn grass or nontoxic outdoor plant ingestion
- Mild oral mucosal or dental trauma
- Bufo toad ingestion (acute transient hypersalivation effect)
- Exposure to cleaning agents, petroleum distillates, and the like
- Marijuana, macadamia nuts toxicosis

INITIAL DATABASE

- No significant serum biochemical changes expected with exposure to routine ready-to-use products
- With systemic effects (paresis, ataxia, myotonia), serum biochemical changes may include:
  - ± Azotemiaa
  - ± Increased liver enzymes
  - ± Increased creatine kinase
  - ± Myoglobinuria
  - ± Metabolic acidosis

ADVANCED OR CONFIRMATORY TESTING

- Rarely needed or done. Identification of source container (contents list on label) can confirm herbicide.
- Antemortem: chilled vomitus, serum, urine, for toxicology herbicide screen within 48-72 hours post exposure
- Postmortem: liver, kidney, muscle, and brain, chilled or frozen for toxicology herbicide screen

TREATMENT

TREATMENT OVERVIEW

Most cases are treated empirically by diluting the orally ingested product with milk or water and by keeping the animal off food and water to control vomiting. Induction of emesis and administration of activated charcoal with supportive care may be needed first if concentrated products have been ingested.

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Oral rinsing with water or milk to dilute, flush, and dampen the contact irritant effect to the oral mucosa
  - Administration of milk or water (2-6 mL/kg PO or via stomach tube [see p. 454]) to dilute ingested product 0-6 hours after ingestion.
  - Bathe with water and mild liquid detergent solution for dermal exposure (acutely; <30 minutes postingestion).
  - Inducing emesis and/or activated charcoal procedures are generally not beneficial or indicated because of rapid absorption; may be considered if concentrated products are involved.
  - Control vomiting (if severe).
    - Withhold food and water for 2 hours after the start of vomiting.
    - Maropitant, 1 mg/kg SQ (or 2 mg/kg PO q 24 h) for up to 5 days, *or*
    - Metoclopramide, 0.2-0.5 mg/kg PO or SQ q 6-12 h
- Supportive care:
  - Intravenous fluids
  - Urine trapping (alkaline diuresis) to enhance chlorophenoxy excretion and decrease risk of renal failure due to

rhabdomyolysis; beneficial if systemic involvement. Consider 1-2 mEq/kg of sodium bicarbonate added to fluids; maintain a urine pH of ≥7.5. Monitor acid-base status closely.
- Forced saline diuresis alone is not likely to enhance clearance of the chemical.
- Gastrointestinal protectants if needed (see p. 440).

POSSIBLE COMPLICATIONS

- Metabolic acidosis (rare)
- Renal and hepatic complications (rare)
- A controversial literature report (Hayes, et al., 1991) suggesting a modest increase in the incidence of lymphoma in dogs exposed to 2,4-D-treated lawns is considered suspect in terms of accuracy by many toxicology experts.

RECOMMENDED MONITORING

Only in patients with systemic effects:

- Serum renal and hepatic values
- Acid-base status

PROGNOSIS AND OUTCOME

- Excellent; self-limiting signs usually resolve in 12-24 hours.
- Good with systemic effects; signs resolve within 24-96 hours; long-term adverse health effects are rare.

PEARLS & CONSIDERATIONS

COMMENTS

- Other common herbicides to which dogs and cats are exposed include *glyphosate* (Roundup) (see p. 1281) and *pendimethalin.* These herbicides also have low order of toxicity, and most exposures result in mild self-limiting gastrointestinal signs.
- Most exposures to phenoxy-type herbicides involve exposure to very low concentrations (<1% active ingredient) on treated lawns and therefore are of low-risk concern.
- “Weed-and-feed” lawn care products contain herbicide (weed) and fertilizer (feed) components. Typically, low risk is expected from accidental exposures to these products unless an insecticide component has been added.
- No significant exposure or risk of acute toxicosis if animal eats treated grass or goes in the treated yard after the spray has already dried (within a few hours).

PREVENTION

Keep product containers locked and away from animals.

CLIENT EDUCATION

- Always read the label and follow label directions before applying any herbicide.
- Allow adequate drying time before allowing pets to reenter.

1ST EDITION AUTHOR: MICHAEL KNIGHT

Herbal Drugs/Natural Supplements Toxicosis

BASIC INFORMATION

DEFINITION

- Herbal preparations are obtained from plants. The use of medicinal plants and herbal medications in humans is a multibillion dollar industry around the world.
- Herbal medications are available in the form of nutritional or dietary supplements, extracts, teas, tablets, powders, creams, ointments, beverages, or tinctures either as a single ingredient or multiple ingredients.
- Toxicosis occurs when pets ingest large amounts of owners' medication (e.g., ma huang, guarana, 5-hydroxytryptophan [5HTP]) or when animal owners use concentrated herbal products (e.g., melaleuca oil) on the animal, assuming all natural products are safe. Adverse effects can also occur secondary to drug interactions with the herbal drugs (e.g., concurrent use of St. John's wort and antidepressants).
- Acute toxicosis is reported commonly in dogs, owing to their indiscrete eating habits. Cats mostly eat a single tablet/capsule. Dogs and cats of all breeds, ages, and both sexes are susceptible.

PEARLS & CONSIDERATIONS

- Safety and efficacy of herbal drugs in pets are not evaluated and labeled as for approved prescription drugs.
- Concentration of active ingredients in the herbal supplement can vary between brands and from plant to plant because of several environmental factors (growth stage, soil conditions, weather, etc.) or manufacturing processes.
- Many pet owners use herbal supplements as alternative/complementary/integrative therapy with or without discussing it with their veterinarian. Since there is usually no warning on the label, many pet owners do not consider herbal drugs/nutritional supplements hazardous and do not keep them out of reach of pets.
- Most herbal supplements contain multiple ingredients, and if their mechanisms of action are similar, one supplement may cause additive or synergistic toxic effects (uncharacteristically severe signs). For example, presence of guarana and green tea or presence of ma huang and guarana together may lead to additive or synergistic toxic effects.
- Below, the most commonly involved ingredients, their actions, and treatments are listed. For more detail, readers are encouraged to read supplemental information or other chapters listed in this book.

HERBAL DRUGS/NATURAL SUPPLEMENTS TOXICOSIS Toxicology of Commonly Used Herbal Ingredients Present in Various Formulations

Common Name(s)	Genus, Species	Toxic Principle if Known	Popular Usage	Toxicity Signs/Major Effect/Actions	Treatment Overview/Comments
Ma huang, Indian common mallow, bitter orange	*Ephedra sinica, Sida cordifolia, Citrus aurantium*	Ephedrine, pseudoephedrine, synephrine	Weight loss, weight lifting, "herbal ecstasy," decongestants	Sympathomimetic effects; hyperthermia, hypertension, tachycardia, tremors, seizures, hallucinations, agitation	See Decongestant Toxicosis, p. 284
ECGC (green tea), guarana, cocoa, cola, kola nut, chocolate	*Camellia sinensis, Paullinia cupana, Cola acuninata, Theobroma cacao*	Caffeine, theobromine (methylxanthines)	Weight loss, "herbal No Doz"	Agitation, hyperactivity, polyuria, polydipsia, cardiac arrhythmias, seizures	See Chocolate Toxicosis, p. 194
Thioctic acid, cinnamon	Alpha lipoic acid (ALA), *Cinnamomum cassia*	Alpha lipoic acid, cinnamon	Diabetic treatment, *Amanita* mushroom poisoning (ALA)	Hypoglycemic effects; hypersalivation, vomiting, hypoglycemia, increased serum liver or renal values, death (ALA)	See Hypoglycemia (), Xylitol Toxicosis, p. 1184
5-HTP	*Griffonia simplicifolia*	5-hydroxytryptophan (5-HTP)	Depression, headaches, insomnia, obesity, over-the-counter antidepressant	Serotonin syndrome; sedation, vomiting, diarrhea, tremors, seizures, ataxia, hyperesthesia, hyperthermia	See Tricyclic Antidepressant Toxicosis,p. 85 and Serotonin Syndrome p. 1427
Purple coneflower	*Echinacea purpurea*	Arabinogalactan	Cold and flu support, immune stimulant, wound healing	Signs due to allergenic effects; vomiting, diarrhea	Low toxicity; no systemic effects likely from acute exposure
Chamomile	*Matricaria recutita, Chamaemelum nobile*	Hydroxycoumarin, bisabolol, chamazulene	Sedative, gastrointestinal ulcers, wound healing, antibacterial, antiinflammatory	Vomiting, diarrhea, lethargy; rarely, anticoagulant effects; epistaxis, hematoma (cats)	Low toxicity; no systemic effects likely; mild GI signs expected with acute ingestion
St. John's wort	*Hypericum perforatum*	Hypericin	Antidepressant, insomnia, anxiety, wound healing, skin conditions	Monoamine oxidase (MAO) inhibitor, depression, vomiting, diarrhea; rarely, tremors, seizures	• See Antidepressant Toxicosis, p. 85. • Decontamination, supportive care
Valerian	*Valeriana officinalis*	Valpotriates, mono- and sesquiterpenes	Sedative, sleep aid, antianxiety	Affects the GABA receptor; lethargy, sedation, muscle	Decontamination, supportive care

Common Name(s)	Genus, Species	Toxic Principle if Known	Popular Usage	Toxicity Signs/Major Effect/Actions	Treatment Overview/Comments
Tea tree oil, pennyroyal oil	*Melaleuca alternifolia, Mentha pulegium*	Melaleuca oil, pulegone, menthofuran	Germicidal, fungal infections, antiseptic, flea control, dermatitis	• Terpenes; essential oils; Orally: vomiting, diarrhea, CNS depression, hepatotoxicity, aspiration pneumonia. • Dermally: transient paresis, ataxia, weakness hypothermia	Cats more sensitive; bathing, fluids, thermoregulation; may need few days of supportive treatment
Grapefruit seed extract	*Citrus X paradise Pausinystalia yohimbine*	Quaternary ammonium compounds, cationic detergents	Disinfectant, antifungal, antimicrobial	Oral ulcers; hypersalivation, vomiting +/− blood, weakness, anorexia, hyperthermia, dermal erythema, pain, ulceration	• Cats more sensitive; see Cleaning Products Toxicosis, p. 217 • Dilution, bathing, GI protectants, pain control, supportive care
Yohimbine		Alpha2-adrenergic blocking agent	Stimulant; hypertension, angina, “herbal Viagra”	• Signs due to alpha2-adrenergic blocking activity; • Hyperactivity, agitation, tremors, seizures, vomiting, diarrhea, hypotension	Decontamination, diazepam, fluids, stabilize heart rate, blood pressure, thermoregulation
Wintergreen extract/oil	*Gaultheria procumbens*	Oil can contain 98% methyl salicylate; essential oils	Topical pain control; oral digestive	Signs similar to aspirin toxicosis; vomiting, diarrhea, gastric ulceration, hyperthermia, sedation, coma, acute hepatic injury	• See Nonsteroidal Antiinflammatory Drugs Toxicosis, p. 768. • Cats more sensitive; GI protectants, fluids, management of acidosis or alkalosis
Evening primrose	*Oenothera biennis*	Oil can contain 50%–70% *cis*-linoleic acid & other fatty acids	Supports cardiovascular function; used for rheumatoid arthritis, multiple sclerosis	Self-limiting stomach upset	Low toxicity; systemic effects not expected; mild vomiting or diarrhea possible

Common Name(s)	Genus, Species	Toxic Principle if Known	Popular Usage	Toxicity Signs/Major Effect/Actions	Treatment Overview/Comments
Kava, yangona, kawa	*Piper methysticum*	Kawain and several other lactones	Beverages prepared from roots used as a relaxant; euphoric effect; sedative	Expected clinical signs similar to benzodiazepines; sedation, ataxia, lethargy, visual disturbances	Decontamination of patient, supportive care
Khat, kat, gat, Kus	*Catha edulis*	Alkaloid katin (amphetamine-like)	Used in East African countries; stimulant, mood elevator; leaves and stems chewed	Amphetamine-like effects; hyperactivity, agitation, seizures, tachycardia, hypertension	See Amphetamine Toxicosis, p. 59
Neem, nim, nimbi	*Azadirachta indica*	Azadiracthin as insecticide; neem oil	Insecticidal properties, birth control agent, hypoglycemic properties	Hypothermia, ataxia, lethargy, coma, in cats	Used for controlling fleas in dips/shampoos on cats; bathing, thermoregulation, supportive care
Ginkgo, ginkyo	*Ginkgo biloba*	Several flavonoids; terpenoids, alkaloid ginkgo toxin in the seed	Leaf extract used for antioxidant properties, dementia treatment, circulatory disorders, neuroprotection	• From leaf extract: vomiting, diarrhea, lethargy. • From seeds: seizures, shaking, tremors possible	• Mild effects from leaf extract • Patient decontamination, diazepam, fluids if seeds involved (treat based on clinical signs).
Ginseng	*Panax quinquefolium; panax ginseng*	Steroid-like compounds, ginsenosides, and panaxosides, saponins,	Roots, teas, cosmetics used for general well-being, aging, diabetes, neurosis, cancer	Vomiting, diarrhea, nervousness, excitation, lethargy, hypoglycemia possible	• Good safety index in humans • Decontamination of patient, fluids, and supportive care (treat based on clinical signs).

Hepatozoonosis

BASIC INFORMATION

DEFINITION

Emerging tickborne protozoal disease of dogs that has a gametocyte stage in white blood cells and a cystic stage in host tissues; common in the southeastern United States.

SYNONYMS

Hepatozoon canis and *Hepatozoon americanum* are the two species known to infect dogs.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Usually outdoor dogs; also reported in foxes, coyotes, jackals, hyenas, bobcats, ocelots.

RISK FACTORS

Areas with large coyote populations. History of tick exposure. Ingestion of deer carcass or other mammal with ticks.

CONTAGION & ZOONOSIS

No reported human cases

GEOGRAPHY AND SEASONALITY

- *H. canis* is endemic in southern Europe, the Middle East, Africa, and South America. Reported in dogs in the Gulf Coast area of the United States in 2008.
- *H. americanum* is endemic in the Gulf Coast area of the United States and now ranges from Oklahoma to Florida.
- Most cases present in the summer and fall.

ASSOCIATED CONDITIONS & DISORDERS

- *H. canis:* usually subclinical unless there is other disease or immunosuppression
- *H. americanum:* pyogranulomatous myositis, marked leukocytosis, fever of unknown origin

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- *H. canis:* usually no overt clinical signs
- *H. americanum:* chronic wasting disease characterized by waxing and waning muscle pain and fever

HISTORY, CHIEF COMPLAINT

- *H. canis:* incidental finding of gametocytes on blood smear. Dogs usually show no clinical signs.
- *H. americanum:* depression, reluctance to move, stiff gait, mucopurulent ocular discharge, weight loss. Dogs may have history of ingesting a deer carcass 3-4 weeks earlier. Some dogs develop transient bloody diarrhea before signs of muscle pain and fever.

PHYSICAL EXAM FINDINGS

Fever, mucopurulent ocular discharge, hyperesthesia, neck guarding, stiffness, ataxia, unwillingness to rise, cachexia, muscle wasting *(H. americanum).*

ETIOLOGY AND PATHOPHYSIOLOGY

- The parasite has a complex life cycle. The definitive host of *H. canis* is the brown dog tick, *Rhipicephalus sanguineus,* and for *H. americanum* it is the Gulf Coast tick, *Amblyomma maculatum.* The dog must ingest the infected tick. Recent information reveals that dogs can also be infected by ingesting small mammals such as cotton rats that live in endemic areas and harbor the disease.
- Sporozoites are released and penetrate the wall of the dog's gastrointestinal tract. These are phagocytized by macrophages and distributed throughout the body to form meronts, or “cysts.”
- The organisms replicate inside the cyst until it ruptures, and merozoites are released. *H. canis* cysts are primarily in the lymph nodes and spleen. *H. americanum* cysts are primarily in skeletal muscle.
- When the merozoites are released, an intense inflammatory reaction occurs, resulting in painful myositis and fever *(H. americanum).*
- Merozoites can either enter leukocytes and become circulating gametocytes infectious to ticks that feed on the dog, or they may enter a macrophage and undergo secondary merogony and continue the cycle of releasing merozoites to cause repeated episodes of pyogranulomatous myositis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of *H. canis* is usually made by finding gametocytes on a blood smear. *H. americanum* should be suspected in dogs with fever, cachexia, ocular discharge, leukocytes, and periosteal proliferation on long bones. Diagnosis can be confirmed with PCR testing or muscle biopsy.

DIFFERENTIAL DIAGNOSIS

- Meningitis
- Diskospondylitis
- Polyarthritis
- Pyometra
- Other tickborne diseases

INITIAL DATABASE

- CBC may reveal extreme leukocytosis (20,000-200,000 cells/mcL; typically mature neutrophilia with left shift possible) and mild nonregenerative anemia. Platelet count is usually normal; thrombocytopenia may indicate coinfection with other tickborne disease.
- Serum chemistry profile: hypoalbuminemia, hyperglobulinemia, elevated serum alkaline phosphatase, low glucose, low blood urea nitrogen are commonly seen.
- Long-bone radiographs: periosteal proliferation secondary to adjacent muscle inflammation is possible.
- Dogs with chronic disease may develop glomerulonephritis with an increased urine protein/creatinine ratio.
- Blood smear or buffy coat smear may reveal gametocytes in circulating white blood cells.

ADVANCED OR CONFIRMATORY TESTING

- Immunofluorescent antibody and PCR tests available for *H. canis* (in Israel)
- PCR test for *H. americanum* and *H. canis is* available through Auburn University Molecular Diagnostics Lab (http://www.vetmed.auburn.edu/index.pl/molecular_diagnostics).
- Definitive diagnosis usually made by finding organisms in muscle biopsy (see p. 1305). Any muscle can be sampled, but hindlimb muscles are most commonly used.

TREATMENT

TREATMENT OVERVIEW

Acute antiprotozoal therapy eradicates circulating organisms. Chronic therapy is necessary to prevent relapses from continued release of merozoites from tissue cysts.

ACUTE GENERAL TREATMENT

- For *H. americanum,* combination therapy for 2 weeks: trimethoprim-sulfadiazine (15 mg/kg PO q 12 h), clindamycin (10 mg/kg PO q 8 h), and pyrimethamine (0.25 mg/kg PO q 24 h). If clinical signs are still evident at 14 days, continue 2 more weeks.
- For *H. canis:* imidocarb (5 mg/kg SQ repeated every 14 days until parasitemia has resolved)
- Nonsteroidal antiinflammatory drugs at standard doses for muscle pain
- Doxycycline (5-10 mg/kg PO q 12-24 h). May be required if there is coinfection with other tickborne diseases.
- IV fluids may be needed for hypoglycemia and dehydration.

CHRONIC TREATMENT

Decoquinate (Deccox 22.7 g/lb Premix [Alphama, Fort Lee, NJ]) at a dosage of 20 mg/kg or 1 tsp/10 kg mixed in food q 12 h for 2 years or until PCR testing is negative will inhibit development of merozoites released from tissue cysts, thereby preventing reinfection of the dog and cyclic bouts of illness. This drug is very safe for long-term use and has not been associated with any known side effects.

NUTRITION/DIET

Dogs with hepatozoonosis usually retain their appetite but often are too painful to move. They should be hand fed and offered water until they become ambulatory. High-calorie diets, such as growth or puppy diets, can help reverse the cachexia and hypoalbuminemia.

BEHAVIOR/EXERCISE

Clients should not allow dogs to eat dead animals that may harbor ticks (e.g., deer carcasses) or consume prey in endemic areas.

POSSIBLE COMPLICATIONS

Dogs may require repeated administration of combination therapy if relapses occur with severe clinical signs.

RECOMMENDED MONITORING

Repeat CBC and physical examination in 2 weeks. If fever, muscle pain, or marked leukocytosis is present, continue combination therapy for 2 more weeks. PCR should be checked every 6 months. Decoquinate can be discontinued when PCR is negative. Some dogs remain infected for >5 years but continue to be free of clinical signs while receiving decoquinate.

PROGNOSIS AND OUTCOME

- Without treatment, American hepatozoonosis is usually fatal within several months.
- With antiprotozoal combination therapy alone, relapses occur requiring repeated therapy. Relapses become more frequent and refractory to treatment. Death usually occurs within 1 year of the initial diagnosis.
- Long-term cure (>5 years) has been achieved with combination therapy followed by long-term decoquinate therapy.

PEARLS & CONSIDERATIONS

PREVENTION

- Effective tick control with a topical acaricide and a repellent collar is recommended.

TECHNICIAN TIPS

- Making a buffy coat smear may enhance the possibility of finding gametocytes.
- Gametocytes appear as oblong intracellular single inclusions in leukocytes (rare).
- Spurious hypoglycemia can occur if the blood sample is not run immediately, because WBCs can metabolize glucose in the tube.

CLIENT EDUCATION

- Clean matted eyes with a warm, moist towel as needed.
- Provide soft bedding.
- Bring food and water to dogs that are nonambulatory.
- Continue all medications for recommended duration. Stopping decoquinate too early can result in reinfestation of the dog and

exacerbation of the disease.

Hepatopathy, Copper-Associated

BASIC INFORMATION

DEFINITION

Accumulation of copper within hepatocytes, leading to hepatotoxicosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Primarily in dogs; rare in cats. Copper accumulates slowly, so clinical signs are typically not present until middle age.

GENETICS & BREED PREDISPOSITION

- Autosomal recessive in Bedlington terriers
- Predisposition in dalmatians, West Highland white terriers, and Skye terriers
- Possible association in Doberman pinschers and Labrador retrievers
- Reported in other canine breeds, but it is unknown if copper accumulation is the cause or effect of hepatopathy.

CLINICAL PRESENTATION

DISEASE FORM/SUBTYPES

- Subclinical
- Chronic inflammatory liver disease/cirrhosis
- Acute hepatic failure with hemolytic anemia (rare)

HISTORY, CHIEF COMPLAINT, AND PHYSICAL EXAM FINDINGS: Patients usually present with features of chronic hepatic disease such as lethargy, vomiting, abdominal distention, or encephalopathy (see p. 212) or less commonly with acute hepatic failure (see p. 503) and hemolytic anemia (see p. 71).

ETIOLOGY AND PATHOPHYSIOLOGY

- Copper homeostasis is maintained by biliary excretion of excess copper.
- Copper is absorbed from ingesta in the small intestine and extracted by hepatocytes.
- Chaperoned around the hepatocyte by a number of proteins before being either released into the serum or excreted in bile. A small amount is stored in lysosomes.
- Abnormal hepatic copper accumulation occurs because of primary inborn error of metabolism or secondary to acquired cholestatic liver disease.
    - In Bedlingtons, copper accumulation in lysosomes is due to a genetic defect in the COMMD1 gene, leading to excessive copper binding by an abnormal metallothionein (a protein required for the final stages of copper excretion into the bile). When the storage capacity of the lysosomes is exceeded, copper breaks out into the cytoplasm, where it is toxic.
    - Genetic basis for copper accumulation in other breeds is unknown.
- Excess copper damages hepatocytes by inducing the formation of free radicals.
- Secondary copper accumulation is due to a generalized impairment in biliary excretion (i.e., cholestasis).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The disorder may be suspected in two contexts: either as part of any cholestatic liver disease (detected as part of evaluation of liver biopsy specimens) or in cases where copper accumulation is the dominant feature of hepatopathy in a dog (e.g., Bedlington terrier) with or without overt clinical signs. Definitive quantification of hepatic copper content, which carries important treatment implications, requires a liver biopsy.

DIFFERENTIAL DIAGNOSIS

- Chronic:
  - Infectious, immune, or toxic causes of inflammatory hepatic disease
  - Hepatic neoplasia
  - Congenital portosystemic shunts
- Acute:
  - Infectious, immune, drug, or toxin-induced (zinc) hemolytic anemia
  - Exposure to hepatotoxic drugs or environmental toxins
  - Infectious canine hepatitis, leptospirosis

INITIAL DATABASE

See pp. 503, 513, , and .

ADVANCED OR CONFIRMATORY TESTING

- Determination of hepatic copper concentration:
  - Quantitative analysis on hepatic wedge or needle biopsies
  - Qualitative analysis by rhodanine or rubeanic acid staining of histopathology specimen. Permits determination of copper distribution within the hepatic lobule.
    - Normal hepatic copper levels from 200-400 mcg/g dry weight (DW)
    - Secondary copper accumulation levels <1000-2000 mcg/g DW
    - Copper >2000 mcg/g dry weight suggests a primary copper abnormality.
    - In Bedlingtons, copper levels gradually increase with age, with levels reported from 850-12,000 mcg/g DW.
    - In West Highland white terriers, copper accumulation does not correlate as well with age (levels up to 3500 mcg/g DW reported).
    - Lower copper levels (1000-2000 mcg/g dry weight) associated with toxicity in some Labradors and Dobermans.
- Histopathologic findings:
  - In Bedlingtons, copper initially accumulates centrilobularly.
    - Initial finding is centrilobular hepatocellular vacuolation followed by degeneration/necrosis and finally inflammation and fibrosis. Progresses to become more panlobular eventually with periportal orientation. Findings can mimic idiopathic chronic hepatitis.
  - In secondary copper accumulation, copper staining located primarily in areas of inflammation or degeneration.
- Genetic test, microsatellite marker (C04107) available to screen Bedlingtons, but may miss disease in some pedigrees (5%-10% false negatives). No test for COMMD1 mutation available.

TREATMENT

TREATMENT OVERVIEW

Decrease hepatic copper concentration, decrease copper absorption.

ACUTE GENERAL TREATMENT

Manage the complications of acute or chronic hepatic disease (see pp. 503, p. 212, and 501).

CHRONIC TREATMENT

- Copper chelators for initial decoppering of liver and maintenance therapy:
  - Penicillamine (10-15 mg/kg PO q 12 h). Increases urinary copper excretion. Works slowly (removes ~900 mcg/g per year), so copper levels take several months to years to decrease. Vomiting is a common side effect; begin at low end of dosage range and titrate upward.
  - Trientine (10-15 mg/kg PO q 12 h). Increases urinary copper excretion and may also block intestinal uptake. Fewer side effects than penicillamine but more expensive.
  - Give all medications on an empty stomach, and follow with a water bolus.
- Inhibit intestinal copper absorption, maintenance therapy.
  - Zinc (100 mg elemental zinc PO q 12 h). Induces intestinal metallothionein, a protein that binds copper, keeping it sequestered within the enterocyte and thus preventing copper absorption. May be combined with chelators (separate administration by 2 hours). Side effects include gastritis, hemolytic anemia, and iron deficiency. Keep serum zinc levels <600 mcg/dL to avoid hemolysis. Effective zinc levels are >200 mcg/dL.

- Reduce dietary intake of copper.
  - Avoid shellfish, nuts, chocolate, mushrooms, and organ meats. Check water supply if not public. Copper restricted prescription diets are available.
- Antioxidants
  - Induction of oxidant stress is central to copper-induced hepatic damage.
  - Vitamin E supplementation (200-400 IU PO q 24 h)
  - *S*-adenosylmethionine (20 mg/kg PO q 24 h).

RECOMMENDED MONITORING

Serum liver enzymes every 4-6 months

PROGNOSIS AND OUTCOME

- Subclinical disease: excellent with therapy
- Chronic: depends on stage. Mild to moderate inflammatory disease: good. Severe inflammatory disease/cirrhosis: guarded.
- Acute: grave

PEARLS & CONSIDERATIONS

COMMENTS

- All Bedlington terriers should be tested at 1 year of age by determination of hepatic copper concentration and/or genetic testing. Affected dogs should not be bred.
- All dogs with chronic inflammatory hepatitis, particularly West Highland white terriers, Doberman pinschers, Skye terriers, Labrador retrievers and dalmatians, should have hepatic copper analysis. If concentrations are > 1000-2000 mcg/g DW, they should be treated to decrease hepatic copper.

AUTHOR: CYNTHIA R. L. WEBSTER

EDITOR: KEITH P. RICHTER

Hepatomegaly

BASIC INFORMATION

DEFINITION

Liver enlargement

EPIDEMIOLOGY

SPECIES, AGE, SEX

Observed in both dogs and cats, more frequently in middle-aged to older animals owing to age-related prevalence of associated diseases. However, younger animals can also present with hepatomegaly (e.g., with feline infectious peritonitis [FIP], congenital veno-occlusive disease, infectious disease, lymphoma).

GENETICS & BREED PREDISPOSITION

- Dogs: Doberman pinschers (inflammatory liver disease), cocker spaniels, Labrador retrievers, Skye terriers; Labrador retrievers (tricuspid dysplasia causing right-sided heart failure)
- Cats: Abyssinians (amyloidosis), Asian breeds (FIP)

CLINICAL PRESENTATION

HISTORY/CHIEF COMPLAINT

Depends on etiology:

- Can be an incidental finding
- Abdominal distention
- Polyuria, polydipsia
- Anorexia, lethargy/weight loss
- Exercise intolerance
- Vomiting/diarrhea
- Pale mucous membranes
- Hepatic encephalopathy
- Coagulopathy
- Cutaneous disease/hair loss/poor haircoat

PHYSICAL EXAM FINDINGS

- Abdominal distention
- Palpable cranial organomegaly
- Ascites
- Icterus
- Concurrent hepatosplenomegaly suggests a multicentric neoplastic, passive congestive, systemic inflammatory/infectious, or anemia-inducing process, or unrelated disorders.

ETIOLOGY AND PATHOPHYSIOLOGY

Hepatomegaly is caused by inflammation, infiltration, congestion/obstruction, infection, or hyperplasia of the liver.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The presence of an enlarged liver is noted on physical examination, radiographs, or abdominal ultrasound. The first diagnostic step

consists of reviewing the history and physical examination for evidence of liver dysfunction. Benign causes of hepatomegaly are common, but hepatomegaly may be the first clue that nonspecific clinical signs are caused by liver disease. Routine blood and urine tests and abdominal ultrasonography, postprandial serum bile acid levels, and diagnostic sampling of the liver help identify cases that require treatment and follow-up.

DIFFERENTIAL DIAGNOSIS

- Inflammatory diseases of the liver:
  - Cholangitis/cholangiohepatitis complex (cats)
  - Cirrhosis (end stage usually produces microhepatica, not hepatomegaly)
  - Abscess
  - Neoplasia
  - Chronic active hepatitis (idiopathic chronic hepatitis) (dogs)
  - Canine breed-specific hepatopathies
- Neoplastic/cystic diseases:
  - Lymphoma, biliary cystadenoma, bile duct carcinoma, hemangiosarcoma, metastatic neoplasia
  - Hepatocellular carcinoma, hepatoma (enlargement of a single lobe)
  - Malignant histiocytosis
  - Diffuse mast cell tumor
  - Parenchymal/biliary cysts
- Extrahepatic obstruction:
  - Pancreatitis
  - Cholelithiasis (rare in dogs and cats)
  - Bile duct neoplasia
  - Biliary mucocele
  - Inspissated bile syndrome of cats
- Metabolic disease:
  - Diabetes mellitus (lipid accumulation)
  - Hepatic lipidosis (cats)
  - Amyloidosis (Abyssinian/Chinese shar-pei)
  - Storage disease (rare in cats and dogs)
  - Hyperadrenocorticism (dogs/glycogen accumulation)
- Drugs:
  - Glucocorticoids
  - Phenobarbital
- Infectious disease (many cause hepatosplenomegaly due to systemic immune stimulation):
  - Bacterial, rickettsial, protozoal, fungal
  - Liver abscess (enlargement localized to a single lobe)
  - FIP
  - Erythrocyte parasitism *(Mycoplasma baemofelts/*hemobartonellosis, *Babesia* spp.)
- Immune-mediated disease (hepatosplenomegaly common secondary to systemic immune stimulation):
  - Immune-mediated hemolytic anemia (IMHA)
  - Immune-mediated thrombocytopenia (ITP)
  - Systemic lupus erythematosus
  - Vasculitis
  - Any systemic immune-mediated disease
- Congestion (often associated with ascites):
  - Right-sided heart failure
  - Budd-Chiari syndrome/venoocclusive disease (rare)
  - Liver lobe torsion (rare)
- Intoxications
- Benign conditions:
  - Nodular hyperplasia (older dogs)
  - Nodular regeneration (associated with severe liver disease)
  - Extramedullary hematopoiesis
  - Individual variation (pseudohepatomegaly)
- Radiographic differential diagnosis for hepatomegaly:
  - Cranial abdominal mass, marked splenomegaly, ascites, dyspnea (caudal displacement of liver), youth (nonmineralized distal ribs gives false impression of liver protruding beyond costal arch)

INITIAL DATABASE

- CBC, chemistry profile, urinalysis, and urine culture
- Abdominal radiographs (most accurate assessment of liver size)

- Abdominal ultrasound
- Thoracic radiographs (cardiac structures, metastatic disease)

ADVANCED OR CONFIRMATORY TESTING

- Coagulation profile (prothrombin time/activated partial thromboplastin time/platelet count), buccal mucosal bleeding time
- Preprandial and postprandial serum bile acids
- Urine bile acids
- Serum ammonia (poor specificity/sensitivity)
- Liver aspirate or biopsy for histopathologic evaluation and culture (aerobic/anaerobic). See p. 1298.
- Copper quantification of biopsy specimen
- Amylase/lipase/pancreatic lipase immunoreactivity
- Adrenocorticotropic hormone (ACTH) stimulation, ACTH level, low-dose dexamethasone suppression test
- Antinuclear antibody test
- Infectious disease titers/PCR
- FIP serology
- Echocardiography/central venous pressure
- Abdominocentesis (if ascites)
- Abdominal CT
- Venography (Budd-Chiari, veno-occlusive disease)
- D-dimer (thromboembolic disease)
- Bone marrow aspirate (immune-mediated hemolytic anemia/immune-mediated thrombocytopenia, lymphoma staging)

TREATMENT

TREATMENT OVERVIEW

Treat specifically on the basis of an established diagnosis. Hepatomegaly is a sign, not an etiology. Suppress the disease process/manage the metabolic condition/treat any infectious or immune-mediated disease with appropriate medication or surgical intervention.

GENERAL TREATMENT

- Inflammatory diseases:
  - Immunosuppressant therapy (i.e., glucocorticoids, azathioprine, cyclosporine)
  - Antioxidant therapy (S-adenosylmethionine, silymarin, zinc, vitamin E)
  - Immune-modulatory medications; ursodeoxycholate, metronidazole
  - Antifibrotics: colchicine, D-penicillamine, methotrexate
  - Antibiotics: metronidazole, amoxicillin, cephalexin, enrofloxacin
  - Gastric protectants
  - Vitamins: carnitine (lipidosis), vitamin C, vitamin E, zinc, vitamin K (if coagulopathy)
  - Dietary therapy
  - Treatment for hepatic encephalopathy: lactulose, neomycin, metronidazole
  - Management for ascites (abdominocentesis/abdominal drainage; diuretics: spironolactone)
  - Fluid therapy
- Neoplastic diseases: surgery/chemotherapy
- Extrahepatic obstruction: supportive care, surgery
- Metabolic diseases:
  - Insulin therapy
  - Colchicine/dimethylsulfoxide for amyloidosis
  - Aggressive feeding (hepatic lipidosis)
  - Lysodren/trilostane/ketoconazole for hyperadrenocorticism
- Infectious diseases:
  - Treatment depends on the organism
- Immune-mediated diseases:
  - Immunosuppressant therapy/depends on the disorder
- Congestion:
  - Treatment depends on the cause

RECOMMENDED MONITORING

Dictated by the disease process. Examples include liver enzyme profile 1-2 weeks post diagnosis, then monthly for 3 months, then

every 3-4 months. Repeat serum or urine bile acids/liver aspirate or biopsy at 6- to 12-month intervals; ACTH-stimulation every 3-6 months; convalescent infectious disease titers/PCR at 4-week to 6-month intervals.

PROGNOSIS AND OUTCOME

Varies with the cause of each disease

PEARLS & CONSIDERATIONS

COMMENTS

- Bile acids are an unnecessary test in an icteric patient (rare exception: icteric patient suspected of having both hemolysis and hepatobiliary disease concurrently, where bile acids can help differentiate).
- Fine-needle aspiration and cytologic evaluation of the liver does not reliably assess hepatic structure or function, even with diffuse hepatopathies.
- Normal serum bile acid levels in a patient with progressively increasing liver enzymes does not preclude the need for liver biopsy.
- Cats with hepatic lipidosis tend to have greater bleeding after liver biopsy than those with other diseases.
- Abnormal urine bile acids test result should be confirmed with serum bile acids measurement before liver biopsy.
- In cats, most diseases of the liver (including cirrhosis) result in hepatomegaly, whereas in dogs this is not necessarily the case.
- Ursodeoxycholate (e.g., Actigall) therapy can interfere with the interpretation of the urine bile acids test.

SUGGESTED READING

Poldervaart RP, et al: Primary hepatitis in dogs: a retrospective review (2002-2006). J Vet Intern Med 23:72–80, 2009

AUTHOR: MAUREEN CARROLL

EDITOR: ETIENNE CÔTÉ

Hepatitis, Canine Infectious

BASIC INFORMATION

DEFINITION

A specific form of liver disease caused by canine adenovirus-1 (CAV-1) that can cause acute death or chronic hepatitis. Infectious canine hepatitis (ICH) is uncommon in well-vaccinated dog populations. Antigenically and genetically distinct from CAV-2 which causes infectious tracheobronchitis.

SYNONYMS

CIH (canine infectious hepatitis); ICH; "blue eye"

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs, coyotes, foxes, wolves, and bears can be infected. Usually the disease is seen in dogs <1 year old, but unvaccinated dogs of any age can be affected.

RISK FACTORS

Nonvaccinated dogs. Resistant to environmental inactivation and survives for days at room temperature on soiled fomites; can remain viable for months at temperatures below 4°C.

CONTAGION & ZOONOSIS

- Dog-to-dog transmission occurs directly or indirectly (oronasal infection from secretions of infected animals—saliva, urine, feces, respiratory secretions)
- Not zoonotic
- The virus is resistant to environmental inactivation and survives for days at room temperature on soiled fomites; can remain viable for months at temperatures below 4°C.

ASSOCIATED CONDITIONS & DISORDERS

Chronic hepatitis may occur if the patient survives the initial viremia.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Animals usually have a poor vaccination history on presentation.
- During the acute viremic stage, animals can become moribund and die within a few hours.
- After the acute viremic stage, animals typically present with vomiting, diarrhea, and/or abdominal pain.

PHYSICAL EXAM FINDINGS

- Fever (can be biphasic), tonsillar enlargement, cervical lymphadenopathy, tachycardia, tachypnea, abdominal tenderness, hepatomegaly
- Icterus uncommon in the acute phase. Icterus and abdominal distention may be seen in advanced cases that survive acute viremic stage.
- Anterior uveitis and corneal edema ("blue eye") are hallmarks. They develop 7-21 days post infection.
- Signs of coagulopathy: petechial and ecchymotic hemorrhages, epistaxis, excessive bleeding from venipuncture sites
- Central nervous system signs consistent with hepatic encephalopathy or viral encephalitis (rare), including depression, seizures, disorientation, coma

ETIOLOGY AND PATHOPHYSIOLOGY

- Adenovirus-1 is transmitted by oronasal exposure to secretions of infected animals, notably urine. It can also be transmitted by fomites, and ectoparasites can harbor CAV-1.
- The virus initially localizes in the tonsils after exposure. From the tonsils, it disseminates to regional lymph nodes and then through the thoracic duct to the systemic circulation.
- Virus is found in body tissues and secretions, including urine, feces, and saliva, 4-8 days post infection.
- The virus is found in many tissues, including the kidneys 10-14 days post infection; secreted in urine for 6-9 months post infection.
- Predilection for hepatic parenchymal cells (causing acute hepatic injury/necrosis) and vascular endothelial cells (multiple organ injury)
- Cytotoxic effects of the virus cause initial cellular injury to the eye, liver, and kidney.
- Subclinical infections are widespread, predominantly in dogs with circulating antibody at the time of infection.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is made based on signalment (young unvaccinated dog) with clinical signs consistent with acute hepatic failure. Confirmation requires ruling out other differentials and serologic testing, virus isolation, or PCR.

DIFFERENTIAL DIAGNOSIS

- Liver disease:
  - Portosystemic shunts
  - Leptospirosis
  - Toxins
  - Copper hepatopathy
  - Cholelithiasis/cholangitis
  - Gallbladder rupture
- Pancreatitis
- Canine distemper

INITIAL DATABASE

- CBC/serum biochemistry profile
  - Neutropenia and lymphopenia initially, then rebound neutrophilia and lymphocytosis.
  - Alanine aminotransferase (ALT) and alkaline phosphatase elevation for 14 days post infection, then decline unless chronic hepatitis occurs. With chronic hepatitis, signs of hepatic synthetic failure (hypoglycemia hypoalbuminemia, low blood urea nitrogen) may be present. Hyperbilirubinemia is uncommon in the acute phase.
- Urinalysis: proteinuria, bilirubinuria (note: mild bilirubinuria is normal in healthy dogs)
- Coagulation panel: changes are most often seen in the viremic stage and include thrombocytopenia, prolongation of prothrombin time, activated partial thromboplastin time, and thrombin time (TT).
- Serum bile acids (postprandial): often elevated with hepatic encephalopathy

ADVANCED OR CONFIRMATORY TESTING

- Cytologic (aspirates, impression smears) or histologic examination of liver: characteristic inclusion bodies (Cowdry type A). Widespread centrilobular to panlobular necrosis.
- Cerebrospinal fluid: usually normal
- Bone marrow aspirate: decreased megakaryocytes during viremic stage
- Serologic testing (complement fixation, immunodiffusion, ELISA), virus isolation, and immunofluorescent testing are available, but an accurate clinical diagnosis is generally possible without these tests.
- PCR techniques can distinguish CAV-1 from CAV-2 infection.
- Similarly, the virus can be cultured from any body tissue 5 days post infection; the kidney is the most persistent site.

TREATMENT

TREATMENT OVERVIEW

Treatment is supportive and nonspecific in nature. Uncomplicated cases may not show improvement in clinical signs for up to 5-7 days.

ACUTE GENERAL TREATMENT

- Fluid therapy
- Correction of coagulation disturbances with fresh frozen plasma or whole blood transfusion (see p. 1347). Supplement with vitamin K, 0.625-1.25 mg/kg PO or SQ q 12 h for up to 36 h.
- *N*-acetylcysteine (50 mg/kg diluted 1 part acetylcysteine to 4 parts 0.9% NaCl, given IV through micropore filter over 1 hour, q 6 h)
- Management of hypoglycemia: intravenous glucose 0.5 g/kg IV bolus (= 1 mL 50% dextrose/kg body weight; before administration, must be diluted with sterile water by at least 50% to avoid phlebitis/perivascular irritation) followed by 2.5%-5% dextrose infused in balanced electrolyte solution
- Lactulose for animals exhibiting neurologic signs (0.5 mL/kg PO q 8 h)

CHRONIC TREATMENT

If chronic hepatitis results (see pp. 212 and 501), the following therapy may be considered:

- Diet: protein-restricted diet in animals with hepatic encephalopathy. All other animals should be given a high-carbohydrate, moderate-fat diet. Dietary fiber has been shown to bind bile acids and aid in their removal; psyllium 1-3 tsp/d can be added to the diet.
- Prednisone or prednisolone: 1-2 mg/ kg PO q 24 h. After clinical improvement, taper the dose to 0.5 mg/kg q 24 h, then q 48 h.
- Colchicine 0.03 mg/kg PO q 24 h may help decrease formation of hepatic fibrosis.
- Vitamin E: 50-400 IU PO q 24 h
- *S*-adenosylmethionine (SAMe): 20 mg/kg PO q 24 h
- Milk thistle: 50-250 mg/kg PO q 12 h

DRUG INTERACTIONS

May need to decrease dosages for drugs metabolized by the liver in acute hepatic failure phase

POSSIBLE COMPLICATIONS

Pyelonephritis, disseminated intravascular coagulation, glaucoma

RECOMMENDED MONITORING

For the acute phase:

- Coagulation times, blood glucose, albumin, blood ammonia levels

For chronic hepatitis:

- Serum bile acids
- Repeat liver biopsy 6 months after starting treatment

PROGNOSIS AND OUTCOME

- Prognosis for acute, fulminant infection is grave: animals often die within hours.
- Long-term prognosis for chronic hepatitis secondary to adenovirus-1 is guarded.
    - Animals with hypoalbuminemia, hypoglycemia, and coagulopathies usually die within 1 week of diagnosis.

PEARLS & CONSIDERATIONS

TECHNICIAN TIP

Puppies with acute fulminant ICH require intensive nursing care, and even with the best treatment, mortality rates are high.

PREVENTION

- Routine vaccination (D***H***LPP or D***H***PP) provides protection against infectious canine hepatitis.

- Modified live vaccine using CAV-2 isolates is used for preventing infectious canine hepatitis. The CAV-2 MLV vaccine confers cross-protection and has fewer side effects (corneal edema, fever) compared to the CAV-1 vaccine.
- A routine initial series followed by a booster at 1 year and then every 3-5 years is recommended.

Hepatitis (Chronic, Idiopathic) of Dogs

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Chronic progressive hepatic disorder of unknown etiology, characterized by parenchymal inflammation, hepatocyte necrosis, and variable fibrosis that can ultimately progress to cirrhosis

SYNONYMS

Chronic active hepatitis, chronic hepatitis/hepatopathy

EPIDEMIOLOGY

SPECIES, AGE, SEX

Middle-aged dogs 3-10 years of age (mean: 7 years). Females tend to be overrepresented.

GENETICS & BREED PREDISPOSITION

Breed predispositions occur in the Labrador retriever, standard poodle, cocker spaniel (see online chapter: Hepatitis (Chronic) of Cocker Spaniel Dogs), and Scottish terrier. There is also chronic hepatitis-associated genetic-based copper accumulation (see p. 517) observed in the Bedlington terrier, West Highland white terrier, Doberman pinscher (see online chapter: Hepatitis (Chronic) of Doberman Pinscher Dogs), Labrador retriever, dalmatian, and Skye terrier.

RISK FACTORS

Drug therapy (including phenobarbital, nonsteroidal antiinflammatory, or potentially any other drug), infectious agents such as leptospirosis, and post toxin-induced hepatic damage may result in hepatitis, which eventually may progress to chronic hepatitis.

CONTAGION & ZOONOSIS

Leptospirosis, canine adenovirus type 1, and canine acidophil cell hepatitis (suspected but poorly documented) are associated with chronic hepatitis and potentially are contagious (all three) and zoonotic (leptospirosis).

ASSOCIATED CONDITIONS & DISORDERS

Hepatic inflammation can occur secondary to disorders such as pancreatitis, peritonitis, or inflammatory bowel disease. The type and character of inflammation in the liver is different from typical progressive idiopathic chronic hepatitis: in these disorders, the inflammation is usually mild, confined to the portal triads, and there is an absence of fibrosis. This is commonly referred to as a *reactive hepatopathy*.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Chronic hepatitis is a progressive disease associated with several clinical stages:

- Subclinical hepatitis associated only with abnormal serum liver enzyme activites
- Clinical hepatitis
- Cirrhosis and hepatic failure

HISTORY, CHIEF COMPLAINT

Historic signs for clinical disease will vary based on the extent of liver damage and include:

- Subclinical:
  - None

- Clinical hepatitis:
  - Vomiting
  - Anorexia
  - Weight loss
  - Lethargy
  - Polyuria or polydipsia
- Cirrhosis/hepatic failure:
  - Abdominal distention from ascites
  - Signs of neurologic dysfunction associated with hepatic encephalopathy (HE)
  - Bleeding due to coagulopathy
  - Anorexia, vomiting, and other signs of gastrointestinal ulceration

PHYSICAL EXAM FINDINGS

Physical findings will vary with severity of disease:

- Subclinical dogs appear normal.
- Abnormal findings in clinically ill dogs include (see also History, above):
  - Icterus
  - Poor body condition
  - Hepatic encephalopathy (see p. 501)
  - Ascites (mainly in cirrhosis/hepatic failure; see pp. 93)

ETIOLOGY AND PATHOPHYSIOLOGY

- In most all cases the etiology is unknown.
- Infectious causes including leptospirosis, canine adenovirus 1 (infectious canine hepatitis) infection and possibly *Helicobacter* spp., *Bartonella* spp., or other infectious agents
- Immune-mediated mechanisms may be responsible, but this has been poorly documented in the dog. Studies measuring liver-associated antibodies or cell-mediated responses in affected cases fail to determine if the response is primary or a secondary phenomenon.
- Drug-associated chronic hepatitis from anticonvulsants, nonsteroidal antiinflammatory drugs (NSAIDs) or trime-thoprim-sulfa antibiotics. It is possible that any drug has potential to cause liver disease.
- Copper-associated liver disease due to defective copper metabolism
- Other conditions such as aflatoxins, chemicals, or other environmental factors may be responsible.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in any dog with historical, physical, biochemical, or imaging-identified signs of hepatobiliary disease; confirmation is achieved via histologic analysis of a liver biopsy specimen.

DIFFERENTIAL DIAGNOSIS

- Acute hepatitis
- Hepatic neoplasia
- Pancreatitis
- Reactive hepatopathies secondary to systemic or metabolic disease and gastrointestinal (GI) disease
- Congenital portosystemic shunts
- Extrahepatic bile duct obstruction

INITIAL DATABASE

- CBC: nonregenerative anemia, variable white blood cell count
- Serum biochemistry profile: increased liver enzyme activities, including alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and γ-glutamyl transferase (GGT). In advanced disease, increased total bilirubin concentration and decreased albumin, glucose, blood urea nitrogen, and/or cholesterol concentrations may occur. Hyperglobulinemia is often observed.
- Urinalysis: bilirubinuria, variable specific gravity, and sometimes ammonium biurate crystalluria associated with hyperammonemia
- Abdominal radiographs: small liver and possibly signs of ascites in advanced disease (cirrhosis/hepatic failure)

ADVANCED OR CONFIRMATORY TESTING

- Elevated serum bile acid concentrations suggesting altered hepatic function or portal shunting
- Elevated plasma ammonia concentrations or ammonia tolerance test (variable results)
- Coagulation tests: prothrombin time (PT), activated partial thromboplastin time (APTT), and proteins inducted by vitamin K antagonism (PIVKA). With advanced disease, these become abnormal and reflect severe liver dysfunction.
- Abdominal ultrasonography: variable hepatic parenchymal changes. Micro-hepatica, nodular liver, and ascites (normal-diameter caudal vena cava and hepatic veins help rule out right-sided heart failure as cause of ascites) in late-stage disease (cirrhosis/hepatic failure).
- Serologic testing for antinuclear antibody (ANA) titer and infectious agents such as *Leptospira interrogans, Bartonella* spp., or other specific tests where indicated
- Abdominocentesis in patients with ascites may reveal either a pure transudate or modified transudate.
- Surgery or laparoscopy: liver may appear normal in subclinical disease or may be small, nodular, and bibrotic/firm in advanced clinical disease.
- Liver biopsy and histopathologic evaluation:
  - Large biopsies (obtained via laparoscopy or laparotomy) are preferred over needle core biopsies or fine-needle aspirates, owing to superior diagnostic accuracy.
  - Liver samples for metal analysis and culture and sensitivity should be obtained.
  - Subclinical disease is associated with infiltration of mononuclear inflammatory cells into portal and parenchymal areas.
  - Clinical disease is associated with evidence of active hepatitis, with areas of piecemeal and bridging necrosis.
  - In cirrhosis, extensive fibrosis and nodular regeneration are present.
  - Histochemical staining for copper and iron are often positive.
- Hepatic metal quantitative analysis: hepatic copper can accumulate secondary to the liver disease; concentrations often range from 600-1500 g/g dry weight liver (normal <400 g/g). Values >1500 g/g could be associated with a primary copper-associated hepatopathy (see p. 517). Hepatic iron is often elevated, and zinc concentrations are frequently subnormal.

TREATMENT

TREATMENT OVERVIEW

- Remove the inciting etiology if identified.
- Provide optimal nutrition.
- Stop the progression of ongoing inflammation.
- Provide for optimal hepatic support.
- Treat specific complications of liver disease as they occur.

ACUTE GENERAL TREATMENT

Acute complications of chronic hepatitis should be treated as they occur. Commonly used treatments during acute management of idiopathic chronic hepatitis include:

- Fluid therapy to correct deficits and electrolyte losses. Supplemental dextrose (2.5%-5%) is recommended; limit sodium with ascites (e.g., switch to low-sodium, isotonic maintenance fluid when patient is hydrated [e.g., Plasmalyte 56 + 5% dextrose, with potassium supplementation]).
- Dextrans, Hetastarch, plasma, or albumin infusions may be used for improving oncotic pressure.
  - Plasma advantages include presence of albumin (contributes positively to protein balance), presence of coagulation factors, and persistence in the circulation (versus protein-losing enteropathy or nephropathy, where the transfused proteins may be lost quickly); drawbacks include cost and short shelf life (fresh) or need to freeze (fresh frozen).
  - Gastric ulceration managed using sucralfate (0.5-1 g PO q 8 h) and famotidine (0.5 mg/kg PO q 12 h) or omeprazole (0.5-1 mg/kg PO q 24 h).
- Avoid cimetidine because of hepatic metabolism.
- HE treatment using cleansing enemas or retention enemas (Betadine diluted 1:10 or lactulose diluted 1:3). If encephalopathy is severe enough to warrant this, the prognosis is poor. Chronic management involves low-protein diets, lactulose, and neomycin or ampicillin (see p. 501).
- Coagulopathies are treated with fresh frozen plasma or fresh whole blood if there is clinical evidence of overt bleeding and anemia. Stored blood should be avoided owing to high ammonia concentrations.
- Ascites treated with abdominocentesis if abdomen is tense and the animal is uncomfortable (see pp. 1192 and p. 1194). Diuretics are less effective and possibly associated with greater side effects in the acute stages of mobilizing ascitic fluid (see below).
- Sepsis is treated with appropriate antibiotics (see p. 1014).

CHRONIC TREATMENT

All therapy discussed below lacks critical scientific review in dogs but reflects the current consensus of a majority of veterinary gastroenterologists:

- Antiinflammatory therapy using prednisolone or prednisone (2.2 mg/kg PO q 24 h; maximum dose 80 mg/d). Dosage is often tapered to an alternate-day therapy once there is clinical improvement. Corticosteroids cause a secondary steroid hepatopathy; monitoring liver enzymes is generally not helpful, but there should be a decline in serum bilirubin concentration and an increase in serum albumin concentration as the patient improves. With ascites, dexamethasone (0.2 mg/kg PO q 24-48 h) should be used instead to avoid mineralocorticoid effect. For corticosteroid-intolerant animals or when additional immunomodulation is desired, azathioprine (2 mg/kg q 24 h for 1 week, then q 48 h) can be given alone or in combination with glucocorticoids. Cyclosporine (5 mg/kg BID tapering to 5 mg/kg PO q 24 hours) can be given for immunosuppression without the need for glucocorticoids, with potentially less side effects than azathioprine.
- Copper chelation is indicated if hepatic copper concentrations are >1000 mcg/g dry liver weight. d-penicillamine or trientine (10-15 mg/kg PO q 12 h) is administered to remove copper. Following chelation, chronic zinc supplementation is used for blocking GI absorption of copper.
- Zinc has antioxidant and antifibrotic effects. Hepatic zinc deficiency occurs in advanced liver disease, and supplementation is indicated with zinc gluconate at 2-3 mg/kg PO q 24 h with deficiency. Higher doses of zinc will block intestinal copper absorption (see p. 517).
- Ursodeoxycholic acid (10-15 mg PO q 24 h) is a hydrophilic bile acid that has immunomodulatory, antioxidant, hepatoprotective, and choleretic effects.
- Antifibrotic drug colchicine (0.03 mg/kg PO q 24 h) inhibits collagen formation. However, few studies report its use in dogs, and human studies fail to show prolonged survival. Side effects are often GI. The angiotensin receptor antagonist, losartan (0.5 mg/kg PO q 12-24 h), recently has shown promise in inhibiting fibrosis in humans.
- Antioxidant therapy is used as adjunct liver support. Selection of one or several antioxidants is suggested, including vitamin E (10 IU/kg PO q 24 h), *S*-adenosylmethionine (20 mg/kg PO q 24 h or q 48 h), milk thistle (silybin complexed with phosphatidylcholine 24-70 mg/day), or others could be used for oxidative damage shown to occur in many dogs having hepatic disease.
- Antibiotics are used to modify GI bacterial flora in HE (see p. 501), to treat or reduce the incidence of secondary infection, or to treat a primary pathogen (leptospirosis or other pathogen).
- Ascites:
    - Medical treatment involves diuretics for long-term chronic management. Spironolactone (0.5-1 mg/kg PO q 12 h) is suggested as the initial diuretic. If failure of ascites control, furosemide (0.5-2 mg/kg PO q 12 h) or combination of both drugs should be considered.
    - Centesis/drainage may be performed intermittently as needed for comfort when patients develop tense ascites (very large volumes of abdominal fluid). Caution is advised because abdominocentesis will result in protein loss to the patient.

NUTRITION/DIET

- Diet is important to supply adequate calories. Palatability is important in advanced cases.
- Dietary protein is restricted only with protein intolerance (HE). Dietary protein content should represent 18%-22% of digestible kcal/day. Feed a high-quality moderate-protein diet given in small multiple feedings. Milk and vegetable protein sources are more beneficial in HE than meat protein-based diets.
- Fermentable fiber may also be beneficial in controlling HE.

DRUG INTERACTIONS

- Avoid drugs that require hepatic metabolism or alter hepatic biotransformation (e.g., cimetidine). Glucocorticoids may cause sodium retention, promote GI ulceration, or precipitate hepatic failure with advanced disease. Glucocorticoids also result in a steroid hepatopathy, making laboratory evaluation of treatment response difficult.
- Penicillamine and zinc should not be given together; penicillamine may chelate zinc.
- Animals with hepatic failure are anesthetic risks. Barbiturates should be avoided, and benzodiazepines should be used with care. Isoflurane or sevoflurane are the gas anesthetics of choice. Propofol, although hepatically metabolized, may be administered to effect (usually requiring a small fraction of normal doses) for anesthetic induction or for controlling seizures due to HE.
- Lidocaine, theophylline, propranolol, captopril, and tetracyclines should be avoided if possible.
- Diuretics may worsen HE, promote dehydration or metabolic alkalosis, and should be used only in otherwise stable patients for the long-term delay of return of ascites or for concurrent conditions (e.g., congestive heart failure).
- NSAIDs may exacerbate GI ulceration.

POSSIBLE COMPLICATIONS

Ascites, HE, GI ulceration, sepsis, disseminated intravascular coagulation, hepatic failure, and death

RECOMMENDED MONITORING

- Monitor general condition, body weight, and behavior.
- Periodic evaluation of laboratory tests (CBC and serum biochemical profile)
- Follow-up liver biopsy provides the best means of evaluating treatment response.

PROGNOSIS AND OUTCOME

- Guarded to fair based on clinical signs at the time of diagnosis and extent of liver damage as determined grossly and histopathologically.
- Most dogs are diagnosed when clinical signs occur, which is usually associated with advanced hepatitis and a guarded prognosis.
- When severe signs of liver failure occur, such as ascites, HE, and hypoalbuminemia, the prognosis is grave.
- Early diagnosis and therapy will prolong survival, but limited studies are available on survival times (cirrhosis 1-2 months; chronic hepatitis I month to 5 years).

PEARLS & CONSIDERATIONS

COMMENTS

- The first clue to chronic hepatitis is unexplained abnormal serum liver enzyme activities.
- Because of the great reserve capacity of the liver, signs of liver failure do not occur until the disease is advanced.
- Therapy in early stages of hepatitis may prolong survival.

CLIENT EDUCATION

- A complete cure is unlikely.
- Medication is generally lifelong but may prolong quality of life and survival times.
- There are few studies evaluating therapy for chronic hepatitis in the dog; repeat liver biopsies are recommended to monitor response to therapy.

Hepatitis (Chronic) of Doberman Pinscher Dogs

BASIC INFORMATION

DEFINITION

A progressive chronic inflammatory liver disease associated with hepatic copper accumulation distinct to Doberman pinschers

SYNONYMS

Chronic active hepatitis in Doberman pinschers, copper-associated chronic hepatitis, Doberman hepatitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Doberman pinschers. Most are diagnosed between the ages of 2 and 7 years. Most are females.

GENETICS & BREED PREDISPOSITION

- The high incidence in this breed suggests a genetic predisposition.
- Occurrence in this breed may have a prevalence of 2%-20% depending on clinical reports.
- Mode of genetic transmission is unknown.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Subclinical hepatitis
- Clinical hepatitis/cirrhosis

HISTORY, CHIEF COMPLAINT

- Dogs with subclinical hepatitis show no clinical signs; the disease is usually discovered incidentally (e.g., diagnostic workup triggered by elevated serum liver enzyme activities on serum biochemistry panel or microhepatica on abdominal imaging).
- Historic signs of early clinical hepatitis are often vague and may be associated with intermittent gastrointestinal signs and weight loss.
- When clinical hepatitis progresses, some or all of the following historic signs may occur:
    - Polydipsia, polyuria
    - Weight loss
    - Abdominal distension
    - Altered mental status associated with hepatic encephalopathy
- In advanced disease liver failure ensues, and the patient may have a rapid deterioration.

PHYSICAL EXAM FINDINGS

With clinical hepatitis some or all of the following may be found:

- Weight loss
- Icterus
- Ascites
- Signs of hepatic encephalopathy (depression/drowsiness, propulsive pacing, seizures; see p. 501)
- Evidence of hemorrhage (gastrointestinal, overt)

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology and mode of genetic transmission are unknown.
- Two theories suggested include either primary copper hepatotoxicity autoimmune mechanisms:
    - Primary copper hepatotoxicosis is supported by the fact that hepatic copper accumulation occurs in affected dogs

prior to hepatitis, and studies demonstrating affected dogs have a defect in biliary copper excretion, and copper chelation therapy improves pathology. Oxidative damage was also shown to occur in the liver from copper accumulation.
- Inappropriate major histocompatibility complex (MHC) class II antigen expression in affected dogs suggests the disease could be an autoimmune disorder, but presence of MHC class II can also occur as a secondary phenomenon.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The combination of signalment (breed) and physical and/or biochemical signs of hepatobiliary disease are strongly suggestive of the diagnosis; confirmation is obtained with liver biopsy.

DIFFERENTIAL DIAGNOSIS

- Hepatic disease from other causes
- Nonhepatic conditions associated with abnormal liver enzymes

INITIAL DATABASE

- Subclinical disease:
  - Elevation in serum alanine aminotransferase (ALT) activity first, followed by increases in other liver enzymes
- Clinical disease:
  - Elevation in serum ALT, aspartate aminotransferase, g-glutamyl transferase (GGT), and alkaline phosphatase (ALP) activities
  - Abnormal serum bile acid concentrations
- Advanced disease with loss of liver function: some or all of the following abnormalities may result:
  - Elevation in serum total bilirubin concentration
  - Low serum albumin, blood urea nitrogen, and glucose concentrations
  - Abnormal clotting times

ADVANCED OR CONFIRMATORY TESTING

- Abdominal radiographs show a small liver ± evidence of ascites (loss of serosal detail, abdominal distention).
- Abdominal ultrasound may demonstrate:
  - A small liver with altered parenchymal echogenicity. Findings vary from normal appearance (in early disease) to heterogeneous mottling, microhepatica with nodular changes, and an irregular surface.
  - Ascites which, on centesis, may be a pure transudate or a modified transudate; the cellular composition is not usually helpful diagnostically.
  - Vascular changes (e.g., multiple extrahepatic portosystemic shunts) associated with portal hypertension
- Surgery or laparoscopy: liver may appear normal in subclinical disease or may be small, micronodular, macronodular, and/or fibrotic in clinical disease.
- Liver biopsy and histopathology:
  - Large biopsies (obtained via laparoscopy or laparotomy) are preferred over small-diameter needle core biopsies or fine-needle aspirates, owing to superior diagnostic accuracy and ability to adequately measure hepatic copper concentrations.
  - Subclinical disease is associated with copper accumulation and infiltration of mononuclear inflammatory cells in centrilobular areas.
  - Clinical disease can progress to a micronodular cirrhosis with bridging fibrosis, piecemeal necrosis, progressive inflammatory infiltrates in the portal triads, and eventually macronodular cirrhosis with regenerative nodules.
  - Histochemical staining for copper is generally positive when copper concentrations are above 1000 mg/g dry weight liver.
- Hepatic metal quantitative analysis: Hepatic copper concentrations often range from 1000 to 2000 mg/g dry weight liver (normal <400 mg/g). Hepatic iron accumulation also occurs, thought to be secondary to chronic inflammation and not diagnostic of this disease specifically, with ranges from 1500 to 7000 mg/g dry weight liver.

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to slow progression of liver disease in subclinical cases, provide specific therapy for chronic hepatitis and

copper accumulation, and provide supportive treatment specifically aimed at controlling or avoiding complications of liver disease, including hepatic encephalopathy, ascites, gastrointestinal ulceration, and nutritional imbalance.

ACUTE GENERAL TREATMENT

- Subclinical and early clinical hepatitis with high copper concentrations (>600 mg/g liver).
  - D-penicillamine or trientine (15 mg/kg PO q 12 h) for 2-4 months or longer after measuring hepatic copper concentrations. Liver lesions improve as a result of lowering copper concentrations. Chelator therapy use should be based on identifying the characteristic histopathologic lesions and hepatic copper concentrations.
  - Glucocorticoid therapy (prednisone or prednisolone, 2-4 mg/kg PO q 24-48 h; maximum dose 80 mg/d) may be beneficial in slowing inflammatory component of liver disease.
  - Ensure adequate nutrient intake.
- Advanced clinical hepatitis (see 513):
  - Treatment for hepatic encephalopathy (see 501): high-quality low-protein diet, lactulose (0.1-0.5 mL/kg PO q 12 h, adjusted to achieve loose fecal consistency) and/or intestinal antibiotics (e.g., neomycin, 20 mg/kg PO q 8 h; ampicillin, 22 mg/kg PO q 8 h; metronidazole, 7.5 mg/kg PO q 12 h; or amoxicillin-clavulanate, 15 mg/kg PO q 12 h). If encephalopathy is severe enough to warrant these efforts, the prognosis is poor.
  - Treatment for ascites: see pp. 93, 501, and .
  - Treatment for gastric ulceration: famotidine (0.5 mg/kg PO q 12 h) or omeprazole (0.5-1 mg/kg PO q 24 h)

CHRONIC TREATMENT

- Copper chelation to maintain hepatic concentrations near normal
- Affected dogs should be placed on a low copper-containing diet (most therapeutic liver diets are low in copper).
  - After adequate chelation, zinc acetate or gluconate may be used for blocking enteric copper uptake. Adequate chelation is most accurately determined by rebiopsy; if rebiopsy is not possible, the change from chelation therapy to zinc therapy is generally warranted after 6-12 months of treatment if the dog is doing well clinically, with improving biochemical parameters.
  - Zinc acetate: 100 mg elemental zinc PO q 12 h as loading dose for 2 months, then 50 mg PO q 12 h. Zinc gluconate: 2-3 mg/kg PO q 12 h.
  - Zinc dose should be adjusted to keep serum zinc concentrations between 200 and 800 mcg/dL. NOTE: blood samples for zinc levels must be drawn into specific tubes (navy top), because standard rubber tops contain zinc.
- Antiinflammatory therapy using prednisolone or prednisone (2 mg/kg PO q 24 h; maximum dose 80 mg/d).
  - Dosage is often tapered to an alternate-day therapy once there is clinical improvement.
  - Glucocorticoids cause a secondary steroid hepatopathy, and monitoring liver enzymes is generally not helpful. However, there should be a decline in serum bilirubin concentration and an increase in serum albumin concentration as the patient improves.
  - With ascites, dexamethasone (0.2 mg/kg PO q 24 h) should be used instead to avoid mineralocorticoid effect.
  - For glucocorticoid-intolerant animals or when additional immunomodulation is desired, azathioprine or cyclosporine can be given alone or in combination with glucocorticoids (see 513).
- Ascites long-term management:
  - In the hydrated patient, diuretics (see previous) also may be used long term, either alone or as an adjunct to abdominal drainage, to delay the recurrence of ascites.
  - Repeated abdominocentesis or drainage (when ascites becomes large-volume/tense, and causes lethargy/inappetence) is also possible for long-term management of ascites (see ,pp. 1192).
- Diet is important to supply adequate calories. Palatability is important in advanced cases. Diets low in copper content should be fed. Dietary protein restriction is necessary only as protein intolerance occurs (i.e., hepatic encephalopathy). Feed a high-quality moderate-protein diet given in small multiple feedings. Milk and vegetable protein sources are better for avoiding hepatic encephalopathy than meat protein–based diets. Fermentable fiber may also be beneficial in controlling hepatic encephalopathy.
- General liver support may include ursodeoxycholic acid (15 mg/kg PO q 24 h), antioxidants (vitamin E, 10-15 IU/kg PO q 24 h); *S*-adenosylmethionine, 20 mg/kg PO q 24 h, or milk thistle [silybin complexed with phosphatidylcholine] 24-70 mg/d and antifibrotics (colchicine, 0.03 mg/kg PO q 24 h; or losartan, 0.5 mg/kg PO q 12-24 h).

DRUG INTERACTIONS

- Penicillamine and zinc should not be given together, as penicillamine may chelate zinc.
- Animals with hepatic failure are anesthetic risks. Barbiturates should be avoided, and benzodiazepines should be used with care, if at all. Isoflurane or sevoflurane are the gas anesthetics of choice. Propofol, although hepatically metabolized, may be administered to effect (usually requiring a small fraction of normal doses) for anesthetic induction and for controlling seizures due to hepatic encephalopathy.
- Lidocaine, theophylline, propranolol, captopril, and tetracyclines should be avoided.
- Diuretics may worsen hepatic encephalopathy, promote dehydration or metabolic alkalosis, and should be used only in otherwise stable patients for the long-term delay of return of ascites or for concurrent conditions (e.g., congestive heart

failure).
- Nonsteroidal antiinflammatory drugs may exacerbate gastrointestinal ulceration.
- Avoid drugs that require hepatic metabolism or alter hepatic biotransformation (e.g., cimetidine). Glucocorticoids may cause sodium retention, promote gastrointestinal ulceration, or precipitate hepatic failure in advanced disease.

POSSIBLE COMPLICATIONS

- Glucocorticoids may precipitate ascites, hepatic encephalopathy, and early death in advanced cases. Therefore, if ascites develops shortly after starting prednisone, consider switching to dexamethasone. If gastrointestinal ulceration develops, it should be addressed as discussed previously.
- Penicillamine and zinc should be given on an empty stomach but may cause vomiting. The risk of vomiting may be reduced by beginning penicillamine at the low end of the dosage range and titrating up. Zinc overdose may cause hemolysis, although the doses required to reach toxic levels are extremely high (many times higher than the therapeutic dose).
- Because von Willebrand disease (see p. 1176) is common in the breed, von Willebrand factor, buccal mucosal bleeding time (see p. 1222), or both should be evaluated prior to biopsy procedures.

RECOMMENDED MONITORING

- CBC, serum biochemistry profile, and urinalysis for disease progression, remission, or complications
- Periodic liver biopsies are the best means of evaluating the stage and progression of the disease during therapy.

PROGNOSIS AND OUTCOME

- Diagnosis and appropriate therapy in subclinical cases may delay or lessen the disease for years.
- Overt clinical manifestations of hepatitis denote advanced disease, and the long-term prognosis is guarded.

PEARLS & CONSIDERATIONS

COMMENTS

- The first abnormality observed in young, subclinically affected dogs is an increase in serum ALT activity, and therefore unexplained ALT activities should be investigated.
- Copper reduction appears to be helpful, but clinical studies evaluating therapy are limited to a small population of affected dogs.
- Diagnosis is confirmed with a liver biopsy; treatment and prognosis depend mainly on whether disease is subclinical (incidental finding, no clinical signs) or clinically overt (presence of advanced signs of liver disease, including encephalopathy and portal hypertension).

CLIENT EDUCATION

- The incidence and genetic mode of inheritance are unknown. Affected dogs or related dogs should not be used for breeding.
- Screening serum levels of liver enzymes in young dogs will lead to an early diagnosis and improved prognosis with therapy. Since the disease is common in the Doberman breed, all dogs should undergo yearly or biannual blood biochemical screening after 2 years of age.

Hepatitis (Chronic) of Cocker Spaniel Dogs

BASIC INFORMATION

DEFINITION

A progressive chronic inflammatory liver disease distinct to cocker spaniels

SYNONYMS

Cocker spaniel hepatitis, chronic hepatitis, chronic idiopathic hepatitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

English and American cocker spaniels are affected. Most are diagnosed between the ages of 2 and 6 years. Both sexes appear to be affected; male predominance.

GENETICS & BREED PREDISPOSITION

The high incidence in this breed suggests a genetic predisposition, but the mode of genetic transmission is unknown. Certain lines of dogs seem to be more affected.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Subclinical hepatitis
- Clinical hepatitis

HISTORY, CHIEF COMPLAINT

- Dogs with subclinical hepatitis show no overt signs.
- Historic signs of early clinical hepatitis are often vague and may be associated with intermittent gastrointestinal signs and weight loss.
- When clinical hepatitis progresses to liver failure, some or all of the following historic signs may occur:
    - Polydipsia, polyuria
    - Weight loss
    - Abdominal distension
    - Anorexia and vomiting
    - Altered mental status associated with hepatic encephalopathy

PHYSICAL EXAM FINDINGS

With clinical hepatitis some or all of the following may be found:

- Weight loss
- Icterus
- Ascites
- Signs of hepatic encephalopathy
- Hemorrhage

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology is unknown, but α-1 antitrypsin (AAT) may be involved.
- Hepatitis is not associated with AAT (also called α-*1 protease inhibitor*) deficiency, but rather cocker spaniels were found to be prone to abnormal accumulation of AAT (type I) in hepatocytes compared to other breeds. Researchers speculate AAT accumulation may contribute to progression of chronic hepatitis but may not be the causative agent.

- Immune mechanisms have not yet been documented in cocker spaniel hepatitis.
- Hepatic copper accumulation is not a consistent feature.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The combination of signalment (breed) and physical and/or biochemical signs of hepatobiliary disease are strongly suggestive of the diagnosis; confirmation is obtained with a liver biopsy.

DIFFERENTIAL DIAGNOSIS

- Hepatic disease from other causes
- Nonhepatic conditions associated with abnormal liver enzyme activities

INITIAL DATABASE

- Subclinical disease:
  - Elevation in serum alanine aminotransferase (ALT) activity
- Clinical disease:
  - Elevation in serum ALT, aspartate aminotransferase (AST), g-glutamyl transferase, and alkaline phosphatase activities
  - Elevated serum bile acid concentrations
- Advanced disease:
  - Elevation in serum total bilirubin concentration
  - Low serum albumin, blood urea nitrogen, and glucose concentrations
  - Abnormal clotting times

ADVANCED OR CONFIRMATORY TESTING

- Abdominal radiographs: microhepatica ± signs of ascites (loss of serosal detail)
- Ultrasound: microhepatica with altered parenchymal echogenicity, ± ascites, ± vascular changes associated with portal hypertension
- Surgery or laparoscopy: small liver; micronodular or macronodular, and fibrotic in advanced clinical disease
- Liver histopathology: subclinical disease is associated with infiltration of mononuclear inflammatory cells into portal and parenchymal areas; clinical disease has evidence of active hepatitis with areas of piecemeal and bridging necrosis. Cirrhosis develops as the disease advances.
- Histochemical staining for AAT may show globoid accumulations within hepatocytes.
- Hepatic metal quantitative analysis: hepatic copper usually normal, but secondary increases in copper may occur. Hepatic iron is increased, thought to be secondary to chronic inflammation; zinc concentrations may be reduced.

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to slow progression of liver disease in subclinical cases, provide specific therapy for chronic hepatitis, and provide general supportive care, treating complications of liver disease such as hepatic encephalopathy, ascites, gastrointestinal ulceration, and nutritional imbalance.

ACUTE GENERAL TREATMENT

- Fluid support
- Treatment of hepatic encephalopathy (see 501)
- Coagulopathies or sepsis are treated as they occur (see 513)

CHRONIC TREATMENT

- Subclinical and early clinical hepatitis (see 513):
  - Glucocorticoid therapy (prednisone or prednisolone, 2 mg/kg PO q 24-48 h; maximum of 80 mg/d) may be beneficial in slowing inflammatory component of the liver disease. Anecdotal reports suggest improved survival following therapy.

Other immunosuppressive therapy such as azathioprine or cyclosporine may be used in addition to or in place of glucocorticoid therapy.
    - Ensure adequate nutrient intake.
    - Provide liver support with antioxidants (vitamin E, 10 IU/kg PO q 24 h; *S*-adenosylmethionine, 20 mg/ kg PO q 24 h; and/or milk thistle [silybin complexed with phosphatidylcholine], 24-70 mg PO q 24 h).
    - Antifibrotics (see) such as colchicine can be used (0.03 mg/kg PO q 24 h), but few studies report its use in dogs, and human studies fail to show prolonged survival. Gastrointestinal side effects are well-recognized. The angiotensin II receptor antagonist, losartan (0.5 mg/kg PO q 12-24 h), recently has shown promise in inhibiting fibrosis in humans.
    - Ursodeoxycholic acid (15 mg/kg PO q 24 h) is given for hepatic support and choleresis.
    - If secondary copper accumulation occurs, chelator or zinc therapy should be used (see 517).
- Advanced clinical hepatitis (see 517):
    - Treatment for hepatic encephalopathy (see 501): high-quality, low-protein diet, lactulose (0.1-0.5 mL/kg PO q 12 h, titrated to achieve loose fecal consistency) and/or intestinal antibiotics (metronidazole, 7.5-10 mg/kg PO q 12 h; or amoxicillin-clavulanate, 15 mg/kg PO q 12 h)
    - Ascites therapy: spironolactone (1 mg/kg PO q 12 h) or furosemide (0.5-2 mg/kg PO q 12 h)
    - Gastric ulceration: famotidine (0.5 mg/kg PO q 12 h) or omeprazole (0.5-1 mg/kg PO q 24 h)

DRUG INTERACTIONS

Avoid drugs that require hepatic metabolism.

POSSIBLE COMPLICATIONS

Glucocorticoids may precipitate ascites, hepatic encephalopathy, and result in an early death in advanced cases.

RECOMMENDED MONITORING

- Young dogs should have periodic liver enzymes measured as screening test to help identify affected dogs.
- Routine CBC, serum biochemistry profile, and urinalysis to monitor disease progression, remission, or complications
- Periodic liver biopsies (yearly) are the best means of evaluating the stage and progression of the disease during therapy.

PROGNOSIS AND OUTCOME

- Diagnosis and appropriate therapy in subclinical cases may slow progression of disease.
- Clinical hepatitis denotes advanced disease and the long-term prognosis is guarded.

PEARLS & CONSIDERATIONS

COMMENTS

- The first abnormality observed in young subclinical dogs is an increase in serum ALT activity. Unexplained elevated serum ALT activities in this breed should be investigated.
- The disease continues to be explored; there is little objective information on chronic hepatitis in cocker spaniels.
- Many dogs are presented when the disease is advanced. The prognosis is poor at this stage.

CLIENT EDUCATION

- The incidence and genetic mode of inheritance are unknown. Affected dogs or related dogs should not be used for breeding.
- Screening laboratory enzymes in young dogs will lead to an early diagnosis and may improve prognosis with therapy.

Hepatic Nodules, Benign

BASIC INFORMATION

DEFINITION

- Hepatic adenoma: benign neoplasia of hepatocytes
- Nodular hyperplasia: discrete accumulation of hyperplastic hepatocytes surrounded by normal hepatocytes
- Nodular regeneration: discrete accumulation of hyperplastic hepatocytes surrounded by abnormal hepatocellular parenchyma, particularly fibrotic changes

SYNONYMS

Nodular hyperplasia: hyperplastic nodules; nodular regeneration: regenerative nodules

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Hepatic adenomas: rare tumors in dogs and cats; patients usually >10 years old
- Nodular hyperplasia: common lesion in old dogs. Incidence in dogs >14 years old: 70%-100%
- Nodular regeneration: seen in dogs with acquired parenchymal hepatic disease. Middle-aged to older dogs

GENETICS & BREED PREDISPOSITION

Nodular regeneration: seen in breeds predisposed to chronic hepatitis (Doberman pinscher, cocker spaniel, Labrador retriever) and copper-storage hepatopathy (Bedlington terrier, West Highland white terrier, Skye terrier)

RISK FACTORS

Nodular regeneration: chronic hepatic disease, cirrhotic/fibrosing liver disease

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Nodular hyperplasia: incidental finding, no clinical signs, rare hepatic failure
- Adenoma: incidental finding, no clinical signs; rarely, abdominal discomfort or rupture with hemoperitoneum or abscessation with signs of chronic infection
- Nodular regeneration: see sections on chronic hepatic diseases (, 512, and 513).

PHYSICAL EXAM FINDINGS

- Hepatic adenoma: rarely abdominal pain, inappetence, ascites and pallor (if ruptured)
- Nodular hyperplasia: normal exam
- Nodular regeneration: see sections on chronic hepatic disease noted above.

ETIOLOGY AND PATHOPHYSIOLOGY

- Nodular hyperplasia: unknown; may be associated with nutritional factors or a result of focal areas of ischemia; not preneoplastic
- Adenoma: unknown; may be associated with chronic inflammation or hepatotoxicity
- Nodular regeneration: compensatory response of the liver to chronic injury

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Their benign nature makes these lesions almost always incidentally encountered during abdominal ultrasound exams or abdominal surgery, or occasionally on abdominal palpation if very large.

DIFFERENTIAL DIAGNOSIS

- Nodular hyperplasia:
  - Primary or metastatic hepatic neoplasia
  - Cirrhosis with nodular regeneration
  - Vacuolar hepatopathy
- Adenoma:
  - Nodular hyperplasia
  - Primary or metastatic hepatic neoplasia
  - Hepatic abscess
- Nodular regeneration:
  - Nodular hyperplasia
  - Metastatic hepatic neoplasia
  - Vacuolar hepatopathy

INITIAL DATABASE

Nodular Hyperplasia:

- Commonly associated with mild to moderate increases in serum alkaline phosphatase (ALP) activity, less commonly with mild increases in serum alanine transaminase (ALT) and aspartate aminotransferase (AST) activities
- Serum bile acids concentration usually normal
- Abdominal ultrasonography reveals single to multiple lesions with highly variable appearance. Easily mistaken for primary or metastatic neoplasia or nodular regeneration.

Hepatic Adenoma:

- Variable increases in ALP, ALT, and AST activities
- Serum bile acids concentration usually normal
  - Leukocytosis ± monocytosis if necrotic regions within adenomas
  - Anemia if adenoma ruptures and hemoperitoneum
- Radiographs may identify a mass in the cranial abdomen or rarely a gas pocket in a necrotic region.
- Abdominal ultrasonography demonstrates a solitary mass with variable echogenicity that may contain cystic cavities and/or blood-or gas-filled spaces. Ascites seen with rupture and hemoperitoneum.

Nodular Regeneration:

- Serum bile acids concentration usually abnormal
- See sections on chronic hepatic disease (pp. 212 and 513).

ADVANCED OR CONFIRMATORY TESTS

General:

- Hepatic histopathology differentiates the three conditions but often requires wedge biopsy, as adjacent hepatic tissue is necessary to make a definitive diagnosis.
- Fine-needle aspiration or single needle biopsies of these focal lesions may result in misdiagnosis of hepatic vacuolar hepatopathy.
- MRI of focal hepatic masses may provide better discrimination of these lesions (future direction).
- Preliminary studies with contrast enhanced ultrasonography have shown some ability to discriminate benign nodules from malignant ones.

Specific:

- Nodular hyperplasia:
  - Well-circumscribed expansive nodule usually <3 cm, containing hyperplastic hepatocytes that often contain cytoplasmic vacuoles and are loosely organized into hepatic cords with discernable portal tracts
  - Nodules surrounded by normal hepatic parenchyma
  - Lipogranulomas are a common associated finding.
- Adenoma:

- Well-circumscribed expansive nodule of variable size containing hyperplastic but well-differentiated hepatocytes arranged in cords that are 1-2 cells thick with a conspicuous absence of portal tracts.
- Adenomas are surrounded by normal hepatic parenchyma.

- Nodular regeneration:
  - Similar histologic appearance as nodular hyperplasia, but surrounding hepatic parenchyma is abnormal, most often with mixed inflammation and fibrosis.

TREATMENT

TREATMENT OVERVIEW

Determine if the focal lesions present on abdominal ultrasound, which may or may not be accompanied by increases in serum hepatic enzyme activities, require any therapeutic intervention.

ACUTE GENERAL TREATMENT

- Nodular hyperplasia:
  - No treatment necessary
- Adenoma:
  - No treatment necessary for small masses not associated with clinical signs
  - Surgical excision for large masses causing abdominal discomfort or for those associated with abscessation or hemorrhage
- Nodular regeneration:
  - Treatment of the underlying disorder (see sections on chronic hepatic disease noted earlier)

RECOMMENDED MONITORING

Sequential monitoring of serum hepatic enzyme activity and abdominal ultrasonography q 4-6 months

PROGNOSIS AND OUTCOME

- Nodular hyperplasia or adenoma: excellent long-term prognosis
- Nodular regeneration: see p. 212

PEARLS & CONSIDERATIONS

COMMENTS

- Nodular hyperplasia is primarily of clinical concern for two reasons:
  - It is a common cause of increased serum ALP activity in older dogs.
  - The ultrasonographic appearance may mimic primary or metastatic hepatic neoplasia.
- Differentiation of the three conditions usually requires hepatic wedge biopsy (obtained via laparoscopy or surgery).

AUTHOR: CYNTHIA R. L. WEBSTER

EDITOR: KEITH P. RICHTER

Hepatic Neoplasia, Malignant

BASIC INFORMATION

DEFINITION

- Primary malignant neoplasm of the liver or biliary tract
- Epithelial origin: hepatocellular carcinoma (most common), hepatocellular adenoma/hepatoma, biliary carcinoma, biliary adenoma, hepatic carcinoid
- Mesenchymal origin: hemangiosarcoma and leiomyosarcoma are the most common.
- Hemolymphatic tumors: lymphoma (dogs, cats) and myeloproliferative disorders (cats). Hepatic lymphoma may be part of multicentric disease or the primary site.
- Metastatic hepatic neoplasia (hemangiosarcoma, histiocytic sarcoma, islet cell carcinoma, pancreatic adenocarcinoma, intestinal adenocarcinoma, leiomyosarcoma, mammary carcinoma, transitional cell carcinoma, renal carcinoma, pheochromocytoma, and others)

SYNONYMS

- Biliary adenoma: biliary cystadenoma in cats
- Biliary carcinoma: cholangiocarcinoma, biliary cystadenocarcinoma

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Primary hepatobiliary tumors are uncommon, accounting for less than 1.5% of all canine neoplasms and 1%-2.9% of all feline neoplasms.
- Hepatocellular carcinoma is the most common primary liver tumor in dogs, accounting for more than half of all hepatobiliary tumors.
- Biliary carcinomas and adenomas are the most common primary hepatic tumors in cats. Biliary tumors are uncommon in dogs.
- Occur primarily in older animals (average age 10-12 years)

GENETICS & BREED PREDISPOSITION

Domestic shorthair cats may have a higher rate of development of hepatic neoplasia than purebred cats.

RISK FACTORS

- Potential causes include aflatoxins, diethylnitrosamine, dichlorobenzidine, aramite, liver flukes *(Clonorchis* spp., *Platynosomum concinnum)*, and radioactive compounds such as strontium 90 and cesium 144.
- Biliary carcinoma can occur in juvenile cats with feline leukemia virus infection.
- In humans, hepatitis B and C and cirrhosis are common risk factors for hepatocellular carcinoma. A similar association with viruses is not known to occur in dogs. Cirrhosis was only found in 7% of dogs with hepatocellular carcinoma.

CONTAGION & ZOONOSIS

As opposed to humans, no association with viral infection has been found.

ASSOCIATED CONDITIONS & DISORDERS

- Paraneoplastic hypoglycemia is occasionally noted in dogs with hepatocellular carcinoma (up to 38% of cases) and less frequently in dogs with hepatocellular adenoma, leiomyosarcoma, and hemangiosarcoma. Serum insulin concentrations are normal to decreased. Potential mechanisms of hypoglycemia include excess use of glucose by the tumor, release of insulin-like factors from the tumor, release of other substances such as somatostatin from the tumor, and secondary hepatic parenchymal destruction with impaired glycogenolysis or gluconeogenesis.
- Paraneoplastic alopecia (see p. 834) has been reported in cats with biliary carcinoma and hepatocellular carcinoma.
- Bile duct obstruction, coagulopathies, and hepatic encephalopathy are uncommon.
- Myasthenia gravis was associated with biliary carcinoma in one report.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Hepatocellular carcinoma—three gross morphologic subtypes: massive, nodular, and diffuse.
    - Massive hepatocellular carcinoma, defined as a large tumor affecting a single liver lobe, represents 53%-84% of cases. The nodular form occurs in 16%-25% and the diffuse form in 0%-19% of cases.
- Biliary carcinoma; also occurs as massive, nodular, or diffuse forms in dogs: massive form occurs in 37%-46%, nodular in 0%-21%, and diffuse in 17%-54% of cases. Biliary carcinomas can also be extrahepatic within bile ducts or gallbladder.
- Hepatic carcinoid: a primary neuroendocrine tumor that is uncommon, typified by aggressive biological behavior, and most commonly diffuse with early metastasis.

HISTORY, CHIEF COMPLAINT

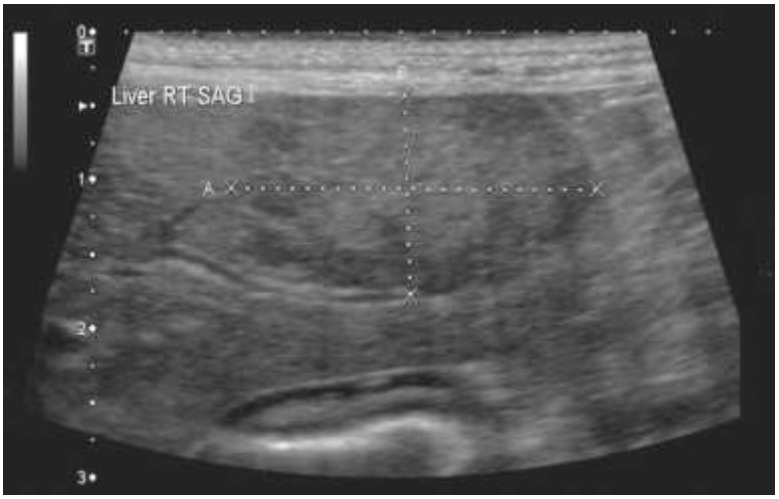
Clinical signs are usually vague and nonspecific. Anorexia, lethargy, weight loss, polydipsia, polyuria, vomiting, and abdominal distention are the most common presenting complaints. Less frequent presenting problems are jaundice, diarrhea, excessive bleeding, and signs of central nervous system dysfunction due to hepatic encephalopathy, hypoglycemia, or central nervous system metastases.

PHYSICAL EXAM FINDINGS

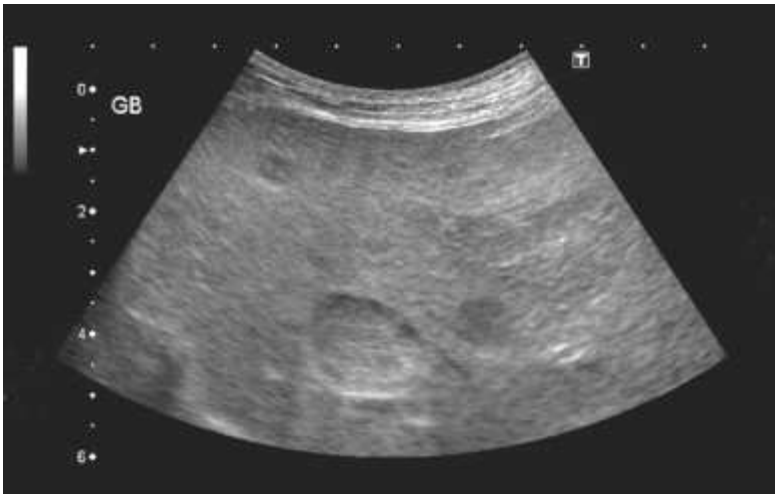
- The most common finding in dogs and cats with primary hepatic tumors is a palpable cranial abdominal mass or marked hepatomegaly.
- Ascites or hemoabdomen may also contribute to abdominal distention.
- Pale mucous membranes due to anemia, jaundice, cachexia, and weakness are other potential findings.

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology unknown
- The more common massive hepatocellular carcinomas generally have a low potential for metastasis, with rates varying from 0%-37%. The less common nodular and diffuse hepatocellular carcinomas have metastatic rates as high as 100% reported.
    - Extrahepatic metastases occur more commonly with biliary carcinoma, with metastasis occurring in 56%-88% of cases.
    - Hepatic carcinoids and sarcomas have the highest metastatic rates, with metastasis occurring in 86%-93% of cases. Metastasis is most commonly to hepatic lymph nodes, peritoneal cavity, and lungs, although widespread metastases can occur.
- Less is known about the metastatic rate of feline malignant hepatobiliary tumors, with estimates of metastasis in 56%-67% of cases; diffuse intraperitoneal involvement is the most common manifestation.



HEPATIC NEOPLASIA, MALIGNANT Abdominal ultrasound: hepatocellular carcinoma. Solitary well-circumscribed complex echogenic liver mass.



HEPATIC NEOPLASIA, MALIGNANT Abdominal ultrasound: metastatic carcinoma. Multiple hypoechoic liver lesions. The larger structure at the bottom of the image is the gallbladder, containing inspissated bile.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Vague nonspecific clinical signs, elevated liver enzymes, and a palpable cranial abdominal mass or hepatomegaly are commonly present. The diagnosis is typically based on the presence of a liver mass or masses which are palpated and/or seen on abdominal ultrasound; conformation is via cytologic or histopathologic examination of smears or biopsy specimens, respectively.

DIFFERENTIAL DIAGNOSIS

- Metastatic hepatic neoplasia (liver metastasis from nonhepatic neoplasia occurs 2.5 times more frequently than primary liver neoplasia in dogs, particularly from primary neoplasia of the spleen, pancreas, and gastrointestinal tract, whereas in cats primary hepatobiliary tumors are more common than metastatic disease).
- Hepatic nodular hyperplasia
- Diffuse hepatomegaly (e.g., vacuolar hepatopathy, hepatic congestion, lipidosis
- Hepatic regenerative hyperplasia, cirrhosis (presence of nodular regeneration)
- Hepatobiliary cysts
- Hepatic abscess

INITIAL DATABASE

- CBC: variable anemia and leukocytosis, pancytopenia may be seen with hematopoietic or lymphoid malignancies that involve bone marrow and only secondarily involve the liver.
- Coagulation profile: prolonged prothrombin times and activated partial thromboplastin times are not common (when coagulopathies occur, they are most common with hepatic hemangiosarcoma).
- Serum chemistry profile: mild to marked increases in liver enzyme activities: alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase (ALP). Hyperbilirubinemia (uncommon in dogs with primary hepatic neoplasia, more common in dogs with metastatic liver disease, occurs in one-third of cats with primary liver tumors). Other quite variable biochemical abnormalities include hypoalbuminemia, hyperglobulinemia, and hypoglycemia.
- Serum bile acids concentration: elevated in 50%-75% of cases, with magnitude of elevation often mild
- Abdominal radiographs: symmetric or asymmetric hepatomegaly, ascites, and caudolateral gastric displacement
- Three-view thoracic radiographs: evaluate for pulmonary metastasis.
- Abdominal ultrasound: very useful for evaluation of the liver when primary or metastatic hepatic neoplasia is suspected:
    - Hepatocellular carcinoma usually appears as a focal hyperechoic or mixed echogenic mass.
    - Primary or metastatic neoplasia often appears as focal or multifocal hypoechoic or mixed echogenic lesions.
    - “Target” lesions, nodules or masses with a hypoechoic rim and a hyperechoic or isoechoic center, are often neoplastic, with a positive predictive value for malignancy of 74% for solitary lesions and 81% for multiple lesions in one report.
    - Hyperplastic nodules are usually multifocal hyperechoic lesions, although hypoechoic or mixed echogenic lesions can occur.
    - The ultrasonographic appearance of hepatic lymphoma is quite variable, ranging from normal to mild diffuse hyperechogenicity or hypoechogenicity, multifocal hypoechoic lesions, or mixed echogenic target lesions.

- Contrast harmonic ultrasound has recently been reported as a method for discriminating between benign and malignant nodules in the liver of dogs. This method requires ultrasound contrast medium and contrast harmonic software.

ADVANCED OR CONFIRMATORY TESTING

- Ultrasound-guided percutaneous fine-needle aspirate for cytology. Cytologic evaluation can correctly diagnose neoplasia in up to 62% of patients with liver tumors, although it is often unreliable. Cytologic evaluation is most useful for the diagnosis of diffuse hemolymphatic tumors such as lymphoma, myeloproliferative disease, and mast cell tumors. There is low risk to the patient with fine-needle aspiration.
- Ultrasound-guided percutaneous core needle biopsy versus laparoscopic biopsy for histopathologic evaluation of liver tissue (confirmatory). Needle biopsies are generally accurate, but because of the small size of biopsy samples, differentiation of nodular hyperplasia from primary hepatic neoplasia may be difficult. Sometimes a larger biopsy specimen obtained via laparoscopy or laparotomy is necessary. Laparoscopy allows for larger biopsy samples and is also useful for staging (observe peritoneal surface and lymph nodes for infiltration or other abnormalities). See p. 1298.
- Peritoneal fluid cytology in animals that have ascites may reveal neoplastic cells, especially in advanced cases, although often ascites is a modified transudate without exfoliation of neoplastic cells.
- Abdominal CT scan or MRI could be considered for lesion characterization and staging. MRI has been shown to be useful for differentiating benign from malignant focal hepatic lesions in dogs.
- α-fetoprotein is an oncofetal glycoprotein that is a useful serum tumor marker for human hepatocellular carcinoma. It was shown to be elevated significantly in 55% of dogs with biliary carcinoma and 75% of dogs with hepatocellular carcinoma, but not in dogs with other primary or metastatic hepatic tumors or other types of liver disease. This assay is not readily available in most veterinary laboratories at this time.

TREATMENT

TREATMENT OVERVIEW

- Surgical removal of the tumor for primary hepatic neoplasia such as hepatocellular carcinoma, hepatoma, and biliary carcinoma
- Chemotherapy for hepatic lymphoma and hepatic mast cell tumor
- Palliative therapy for metastatic hepatic cancer

ACUTE GENERAL TREATMENT

- Supportive therapy for paraneoplastic hypoglycemia, coagulopathies, or hepatic encephalopathy
- Liver lobectomy for primary hepatic tumors involving a single lobe. Fewer biliary carcinomas can be resected, owing to the higher percentage that are multifocal or metastatic at presentation.
- Treatment options are very limited for nodular, diffuse, and metastatic liver cancer.

CHRONIC TREATMENT

- Chemotherapy for hepatic lymphoma, mast cell tumor, myeloproliferative disease, and possibly for hemangiosarcoma
- No effective chemotherapy or radiation therapy protocols have been reported for primary hepatic tumors.
- Several chemotherapy drugs have been used anecdotally (carboplatin, gemcitabine, mitoxantrone, doxorubicin, 5-fluorouracil), although efficacy has not been proven. Given the poor response in humans with hepatobiliary cancer, it is unlikely that systemic chemotherapy with the currently available agents will play a major role in the treatment of hepatobiliary cancer in dogs and or cats.
  - Chemoresistance may be due to expression of P-glycoprotein, which is associated with multidrug resistance, and/or the presence of detoxification enzymes contained in hepatocytes.
- Newer treatment modalities such as intraarterial chemotherapy, transarterial chemoembolization, percutaneous ethanol injection, microwave coagulation, and immunotherapeutic strategies may be applicable in veterinary patients. A novel treatment method for hepatocellular carcinoma in dogs using fractional excision with a Cavitron ultrasonic surgical aspirator has recently been described.

POSSIBLE COMPLICATIONS

- Hemorrhage is the most common surgical complication. Blood products should be available in the event a transfusion is necessary.
- Although not common, hypoglycemia is a potential transient complication of extensive partial hepatectomy.

RECOMMENDED MONITORING

After removal of primary liver tumors, follow-up abdominal ultrasound and three-view thoracic radiographs are recommended every 3-6 months for 1-2 years.

PROGNOSIS AND OUTCOME

- For massive hepatocellular carcinoma treated by liver lobectomy, the prognosis is good with a complete excision, with average survival times of more than a year and many patients being cured.
- The median survival time for massive hepatocellular carcinoma treated with liver lobectomy is >1460 days, with high serum ALT and AST activity and right-sided tumors conveying a worse prognosis.
- The prognosis for nodular or diffuse hepatocellular carcinoma is poor.
- Biliary carcinoma, hepatic carcinoids, and hepatic sarcomas have a worse prognosis, as they are commonly nodular or diffuse, resistant to chemotherapy, and have high metastatic rates.
- Hepatic lymphoma has a variable prognosis depending on the grade and response to chemotherapy.
- The liver is a common site of metastasis for a variety of cancers, and metastatic liver disease has a poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- The most common primary hepatobiliary tumor in dogs is a massive hepatocellular carcinoma. With liver lobectomy providing a complete excision of massive hepatocellular carcinoma, long-term survival or cure is common.
- The most common feline hepatobiliary tumors are bile duct carcinoma and biliary cystadenoma. Bile duct carcinoma has a high metastatic rate and a poor prognosis, whereas biliary cystadenoma is benign and generally has a good prognosis.

AUTHOR: STEVE HILL

EDITOR: KEITH P. RICHTER

Hepatic Lipidosis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A well-recognized syndrome in cats, characterized by excessive accumulation of fat (triglyceride) in the liver; associated with severe intrahepatic cholestasis and hepatic dysfunction

SYNONYMS

Fatty liver syndrome, feline hepatic lipidosis (FHL), idiopathic hepatic lipidosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Cats; middle-aged or older

RISK FACTORS

Obesity before onset of anorexia; prior stressful event (boarding, surgery, change in living arrangements, diet change) preceding anorexia; systemic diseases associated with anorexia and a catabolic state. May be associated with pancreatitis.

ASSOCIATED CONDITIONS & DISORDERS

Cholangitis, pancreatitis, inflammatory bowel disease, systemic neoplasia, diabetes mellitus, toxin-or drug-induced injury (stanozolol, tetracyclines), and many other systemic disorders associated with anorexia and weight loss

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Idiopathic hepatic lipidosis: primary disorder of unknown cause
- Secondary hepatic lipidosis: associated with inciting cause (see Associated Conditions and Disorders above)

HISTORY, CHIEF COMPLAINT

Prolonged anorexia, often several weeks in duration; rapid weight loss (often >25% of body weight). History of stressful event (see Risk Factors above), or nonhepatic diseases associated with anorexia. Other signs: lethargy, depression, sporadic vomiting, constipation, or diarrhea.

PHYSICAL EXAM FINDINGS

Icterus, hepatomegaly, dehydration, muscle wasting, seborrhea, pale mucous membranes, weight loss. Overt findings of hepatic encephalopathy (ptyalism, severe depression, stupor) or bleeding are uncommon and indicate severe liver failure. Head or neck ventroflexion may occur with severe electrolyte imbalances (hypokalemia, hypophosphatemia) or thiamine deficiency.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cats have higher nutritional requirements for protein, essential amino acids, and essential fatty acids than dogs.
- Systemically ill cats have a propensity for accumulating fat in their hepatocytes.
- Profound anorexia and stress may be associated with hormonal (catecholamines, other) alterations that influence fat metabolism and predispose to peripheral fat mobilization and hepatic fat uptake.
- Obese cats appear unable to adapt to metabolism of fat for energy during starvation. The exact metabolic or biochemical aberrations in cats with hepatic lipidosis are unknown, but there appears to be an imbalance between mobilization of peripheral fat, hepatic use of fatty acids for energy, and hepatic dispersal of triglycerides.
- Lipid accumulation is not directly toxic to liver but is a marker for an underlying metabolic disorder.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the findings of icterus in an afebrile obese cat with a history of anorexia and weight loss and laboratory features of hyperbilirubinemia, increased serum alkaline phosphatase (ALP) activity with normal to mildly increased serum gamma-glutamyltransferase (GGT) activity and a non-inflammatory CBC. Definitive diagnosis requires liver biopsy, but cytology often suffices for a presumptive diagnosis (though cytology can yield false-positive results).

DIFFERENTIAL DIAGNOSIS

- Cholangitis/cholangiohepatitis
- Pancreatitis
- Hepatic manifestations of feline infectious peritonitis
- Hepatic neoplasia
- Drug-or toxin-induced hepatic injury
- Extrahepatic bile duct obstruction

INITIAL DATABASE

- CBC:
  - Normocytic, normochromic anemia
  - Poikilocytosis (acanthocytes and elliptocytes)
  - Hemolysis (secondary to hypophosphatemia or Heinz bodies)
  - Mature neutrophilia and lymphopenia (stress response)
- Serum biochemistry profile:
  - ALP: moderate to marked increases. Earliest biochemical change; precedes hyperbilirubinemia.
  - Alanine aminotransferase (ALT): mild to moderate increases
  - GGT: normal to mild increase (as opposed to increased serum GGT activity seen with other feline cholestatic disorders). The finding of a greater magnitude of elevation of ALP compared with GGT is highly suggestive of feline hepatic lipidosis (seen in virtually 100% of cases).
  - Hyperbilirubinemia
  - Hyperammonemia, hypoalbuminemia, hypoglycemia (severe hepatic dysfunction)
- Urinalysis: may show bilirubinuria (always abnormal in the cat)
- Coagulation abnormalities (prothrombin time and proteins induced by vitamin K antagonism increased; hypofibrinogenemia)
- Abdominal radiographs: normal to increased liver size
- Abdominal ultrasound: normal to increased liver size; diffusely hyperechoic parenchyma (seen in virtually 100% of cases), far field beam attenuation, vessels difficult to recognize. Ascites rare. Evaluate for concurrent pancreatitis or other disorders causing secondary hepatic lipidosis.
- Bile acids: usually elevated (not necessary to measure if hyperbilirubinemia is present)

ADVANCED OR CONFIRMATORY TESTING

- Fine-needle aspiration and cytologic evaluation of the liver are preferred over liver biopsy (less invasive, allows presumptive diagnosis of hepatic lipidosis). However, cytologic evaluation is not accurate in diagnosing other hepatopathies, and therefore these may be missed. False-positive results also commonly occur. In hepatic lipidosis, cytologic evaluation reveals vacuolated hepatocytes without inflammation. Correction of any coagulopathy with vitamin K1 prior to performing liver aspirate or biopsy is warranted. However, coagulation studies do not necessarily predict bleeding tendency after liver aspirate or biopsy.
- Liver biopsy provides definitive diagnosis. Not routinely performed when supporting lab work (in particular the elevated serum ALP activity relative to serum GGT activity) and fine-needle aspirate and cytologic study suggest the diagnosis, unless there is failure to respond to therapy for hepatic lipidosis or a high level of suspicion of other primary hepatic disorder(s) exists. With hepatic lipidosis, the biopsy sample typically is a pale tan/yellow color and floats in formalin. Biopsy results show severe vacuolization of hepatocytes (>50% of acinar unit involved). Inflammation and necrosis absent. Vacuoles stain positive for fat with oil red O.
- Consider serum feline pancreatic lipase immunoreactivity to evaluate for concurrent feline pancreatitis (see p. 817). Consider serum cobalamin (vitamin B12) levels if underlying primary intestinal disorder suspected.
- Evaluate for underlying systemic disorder as necessary.

TREATMENT

TREATMENT OVERVIEW

- Correct fluid and electrolyte abnormalities.
- Control complications of liver failure.
- Give nutritional support to provide adequate calorie and protein intake.
- Treat underlying systemic disorder if identified.

ACUTE GENERAL TREATMENT

- Initial fluid therapy: intravenous balanced electrolyte solution supplemented with KCl using conventional sliding scale (20-40 mEq/L). Monitor serum potassium twice daily initially and readjust as needed; avoid lactated Ringer's solution (impaired lactate metabolism in severe hepatic lipidosis); avoid dextrose supplementation unless hypoglycemic (promotes hepatic lipid deposition).
- Vitamin K1 (0.5-1.5 mg/kg SQ q 12 h for three injections) for coagulopathy
- Water-soluble vitamin supplementation:
  - B-complex vitamins (added to fluids: 1-2 ml/L).
  - Cobalamin (vitamin B12): 250 mcg SQ initially while awaiting serum cobalamin levels. If decreased serum cobalamin is documented (primary intestinal disease), continue with 250 mcg SQ once weekly.
  - Thiamine supplementation (if severe ventroflexion of neck): 50-100 mg PO/cat/d for 1 week. Use with caution: potential anaphylactic reactions.
- Blood transfusion as needed for anemia (preferably fresh; stored blood can exacerbate encephalopathy due to high ammonia concentration).

NUTRITION/DIET

- Nasogastric tube feeding of CliniCare (Abbott Veterinary Diets) for initial 24-48 hours (see p. 1269). This will allow initial stabilization prior to general anesthesia for long-term feeding tube placement.
- Place gastrostomy or esophagostomy tube (by least invasive method possible; see pp. 1267 and p. 1273).
  - Feed Maximum Calorie (The Iams Co.), Prescription Diet a/d (Hill's Pet Nutrition), or other complete and balanced feline diet. Do not restrict dietary protein unless overt signs of hepatic encephalopathy are present.
  - Provide 40-60 kcal/kg/d. Start with ¼ to ½ of daily requirements given through tube and divided into 4-6 feedings. Gradually increase to daily requirements over 3-4 days.
  - If vomiting occurs, consider metoclopramide (0.4 mg/kg q 8 h SQ or through the tube 30 minutes before feeding), cisapride (1 mg/kg q 8 h through the tube), prochlorperazine (0.1-0.3 mg/kg q 8-12 h SQ or IV) or maropitant (1 mg/kg IV, SQ, PO), or tube feedings by slow constant rate infusion. Be sure that any tablet-formulated medications are ground to a fine powder before being administered through the tube; otherwise, there is a risk of tube occlusion.
  - Tube feeding usually required for 3-6 weeks (or longer in some cases) pending clinical and biochemical improvement.
  - Do not remove tube until cat eating on its own for at least a week.
- Other dietary supplements used empirically:
  - l-carnitine 250-500 mg PO q 24 h (essential cofactor for fatty acid oxidation; relative carnitine deficiency in hepatic lipidosis)
  - Taurine 250-500 mg PO q 24 h for initial 7-10 days (plasma levels have been found to be decreased in many cats with hepatic lipidosis; required for bile acid conjugation)
  - Vitamin E (water soluble form) 50-100 units/cat PO q 24 h (antioxidant)
  - s-adenosylmethionine (SAMe; Denosyl SD4 [Nutramax Labs]) 20 mg/kg PO q 24 h (glutathione source). Do not give through the tube (would disrupt enteric coating).

POSSIBLE COMPLICATIONS

- Hepatic encephalopathy (see p. 501):
- Hypophosphatemia (see p. 969)
- Heinz body hemolysis:
  - Cats with hepatic lipidosis have decreased hepatic glutathione and are at risk for red blood cell oxidant injury/Heinz body hemolysis. For critical Heinz body hemolytic anemia, provide glutathione source as *N*-acetylcysteine 140 mg/kg (20% solution diluted at least 1:2 with saline) IV over 20 to 30 minutes through 0.25-mm nonpyrogenic filter; then 70 mg/kg IV q 8-12 h depending on clinical signs. When enteral feeding is established, switch to SAMe 20 mg/kg PO q 24 h (do not give through the tube so the enteric coating is not disrupted) as a glutathione source. Propofol does not appear to be a risk factor for Heinz body hemolytic anemia in cats with hepatic lipidosis.
- Hypomagnesemia:
  - Monitor serum magnesium. Supplement if mg < 1.2 mg/dL. Magnesium sulfate (8.13 mEq/g) and magnesium chloride (9.25 mEq/g) salts available in 50% solution; dilute to a concentration of 20% or less in 5% dextrose in water. Give 0.75-1 mEq/kg/d constant rate infusion.

RECOMMENDED MONITORING

Biochemical improvement (decreases in bilirubin, ALP, ALT) usually seen within 1-2 weeks of initiating tube feeding. Normalization

may take several weeks.

PROGNOSIS AND OUTCOME

- Early diagnosis is key to successful management.
- Recovery in approximately 60%-85% of cases. If the cat survives the initial few days, the prognosis for complete recovery is excellent.
- Poorer prognosis with concurrent pancreatitis

PEARLS & CONSIDERATIONS

COMMENTS

- Oral appetite stimulants usually are inadequate for aggressive nutritional support required for feline hepatic lipidosis therapy. Oral diazepam is associated with idiosyncratic hepatic necrosis in cats.
- Correct fluid and electrolyte imbalances before anesthesia for tube placement.
- In critically ill cats with hepatic lipidosis, the stress of general anesthesia may be fatal. Therefore initial feeding through a nasogastric tube (placed in awake state) before anesthesia for long-term feeding tube placement is recommended. Once the patient is more stable, anesthesia for long-tereeding tube placement can be more safely accomplished.
- Establishing the diagnosis, identifying any underlying causes (which may require long-term treatment), and initial management (often requires several days of hospitalization, including anesthesia and feeding tube placement) can be costly, time consuming, but ultimately rewarding.
- Evaluate for underlying systemic disorder (feline hepatic lipidosis may be secondary).
- Strategies to control vomiting are important for a successful outcome.

PREVENTION

- Do not switch obese cats to unpalatable diet for weight loss. Consider smaller amounts of favorite food given in parallel (not mixed in) with a weight-loss diet to avoid reducing appetite while allowing the cat to become accustomed to the new food.
- l-carnitine (250 mg/cat PO q 24 h) may improve fatty acid oxidation in obese cats undergoing weight loss but won't prevent hepatic lipidosis.

CLIENT EDUCATION

- Tube feeding for 3-6 weeks (or longer) at home will be required for recovery.
- Recurrence is unlikely unless an underlying chronic cause is present; the owner should take care to not allow cat to become anorexic again.

EDITOR: KEITH P. RICHTER

Hepatic Injury, Acute

BASIC INFORMATION

DEFINITION

Sudden insult to the liver, which if severe enough to compromise at least 70%-80% of functional hepatic tissue, results in acute hepatic failure

SYNONYM

Acute or fulminant hepatic failure

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats; no age or sex predilection

RISK FACTORS

Drug administration; free-roaming animals with access to potential hepatotoxins (chemicals and pesticides, pond water [blue-green algae], poisonous mushrooms, cycad palms)

CONTAGION & ZOONOSIS

Infectious diseases (see Etiology and Pathophysiology below) for dog-to-dog or cat-to-cat transmission; leptospirosis (dog-to-human)

GEOGRAPHY AND SEASONALITY

Cycad palm toxicosis (dogs): southern United States and Hawaii; fungal: Mississippi and Ohio River Valley (dogs: histoplasmosis), southwestern United States (dogs: coccidioidomycosis). Blue-green algae hepatotoxicity (dogs): late summer or early fall.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Unexpected finding of increased serum liver enzyme activities and bilirubin concentration detected on routine biochemistries (mild hepatic injury or reactive hepatopathy secondary to systemic disorder) in patient who is asymptomatic or has only minimal clinical signs
- Clinical and biochemical evidence of acute hepatic failure (liver dysfunction occurring in the absence of known preexisting liver disease, accompanied by hepatic encephalopathy and coagulopathy). Findings reflect general hepatic dysfunction rather than specific underlying cause

HISTORY, CHIEF COMPLAINT

- History of recent drug administration (prescription, over-the-counter, herbals, or dietary supplements may be implicated) or exposure to other potential hepatotoxins (e.g., aflatoxin-contaminated pet food: feeding from a new bag of food, or multiple affected dogs in a household)
- Acute onset of anorexia, lethargy, vomiting, and diarrhea in previously healthy animal
- Other signs: polyuria/polydipsia, hepatic encephalopathy, signs of extrahepatic or multisystemic disease, dependent on underlying cause

PHYSICAL EXAM FINDINGS

- Dehydration, icterus (+/−), excessive bleeding (hematemesis, melena, hemorrhages of skin or mucous membranes) and hepatic encephalopathy indicate severe hepatic failure.
- Other findings dependent on specific cause (e.g., fever: consider infectious causes or secondary to acute pancreatitis; signs of abdominal pain: acute pancreatitis, cholangitis, liver abscess, acute swelling and stretching of liver capsule [nonspecific])

ETIOLOGY AND PATHOPHYSIOLOGY

- Drugs and anesthetics:
  - Hepatic drug reactions may be classified as predictable (e.g., acetaminophen) or idiosyncratic (most drugs). Usually acute but may be chronic (phenobarbital, primidone, lomustine).
  - Acetaminophen (dogs and cats), amiodarone (dogs), azathioprine (dogs), carprofen and other nonsteroidal antiinflammatory drugs (NSAIDs) (dogs), clonazepam (cats), danazol (dogs), diazepam (cats), doxycycline (dogs), glipizide (cats), griseofulvin (cats), halothane (dogs), itraconazole (dogs and cats), ketoconazole (dogs and cats), lomustine (dogs), methimazole (cats), methoxyflurane (dogs), mitotane (dogs), nitrofurantoin (dogs), oxibendazole (dogs), phenobarbital (dogs), primidone (dogs), potentiated sulfonamides (dogs), stanozolol (cats), tetracycline (dogs and cats), thiacetarsemide (dogs)
  - Idiosyncratic reaction can occur with *any* drug. Diagnosis is presumptive; cannot be proven. Do not rechallenge with suspect drug. Withdrawal of hepatotoxic drug can result in improvement or resolution of hepatic injury (within days to weeks), depending on severity of lesion.
- Biological substances:
  - Aflatoxin (contaminated dog food)
  - *Amanita* mushrooms
  - Blue-green *algae*
  - Sago palms
  - Hornet stings
  - Herbal derivatives (pennyroyal oil, chaparral leaf, comfrey, jin bu huan, kava kava)
  - Xylitol (5-carbon sugar alcohol used as a sugar substitute and is anticariogenic)
- Chemicals and toxins:
  - Carbon tetrachloride
  - Dimethylnitrosamine
  - Metals (e.g., copper, lead, iron, zinc)
  - Organochloride pesticides
  - Many others
- Infectious agents:
  - Viral: infectious canine hepatitis, canine herpesvirus, feline infectious peritonitis, virulent feline calicivirus
  - Bacterial: leptospirosis, liver abscess, cholangitis/cholangiohepatitis, *Bartonella* spp.
  - Fungal: histoplasmosis, coccidioidomycosis, others
  - Protozoal: *Toxoplasma gondii, Babesia* spp., *Cytauxzoon felis*
  - Rickettsial: *Ehrlichia* spp., *Rickettsia rickettsiae*
- Systemic or metabolic disorders:
  - Acute pancreatitis
  - Extrahepatic infection, septicemia, endotoxemia
  - Hemolytic anemia and DIC
  - Inflammatory bowel disease
  - Feline hepatic lipidosis
  - Copper storage hepatopathy
- Miscellaneous causes of liver injury:
  - Trauma
  - Heat stroke
  - Liver lobe torsion
  - Thromboembolic disease
  - Shock
  - Surgical hypotension and hypoxia

DIAGNOSIS

DIAGNOSTIC OVERVIEW

When acute hepatic injury or overt hepatic failure is detected, obtain a thorough history for potential hepatotoxin exposure, and evaluate for systemic disorders that could secondarily affect the liver. Evaluate for primary hepatobiliary disease with biochemical and imaging studies. If a cause of liver injury/failure is not apparent, consider liver biopsy to further characterize the type of injury and look for an underlying cause.

DIFFERENTIAL DIAGNOSIS

- For acute hepatic injury accompanied by icterus/hyperbilirubinemia:
  - Prehepatic causes (hemolytic anemia)

- Posthepatic causes (biliary obstruction)
- Sepsis

- Chronic hepatic disease; recent decompensation of chronic hepatic disease may mimic acute hepatic injury:
  - Determine if subtle signs of chronic illness (weight loss, poor body condition) are present.
  - Findings of ascites, small liver, and hypoalbuminemia suggest chronic rather than acute disease.
  - Chronic liver disease in the final phases of decompensation may not warrant the same aggressive therapeutic approach as acute hepatic failure, because the long-term prognosis is poor.

INITIAL DATABASE

- Routine hematologic and biochemical evaluation:
  - Inflammatory CBC (infectious diseases, acute pancreatitis, extrahepatic infections with secondary reactive hepatopathy); also for ruling out hemolytic anemia as cause of icterus.
  - Serum biochemistry profile: increased serum alanine aminotransferase activity, especially with hepatic necrosis; increased alkaline phosphatase activity; hyperbilirubinemia; hypoglycemia (like hyperammonemia and coagulopathy) suggests severe hepatic dysfunction; xylitol toxicosis also associated with hypoglycemia due to excess insulin release; hypoalbuminemia suggests chronic rather than acute disease; azotemia: consider dehydration or concurrent renal damage (leptospirosis, NSAIDs)
  - Increased serum bile acids
  - Coagulopathy: prolonged PT and APTT, low fibrinogen, low plasma protein C, thrombocytopenia
  - Other findings depend on underlying systemic disorder.
  - Urinalysis: hyperbilirubinuria (small degrees of bilirubinuria may be normal in dogs, because dogs can conjugate bilirubin renally). In cats, all bilirubinuria is considered pathologic.
- Imaging:
  - Abdominal radiographs: liver normal or increased in size
  - Abdominal ultrasound: liver normal or increased in size; variable changes in echogenicity; hypoechoic mass or fluid collection possible (abscess). Evaluate gallbladder and bile ducts to rule out disorders other than acute hepatic injury as a cause of jaundice/icterus, such as posthepatic disorders including extrahepatic biliary tract disease (gallbladder mucocele, cholecystitis, cholelithiasis) or obstruction (distended gallbladder and bile ducts). Evaluate pancreas for acute pancreatitis; other findings dependent on underlying multisystemic or extrahepatic disorder.

ADVANCED OR CONFIRMATORY TESTING

- Liver biopsy:
  - Characterize hepatic lesion histologically; hepatic necrosis most common lesion associated with acute hepatic failure; differentiate acute from chronic (fibrosis, nodular regeneration). May provide specific diagnosis (infectious diseases).
- Fine-needle aspiration and cytologic evaluation of the liver: rapid screening for mycoses, neoplasia, feline hepatic lipidosis, abscess (ultrasound-guided); accuracy is poor for many hepatic diseases.
- Bacterial cultures: aerobic and anaerobic of liver and bile (cholangitis, abscess)
- Serum antibody titers for infectious diseases (leptospirosis, mycoses, toxoplasmosis, others)
- Tests to evaluate for systemic or extrahepatic disorders (pancreatic lipase immunoreactivity for acute pancreatitis; thoracic radiographs for systemic fungal infection, toxoplasmosis, metastatic neoplasia)
- If aflatoxin contamination of pet food is suspected, save a sample of suspect food in an airtight bag, with packaging information including product and date code. Submit food for aflatoxin level determination. Because of the rapid metabolism and excretion of aflatoxin, detection of aflatoxin in serum and liver tissue is less reliable.

TREATMENT

TREATMENT OVERVIEW

For patients with mild hepatic injury (not in acute hepatic failure) showing few or no clinical signs, treat underlying systemic disorder, discontinue any potentially hepatotoxic medications, provide supportive care including oral hepatoprotective agents such as *S*-adenosylmethionine (SAMe) and silybin, and monitor liver biochemistries to assess response. For patients with acute hepatic failure, intensive supportive therapy is warranted as described below. The goal of treatment is to allow adequate time for hepatic regeneration and repair, prevent or control complications of liver failure, and treat the underlying cause when possible.

ACUTE GENERAL TREATMENT

- IV fluid therapy with balanced electrolyte solution; supplement with KCl using conventional sliding scale(20-40 mEq/L to start); maintain normoglycemia by adding 2.5%-5% dextrose to fluids. Avoid alkalosis in hepatic encephalopathy (give 0.9% saline rather than lactated Ringer's solution).
- Treat underlying cause when possible; discontinue any suspect drug; start amoxicillin or penicillin for empirical treatment of

suspected leptospirosis (dogs), or broad-spectrum systemic antibiotics for sepsis.

- Give *N*-acetylcysteine as a glutathione source/antioxidant for treatment of acetaminophen toxicity at 140 mg/kg (10% or 20% solution diluted at least 1:2 with saline) IV over 20-30 minutes through 0.25-m nonpyrogenic filter; then 70 mg/kg IV or PO q 6 h for 7 treatments. May also be beneficial for treatment of other drug-induced injuries (carprofen, potentiated sulfonamides, diazepam, methimazole, others), aflatoxin-induced hepatic injury, or organic solvents and heavy metal toxicity.
- Other hepatoprotective therapy (empirical therapy):
  - SAMe, 20 mg/kg PO q 24 h, as a glutathione source (given as follow-up to IV *N*-acetylcysteine when oral therapy is tolerated)
  - Silybin (milk thistle) protective against *Amanita* mushroom toxicity in an experimental study in dogs at 50 mg/kg IV. Oral dose for dogs and cats is 20-50 mg/kg q 24 h of 60%-80% silybin but poor absorption. Veterinary product, Marin (Nuramax Laboratories Inc.), 5-10 mg/kg q 24 h, contains silybin bound to phosphatidylcholine to improve gastrointestinal absorption.
  - Vitamin E (15 IU/kg PO q 24 h) as an antioxidant
- For nonspecific control of vomiting use antiemetics such as maropitant (1 mg/kg SQ q 24 h or 2 mg/kg PO q 24 h), metoclopramide (0.2-0.4 mg/kg IV, IM, SQ, PO q 6-8 h or 1-2 mg/kg/24 h IV constant rate infusion), or ondansetron (0.1-0.2 mg/kg SQ or slow IV q 8 h).
- Treat or prevent gastric ulceration with famotidine (0.5-1 mg/kg IV or PO q 12-24 h), omeprazole (0.7-1 mg/kg PO q 12-24 h) or pantoprazole (0.7-1 mg/kg IV q 12-24 h).
- For treatment of coagulopathy, give fresh-frozen plasma and parenteral vitamin K1 (0.5-1 mg/kg q 12-24 h SQ for two or three doses or until PT normalizes).
- Treat for hepatic encephalopathy (if present; see p. 501) using a high-quality low-protein diet, lactulose (0.1-0.5 mL/kg PO q 12 h, adjusted to achieve soft fecal consistency), and/or intestinal antibiotics such as metronidazole (7.5-10 mg/kg PO q 12 h) or amoxicillin-clavulanate (15 mg/kg PO q 12 h).

CHRONIC TREATMENT

- Consider empirical oral hepatoprotective therapy (SAMe, silybin, or vitamin E) until evidence of hepatic injury resolves.
- Glucocorticoids are generally not warranted.

NUTRITION/DIET

Provide adequate dietary protein and calories. Do not restrict dietary protein unless hepatic encephalopathy is present (see p. 501); choose nonmeat protein sources such as dairy (e.g., cottage cheese) and eggs.

DRUG INTERACTIONS

Avoid drugs that require hepatic metabolism

POSSIBLE COMPLICATIONS

- Hepatic encephalopathy
- Hypoglycemia
- Coagulopathy and anemia
- Gastrointestinal ulceration
- Septicemia

RECOMMENDED MONITORING

- Serum biochemistry profiles
- Blood glucose
- Serum bile acids (anicteric patients)
- Packed cell volume/total protein (anemia/bleeding)

PROGNOSIS AND OUTCOME

- If patient presents with signs of advanced liver failure (e.g., hepatic encephalopathy, coagulopathy, hypoglycemia), the prognosis is guarded.
- For milder hepatic injury, complete recovery is possible, especially when underlying cause is detected and treated.

PEARLS & CONSIDERATIONS

COMMENTS

- Clinical and laboratory features reflect general hepatic failure; they are not specific for underlying cause of hepatic injury.
- Always consider an adverse drug reaction as the cause of acute hepatic injury or failure, as discontinuing suspect drug can result in improved hepatic function.

PREVENTION

- Vaccinate for infectious diseases (e.g., infectious canine hepatitis, leptospirosis).
- Monitor liver enzymes when prescribing a drug with potential to cause hepatotoxicity; promptly discontinue if enzyme elevations arise.
- Avoid reexposure of patient to drug suspected to have caused hepatic reaction.

AUTHOR: SUSAN E. JOHNSON

EDITOR: KEITH P. RICHTER

Hepatic Encephalopathy

BASIC INFORMATION

DEFINITION

A reversible metabolic central nervous system (CNS) disturbance secondary to hepatic disease

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Congenital hepatic vascular disease: young
- Acquired hepatic disease: middle-aged to older

GENETICS & BREED PREDISPOSITION

- Hepatic vascular disease: several breed predispositions (see p. 905)
- Acquired liver disease: see pp. 1054, and 513.

RISK FACTORS

- Acute hepatic disease
- Hepatotoxic drugs and toxins
- Congenital hepatic vascular disease:
    - Single portosystemic vascular anomalies
    - Primary hypoplasia of the portal veins (microvascular dysplasia)
    - Hepatic arteriovenous fistula or malformation
- Multiple acquired portosystemic shunts secondary to portal hypertension from chronic hepatic disease

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Historic signs of chronic liver disease typically are episodic, involving three systems:

- Neurologic: diffuse cerebral disturbance: lethargy, poor appetite, aimless wandering, head pressing, disorientation, seizures, blindness, depression, stupor, coma, behavioral changes. Poor anesthesia tolerance/prolonged recovery.
- Gastrointestinal (GI): vomiting, diarrhea, poor weight gain, ptyalism (cats)
- Urinary: polyuria and polydipsia, stranguria, pollakiuria, dysuria, and/or hematuria associated with ammonia biurate uroliths

PHYSICAL EXAMINATION

- Signs of diffuse cerebral disease but may be subclinical at the time of examination owing to the episodic nature of hepatic encephalopathy. Rarely, multifocal and lateralizing neurologic signs are present.
- Congenital patients: stunted growth possible
- Cats with congenital portosystemic shunts often have copper-colored irises.
- Acquired hepatic disease: ascites, icterus
- Acute hepatic failure: initial neuroexcitatory behavior (restlessness, agitation, seizure) progressing to more neuroinhibitory states (depression, coma)
- Hepatic arteriovenous fistula: a continuous murmur may be ausculted on the cranioventral abdomen.

ETIOLOGY AND PATHOPHYSIOLOGY

Complex multifactorial etiology:

- Associated with the accumulation of neurologic toxins, most likely of gut origin, that escape hepatic detoxification as a result of shunting of blood away from the portal vasculature into the systemic vasculature.
- GI toxins derived primarily from bacterial metabolism of proteinaceous waste
    - Ammonia generation in the colon

- Endogenous benzodiazepine-like substances
- Alterations in inhibitory (γ-aminobutyric acid) and excitatory (glutamate) neurotransmitter balance playing a secondary role
- Low-grade cerebral edema due to astrocyte detoxification of ammonia to glutamine may also play a role in the development of chronic hepatic encephalopathy associated with portosystemic shunting.
- Pathophysiology of encephalopathy associated with acute hepatic failure is distinct from chronic hepatic en cephalopathy and is complicated by development of overt intracranial hypertension with cerebral edema secondary to alterations in the blood-brain barrier, disturbances in cerebral blood flow, and release of neurotoxic substances by the necrotic liver; frequently is complicated by neuroglycopenia.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A tentative diagnosis is made when a patient with liver disease shows signs of neurologic dysfunction.

DIFFERENTIAL DIAGNOSIS

- Neurologic signs: hypoglycemia, lead toxicity, congenital CNS malformation such as hydrocephalus or storage disease, infectious encephalitis/meningitis (e.g., feline infectious peritonitis infection, toxoplasmosis, neosporosis, canine distemper encephalitis), granulomatous meningoencephalitis, CNS neoplasia, thiamine deficiency (cats).
- Chronic GI or urinary signs may mimic primary GI disease or suggest primary genitourinary or endocrine disorders.

INITIAL DATABASE

- CBC: microcytosis, poikilocytosis (cats)
- Serum biochemistry profile:
  - Hepatic vascular disease: profile results may be normal or show mild hypoalbuminemia, low blood urea nitrogen, mild increases in serum alanine aminotransferase and serum alkaline phosphatase (ALP) activities (some elevation of ALP activity in young animals may be normal bone isoenzyme), hypocholesterolemia, hypoglycemia (especially in young toy breeds)
  - Acquired hepatic disease: hypoalbuminemia, moderate to severe increases in all serum hepatic enzyme activities, ± hyperbilirubinemia, hypercholesterolemia or hypocholesterolemia, hypoglycemia (with acute hepatic failure)
- Urinalysis: isosthenuria common; ammonia biurate crystalluria, hematuria, pyuria, bacteruria possible

ADVANCED OR CONFIRMATORY TESTING

Clinical Pathology:

- Total serum bile acids: sensitive for the detection of congenital or acquired portosystemic shunting (2-hour postprandial sample more sensitive)
- Blood ammonia: specific indicator of hepatic encephalopathy but can be normal even during overt hepatic encephalopathy. Ammonia tolerance test more sensitive to detect hepatic encephalopathy but may induce severe neurologic signs.
- Urinary bile acids: less sensitive than serum bile acids in the dog (but may be more convenient)
- Abdominal effusion: pure or modified transudate

Imaging:

- Abdominal ultrasound:
  - Portosystemic vascular anomaly: identification of a vascular communication between the intrahepatic or extrahepatic portal circulation and the systemic vasculature (see p. 905), microhepatica, renomegaly, urolithiasis
  - Primary hypoplasia of the portal veins (see p. 723): ± microhepatica, ± abdominal effusion, may be unremarkable
  - Hepatoarteriovenous fistula or malformation: identification of fistula, abdominal effusion
  - Chronic hepatitis/hepatopathies, cirrhotic/fibrosing liver disease: microhepatica, possible nodular liver with cirrhosis, abdominal effusion; visualization of multiple portosystemic shunts may be difficult.
- Rectal or splenic technetium scans (see p. 1259):
  - Abnormal with single or multiple portosystemic shunts and normal with primary hypoplasia of the portal veins without portal hypertension (microvascular dysplasia)

Histopathology:

- Hepatic histopathology:
  - Same pattern of changes (arteriolar proliferation, hepatic atrophy, attenuation of portal vasculature, lobular collapse)

seen with all forms of hepatic vascular disease

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to lower levels of circulating neurotoxins by modulating GI protein metabolism, maintain optimum nutritional plane, and control precipitating factors.

ACUTE AND CHRONIC TREATMENT

- Nothing per os if stupor or coma is present
- Address fluid and electrolyte imbalances, avoid lactated solutions with acute hepatic failure, sodium restrict fluids with ascites, potassium and glucose supplementation as needed, B vitamins (especially thiamine and cobalamin in cats).
- Medications that increase GI protein tolerance
    - Lactulose: drug of choice. Nonabsorbable disaccharide broken down by colonic bacteria into short-chain fatty acids. Traps soluble NH3 as $NH4^+$, which is nonabsorbable and thus excreted in the feces. Alters bacterial metabolism so that less ammonia is generated.
        - Titrated from an initial dose of 0.5 to 1 mL/kg PO q 8-12 h to dose that produces 3-4 soft stools per day. If stupor or coma is present, may be given rectally in a retention enema (see p. 1258).
    - Antibiotics:
        - Alter bacterial metabolism, synergistic with lactulose
        - Metronidazole (7.5 mg/kg PO q 8-12 h, low dose to avoid neurotoxicity secondary to decreased hepatic metabolism of the antibiotic); *or*
        - Neomycin (10-22 mg/kg PO q 12 h) (may be difficult to obtain; can be given orally or as a retention enema) or ampicillin (22 mg/kg PO q 12 h)
- Seizures: control seizure activity:
    - Barbiturates (e.g., phenobarbital 6-10 mg/kg slowly IV to effect); the patient should be monitored closely for respiratory depression.
    - Propofol is useful for controlling hepatic encephalopathy–induced status epilepticus. Because it is metabolized by the liver, small doses may be used and may have a longer duration of action. Maintain an anesthetized state for several hours before tapering and observing for recurrence. Monitor for apnea during use.
- If patient is seizuring due to hepatic encephalopathy from acute liver injury: cerebral edema is likely, and the prognosis is grave (seizures often refractory to treatment).
    - Mannitol (0.5 g/kg given IV over 10-15 minutes).
    - Infusion of *N*-acetylcysteine (140 mg/kg IV initially followed by 70 mg/kg as needed) may correct disturbances in microcirculation.
    - Corticosteroids of no benefit and may be detrimental.
    - Monitor closely (q 4 h) for hypoglycemia; may require infusion of high concentrations of dextrose-containing solutions.
- Control precipitating factors:
    - Oral protein loading: gastrointestinal hemorrhage, high protein meals
    - Catabolic conditions such as infections, dehydration, azotemia
    - Alkalosis with hypokalemia: increases renal ammonia production
    - Synergistic neural inhibition with sedatives, tranquilizers, or anesthetic agents; use these with caution if at all (e.g., diazepam).
    - Constipation
    - Transfusion with stored blood products containing high ammonia concentrations
- Medications to increase GI protein tolerance are first-line therapy (see Acute General Treatment above).

NUTRITION/DIET

- Adequate calories to avoid catabolism of muscle, which is highly ammongenic and may make control of hepatic encephalopathy difficult.
- Modulation of protein content: high-quality protein derived preferably from plant and dairy products. Start with diet containing minimum daily protein requirements (cat: 6.5 g/100 kcal; dog: 5.1 g/100 kcal) in combination with medications to increase protein tolerance and decrease protein only if necessary.
- Increase fiber content (e.g., by adding bran or canned/cooked pumpkin).
- Vitamin supplementation: thiamine in cats (50-100 mg PO daily), vitamin K (if associated coagulopathy) initially parenterally (0.5 mg/kg SQ q 12 h) for 5-7 days then once weekly.
- Sodium restriction necessary only with ascites: 0.04-0.05 g/100 kcal.

DRUG INTERACTIONS

- Neuroinhibitory drugs (e.g., sedatives, anesthetics, and tranquilizers) should be used cautiously, as they may potentiate the neuroinhibition of hepatic encephalopathy.
- Avoid drugs that depend heavily on hepatic metabolism and/or excretion if possible.

RECOMMENDED MONITORING

- Blood ammonia concentration
- Mentation and appetite at home
- Body weight and body condition score
- Serum albumin

PROGNOSIS AND OUTCOME

Depends on nature of underlying liver disease causing encephalopathy:

- Hepatic vascular disease (portosystemic shunt, microvascular dysplasia, arteriovenous fistula or malformation): in general, clinical signs of hepatic encephalopathy due to congenital hepatic vascular disease respond quickly and fully to appropriate drug and dietary intervention. Long-term prognosis depends on whether the congenital intrahepatic or extrahepatic shunt can be fully attenuated or the arteriovenous fistula can be resected (in which case signs of hepatic encephalopathy typically abate) and whether these conditions are complicated by primary hypoplasia of the portal veins (microvascular dysplasia), which causes continued shunting of blood from the portal circulation.
- Acquired chronic hepatic disease: clinical signs of hepatic encephalopathy generally abate with proper intervention, but long-term prognosis depends on severity of the underlying hepatic disorder. Generally, patients with signs of severe hepatic encephalopathy due to acquired hepatic diseases have a very poor prognosis unless the underlying disease can be reversed.
- Acute liver failure: encephalopathy generally is more refractory to therapy, probably reflecting a more complex underlying cerebral lesion or process. Encephalopathy progressing to coma or stupor (grade 3-4) is considered a grave prognostic sign and is one of the criteria used for determining the need for transplantation in human patients.

PEARLS & CONSIDERATIONS

COMMENTS

- Normal blood ammonia concentration does not rule out the presence of hepatic encephalopathy.
- Initial treatment of hepatic encephalopathy involves steps to increase dietary protein tolerance (nonabsorbable disaccharides and antibiotics) in combination with dietary protein modulation, but not excessive restriction.
- Be aware of common comorbid conditions that can complicate control of hepatic encephalopathy, such as GI bleeding, dehydration, hypokalemia, azotemia, constipation, and alkalosis.
- Encephalopathy accompanying acute hepatic failure differs from that accompanying congenital vascular disorders or chronic hepatic failure in that it involves the development of overt cerebral edema and an initial neuro-excitatory state often refractory to therapeutic intervention. In addition, patients with signs of severe hepatic encephalopathy due to acquired hepatic diseases have a very poor prognosis.

CLIENT EDUCATION

Hepatic encephalopathy is an episodic chronic condition that cannot be cured but can be controlled with strict adherence to dietary modulation and drug therapy.

BASIC INFORMATION

DEFINITION

An infection of feline red blood cells (RBCs) with the bacterial organisms *Mycoplasma haemofelis*, "*Candidatus* Mycoplasma turicensis" or "*Candidatus* Mycoplasma haemominutum." *Mycoplasma haemofelis* is the most pathogenic species and it causes hemolytic anemia, which is usually extravascular.

SYNONYM

Haemobartonella felis (outdated); feline hemotropic (or hemotrophic) mycoplasmosis; feline infectious anemia

EPIDEMIOLOGY

SPECIES, AGE, SEX

Domestic and wild felines of all ages. Young cats may be more likely to present with hemolytic anemia secondary to *Mycoplasma haemofelis* infection. Male cats are more likely to be infected than females, possibly due to roaming and fighting behavior.

RISK FACTORS

- Access to outdoors
- Bloodsucking arthropods, including fleas, ticks, and mosquitoes, have been suggested to play a role in transmission.
- Underlying retrovirus infection, in particular with feline immunodeficiency virus
- A history of cat bite abscess often precedes hemoplasmosis by a few weeks, and hemoplasmas have been detected in saliva, suggesting a possible mode of transmission.

CONTAGION AND ZOONOSIS

- Transplacental spread has been hypothesized.
- Transmission via blood transfusion is possible.
- The DNA of *Mycoplasma haemofelis* has been detected in a person coinfected with HIV and *Bartonella henselae* from Brazil, so these organisms may have zoonotic potential.

GEOGRAPHY AND SEASONALITY

Worldwide

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute, chronic, or subclinical
- Clinical signs depend on anemia (severity and rate of development)

HISTORY, CHIEF COMPLAINT

- Acute: sudden death, weakness, depression, collapse, pale mucous membranes, tachypnea, anorexia, ± vomiting, neurologic signs
- Chronic: lethargy, anorexia, weight loss
- Subclinical: no abnormalities reported; more likely with *"Candidatus* M. turicensis" and *"Candidatus* M. haemominutum" infections

PHYSICAL EXAM FINDINGS

- Acute: pale mucous membranes, fever, tachypnea, tachycardia, mental depression, weakness, splenomegaly, systolic cardiac murmur due to amnesia, rarely icterus

- Chronic: pale mucous membranes, poor body condition, weakness, splenomegaly

ETIOLOGY AND PATHOPHYSIOLOGY

- Three species of feline hemotropic mycoplasmas have been identified in cats:
  - *Mycoplasma haemofelis:* this is the most pathogenic species, causing hemolytic anemia in immunocompetent cats.
  - *"Candidatus* Mycoplasma haemominutum": this is detected in as many as one in five cats visiting veterinary hospitals and is usually not associated with hemolytic anemia.
  - *"Candidatus* Mycoplasma turicensis": this is the most recently recognized species, and its pathogenicity may lie between that of *M. haemofelis* and "*Candidatus* M. haemominutum."
- Coinfection may occur with two or more hemoplasma species.
- Organisms reside on the surface of—and possibly replicate within—RBCs, causing RBC destruction, which is predominantly extravascular, and ultimately a regenerative anemia, possibly via increased RBC fragility, erythrophagocytosis, and/or immune-mediated destruction.
- Appearance of large numbers of organisms on blood smears is associated with precipitous declines in the hematocrit, after which organisms may disappear for several days. Eventually cats recover from this phase of infection, after which the hematocrit increases, and organisms disappear from blood smears. A carrier state may develop in some cats, especially those infected with *"Candidatus* M. haemominutum."

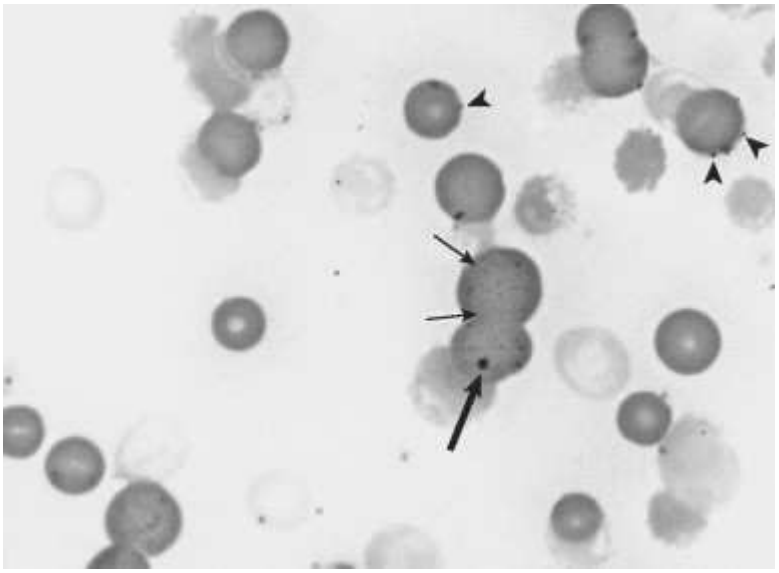
DIAGNOSIS

DIAGNOSTIC OVERVIEW

This diagnosis becomes suspected either when a cat is anemic or when a blood smear appears to be consistent with RBC infection by these organisms. Hemoplasmas are unculturable mycoplasmas, so diagnosis relies on organism identification on blood smears (which has low sensitivity and specificity) or molecular diagnosis using PCR. PCR assays are considered the gold standard for diagnosis, but results must be interpreted differently depending on the hemoplasma species detected.

DIFFERENTIAL DIAGNOSIS

- Primary immune-mediated hemolytic anemia
- Heinz body anemia (acetaminophen toxicity, zinc toxicity, diabetic ketoacidosis, ingestion of onions or baby food containing onion powder)
- Cytauxzoonosis
- Hereditary erythrocyte disorders such as those of Abyssinian and Somali cats
- External or internal blood loss
- Feline leukemia virus (FeLV) infection



HEMOTROPIC MYCOPLASMOSIS, CAT Hematologic differential diagnosis. The larger Howell-Jolly body *(large arrow)* or multiple punctate appearance of basophilic stippling (seen throughout the two red cells in the center of the image *[small arrows]*) should not be mistaken for *M. haemofelis (many arrowheads)*.

(Courtesy of Department of Clinical Pathology, Atlantic Veterinary College; reproduced with permission.)

INITIAL DATABASE

- Blood smear: visual identification of organism:
  - Nonrefractile basophilic cocci, rods, or ring-forms on the surface of RBCs
  - Such cytologic detection of organisms is <50% sensitive. In addition, *"Candidatus* M. turicensis" has never been seen on blood smears.
  - For optimal recognition, a thin fresh blood smear should be made immediately after blood collection (prior to adding EDTA) and stained with Romanowsky stains.
  - False-positive results are common owing to confusion with Howell-Jolly bodies, Heinz bodies, stain precipitates, or refractile artifacts (see figure).
- CBC: regenerative anemia, macrocytosis, normoblastosis, ± mild to moderate neutrophilia and monocytosis are typical. Thrombocytopenia may also be noted. Anemia may be nonregenerative if disease is very acute.
- Serum biochemistry profile: typically unremarkable; hyperbilirubinemia uncommon despite hemolysis, occasional elevations in alanine aminotransferase, alkaline phosphatase.
- Urinalysis: unremarkable
- Abdominal imaging: changes are minimal. Diffuse, mild to marked splenomegaly possible.
- Retrovirus testing: to rule out coinfection

ADVANCED OR CONFIRMATORY TESTING

- Hemoplasmas cannot be cultured in the laboratory.
- If doubt persists, blood can be submitted for PCR testing, which is more sensitive and specific than blood smear detection. Consult the laboratory to determine which hemoplasma species its PCR assays detects. Cats testing positive for "*Candidatus* M. turicensis" or *"Candidatus* M. haemominutum," should still undergo a thorough investigation to rule out alternative causes of anemia, because they have not been definitely associated with disease.

TREATMENT

TREATMENT OVERVIEW

The antimicrobial of choice for treatment is doxycycline, although enrofloxacin may also be effective. Treatment leads to resolution of anemia for cats infected with *M. haemofelis* but may not completely eliminate the infection as determined using PCR. Therapeutic goals are resolution of acute clinical bacteremia and restoration of red cell volume.

ACUTE GENERAL TREATMENT

- Supportive care:
  - Blood transfusion (see p. 1347) or oxygen-carrying compounds for severe anemia
  - IV crystalloid fluid replacement as needed
- Doxycycline is the drug of choice for reduction of bacteremia: 10 mg/kg PO q 24 h for a minimum of 14 days.
- Fluoroquinolones may also be effective: enrofloxacin, 5 mg/kg PO q 24 h for a minimum of 14 days.
- Cats may remain PCR-positive after treatment; no antimicrobial therapy has been shown to completely eliminate infection. Treatment of cats that are not anemic and showing no clinical signs is therefore not recommended.
- Use of glucocorticoids should be restricted to cats not responding to antimicrobial therapy alone, or when the diagnosis is uncertain and primary immune-mediated hemolytic anemia is possible.

DRUG INTERACTIONS

- Fluoroquinolones given at high doses may cause blindness in cats; do not exceed 5 mg/kg q 24 h.
- Doxycycline: esophagitis/esophageal strictures in cats. Follow oral doxycycline administration with a bolus of water or food to ensure passage into the stomach.

RECOMMENDED MONITORING

Packed cell volume or CBC

PROGNOSIS AND OUTCOME

Severity of infection varies from subclinical to life threatening. Prognosis is generally good with intensive supportive care when needed and appropriate antibiotic treatment. Infections may recrudesce with stress or other disease.

PEARLS & CONSIDERATIONS

PREVENTION

- To decrease risk of exposure, confine cats indoors or reduce contact with other felines, especially feral populations.
- Neuter to decrease roaming and fighting in outside cats.
- Practice effective flea and tick control.

AUTHOR: JANE E. SYKES

EDITOR: DOUGLASS K. MACINTIRE

Hemothorax

BASIC INFORMATION

DEFINITION

Accumulation of blood within the pleural space; a relatively infrequent cause of respiratory disease but somewhat common cause of pleural space disease, especially in dogs

SYNONYM

Pleural hemorrhage

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Both dogs and cats can be affected.
- Any age, breed, or sex of cat and dog is susceptible, but traumatic hemothorax may be more common in dogs.

GENETICS & BREED PREDISPOSITION

Dogs or cats with congenital coagulopathies are predisposed.

RISK FACTORS

Common:

- Trauma
- Coagulopathy
    - Anticoagulant rodenticide ingestion
- Intrathoracic neoplasia

Uncommon/rare:

- *Spirocerca lupi* (esophageal worm)
- *Angiostrongylus vasorum*
- Pneumonia *(S. equi* subsp. *zooepidemicus)*
- Esophageal or migrating intrathoracic foreign body
- Fat embolism
- Thymic hemorrhage
- Congenital coagulation disorder

GEOGRAPHY AND SEASONALITY

S. lupi is more prevalent in warmer climates (southern United States); most cases of *A. vasorum* infections have been reported from Europe and Canada.

ASSOCIATED CONDITIONS & DISORDERS

- Pleuritis
- Pyothorax
- Intrathoracic neoplasia
- Reexpansion pulmonary edema
- Pulmonary contusions
- Lung lobe torsion
- Fibrosing pleuritis
- Hypovolemic shock

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Increased respiratory effort or respiratory distress
  - Open-mouth breathing
  - Restrictive breathing pattern
  - Tachypnea
- Lethargy
- Exercise intolerance
- Weakness or collapse
- History of trauma or anticoagulant rodenticide ingestion

PHYSICAL EXAM FINDINGS

- Dyspnea and/or tachypnea
- Decreased heart and lung sounds ventrally on thoracic auscultation; may detect a fluid line
  - Increased bronchovesicular lung sounds dorsally
  - Cats may not have any appreciable change in thoracic auscultation.
- Pain when breathing (associated with trauma)
- Peritoneal effusion or other evidence of hemorrhage
- Signs consistent with hypovolemic shock (tachycardia, pale mucous membranes, weak pulses, prolonged capillary refill time)

ETIOLOGY AND PATHOPHYSIOLOGY

- Local factors that disrupt the integrity of vascular structures within the thoracic cavity:
  - Trauma to the lung, heart, mediastinum, or thoracic great vessels
  - Primary or metastatic neoplasia (hemangiosarcoma, mesothelioma, osteosarcoma, and pulmonary carcinoma) involving intrathoracic structures (including ribs, vertebral bodies)
  - Lung lobe torsion
  - Herniated abdominal viscera
  - Thymic hemorrhage (young animals)
  - Hemorrhagic pneumonia (*S. equi* subsp. *zooepidemicus)*
  - Pulmonary infarction (rare)
  - Migrating foreign body (uncommon)
  - Fat embolism (rare)
- Increased spontaneous bleeding tendencies, more often secondary to clotting-factor deficiencies/defects than to platelet disorders
  - Most commonly anticoagulant rodenticide ingestion
  - Congenital disorders of coagulation possible
  - Vitamin K deficiency secondary to poor intestinal lipid absorption is a very rare cause of vitamin K–responsive coagulopathy to consider in animals with a concurrent history compatible with chronic small-intestinal enteropathies.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on a known history of trauma or anticoagulant rodenticide ingestion and appropriate clinical signs. Confirmation requires assessment of packed cell volume (PCV) and total protein (TP) of the effusion. The proportion of blood needed to classify an effusion as hemorrhagic is variable, but generally an effusion with Hct > 3% should be viewed as having a hemorrhagic contribution.

DIFFERENTIAL DIAGNOSIS

- Other pleural space disease
  - Hydrothorax (see p. 882), pyothorax, chylothorax, pneumothorax
- Diaphragmatic hernia
- Pulmonary parenchymal disease
- Intrathoracic neoplasia
- Pericardial effusion

INITIAL DATABASE

- CBC:
  - Can be normal if hemorrhage is acute; may reveal mild anemia if hemorrhage is chronic and slow
  - Increased numbers of nucleated red cells, thrombocytopenia, acanthocytes, and schistocytes are suggestive of hemangiosarcoma.
  - Inflammatory and/or stress leukogram
- Serum biochemistry profile:
  - Hypoalbuminemia (if enough time has passed for fluid shifts)
  - Hypoalbuminemia, hypocholesterolemia, hypoglycemia, and low BUN in patients with coagulopathy secondary to hepatic failure.
- Thoracic radiographs:
  - Radiographic appearance depends on fluid volume:
    - Small volumes may result in only the presence of interlobar fissure lines.
    - Larger volumes may reveal scalloping or retraction of lung lobes from the thoracic wall, blunting of the lung lobes, impaired visualization of the cardiac silhouette (especially on dorsoventral views), or the presence of a soft tissue opacity ventrally on lateral views.
  - May help with visualization of primary or metastatic neoplasms
    - The presence of pleural effusion can obscure parenchymal lesions, so if neoplasia is a concern, repeat thoracic radiographs after thoracocentesis.
  - May reveal evidence of trauma (rib fractures and pulmonary contusions)
  - Assess integrity of the diaphragm
  - Thoracocentesis prior to radiography increases ability to visualize underlying cause such as neoplasia or diaphragmatic hernia, or concurrent disease such as pulmonary contusions.
- Thoracocentesis (see p. 1338):
  - Fluid obtained should be collected in EDTA (purple-top) and plain (red-top) tubes for evaluation.
  - PCV and TP will be similar to that of peripheral blood in acute cases.
- Prothrombin time (OSPT) and activated partial thromboplastin time (APTT) if anticoagulant rodenticide intoxication or congenital coagulopathy is suspected.
  - Prolonged OSPT and APTT are expected in patients with vitamin K rodenticide intoxication.
  - Abnormalities of coagulation times seen with congenital coagulopathy will reflect the specific defect; prolongation of only the OSPT, only the APTT, or both are possible.
  - Can also be supportive of disseminated intravascular coagulation (DIC).

ADVANCED OR CONFIRMATORY TESTING

- Pleural effusion cytologic examination:
  - Useful for neoplasia (lymphoma) and infectious cases, although an absence of either does not preclude them as causes of hemothorax.
  - Erythrophagocytosis or hemosiderin in macrophages is indicative of chronicity.
- Thoracic ultrasonography:
  - Should be performed prior to thoracocentesis to improve visualization of intrathoracic structures unless the patient is in respiratory distress
  - Confirms pleural effusion
  - Can guide thoracocentesis
  - Investigation for tumors (pulmonary, mediastinal, heart base, or right auricular masses), lung lobe torsion, abdominal organs within the thoracic cavity, pulmonary thromboembolism
- Thoracic CT:
  - Similar to thoracic ultrasonography, but thoracocentesis should be performed prior to imaging to improve visualization of parenchyma and vasculature.
- Proteins induced by vitamin K antagonism (PIVKA):
  - Abnormality is suggestive of rodenticide ingestion.
  - More sensitive than OSPT and APTT
- D-Dimers:
  - Elevations are supportive of DIC and thromboembolism.
- Exploratory thoracotomy (usually median sternotomy):
  - Diagnostic test of choice when the cause of hemothorax is not explained by history, physical examination, and results of other diagnostic tests.

TREATMENT

TREATMENT OVERVIEW

- Stabilization of patient and treatment for shock if hemothorax is secondary to trauma
- Improve respiratory function with supplemental oxygen and/or removal of hemorrhage in patients that are in distress.

- Because autotransfusion occurs rapidly, resulting in resolution of hemothorax within days, complete removal of blood is typically unnecessary unless large volumes of hemorrhage are present. Consequently, thoracocentesis should be performed primarily to alleviate respiratory distress.
- Identification and treatment of underlying cause when possible

ACUTE GENERAL TREATMENT

- Improve oxygenation via an intranasal cannula, face mask, or oxygen cage (see p. 1318).
- Thoracocentesis if in respiratory distress
  - Complete drainage is generally not necessary.
- Transfusion with whole blood, packed red blood cells, and/or plasma (coagulation disorders) if severe anemia.
- Vitamin K1 1-2.5 mg/kg PO q 12 h for 14-30 days depending on the anticoagulant rodenticide ingested
  - Can administer subcutaneously initially at same dose
  - Anaphylactic reactions have been reported following intravenous administration.
- Stabilization of respiratory and circulatory function if secondary to trauma or diaphragmatic hernia
  - Mechanical ventilatory support may be necessary if pulmonary contusions are present.

CHRONIC TREATMENT

- Repeated thoracocentesis or thoracostomy tube placement
  - Relieves respiratory distress
  - Prevents atelectasis
  - Can quantify hemorrhage
  - Removal of blood can reduce the risk of development of pleuritis, empyema (pyothorax), and pleural fibrosis.
- Management of pneumonia or systemic disease if present
- Exploratory thoracoscopy or thoracotomy to surgically excise tumors or locate and ligate bleeding vessels if hemothorax is unexplained or persists despite conservative interventions
- For some patients, chemotherapy may be indicated following cytologic or histologic confirmation of tumor type.

BEHAVIOR/EXERCISE

Activity should be limited until hemorrhage, anemia, or traumatic injuries have resolved.

POSSIBLE COMPLICATIONS

- Recurrent effusion
- Dyspnea from large-volume pleural effusion
- Related to thoracocentesis or thoracostomy tube placement
  - Pneumothorax
  - Parenchymal injury and further hemorrhage
- Pleuritis, empyema, or fibrosis
- Rapid reexpansion of lungs can result in reexpansion pulmonary edema.
  - More common with chronic effusions
  - Risk can be minimized by removing large-volume effusions gradually over several hours.

RECOMMENDED MONITORING

- Respiratory rate and effort
- Thoracic radiographs or ultrasound
  - Assess need for repeated thoracocentesis.

PROGNOSIS AND OUTCOME

- Dependent on underlying cause
  - Variable with trauma
  - Good with appropriate treatment of anticoagulant rodenticide intoxication
  - Poor to guarded with most neoplasms and congenital coagulation disorders

PEARLS & CONSIDERATIONS

COMMENTS

- Hemorrhagic pleural effusion fluid should not clot after removal from the pleural space unless there is continuous bleeding.
- Trauma significant enough to cause hemothorax will likely result in pulmonary contusions.
- Cats may require thoracocentesis prior to other diagnostics, as they are easily stressed and can decompensate quickly.
- In patients with no history of trauma and no evidence of a coagulation defect, neoplasia is a common cause of hemothorax.

PREVENTION

- Minimize risk of blunt trauma (automobile accident) by using leashes or keeping in enclosed areas.
- Limit access to anticoagulant rodenticides.

TECHNICIAN TIPS

- When obtaining blood from patients with known or suspected hemothorax, ideally draw as much blood as needed to accomplish all laboratory diagnostics (CBC, biochemical profile, coagulation tests) at the first draw to minimize venipunctures in case other bleeding tendencies are present.
- Maintain pressure on venipuncture sites a bit longer than for normal dogs in case there is a more widespread bleeding disorder present.
- Avoid cystocentesis urine collection until cause of hemothorax has been identified.
- Collect effusion as aseptically as possible; in occasional cases, especially traumatic hemothorax, hemorrhagic effusion may be autotransfused.

CLIENT EDUCATION

Most cases of hemothorax can be avoided by minimizing risk of trauma and access to anticoagulant rodenticides.

Hemorrhagic Gastroenteritis

BASIC INFORMATION

DEFINITION

Acute and profuse hematemesis and hemorrhagic diarrhea accompanied by hypovolemia; may progress to circulatory collapse, multiple organ dysfunction and death

SYNONYMS

Acute hemorrhagic enteritis, acute hemorrhagic enteropathy, HGE

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs, usually young (mean of 5 years)

GENETICS & BREED PREDISPOSITION: Hemorrhagic gastroenteritis (HGE) can occur in any breed; toy and small breed dogs may be predisposed.

RISK FACTORS: None known; most dogs are otherwise healthy.

CONTAGION & ZOONOSIS: Does not appear to be contagious or zoonotic

GEOGRAPHY AND SEASONALITY: More prevalent in urban dogs

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Anorexia and lethargy may be noted initially.
- Acute onset of vomiting; this may be profuse and often contains fresh blood.
- Acute onset of diarrhea; this may be brown initially but soon becomes grossly bloody; consistency varies from watery to jamlike.

PHYSICAL EXAM FINDINGS

- Depressed but afebrile
- Markers of perfusion: heart rate, pulse quality, gum color, capillary refill time (CRT) are all normal in the early stages of the disease. As fluid is lost into the gastrointestinal tract, signs of hypovolemia quickly develop, characterized by pallor, slow CRT, and tachycardia.
- Skin turgor may not reflect the full extent of fluid losses. Patients may be moribund at presentation if veterinary attention is delayed.
- Abdominal palpation reveals fluid-filled bowel loops with nonlocalized discomfort.
- Rectal examination: fresh dark blood or strawberry jam–like feces.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cause unknown, but an anaphylactic reaction to unidentified bacterial antigens has been implicated.
- *Clostridium perfringens* enterotoxins and enteropathogenic/enterotoxigenic *E. coli* have been associated with HGE, but causal relationships have not been demonstrated.
- Peracute, massive increase in intestinal permeability results in extravasation of fluid, proteins, and red blood cells into the intestinal lumen.
- Loss of plasma water, electrolytes, and protein can be extreme. Packed cell volume will rise rapidly and often exceeds 65%.
- If untreated, disease can progress to hypovolemic shock and death.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A presumptive diagnosis (sufficient to start treatment) is made based on acute gastroenteritis associated with erythrocytosis (hematocrit often >65%). Dogs with HGE can die unless the disorder is recognized quickly and treated aggressively. It is important to rule out other possible causes of bloody vomiting and diarrhea, but treatment should not be delayed while diagnostic tests are performed.

DIFFERENTIAL DIAGNOSIS

- Infectious: viral (parvovirus) or bacterial *(Salmonella, Campylobacter enteritidis)*
- Dietary indiscretion, toxicity
- Hypoadrenocorticism
- Intestinal volvulus, partial obstruction or intussusception
- Other causes of hypovolemic or endotoxic shock, such as intestinal perforation, peritonitis
- Necrotizing pancreatitis
- Coagulopathy

INITIAL DATABASE

- Hematocrit is classically elevated, often >65%; total solids are low or borderline normal.
- CBC: expect to see hemoconcentration with a stress leukogram; immature neutrophils or mild toxicity may be noted; modest thrombocytopenia is common.
- Serum biochemistry profile: increased blood urea nitrogen and alanine aminotransferase activity are expected; hypokalemia and panhypoproteinemia are also common; metabolic acidosis may be severe.
- Urinalysis: unremarkable; high specific gravity expected in response to hypovolemia
- Coagulation profile: usually normal early on; may show abnormalities if condition progresses to disseminated intravascular coagulation (DIC)
- Fecal evaluation (centrifuged flotation and saline preparation): no pathogens noted
- Fecal stained microscopic exam: increased numbers of red cells, some white cells; organisms consistent with clostridial spores (“safety pins”) may be present.
- Fecal ELISA for parvovirus (if neonate or unvaccinated): negative
- Abdominal radiographs: fluid and gas-filled small-intestinal loops; colon may be empty.
- Colloid oncotic pressure (COP): usually normal at presentation but then declines
- +/− Cortisol (if breed type or other clinical findings suggest hypoadrenocorticism): baseline cortisol should be >2 µg/dL/55 nmol/L.

TREATMENT

TREATMENT OVERVIEW

- Quickly restore and maintain an effective circulating volume.
- Recognize the need for colloid support along with crystalloid fluid replacement.
- Anticipate complications of hypovolemia and widespread gastrointestinal mucosal compromise.

ACUTE GENERAL TREATMENT

- Initiate fluid resuscitation with IV fluid therapy:
  - Colloids (e.g., Hetastarch) should be started immediately. Administer a bolus of 5 mL/kg over 20 minutes if the patient is substantially hypovolemic; otherwise begin a continuous rate infusion of 1 mL/kg/h; total daily dose should not exceed 20 mL/kg.
  - Crystalloid fluids should be administered concurrently. Replacement-type fluids should be used (e.g., Normosol-R, lactated Ringer's, Plasmalyte 148, 0.9% NaCl). If necessary, calculate a shock dose of crystalloids (90 mL/kg), and bolus one-third of this amount over 20-30 minutes. Do not administer Normosol-R rapidly, as this fluid contains acetate and may cause refractory hypotension.
  - Aim to replace lost volume (estimated by % dehydration × body weight in kg) over 12 hours.
  - Continue fluids at a rate necessary to replace ongoing losses and meet maintenance requirements.
  - If available, use COP measurement to guide colloid administration.
- Electrolyte disturbances are common; hypokalemia should be addressed specifically, but changes in sodium and chloride should self-correct with standard fluid therapy.
- Antibiotics are recommended, given the potential for bacterial translocation across the intestinal epithelium.
  - Ampicillin: 30 mg/kg IV q 8 h (adequate choice in most cases); *or*
  - Ampicillin/sulbactam (Unasyn): 50 mg/kg IV q 8 h (effective against β-lactamase-producing bacteria); *or*

- Enrofloxacin: 10 mg/kg slow IV q 24 h (if sepsis is suspected)
- Antiemetics should be administered if vomiting is persistent
  - Maropitant (1 mg/kg SQ q 24 h) is an effective first choice (patient must be >16 weeks old); *or*
  - Metoclopramide (1.1-2.2 mg/kg/24 h given as constant rate infusion)
- Antacids and gastric protectants should be administered in patients with hematemesis
  - Famotidine (0.5 mg/kg IV or SQ q 12-24 h); *and/or*
  - Sucralfate (250-1000 mg/dog PO q 8 h); begin when vomiting has stopped

NUTRITION/DIET

- Withhold water until vomiting is adequately controlled, then offer small amounts every 1-2 hours.
- Food should be provided as soon as the patient is interested in eating and vomiting is reduced. Easily digestible diets may be beneficial (e.g., boiled white rice with cottage cheese or boiled chicken), as gastric emptying times are shorter, and fecal volume is minimized.
- Probiotics +/− prebiotics should be considered, as disruption of the normal intestinal flora is both a likely cause and consequence of HGE.

POSSIBLE COMPLICATIONS

- Condition may progress to hypovolemic shock, DIC, and death if not treated appropriately.
- Esophagitis may occur if vomiting is persistent.
- Obtunded patients are vulnerable to aspiration pneumonia.
- Translocation of bacterial across the compromised gastrointestinal mucosa may result in sepsis.
- Cardiac arrhythmias can occur secondary to poor perfusion.

DRUG INTERACTIONS

Metoclopramide is incompatible with many antibiotics (including ampicillin); the infusion must be discontinued while other medications are administered.

RECOMMENDED MONITORING

- Monitor vital parameters (temperature, heart rate, mucous membranes, CRT, pulse quality, blood pressure) and ongoing fluid losses every 2 hours.
- Hematocrit and total solids every 4-6 hours.
- Glucose, BUN, and electrolytes should be checked every 6-8 hours initially.
- COP should be checked every 6-8 hours or as needed to guide decisions about colloid therapy.

PROGNOSIS AND OUTCOME 

- Recovery is usually rapid and complete over 1-2 days; some severely affected dogs may require supportive therapy for several days before return of normal GI function.
- Condition can progress quickly to multiple organ dysfunction syndrome, DIC, and death without appropriate fluid therapy.
- A total of 10% of affected dogs may die despite therapy.

PEARLS & CONSIDERATIONS 

COMMENTS

- The diagnostic hallmark for HGE is a markedly elevated hematocrit with normal to slightly low total protein.
- Colloid support is often essential and should not be overlooked.
- Rule out hypoadrenocorticism, especially in a high-risk breed (e.g., Nova Scotia Duck Tolling Retriever Portuguese water dog, standard poodle, West Highland white terrier).

CLIENT EDUCATION

A total of 10%-15% of dogs will have repeated episodes of HGE.

1ST EDITION AUTHOR: AMIE KOENIG

Hemorrhage

BASIC INFORMATION

DEFINITION

- The loss of blood from the vascular space into surrounding tissues or from body surfaces
- Clinical signs of hemorrhage result from one of two general mechanisms:
  - Blood loss from damaged or diseased blood vessels
  - Bleeding diatheses: defects causing failure of normal hemostatic processes

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of all breeds and either sex may be affected, with specific predilections depending on underlying cause. Blood vessel defects are generally acquired disorders, whereas bleeding diatheses may be hereditary traits (e.g., von Willebrand disease) or acquired disorders (e.g., coagulopathy of rodenticide poisoning).

GENETICS & BREED PREDISPOSITION

See pp. 491, , and online chapter: Platelet Dysfunction.

RISK FACTORS: See pp. 491, , and .

ASSOCIATED CONDITIONS & DISORDERS

- Blood vessel defects typically arise from:
  - Traumatic or surgical injuries
  - Inflammatory or neoplastic conditions causing vessel erosion and infiltration
- Bleeding diatheses are classified as:
  - Failure of platelet plug formation (primary hemostatic defects)
  - Failure of fibrin clot formation (secondary hemostatic defects = coagulopathies)
- Disease conditions such as hypertension, anemia, and hyperviscosity alter the normal flow properties of blood (hemorrheology) and are associated with microvascular hemorrhage.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Subtype classification based on:

- Duration: acute versus chronic hemorrhage
- Location: focal or regional versus multiple anatomic sites
- Tissue or vessel involvement: capillary bleeding versus hemorrhage into joint space, body cavities
  - Primary hemostatic defects (failure of platelet plug formation [e.g., from thrombocytopenia or platelet dysfunction] cause signs of hemorrhage involving capillaries and small vessels [arterioles, venules], clinically evident as petechiae, ecchymoses, bleeding from mucosal surfaces, and nonspecific bleeding from surgical and traumatic wounds).
  - Secondary hemostatic defects (coagulopathies; failure of fibrin clot formation [e.g., from coagulation factor deficiency]) generally cause spontaneous hemorrhage into body cavities or potential spaces (i.e., pleural space, intramuscular tissue planes), resulting in hemothorax, hemoabdomen, hemarthrosis, hematoma formation, and nonspecific bleeding from surgical and traumatic wounds.

HISTORY, CHIEF COMPLAINT: Depends on underlying cause. Frank hemorrhage, hematoma formation, and petechiae are obvious signs that may prompt owners to seek veterinary care. Additional signs include pallor and collapse due to acute hemorrhagic shock, or gradual onset of weakness due to chronic blood-loss anemia.

PHYSICAL EXAM FINDINGS

- Physical exam alone may differentiate vessel defects from systemic bleeding diatheses:
  - Frank hemorrhage due to traumatic or surgical blood vessel injury, or vessel infiltration due to solid tumors or inflammatory mass lesions, may be obvious on physical exam or via ancillary diagnostics (endoscopy, radiography).
  - Petechiae evident on cutaneous or mucosal surfaces or funduscopic exam indicate primary hemostatic defect.

    - Retinal hemorrhage and alterations of the normal retinal vasculature may result from abnormal blood flow (hemorrheologic defects such as systemic hypertension, hyperviscosity, anemia).
- Other signs are nonspecific (epistaxis, hematuria, melena, hematemesis, hemothorax, hemoabdomen).
- Hemorrhage from multiple anatomic sites and/or recurrent episodes are suggestive of a bleeding diathesis rather than blood vessel defects.

ETIOLOGY AND PATHOPHYSIOLOGY

- Blood vessel defects: physical disruption, as described above
- Bleeding diatheses:
    - Acquired primary hemostatic defects:
        - Thrombocytopenia is the most common bleeding diathesis.
        - Platelet dysfunction
    - Hereditary primary hemostatic defects:
        - Platelet dysfunction/thrombopathia
        - von Willebrand disease
    - Acquired coagulopathies (secondary hemostatic defects):
        - Vitamin K deficiencies (anticoagulant rodenticide intoxication, biliary obstruction, chronic oral antibiotic administration, warfarin overdose, neonatal)
        - Hepatic synthetic failure (hepatic necrosis, atrophy, portosystemic shunts)
        - Consumptive coagulopathy (disseminated intravascular coagulation [DIC])
        - Drug intoxications, envenomation, complication of heparin, hetastarch, dextran, fibrinolytic drug therapy
        - Dilutional coagulopathy: platelet and/or factor deficiency secondary to massive transfusion with stored blood products or high-volume fluid administration
    - Hereditary coagulopathies (secondary hemostatic defects):
        - Hemophilia
        - Autosomal factor deficiencies

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Vascular injury is by far the most common cause of hemorrhage, and clinicians should begin with a thorough physical exam to identify a source of injury. If history and exam are inconsistent with injury, a prompt evaluation for hemostatic defects is warranted to avoid delays in treatment.

DIFFERENTIAL DIAGNOSIS

Blood vessel defect versus bleeding diathesis:

- Initial physical exam and imaging studies may define the site and cause of vessel defects.
- If a vessel defect cannot be defined on physical exam, blood pressure measurement and screening tests to rule out bleeding diatheses must be performed *before* performing invasive procedures.

INITIAL DATABASE

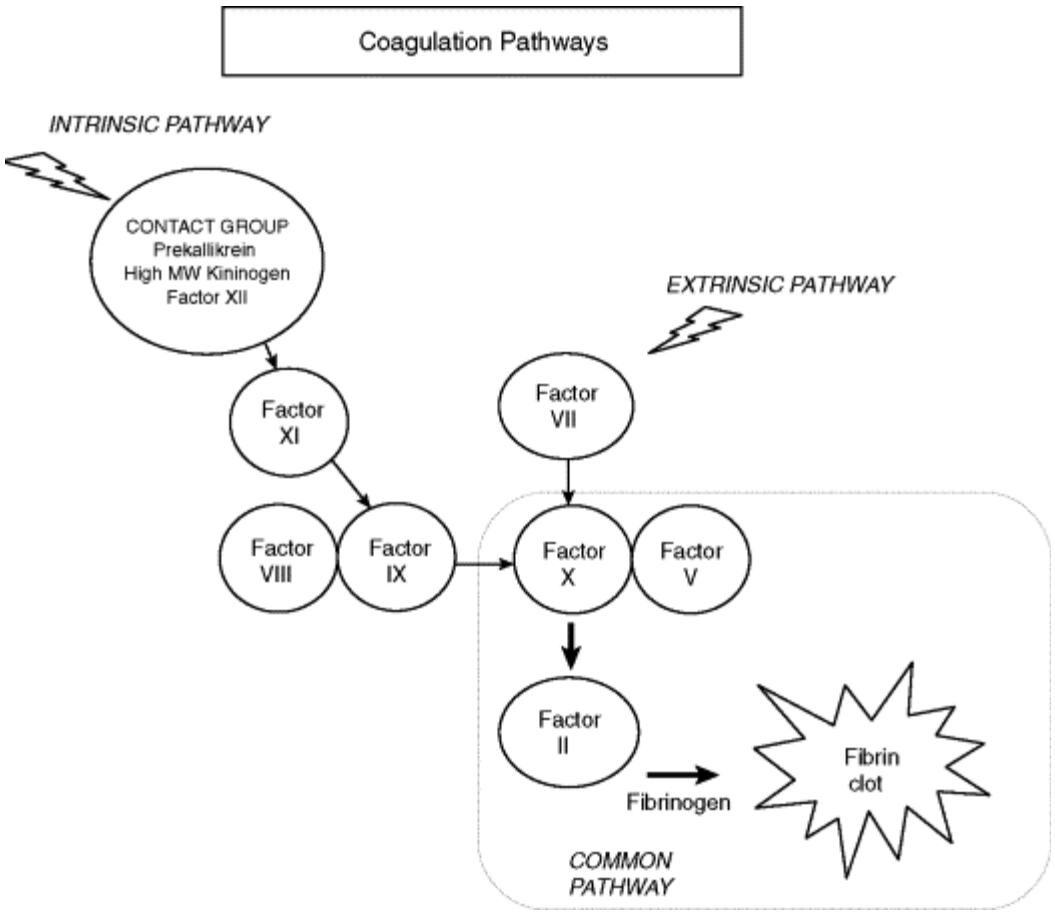
- Thorough physical exam to define nature and location of hemorrhage
- Baseline hematocrit and plasma protein
- Platelet count
- Blood pressure measurement:
    - Normal in calm setting, awake and resting patient, repeatable measures using Doppler: systolic <180 mm Hg (dog, cat)
    - Hypertension and other cause(s) of hemorrhage may coexist.
- Coagulation screening tests: if evidence points to bleeding diathesis:
    - Activated clotting time (ACT; see p. 1440):
        - Expected time to fibrin clot end-point ~120 seconds (dogs and cats)
        - Deficiencies of the intrinsic or common pathway factors cause prolongation of the ACT.
        - Normal values should be established for each test method.
    - Activated partial thromboplastin time (APTT; see p. 1441):
        - The APTT, like ACT, is sensitive to deficiencies of intrinsic or common pathway factors; however, APTT is generally a more specific and reproducible test than the ACT.
        - Long APTT is seen in hereditary coagulopathies such as hemophilia and in combined factor deficiencies such

as rodenticide intoxication and DIC.
        - Prolongation of APTT to a target value of 1.5-2 times baseline is used for adjusting unfractionated heparin dosage.
        - Hemorrhage caused by blood vessel defects or primary hemostatic defects (platelet abnormalities) should not produce abnormal APTT results.
    - Prothrombin time (PT; see p. 1513):
        - Test is sensitive to deficiencies of extrinsic and common pathway factors.
        - Specific prolongation of PT is an indication of factor VII deficiency. Because factor VII is vitamin K–dependent with short plasma half-life (3-6 hours), prolongation of PT develops in conditions causing vitamin K deficiency (e.g., anticoagulant rodenticide, severe hepatopathy).
        - The anticoagulant effect of warfarin and its dosage adjustments are based on prolongation of PT and its standardized derivative, the international normalized ratio (INR).
        - PIVKA (proteins induced by vitamin K absence or antagonism) testing performed using the Thrombotest assay provides information equivalent to the PT.
        - Hemorrhage caused by blood vessel defects or primary hemostatic defects (platelet abnormalities) should not produce abnormal PT results.
    - Thrombin clotting time (TCT) and fibrinogen:
        - Detect a lack of clottable fibrinogen
        - Long TCT and low fibrinogen develop in patients with severe hepatic insufficiency (due to synthetic failure) or dilutional coagulopathy and hemorrhagic DIC (due to depletion of fibrinogen).
        - Vitamin K deficiency does not prolong TCT or decrease fibrinogen values.
        - Hemorrhage caused by blood vessel defects or primary hemostatic defects (platelet abnormalities) should not produce abnormal TCT or fibrinogen results.
- Coagulopathies cause prolongation of one or more coagulation screening tests:
    - The pattern of abnormalities depends on which factor or groups of factors are deficient (see p. 491).
    - Expected coagulation screening test results for common coagulopathies:
        - Vitamin K deficiencies: prolonged ACT, APTT, and PT (but fibrinogen and TCT are normal) due to impaired activation of factors II, VII, IX, and X.
        - Severe hepatic synthetic failure causes deficiencies of all factors and fibrinogen. ACT, APTT, PT, TCT are long and fibrinogen is low.
        - Hemorrhagic DIC typically results in depletion of all factors and fibrinogen. Mild to severe prolongation of clotting times and low fibrinogen accompany hemorrhagic DIC. In contrast, high fibrinogen may accompany thrombotic DIC and other hypercoagulable syndromes.
        - Hemorrhage due to anticoagulant drug overdose or envenomation causes factor inhibition or fibrinogen depletion. All coagulation screening tests will detect severe drug overdose; however APTT and PT are preferentially sensitive to unfractionated heparin and warfarin levels, respectively.

ADVANCED OR CONFIRMATORY TESTING

Based on results of initial database:

- Thrombocytopenia workup may include repeat evaluation, including fresh blood smears, to rule out collection/laboratory artifact; bone marrow, spleen, and lymph node aspiration and cytologic evaluation; serologic evaluation to detect evidence of pathogens; platelet-associated antibody testing.
- Evaluation for platelet dysfunction (see online chapter: Platelet Dysfunction).
- Ancillary diagnostics to differentiate coagulopathies include specific coagulation factor analyses, determinations of antithrombin activity and fibrin breakdown products, and drug detection (e.g., heparin or warfarin levels).



HEMORRHAGE The coagulation cascade.

TREATMENT OVERVIEW

The two main goals are to control active bleeding and stabilize the patient with one or more of the following: local wound care, supportive medical therapy, and/or transfusion therapy. It is important to collect pretreatment samples to perform screening and confirmatory tests.

ACUTE GENERAL TREATMENT

- Hemorrhagic/hypovolemic shock: volume replacement (intravenous fluid therapy), red cell replacement (see p. 1347)
- Blood vessel injuries: control bleeding after visualization of the damaged vessels (physical examination, endoscopic examination, ultrasound examination, or surgical exploration).
- Bleeding diatheses: identify and correct the underlying cause of acquired bleeding diatheses; transfusion if needed to correct hereditary defects or pending response to medical management.

CHRONIC TREATMENT

Depends on underlying cause of hemorrhage

DRUG INTERACTIONS

Avoid drugs with anticoagulant or antiplatelet effects (e.g., nonsteroidal antiinflammatory drugs, clopidogrel, sulfonamides, heparin, warfarin, plasma expanders, estrogens, cytotoxic drugs)

POSSIBLE COMPLICATIONS

- Uncontrolled hemorrhage and hemorrhagic shock are potentially fatal conditions.
- Chronic hemorrhage may result in iron-deficiency anemia, requiring iron supplementation for appropriate bone marrow response.

RECOMMENDED MONITORING

Resolution of hemorrhage is demonstrated by:

- Cessation of active bleeding
- Fading of petechiae, absence of development of new lesions
- Stabilization and normalization of hematocrit/plasma protein
- Correction of low platelet count and/or long clotting times

PROGNOSIS AND OUTCOME

Depends on:

- Initial stabilization and correction of hemorrhagic shock
- Ability to identify and correct vessel defect or cause of acquired bleeding diatheses
- Ability to diagnose and manage hereditary bleeding diatheses

PEARLS & CONSIDERATIONS

COMMENTS

- Blood vessel injury or infiltration is by far the most common cause of hemorrhage.
- Screening for common bleeding diatheses by performing platelet count and ACT (or point-of-care APTT and PT) is indicated early in the diagnostic workup of patients with hemorrhage.
- Anticoagulant rodenticide intoxication is a common acquired coagulopathy. Vitamin K therapy (vitamin K1, 2 mg/kg PO or SQ q 24 h) and plasma transfusion (if severe hemorrhage) should be initiated pending results of coagulation screening, regardless of specific history of product ingestion (see p. 83).
- Results of coagulation tests (PT, APTT) that are below the normal range do not indicate hypercoagulability.

AUTHOR: MARJORY B. BROOKS

EDITOR: SUSAN M. COTTER

Hemoptysis

BASIC INFORMATION

DEFINITION

Expectoration or coughing up of blood or blood-stained sputum from the respiratory tract

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dependent on underlying cause
- Young pure-breed animals: coagulopathies
- Young to middle-aged animals: infectious diseases, trauma
- Older animals: neoplasia

GENETICS & BREED PREDISPOSITIONS: von Willebrand disease (many canine breeds; cats: Himalayan), hemophilia (dogs: many breeds; cats: British shorthair, Siamese)

RISK FACTORS

- Coagulopathies:
  - Immune-mediated disease: young to middle-aged, small to medium female dogs
  - Rickettsial disease: dogs living in or traveling to endemic areas
  - Thrombasthenia: otter hounds
  - Thrombopathia: basset hounds
  - von Willebrand disease: Doberman pinschers, Airedales, German shepherds, Scottish terriers, Chesapeake Bay retrievers, and many other breeds; cats
  - Hemophilia A: German shepherds and many other breeds; cats
  - Hemophilia B: Cairn terriers, coonhounds, St. Bernards, and other breeds; cats
- Pulmonary thromboembolism:
  - Neoplasia
  - Hyperadrenocorticism
  - Cardiac disease
  - Immune-mediated hemolytic anemia

CONTAGION & ZOONOSIS: Systemic fungal infections (risk of common-source infection)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Some or all may be present:

- Coughing up of blood: usually foamy consistency
- Hematemesis: from swallowing blood from the respiratory tract
- With coagulopathy: hematochezia, melena, hematuria, or hemorrhage from other areas of the body
- With pulmonary disease: coughing, exercise intolerance, dyspnea, syncope

PHYSICAL EXAM FINDINGS

- Melena: from swallowing blood
- Nasal hemorrhage
- With coagulopathy: possibly petechiae, ecchymoses, hematomas, hematochezia, melena, hematuria, retinal hemorrhages

ETIOLOGY AND PATHOPHYSIOLOGY

Bleeding disorder:

- Thrombocytopenia:

    - Immune-mediated disease: idiopathic disease, systemic lupus erythematosus, drug reaction
    - Rickettsial disease: ehrlichiosis, Rocky Mountain spotted fever
    - Bone marrow disease: neoplasia, aplastic anemia, infectious (fungal, rickettsial, or viral)
    - Disseminated intravascular coagulation (DIC)
- Thrombopathia:
    - Congenital: von Willebrand disease, thrombasthenia, thrombopathia
    - Acquired: nonsteroidal antiinflammatory drugs, hyperglobulinemia (ehrlichiosis, multiple myeloma), uremia, DIC
- Coagulation factor defect:
    - Congenital: hemophilia A (factor VIIIc deficiency) and hemophilia B (factor IX deficiency)
    - Acquired: anticoagulant rodenticide (warfarin) intoxication, hepatobiliary disease, DIC

Pulmonary Disease:

- Pulmonary hypertension
- Pulmonary thromboembolism
- Trauma
- Foreign body
- Bronchiectasis
- Infection: fungal (blastomycosis, histoplasmosis, coccidioidomycosis), bacterial, or parasitic (*Paragonimus kellicotti*, *Capillaria aerophila*, *Aelurostrongylus abstrusus*, *Filaroides hirthi*)
- Neoplasia: primary or secondary
- Lung lobe torsion

Cardiovascular Disease:

- Heartworm
- Severe cardiogenic pulmonary edema
- Arteriovenous fistula

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is either a part of the chief complaint or is noted during hospitalization. Diagnostic testing first must evaluate the possibility of a systemic disorder (bleeding disorder, systemic hypertension). If none, evaluation of the pharynx and respiratory system typically begins with oral examination, thoracic radiographs, and sedated pharyngeal examination as needed.

DIFFERENTIAL DIAGNOSIS

See Etiology and Pathophysiology above.

INITIAL DATABASE

- CBC:
    - Anemia: if sufficient hemorrhage has occurred
    - Thrombocytopenia
    - Neutrophilia: stress; infection; neoplasia
    - Pancytopenia: bone marrow disease
- Urinalysis:
    - Usually normal
    - Hematuria with coagulopathy
    - Avoid sampling by cystocentesis until coagulation status is known
- Biochemistry profile:
    - Hypoproteinemia: if enough hemorrhage has occurred
    - High blood urea nitrogen with normal creatinine: possible, owing to gastrointestinal blood
    - Hyperglobulinemia: ehrlichiosis, multiple myeloma
    - High alanine aminotransferase (ALT), aspartate aminotransferase (AST), and total bilirubin: severe hepatic disease with coagulopathy possible

ADVANCED OR CONFIRMATORY TESTING

- Other laboratory tests:

- Coagulation profile: prolonged times with coagulation factor defects; normal with thrombocytopenia and thrombopathia
- Platelet function testing (e.g., bleeding time, von Willebrand factor analysis): for suspected coagulopathy despite normal platelet count and coagulation profile
- *Ehrlichia* and Rocky Mountain spotted fever titers/PCR
- Blood gas analysis (pulmonary disease)

- Diagnostic imaging:
  - Thoracic radiographs: pulmonary/cardiac disease, thoracic trauma, metastatic disease
  - CT scan: more sensitive than radiographs for some diseases, but requires general anesthesia
  - Echocardiography
- Other diagnostic procedures:
  - Bronchoscopy: examine lower airways, remove foreign bodies, bronchoalveolar lavage.
  - Cytologic and histopathologic examination and bacterial and fungal culture and sensitivity testing: lung tissue sample
  - Fine-needle aspirate/lung biopsy: pulmonary masses
  - Scintigraphy: ventilation/perfusion scan

TREATMENT

TREATMENT OVERVIEW

Stop the hemorrhage, and treat the primary cause.

ACUTE GENERAL TREATMENT

- Establish a patent airway.
- Oxygen supplementation
- Minimize activity or stimuli that precipitate hemorrhage episodes.
- Whole blood or packed red blood cell transfusion may be needed with severe anemia.

SPECIFIC TREATMENT

- Bleeding disorder:
  - von Willebrand disease: plasma or cryoprecipitate for acute bleeding (see p. 1347)
  - Hemophilia A: plasma or cryoprecipitate for acute bleeding; no long-term treatment
  - Hemophilia B: plasma for acute bleeding; no long-term treatment
  - Anticoagulant rodenticide intoxication: plasma for acute bleeding and vitamin K supplementation
  - Liver disease and DIC: treat and support the underlying cause; plasma may be beneficial.
  - Discontinue all nonsteroidal antiinflammatory drugs.
- Pulmonary disease:
  - Pulmonary hypertension: treat underlying etiology.
  - Pulmonary thromboembolism: treat underlying etiology.
  - Infection: treat specific infectious etiology.
  - Neoplasia: surgery
  - Lung lobe torsion: surgery
- Cardiovascular disease:
  - Heartworm: specific therapy
  - Cardiogenic pulmonary edema: diuretics, venodilators, oxygen supplementation
  - Arteriovenous fistula: surgery

POSSIBLE COMPLICATIONS

- Anemia
- Collapse state
- Respiratory failure

RECOMMENDED MONITORING

- Hematocrit
- Platelet count with thrombocytopenia
- Coagulation profile with coagulation factor defects
- Blood pressure with hypertension
- Monitor clinical signs

PROGNOSIS AND OUTCOME

Dependent on cause.

PEARLS & CONSIDERATIONS

COMMENTS

- Hemoptysis not a diagnosis but a clinical sign.
- Consider systemic diseases and cardiovascular diseases as well as primary pulmonary conditions.

CLIENT EDUCATION

Monitor for recurrence of presenting signs (coughing up of blood, presence of blood-stained sputum).

AUTHOR: REMO LOBETTI

EDITOR: ETIENNE CÔTÉ

Hemophilias and Other Hereditary Coagulation-Factor Deficiencies

BASIC INFORMATION

DEFINITION

Congenital hemostatic defects caused by mutations that impair the production of active clotting factors

SYNONYMS

Specific defects are classified by the deficient factor, with alternate names in common use for factors I, VII, VIII, and IX:

Hemophilias and Other Hereditary Coagulation-Factor Disorders

Deficient Factor	Alternate Name
Fibrinogen (factor I)	Dysfibrinogenemia, hypofibrinogenemia
Factor II	Prothrombin deficiency
Factor VII	Proconvertin or extrinsic factor deficiency
Factor VIII	Hemophilia A or classic hemophilia
Factor IX	Hemophilia B or Christmas disease
Factor X	Stuart Prower deficiency
Factor XI	Hemophilia C
Factor XII	Hageman trait

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats: severe bleeding disorders typically manifest by age 6-12 months.
- Males almost exclusively affected in hemophilia A and B (factor VIII and factor IX deficiencies)
- Males and females equally affected in all other factor deficiencies

GENETICS & BREED PREDISPOSITION

- X-linked recessive inheritance pattern: hemophilias A and B
- Autosomal recessive (or incomplete dominant): all other factor deficiencies
- Breed predisposition:
  - Dogs: hemophilia A is the most common hereditary coagulation defect and may develop in any purebred or mixed-breed dog (presumably due to de novo mutations). A mild to moderate form of hemophilia A has been propagated widely in German shepherds. Less common defects: factor VII deficiency in beagles, factor X deficiency in Jack Russell terriers, factor XI deficiency in Kerry blue terriers.
  - Cats: hemophilia A and B in any breed and domestic cats. Factor XII deficiency is the most common hereditary factor deficiency in domestic and Siamese cats. Combined deficiency of factors II, VII, IX, and X in Devon rex cats.
  - Note: mutations causing factor deficiencies can arise in any breed.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Severe bleeding tendency: deficiencies of factors I, II, VIII, IX, and X
- Mild to moderate bleeding tendency: deficiencies of factors VII, XI, and some forms of factor VIII and IX deficiency
- No clinical signs: factor XII deficiency

HISTORY, CHIEF COMPLAINT

- Severe forms: spontaneous and recurrent hematoma formation, weakness, or dyspnea due to bleeding into body cavities, lameness due to hemarthrosis, prolonged and potentially fatal bleeding from loss of deciduous teeth or minor wounds
- Mild forms: few spontaneous or severe bleeds, abnormal bleeding typically observed after surgical or traumatic injury

PHYSICAL EXAM FINDINGS

- Abnormal hemorrhage:
  - Manifestations of hemorrhage into body cavities or potential spaces (hemarthrosis, hematoma, hemoabdomen, hemothorax, central nervous system hemorrhage)
  - Bleeding from traumatic/surgical wounds
  - Occasionally epistaxis or intraocular bleeds
  - In contrast to platelet disorders, factor deficiencies rarely cause petechiae or ecchymoses.
- Pallor (blood-loss anemia)

ETIOLOGY AND PATHOPHYSIOLOGY

- Specific factor deficiencies are caused by mutations in the corresponding coagulation factor genes.
- De novo mutations occur most often in the factor VIII gene.
- Mutations causing mild to moderate clinical signs are more likely to become widely propagated in a breed or line.
- Although factor XII deficiency causes prolongation of the activated clotting time (ACT) and activated partial thromboplastin time (APTT) coagulation screening tests, it does *not* cause a clinical bleeding tendency.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Relatively high prevalence of hemophilia warrants coagulation screening tests be performed early in the diagnostic workup of any male with signs of spontaneous or abnormal hemorrhage.

DIFFERENTIAL DIAGNOSIS

- Acquired coagulation disorder (e.g., rodenticide intoxication, liver disease, disseminated intravascular coagulation)
- Thrombocytopenia
- Hereditary platelet function defect or von Willebrand disease
- Bleeding caused by tissue injury or infiltrative disorder
- Defect of fibrinolysis

INITIAL DATABASE

- Thorough physical exam to define site(s) of hemorrhage. Hemorrhage from more than a single site suggests a hemostatic defect rather than blood loss from damaged or diseased blood vessels.
- Baseline hematocrit and plasma protein
- Platelet count: usually normal unless brisk hemorrhage (platelet loss)
- Point-of-care coagulation screening tests (*, markedly abnormal):
  - ACT: prolonged (factors I, II, VIII, IX, X, XI, and XII deficiencies) or normal (factor VII deficiency)
  - APTT: prolonged (factors I, II, VIII, IX, X, XI*, and XII* deficiencies) or normal (factor VII deficiency)
  - Prothrombin time (PT): prolonged (factors I, II, VII, and X deficiencies) or normal (factors VIII, IX, XI, and XII deficiencies)
- Laboratory coagulation panel:
  - APTT, PT: as above
  - Fibrinogen: low (factor I deficiency), normal for others
  - Thrombin clotting time: prolonged (factor I deficiency), normal for others

ADVANCED OR CONFIRMATORY TESTING

Definitive diagnosis based on identifying low levels of specific coagulation factors:

- Clottable fibrinogen (factor I)
- Coagulant activity assays (factors II through XII)

TREATMENT

TREATMENT OVERVIEW

Patients with confirmed factor deficiencies but without clinical signs should receive a prophylactic transfusion prior to surgery. Patients with confirmed factor deficiencies who are actively bleeding may require repeated transfusions and, rarely, withdrawal of blood if compromising vital functions (e.g., large-volume pleural effusion). In both categories of patients, avoidance of unnecessary surgery or trauma are important.

ACUTE GENERAL TREATMENT

- Transfusion to supply hemostatic levels of the deficient factor:
  - Use of plasma components reduces risk of intravascular volume overload and red cell sensitization while maximizing factor replacement.
  - Fresh frozen plasma (10-12 mL/kg IV):
    - "Broad-spectrum" replacement therapy for deficiencies of fibrinogen and factors II through XI
  - Cryoprecipitate (unit dosage varies for different suppliers):
    - Replacement therapy for fibrinogen defects and factor VIII deficiency
  - Cryopoor plasma or cryosupernatant (10-12 ml/kg IV):
    - Replacement therapy for factors II, VII, IX, X, and XI deficiencies
- Replacement of red cells for severe blood-loss anemia:
  - Fresh whole blood (12-20 mL/kg) or packed red cells (6-12 mL/kg) (see p. 1347)

CHRONIC TREATMENT

- Intermittent transfusion as needed to control hemorrhagic events
- Preoperative transfusion to prevent abnormal bleeding
- Avoidance of unnecessary invasive procedures

BEHAVIOR/EXERCISE

- Strenuous activity should be avoided to help limit intraarticular hemorrhage.
- Hemophilic cats should remain indoors, dogs should be supervised when outdoors.
- Owners must balance quality of life with reasonable exercise restriction.

DRUG INTERACTIONS

Avoid drugs with anticoagulant or antiplatelet effects (e.g., nonsteroidal antiinflammatory drugs [NSAIDs], clopidogrel, sulfonamides, heparin, warfarin, plasma expanders, estrogens, cytotoxic drugs)

POSSIBLE COMPLICATIONS

- Red cell sensitization causing transfusion reactions:
  - Transfuse plasma components when possible.
  - Feline transfusion: donor and recipient must be type matched for any transfusion.
  - Canine transfusion: after the first red cell transfusion, perform crossmatch before subsequent transfusions.
- Development of inhibitory antifactor antibodies (rare complication)

RECOMMENDED MONITORING

Adequate factor replacement is demonstrated by:

- Cessation of active bleeding
- Stabilization of hematocrit/plasma protein
- Resolution of lameness and hematoma

PROGNOSIS AND OUTCOME

- Mild to moderate factor deficiencies: good quality of life possible; patient may require occasional transfusion.
- Severe factor deficiencies: fair to poor prognosis due to recurrent bleeds and dependence on repeated transfusion; acute

fatal bleeds may occur.

PEARLS & CONSIDERATIONS

COMMENTS

- Hemophilia A (factor VIII deficiency) is the primary rule out for abnormal bleeding in young male dogs and cats.
- Feline factor XII deficiency does not cause a clinical bleeding diathesis and is typically identified in the course of preoperative workup for an acquired disease process.

PREVENTION

- Factor-deficient dogs and cats should never be used for breeding.
- Familial testing is indicated to identify asymptomatic carriers before they are bred.

TECHNICIAN TIPS

- Consider hereditary bleeding disorders (especially hemophilia) in any dog or cat with abnormal hemorrhage. A blue-top tube (sodium citrate anticoagulant) should be drawn for coagulation screening tests (APTT, PT, fibrinogen).

CLIENT EDUCATION

Definitive diagnosis aids in determining prognosis, selecting appropriate transfusion therapy, and genetic counseling.

AUTHOR: MARJORY B. BROOKS

EDITOR: SUSAN M. COTTER

Hemolytic-Uremic Syndrome

BASIC INFORMATION

DEFINITION

An uncommon, severe disease characterized by nonimmune-mediated microangiopathic hemolytic anemia, acute renal failure, and thrombocytopenia. This disease in humans is usually associated with Shiga toxin–producing *Escherichia coli* (STEC) infections and diarrhea or (rarely) other gram-negative bacteria that produce Shiga toxins. A similar syndrome has been reported in dogs and cats.

SYNONYMS

Alabama rot, cutaneous and renal glomerular vasculopathy (CRGV) of greyhounds, Greentrack disease

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Mainly dogs; very rare in cats
- No age or sex predilection

GENETICS & BREED PREDISPOSITION: Reported most frequently and originally in racing greyhounds. Genetic predispositions are difficult to evaluate because of outbreaks in affected kennels among littermates with a common food source.

RISK FACTORS: A diet including inappropriately cooked or raw meat may predispose to STEC infections.

CONTAGION & ZOONOSIS: Contaminated beef ingestion is most widely responsible for hemolytic-uremic syndrome (HUS) in humans, and common-source exposure could occur in pets. There have been reports of outbreaks in children associated with petting zoos.

GEOGRAPHY AND SEASONALITY: First noted in Alabama dog racing tracks

ASSOCIATED CONDITIONS & DISORDERS: Similar condition noted in some cats after renal transplantation. Important to distinguish the thrombotic signs of HUS from those associated with disseminated intravascular coagulation (DIC). Prothrombin time is normal or slightly increased, and fibrinogen is normal or high with HUS.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: HUS and cutaneous/renal glomerular vasculopathy are similar, although HUS typically does not have the cutaneous lesions associated with CRGV.

HISTORY, CHIEF COMPLAINT

- History may include feeding raw or undercooked beef. Usually the initial complaint is hemorrhagic diarrhea, although not always reported. Diarrhea episode could have occurred up to 2 weeks before the onset of clinical signs.
- Lethargy or cutaneous lesions may be the primary complaint, as well as vomiting, limb edema, and anorexia.

PHYSICAL EXAM FINDINGS

- In CRGV, cutaneous lesions are multifocal erythematous swellings commonly located on the tarsus, stifle, medial thigh, and rarely forelimb. Lesions may become ulcerated with serosanguineous discharge.
- Physical findings common to both CRGV and HUS include those typical of anemia and acute renal failure, with hemoglobinuria often present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Shiga toxin–producing *E. coli*, usually serotype 0157:H7, causes endothelial injury via circulating Shiga toxins which generate a systemic prothrombotic response, microangiopathic hemolytic anemia, and renal failure.
- Glomerular disease noted in cutaneous and renal glomerular vasculopathy

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected based on the history of exposure to raw or undercooked meat and the clinical signs of diarrhea, possibly cutaneous lesions, and the laboratory signs of azotemia, anemia, +/- thrombocytopenia. Confirmation requires a positive fecal culture on sorbitol MacConkey agar.

DIFFERENTIAL DIAGNOSIS

- Leptospirosis, sepsis, systemic inflammatory diseases
- Any disease causing acute renal failure or vasculitis
- Immune-mediated hemolytic anemia

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis
  - Anemia, presence of schistocytes, and thrombocytopenia are typical.
  - Ensure adequate platelet count if renal biopsy is being considered.
  - Azotemia and isosthenuria may precede, coexist with, or be absent. Generally, increased blood urea nitrogen, creatinine, and phosphorus are seen. Hyperkalemia or other electrolyte changes are possible.
  - Proteinuria possible with glomerular disease (cutaneous and renal glomerular vasculopathy)
  - Hemoglobinuria commonly is present (discolored urine; positive blood result on dipstick but no erythrocytes on sediment exam).
- Coagulation panel with D-dimer or fibrin/fibrinogen degradation product (FDP) analysis: evidence of thrombosis (e.g., increased D-dimer or FDPs, decreased platelet count), normal to slightly prolonged PT, increased or normal fibrinogen
- Urine culture: rule out urinary tract infection as cause of proteinuria.
- Arterial blood pressure measurement: rule out systemic hypertension associated with renal disease.

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound ± renal biopsy. Assess blood pressure and platelet count first.
- Skin biopsy of representative lesions
- Culture of feces on sorbitol MacConkey agar of STEC 0157:H7

TREATMENT

TREATMENT OVERVIEW

Treatment mainly consists of aggressive intravascular fluid-volume replacement, blood transfusions as needed, blood pressure lowering agents as needed, and general supportive care (e.g., nutrition, soft padded bedding, urinary catheter, etc.). Early referral to a regional dialysis center should be considered for animals in acute renal failure.

ACUTE GENERAL TREATMENT

- Aggressive intravascular volume expansion with crystalloids during the diarrhea phase (early) appears to be preventive for the renal failure component of this disease in children.
- Treat oliguric or anuric renal failure intensively (see p. 1369).
  - Transfusion if severe anemia (hematocrit < 18% or physical/laboratory signs of decreased perfusion such as depressed mentation, weak pulses, cold extremities, increased lactate)
  - Consider early referral to a regional dialysis center.
  - After appropriate volume expansion, if urine output deficient and blood pressure adequate, attempt to increase urine output with either mannitol (0.5 g/kg IV over 30 minutes) or if volume overloaded, furosemide (0.2-0.5 mg/kg/h IV constant rate infusion)
- Avoid antibiotics, as several classes (e.g., fluoroquinolones, trimethoprim-sulfa, β-lactams) lead to increased expression of the Shiga toxin and have been associated with increased risk of developing HUS when used during the diarrhea phase in children.
- Avoid NSAIDS and antimotility agents.
- Analgesia is essential, opioids such as fentanyl or morphine should be considered.
- Nutritional support as needed

CHRONIC TREATMENT

Hypertension may be treated with amlodipine (0.05-0.2 mg/kg PO q 24 h).

POSSIBLE COMPLICATIONS

- Hemorrhage from severe thrombocytopenia or disseminated intravascular coagulation
- Bacterial translocation and sepsis from hemorrhagic diarrhea
- Systemic hypertension
- Chronic glomerulonephritis/protein-losing nephropathy
- Poorly healing cutaneous lesions

RECOMMENDED MONITORING

- Perfusion parameters such as mentation, pulse quality, extremity temperature, lactate, and so forth should be monitored frequently (e.g., q 6 h).
- Renal values on serum chemistry (blood urea nitrogen, creatinine, electrolytes)
- Hematocrit and platelet count
- Urine output
- Blood pressure
- Pain

PROGNOSIS AND OUTCOME

- Often a fatal disease if the patient is in acute renal failure and the owner cannot afford referral to a dialysis center
- Survivors may have chronic kidney disease or glomerular disease.

PEARLS & CONSIDERATIONS

COMMENTS

- There are no data to indicate that plasma exchange (which is used for removing antibodies in a similar syndrome, thrombotic thrombocytopenic purpura, in humans) has any benefit.
- Early intensive therapy with intravascular fluids is the key to survival and perhaps prevention once initial sign of hemorrhagic diarrhea is noted.

PREVENTION

For the cases initiated by ingestion of STEC 0157:H7, prevention depends on removal of inadequately cooked beef from diet.

EDITOR: DOUGLASS K. MACINTIRE

1ST EDITION AUTHOR: JEFFREY SIMMONS

Hemoabdomen

BASIC INFORMATION

DEFINITION

Hemoabdomen is characterized by the presence of free blood within the peritoneal cavity.

SYNONYM

Hemoperitoneum

EPIDEMIOLOGY

SPECIES, AGE, SEX: Young dogs are more likely to develop hemoabdomen secondary to trauma. Older large-breed dogs without a history of trauma often develop hemoabdomen due to a ruptured splenic or hepatic mass such as hemangiosarcoma.

GENETICS & BREED PREDISPOSITION: Large-breed older dogs are predisposed to hemangiosarcoma.

RISK FACTORS: Dogs that roam may ingest anticoagulant rodenticides, although this rarely results in hemoabdomen.

ASSOCIATED CONDITIONS & DISORDERS: Animals with hemangiosarcoma can develop pericardial effusion due to rupture of a concurrent right atrial hemangiosarcoma.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History can range from reports of episodes of acute collapse to mild lethargy. Some dogs will present for evaluation of gastrointestinal signs such as vomiting or a distended abdomen. Many dogs have a history of weakness, collapse, or transient polyuria/polydipsia during the weeks before presentation. Presumptively, this indicates a prior hemorrhagic episode.
- Some but not all dogs with anticoagulant rodenticide toxicosis will have a known history of ingestion of thoison. Anticoagulant rodenticide intoxication much more commonly results in hemothorax, mediastinal, or subcutaneous bleeding rather than hemoabdomen.

PHYSICAL EXAM FINDINGS

- Most physical examination findings are referable to blood loss and hemorrhagic shock. The clinical signs will vary depending on the severity of shock. Dogs may have pale mucous membranes, tachypnea, tachycardia, and bounding pulses. An abdominal fluid wave may be present. In some cases, a discrete abdominal mass (e.g., ruptured neoplasm) may be palpable.
- A traumatic cause for hemoabdomen may be apparent owing to the presence of additional injuries.
- Animals with anticoagulant rodenticide toxicosis may have bruising at venipuncture sites.

ETIOLOGY AND PATHOPHYSIOLOGY

- In dogs without a history of trauma and a normal coagulation profile, hemangiosarcoma is the most likely diagnosis.
- Benign splenic hematomas account for a substantial proportion of canine splenic masses in general but comprise only 5%-10% of the splenic masses seen in dogs with hemoabdomen.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The clinician should work to quickly rule in or rule out hemoabdomen (and/or pericardial effusion) in any middle-aged to older dog presenting with collapse and hypotension. Use of abdominal ultrasound provides the quickest diagnosis of free abdominal effusion and allows for ultrasound-guided centesis.

DIFFERENTIAL DIAGNOSIS

- Ruptured hemangiosarcoma
- Ruptured splenic hematoma
- Other ruptured abdominal mass
- Trauma
- Anticoagulant rodenticide toxicity

INITIAL DATABASE

- Packed cell volume and serum total protein
- Prothrombin time and activated partial thromboplastin time
- CBC with manual platelet count
- Serum biochemical profile
- Abdominocentesis:
    - Nonclotting bloody effusion: if neoplasia or coagulopathy
    - Bloody effusion with clots: if trauma; rarely, with voluminous bleed from mass

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound to identify the source of hemorrhage in dogs with hemangiosarcoma and splenic hematoma
- Abdominal radiography may be minimally helpful in the presence of free abdominal fluid.
- Whenever possible, thoracic radiographs and echocardiography should be performed before surgery in dogs with hemoabdomen and an abdominal mass (rule out metastasis/poor prognosis).
- Blood rodenticide levels can be performed in cases of suspected toxicosis.

TREATMENT

TREATMENT OVERVIEW

Dogs with hemoabdomen frequently present with severe cardiovascular instability. Once cardiovascular instability is identified (poor pulse quality, cold extremeties, mentation changes, very pale/white mucous membranes), the clinician should work to obtain vascular access and begin resuscitation with intravenous fluids and/or blood products as indicated. Initial treatment should be directed toward reversing the signs of cardiovascular in stability. Further treatment should focus on preventing ongoing hemorrhage.

ACUTE GENERAL TREATMENT

- Intravenous fluids as indicated by the patient's cardiovascular status.
- Blood transfusion in patients with a packed cell volume < 20%-25% that are hemodynamically unstable (e.g., concurrent hypotension, hemorrhagic shock, or rapid sustained ventricular arrhythmia)
- Patients with a coagulopathy should be treated with 15 mL/kg of fresh frozen plasma or 30 mL/kg of fresh whole blood.
- Emergent laparotomy is indicated in dogs with ongoing intraabdominal hemorrhage.
- Dogs with abdominal neoplasia benefit from surgical removal of the bleeding tumor once they are hemodynamically stable, although postoperative survival times may only range from weeks to months, depending on the nature of the neoplasm.

CHRONIC TREATMENT

- Patients with neoplasia may benefit from chemotherapy.
- Anticoagulant rodenticide toxicosis: vitamin K1, 5 mg/kg SQ, then 2.5 mg/kg/d PO for 2-6 weeks as required for the specific toxin ingested.

POSSIBLE COMPLICATIONS

- Ongoing hemorrhage
- Some splenic or liver masses have metastasized by the time of laparotomy, and the masses may not be resectable.
- Severe ventricular arrhythmia may develop and may require antiarrhythmic therapy.

RECOMMENDED MONITORING

- Cardiac electrocardiogram monitoring is indicated owing to the high frequency of arrhythmia in dogs with splenic disease.
- Frequent reassessment of the packed cell volume/total solids is warranted in the initial urgent setting.
- Coagulation times should be rechecked after the completion of plasma transfusions.
- Specific long-term monitoring depends on cause. Typically, dogs with hemoabdomen are reassessed within 10 postoperative

days (history, physical examination, CBC; other tests based on these findings and original etiology), and again 2-4 weeks later barring complications.

PROGNOSIS AND OUTCOME

- Often, exact prognosis is only determined in the postoperative period, with histopathologic assessment of biopsies.
- Dogs with hemangiosarcoma have a poor prognosis, with an average survival of 3-6 months with surgical treatment and 2-3 weeks without surgery.
- Dogs with splenic hematomas may be cured with splenectomy.
- Traumatic hemoabdomen usually responds well to supportive nonsurgical management.

PEARLS & CONSIDERATIONS

COMMENTS

- In patients with acute hemorrhage, the serum total protein will fall before the packed cell volume.
- It is essential to submit large sections of spleen (or the entire spleen) for histopathologic analysis of splenic masses. Otherwise, some splenic biopsies that are interpreted by the pathologist as a hematoma are actually hemangiosarcoma, as the tumor is small and there is a massive hematoma surrounding it.
- Benign splenic hematomas account for a large proportion of canine splenic masses in general, but hematomas make up only 5%-10% of the splenic masses seen in dogs with hemoabdomen.
- Any collapsed large-breed dog should be evaluated for possible hemoabdomen.

PREVENTION

Keep dogs confined or supervised to prevent trauma and rodenticide intoxication.

CLIENT EDUCATION

Advise owner to present older dogs with lethargy for evaluation in a timely fashion.

Hematuria

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

The presence of blood (gross or microscopic) in the urine is encountered commonly in dogs and cats.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs or cats of either gender and any age may develop hematuria for a variety of benign or pathologic reasons.

GENETICS & BREED PREDISPOSITION: Welsh corgi (renal telangiectasia), Abyssinian cats (glomerular disease)

RISK FACTORS

- Acquired or hereditary coagulopathies (e.g., rodenticide intoxication, thrombocytopenia, hemophilia)
- Upper or lower urinary tract trauma, neoplasia, infection, or inflammation
- Urolithiasis
- Renal insult (e.g., acute renal failure, glomerulonephritis, renal infarcts)
- Vascular malformation
- Urinary parasites *(Capillaria plica, Dioctophyma renale)*
- Cyclophosphamide administration
- Prostatitis
- Proestrus

ASSOCIATED CONDITIONS & DISORDERS

- Very rarely, urinary obstruction due to blood clots
- Very rarely, anemia accompanies renal hematuria

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Macroscopic hematuria: grossly discolored, bloody urine
- Microscopic hematuria: >5 red blood cells (RBCs)/hpf without overt urine discoloration

HISTORY, CHIEF COMPLAINT

- Gross hematuria may occur at initiation of urination, throughout urination, or at the end of urination:
  - Initial hematuria: lower urinary tract or reproductive origin
  - Total hematuria: origin anywhere along urinary/reproductive tract
  - Terminal hematuria: upper urinary tract, bladder origin
- Depending on causation, any of the following may be reported:
  - Red, pink, or brown urine (macroscopic) (see also p. 312)
  - Dysuria/stranguria (suggestive of lower urinary tract disorders)
  - Pollakiuria (suggestive of lower urinary tract disorders)
  - Bloody discharge from penis or vulva unassociated with urination (suggestive of genital origin)
  - Abdominal pain
  - Systemic signs (e.g., lethargy, anorexia, vomiting) suggestive of upper urinary disorders, obstruction, or rupture

PHYSICAL EXAM FINDINGS: Depending on etiology, findings may include:

- Palpable renal/bladder/urethral mass effect
- Prostatomegaly
- Abdominal pain
- Bleeding unrelated to the urinary/genital tract (e.g., petechiae, ecchymoses, epistaxis), suggesting systemic bleeding disorder

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary (coagulation factors) or secondary (platelet) hemostatic defects or vasculitis may result in hematuria in the absence of urinary or reproductive disorders.
- Bleeding anywhere along the length of the urinary tract or from the reproductive tract may cause hematuria.
- A variety of inflammatory, infectious, neoplastic, traumatic, or toxic insults may result in hematuria. Traumatic cystocentesis can cause iatrogenic hematuria.
- Vascular malformations (e.g., telangiectasia) are a rare but important cause of marked hematuria.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

In most cases, a presumptive diagnosis can be achieved on the basis of history, examination, urinalysis, and abdominal radiographs and/or ultrasound.

DIFFERENTIAL DIAGNOSIS

- Pigmenturia
- Hemoglobinuria
- Myoglobinuria

INITIAL DATABASE

- History reviewed for drugs/toxins (e.g., cyclophosphamide, phenols) or iatrogenic procedures (e.g., urinary catheterization, cystocentesis) that might induce hematuria
    - If microscopic hematuria is observed after cystocentesis, later evaluation of a voided sample is warranted.
- Rectal examination: prostate, intrapelvic urethra
- Digital vaginal exam/cytologic evaluation if vulvar bleeding between urinations
- Urinalysis: hematuria differentiated from hemoglobinuria, myoglobinuria, or pigmenturia (all of which discolor urine and may produce a positive blood result by urine dipstick) by presence of intact RBC on microscopic exam (hematuria only)
    - Cystocentesis is avoided if coagulopathy, ascites, peritonitis, or neoplastic bladder disease is possible.
    - Urethral catheterization: detection of urethral calculi/mass, urine collection
    - Hematuria in samples obtained by catheterization or cystocentesis suggests origin is kidney(s), ureter(s), or bladder. Conversely, if RBC absent from these samples but present in voided urine, source of bleeding is likely urethra or reproductive tract.
- CBC: thrombocytopenia suggests hemostatic defect; neutrophilia suggests upper urinary infection/inflammation; anemia may correlate to degree of blood loss.
- Serum biochemical profile: azotemia and hyperkalemia suggest renal disease or urinary obstruction/rupture.
- Urine culture is indicated when bacteria/pyuria are detected.
- Abdominal radiographs: shape and size of kidneys, bladder, prostate evaluated. Radiopaque stones may be observed.
- Abdominal (urinary and genital) ultrasound: renal parenchyma, bladder wall and luminal content, prostate, uterus, and portions of ureters/urethra evaluated for masses/radiolucent stones.

ADVANCED OR CONFIRMATORY TESTING

- If coagulopathy is suspected, platelet count, bleeding time, prothrombin time, activated partial thromboplastin time, and/or activated coagulation time are indicated.
- Excretory urographic contrast studies (see p. 1265) may delineate masses, stones, or tears in the urinary tract not previously identified.
- Cystoscopy may identify source of bleeding from vagina, urethra, bladder, or either kidney/ureter.
- Traumatic catheterization when urethral/bladder mass detected allows cytologic evaluation.
- Consider biopsy of kidney, bladder, prostate, urethra as appropriate.
- Bladder tumor antigen test unreliable in the face of hematuria

TREATMENT

TREATMENT OVERVIEW

Treatment for hematuria depends entirely on the cause.

ACUTE GENERAL TREATMENT

- Coagulopathy is addressed directly.
- Traumatic injury may require supportive care alone or surgical intervention.
- Urinary calculi are treated via medical dissolution and/or mechanical removal, depending on type and location of stone.
- Urinary tract or reproductive infections are treated with appropriate antibiotics.
- Neoplastic disease may require surgical intervention (e.g., unilateral renal carcinoma) or chemotherapy (e.g., transitional cell carcinoma).
- Drugs (e.g., cyclophosphamide, nonsteroidal antiinflammatory drugs) that might induce hematuria disallowed
- Rarely, renal hematuria may lead to blood loss sufficient to warrant transfusion.

CHRONIC TREATMENT

Dependent on cause

POSSIBLE COMPLICATIONS

Rarely, blood clots lead to ureteral or urethral obstruction.

RECOMMENDED MONITORING

Dependent on cause

PROGNOSIS AND OUTCOME

Dependent on cause

PEARLS & CONSIDERATIONS

COMMENTS

- Generally, hematuria is a sign of underlying disease rather than a primary disorder.
- Renal telangiectasia is an uncommon hereditary condition in Welsh corgi dogs, resulting in potentially profound renal bleeding due to vascular malformations. Diagnosis depends on biopsy, and organs other than the kidney may be involved.
- Benign essential hematuria is an uncommon disorder of young dogs in which no cause for profound, persistent hematuria can be identified. Often it occurs unilaterally; removal of the affected kidney is curative.

TECHNICIAN TIP

- Cystocentesis should not be performed on animals with hematuria until the clinician is reasonably certain that the animal (1) does not have a coagulopathy and (2) does not have a transitional cell carcinoma.

AUTHOR & EDITOR: LEAH A. COHN

Hematochezia

BASIC INFORMATION

DEFINITION

The presence of bright red streaks of blood on the surface of or admixed into the stool

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dependent on underlying cause
- Older animals: neoplasia
- Younger animals: parasites

RISK FACTORS: The most common risk factor for hematochezia is colitis. Neoplasia is less commonly responsible. Coagulopathies are a rare cause of hematochezia.

ASSOCIATED CONDITIONS & DISORDERS: Clinically significant anemia very uncommonly occurs as a result of hematochezia.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Animals presenting with hematochezia will also commonly present with mucus in the stool, straining, and difficulty defecating; all are manifestations of colonic disease.
- Animals with hematochezia rarely present signs of systemic illness.

PHYSICAL EXAM FINDINGS

- These animals generally look clinically healthy. Involuntary weight loss should *not* be present; if it is, severe colonic disease (e.g., infiltrative disease) or complications of colonic disease (e.g., malignancy) should be investigated.
- The perianal area may be soiled with blood, fecal material, and/or mucus.
- The anus may be inflamed and ulcerated.
- A mass (neoplasm), swelling (anal gland abscess), or fissure (perianal fistula) around the anus may be visible.
- A rectal examination can confirm the presence of hematochezia and is essential in any patient with a presenting complaint of hematochezia.

ETIOLOGY AND PATHOPHYSIOLOGY

Blood most commonly originates from the anus, rectum, and/or descending colon.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Hematochezia should be suspected in an otherwise healthy dog presenting soft, fresh blood-streaked stool with mucus accompanied by straining and painful defecations. Tests begin with fecal analysis and examination of the patient for signs of rectoanal disease or systemic bleeding disorders.

DIFFERENTIAL DIAGNOSIS

- Diseases involving the anus:
  - Anal sacculitis/abscess
  - Perianal fistula
  - Neoplasia (anal sac tumor)
  - Perineal hernia

    - Rectal stricture
    - Trauma
    - Foreign body
- Diseases involving the rectum and colon:
    - Proctitis
    - Colitis:
        - Idiopathic
        - Inflammatory
        - Infectious *(Campylobacter, Clostridium, Histoplasmosis)*
        - Stress
    - Parasites:
        - Hookworms, whipworms, coccidia, roundworms
    - Neoplasia:
        - Benign: rectal polyp
        - Malignant: lymphoma, carcinoma
    - Rectal prolapse
    - Mucosal trauma (foreign body, hair balls, enemas)
    - Dexamethasone administration (especially in the presence of intervertebral disk disease)
    - Coagulation disorders (usually accompanied by bleeding from other sites)

INITIAL DATABASE

- Rectal examination including anal sac palpation
- Fecal examination for parasites
- Fecal smear, culture, *Clostridium* toxin detection
- Results of trial therapy (see Acute General Treatment below)

ADVANCED OR CONFIRMATORY TESTING

Advanced testing should be considered in patients with systemic signs of illness, persistent or recurrent episodes of hematochezia. Tests are selected based on history, physical exam, and initial database results:

- CBC
- Serum biochemistry profile
- Urinalysis
- Coagulation profile
- Abdominal radiographs
- Abdominal ultrasound
- Colonoscopy

TREATMENT 

TREATMENT OVERVIEW

Initial therapy consists of dietary change, broad-spectrum dewormer, and an antibiotic to control bacterial overgrowth. Unresponsive chronic cases may benefit from referral to a specialist for colonoscopy.

ACUTE GENERAL TREATMENT

- Nonspecific trial therapy can be attempted in an animal without systemic signs:
    - Broad-spectrum dewormer (e.g., fenbendazole, 50 mg/kg PO q 24 h × 5 days)
    - Trial course of metronidazole (e.g., 7-15 mg/kg PO q 12 h × 7 days maximum)
- Dependent on the underlying disease:
    - Perianal fistulas: immunosuppressive therapy
    - Infectious colitis: *Clostridium:* metronidazole, amoxicillin, *Campylobacter:* tylosin
    - Neoplasia: surgical excision, chemotherapy, radiation therapy
    - Stricture: surgery
    - Perianal hernia: surgical correction

CHRONIC TREATMENT

- Dependent on the underlying disease

- Colitis (see pp. 227 and)

NUTRITION/DIET

- Diet containing fermentable fiber
- Low-residue diet

POSSIBLE COMPLICATIONS

Perforated colon:

- Neoplasia
- Dexamethasone therapy (especially in the presence of intervertebral disk disease)

PROGNOSIS AND OUTCOME

Dependent on underlying disease

PEARLS & CONSIDERATIONS

COMMENTS

Hematochezia should not be confused with melena, which refers to the presence of dark, tarry stool caused by digested blood from the upper digestive tract or small intestine.

PREVENTION

Handwashing after caring for patients is essential, as some causes of hematochezia are zoonotic.

Hemangiosarcoma

Video Available on Website

BASIC INFORMATION

DEFINITION

A malignant, highly metastatic tumor arising from vascular endothelial cells. Most commonly arises within the spleen, right auricle or right atrium, and skin or subcutaneous tissues.

SYNONYMS

HSA, angiosarcoma, malignant heman-gioendothelioma

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Feline: 8-10 year median, males > females. Uncommon
- Canine: common
  - Cutaneous: adults (range 4-10+ years), no sex predilection
  - Noncutaneous: 8-10 year median, neutered animals may be at increased risk

GENETICS & BREED PREDISPOSITION

- Feline: no genetics or specific breed predisposition known
- Canine:
  - Cutaneous: no genetics known, although breeds with short-haired coats are predisposed (e.g., whippets, pit bulls, dalmatians)
  - Noncutaneous: no genetics known; tend to affect large-breed dogs such as German shepherds and golden retrievers

RISK FACTORS

- Feline: none known
- Canine:
  - Cutaneous: dermal hemangiosarcoma arises on nonhaired skin and is associated with ultraviolet (UV) light exposure. Subcutaneous hemangiosarcoma arises in haired skin and is not associated with UV exposure.
  - Noncutaneous: none known, but breed predisposition suggests a genetic etiology.
  - Cardiac hemangiosarcoma is the most common reason for pericardial effusion.

ASSOCIATED CONDITIONS & DISORDERS

- Feline: none known
- Canine:
  - Cutaneous:
    - UV exposure may also predispose to cutaneous hemangioma or squamous cell carcinoma.
  - Noncutaneous:
    - With either splenic, hepatic, or right atrial/auricular appendage HSA, potentially life-threatening hemorrhage can occur. Occasionally, large subcutaneous hemangiosarcoma tumors may bleed.
    - Pericardial effusion can result in potentially fatal cardiac tamponade.
    - Splenic, hepatic, and right atrial/auricular appendage HSA are associated with cardiac arrhythmias.
    - In any patient with hemangiosarcoma, disseminated intravascular coagulation (DIC) may arise in conjunction with thrombocytopenia and triggering of the coagulation cascade by the formation of abnormal (tumor-related) vascular channels.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Feline: subcutaneous and splenic lesions are most common, but hemangiosarcoma can arise anywhere in the body, including

such diverse tissues as bone, gastrointestinal (GI) tract, and skin.

- Canine:
  - Cutaneous:
    - Tends to arise on lightly haired areas such as the ventral abdomen. Tumors that are <5 cm in diameter and confined to the dermis are classified as stage I. Tumors that are >5 cm in diameter or invade subcutaneous or deeper tissues are classified as stage II or III.
  - Noncutaneous:
    - Splenic lesions are most common, followed by HSA of the right atrial/auricular appendage and skin. Primary HSA of the liver can occasionally occur, but most often, hepatic lesions are metastases from another site. As with cats, hemangiosarcoma can arise anywhere.
    - Cardiac tamponade due to intrapericardial hemorrhage from the tumor site
    - Occasionally can be an incidental finding without associated clinical signs

HISTORY, CHIEF COMPLAINT

- Feline:
  - Cutaneous: bleeding from the mass in a patient that is otherwise well may be the chief complaint.
  - Noncutaneous: typically, nonspecific signs such as inappetence/anorexia, weight loss, lethargy, and vomiting are the basis for seeking veterinary attention.
- Canine:
  - Cutaneous: history of extensive sunlight exposure and development of one or more cutaneous masses
  - Noncutaneous:
    - Often nonspecific complaints (e.g., mild exercise intolerance, mild decrease in appetite, weight loss) commonly attributed at first to “old age,” or environmental change (weather), but then culminating in subacute (days before presentation) or acute (hours before presentation) deterioration with lethargy, weakness, tachypnea, inappetence/anorexia, and/or abdominal distension.
    - Acute onset of weakness or collapse is often mentioned, associated with tumor rupture and hemorrhage.
    - Collapse may be self-resolving by the time the patient is presented for veterinary attention, but physical signs of hemorrhage, abdominal mass, or arrhythmia persist.
    - Cardiac (overlap or combination of the following is possible):
      - Acute collapse with pallor; may have partially resolved over preceding hours or days
      - General malaise, lethargy, anorexia, exercise intolerance
      - Visible abdominal distension

PHYSICAL EXAM FINDINGS

- Feline: Cutaneous or subcutaneous lesions are typically readily identified on physical examination. Visceral disease is often evident on abdominal palpation. Other possible findings include pale mucous membranes, weak pulses.
- Canine:
  - Cutaneous:
    - Single or multiple cutaneous tumors, typically on the ventral abdomen. Usually raised, hairless, smooth, and dark-red lesions, although they may also appear as polypoid, hairless lesions that are the same color as surrounding skin.
  - Noncutaneous:
    - Most often, findings are related to tumor rupture and hemorrhage into a body cavity. The most common physical findings include lethargy, pale mucous membranes, abdominal fluid wave, sinus tachycardia (reflex), and weak pulses.
    - A palpable intraabdominal mass is often present, and such masses should be palpated with great care to avoid further damaging any fragile blood vessels on the surface of the neoplasm and inducing further hemorrhage.
    - Soft heart sounds, cardiac arrhythmia, and signs of circulatory failure may be present either as a result of a ruptured abdominal hemangiosarcoma, cardiac hemangiosarcoma and subsequent pericardial effusion, or both.
    - In some cases: jugular distension, pulsus paradoxus, positive hepatojugular reflux

ETIOLOGY AND PATHOPHYSIOLOGY

- Cutaneous hemangiosarcoma is associated with UV light exposure. Cutaneous hemangiosarcoma is less likely to metastasize and is not usually associated with underlying visceral disease/involvement; subcutaneous hemangiosarcoma may metastasize and may be a marker for underlying visceral disease/involvement.
- Malignant vascular endothelial cells form abnormal vascular channels.
- Microangiopathic disease (abnormal blood vessels in the neoplasm) results in platelet aggregation, red blood cell morphology changes, and DIC
- Tumor rupture leads to anemia, weakness, and inappetence/anorexia.

- Cardiac hemangiosarcoma is usually seen as right atrial/auricular infiltration of neoplastic cells that grow on the epicardial surface and ultimately cause rupture of superficial myocardial vessels of varying sizes, triggering bleeding into the pericardial space. The result is cardiac tamponade when intrapericardial pressure exceeds right atrial and ventricular filling pressures.
- Metastatic disease occurs within the lungs, mesentery, and throughout the body.
- Death is due to uncontrollable bleeding from tumor rupture.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Feline (subcutaneous): abscess, other neoplasia such as injection-site sarcoma, fibrosarcoma
- Feline (splenic): splenic mast cell tumor, lymphoma, nodular hyperplasia, other sarcoma
- Canine (cutaneous/subcutaneous): hemangioma, soft tissue sarcoma, mast cell tumor
- Canine (splenic): splenic torsion, lymphoma, hemangioma, hematoma, extramedullary hematopoiesis, nodular regeneration, other sarcoma
- Canine (hepatic): hepatocellular adenoma/adenocarcinoma, hematoma
- Canine (cardiac): idiopathic benign pericardial effusion, other neoplasia (chemodectoma, mesothelioma, lymphoma), hemopericardium (atrial rupture, anticoagulant rodenticide intoxication), exudative/infectious pericarditis, congestive heart failure (right-sided), diaphragmatic pericardial-peritoneal hernia, hydropericardium due to hypoalbuminemia, pericardial cysts, diseases that cause radiographic enlargement of the cardiac silhouette (dilated cardiomyopathy, severe atrioventricular endocardiosis/valvular heart disease, etc.)

INITIAL DATABASE

- Careful abdominal palpation, assessment for a fluid wave
- Auscult heart and check for synchronous pulses.
- CBC, chemistry profile, urinalysis, coagulation profile
  - Anemia (regenerative or nonregenerative, depending on acuity) and hypoproteinemia are common due to blood loss (e.g., abdominal hemorrhage).
  - Schistocytosis (see pp. 1516 and) may be noted as a result of microangiopathic damage of red blood cells traveling through abnormal vessels in the neoplasm.
- Thoracic and abdominal radiographs
  - Mass effect is commonly apparent on abdominal radiographs; detail may be obscured by abdominal effusion.
  - Pulmonary metastasis of hemangiosarcoma can involve many (hundreds to thousands) 1-to 2-mm nodules, which appear radiographically in the lungs as an interstitial pattern.
  - Cardiac silhouette may be enlarged (globoid), indicating pericardial effusion.
  - Lack of globoid cardiac silhouette does not rule out pericardial effusion.
  - Cardiac silhouette rarely affected by presence of a mass lesion
- Abdominal ultrasound if suspected splenic or hepatic lesion (abdominal effusion/distension, abdominal mass). Utility of ultrasound for patients with a palpable abdominal mass:
  - Confirm presence of the mass, its organ of origin, and likelihood of resectability.
  - Identify lesions suggesting metastasis.
  - Identify abdominal fluid; if small in volume, guide needle abdominocentesis.
  - Identify internal structure of mass, indicating feasibility of fine-needle aspiration/core biopsy (mixed echogenicity and high vascularity contraindicate these procedures in hemangiosarcoma).
- Echocardiography:
  - Right atrial wall collapse (“sail sign;” the right atrial wall motion seen in pericardial tamponade resembles a sail flapping in the wind).
  - Diastolic collapse of RV wall if severe tamponade
  - Tumor mass or blood clot from bleeding tumor may be seen bobbing in fluid adjacent to or involving a thickened (infiltrated) right atrial/auricular wall.
  - Diminished right atrium, right ventricle, left ventricle volume
  - Swinging motion of the heart within the anechoic pericardial fluid
  - Mass seen occasionally within the right atrium; absence of mass does not exclude hemangiosarcoma because of limitations of imaging right auricle with routine (transthoracic) echocardiography.
  - Doppler evaluation of pulmonic flow shows large variation in beat-to-beat peak velocities.
- Electrocardiogram if an arrhythmia is present on physical exam, and if splenic involvement, cardiac involvement, or recent hemorrhage is evident. Most common arrhythmias include electrical alternans (25% of the time), diminished R wave amplitudes (50% of the time), arrhythmias (rare).
- Fine-needle aspiration cytology of regional lymph node in patients with cutaneous HSA.

ADVANCED OR CONFIRMATORY TESTING

- Surgical biopsy is the gold standard for diagnosis. The entire spleen should be submitted; some laboratories request it to be shipped chilled on ice (not frozen), whereas others request it be fixed in 10:1 ratio of formalin/tumor for 24-48 hours, after which the fixed tissues can be sent to the laboratory in a small amount of formalin.
- Contrast ultrasonography is becoming more widely used to assess the nature of ultrasonographically identified splenic and hepatic nodules. Metastatic liver nodules are characterized by a hypoechoic appearance, in contrast to benign nodules which are isoenhancing.
- Fine-needle aspiration cytology or cytologic evaluation of hemorrhagic fluids is rarely diagnostic. Fine-needle aspiration cytology of visceral masses may result in hemorrhage and is not recommended in cases of suspected splenic, cardiac, and any other noncutaneous form of hemangiosarcoma (see Pearls & Considerations below).
- Pericardial fluid pH: controversial. One study indicated pericardial pH > 7 as highly indicative of neoplasia and pericardial pH < 7 as highly indicative of benign effusion, whereas another study showed no such differentiation.
- Serum troponin-1 elevation suggests hemangiosarcoma. This blood test may be performed locally at a human hospital (human assay is accurate in dogs) or may be performed at referral veterinary laboratories.

TREATMENT

TREATMENT OVERVIEW

- Reduce tumor burden and prevent/minimize future hemorrhagic episodes.
- Relief of tamponade (palliative)
- Control metastatic disease.
- Prolong survival.

ACUTE GENERAL TREATMENT

- Cutaneous (either species):
  - Surgery to remove tumor
- Noncutaneous (either species):
  - If evidence of recent or ongoing hemorrhage: IV fluids ± oxygen ± transfusion (see p. 489)
  - Pericardiocentesis (see p. 1325) if pericardial effusion causing cardiac tamponade is present
  - Diuretics: contraindicated in acute pericardial effusion/cardiac tamponade
  - Once the patient is stable, surgery to remove the tumor or pericardectomy to prevent recurrence of tamponade

CHRONIC TREATMENT

- Feline and canine (cutaneous): surgery alone may be curative in most patients with dermal HSA. Margins should be at least 1-3 cm wide and 1 or more fascial planes deep.
- Feline and canine (noncutaneous and stage II cutaneous HSA):
  - Chemotherapy with a protocol of five doses of doxorubicin (dog, 30 mg/m^2 IV; cat, 25 mg/m^2 IV) given every 3 weeks. Special handling requirements and potentially severe or life-threatening adverse patient effects exist with this chemotherapeutic drug. Concerns and rapid evolution of protocols warrant consultation with/referral to an oncologist.
  - Consider adjuvant radiation therapy for patients with incompletely excised subcutaneous stage-II HSA.
- Canine visceral/noncutaneous HSA:
  - Metronomic chemotherapy with piroxicam (0.3 mg/kg PO q 24 h), etoposide (50 mg/m^2 PO q 24 h for 21 days, alternating every 3 weeks with cyclophosphamide), and cyclophosphamide (12.5-25 mg/m^2 PO q 24 h for 21 days, alternating every 3 weeks with etoposide) was more effective than 5 doses of doxorubicin (dosed as above) in one study.
- Canine cardiac HSA:
  - Subtotal pericardectomy (usually performed following second event of tamponade)
  - Right auricular ablation: removal of tumor mass (difficult and may not prolong life)
  - Right auricular ablation plus chemotherapy (see Prognosis and Outcome below)
  - Repeated pericardiocenteses

POSSIBLE COMPLICATIONS

- General chemotherapy toxicities: myelosuppression, GI upset
- Specific doxorubicin toxicities: allergic reaction during administration, perivascular sloughing with drug extravasation, cumulative myocardial toxicity (dogs) and heart failure, cumulative renal toxicity (cats)
- Specific cyclophosphamide toxicities: sterile hemorrhagic cystitis; administration concurrent with furosemide (1-2 mg/kg with each dose of cyclophosphamide) may prevent this side effect.
- Etoposide is a chemotherapy drug not widely used in veterinary medicine. No specific toxicities were noted in dogs treated at

the aforementioned dose.

RECOMMENDED MONITORING

- Feline and canine (cutaneous): recheck physical examination every 3-4 months.
- Feline and canine (noncutaneous): weekly CBC initially, thoracic radiographs every 1-2 months, abdominal ultrasound every 1-2 months
- Echocardiography 24 hours after pericardiocentesis; 1 week after pericardiocentesis, monthly thereafter

PROGNOSIS AND OUTCOME

- Feline and canine (cutaneous): <30% of patients with dermal (stage I) HSA will develop metastases, so complete surgical excision can be curative.
- Feline and canine (noncutaneous and stage II cutaneous):
  - Highly metastatic, so when treated with surgery alone, median survival may be only 2-3 months. There are occasional reports of patients surviving several months, but survival up to or beyond 1 year is very uncommon.
  - If all grossly detectable neoplastic tissue can be removed surgically, adjuvant chemotherapy may extend survival to a median time of 6 months.
  - If grossly apparent neoplastic tissue persists in postoperative period, median survival time approximates 2 months.
  - Adjuvant radiation therapy can be considered for patients with incompletely excised stage II cutaneous hemangiosarcoma, but limited data prevent any clear conclusions regarding benefit.
  - Right auricular ablation plus chemotherapy may prolong life (median survival in 8 dogs with right auricular ablation alone, 42 days versus in 8 other dogs with right auricular ablation plus chemotherapy, 175 days)

PEARLS & CONSIDERATIONS

COMMENTS

- Hemangiosarcoma is a locally aggressive, highly metastatic tumor that most often arises within the spleen, right atrium, or skin in dogs.
- Most often hemangiosarcoma of the liver is due to metastatic disease, since primary hepatic hemangiosarcoma is uncommon.
- Nodules of ectopic splenic tissue on the omentum, and regenerative hepatic nodules, are benign, dark-red/brown tissue nodules that must not be misinterpreted as hemangiosarcoma metastases during laparotomy in a patient with a splenic mass. Biopsy is advised to avoid misdiagnosis.
- Although rare in cats, this tumor has a similarly aggressive biological behavior.
- Fine-needle aspiration/cytologic evaluation and core biopsy are often unrewarding because of poor cellular yield and blood dilution. Both carry the real possibility of causing rupture of the tumor and potentially life-threatening hemorrhage and are therefore *contraindicated* for evaluation of masses when hemangiosarcoma is on the differential diagnosis list: masses of splenic, hepatic, renal, or cardiac origin that, on ultrasound exam, are of mixed echogenicity and may be highly vascularized based on color flow Doppler assessment.
- Fine-needle aspiration and cytologic evaluation may be considered for evaluation of skin masses for which hemangiosarcoma is on the differential diagnosis list, but diagnostic yield may be limited for the same reasons.
- Cutaneous hemangiosarcoma in both dogs and cats has a less metastatic behavior, and surgical excision may be curative.
- Even with doxorubicin chemotherapy, reported survivals are short (~6 months) in both species. The best chemotherapy protocol for the treatment of hemangiosarcoma remains unknown, as no randomized clinical trials have compared reported protocols. Combining doxorubicin with cyclophosphamide appears to be well tolerated and may provide longer survival times than doxorubicin alone. Adding vincristine to a doxorubicin and cyclophosphamide protocol is associated with more significant toxicity than with doxorubicin and cyclophosphamide or doxorubicin alone. Alkylating agents such as lomustine and ifosfamide may prove to have activity against this disease; however, large studies documenting efficacy are lacking. Experimentally, immunotherapy appears to be of benefit, but no effective immunotherapies are commercially available.

CLIENT EDUCATION

- Watch for recurrent signs associated with return of tamponade.
- Watch for signs of respiratory embarrassment associated with pulmonary metastasis.

PREVENTION

The development of cutaneous hemangiosarcoma is related to UV light exposure. Minimize sun exposure in animals with white or thin haircoats.

Hemangiosarcoma, Cardiac

Video Available on Website

BASIC INFORMATION

DEFINITION

Malignancy of vascular endothelial origin involving cardiac tissue as either a primary or metastatic site. The neoplasm usually is located in the right auricle but may be seen also in the atria and ventricles. Regardless of location, it usually causes a hemorrhagic pericardial effusion.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs: older adults, both sexes. Extremely rare in the cat.

GENETICS & BREED PREDISPOSITION: Dogs: genetics unknown, but golden retriever, German shepherd, rottweilers, greyhounds, and other large-breed dogs are overrepresented. Cats: rarely.

RISK FACTORS: Dogs: most common reason for pericardial effusion

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Cardiac tamponade due to intrapericardial hemorrhage from the tumor site
- Occasionally can be an incidental finding on echocardiography without associated clinical signs

HISTORY, CHIEF COMPLAINT: Three forms of presenting complaints (some overlap/combination possible):

- Acute collapse with pallor; may have partially resolved over preceding hours or days
- General malaise, lethargy, anorexia, exercise intolerance
- Visible abdominal distention

PHYSICAL EXAM FINDINGS

- Tachycardia, muffled heart sounds, thready/weak pulse, abdominal distension
- In some cases: jugular distension, pulsus paradoxus, positive hepatojugular reflux

ETIOLOGY AND PATHOPHYSIOLOGY

- *Primary*: usually seen as right atrial/auricular infiltration of neoplastic cells that grow on the epicardial surface and ultimately cause rupture of superficial myocardial vessels of varying sizes, triggering bleeding into the pericardial space. The result is cardiac tamponade when intrapericardial pressure exceeds right atrial and ventricular filling pressures.
- *Systemic:* seen as metastatic site from primary involvement of liver or spleen.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Recent-onset abdominal distension, and/or weakness coupled with physical exam findings of dull or muffled heart sounds and a thready weak pulse provide sufficient evidence to pursue thoracic radiography and echocardiography early in the patient evaluation process.

DIFFERENTIAL DIAGNOSIS

Other causes of pericardial effusion:

- Idiopathic benign pericardial effusion
- Other tumors such as chemodectoma, mesothelioma, lymphoma, pericardial teratoma

- Pericardial lipoma, granuloma, or abscess
- Hemopericardium (atrial rupture, anticoagulant rodenticide intoxication)
- Exudative/infectious pericarditis
- Congestive heart failure (right-sided)
- Peritoneopericardial diaphragmatic hernia
- Hydropericardium due to hypoalbuminemia
- Pericardial cysts
- Diseases that cause radiographic enlargement of the cardiac silhouette (dilated cardiomyopathy, severe, advanced atrioventricular endocardiosis/valvular heart disease, severe right ventricular enlargement)

INITIAL DATABASE

- CBC: regenerative anemia
- Serum chemistry: usually unremarkable unless hepatic involvement
- Electrocardiogram: electrical alternans (25% of cases), diminished R wave amplitudes (50% of cases), arrhythmias (rare)
- Thoracic/abdominal radiographs: enlarged globoid cardiac silhouette possible (80% of time), caudal vena caval distention, pleural effusion, ascites, hepatomegaly. With hemangiosarcoma, multifocal pulmonary metastases may appear as an interstitial pattern.
- Echocardiography: most accurate diagnostic test. (see two video clips)
  - Confirm presence of fluid accumulation between the epicardium and the pericardium.
  - Right atrial wall collapse (“sail sign”; the right atrial wall motion seen in pericardial tamponade resembles a sail flapping in the wind).
  - Diastolic collapse of RV wall if severe tamponade
  - Tumor mass or blood clot from bleeding tumor may be seen bobbing in fluid adjacent to or involving a thickened (infiltrated) right atrial/auricular wall.
  - Diminished right atrium, right ventricle, left ventricle volume
  - Swinging motion of the heart within the anechoic pericardial fluid
  - Mass seen occasionally in/on the right atrial wall in 83% of cases with skilled echocardiographer; absence of mass does not exclude hemangiosarcoma because of limitations of imaging right auricle with routine (transthoracic) echocardiography.
  - Doppler evaluation of pulmonic flow shows large variation in beat-to-beat peak velocities.
- Abdominal ultrasonography: evaluate liver, spleen, omentum for presence of primary neoplasia.

ADVANCED OR CONFIRMATORY TESTING

- Pericardial fluid cytology:
  - Typically indicates extensive bleeding and minimal exfoliation
  - Mainly useful to exclude infectious pericardial effusion and lymphoma
  - Cytologic evaluation alone is highly unreliable: 74% of malignancies not detected; 13% of benign pericarditis cases erroneously classified as malignant.
- Pericardial fluid pH: controversial. One study indicated pericardial pH > 7.0 as highly indicative of neoplasia and pericardial pH < 7.0 as highly indicative of benign effusion, whereas another study showed no such differentiation.
- Serum troponin-1 elevation suggests hemangiosarcoma. This blood test may be performed locally at a human hospital (human assay is accurate in dogs) or may be performed at some referral veterinary laboratories.
- Contrast CT/cardiac MRI/magnetic resonance angiography (MRA), transesophageal echocardiography (TEE)

TREATMENT

TREATMENT OVERVIEW

Pericardiocentesis with drainage of the pericardial effusion is a mandatory first step once the diagnosis is confirmed. Complete patient evaluation for evidence of neoplasia elsewhere is imperative once the emergency correction of tamponade has been achieved.

ACUTE GENERAL TREATMENT

- Pericardiocentesis and drainage of accumulated effusion (see p. 1325)
- Diuretics: contraindicated in acute pericardial effusion/cardiac tamponade

CHRONIC TREATMENT

- Subtotal pericardectomy (usually performed following second event of tamponade)

- Right auricular ablation: removal of tumor mass (difficult and may not prolong life)
- Right auricular ablation plus chemotherapy (see Prognosis and Outcome below)
- Repeated pericardiocenteses

POSSIBLE COMPLICATIONS

- Almost all cases have pulmonary metastasis at time of initial diagnosis even though they may not be detected by thoracic radiography.
- Additional tumor sites: liver, spleen, skin, ventricle, brain, kidney

RECOMMENDED MONITORING

- Echocardiography 24 hours after pericardiocentesis; 1 week after pericardiocentesis, monthly thereafter
- Thoracic radiographs monthly

PROGNOSIS AND OUTCOME

- Poor to grave: most patients have recurrent bleeding from the tumor site, requiring repeat pericardiocentesis; metastatic disease usually present.
- Right auricular ablation plus chemotherapy: may prolong life (median survival in 8 dogs with right auricular ablation alone, 42 days versus in 8 other dogs with right auricular ablation plus chemotherapy, 175 days)

PEARLS & CONSIDERATIONS

COMMENTS

- Life expectancy < 6 months
- Often the mass seen bobbing around within the pericardial fluid is actually an organized blood clot associated with tumor tissue invading the right atrial/auricular wall.

CLIENT EDUCATION

- Watch for recurrent signs associated with return of tamponade.
- Watch for signs of respiratory embarrassment associated with pulmonary metastasis.

AUTHOR: N. JOEL EDWARDS

EDITOR: ETIENNE CÔTÉ

Hemangiopericytoma

BASIC INFORMATION

DEFINITION

A common, locally invasive, slowly progressive tumor that occurs most commonly on the limbs of large-breed dogs; carries a fair to good prognosis with either complete excision or incomplete excision combined with radiation therapy

SYNONYMS

Malignant schwannoma, neurofibrosarcoma, peripheral nerve sheath tumor

EPIDEMIOLOGY

SPECIES, AGE, SEX: Common in middle-aged to older dogs; rare in cats

GENETICS & BREED PREDISPOSITION: Large-breed dogs may be overrepresented.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Most animals are presented for evaluation of a progressively enlarging mass noticed by the owner. Pets with hemangiopericytoma in certain locations may be presented because of clinical signs related to the location of the tumor (e.g., limb tumors may result in lameness).

PHYSICAL EXAM FINDINGS

- Visible or palpable mass, more commonly on the limbs (any location on the limbs)
- Mass is usually firm and fixed to underlying tissues. Occasionally, the mass can be hairless or ulcerated.
- Regional lymphadenopathy may be present secondary to inflammation caused by the tumor or (rarely) lymph node metastasis.
- The remainder of the physical examination typically is unremarkable.

ETIOLOGY AND PATHOPHYSIOLOGY

- Hemangiopericytoma has some histologic features similar to the tumor of the same name in humans, but the actual cell of origin of this tumor is disputed.
- Hemangiopericytomas are spontaneously occurring in most cases in dogs.
- Disturbance caused by hemangiopericytomas depends on the location of the primary tumor and invasion into and destruction of surrounding normal structures.
- Hemangiopericytomas are typically slow growing and slow to metastasize. Over time they can invade into surrounding soft-tissue structures.
- It is still unclear whether hemangiopericytomas, schwannomas, and nerve sheath tumors are identical or related but distinct tumors. Immunohistochemistry may be able to differentiate these similar tumor types, but since they have similar biological behavior, differentiating the specific tumor type may not add useful information.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis can only be confirmed via histopathology, although additional tests such as diagnostic imaging (e.g., CT or MRI) are often helpful in defining the extent of the tumor.

DIFFERENTIAL DIAGNOSIS

- Other soft-tissue sarcomas
  - Fibrosarcoma
  - Malignant fibrous histiocytoma

    - Others
- Mast cell tumors
- Other skin and subcutaneous tumors
- Benign or nonneoplastic masses
    - Benign tumor (e.g., lipoma)
    - Abscess
    - Elbow hygroma

INITIAL DATABASE

- Fine-needle aspiration and cytologic evaluation may help identify the tumor type before other diagnostics.
- Three-view thoracic radiographs to rule out pulmonary metastases
- Radiographs of the affected area may rarely reveal involvement of underlying bone.
- Fine needle aspirate of draining lymph nodes help rule out metastasis.

ADVANCED OR CONFIRMATORY TESTING

- Biopsy is the diagnostic procedure of choice.
    - Definitive diagnosis of hemangiopericytoma is based on histopathologic evaluation of the tumor tissue.
    - Biopsy is typically excisional, with removal of the entire tumor if possible or removal of the greatest feasible extent of tumor mass if not entirely resectable.
    - Incisional biopsy may be performed to obtain the diagnosis before treatment, especially in cases where multiple treatment modalities might be necessary (e.g., preoperative radiation).
    - Occasionally, special immunohistochemical stains may be necessary to differentiate hemangiopericytoma from other types of soft-tissue sarcomas, especially with poorly differentiated tumors.
- CT or MRI may be necessary to delineate the local extent of the tumor and plan for surgery or radiation therapy.
- Histopathologic grade of the tumor is necessary for determining prognosis and treatment of most soft-tissue sarcomas (see p. 1034). Although most hemangiopericytomas are low to intermediate grade, high-grade tumors can occur and may be more likely to metastasize.

TREATMENT

TREATMENT OVERVIEW

Definitive treatment is based on complete eradication of the primary tumor whenever possible. Since metastasis of this type of tumor is rare, additional treatment such as chemotherapy is rarely used but could be considered for high-grade tumors or tumors that have already metastasized. Palliative treatment options, such as palliative radiation, may help control pain or discomfort in patients with advanced tumors or in patients where definitive treatment cannot be tolerated.

ACUTE AND CHRONIC TREATMENT

- Aggressive surgical resection (aim: 3-cm margins; often not possible, especially on distal limb). Radiation therapy, and/or chemotherapy may be used (see p. 1034).
- Tumors that are incompletely resected or cannot be surgically resected (e.g., highly invasive or metastatic) may be treated with a combination of radiation therapy and surgery, which is associated with favorable long-term outcomes.
- Radiation therapy alone provides good long-term outcomes, although tumor control rates are higher with combined surgery-radiation therapy.
- Chemotherapy may be indicated for hemangiopericytomas that are high grade based on histologic features.

POSSIBLE COMPLICATIONS

Complications of treatment for hemangiopericytomas depend on types of treatments and location of primary tumor.

RECOMMENDED MONITORING

- Following appropriate local treatment of the primary tumor, routine followup up examination is indicated to monitor for local recurrence and metastasis. High-grade tumors may require more frequent monitoring for metastases during and after chemotherapy administration.
    - Dogs likely to develop metastasis (splenic tumors, high-grade tumors) should be monitored closely (every 2-3 months) with physical exam, including lymph node palpation and thoracic radiographs.
    - Dogs with low-or intermediate-grade tumors that have adequate treatment should have physical examinations done every 2-3 months or more frequently depending on risk of side effects from treatment. Thoracic radiographs could be

done less frequently (6 months and 1 year after therapy).

PROGNOSIS AND OUTCOME

- Prognosis is excellent for most hemangiopericytomas with appropriate treatment. This includes either complete surgical resection with clean histopathologic margins or incomplete resection combined with radiation therapy.
    - Combined surgery-radiation therapy treatment results in long-term tumor control in 86% of dogs with hemangiopericytoma. Survival times for dogs treated this way were >5 years, with 85% tumor free at 3 years.
    - Radiation therapy alone has resulted in 1-year tumor control rates of up to 75% at higher doses. However, these studies used suboptimal radiation dose schedules. In certain situations where surgery is not indicated, radiation may be used for providing some degree of tumor control.
- High-grade hemangiopericytoma is rare and information is limited regarding prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

Despite uncertainty about the cell of origin for these tumors, hemangiopericytoma, peripheral nerve sheath tumor, schwannoma, and neurofibrosarcoma generally have the same biological behavior and should be treated in the same way.

CLIENT EDUCATION

Pet owners can be educated to monitor their pets for the occurrence of masses under the skin and have such masses evaluated in a timely fashion. Early detection may allow for easier treatment via surgery and may help avoid the need for radiation therapy.

AUTHOR: JOHN FARRELLY

EDITOR: KENNETH M. RASSNICK

Helicobacter Gastritis

DEFINITION

EPIDEMIOLOGY

RISK FACTORS: Environmental conditions may play a role, as higher infection rates are found in shelter and colony dog and cats as compared to pets.

- The mode of transmission is unknown, although oral-oral and fecal-oral routes may occur. Vector transmission (flies) may occur. Waterborne infections may be important in certain areas' supplies. *Helicobacter* gastritis has zoonotic potential.
- One of the most important reasons for concern about *Helicobacter* infections in dogs and cats is the zoonotic potential for transmission to humans. Careful consideration is warranted because of the association of human *Helicobacter pylori* infection with human peptic ulcer disease and an increased risk of gastric cancer. Most evidence suggests this potential is very low, and although several species of *Helicobacter* may affect dogs and cats, *H. pylori* is very uncommonly isolated from cats and has not been isolated from dogs.

CLINICAL PRESENTATION

- Chronic vomiting, intermittent inappetence, and pica may be seen.

PHYSICAL EXAM FINDINGS: There are no specific findings on physical examination suggestive of *Helicobacter* gastritis.

- Multiple species of *Helicobacter* have been isolated from dogs and cats:
  - Cat: *H. felis, H. pamatensis, H. pylori, H. heilmanii*. Approximately 41%-100% of healthy cats and 57%-100% of vomiting cats have *Helicobacter*-like organisms.
  - Gastritis, erosion, and ulceration occur as a consequence of ammonia production (the bacteria produce urease) and other secretory products of the organism that damage epithelial cells and induce gastric acid secretion.

DIAGNOSTIC OVERVIEW

DIFFERENTIAL DIAGNOSIS

        - Gastric parasites
        - Foreign body
    - Nongastric diseases causing vomiting:
    - Systemic diseases (hypoadrenocorticism, hyperthyroidism, heartworm disease, renal disease, liver disease, neoplasia)
    - Drug therapy

      CBC, serum biochemistry profile, urinalysis, and fecal flotation are normal in *Helicobacter* gastritis but are indicated to identify other (systemic) causes of vomiting.

    - Noninvasive studies:
    - Serologic titers: not commercially available; specificity of 95% and sensitivity of 79% when ELISA and immunoblotting were used in combination.
  - Invasive studies:
  - Biopsy (endoscopic or surgical) and histologic evaluation: Warthin-Starry silver stains, Giemsa, or toluidine blue improve identification over routine H&E staining. Squash preps stained with Diff-Quik are useful for rapid identification.
  - Culture: least sensitive method, difficult to culture. Can identify antimicrobial sensitivity.

TREATMENT

Identification of *Helicobacter* organisms or other evidence of helicobacteriosis in dogs and cats warrants treatment if signs of gastritis are present and there is concurrent evidence of chronic gastritis. Eradication of the organism should be the goal for long-term resolution of clinical signs.

- Triple therapy: amoxicillin, 20 mg/kg PO q 12 h; metronidazole, 10 mg/kg PO q 12 h; and clarithromycin, 7.5 mg/kg PO q 12 h for 14 days (first choice)
- It should be noted that although combination antibiotic therapy is the treatment of choice, a combination of amoxicillin,

metronidazole, and bismuth subsalicylate resulted in eradication in only 75% at 4 weeks and 43% of treated dogs at 6 months. It is unknown whether therapeutic failure (lack of eradication) is related to an inability to clear the organism or reinfection. There are no studies reported on the efficacy of the author's listed first choice.

The prognosis is good for initial resolution of clinical signs if the gastritis is due to *Helicobacter* spp. infection. The chance for recurrence is high owing to failure to eradicate the infection or reinfection.

Heat Stroke/Hyperthermia

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Hyperthermia: elevation of the core body temperature. May occur as a result of exposure to endogenous pyrogens (i.e., fever) or may be the result of excessive external (heat stroke) or internal (muscle fasciculations, seizures) heat.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs, cats. Pediatric or geriatric animals are at higher risk.

GENETICS & BREED PREDISPOSITION: Increased likelihood in:

- Brachycephalic dog breeds; other upper airway obstructions such as laryngeal paralysis
- Obese patients
- Dark-colored or long haired dogs

RISK FACTORS

- Excessive muscle fasciculations:
  - Status epilepticus
  - Metaldehyde or garbage (mycotoxin) intoxication
  - Hypocalcemic tetany
- Excessive external heat/inadequate heat dissipation:
  - Exposure to high ambient temperatures, including enclosure in small spaces such as clothes dryers or cars
  - Vigorous exercise
  - Respiratory abnormalities such as brachycephalic syndrome or laryngeal paralysis
  - Obesity
  - Cardiopulmonary disease
- Endogenous pyrogens:
  - Sepsis
  - Febrile paraneoplastic syndrome
- Other:
  - Drugs such as phenothiazines, opioids (cats), cardiac medications, inhalant anesthetics (halothane), amphetamines, or macadamia nuts
  - Central nervous system lesions

GEOGRAPHY AND SEASONALITY: More common in early summer before heat acclimatization occurs (e.g., outdoors) or on hottest summer days (e.g., trapped in closed car)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Hemodynamic and respiratory stabilization of the patient is a priority and may need to precede the complete history taking.
- Dogs generally present due to excessive panting or collapse or after being found overheated.
- Most commonly, animals will present with a history of environmental exposure (outside on a hot day without access to shade, left in a car) or recent strenuous physical activity such as hunting, chasing, or seizures.
- It is helpful to obtain information suggesting laryngeal paralysis (recent voice change, upper respiratory stridor), dysphagia, cardiac medications, or prior seizure history to identify an underlying risk factor if possible

PHYSICAL EXAM FINDINGS

- Elevated rectal temperature:
  - Generally >40°C (105.8°F). Note that emergency treatment by owner before arrival may lower the rectal temperature so that the actual peak temperature is not known.
  - Altered mental status
- Hyperemic mucous membranes

- Increased respiratory effort and loud upper airway sounds
- Petechiae

ETIOLOGY AND PATHOPHYSIOLOGY

- Elevation of core body temperature results in activation of inflammatory cytokines, alters mitochondrial function, breaks down lipids within cell walls, denatures proteins and enzymes, and leads to cell necrosis.
- Pulmonary: disruption of pneumocytes of the alveolar endothelium and pulmonary capillary beds leads to protein-rich fluid accumulating within the alveolar space, altering surfactant and inciting additional inflammation, which in turn reduces gas exchange, increases the shunt fraction, and reduces pulmonary compliance. This can lead to noncardiogenic pulmonary edema (), severe hypoxemia, and acute respiratory distress syndrome ().
- Cardiovascular: hyperthermia, hypoperfusion and acidosis cause ischemia and necrosis of cardiac myocytes and Purkinje fibers, leading to ventricular arrhythmias (), conduction disturbances, and myocardial dysfunction.
- Hematologic: endothelial cells are particularly prone to thermal injury. When damaged, these cells release procoagulant factors, activate and/or destroy platelets, activate complement and clotting cascades, which causes a systemic inflammatory response and coagulation. Disseminated intravascular coagulation (DIC;) is a common cause of death in severely affected patients.
- Renal: acute kidney injury can occur as a result of direct thermal injury, microemboli, hypoxia, and hypoperfusion. Renal failure is common in severe heatstroke.
- Neurologic: excess inflammatory and endogenous cytokines and microemboli can result in cerebral edema and neuronal tissue death.
- Malignant hyperthermia is an extremely rare genetically based disorder involving rapid-onset hyperthermia, usually triggered by such specific agents as halothane or succinylcholine.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of hyperthermia is generally straightforward (markedly elevated body temperature), and diagnostic efforts are mainly aimed at identifying and monitoring secondary complications that occur in severe cases, and an inciting cause if one is not known from the history alone.

DIFFERENTIAL DIAGNOSIS

Hyperthermia: heat stroke, fever

INITIAL DATABASE

- Complete physical exam including neurologic examination (see p. 1311)
  - In heat stroke, mental status is important prognostically, as dogs that are obtunded are less likely to survive.
- CBC: hemoconcentration is common and can be severe. The presence of nucleated red blood cells occurs in up to 68% of cases. A neutrophilic leukocytosis is most common, but patients can also be leukopenic due to peripheral neutrophil chemotaxis and migration. Most animals (62%) are thrombocytopenic at admission, and 83% become thrombocytopenic during hospitalization.
- Serum biochemistry profile: elevation in creatinine kinase from muscle damage is the most common abnormality noted, occurring in nearly every case. Elevations in ALT, AST, and ALP are also very common but rarely affect patient outcome. Hypoglycemia and elevated creatinine values can occur in more than 50% of patients and are negative prognostic features.
- Prothrombin time (PT), activated partial thromboplastin time (APTT) are frequently prolonged in severely affected patients and these elevations are of negative prognostic value.

TREATMENT

TREATMENT OVERVIEW

Treatment goals:

- With obtunded/comatose patients, immediate intubation to secure a patent airway is paramount to improve gas exchange, provide additional oxygen supplementation, reduce the risk of aspiration. and allow for additional heat dissipation.
- Active cooling
- Determine etiology and treat underlying cause as needed.
- Manage complications such as DIC, acute renal failure, sepsis, or cerebral edema.

ACUTE GENERAL TREATMENT

- Lukewarm (room temperature) IV fluids and cool water baths to decrease temperature while avoiding excessive peripheral vasoconstriction. Additional cooling techniques can include infusing the bladder with sterile, lukewarm fluid or cold water gastric lavage. Peritoneal lavage invasive, time consuming, and not clearly superior.
  - Active external cooling should be discontinued once the rectal temperature reaches 103-103.5°F (39.2-39.4°C) to reduce the risk of severe hypothermia.
- Treat hypoglycemia () if present.
- Mannitol (20% injectable solution [200 mg/mL]: 0.5-1 g/kg given IV slowly over 15-20 minutes) may be used if increased intracranial pressure is suspected.
- Seizure activity should be managed with diazepam, 0.2-0.5 mg/kg IV, repeated up to three times; if ineffective, either phenobarbital (4 mg/kg IV q 30 minutes up to 16 mg/kg) or propofol continuous rate infusion (CRI) (6 mg/kg IV bolus followed by 0.1-0.2 mg/kg/min).
- Ventricular arrhythmias (see p. 1165) should be triaged and treated if necessary.
- Fresh frozen plasma (10-15 mL/kg) should be administered if coagulation times are prolonged or there is clinical evidence of bleeding.
- Broad-spectrum antibiotics such as cefazolin (22 mg/kg IV q 8 h), enrofloxacin (5-20 mg/kg IV q 24 h), and metronidazole (10-15 mg/kg IV q 12 h) are indicated empirically owing to venous pooling within the splanchnic circulation and risk for bacterial translocation.

POSSIBLE COMPLICATIONS

- DIC
- Acute renal failure
- Gastrointestinal sloughing/bacterial translocation
- Hepatic failure
- Other components of multiple organ dysfunction syndrome (MODS)
- Cerebral edema
- Bone marrow dysfunction may result in leukopenia and circulating nucleated red blood cells.

RECOMMENDED MONITORING

- Continuous ECG monitoring for changes in heart rate or worsening arrhythmia
- Frequent respiratory monitoring and blood gas evaluation as clinically indicated
- Serial neurologic evaluation
- Blood pressure monitoring (try to maintain systolic at >100-120 mm Hg) and blood glucose assessment (aim for 80-140 mg/dL) q 2-4 h as clinically indicated)
- Urine output (goal of >1-2 mL/kg/h)
- Coagulation times if initially prolonged or evidence of bleeding
- Platelet count

PROGNOSIS AND OUTCOME

- The prognosis associated with heatstroke varies widely depending on clinical severity at hospital admission. Animals recovering from heatstroke do not generally have any long-term side effects but may be at increased risk of future heatstroke.
- Initial body temperature has NOT been correlated with outcome.
- The following have been associated with a poor prognosis:
  - Coagulopathy (PT >18 sec, APTT >30 sec) at admission
  - Nucleated red blood cells >18/100 WBC
  - Hypoglycemia (<47 mg/dL)
  - Serum creatinine (>1.5 mg/dL) after 24 hours
  - Seizures
  - Delayed admission
  - Obesity

PEARLS & CONSIDERATIONS

COMMENTS

- Aggressive early cooling warranted

- Avoid overcorrection/hypothermia.
- Multiple organ failure including DIC is possible.

PREVENTION

Avoid exposing the animal to high ambient temperature or prolonged physical activity.

TECHNICIAN TIPS

- Avoid jugular venipuncture until patient coagulation status can be ascertained.
- Avoid hypothermia by discontinuing active cooling when temperature reaches 103°F-103.5°F (39.2-39.4°C).
- Monitor for recurrent respiratory distress upon extubation, particularly in those animals with brachycephalic syndrome or laryngeal paralysis. Prolonged intubation, temporary tracheotomy (see p. 1344) or definitive airway correction may be required.
- Placement of a urinary catheter and closed collection system allows for frequent, accurate calculation of urine output and characterization.

CLIENT EDUCATION

- Educate clients about the dangers of leaving dogs in cars on hot days, or prolonged exercise on hot days, or if upper airway diseases exist.
- Clinical signs such as weakness and panting in hot weather may be an emergency; institute cooling measures and consult a veterinarian.

Heartworm Disease, Dog

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Heartworm disease is the clinicopathologic manifestation of infestation with *Dirofilaria immitis,* an intravascular parasite that resides in the pulmonary arteries, and less often the right side of the heart and venae cavae. It results in pneumonitis, pulmonary endarteritis, pulmonary hypertension (PH), pulmonary thromboembolism (PTE), and/or cor pulmonale.
- An occult heartworm (HW) infection is defined as an infection in which microfilariae are not detectable in blood.

SYNONYM

Heartworm (HW) infection

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Wild and domestic canids most commonly; lower prevalence in cats
- Most dogs are 3-6 years old when diagnosed (uncommon in dogs <1 year old).

GENETICS & BREED PREDISPOSITION

- Sporting breeds are predisposed.
- Caval syndrome occurs most commonly in spring and early summer in middle-aged males housed outdoors.

RISK FACTORS

- Lack of HW-preventive drug administration in endemic areas. Most dogs become infected in summer.
- Signalment and lifestyle: for example, male outdoor dogs are more likely to become infected than female indoor dogs.

CONTAGION & ZOONOSIS: Human infections are rare (typically with aberrant migration), not directly associated with a specific heartworm-infected pet, and usually innocuous.

GEOGRAPHY AND SEASONALITY

- Throughout the United States, especially within 150 miles of the Gulf of Mexico and Atlantic coastlines and along the Mississippi River and its tributaries
- Also endemic in Australia, Japan, and some Mediterranean countries
- HW transmission is unlikely in regions or seasons where the ambient temperature does not average more than 65°F (18°C) during a 30-day period.
- Prophylactic failures (often with presumed good client compliance) have been noted along the Mississippi River Delta. One explanation is macrolide resistance, although this has yet to be confirmed.

ASSOCIATED CONDITIONS & DISORDERS

- Aberrant migration of larvae can result in neurologic, dermatologic, and ophthalmic complications.
- Retrograde migration of part of the worm burden into the right atrium and cavae can result in heartworm caval syndrome (common in highly endemic areas), a serious complication involving entanglement of a worm mass in the tricuspid valve apparatus, causing intravascular hemolysis, an acute-onset murmur of tricuspid regurgitation, and signs of forward (hypoperfusion) and backward (congestive) heart failure.
- PTE may be due to dead worms (natural or pharmacologic death) or intravascular thrombi formed as a consequence of the infection.
- PH can occur secondary to pulmonary vascular disease and may result in congestive heart failure (CHF), hemoptysis, and exercise intolerance.
- CHF (uncommon) with signs of right-sided heart failure (ascites and occasionally pleural effusion)
- Allergic pneumonitis (somewhat common) and eosinophilic granulomatosis (rare)
- Glomerulonephritis (virtually all dogs with HW infection; typically mild)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Class 1: few or no overt clinical signs. Class 2: moderate clinical signs. Class 3: severe clinical signs. Class 4: caval syndrome.

HISTORY, CHIEF COMPLAINT

- Most dogs with HW infection are in class 1 and show no clinical signs. HW infection is detected as part of routine blood screening.
- When clinical signs exist, coughing is the most common complaint.
- Other complaints include exercise intolerance, weight loss, syncope or collapse, and manifestations of right-sided congestive heart failure induced by pulmonary hypertension.
- Acute dyspnea secondary to PTE.

PHYSICAL EXAM FINDINGS

- Dogs not showing overt clinical signs to the owner usually have no abnormal physical examination findings.
- Spontaneous or inducible cough possible upon tracheal palpation.
- A split second (S^2) heart sound may be heard if severe pulmonary hypertension is present.
- Jugular venous pulsations and a right apical holosystolic murmur indicate tricuspid regurgitation (a harsh-sounding murmur is often present with caval syndrome).
- Palpable fluid wave (ballottement) if abdominal distention (ascites), and jugular venous distention if CHF
- Discolored urine (from hemoglobinuria), murmur of tricuspid regurgitation, tachypnea/dyspnea, collapse, and right-sided CHF and/or left-sided forward failure indicate caval syndrome.

ETIOLOGY AND PATHOPHYSIOLOGY

- Female mosquitoes serve as intermediate hosts after feeding on microfilaria-positive dogs.
- Microfilariae develop within the mosquito into L3 larvae and can infect another dog within 2-2.5 weeks.
- Patent infection (microfilaremia) occurs 6-7 months after inoculation of susceptible host by infective (L3) larvae.
    - Occult (amicrofilaremic) infections exist during this a prepatent period; other causes of occult infection include immune-mediated microfilarial destruction, unisex infections, acute high-dose or chronic macrolide prophylactic administration.
- Disease severity is determined in part by the duration of infection, number of adult HW, the host's response to live and dead heartworms, and amount of exercise.
- *Wolbachia* sp. (an obligate intracellular gram-negative bacterium) appears to have a symbiotic relationship with *D. immitis* and may exacerbate the inflammatory response by releasing endotoxins and antigens associated with worm death.
    - *Wolbachia* sp. are necessary for *D. immitis* reproduction.
    - Microfilariae produced in absence of *Wolbachia* sp. do not become infective in the mosquito.
- Response of the pulmonary arteries:
    - Damage from direct contact and other mechanisms (e.g., immune mediated) to vessel intima
    - Villous proliferation of the intima and subintimal smooth muscle
    - Pulmonary hypertension: results from obstruction to blood flow (PTE) and reduced vascular compliance induced by endothelial and medial thickening and probably biological incompetence (failure of damaged vessels to respond to vasodilatory stimuli)
    - Results in dilated pulmonary arteries that can be tortuous and truncated
- Response of the pulmonary parenchyma:
    - Deposition of HW antigen within the microvasculature causes parenchymal immune/allergic reactions (periarterial edema and inflammation).
    - Corticosteroid-responsive allergic pneumonitis in 14% of HW infections
    - Severe chronic HW infection causes irreversible pulmonary fibrosis with PH.
- Cardiac response:
    - Right ventricular enlargement secondary to moderate-severe PH and subsequent tricuspid regurgitation and myocardial failure
    - Right-sided congestive heart failure (ascites) in up to 50% of severe HW infections
- Systemic response:
    - Renal: glomerulonephritis, proteinuria, hypoalbuminemia, and decreased antithrombin III (increases pulmonary thromboembolic risk)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is made in one of two contexts: an incidental finding of a positive antigen test in an overtly healthy dog (more common) or overt clinical signs caused by infection-related secondary lesions. The antigen test is the confirmatory test of choice, and additional testing is indicated based on severity of physical signs and thoracic radiographic changes.

DIFFERENTIAL DIAGNOSIS

- Microfilaria: *Acanthocheilonema reconditum* (formerly *Dipetalonema reconditum)* microfilariae are shorter, narrower, and have a blunted head when compared to *D. immitis* microfilariae.
- Coughing: primary bronchointerstitial disease, collapsing trachea, infectious tracheobronchitis, pneumonia, left-sided congestive heart failure
- Pulmonary hypertension: PTE (due to other causes); chronic pulmonary disease; cyanotic right-to-left shunting cardiac disease such as patent ductus arteriosus and ventricular septal defect with primary or secondary PH; and primary PH.
- CHF: primary or secondary myocardial failure, chronic congenital or acquired valvular disease
- Pulmonary granulomas: primary and metastatic neoplasia

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: evidence of hemolysis and hemoglobinuria if class 4 (caval syndrome). Pathologic proteinuria common due to glomerulonephritis; may be reversible with treatment.
- Electrocardiography may demonstrate a right axis shift (prominent S waves in leads I, II, III, and V3, indicating PH and right ventricular enlargement) and/or atrial or ventricular arrhythmias in moderate to severe cases.
- Thoracic radiographs
    - Dilated and sometimes tortuous, truncated pulmonary arteries
    - Patchy mixed interstitial-alveolar pattern with perivascular infiltrates demonstrated primarily in caudal lung lobes
    - Right heart enlargement
    - Enlarged caudal vena cava if CHF is present or imminent

ADVANCED OR CONFIRMATORY TESTING

- HW antigen tests (ELISA and immuno-chromatographic) are specific, sensitive, and some are semiquantitative.
    - False-negative results with low female worm burdens or immature infections
- Microfilaria: filter and modified Knott's tests preferred over wet direct blood smear.
    - Only indicated if no history of macrolide heartworm prophylaxis and patent infection is suspected
    - Indicated to ascertain presence of microfilariae in dogs with HW infection before institution of therapy
- Echocardiography for moderate to severe HW infection to assess PH and caval syndrome:
    - Dilated pulmonary arteries
    - Parallel linear hyperechoic densities in pulmonary arteries (and sometimes the right heart and venae cavae) with large worm burdens
    - Right ventricular eccentric and concentric hypertrophy with flattened intraventricular septum in severe cases
    - High-velocity tricuspid regurgitation or pulmonic insufficiency on echo-Doppler with PH (TR Vmax greater than 3 m/s)

TREATMENT

TREATMENT OVERVIEW

- Eliminate worm burden and microfilariae (if present).
- Address complications.
- Prevent future infection.

ACUTE GENERAL TREATMENT

- Pulmonary thromboembolism:
    - Oxygen therapy (oxygen cage at 40% O2 or nasal insufflation at 50-100 mL/kg) (see p. 1318)
    - Cage rest
    - Corticosteroids (prednisone, 1 mg/kg PO q 24 h for 7-10 days)
    - Antithrombotic therapy (aspirin, 2.5-5 mg/kg PO q 12 h; or heparin, 75 IU/kg SQ q 8 h for 5 to 7 days or until the platelet count normalizes) is controversial.
- Allergic pneumonitis: cage rest and corticosteroids (prednisone, 1 mg/kg PO q 24 h for 7-10 days)
- Adulticide therapy:
    - Melarsomine (Immiticide):
        - Up to 96% efficacy after two doses; 50% of worm burden killed after a single dose
        - Plan A: melarsomine administered once at 2.5 mg/kg IM, followed by two injections at 2.5 mg/kg 24 hours

apart, given 1-3 months later (authors' preference)
- Plan B: melarsomine administered as two 2.5 mg/kg IM injections given 24 hours apart
- Strict adherence to manufacturer's instructions for intramuscular injection of arsenical agent.
- Consider corticosteroids (prednisone, 1 mg/kg PO q 24 h) or administration of a nonsteroidal antiinflammatory drug (NSAID) at manufacturer's recommended dosage at the time of IM injections to reduce injection site inflammation.
- Ideally, during the transmission season, adulticide therapy should follow 2-3 months of prophylactic therapy.
- Doxycycline (10 mg/kg PO q 24 h) may be administered for 1 month prior to and possibly for 2 weeks after each round of adulticide therapy.
- Exercise restriction for 4-6 weeks after melarsomine injections

- Macrolides as adulticides:
  - Recent studies suggest that an aggressive (off-label) macrolide protocol (ivermectin 6 mcg/kg PO weekly), coupled with a complex regimen of doxycycline (10 mg/kg PO q 24 h from weeks 0-6, 10-12, 16-18, 22-26, and 28-34) will hasten worm death (~80% within 8-9 months) in experimental transplanted HW infections.
  - Ivermectin and selamectin at preventive dosages have a 40%-100% efficacy against young HW infections when administered continuously for 18 or 31 months, respectively.
  - Milbemycin: modest adulticide activity
  - Pulmonary and vascular manifestations of HW infection still result during macrolide adulticide therapy, especially if patient is active.
  - Ivermectin at preventive dosage, with or without doxycycline, is reserved for cases in which financial constraints or concurrent medical problems prohibit melarsomine therapy; should be used only after assurance that microfilariae are cleared (to reduce risk of parasite resistance).

- Worm embolectomy:
  - Blind or fluoroscopically (or sonographically) guided surgical removal of HW from the venae cavae and right heart with alligator forceps, an endoscopic basket retrieval device, or loop snare device
  - Avoid damaging the HW when extracting them (PTE and/or anaphylactoid reaction)
- Microfilaricide therapy:
  - No agent is currently approved by the U.S. Food and Drug Administration for the elimination of microfilariae.
  - Macrolide therapy:
    - Ivermectin: 0.05 mg/kg (about eight times the preventive dose). Ivermectin (Ivomec) diluted 1:9 in propylene glycol or sterile water, administered orally at 1 mL/20 kg. Strongly discouraged by the American Heartworm Society.
    - Milbemycin: 0.5-0.99 mg/kg PO (same as preventive dose)
  - Adverse reactions in approximately 10% receiving microfilaricidal dosage:
    - Shock, depression, hypothermia, and vomiting
    - Fluid and corticosteroid (dexamethasone, 2-4 mg/kg IV) therapy if severe
    - Diphenhydramine (2 mg/kg IM) and dexamethasone (0.25 mg/kg IV) administered prophylactically to prevent adverse reactions
  - The authors' recommendation for microfilaricidal therapy is to initiate routine macrolide prophylactic therapy at the time of diagnosis, to be accompanied or followed by adulticide therapy, depending on season (see Adulticide therapy, above). The clearance of microfilariae should be confirmed.
    - Ivermectin, selamectin, or moxidectin may be used (see Chronic Treatment below) as "slow microfilaricides."
    - Milbemycin is more rapidly microfilaricidal at the preventive dosage. Patients should be hospitalized, pretreated as described above using diphenhydramine and dexamethasone, and observed for 8 hours for adverse reactions.

CHRONIC TREATMENT

- Preventive therapy:
  - Wide window of efficacy with up to 2-month "reachback effect" (elimination of developing larvae that have been in the dog for 2 months).
    - "Reachback effect" can be extended to 3 months with continuous 12-month administration. Extent of "reachback effect" may vary temporally and geographically.
  - Ivermectin (Heartguard): 6-12 mcg/kg PO monthly; *or*
  - Selamectin (Revolution): 6-12 mg/kg topically monthly; *or*
  - Milbemycin (Interceptor): 0.5-0.999 mg/kg PO monthly; *or*
  - Moxidectin/imidacloprid topical (Advantage Multi; imidacloprid 10 mg/kg, moxidectin 2.5-6.8 mg/kg topical monthly) or moxidectin injectable (Proheart 6; 0.17 mg/kg SQ every 6 months)
    - Preventive doses are gradually microfilaricidal; see above for precautions.
    - Package insert states that injectable moxidectin should not be administered to HW+ dogs.
- Congestive heart failure: see pp. 468, 470
- Pulmonary hypertension: see p. 935
  - Adulticidal therapy when deemed safe

POSSIBLE COMPLICATIONS

- Injection site inflammation (adulticide)
- PTE

PROGNOSIS AND OUTCOME

- Good in mild to moderate HW infections
- Fair to guarded in severe cases
- Poor to grave even with treatment in caval syndrome, severe PTE, and CHF

PEARLS & CONSIDERATIONS

COMMENTS

- Virtually all infected dogs are candidates for adulticide therapy (exception: surgical removal of worms in class 4/caval syndrome patients or those undergoing severe PTE or CHF in which increasing worm death will worsen situation).
- Macrolide “slow-kill” adulticide method using preventive drugs rather than melarsomine is easier but does not prevent pathologic response and potentially permanent or life-threatening lesions from HW infection. It also may contribute to the problem of resistance.
- Exercise restriction is an extremely important part of HW infection therapy.

CLIENT EDUCATION

- HW infection is a preventable disease.
- Most preventives are broad-spectrum antiparasitic drugs.
- Importance of year-round preventives:
    - Enhanced “reach-back effect”
    - Adulticidal effect
    - Other parasiticidal effects
    - Reduced issues of compliance

Heartworm Disease, Cat

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Heartworm disease (HWD) is the clinico-pathologic manifestation of infestation with *Dirofilaria immitis,* an intravascular parasite that resides in the pulmonary arteries, the right side of the heart, and venae cavae. This infestation results in pneumonitis, pulmonary endarteritis, pulmonary thromboembolism (PTE), and uncommonly, pulmonary hypertension (PH) with/without cor pulmonale.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Felids are atypical hosts for this canine parasite.
- There is no age predilection (range 1-17 years).
- Male cats generally have an increased risk of exposure and have a higher incidence than females when infected experimentally.

RISK FACTORS

- Cats not receiving heartworm (HW) preventative in endemic areas are at risk, with varying seasonal individual risk determined by season of the year and geographic location.
- Outdoor cats are predisposed, but indoor cats are also at risk (up to one quarter of cats with HWD are indoor cats).
- Feline leukemia virus and feline immunodeficiency virus are not predisposing factors.

CONTAGION & ZOONOSIS: Cats with mature heartworm infection do not provide a threat of transmission to other cats, dogs, or humans (see p. 477).

GEOGRAPHY AND SEASONALITY

- The frequency of feline HW infection correlates with that of dogs in the same geographic region but at a lower incidence (infection rate is 5%-20% that of the dog).
- Reported worldwide and is endemic throughout most parts of the United States
- HW transmission is unlikely in regions or seasons where the ambient temperature does not average over 65○F (>18°C) during a 30-day period.
- Prevalence: in shelter cats (up to 14%) and 9% in pet cats presented for cardiorespiratory signs (26% of these cats were HW antibody positive, indicating HW exposure). Nationwide in the United States, exposure rate likely exceeds 12%.
- Clinical signs associated with early infection occur in late fall and early winter.

ASSOCIATED CONDITIONS & DISORDERS

- Aberrant migration of larvae more common in cats (neurologic, dermatologic, and ophthalmic complications)
- Heartworm-associated respiratory disease (HARD): clinical and histopathologic findings of cats when they abort infections before heartworm maturation (“pulmonary larval dirofilariasis”).
- Pulmonary thromboembolism (PTE) may be due to dead worms (natural or pharmacologic death) or intravascular thrombi formed in response to the infection, resulting in vascular occlusion, infarction, and sometimes acute respiratory death.
- Pulmonary edema, often fulminant, with pulmonary thromboembolism possibly representing acute respiratory distress syndrome (ARDS). This may result acutely after adult worm death.
- Eosinophilic pneumonitis with cough, wheezing, dyspnea
- Congestive heart failure (CHF) is uncommon; signs of right-sided heart failure occur, usually a pleural effusion (either hydrothorax or chylothorax) and/or ascites.
- *Wolbachia* sp. (see p. 477): vital for filariae reproduction and possible contributor to pulmonary lesions; elimination of this symbiotic bacterium may play a role in adulticide therapy.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Clinical classification: (1) no clinical signs, (2) acute or peracute, and (3) chronic (most common)
- Most feline HW infections are occult infections, defined as an infection in which microfilaria are not detectable; microfilaremia in cats is uncommon (<20%), inconsistent, and transient.

HISTORY, CHIEF COMPLAINT

- ≈28% of cats with HW infection show no clinical signs.
- Chronic signs usually predominate (cough [38%], dyspnea [48%], vomiting, anorexia, weight loss, lethargy, exercise intolerance, and rarely, right-sided CHF).
- Acute signs include tachypnea/dyspnea secondary to PTE or severe pneumonitis or ARDS. Sudden death occurs in approximately 10%.

PHYSICAL EXAM FINDINGS

- Usually nonspecific. There appears to be no correlation between the clinical signs, physical examination, and radiographic changes.
- Adventitial lung sounds may be present.
- An audible heart murmur and/or gallop rhythm is uncommon and CHF is rare. Jugular venous distention, dyspnea, diminished lung sounds, and (rarely) ascites may be detected if CHF is present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Female mosquitoes serve as intermediate hosts after feeding on microfilaria-positive dogs.
- Being an atypical host, cats have an inherent resistance.
    - Lower worm burdens (usually fewer than 6, typically 1 to 3)
    - Shortened worm patency period
    - High frequency of amicrofilaremia or low microfilaria counts
    - Shortened lifespan of adult heartworms (2-3 years, although some new information suggests that worms may live up to 4 years).
- Disease severity is determined in part by the number of adult HW and the host's response to live and dead heartworms.
    - Pulmonary response is more severe in cats compared to dogs.
    - Clinical signs can be seen prior to maturation of the larvae (HARD).
- Response of the pulmonary arteries, pulmonary parenchyma, and air spaces
    - Eosinophilic infiltrates predominate.
    - Pulmonary arterial medial and intimal hypertrophy with or without thrombosis, often resulting in obliteration of the vascular lumen
    - Altered vascular permeability allows plasma leakage, producing noncardiogenic pulmonary edema (ARDS) which is typically fatal.
    - Chronic changes can result in diminished pulmonary function, hypoxemia, dyspnea, and cough.
- Acute or sudden death of affected cats is typically associated with adult worm death and resultant respiratory failure.
    - Lungs are considered to be the “shock organ” in feline HW disease.
    - Immune-mediated reaction to HW antigens produces bronchiolar and bronchial constriction, pulmonary congestion and interstitial edema, acute inflammatory interstitial disease, superficial pulmonary hemorrhage, and periarterial hemorrhage with subsequent fatal respiratory failure.
    - Heartworm embolism
        - Smaller feline pulmonary arterial tree with less collateral circulation is more susceptible to worm embolization with subsequent pulmonary infarction.
        - May contribute to episodes of dyspnea and/or sudden death

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis should be suspected when a cat in an endemic geographic area demonstrates signs of respiratory dysfunction or other systemic signs if differential diagnoses that are more likely have been ruled out. Serum antibody testing, thoracic radiography, and echocardiography each may contribute to confirming the diagnosis, and the tests are selected in sequence depending on availability and cost.

DIFFERENTIAL DIAGNOSIS

- Cat with respiratory signs:
    - Bronchitis or asthma

- Lungworms *(Aelurostrongylus abstrusus)*
- *Paragonimus kellicotti* infection
- Pleural effusions (pyothorax, hydrothorax, chylothorax, or neoplastic)
- Pneumothorax

- Cat with neurologic signs (brain or spinal cord):
  - Various inflammatory, ischemic, neoplastic, or degenerative diseases of central nervous system
- Cat with gastrointestinal (GI) signs:
  - Various systemic diseases such as primary GI disease, neoplasia, hyperthyroidism, and renal failure

INITIAL DATABASE

- CBC, chemistry profile, urinalysis
  - Mild nonregenerative anemia or eosinophilia in about 33%
  - Basophilia is highly suggestive, but rare.
- Tracheal wash or bronchoalveolar lavage may contain eosinophils with or without the presence of peripheral eosinophilia.
- Fecal examination for lung parasites (flotation, sedimentation, Baermann procedure)
- Electrocardiography may demonstrate a right axis shift and/or atrial or ventricular arrhythmias in severe cases (uncommon).
- Imaging:
  - Thoracic radiographs (variable findings depending on duration of infection and HW infection severity).
    - Enlarged and sometimes torturous, truncated caudal pulmonary arteries. Right heart enlargement, common in dogs, is unusual in cats.
    - Patchy mixed interstitial-alveolar pattern with perivascular infiltrates (primarily in caudal lung lobes)
    - Radiographic vascular findings are transient.
    - Mimics asthma with bronchovascular pattern and pulmonary hyperinflation

ADVANCED OR CONFIRMATORY TESTING

- The diagnosis of HW infestation/disease in cats can be difficult and often requires an elevated index of suspicion and serial application of diagnostic tests.
- Microfilaria: Most cats are amicrofilaremic. Filter and modified Knott's tests preferred over wet direct blood smear. A positive result is uncommon but diagnostic.
- HW antibody tests:
  - Used in the detection of *exposure* to HW and possible HARD or mature HWI; does not prove ongoing infection
  - Used for “ruling out” HW infection in cats with compatible signs. However, at least 14% of cats with mature HW infection may be antibody-negative.
  - Approximately 2% of HW-infected, antibody-negative cats are HW antigen positive.
- HW antigen tests (ELISA and immuno-chromatographic; assess for antigen elaborate by adult female HW) are specific, and some are semiquantitative. A positive result is diagnostic.
  - High number of false-negative results due to low female worm burdens or immature infections.
  - Recently an antigen test for felines has been marketed (adaptation of the canine test with reported 15% increase in sensitivity; IDEXX SNAP Feline Heartworm Antigen test).
  - Clinical signs can occur *before* the presence of detectable HW antigen.
- Echocardiography:
  - Dilated pulmonary arteries
  - Parallel linear hyperechoic densities in pulmonary arteries, the right heart and/or the venae cavae
  - HW found with echocardiography in 78% of 9 naturally infected cats in one study.

TREATMENT

TREATMENT OVERVIEW

- Address complications.
- Prevent future infection.
- Adulticide therapy is generally not recommended.

ACUTE GENERAL TREATMENT

- Cats with HW infection should receive HW preventive medication (see Chronic Treatment, below) and short-term corticosteroids (prednisone, 1-2 mg/kg PO q 8-48 h) can be used for managing respiratory signs.
- Emergency therapy for acute dyspnea:
  - Oxygen therapy (oxygen cage at 40% O2 or nasal insufflation at 50-100 mL/kg; see p. 1318)
  - Cage rest

- Corticosteroids (dexamethasone, 1 mg/kg IV or IM; or prednisolone sodium succinate, 50-100 mg/cat IV)
- Bronchodilator therapy (aminophylline, *6.6* mg/kg IM q 12 h)
- Antithrombotic therapy: aspirin (80 mg PO q 72 h) is controversial.

- Worm embolectomy
  - Can be considered, although mortality rates in one report (2 of 5) thought to be unacceptable
- Microfilaricide therapy
  - No agent is currently approved by the U.S. Food and Drug Administration for the elimination of microfilaria.
  - The authors' recommendation for microfilaricidal therapy is to initiate macrolide prophylactic therapy at the time of diagnosis.
    - Ivermectin (Heartguard): 25 mcg/kg PO monthly, *or*
    - Selamectin (Revolution): 6-12 mg/kg topically monthly, *or*
    - Milbemycin (Interceptor): 2 mg/kg PO monthly
      - Preventive doses are microfilaricidal.
      - Patients with microfilaria should be observed at home or hospitalized possibly, pretreated with diphenhydramine and dexamethasone, and observed for 8 hours for adverse reactions.
  - Imidacloprid-moxidectin (Advantage Multi): 10 mg/kg imidacloprid and 1 mg/kg moxidectin applied topically monthly

CHRONIC TREATMENT

- Preventive therapy:
  - Ivermectin (Heartguard): 25 mcg/kg PO monthly
  - Selamectin (Revolution): 6-12 mg/kg topically monthly
  - Milbemycin (Interceptor): 2 mg/kg PO monthly
    - Preventive doses are microfilaricidal; risk of anaphylactic reaction in cats with microfilaremia (although infrequent owing to low microfilarial numbers).
  - Imidacloprid-moxidectin (Advantage Multi): 10 mg/kg imidacloprid and 1 mg/kg moxidectin applied monthly
- CHF:
  - Conventional therapy, individualized to patient needs:
    - Furosemide (2-3 mg/kg PO q 8-12 h)
    - Spironolactone (1-2 mg/kg PO q 12-24 h)
    - Angiotensin-converting enzyme inhibitor (enalapril, 0.5 mg/kg PO q 12-24 h)
    - Periodic abdominocentesis/thoracocentesis
    - Oxygen therapy
    - Extreme exercise restriction
    - Amlodipine (0.1-0.2 mg/kg PO q 24 h) to reduce pulmonary hypertension
- Eosinophilic pneumonitis:
  - Corticosteroids (prednisone, 2 mg/kg/day, tapering over 4 weeks; reinstitute as needed at lowest q 48 h dosage that maintains the cat free of clinical signs).
  - Bronchodilators (optional; aminophylline, *6.6* mg/kg IM q 12 h)

PROGNOSIS AND OUTCOME

- Good in mild to moderate HW infestations.
  - For most patients that survive the initial insult, the median survival time may be much greater than 1 year.
- Fair to guarded in severe cases.
- Overall, prognosis similar to hypertrophic cardiomyopathy, which shares a median age of diagnosis with HW infection of roughly 6 years.
- Recent studies suggest that some cats remain asymptomatic and self-cure, with the infection often unrecognized.

PEARLS & CONSIDERATIONS

COMMENTS

- Preventive therapy is indicated in cats that are in HW-endemic areas.
- Signs may be peracute, acute, chronic, or absent in cats with HWI.
- Most often signs are respiratory.
- Consider HWI whenever feline bronchial disease is suspected.
- Cats which resist mature infection may still develop clinical signs produced by immature heartworms.
- Adulticide therapy is generally not recommended.
- Diagnosis may be difficult, requiring a high index of suspicion and multiple tests including HW antibody tests, HW antigen tests, thoracic radiography, and echocardiography.

CLIENT EDUCATION

- HW infection is a preventable disease.
- Most preventatives are broad-spectrum antiparasitic drugs.
- Importance of year-round preventatives
    - Issues of compliance

Heart Murmurs

BASIC INFORMATION

DEFINITION

Normal blood flow in the circulatory system is laminar in nature and very quiet. When laminar flow through the heart is altered, turbulence develops, causing a sound that can be heard: a heart murmur. This can be most easily likened to a slow-flowing, wide river undulating quietly back and forth. Suddenly an obstruction such as a large boulder is placed in the river, and now the quiet river becomes a noisy one as the water flows around the rock creating turbulence.

EPIDEMIOLOGY

SPECIES, AGE, SEX: A heart murmur is a clinical sign which may develop in any animal. Pathologic murmurs caused by structural heart lesions generally increase in intensity with age and disease progression. “Benign” heart murmurs of young, growing dogs and cats are noted to be:

- Soft (grade II/VI or less)*
- Systolic*
- Point of maximal intensity: left hemithorax*
- Abolished with an increase in heart rate or change in body position
- Disappear by age 16 weeks

* Can also occur with a murmur caused by a congenital heart malformation

GENETICS & BREED PREDISPOSITION: Many breeds are predisposed to congenital heart malformations that are associated with heart murmurs (e.g., patent ductus arteriosus, subaortic stenosis, pulmonic stenosis, ventricular septal defect, tricuspid dysplasia, etc.) and adult-onset disorders, some of which have a heritable basis (myxomatous mitral valve disease, dilated cardiomyopathy etc.).

RISK FACTORS

- Heart murmurs are associated with diseases of the heart (myocardium, heart valves, the endothelial lining of the heart) and great vessels.
- Heart murmurs of secondary cardiac origin are associated with noncardiac entities such as fever, anemia, hyperthyroidism, extreme thinness or obesity, and pregnancy. These murmurs are systolic, soft (<III/VI), and more intense on the left side.
- Heart murmurs develop with congenital and acquired heart defects.
- Physiologic murmurs are rare in adult dogs and cats; this is a murmur present in the absence of any cardiac or systemic abnormalities. Dynamic right ventricular outflow turbulence (dRVOT) has been described in the cat, and is associated with obstruction to flow in the ventricle; clinical consequences may develop over time.
- Murmurs may also be identified in the veins and arteries under circumstances that cause nonlaminar flow, such as arteriovenous fistulas or extravascular partial obstructions.
- Systemic infection may cause bacterial endocarditis (see p. 346).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Heart murmurs may be noted during a routine examination in a patient that is otherwise well. The goal is to identify the cause of the murmur (may be highly suggestive based on signalment, history, and exam, or may require diagnostic testing).
- Heart murmurs may be noted in a patient that is systemically ill (e.g., anemic). Ascertain whether the murmur can be explained by the systemic illness alone (see Risk Factors) or whether an underlying heart problem is coexistent (e.g., endocarditis).
- Heart murmurs may be noted in patients with overt signs compatible with heart disease (dyspnea, exercise intolerance, collapse, signs of thromboembolism). The murmur is a clue that these generalized signs may be caused by a heart problem, and that cardiac diagnostic testing is indicated.

PHYSICAL EXAM FINDINGS

- Murmurs should be identified during the physical examination process. Using the stethoscope, the dog or cat's thorax is thoroughly auscultated first using the diaphragm and then the bell of the instrument. All four valve areas—mitral, tricuspid, pulmonic and aortic regions—are ausculted listening for abnormalities of the heart rate and rhythm, as well as alterations in the heart sounds (see p. 433) and most commonly, a heart murmur. If a murmur exists, it must be identified with respect to timing, intensity, and musical tonality as well as where it is heard on the thorax and if the sounds spread to other parts of the thorax or into the jugular region of the neck.
- Murmurs are described as to their intensity, using a grading system of VI maximum, with a I/VI being the least intense and barely heard; II/VI being soft but unmistakenably heard; III/VI being easily distinguished; IV/VI being intense but without a palpable thrill; V/VI being loud, intense, and associated with a precordial vibration (thrill) on the thorax where it is auscultated; and a VI/VI being so loud it is heard with the stethoscope off the thorax and so intense a thoracic thrill is present.
- The murmur is identified as to when it occurs—in systole, diastole, or seamlessly through both of these physiologic periods of the heart cycle (“continuous”). Murmurs are also noted as being early, mid, or late (within systole or diastole) and are then characterized by their musical quality or tone such as high frequency, midrange, or low frequency. While not always true, usually the intensity of the murmur correlates with the severity of the disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Systolic murmurs are associated with congenital conditions such as aortic stenosis, pulmonic stenosis, septal defects, atrioventricular valve dysplasia, tetralogy of Fallot, and other less common congenital lesions.
- Acquired systolic murmurs are auscultated with mitral valvular heart disease (insufficiency), cardiomyopathies, anemia, fever, hyperthyroid disease, heartworm disease, endocarditis, and diastolic dysfunction syndromes.
- Diastolic murmurs in small-animal veterinary medicine are unusual but are associated with mitral stenosis, aortic valvular insufficiency, pulmonic valvular insufficiency.
- Continuous murmurs are heard with patent ductus arteriosus or A-V vascular shunting lesions, either centrally or in the peripheral vascular system.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Heart murmurs must be differentiated from breath sounds. In animals with particularly noisy breathing, respiratory distress, or anxiety, the breath sounds may be confused with heart murmurs because of the noise occurring from the thorax or upper respiratory system during auscultation and physical examination.

INITIAL DATABASE

- Depends on the context in which the murmur is noted (see History, Chief Complaint)
- Thoracic radiographs: diagnostic test of choice for left-sided congestive heart failure (pulmonary edema)
- Echocardiography: diagnostic test of choice for pinpointing the cardiac lesion responsible for the murmur
- CBC, serum chemistry panel, urinalysis, abdominal imaging: as indicated for systemic disorders
- Cardiac biomarkers (particularly NT-proBNP): helpful in distinguishing cardiac from noncardiac thoracic disease; may have significance in correlating with the phase of cardiac disease, especially in the cat and possibly in the dog.

TREATMENT

TREATMENT OVERVIEW

Treatment of heart murmurs is not an option. The veterinarian must identify the murmur first, then the cause of the murmur, and then make associations with the disease condition present. The presence of a murmur does not mean the animal requires therapy. The intensity of the murmur usually directly relates to the severity of the disease; increased radiographic vertebral heart score together with a murmur is usually a good indication of the severity of the cardiac disease.

PROGNOSIS AND OUTCOME

Highly variable, depending on the underlying cause of the murmur. The prognosis of a patient with a heart murmur is influenced by the disorder causing the murmur, not by the murmur itself.

PEARLS & CONSIDERATIONS

COMMENTS

- In dogs that are panting, anxious, sniffing, or whining, closure of the mouth and intermittent occlusion of the dog's nostrils for 2-3 seconds at a time is useful for intermittently masking breath sounds that interfere with auscultation of the heart.
- In cats, the sound of running water, or “scruffing” (lifting the skin of the nape of the neck) helps abolish purring.
- A systolic whoop is an uncommon but strikingly loud (VI/VI) systolic murmur produced by resonance of the mitral valve. It may appear or disappear spontaneously and is not related to the presence or severity of any underlying heart problem, although further monitoring is indicated.

EDITOR: ETIENNE CÔTÉ

Heart Failure, Chronic

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Heart failure (HF) is a syndrome that results from impaired filling or emptying of the heart, typically manifesting with cardiogenic edema or effusion.
- A new classification system can be applied to heart failure in small-animal practice. In this schema, patients with heart failure are staged as follows:
  - Class A—patients at risk for heart failure (no overt or occult signs of heart disease)
  - Class B—patients that have structural heart disease but have not developed heart failure
  - Class C—patients that have *or previously have had* clinical signs of heart failure
  - Class D—patients with refractory heart failure
- Here, the term *chronic HF* is used as a synonym for Class C heart failure as described above. Urgent therapy of acute or decompensated heart failureis addressed elsewhere (see p. 468).

SYNONYM

Congestive heart failure

EPIDEMIOLOGY

SPECIES, AGE, SEX: HF is a syndrome that can result from practically any cardiac disease; signalment reflects predispositions for the causative disorder:

- Geriatric small-breed dogs: chronic mitral and tricuspid regurgitation due to myxomatous valve disease
- Adult large-and giant-breed dogs: dilated cardiomyopathy (DCM)
- Cats: hypertrophic cardiomyopathy (HCM; males > females), restrictive/unclassified cardiomyopathy

GENETICS & BREED PREDISPOSITION

- DCM: Doberman pinschers, Great Danes, Irish wolfhounds, and other large-and giant-breed dogs
- Mitral and tricuspid regurgitation due to chronic myxomatous valve disease: geriatric small-breed dogs including Cavalier King Charles spaniels, dachshunds, and many others
- HCM: inherited in Maine coon cats and Ragdoll cats. It is possible that feline HCM generally is a genetic disease

RISK FACTORS: Electrocardiographic and echocardiographic variables that predict the development of HF in Doberman pinschers have been described. In Irish wolfhounds and other giant-breed dogs, atrial fibrillation sometimes precedes the development of HF. In small-breed dogs, a murmur caused by myxomatous mitral degeneration is a risk factor for development of HF, but there is great interindividual variability in the rate at which valvular disease progresses. In cats, echocardiographically evident left atrial enlargement is associated with the development of HF.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Left-sided HF results in pulmonary edema.
- Right-sided HF causes ascites and sometimes concurrent pleural effusion.
- In cats, pleural effusion results from left-, right-, or biventricular HF; ascites is uncommon.

HISTORY, CHIEF COMPLAINT: Clinical signs such as respiratory distress generally have improved or resolved with initial treatment, but signs such as progressive abdominal distension, syncope, lethargy, and weight loss may persist. Patients with chronic heart failure are subject to episodes of acute/decompensated heart failure.

PHYSICAL EXAM FINDINGS

- Patients with HF due to mitral/tricuspid myxomatous valve disease have a cardiac murmur; usually the murmur is loud, and its intensity is generally not affected by treatment.

- An audible third or fourth heart sound—a gallop—reflects high atrial pressures and reduced ventricular compliance. In dogs, it is a relatively specific marker of HF.

ETIOLOGY AND PATHOPHYSIOLOGY

- Congestive signs result when high venous pressures cause the development of edema or cavitary effusions.
- In dogs, HF that results primarily from systolic dysfunction—failure of the ventricle to completely empty—is most common.
- HF in cats usually results from diseases that impair ventricular filling; diastolic ventricular pressures are abnormally high when ventricular volume is normal or small.
- High filling pressures are reflected upstream to the venous circulation, resulting in edema or pleural effusion.
- HF is associated with neuroendocrine activation: specifically, impaired cardiac performance leads to increased activity of the renin-angiotensin-aldosterone system (RAAS) and the adrenergic nervous system (ANS).
- Angiotensin II (ATII) is the biologically active product of a biochemical cascade for which the final step is catalyzed by angiotensin-converting enzyme (ACE).
- ATII is a vasoconstrictor, but it also stimulates the release of aldosterone, augments activity of the ANS, and acts as a cardiomyotrophic factor.
- Activation of the RAAS and ANS serves to temporarily maintain perfusion pressure and cardiac output.
- Vasoconstriction increases vascular resistance so that blood pressure is maintained when cardiac output is subnormal. In patients with mitral/tricuspid myxomatous valve disease or DCM, vascular resistance is high, causing a detrimental increase in after-load; this partly explains the beneficial effect of vasodilators.
- It is now generally accepted that neuroendocrine activation associated with cardiac dysfunction is initially beneficial but ultimately detrimental and contributes importantly to the pathogenesis of progressive cardiac dysfunction. Current therapies for chronic HF reflect this conceptual framework.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Chronic heart failure is present when acute/decompensated heart failure is treated successfully, but the underlying cause cannot be cured. Therefore, clinical features of chronic heart failure include a history of acute/decompensated heart failure, with partial or complete resolution of signs with treatment but persistence of the underlying cardiac lesion.

DIFFERENTIAL DIAGNOSIS

Other causes of respiratory distress, cough, abdominal distension, lethargy, inappetence, and weight loss (cardiac cachexia)

INITIAL DATABASE

- Thoracic radiography:
  - Left atrial enlargement with pulmonary opacities is diagnostic of left-sided HF (see p. 468).
  - With diuretic treatment of decompensated HF, clinical improvement is usually rapid (minutes to hours), but radiographic resolution of pulmonary infiltrates may take 12-24 hours.
  - Cats commonly develop pleural effusion in association with left-sided cardiac disease.
- Electrocardiography (ECG) is indicated when arrhythmias complicate the presentation. Atrial fibrillation is commonly associated with heart failure in large-breed dogs, but tachyarrhythmia of virtually any type may complicate the presentation of heart failure (see p. 468).
- Noninvasive estimation of systemic blood pressure using the Doppler cuff or oscillometric method should be considered. The finding of systemic hypertension (SH) provides evidence of concurrent disease; that is, SH may complicate HF, but it is not a result of HF. However, documented SH should be treated, since untreated SH may accelerate the progression of the primary cardiac disorder.
- Serum biochemistry profiles: provide useful ancillary information and are important in monitoring the effects of therapy (especially renal and electrolyte effects).

ADVANCED OR CONFIRMATORY TESTING

B-type natriuretic peptide (BNP) is released by cardiomyocytes in response to increases in ventricular filing pressures. Elevated circulating BNP is a marker of the heart failure state, but the diagnostic utility assay has yet to be fully clarified.

Echocardiography generally provides the diagnosis of the underlying cardiac disorder. Echocardiography is complementary to physical examination and thoracic radiography but does not replace them.

TREATMENT

TREATMENT OVERVIEW

- Correction/cure of the underlying cause when possible
- In all cases, increase in quality and duration of life
- Although individual patient characteristics must be taken into account, poly-therapy consisting of furosemide, an ACE inhibitor, and pimobendan with or without digoxin has become standard treatment for management of class C HF in the dog.
- There is uncertainty regarding optimal therapy for cats with HF resulting from diastolic dysfunction; furosemide and an ACE inhibitor, with or without beta-blockade, are widely used.

CHRONIC TREATMENT

- Diuretics. Furosemide is the most effective agent for management of congestive signs.
  - In dogs, a dose of 1 mg/kg PO q 12 h is often initially adequate when given concurrently with ancillary agents such as ACE inhibitors and pimobendan. Cats with HF generally require lower initial doses (0.5-1 mg/kg PO q 12-24 h).
  - Furosemide is used first, but the progressive nature of the HF state generally requires adjustment of doses. If clinical signs suggest diuretic resistance or if electrolyte derangements are documented, other diuretics such as hydrochlorothiazides (2-4 mg/kg PO q 12 h) or spironolactone (1-2 mg/kg PO q 12 h [dog]) can be added. Doing so allows for synergistic diuretic action: Different diuretics act in different parts of the nephron, which minimizes the negative effects of long-term (weeks or more) administration of high doses of a single diuretic (e.g., >3-4 mg/kg q 8-12 h furosemide).
  - Diuretic dose should be determined by clinical response; the optimal dose is the lowest one that eliminates congestive signs.
  - Excessive diuretic administration may decrease renal perfusion, creates electrolyte imbalances, and contributes to potentially harmful neuroendocrine activation.
  - Most patients require lifelong diuretic administration; progression of the underlying disorder generally necessitates increases in furosemide dose and/or the use of additional diuretics.
  - Furosemide administration sometimes can be tapered or temporarily discontinued in cats with hypertrophic cardiomyopathy.
- ACE inhibitors partially blunt the effects of RAAS activation and reduce afterload.
  - ACE inhibition has proven benefits for patients with chronic HF caused by systolic dysfunction; preliminary evidence suggests a benefit for patients with chronic HF caused by diastolic dysfunction (e.g., cats with HF caused by hypertrophic or restrictive/unclassified cardiomyopathy).
  - Of the ACE inhibitors, veterinary experience is greatest with enalapril (0.5 mg/kg PO q 12-24 h [dog]), benazepril (0.25-0.5 mg/kg PO q 24 h [dog], 0.5-1 mg/kg PO q 24 h [cat]), and ramipril (0.125 mg/kg PO q 24 h [dog]).
- Digoxin:
  - 0.22 mg/m^2 PO q 12 h [dog]; 0.03125 mg/cat PO q 48 h
  - Weak positive inotrope that has potentially beneficial neuroendocrine effects; digoxin inhibits adrenergic activity and increases vagal tone.
  - Important in management of patients with both systolic dysfunction (e.g., dilated cardiomyopathy) and atrial fibrillation; benefit to patients with sinus rhythm is uncertain. Digoxin is generally contraindicated in HCM.
- Pimobendan (0.1-0.3 mg/kg PO q12 h administered when stomach is empty) is a phosphodiesterase inhibitor that acts as an “inodilator.” It is indicated for the treatment of dogs that have developed Class C heart failure due to valvular disease or dilated cardiomyopathy.
  - Pimobendan decreased mortality when compared to benazepril in patients with HF due to valvular disease. The evidence that pimobendan decreases mortality in Doberman pinschers with class C heart failure due to DCM is strong.
  - Unfortunately, information that relates to the effect of pimobendan in dogs receiving standard therapy of an ACE inhibitor and furosemide is sparse. While it is accepted that these drugs can and probably should be used together, there are unanswered questions that relate to staging of therapy.
  - The concurrent use of pimobendan, an ACE inhibitor, and furosemide as initial therapy can be justified, as can staged therapy in which an ACE inhibitor or pimobendan is used as rescue therapy in the event of clinical deterioration.
  - Adverse effects associated with the administration of pimobendan are apparently uncommon, although there is some evidence that pimobendan might harm patients with mild subclinical valvular disease. Accordingly, the use of this drug should be reserved for patients with Class C or D HF due to valvular or myocardial disease. A proarrhythmic effect is possible but appears uncommon, if it even exists in dogs.
- β-Blockers (BB). There is experimental evidence that supports the use of BB in dogs with dilated cardiomyopathy or advanced mitral/tricuspid valve disease.
  - BB are negative inotropes that can induce acute HF if given at an inappropriately high initial dose or if the dose is increased too quickly; dose must be gradually titrated over weeks from a low initial dose to a target dose, typically beginning at 0.1 mg/kg PO q 12 h (carvedilol) or 0.1-0.2 mg/kg PO q 12 h (metoprolol).
  - BB are never started before a patient's pulmonary edema has resolved.

- Spironolactone (1-2 mg/kg PO q 12 h [dog])
  - In chronic HF, excess aldosterone may contribute to the development of myocardial fibrosis.
  - Spironolactone is an aldosterone antagonist, and as such it may limit the detrimental effects of hyperaldosteronemia; careful monitoring of electrolytes is advised.
  - Minimal diuretic efficacy as monotherapy in the dog.
  - Severe facial dermatitis in 30% of cats makes this drug relatively contraindicated in this species.
- Cautious addition of amlodipine (0.0625-0.25 mg/kg PO q 24 h [dog],0.125 mg/kg-0.25 mg/kg PO q 24 h [cat]) to conventional therapy can be considered for patients with refractory HF or for those in which SH complicates the clinical presentation. Blood pressure monitoring is essential.
- Moderate dietary sodium restriction generally is indicated. If palatable to the patient, low-sodium diets may reduce diuretic requirements.

NUTRITION/DIET

Moderate sodium restriction, adequate protein and energy content, and palatability are important attributes of an optimal diet for HF patients (see p. 168).

POSSIBLE COMPLICATIONS

- "Cardiorenal syndrome": azotemia associated with diuretic administration and diminished cardiac performance
  - When azotemia is encountered in patients receiving furosemide and ACE inhibitors, *furosemide* is first decreased by 50%, provided the patient is free of congestive signs. If creatinine does not decrease, diuretic therapy is discontinued, provided congestive signs are not evident. Only if this is unsuccessful is the ACE inhibitor discontinued.
  - There are unfortunately few alternatives for patients that develop clinical signs specifically due to azotemia when congestive signs are present concurrently; this may reflect medically intractable heart failure. However, caution must be exercised, as "overinterpretation" of radiographs or abnormal lung sounds (e.g., pulmonary rales/crackles due to interstitial lung fibrosis, not edema) can lead to inappropriately high diuretic doses, volume depletion, and azotemia.

RECOMMENDED MONITORING

- Serum urea, creatinine, and electrolytes
- Serum digoxin concentration

PROGNOSIS AND OUTCOME

Despite favorable initial response, heart failure is generally associated with a poor long-term prognosis unless the causative disorder is curable.

PEARLS & CONSIDERATIONS

COMMENTS

- Current therapy of heart failure reflects the understanding that activation of the ANS and RAAS is central to the pathogenesis of the syndrome.
- When the causative disorder is not curable, chronic HF is a progressive and terminal syndrome. Therefore attempts to identify a correctable cause are important; some patients with dilated cardiomyopathy respond to supplementation with nutraceuticals such as taurine and L-carnitine.

PREVENTION

- In patients with clinically silent dilated cardiomyopathy, the onset of heart failure may be delayed by the administration of ACE inhibitors and BB.
- ACE inhibition has a modest but probably positive effect on the time to development of class C HF in canine patients with left atrial enlargement due to mitral valve regurgitation.
- Evidence that medical therapy slows the progression HCM is currently lacking.

CLIENT EDUCATION

Management of the veterinary patient with chronic HF requires careful monitoring and relatively frequent adjustment of medical therapy.

Heart Failure, Acute/Decompensated

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Acute (or decompensated) congestive heart failure (HF) is characterized by the sudden onset of clinical signs associated with pulmonary edema or cavitary effusions that develop as a consequence of heart disease. Acute/decompensated HF is a common cause of respiratory distress that is most often associated with worsening cardiac performance in patients with chronic heart disease.

SYNONYMS

Acute congestive heart failure, decompensated heart disease, overt heart failure

EPIDEMIOLOGY

SPECIES, AGE, SEX: Signalment reflects predispositions for the causative heart disorder. Examples:

- Geriatric small-breed dogs: chronic mitral/tricuspid regurgitation (myxomatous valve disease)
- Cats: hypertrophic cardiomyopathy (HCM)

GENETICS & BREED PREDISPOSITION

- Dilated cardiomyopathy (DCM): Doberman pinschers, Great Danes, Irish wolfhounds, and other large-and giant-breed dogs
- Mitral/tricuspid myxomatous valve disease: Cavalier King Charles spaniels, dachshunds, many others
- HCM: inherited in Maine coon cats and in Ragdoll cats; it is possible that feline HCM generally is a genetic disease.

RISK FACTORS

- In patients with underlying heart disease:
  - Dietary sodium excess
  - Acute intravascular volume load (e.g., parenteral fluids)
  - Possibly corticosteroids (HCM cats)
  - Possibly ketamine/tiletamine (HCM cats)
- Electrocardiographic, echocardiographic variables: predictive of likelihood of future HF or sudden, unexpected death in Doberman pinschers with DCM

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Left-sided HF results in pulmonary edema.
- Right-sided HF causes ascites and sometimes concurrent pleural effusion.
- In cats, pleural effusion may result from left-and/or right-sided heart disease.

HISTORY, CHIEF COMPLAINT

- Respiratory signs predominate. Specifically, the characteristic manifestations include tachypnea, dyspnea, and, in the dog, cough. Heart failure seldom causes coughing in cats.
- Clients may report that the patient appears to be uncomfortable, restless, or unwilling to lie down.

PHYSICAL EXAM FINDINGS

- Tachycardia is a relatively consistent, although nonspecific, finding in dogs with HF. Heart rate of cats with acute HF differs little from heart rate of healthy cats. Some cats with acute HF have bradycardia.
- The presence of respiratory sinus arrhythmia is generally inconsistent with acute HF; other explanations for the clinical signs should be considered.
- In patients with pulmonary edema, tachypnea and respiratory distress are usually apparent during the physical examination.
- Dogs with acute HF due to mitral or tricuspid regurgitation caused by myxomatous valve disease have a cardiac murmur;

usually the murmur is loud (=III/VI).
- An audible, low-frequency third or fourth heart sound—a gallop—reflects high atrial pressures and reduced ventricular compliance. Relatively specific marker of acute HF in dogs.

ETIOLOGY AND PATHOPHYSIOLOGY

- Congestive signs result when high venous pressures cause the development of edema or cavitary effusions.
- In dogs, HF that results primarily from systolic dysfunction—failure of the ventricle to completely empty—is most common.
- HF in cats usually results from diseases that impair ventricular filling (diastolic dysfunction).
- HF is associated with neuroendocrine activation that temporarily maintains perfusion pressure and cardiac output through vasoconstriction and increases in heart rate and contractility.
- In patients with systolic dysfunction, systemic vascular resistance rises disproportionately, causing a detrimental increase in after load; this explains the beneficial effect of vasodilators.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Heart failure is a clinical or radiographic diagnosis:

- Left heart failure is defined by the presence of radiographic pulmonary opacities in association with left atrial enlargement.
- Right heart failure is defined by the finding of ascites in association with jugular venous distension and/or evidence of right atrial/right ventricular enlargement from imaging studies.

DIFFERENTIAL DIAGNOSIS

Other causes of respiratory distress and/or cough:

- Chronic sterile bronchitis
- Collapsing trachea
- Allergic airway disease
- Noncardiogenic pleural effusion
- Intrathoracic mass
- Pneumonia
- Pneumothorax

INITIAL DATABASE

- Thoracic radiographs: radiographic findings of left atrial enlargement together with pulmonary opacities are diagnostic of left-sided HF.
- Electrocardiography (ECG) is indicated when arrhythmias complicate the presentation.
- Serum biochemistry profile and urinalysis: in all cases, preferably before initiating treatment

ADVANCED OR CONFIRMATORY TESTING

- Echocardiography defines the causative disorder.
    - Elevated circulating NT-proBNP is a marker of HF; the diagnostic utility of the assay has yet to be fully clarified.

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is to restore ventilatory function by eliminating lung edema or pleural effusion, and in some cases, improving cardiac performance.

ACUTE GENERAL TREATMENT

- Rest
- Judicious/minimal restraint and other measures for reducing anxiety are essential.
- Furosemide: diuretic of choice in acute HF. Dose and dosage interval are best determined by clinical response.

    - Initially: relatively high dose (2-6 mg/kg IV, IM). If no overt (e.g., respiratory) evidence of effect, this dose can be repeated within 45-60 minutes.
    - If respiratory rate and effort decrease: 1-2 mg/kg IV or IM q 1-6 h until respirations normalize.
    - The effect of furosemide is rapid but short lived; low doses at short intervals may limit adverse effects.
    - Constant rate infusion of furosemide is an alternative to frequent bolus administration, but advantages in veterinary patients are uncertain; dosage = total projected daily dosage of furosemide divided by 24 as the hourly rate of the infusion.
    - In general, cats require lower doses than dogs.
- Supplementary oxygen
- Morphine (0.05-0.3 mg/kg SQ, IM, or IV) should be considered for dogs that are anxious from respiratory distress.
- Thoracocentesis (see p. 1338) if physical or radiographic findings indicate that pleural effusion is likely responsible for respiratory distress.
- Transdermal nitroglycerin (0.5-3 cm q 12 h) may reduce venous pressures. Efficacy undetermined.
- Patients with systolic dysfunction and evidence of diminished cardiac output at rest may benefit from intravenous administration of nitroprusside (0.5-15 mcg/kg/min) and/or dobutamine (2-15 mcg/kg/min) constant rate infusion. Careful monitoring required.
- Dogs with acute/decompensated HF due to valvular disease or dilated cardiomyopathy may benefit from administration of the inodilator pimobendan (0.25 mg/kg PO q 12 h), particularly if there are findings such as prerenal azotemia, hyponatremia, or hypothermia that suggest diminished cardiac output. The use of pimobendan in acute (or decompensated) HF has not been systematically evaluated.
- IV or SQ fluid administration is generally contraindicated unless used as a vehicle for the administration of drugs or electrolytes.
- Angiotensin-converting enzyme inhibitors, other diuretics: considered once patient is stable (see p. 470).

POSSIBLE COMPLICATIONS

- Hypovolemia/impaired renal perfusion due to excessive diuresis
- Hypotension

RECOMMENDED MONITORING

- Frequent monitoring of vital signs, mucous membranes, body weight
- ECG if arrhythmias
- Flow-directed (Swan-Ganz) pulmonary artery catheterization and/or arterial cannula can be considered for hemodynamic monitoring of severely affected dogs admitted to an intensive care unit; rarely performed.

PROGNOSIS AND OUTCOME

- Most patients presented for first treatment of acute HF respond promptly to conservative therapy consisting of rest, supplemental oxygen, furosemide, and in some cases nitroglycerin.
- Despite favorable initial response, HF is generally associated with a poor long-term prognosis unless the causative disorder is curable.

PEARLS & CONSIDERATIONS

COMMENTS

- Although ancillary therapy including vasodilators and inotropes may speed recovery from acute HF, most patients that are destined to recover respond to conservative management.
- Response to empirical therapy is diagnostically useful. When treatment is based on a presumptive diagnosis, failure to respond to diuretic suggests the possibility that clinical signs are due to primary respiratory tract disease or that the patient has refractory HF.

CLIENT EDUCATION

Chronic medical therapy is generally required even after apparent recovery.

Heart Base Tumor

BASIC INFORMATION

DEFINITION

A general term describing a cardiac tumor of any type located at the base of the heart in association with the ascending aorta and/or pulmonary trunk, but without right atrial involvement

SYNONYMS

Chemoreceptor cell tumor: chemodectoma, aortic body tumor, nonchromaffin paraganglioma

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: second most common cardiac tumor, mean age 10 years (range (5-15 years), males may be overrepresented in predisposed breeds.
- Cats: reported but rare

GENETICS & BREED PREDISPOSITION: Brachycephalic breeds (English bulldogs, boxers, Boston terriers) appear to be predisposed.

RISK FACTORS: Chronic hypoxemia may be a contributing factor.

ASSOCIATED CONDITIONS & DISORDERS: Pericardial effusion, right-sided congestive heart failure

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Most commonly causes clinical signs due to pericardial effusion and cardiac tamponade
- May be an incidental finding

HISTORY, CHIEF COMPLAINT

- Acute collapse
- Lethargy/exercise intolerance
- Abdominal distension
- Anorexia/inappetence
- Cough or tachypnea/dyspnea

PHYSICAL EXAM FINDINGS

- Findings associated with pericardial effusion (tachycardia, weak peripheral pulses, and muffled heart sounds)
- Findings consistent with right-sided congestive heart failure (ascites, hepatomegaly jugular distention/pulsation)
- ± Tachypnea/dyspnea

ETIOLOGY AND PATHOPHYSIOLOGY

- Chemodectoma:
  - Tumor of specialized neuroepithelial cells within the adventitia of the aortic arch; majority of heart base tumors in dogs
  - Typically benign and slow growing but may be very large at the time of diagnosis; occasionally locally invasive and rarely metastatic
- Ectopic thyroid carcinoma:
  - 5%-10% of heart base tumors in dogs; usually nonfunctional
  - Biological behavior not well characterized
- Mesothelioma may occasionally form a mass lesion at the heart base (dogs).

- Regardless of type, heart base tumors typically result in pericardial effusion, causing cardiac tamponade and right-sided congestive heart failure.
- Compression of cardiac structures and great vessels impeding inflow or outflow is possible with a large mass.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is most often made with echocardiographic identification of a mass at the heart base. While a presumptive diagnosis of chemodectoma is often based on echocardiographic appearance, Definitive diagnosis of the tumor type requires histopathologic evaluation of tissue.

DIFFERENTIAL DIAGNOSIS

- Other intrapericardial tumors (hemangiosarcoma, mesothelioma, lymphoma, rare primary cardiac tumors, metastatic tumors)
- Other causes of pericardial effusion (see p. 854)

INITIAL DATABASE

- Echocardiography: diagnostic test of choice. Heart base tumors typically originate from the ascending aorta, most commonly the left cranial aspect, and lie between the aorta and the main pulmonary artery. They are usually homogeneous with smooth margins. Presence and severity of pericardial effusion is also assessed.
- Thoracic radiographs: enlarged or globoid cardiac silhouette in most but not all cases of pericardial effusion (80%). A soft-tissue mass effect at the heart base; may cause dorsal and lateral deviation of the trachea.
- Electrocardiogram: normal sinus rhythm or sinus tachycardia with low amplitude QRS complexes. Electrical alternans is suggestive but insensitive for pericardial effusion (50%).
- CBC, serum biochemistry profile, and urinalysis: often unremarkable

ADVANCED OR CONFIRMATORY TESTING

- Cytology and pH of the pericardial effusion: not generally useful. Heart base tumors typically do not exfoliate cells, reactive mesothelial cells mimic malignant cells, and there is much overlap in pH between causes.
- Histopathology of the tumor: allows a Definitive diagnosis of tumor type.

Requires surgical biopsy and often does not alter treatment plan.

TREATMENT

TREATMENT OVERVIEW

Treatment is generally aimed at removal of pericardial fluid when cardiac tamponade occurs and eliminating recurrent effusion. When a heart base tumor is an incidental finding, initially no treatment may be necessary.

ACUTE GENERAL TREATMENT

- Pericardiocentesis (see p. 1325) is essential when cardiac tamponade is present but may not be necessary if only mild effusion is present and not causing hemodynamic effects.
- Diuretics are contraindicated in acute treatment of cardiac tamponade.

CHRONIC TREATMENT

- Repeated pericardiocentesis as needed for recurrent pericardial effusion
- Diuretics to delay effusion recurrence are controversial.
- Pericardiectomy alone is an effective palliative treatment for recurrent pericardial effusion. Less-invasive alternatives to surgical pericardiectomy include thoracoscopic pericardiectomy (see p. 1340) and percutaneous balloon pericardiotomy.
- Complete surgical resection is rarely possible owing to high vascularity of the tumor and close association with great vessels.

POSSIBLE COMPLICATIONS

- Pericardiocentesis related (see p. 1325)

- Surgical complications related to pericardiectomy. Surgical resection carries substantial risks.
- As most heart base tumors are benign, metastasis is rare but has been reported.

RECOMMENDED MONITORING

- Follow-up exams and echocardiography to assess for recurrent pericardial effusion and tumor progression
- Thoracic radiographs and possibly abdominal ultrasound for tumor staging

PROGNOSIS AND OUTCOME

- Guarded to fair without pericardiectomy
- Pericardiectomy alone improves survival time considerably.

PEARLS & CONSIDERATIONS

COMMENTS

- Characteristic echocardiographic findings lead to the presumptive diagnosis of a heart base tumor and the possibility of a better prognosis with pericardiectomy than with other cardiac tumors such as hemangiosarcoma.
- Cytologic and biochemical evaluation of pericardial fluid are unreliable.

CLIENT EDUCATION

- Pericardiocentesis and pericardiectomy are both palliative and not curative.
- Pericardiectomy will likely lead to longer survival time, with fewer clinical signs in the interim.

Head Trauma

BASIC INFORMATION

DEFINITION

Traumatic injury resulting in damage to soft tissues of the head, the skull, intracranial structures, or some combination of these

EPIDEMIOLOGY

SPECIES, AGE, SEX: Animals of any age or breed. Young animals may be overrepresented (lifestyle, increased risk of traumatic injury).

ASSOCIATED CONDITIONS & DISORDERS

- Traumatic injuries affecting other body systems
- Head trauma may increase the risk for future seizure disorders.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of traumatic event
- Owners may report loss of consciousness, inappropriate behavior, or seizure activity.

PHYSICAL EXAM FINDINGS

- Signs of hypotensive shock (e.g., tachycardia, hypotension, pale mucous membranes) may be present.
- Neurologic exam (see p. 1311): indicators of intracranial injury:
  - Pupil asymmetry, abnormal pupil reactivity (excluding ocular trauma).Dilated unresponsive pupils (in the absence of ocular trauma or atropine) indicate severe neurologic injury and a poor outcome.
  - Diminished or absent oculocephalic (doll's eye) reflex
  - Postural reaction deficits (may be due to spinal injury [see p. 1039]; note remainder of neurologic findings).
  - Diminished or altered consciousness (may be due to shock; note remainder of physical exam).
- Skull fractures may be palpable.
- Respiratory, musculoskeletal, and other body systems may show signs of traumatic injury.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cerebral blood flow (CBF) is mainly determined by blood pressure. Auto-regulation maintains blood flow to brain over a variety of pressures but is lost when systolic arterial blood pressure <50 mm Hg or during neuronal injury (at which time arterial blood pressure dominates control of blood flow to the brain).
- Cerebral perfusion pressure (CPP = mean arterial pressure [MAP] – intracranial pressure [ICP]) is used for estimating CBF. As ICP rises or MAP drops, cerebral perfusion decreases.
- Trauma can result in primary (at the time of incident, due to direct neuronal damage and hemorrhage) or secondary (hours or days after the incident, due to energy depletion, free radical generation, cytokine release) insults to the brain. Treatment aims to prevent or limit secondary effects.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on a history of trauma with physical signs of intracranial injury. Complete neurologic evaluation is essential for establishing treatment plan and prognosis. Concurrent traumatic injuries affecting other body systems are common and should be ruled out as part of the diagnostic plan.

DIFFERENTIAL DIAGNOSIS

- Rule out other causes of intracranial disease (i.e., neoplasia, infectious, inflammatory, congenital), especially when trauma is suspected but was not witnessed.
- Animals in hypotensive shock may manifest altered consciousness without neurologic damage. Await full neurologic assessment until initial stabilization has been completed.
- Metabolic diseases (e.g., hypoglycemia, liver disease) may also affect neurologic exam and should be considered as differentials if no traumatic event is reported or if the history is uncertain.

INITIAL DATABASE

- Baseline tests (packed cell volume/total solids, blood glucose, blood urea nitrogen); initial assessment of some metabolic causes of altered mentation:
  - Consider transfusion if necessary (severe anemia/hemorrhage) to support adequate oxygen delivery to tissues.
  - Avoid causing hyperglycemia, which may be associated with poor outcome in head injury.
  - With azotemia or dehydration, diuretics (mannitol/furosemide) should be used with caution if at all; tissue perfusion (normotension) is most important.
- Blood pressure:
  - Identify and correct hypotension.
  - Systemic hypertension may be seen with elevated intracranial pressures or a consequence of pain or anxiety.
- Blood gas or pulse oximetry:
  - Identify hypoxemia (e.g., Pao2 <80 mm Hg when breathing room air) to provide supplemental oxygen.
  - Identify and correct hypercarbia (elevated PaCO2, e.g., >35 mm Hg).
- Heart rate/electrocardiogram
  - Sinus tachycardia common with shock or volume depletion; ventricular arrhythmias possible (see p. 1165)
  - Bradycardia may be seen with elevated ICP; in a comatose patient, it suggests brain herniation.

ADVANCED OR CONFIRMATORY TESTING

- Radiographs
  - May be useful in identifying skull fractures
  - Of limited value in the overall assessment of intracranial injury
- CT
  - Ideal imaging modality if available; requires general anesthesia, but some comatose/obtunded patients have been imaged without anesthesia.
  - Evaluate for skull fractures, hemorrhage, or other injuries
- ICP monitoring
  - Useful for directing therapies and limiting consequences of elevated intracranial pressures
  - May also be prognostic
  - Infrequently used in veterinary medicine
  - Requires skill and advanced care

TREATMENT 

TREATMENT OVERVIEW

Treatment is aimed at ensuring adequate cerebral perfusion. Important goals include maintaining adequate systemic blood pressure and systemic oxygenation (oxygen delivery to tissues).

ACUTE TREATMENT

- Maintain mean blood pressure above 60 mm Hg (generally signifies that systolic blood pressure >90 mm Hg): essential in management of head trauma, managed via titration of intravenous fluids. Options:
  - Crystalloids (e.g., 0.9% NaCl or lactated Ringer's solution) at shock doses IV (60-90 mL/kg for dog, 45-60 mL/kg for cat), unless renal/cardiovascular/dilutional contraindication; exact dose is titrated to blood pressure.
    - Concurrent use of colloids or hypertonic saline may limit cerebral edema that can occur with aggressive fluid administration.
    - Avoid fluids with excessive free water (maintenance fluids, 5% dextrose in water, 0.45% saline).
  - Colloids, e.g., hetastarch, pentastarch (10-20 mL/kg/d IV). Oncotic effect draws free water from the interstitium into the vasculature. May potentiate effects of lower molecular weight substances (i.e., mannitol). Useful for intravascular support with limited fluid volumes.
  - Hypertonic saline (7.5%), 4 mL/kg IV slowly. Short-lived osmotic action draws fluid from cerebral interstitium; combination with crystalloids prolongs osmotic effect.
    - May also limit other secondary effects of head injury. Only used if patient is adequately hydrated.

- Decrease intracranial pressure:
  - Mannitol (0.5-1 g/kg IV q 6-8 h; limit to three bolus injections/24-h period). Osmotic diuretic with free-radical scavenging properties. Increases intravascular osmolarity and draws fluid in from cerebral tissue. Decreases blood viscosity, increases cerebral blood flow. Potential adverse effects:
    - Diuresis may decrease blood volume and consequently blood pressure (ensure adequate blood pressure and volume status before administration).
    - May result in "reverse osmotic shift." In areas of hemorrhage, mannitol may leak into interstitium, worsening cerebral edema. The effects of mannitol on lowering ICP may outweigh these potential effects on damaged areas.
  - Furosemide (2-5 mg/kg IV in coordination with mannitol). Decreases production of cerebrospinal fluid and causes diuresis; may potentiate effects of mannitol and decrease ICP. Caution: diuretic action may also worsen intravascular volume contraction and lead to hypovolemia.
- Maintain adequate oxygenation:
  - Supplemental oxygen as needed (see p. 1318)
  - Ensure adequate oxygen-carrying capacity (hematocrit/hemoglobin) and delivery (adequate blood pressure).
- Miscellaneous therapies:
  - Surgery:
    - Craniotomy may be indicated for removal of hematomas, control of hemorrhage in the case of depressed skull fractures, or for removal of penetrating objects.
    - Results in a substantial decrease in ICP (15% with craniotomy and an additional 65% reduction with durotomy) and is superior in relief of elevated ICP compared to any medical therapy.
    - CT is useful for evaluation of injuries and determining need for surgical intervention.
  - Hyperventilation:
    - Has been advocated in head injury, although its use is controversial
    - Lowers CO2. Resultant vasoconstriction decreases cerebral perfusion pressure and decreases ICP. However, decreased perfusion to brain parenchyma may have deleterious consequences.
    - Current recommendation: ventilate patient such that Paco2 = 30-35 mm Hg.
  - Barbiturates:
    - Can use pentobarbital to effect (4-16 mg/kg IV titrated for induction, then 0.2-1 mg/kg/h to maintain sedation
      - Decreases cerebral metabolic rate and vasoconstricts, decreasing ICP
      - Studies evaluating efficacy controversial
      - May cause respiratory or cardiac depression, which is severely problematic in the head-injured patient
      - If used, intensive nursing care is essential to monitor respiration (intubation and mechanical ventilation may be necessary) as well as blood pressure and temperature.
      - Often discussed as "last resort"
      - May be beneficial for seizure control or in an extremely agitated animal
  - Hypothermia:
    - Results in decreased cerebral metabolic rate, decreased cerebral perfusion via reflex vasoconstriction, and consequently decreases ICP
    - May also limit secondary brain injury by limiting neuroexcitatory activities and suppression of local inflammatory response
    - Can be associated with coagulation abnormalities, cardiac disturbances, and hypotension
    - Moderate hypothermia (32-33°C) has been reported to be efficacious in human trials and animal models of brain injury. Clinical use in veterinary patients is uncertain
  - Glucocorticoids:
    - Methylprednisolone sodium succinate (30 mg/kg slow IV over 10 minutes) after initial resuscitation may be best choice
    - Use of corticosteroids in head injury is highly controversial and generally not recommended. Human studies have failed to show benefit.
    - Potential benefits due to antiinflammatory and free radical scavenging effects
    - May be associated with several complications (hyperglycemia, gastric ulceration, decreased wound healing, and infection)

NUTRITION/DIET

- Supplemental nutrition may be needed in severely compromised patients.
  - Enteral route preferred if possible/safe (see p. 1267)
  - Parenteral nutrition (see p. 1322) may be needed in patients at risk for aspiration pneumonia.

BEHAVIOR/EXERCISE

- Animals with severe neurologic deficits may be recumbent with limited mobility.
  - Range-of-motion exercises and physical rehabilitation (see p. 1329) may be beneficial for these patients.

POSSIBLE COMPLICATIONS

- Infection (aspiration pneumonia, nosocomial infection)
- Seizures
- Renal failure
- Persistent neurologic deficits

RECOMMENDED MONITORING

- Assess neurologic status:
  - Repeated examination may aid in the evaluation of efficacy of therapy.
  - Imaging (CT scan) may be helpful in assessing injury.
  - Therapy to decrease intracranial pressure if indicated
- Monitor oxygenation (arterial blood gas/pulse oximetry).
- Ensure adequate blood pressure.

PROGNOSIS AND OUTCOME

- Prognosis is dependent on severity and type of injury:
  - Fair to good with minor, nonprogressive injury
  - Severely injured animals have poorer short-term recovery rates and may have longer rehabilitation/recovery periods if they survive.
- Modified Glasgow Coma Score (MGCS; see box) has been used for scoring injury severity in head trauma and has been correlated to outcome.

PEARLS & CONSIDERATIONS

COMMENTS

- Head trauma is a common and serious injury in dogs and cats.
- Clinicians must recognize the signs of progressive neurologic injury.
  - The MGCS may be helpful as a monitoring tool.

Modified Glasgow Coma Score

Motor Activity	
Normal gait, normal spinal reflexes	6
Hemiparesis, tetraparesis, or decerebrate activity	5
Recumbent, intermittent extensor rigidity	4
Recumbent, constant extensor rigidity	3
Recumbent, constant extensor rigidity with opisthotonos	2
Recumbent, hypotonia of muscles, depressed or absent spinal reflexes	1
Brainstem Reflexes	
Normal pupillary light reflexes and oculocephalic reflexes	6
Slow pupillary light reflexes and normal to reduced oculocephalic reflexes	5
Bilateral unresponsive miosis with normal to reduced oculocephalic reflexes	4
Pinpoint pupils with reduced to absent oculocephalic reflexes	3
Unilateral unresponsive mydriasis with reduced to absent oculocephalic reflexes	2
Bilateral unresponsive mydriasis with reduced to absent oculocephalic reflexes	1

Level of Consciousness	
Occasional periods of alertness, responsive to environment	6
Depression or delirium, capable of responding to environment but response may be inappropriate	5
Stupor, responsive to visual stimuli	4
Stupor, responsive to auditory stimuli	3
Stupor, responsive only to repeated noxious stimuli	2
Coma, unresponsive to repeated noxious stimuli	1

Total: _____

- Assessment
  - Good prognosis 15-18
  - Guarded prognosis 9-14
  - Grave prognosis 3-8

TECHNICIAN TIPS

- Diligent monitoring and nursing care are important for an optimal outcome.
  - Even subtle changes in neurologic assessment can be important and should be brought up with the attending veterinarian.
  - Comprehensive nursing care is important to prevent complications such as nosocomial infection or aspiration pneumonia.

CLIENT EDUCATION

- Clients must be informed of the potential for long recovery periods with severely injured animals.
- Clients should also be made aware of the need for intensive treatment and monitoring of animals with head injury.
- The MGCS may be helpful in quantitating injury severity in order to provide the client with a prognosis.

Head Tilt

BASIC INFORMATION

DEFINITION

Tilting of the head in a clockwise or counterclockwise direction along the long axis of the body. The head may be tilted due to a disorder of balance (vestibular disease) or due to discomfort from a dermatologic problem (acute moist dermatitis of the lateral face, or otitis externa). Head tilt due to an orthopedic problem (torticollis) is rare in small animals.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Idiopathic vestibular disease dogs >8 years; any age in cats

GENETICS & BREED PREDISPOSITION

- Otitis externa/dermatitis: usually “floppy eared” breeds of dogs with long pinnae (e.g., spaniels, retrievers)
- Congenital vestibular disease (uncommon): Doberman pinscher, cocker spaniel, German shepherd, others

GEOGRAPHY AND SEASONALITY: Idiopathic vestibular disease in cats may predominate in late summer/early fall

ASSOCIATED CONDITIONS & DISORDERS

- If head tilt is of vestibular origin, concurrent nystagmus, ataxia, circling, and/or vomiting may occur.
- If head tilt is associated with otitis externa/dermatitis, concurrent vigorous head shaking is common.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Vestibular disease (peripheral or central)
- Associated with discomfort (e.g., otitis externa or dermatitis ventral to the ear)

HISTORY, CHIEF COMPLAINT

- Head tilt associated with idiopathic vestibular disease; usually acute onset:
  - Vomiting followed by head tilt, ataxia, and circling/rolling for the next 1-2 hours is common
  - Owners may not report nystagmus.
- Head tilt associated with otitis externa/dermatitis:
  - Signs of pain of the affected ear/dermatitis lesion
  - Scratching of ear/affected skin
  - Rubbing of face on the floor

PHYSICAL EXAM FINDINGS

- Head tilt associated with peripheral vestibular disease (one or more maybe present):
  - Head tilt is always toward the side of the lesion.
  - Nystagmus (horizontal or rotary) with fast phase away from the side of the head tilt (see p. 772).
  - Circling
  - Ataxia with falling to the side of the head tilt
- Head tilt associated with central vestibular disease (one or more may be present):
  - Head tilt is toward the side of the lesion.
  - Nystagmus (horizontal, rotary, or vertical) with fast phase away from the side of the head tilt (see p. 772)
  - Circling
  - Ataxia
  - Proprioceptive deficits, motor weakness on the side of the lesion
  - Rarely, central vestibular disease may cause paradoxical signs (head tilt away from the side of the lesion). Proprioceptive deficits indicate the true side of the lesion (ipsilateral).
  - Other cranial nerve deficits (V, VI, VII)

- Head tilt associated with otitis externa/dermatitis:
  - Otitis externa (frequently suppurative)
  - Moist dermatitis ("hot spot") just ventral to the ear but covered by the pinna

ETIOLOGY AND PATHOPHYSIOLOGY

- Peripheral vestibular disease:
  - Idiopathic
  - Infection (otitis media/interna)
  - Neoplasia
  - Hypothyroidism (rare)
  - Post middle ear surgery
  - Intoxication (e.g., aminoglycoside antibiotics; rare)
  - Congenital/hereditary
- Central vestibular disease:
  - Infection
  - Inflammation
  - Neoplasia
  - Trauma
- Otitis externa/dermatitis:
  - Dogs: secondary to atopy, food hypersensitivity/allergy, hypothyroidism
  - Bacterial
  - Yeast
  - Mites (cats)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Head tilt is most commonly caused by vestibular dysfunction. Therefore, the diagnostic process should seek to identify whether the brain (central) or inner/middle ear (peripheral) is the site of the lesion, which can usually be determined with a clinical neurologic exam. Further testing is selected based on a differential diagnosis list elaborated from history, physical exam, and neurologic exam findings.

INITIAL DATABASE

- CBC, serum chemistry profile, and urinalysis: usually normal
- Otoscopic exam:
  - Otitis externa, polyp, blood (head trauma) are possible.
  - Careful examination may reveal fluid in the middle ear with infectious causes.
- Tympanic bulla radiographs
- In otitis externa, consider evaluation for atopy, food hypersensitivity/allergy, and hypothyroidism

ADVANCED OR CONFIRMATORY TESTING

- Serum thyroid assays if cutaneous, biochemical, or other signs suggesting hypothyroidism are present (dogs).
- MRI or CT if inner ear or intracranial lesion is suspected based on case information to date.
- Cerebrospinal fluid analysis if intracranial disease is considered.

TREATMENT

TREATMENT OVERVIEW

- Improve the clinical condition by decreasing nausea, anorexia, skin and external ear irritation, and pain.
- Treat primary cause when possible.

ACUTE GENERAL TREATMENT

- Vestibular:
  - No specific therapy is available for treatment of idiopathic vestibular syndrome in dogs or cats. Glucocorticoids do not

appear to help.
    - Other specific causes will require treatment based on etiology.
    - It may be difficult for the animal to walk or stand, so good nursing care including ability for the animal to get to food and water as well as appropriate care to prevent urine or fecal scalding are very important.
- Dermatologic:
    - In cases of moist dermatitis, clipping the hair of the affected area and gentle cleaning with an antiseptic are recommended (see p. 30).

PROGNOSIS AND OUTCOME

- Vestibular:
    - The prognosis for idiopathic vestibular disease is excellent (dog and cat), but recurrence is possible.
    - With idiopathic vestibular disease, a head tilt may remain after resolution of all other signs.
    - The prognosis for neoplasia and all causes of central vestibular nystagmus is guarded to poor, depending on the exact cause, ability to treat, and response to therapy.
- Dermatologic:
    - The prognosis for otitis externa is good, but chronic cases may require advanced treatment or occasionally surgery.
    - Moist dermatitis ventral to the ear has an excellent prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- In a majority of cases in dogs and cats, acute-onset head tilt is caused by idiopathic peripheral disease and will resolve spontaneously in 1-2 weeks.
- Idiopathic vestibular disease is a diagnosis of exclusion.
- Nearly all central vestibular disease cases will have other central nervous system signs (proprioceptive defects, weakness, other cranial nerve involvement).

CLIENT EDUCATION

- When idiopathic vestibular disease is the primary consideration, the owners need to know that the problem will usually resolve with time.
- Otitis externa may become a chronic problem; owners should be advised that rechecks are needed even if the animal appears normal.

AUTHOR: JAMES B. MILLER

EDITOR: ETIENNE CÔTÉ

Halitosis

BASIC INFORMATION

DEFINITION

An offensive odor emanating from the oral cavity, which may arise from intraoral or extraoral causes

SYNONYMS

Bad breath, oral malodor

EPIDEMIOLOGY

SPECIES, AGE, SEX: Any species, age, and sex may be affected.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Halitosis is a leading concern of pet owners, as it can negatively affect their relationship with the beloved pet.

PHYSICAL EXAM FINDINGS

- A complete physical examination must always include a thorough oral examination.
- Most intraoral disorders that cause halitosis are apparent upon examination of the oral cavity and surrounding tissues.
- General physical findings can vary greatly depending on the underlying disease process. For example, oral manifestations of leptospirosis vary depending on the serovar and may include halitosis, petechiae, oral hemorrhages, ulceration, glossitis with necrosis, and sloughing of the tongue.
- Attention should also be paid to the prepuce/vulva via inspection and to the anal sacs via palpation, because licking of these structures or their secretions is a recognized cause of halitosis in dogs and cats.

ETIOLOGY AND PATHOPHYSIOLOGY

- Intraoral causes:
  - Plaque and calculus accumulation, gingivitis, periodontitis, stomatitis
  - Cheilitis, lip fold pyoderma
  - Osteomyelitis, osteonecrosis
  - Oral tumors (particularly those that outgrow their blood supply and become necrotic, e.g., malignant melanoma, osteosarcoma)
  - Foreign bodies, oral implants
  - Oronasal communications
- Extraoral causes: see Differential Diagnosis

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Physical examination helps differentiate between intraoral and extraoral causes; further diagnostic tests are selected accordingly.

DIFFERENTIAL DIAGNOSIS

The DAMNIT scheme can be utilized as a guide to differential diagnosis:

- *D*evelopmental, degenerative: congenital and acquired palate defects/oronasal communications
- *A*utoimmune, anatomic, allergic: pemphigus vulgaris, systemic lupus erythematosus, erythema multiforme, drug eruption; “mouth breathing” associated with brachycephalic head conformation
- *M*etabolic, mechanical: diabetic ketoacidosis, uremia/renal failure, hepatic dysfunction causing hyperammonemia; retention of food debris

- *N*utritional, neoplastic: gastroesophageal reflux; oral, pharyngeal, esophageal, gastric neoplasia; dietary indiscretion/consumption of spoiled food
- *I*nfectious, inflammatory or idiopathic: dental plaque/calculus (oral bacteria), periodontal disease (gingivitis and periodontitis), gingival hyperplasia, contact mucositis and contact mucosal ulceration, stomatitis; leptospirosis; local and systemic fungal diseases; cheilitis and lip fold pyoderma; bronchitis, pneumonia; infection with feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), feline calicivirus (FCV) or feline herpesvirus (FHV)
- *T*oxic, traumatic: toxic epidermal necrolysis, trauma from malocclusion, tooth fracture, jaw fracture, nonhealing oral wounds, oral foreign body

INITIAL DATABASE

Sensory evaluation and complete physical examination (including oral examination in the awake patient)

ADVANCED OR CONFIRMATORY TESTING

- CBC, chemistry panel, urinalysis: if history and physical examination suggest an extraoral cause
- Viral testing: FeLV and FIV in cats with stomatitis (feline coronavirus and feline herpesvirus testing uncommonly performed because of great number of clinically healthy carriers, and positive results likely would not change treatment plan).
- General anesthesia, oral examination, and biopsy of suspicious lesions
- Case-specific advanced diagnostics centered on the mouth and upper airway when an intraoral cause is suspected (e.g., dental radiography, CT, thoracic radiographs for metastasis check of suspected oral neoplasms) and systemic evaluations (e.g., leptospirosis testing) when an extraoral diagnosis is suspected.
- Identify and quantify volatile sulfur compounds or volatile organic compounds with gas chromatography, mass spectroscopy, and sulfide meters (in research settings).

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is to control halitosis by addressing its underlying intraoral or extraoral causes. For intraoral causes, primary treatment is often followed by preventive care. For extraoral causes, treatment of the underlying disorder is the basis of therapy.

ACUTE GENERAL TREATMENT

- Improve oral hygiene via professional dental cleaning and periodontal therapy, with specific attention to treatment of oral disease associated with halitosis (e.g., extraction of teeth with severe periodontitis).
- Specific treatment for halitosis caused by extraoral disorders is directed towards the underlying disorder.

CHRONIC TREATMENT

- Maintain a healthy periodontium via routine home oral hygiene (daily tooth brushing, application of chlorhexidine products onto teeth and gums, use of diets, treats, and chew toys that help control plaque and calculus accumulation) and professional dental cleaning and periodontal therapy.
- Treat extraoral causes of halitosis.

NUTRITIONAL/DIETARY THERAPEUTICS

Home oral hygiene products, diets, treats, and toys proven to control plaque and calculus accumulation (see the Veterinary Oral Health Council website: http://vohc.org/)

RECOMMENDED MONITORING

Follow-up as indicated for routine management of underlying intraoral or extraoral cause

PROGNOSIS AND OUTCOME

Generally depends on the ability to eliminate underlying cause

- Fair to good prognosis: periodontitis, gingival hyperplasia, anal sac disease when treatment and prophylaxis are implemented properly and maintained consistently (active disorders that usually require ongoing care)

- Guarded prognosis: oral neoplasia, leptospirosis, opportunistic infection secondary to retroviral disease; the severity of the causative problem may make halitosis difficult to control.

PEARLS & CONSIDERATIONS

COMMENTS

A nonmalodorous oral cavity improves the human-animal bond as well as the pet's health and well-being.

PREVENTION

- Plaque accumulation on teeth, a major cause of halitosis, can easily be prevented by daily home oral hygiene and yearly professional dental cleaning and periodontal therapy.
- Other intraoral causes of halitosis can be recognized early by means of home oral examination by the owner and professional oral examination by the veterinarian during wellness visits.

TECHNICIAN TIPS

Technicians are on the frontline of identifying oral disorders pathologies including halitosis in at least two important ways: bringing oral abnormalities to the attention of the clinician and demonstrating proper home oral hygiene techniques to the owner.

CLIENT EDUCATION

- The oral cavity can be easily assessed by most owners.
- Halitosis is obvious, abnormal, and requires appropriate veterinary intervention.
- Home oral hygiene is important to general health.

Ivermectin Toxicosis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Clinical syndrome associated with exposure to the macrocyclic lactone antiparasitic drug, ivermectin

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Very young animals may be at increased risk: immature blood-brain barrier.
- Dogs more likely to be involved; however, some sensitive cats may show clinical signs at the recommended doses.

GENETICS & BREED PREDISPOSITION

A defect in p-glycoprotein multidrug transporter in the blood-brain barrier has been identified as an autosomal recessive trait (MDR-1/ABCB1 gene mutation) in some individuals of several dog breeds including collies, Shetland sheepdogs, Australian shepherds, English shepherds, and Old English sheepdogs (see p. 706). Some German shepherds and greyhounds or other breeds may be relatively more sensitive to ivermectin and may show clinical signs at doses lower than previously reported.

RISK FACTORS

- Use of large-animal formulations in small animals holds risks of dilution errors and accidental overdosage.
- Animals with preexisting central nervous system (CNS) disease or disruption of the blood-brain barrier (e.g., due to trauma) may be at increased risk of toxicosis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute: onset of signs within 4-12 hours of exposure
- Subacute: onset of signs within 48-96 hours, especially with exposure by injection or after multiple daily doses

HISTORY, CHIEF COMPLAINT

- History of exposure to ivermectin-containing product
- Depression, disorientation, vocalization, stupor, ataxia, tremors, vomiting, anorexia, recumbency, blindness, coma, seizure, death

PHYSICAL EXAM FINDINGS

- Mydriasis (bilateral) ± blindness (clinical: pupillary light reflexes generally intact)
- CNS depression: mild to stupor or coma
- Ataxia (proprioceptive)
- Disorientation
- Hypersalivation
- Tremors
- ± Bradycardia
- ± Vomiting
- ± Seizures
- Hypothermia (recumbency) or hyperthermia (tremor/seizure)

ETIOLOGY AND PATHOPHYSIOLOGY

Macrocyclic lactones enhance the release of γ-aminobutyric acid (GABA), an inhibitory neurotransmitter:

- In insects, GABA-mediated neurons are present throughout the peripheral nervous system, and enhanced GABA release

results in paralysis.
- In mammals, GABA-mediated neurons are restricted to the CNS, and in normal mammals the blood-brain barrier excludes ivermectin at therapeutic dosages.
- In overdose situations or in mammals with blood-brain barrier defects, ivermectin enters the CNS and exerts an inhibitory effect, resulting in CNS depression.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The combination of suspected or known exposure (acute or repeated) and CNS signs (progressive ataxia, weakness, mydriasis, seizures, coma) 12-96 hours after exposure is sufficient to establish a working diagnosis and begin treatment. There is no specific confirmatory test.

DIFFERENTIAL DIAGNOSIS

- Other intoxications (marijuana, benzodiazepines, barbiturates, ethylene glycol, isoxazole mushrooms)
- Brain neoplasia
- Encephalitis
- Hepatic encephalopathy

INITIAL DATABASE

- Neurologic exam (see p. 1311): asymmetric neurologic deficits are *inconsistent* with intoxication.
- No specific clinical pathologic alterations expected
- Baseline CBC, serum chemistry profile, urinalysis, postprandial bile acids (± thoracic/abdominal diagnostic imaging) to rule out other possible etiologies

ADVANCED OR CONFIRMATORY TESTING

- A comatose animal may return to temporary consciousness after physostigmine administration (1 mg/40 lb or 0.06 mg/kg IV). This should not be considered confirmatory, as physostigmine can reverse depression from many CNS depressants.
    - Physostigmine should be used with care; may trigger seizure activity.
- Ivermectin sensitivity testing (see p. 706)
- Ivermectin can be detected in liver, adipose tissue, brain, or serum.
    - Serum levels may not correlate well with clinical signs, however. Presence of ivermectin in the serum can help confirm exposure (if uncertain/ unknown).

TREATMENT

TREATMENT OVERVIEW

First priority is given to managing critical CNS abnormalities (seizures, coma). If signs are less severe or absent, treatment consists of inducing vomiting (within 2 hours of ingestion) and giving activated charcoal (within 8–12 hours of ingestion). Experimental treatments exist for severe toxicoses.

ACUTE GENERAL TREATMENT

- Manage seizures (see p. 1009):
    - Diazepam (0.25–2 mg/kg IV) PRN
    - Gas anesthetics, propofol if diazepam ineffective
    - Avoid barbiturates because of residual CNS depression.
    - Minimize sensory stimuli.
- Manage comatose animals:
    - Maintain airway, assist respiration as needed.
    - Thermoregulation essential
    - Atropine (0.01–0.02 mg/kg IV) for bradycardia
    - Frequent turning to prevent decubital ulcers
    - Urinary catheter and hygiene to avoid urine scald
    - Physostigmine (as above)

        - Duration of action 30-90 minutes (may allow time for feeding animal). Does not shorten recovery time.
- Decontamination of patients:
    - Emesis (see p. 1364)
        - Not recommended in animals already showing clinical signs (risk of aspiration).
    - Gastric lavage (see p. 1281)
        - For large ingestions
    - Activated charcoal (majority of ingested ivermectin is excreted in feces):
        - Initial dose: 1-4 g/kg PO or labeled dosage of commercial product when ingestion occurred <12 h earlier
        - Repeat administration q 8-12 h in animals showing overt signs.
        - Subsequent doses: half initial dosage is used to avoid osmotic fluid shifts and hypernatremia; monitor serum sodium.
- Experimental therapy: Intralipid 20% (dogs):
    - 1.5 mL/kg given IV over 10–15 minutes, followed by IV continuous rate infusion of 15 mL/kg over 30–60 minutes. Repeat bolus q 4 h for 3 doses. Monitor for lipemia prior to each dose. If evidence of lipemia, wait 2 hours, then recheck prior to redosing.
    - Intralipid may help trap (bind) highly lipophilic medications like ivermectins, thus making them unavailable. Efficacy and safety of this therapy has not been determined in dogs. Consider using when other treatment methods are not working.
    - Monitor for pancreatitis.

CHRONIC TREATMENT

- Repeated dosing of activated charcoal; check serum sodium 3 h after dosage if repeated doses, due to hypernatremia risk.
- Nursing care:
    - Frequent turning
    - Prevent urine scald.
    - Thermoregulation

NUTRITION/DIET

Tube feeding may be needed for recumbent/comatose animals for several days.

DRUG INTERACTIONS

Avoid drugs that may contribute to CNS depression (e.g., barbiturates).

POSSIBLE COMPLICATIONS

- Decubital ulcers
- Aspiration of activated charcoal or food
- Retinopathy has been reported in two dogs.

RECOMMENDED MONITORING

- Respiration
- Body temperature
- Heart rate
- Fluid/electrolyte balance

PROGNOSIS AND OUTCOME

- No specific antidote
- Prognosis depends on dose, relative individual sensitivity, and provision of good nursing care. Most animals recover with good supportive/nursing care.
    - Animals surviving >24 hours have reasonable prognosis, even though supportive care may be necessary for days or possibly weeks.

PEARLS & CONSIDERATIONS

COMMENTS

- Other macrocyclic lactones with similar mechanisms of action and clinical effects include milbemycin, moxidectin, selamectin, doramectin, eprinomectin, and abamectin.
- In general, doses up to 10 times the recommended *heartworm preventive doses* of milbemycin and ivermectin are well tolerated, even by sensitive (e.g., MDR-1 mutant) dogs.
- Toxic dose of ivermectin in collies and other sensitive breeds ranges between 0.1 and 0.2 mg/kg (15–30 times the therapeutic heartworm preventative dose but equal to the doses sometimes recommended for dermatologic or heartworm microfilaricide treatment) and 2.5–40 mg/kg (>200 times) in beagles.
- Because ivermectin is eliminated primarily through the bile and undergoes enterohepatic recirculation, activated charcoal can be of benefit even if the exposure was parenteral.
- Animals receiving repeated high doses of ivermectin for dermatologic or other reasons should be closely monitored for mydriasis or ataxia that may develop after several doses.
- Very high risk of moxidectin overdose when some equine moxidectin products containing 1.87% moxidectin (18,700 mcg/mL) are used in dogs.

PREVENTION

- Avoid large-animal products (concentration: 10 mg/mL which equals 10,000 mcg/mL) in companion animals to avoid risk of dilution errors. To prevent accidental exposure of dogs to spilled product, keep dogs out of area while horses are being dewormed.

TECHNICIAN TIPS

- Ivermectin toxicosis is less common (and therefore, more easily overlooked), owing to the wide availability of other effective antiparasitics.
- Profoundly affected patients may be comatose, and in such cases, the patient's life can depend on good airway protection (when tube feeding or if vomiting), hygiene (to prevent urine scald and fecal contamination), and pressure sore prevention (turning, topical therapy PRN).

Iris Abnormalities

BASIC INFORMATION

DEFINITION

Iris abnormalities include any change in the color, character, or appearance of the iris, including acquired changes secondary to anterior uveitis, neoplasia, ocular melanosis, or cyst formation, as well as developmental changes (e.g., persistent pupillary membranes [PPMs]). Other relevant definitions include those for rubeosis iridis (blood vessel formation on the surface of the iris) and synechia (adhesion of iris-to-cornea [anterior] or iris-to-lens [posterior]).

SYNONYMS

Uveal disease, ocular melanosis (once termed pigmentary glaucoma)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Anterior uveal neoplasia usually is seen in middle-aged to older animals.
- Ocular melanosis is seen in Cairn terriers and does not demonstrate age or sex predisposition.
- Uveal cysts most frequently are found in middle-aged to older animals (rare in cats).
- PPMs are congenital; pupillary membranes usually atrophy by 6 weeks of age in most puppies, but if not PPMs may be detected in all age groups (rare in cats).

GENETICS & BREED PREDISPOSITION

- Uveal melanoma has a suspected genetic predisposition in the Labrador retriever, golden retriever, and German shepherd.
- Ocular melanosis is an inherited, probably autosomal dominant condition in Cairn terriers.
- Uveal cysts: predisposed breeds include golden retrievers, Labrador retrievers, Boston terriers, Great Danes, rottweilers; see p. 1149).
- Heritable cause suspected for PPMs in basenjis, Pembroke Welsh corgis, chow chows, mastiffs, and others.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Uveitis (see p. 1151)
- Uveal neoplasia (see p. 620)
- Uveal cysts (see p. 1149)
- PPMs

HISTORY, CHIEF COMPLAINT

- Anterior uveitis: see p. 1151
- Uveal neoplasia: see p. 620
- Ocular melanosis: any or all of the following:
  - Change in color of the iris to dark brown
  - Cloudy/hazy appearance to the eye in cases of secondary glaucoma
- Uveal cysts: see p. 1149
- PPMs: any or all of the following:
  - Usually incidental findings
  - Cloudiness of eye
  - Cloudiness/opacities in pupil

PHYSICAL EXAM FINDINGS

- See History, Chief Complaint above.

- Ocular melanosis: any or all of the following:
  - Dark pigment-colored thickening of the iris root/base
  - Episcleral/scleral pigment plaques
  - Release of pigment into aqueous humor, with pigment deposition in aqueous drainage pathways
  - Pigmentation of the tapetal fundus +/− on the surface of the optic disk
  - Secondary glaucoma in severe cases
- PPMs: any or all of the following:
  - Single or multiple fine strands (rarely sheets) of iris tissue originating from the iris collarette and inserting on:
    - Adjacent iris; typically benign, incidental finding
    - Anterior lens; often associated with anterior capsular cataracts
    - Corneal endothelium; associated with varying degrees of corneal scarring and/or edema
    - Iris sheets; most severe form (sheet of tissue bridging pupil); associated with vision impairment

ETIOLOGY AND PATHOPHYSIOLOGY

- The uveal tract (or vascular layer) of the eye is composed of the iris, ciliary body, and choroid (see figure,p. 1151). The iris is the most anterior of these and is a thin diaphragm containing blood vessels, connective tissue, melanocytes, and two muscles—the iris sphincter and the iris dilator. In the center of the iridal diaphragm is a circular aperture, the pupil.
- Anterior uveitis (see p. 1151)
- Uveal neoplasia (see p. 620)
- Ocular melanosis: inherited thickening and pigmentation of the iris caused by increased melanocytes and (to a lesser extent) melanophages, with release of pigmented material into the aqueous humor and pigment deposition in the episclera/sclera ± posterior segment. Secondary glaucoma can result from extensive pigment deposition in the aqueous drainage pathways.
- Uveal cysts (see p. 1149)
- PPMs: nonvascular remnants of the tunica vasculosa lentis, which appear as iris strands or sheets originating in the iris collarette (midway point between iris base and pupillary margin). PPMs extend across the iris to insert on adjacent iris, lens, or cornea. When they insert on lens or cornea, opacification of these structures may occur. PPMs are a developmental defect that may have a heritable component in some breeds.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is generally suspected via the chief complaint or emerges as an incidental finding on physical exam. Characterization of an iris problem is based on a careful examination of the anterior chamber and iris surface with magnifying head loupes and diffuse and focal light sources.

DIFFERENTIAL DIAGNOSIS

- Discoloration of iris:
  - Pigmentation:
    - Uveal melanoma (variable appearance in the dog [focal] versus cat [mainly diffuse]; solid tissue; may cause dyscoria [misshapen/distorted pupil] and/or anisocoria [unequal or asymmetric pupils])
    - Ocular melanosis of Cairn terriers
    - Uveal cyst (round to ovoid, single or multiple, often translucent; see p. 1151)
    - Chronic anterior uveitis
  - Depigmentation:
    - Chronic anterior uveitis
    - Uveal neoplasm
  - Reddening:
    - Rubeosis iridis
    - Iridal hemorrhage
    - Uveal neoplasm
- Iris mass:
  - Uveal neoplasm
  - Uveal cyst
- Iris strands:
  - PPMs (arise from iris collarette; typically fine strands)
  - Synechiae (anterior: typically arise from base of iris or pupillary margin; posterior: arise from pupillary margin or posterior aspect of iris; often result in dyscoria [abnormal pupil shape])

INITIAL DATABASE

- Complete ophthalmic examination
- Variable depending on underlying condition

ADVANCED OR CONFIRMATORY TESTING

Variable depending on underlying condition:

- Ocular ultrasound (differentiate uveal neoplasm from cyst)

TREATMENT

TREATMENT OVERVIEW

Treatment of iris abnormalities varies widely, but fortunately diagnosis and subsequent treatment decisions are usually straightforward based on clinical signs.

ACUTE GENERAL TREATMENT

- Directed at underlying condition and, when possible, cause
- PPMs do not generally require treatment unless substantial corneal and/or lens opacification is/are present:
  - Iris-to-cornea PPMs may cause significant corneal edema which may benefit from topical 5% hypertonic saline ophthalmic solution or ointment q 6–12 h; continued long-term if clinical improvement noted.
  - Iris-to-lens PPMs can lead to cataract formation; if cataract is causing vision impairment, cataract surgery may be warranted (see p. 181).

POSSIBLE COMPLICATIONS

- Variable depending on underlying condition
- Cataracts and corneal edema associated with PPMs are rarely progressive.

PROGNOSIS AND OUTCOME

- Prognosis for *anterior uveitis* depends on severity at presentation, individual variation on severity and frequency of recurrences, underlying etiology, and client compliance.
- Primary intraocular neoplasia usually carries a poor prognosis for saving the eye but good prognosis for systemic health.
- Ocular melanosis has a variable rate of progression and usually carries a poor prognosis for saving the eye if secondary glaucoma develops.
- Uveal cysts and PPMs rarely cause problems with vision or ocular comfort.

PEARLS & CONSIDERATIONS

COMMENTS

- Most iridal abnormalities can be readily diagnosed on basis of clinical signs.
- Anterior uveitis requires immediate therapeutic intervention.

PREVENTION

Avoid breeding affected or closely related dogs predisposed to breed-related iris abnormalities.

AUTHOR: STEVEN R. HOLLINGSWORTH

EDITOR: CHERYL L. CULLEN

Ionophore Toxicosis

BASIC INFORMATION

DEFINITION

- Ionophores are antiparasitic fermentation products of *Streptomyces* fungi. They are used primarily as feed additives to increase feed efficiency and weight gain, and as coccidiostats in ruminants and poultry.
- Toxicosis results from accidental ingestion of livestock or poultry feed containing ionophores and is character-ized by acute central nervous system (CNS) dysfunction within 12 hours of large ingestions. Signs relate mainly to muscle damage within 24-96 hours of smaller ingestions.

SYNONYMS

Some of the commonly available ionophores are monensin (Rumensin, Coban), lasalocid (Bovatec, Avatec), salinomycin (Sacox, Bio-Cox), narasin (Monteban), semduramicin (Aviax), laidlomycin propionate (Cattlyst)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All animals susceptible; dogs mainly involved compared to cats
- Dogs are attracted to livestock or poultry feed that may contain the ionophore. Cats rarely attracted to these products.

GENETICS & BREED PREDISPOSITION

Farm dogs have greater access to ionophore-containing poultry or cattle feed.

RISK FACTORS

- Ionophore premix formulations (concentrated) are much more dangerous than ready-to-feed products.
- Patients with underlying cardiac or myopathic conditions could be at heightened risk of toxic effects.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute onset from high doses (<12 hours): acute CNS depression, ataxia, recumbency
- Subacute onset from lower doses (24-96 hours): generalized weakness, lethargy, anorexia
- Duration of effect: acute exposures, 2-10 days. Significant muscle involvement may produce permanent myopathy to variable degree. Cardiac lesions not commonly reported in dogs and cats (versus horses).

HISTORY, CHIEF COMPLAINT

- History of exposure to ionophore (livestock or poultry feed)
- Combination of possible access to ionophore and acute onset of progressive CNS depression, hind limb or full body weakness, or collapse
- Anorexia, diarrhea

PHYSICAL EXAM FINDINGS

- As listed above, plus ataxia, triplegia, hyporeflexia, tachypnea/dyspnea, tachycardia/arrhythmia, hyperthermia, tongue laxity
- Urine discoloration (myoglobin)

ETIOLOGY AND PATHOPHYSIOLOGY

Ionophore-induced cation transport across cell membranes results in intracellular calcium overload, mitochondrial disruption, catecholamine release, skeletal and myocardial muscle ischemia, necrosis and fibrosis, and acute renal tubular failure from myoglobin deposition.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is from history or evidence of exposure and clinical signs of ataxia, CNS depression, muscle weakness within 12 hours of exposure. No timely testing is available to confirm diagnosis. Presence of high amounts of ionophores in the feed can help determine exposure.

DIFFERENTIAL DIAGNOSIS

- Other intoxications (e.g., ivermectin, amitraz, bromethalin, macadamia nuts, alcohols, muscle relaxants [e.g., baclofen], hypoglycemic agents [e.g., xylitol, artificial sweetener], cardiac glycosides, sedatives, or painkillers [e.g., opioids, barbiturates, benzodiazepines, phenothiazines], and phenoxy herbicides)
- Rhabdomyolysis
- Neuromuscular disease (botulism, myasthenia gravis, polyradiculoneuritis, tick paralysis)
- Hypoadrenocorticism

INITIAL DATABASE

- Baseline serum biochemistry profile, including electrolytes and calcium
- Electrocardiogram (ECG); early indicator of myocardial involvement. ECG alterations (S-T segment depression, atrial fibrillation, paroxysmal atrial tachycardia), sinus tachycardia possible.
- Baseline and follow-up monitoring of skeletal muscle enzymes: creatine kinase (CK), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH). Also note increase in alanine aminotransferase. CK is the most sensitive indicator, noted within 4-6 hours of acute insult, maximum at 6-12 hours. AST rises more slowly, may persist for several days. LDH is less dramatic, reaches maximum levels within 48-72 hours.
- Myoglobin (serum and urine). Absent in serum/urine of the healthy animal, released rapidly from damaged muscle/tissue; sensitive indicator of myone-crosis.
- Blood pressure
- Arterial blood gas

ADVANCED OR CONFIRMATORY TESTING

- Feed analysis may help determine ionophore concentration and dose consumed by the animal. Beneficial to affected patient (confirmation of toxic exposure) if known at time of intoxication; otherwise, retrospective confirmation.
- Histopathologic exam of tissues: various stages of focal myocyte degeneration, vacuolation, necrosis, and fibrosis.

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to induce emesis (within 2 hours of exposure) and administer activated charcoal followed by supportive care (intravenous fluids). Do not induce emesis if clinical signs are present. Administration of charcoal and fluids depends on the risk (dose), and most sus-

pects or confirmed cases should receive them because dose of exposure usually is not known.

ACUTE GENERAL TREATMENT

- Reduce gut absorption:
  - Induce emesis (dogs) if exposure is within 2 hours (seep. 1364).
  - Activated charcoal with a cathartic (1-4 g/kg PO, repeat in 6-8 hours if initial exposure is high).
- Supportive care:
  - Intravenous fluids 0.9% saline, typically at 1.5 to 2 times maintenance rate; caution if exhibiting cardiopulmonary signs. Ensure adequate perfusion to avoid/reduce renal tubu-lar damage (myoglobin-associated), and assist compensation of expected low-moderate degree of acidosis.
  - Urine alkalinization with sodium bicarbonate to reduce myoglobin deposition in renal tubules is controversial but not necessarily contraindicated; ensure acid-base, electrolyte, and cardiac monitoring.
  - Treat cardiac abnormalities as indicated from abnormal ECG tracings (see p. 1165). CAUTION: lidocaine may potentiate monensin toxicity.
  - Correct electrolyte imbalances, assess and manage expected metabolic acidosis.

- Oxygen support as indicated from pulse oximetry readings and pulmonary condition.
- Dialysis benefit unknown but may be indicated if severe renal failure is of concern.
- Calcium channel blockers, calcium antagonists or modulators are *not* recommended.

CHRONIC TREATMENT

Patient should not be stressed (minimize activity) and should be rested for several weeks (muscle recovery).

DRUG INTERACTIONS

Concurrent administration of chloramphenicol, tiamulin, erythromycin, sulfonamides, or cardiac glycosides is contraindicated: can potentiate ionophore toxicosis.

POSSIBLE COMPLICATIONS

Skeletal muscle fibrosis, vacuolization of peripheral sensory and motor nerves possible

RECOMMENDED MONITORING

- Selected cardiac, renal, acid-base, and muscle chemistries
- ECG

PROGNOSIS AND OUTCOME

- Poor if extensive damage to skeletal muscle occurs
- The relative degree of myofibrosis will determine the long-term prognosis.
- May require retirement of high-performance patients (e.g., breeding, sporting, trial dogs)

PEARLS & CONSIDERATIONS

COMMENTS

- Occurrence of ionophore toxicosis in dogs and cats is low.
- Monensin: canine acute oral LD50 = 10-20 mg/kg. Lasalocid: field cases reported at 166-210 mg/kg/d of dog food (10-15 mg/kg/d of lasalocid). Salinomycin: reported oral toxicosis in cats at 440 mg/kg in cat food.
- Relay (secondary) toxicosis has been reported in dogs consuming dead chickens containing ionophores (lasalocid).
- Intoxication from accidental ionophore adulteration of dog food has also been reported.

TECHNICIAN TIP

Subtle signs of muscle pain (myalgia), including mild lameness or new-onset tenderness or resentment of palpation over thigh or lumbar muscles, may not be apparent in the exam room and may first be detected during handling or longer interaction with an affected dog.

PREVENTION

Do not allow dogs and cats to enter cattle or poultry farms where ionophores are stored or being fed.

EDITOR: SAFDAR A. KHAN

1ST EDITION AUTHOR: MICHAEL W. KNIGHT

Intussusception

BASIC INFORMATION

DEFINITION

- Invagination of one segment of the gastrointestinal (GI) tract into the lumen of an adjacent segment
- *Intussusceptum* is the invaginated segment, and the *intussuscipiens* is the outer or enveloping segment.

SYNONYMS

Intestinal telescoping, enteroenteric intussusception (also called *intestinal intussusception)*

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Intestinal intussusception usually occurs in animals <1 year unless associated with neoplasia.
- Gastroesophageal intussusception is most common in dogs <3 months old.

GENETICS & BREED PREDISPOSITION

Siamese and Burmese cats, German shepherds, and shar-peis may be predisposed.

RISK FACTORS

Infectious gastroenteritis (parasitic, bacterial, or viral); foreign-body ingestion; intestinal mass/neoplasia; previous surgery; canine renal transplantation, peritonitis; organophosphate intoxication

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Any of the following sites can be involved: gastroesophageal (see p. 527), pylorogastric, enteroenteric, enterocolic.
- Intussusception most commonly occurs in direction of normal peristalsis, with intussusceptum as proximal segment, but reverse can also occur (e.g., gastroesophageal intussusception).
- More than one site can be involved, or two invaginations may occur at the same site.

HISTORY, CHIEF COMPLAINT

- Diarrhea, hematochezia, vomiting, anorexia, lethargy, and weight loss
- Respiratory distress if gastroesophageal intussusception
- Signs can be acute or chronic.

PHYSICAL EXAM FINDINGS

- Palpable, sausage-shaped abdominal mass is characteristic but may not be present (or may be precluded by guarding/abdominal wall tension).
- Signs of pain on abdominal palpation
- Dehydration, tachycardia (more severe signs associated with more proximal obstruction)
- Poor body condition can be seen in chronic cases.
- Intussusception may protrude from

ETIOLOGY AND PATHOPHYSIOLOGY

- Proposed cause is structural or functional heterogeneity within the bowel wall, resulting in an alteration of intestinal pliability or motility.
- Intussusception produces partial or complete intestinal obstruction.

- Increased intraluminal pressure and kinking causes collapse of mesenteric blood vessels. Avulsion of vessels can also occur.
- Bowel wall becomes edematous and may become ischemic.
- Necrosis of the bowel wall, with leakage of contents contained by a fibrin seal between the layers of the intussusception, may occur. If leakage is not contained, peritonitis develops.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

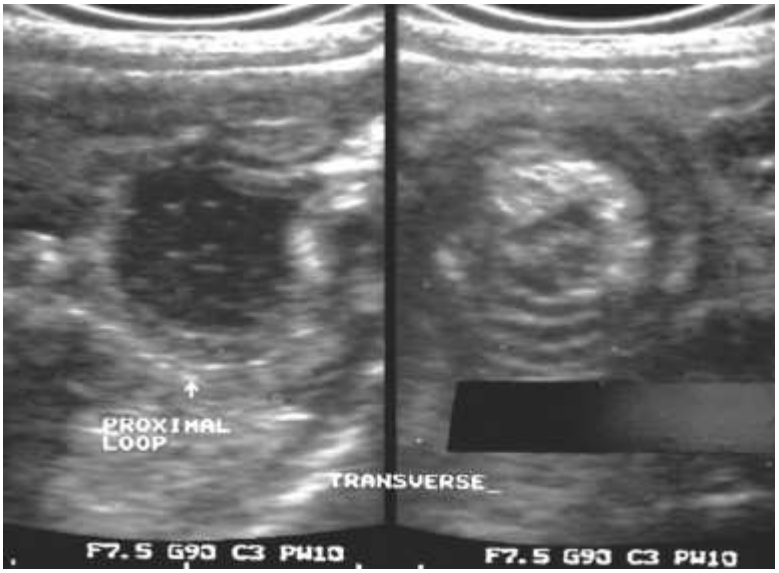
The diagnosis of enteroenteric (intestinal) intussusception is suspected based on history and typical physical examination findings if present. Confirmation is obtained with abdominal ultrasound exam or surgical exploration (either one is pathognomonic).

DIFFERENTIAL DIAGNOSIS

- Gastroenteritis associated with infection or dietary indiscretion
- Intestinal obstruction associated with foreign body, neoplasia, abscess, or granuloma
- Physiologic ileus
- Rectal prolapse if intussusception protruding through anus (see p. 963)

INITIAL DATABASE

- CBC may show evidence of a stress leukogram or anemia. Increased red blood cell count may be seen with dehydration.
- Serum chemistry profile may show evidence of dehydration (increased total protein, azotemia), hypokalemia, hypochloremia, hyponatremia, or hypoproteinemia. Alkalosis may be seen with proximal obstructions.
- Abdominal radiographs: fluid- or gas-distended intestinal loops. Tubular mass effect (sausage shape) of the intussusception may be seen in the small intestine or in a gas-filled colon.
- Thoracic radiographs: soft-tissue density within esophagus if gastroesophageal intussusception
- Fecal flotations (serial until positive result or total of three): indicated in all cases of intussusception, to assess possible parasitic causes



INTUSSUSCEPTION Ultrasound appearance of small-intestinal intussusception. *Left,* Dilated, poorly motile jejunum located proximal to the intussusception. *Right,* Characteristic multilayered, “target” appearance of intussuscepted small intestine. Horizontal bar below intussuscepted bowel is artifactual.

(Courtesy Dr. Richard Walshaw.)

ADVANCED OR CONFIRMATORY TESTING

- Contrast radiography with upper GI radiographic contrast study or barium enema: filling defect caused by intussusceptum seen within intussuscipiens
- Ultrasonography: concentric rings seen in transverse plane (“target sign”)

TREATMENT

TREATMENT OVERVIEW

Hypovolemia should be corrected prior to surgical intervention. At surgery, an attempt is made to reduce the intussusception. If it is not reducible or there is bowel damage, a resection and anastomosis is indicated. Enteroplication may be considered to prevent recurrence.

ACUTE GENERAL TREATMENT

- Intravenous crystalloids to correct dehydration or treat for shock. Colloids may be helpful with hypoproteinemia. If severe hypochloremia/hyponatremia, treat with 0.9% NaCl. Provide potassium supplementation if hypokalemic.
- Perioperative antibiotics (e.g., cefazolin, 22 mg/kg IV q 2 h) during perioperative period
- Enteroenteric or enterocolic intussusceptions; at the time of surgical exploration, reduce intussusception by applying pressure to intussuscipiens while *gently* pulling on intussusceptum:
    - Resection and anastomosis if unable to reduce intussusception, a mass is present, or there is nonviable bowel
- With enteroenteric intussusception, perform enteroplication if recurrence appears likely based on inability to correct underlying disease.
- With gastroesophageal intussusception, perform gastropexy of fundus and pylorus to prevent recurrence.

CHRONIC TREATMENT

- Opioid analgesia after surgery may decrease risk of recurrence.
- Treat infectious enteritis that may have caused intussusception.
- Antibiotics should be continued after surgery if peritonitis is present.
- Enteroplication if not performed at first surgery and postoperative intussusception recurs

POSSIBLE COMPLICATIONS

- Recurrence of intussusception occurs in 11%–25% of patients.
- Peritonitis associated with bowel rupture
- Leakage or dehiscence of intestinal suture line
- Entrapment and strangulation of bowel between enteroplication sutures
- Foreign body entrapment in bend of intestine created by enteroplication

RECOMMENDED MONITORING

- Monitor hydration status and serum electrolyte concentrations.
- Monitor for signs of intestinal suture line dehiscence and peritonitis (increased body temperature, abdominal pain, hypoglycemia).
- If clinical signs recur after surgery, repeat imaging to evaluate for possible recurrence of intussusception or complication associated with enteroplication.

PROGNOSIS AND OUTCOME

- Depends on cause, location, and duration of intussusception.
    - Good if fluid and electrolyte abnormalities are corrected and there is immediate surgical intervention.
    - Patients with proximal GI tract intussusception, generalized peritonitis, or underlying malignant intestinal neoplasia have a worse prognosis.
- Up to 25% recurrence is reported if enteroplication is not performed in association with surgical correction of intestinal intussusception.
- Severe complications are associated with enteroplication in 19% of dogs.

PEARLS & CONSIDERATIONS

COMMENTS

For each patient, the risk of recurrence must be weighed against the risk of complications associated with enteroplication:

- The decision is based largely on whether an underlying cause that can be corrected has been identified.
- If enteroplication is performed, create gentle loops along entire length of small intestine (from duodenocolic ligament to ileocolic junction); sutures 5-10 cm apart.
- Spontaneous reduction of intussusception has been reported in dogs; however, recurrence that requires surgical intervention may occur.

EDITOR: RICHARD WALSHAW

Intraocular Neoplasia

BASIC INFORMATION

DEFINITION

- Primary intraocular neoplasms arise from the vascular intraocular tunic (iris, ciliary body, choroid). In cats, primary undifferentiated sarcoma arises from undetermined cell population, most likely lens epithelium. Neoplasia of the fibrous tunic, adnexa (eyelids, conjunctiva, lacrimal glands), and orbit are covered in additional detail elsewhere (see p. 1045 ,p. 711 , and p. 790).
- Secondary intraocular neoplasia occurs through metastasis or (rarely) by extension from adjacent tissues.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Melanoma/melanocytoma affects dogs and cats, usually older adults (>7 years), although also seen in young dogs <4 years old
- Medulloepithelioma usually affects animals 1–4 years of age.
- Primary sarcoma occurs only in cats, of any age.

GENETICS & BREED PREDISPOSITION

- Uveal melanoma has demonstrated genetic predisposition in Labrador retrievers, suspected in golden retrievers, German shepherds.
- Mode of inheritance suspected to be autosomal dominant

ASSOCIATED CONDITIONS & DISORDERS

Uveitis, glaucoma, retinal detachment, intraocular hemorrhage can occur secondary to intraocular neoplasia.

CLINICAL PRESENTATION

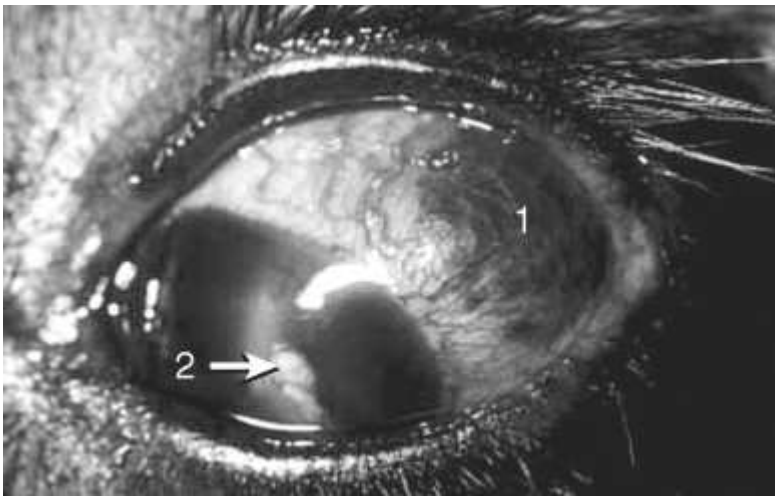
HISTORY, CHIEF COMPLAINT

- Change in appearance of the eye: redness, cloudiness, swelling, darkening of iris, mass noted
- Pain, blepharospasm
- Loss of vision

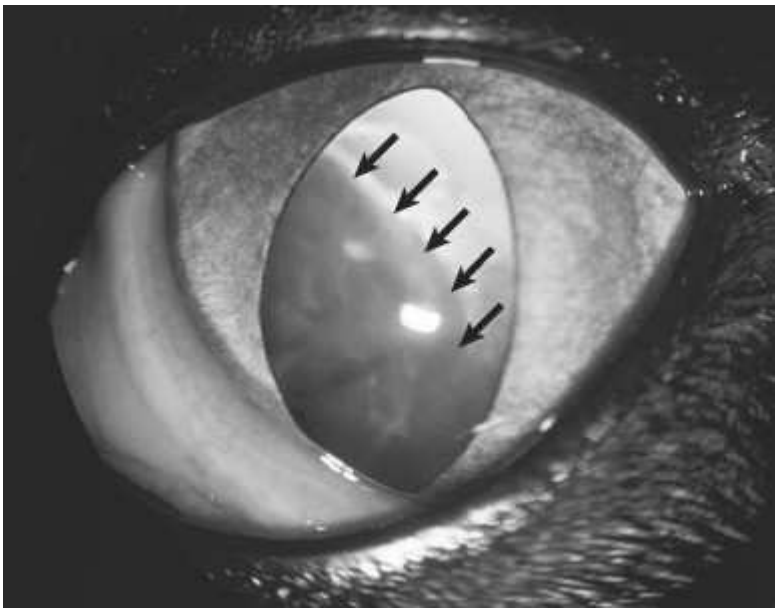
PHYSICAL EXAM FINDINGS

- Findings directly associated with tumor:
  - Mass which may be pigmented (melanoma/melanocytoma) or pink in color (more likely ciliary body adenoma/adenocarcinoma, or metastatic neoplasia) within the iris or pupil
  - Not all melanomas are pigmented, nor are all pigmented masses melanomas (histologic diagnosis).
  - Extension of mass through sclera
  - Diffuse hyperpigmentation of iris (more often in cats)
  - Dyscoria (abnormally shaped pupil), anisocoria (pupil of different size than the contralateral pupil)
  - Shallow anterior chamber
  - Intraocular hemorrhage
  - Displacement of lens (see p. 644)
- Findings associated with secondary glaucoma/uveitis:
  - Elevated intraocular pressure (glaucoma)
  - Fixed, dilated pupil
  - Corneal edema
  - Scleral injection
  - Aqueous flare
  - Hyphema
  - Lens luxation

- If chronic, retinal degeneration and peripapillary (area around the optic disc) hyperpigmentation



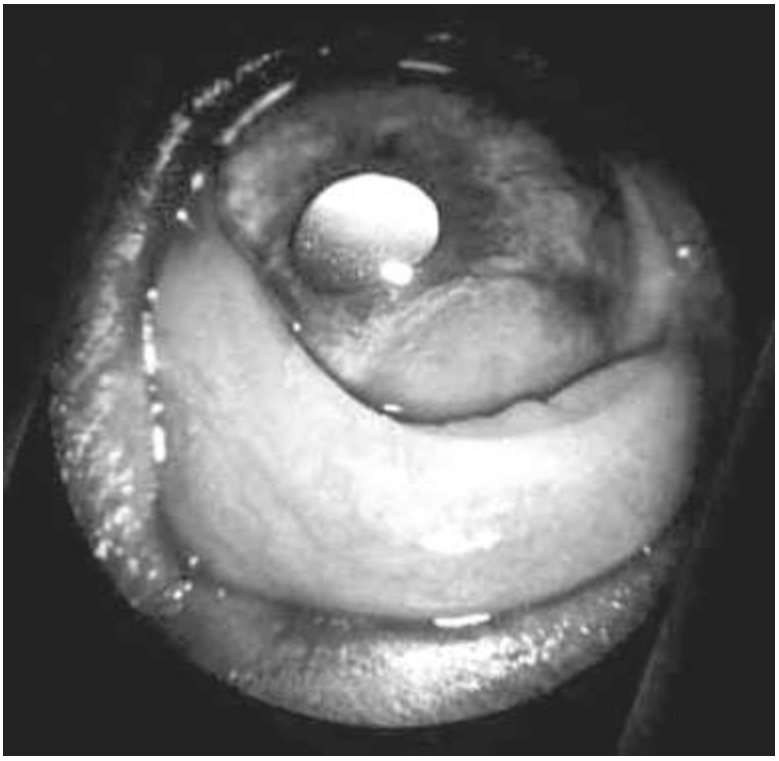
INTRAOCULAR NEOPLASIA Uveal melanoma in a dog with corneal and extrascleral extension *(1).* Note white area of calcific corneal degeneration at leading edge of corneal extension *(2).* Enucleation is recommended.



INTRAOCULAR NEOPLASIA Pink, vascular mass visible within the pupil in a cat. Appearance is typical of a ciliary body adenoma/adenocarcinoma, but metastatic neoplasia is also possible.

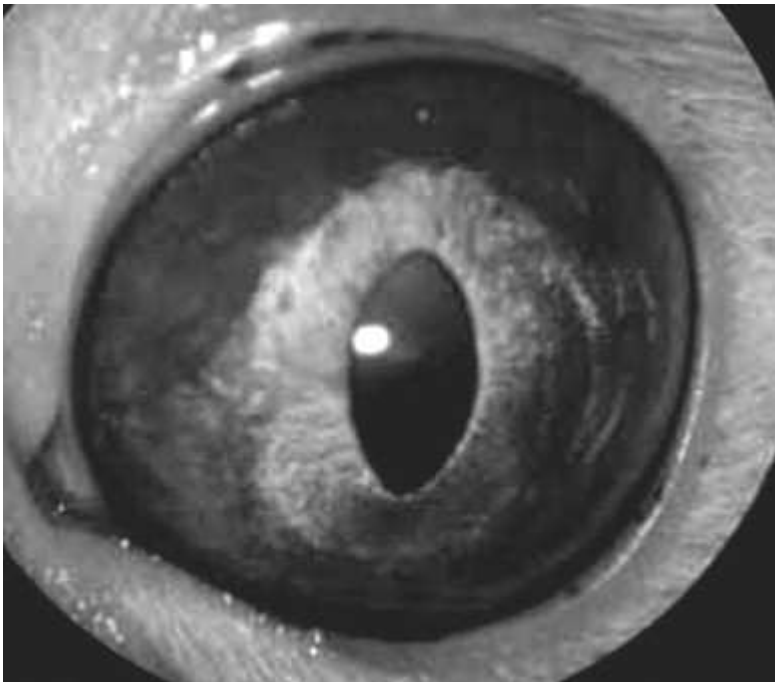
ETIOLOGY AND PATHOPHYSIOLOGY

- Proliferation of uveal melanocytes or ciliary body epithelium, cause unknown
- Melanoma originates most commonly in the anterior uvea (iris and ciliary body), unlike humans, where most are of choroidal origin.
- Undifferentiated sarcoma in cats occurs months to years after blunt or penetrating trauma to the eye. Damage to lens epithelium is implicated as initiating factor.
- Primary tumors in dogs are benign and although locally invasive, rarely metastasize.
- Ciliary body tumors rarely metastasize.
- Uveal melanoma in cats may metastasize.
- Primary intraocular sarcoma in cats frequently metastasize.



INTRAOCULAR NEOPLASIA Lymphoma metastatic to the iris and third eyelid in a dog. Diagnosis was made by biopsy of the third eyelid.

(Photograph from Dr. Robert L. Peiffer, Jr. with permission.)



INTRAOCULAR NEOPLASIA Diffuse iris melanoma in a cat. Note the raised, “velvety” appearance distinguishing this from benign iris hyperpigmentation. Enucleation is recommended.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Goals of diagnosis are to confirm neoplasia versus other processes and differentiate primary versus secondary and malignant versus

benign intraocular neoplasm.

DIFFERENTIAL DIAGNOSIS

- Iris cyst
- Diffuse iris melanocytosis, hyperpigmentation
- Granulomatous uveitis with accumulation of inflammatory nodules within iris stroma
- Other causes of uveitis, glaucoma, intraocular hemorrhage

INITIAL DATABASE

- Ophthalmic examination (see p. 1313) including evaluation of vision and pupillary light reflexes, measurement of intraocular pressure; direct visualization of mass may allow conclusive diagnosis.
- Ocular ultrasonography may confirm and delineate mass that cannot be directly visualized because of location or lack of clarity of ocular media. Tumor appears as a hyperechoic mass within iris or ciliary body and may be difficult to differentiate from organized hemorrhage.
- Systemic evaluation to rule out metastatic disease (CBC, serum biochemistry panel, urinalysis, thoracic and abdominal radiographs and ultrasonography)

ADVANCED OR CONFIRMATORY TESTING

- Aqueocentesis may not be diagnostic, as tumors often do not exfoliate cells into the aqueous; most valuable for lymphoma.
- Fine-needle aspirate of mass is often nondiagnostic owing to inadequate size of sample.
- Biopsy of mass may be accompanied by hemorrhage.

TREATMENT

TREATMENT OVERVIEW

Treatment is based on assessment of presence of vision and potential to preserve comfortable globe. Goals are to prevent progressive growth of tumor (preserving vision and comfort) and alleviate discomfort caused by secondary glaucoma in blind eye.

ACUTE GENERAL TREATMENT

- Primary intraocular tumors:
  - Enucleation is indicated if irreversible blindness and pain due to secondary glaucoma
  - Due to their metastatic potential, enucleation is indicated for iris melanoma and primary sarcoma in cats.
  - Conservative monitoring alone may be justified in older dogs, based on likely slow growth of primary tumor.
  - Sector iridectomy may provide incomplete excision and is often accompanied by hemorrhage and secondary glaucoma; may be only surgical option for nonpigmented tumors.
  - Diode laser treatment, transcorneally or through a limbal incision, is effective for pigmented tumors.
- Secondary intraocular tumors: treatment is directed at primary neoplasm if possible. If systemic prognosis warrants, enucleation may be indicated for comfort.

POSSIBLE COMPLICATIONS

- Laser treatment of large lesions may be accompanied by significant inflammation and may precipitate secondary glaucoma.
- Regrowth of tumor is possible following laser treatment.

RECOMMENDED MONITORING

Long-term monitoring to detect recurrent growth is indicated after laser treatment.

PROGNOSIS AND OUTCOME

- Primary neoplasms of the iris and ciliary body in dogs are nearly always benign and very rarely metastasize.
- Iris melanomas in cats are malignant tumors and may metastasize.
- Primary intraocular sarcomas in cats are locally aggressive and often metastasize.

PEARLS & CONSIDERATIONS

COMMENTS

- Assessment of vision is a primary factor in determining treatment recommendation. If eye has functional vision, laser treatment should be considered for localized lesions; if eye is blind, enucleation is recommended.
- For malignant melanoma and sarcoma in cats, enucleation is advisable.

PREVENTION

Iris melanoma in dogs: avoid breeding affected or closely related individuals.

Intervertebral Disk Disease

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Degeneration and displacement of disk material into the vertebral canal or intervertebral foramen, causing variable clinical signs that include discomfort (ranging from mild to excruciating) and/or gait disturbance (ranging from mild ataxia to paralysis)

SYNONYMS

Disk herniation, disk protrusion, disk extrusion, disk rupture, disk prolapse

EPIDEMIOLOGY

SPECIES, AGE, SEX

Most common in young to middle-aged, chondrodystrophic breeds, owing to chondroid metaplasia of the intervertebral disks. Cats: most commonly seen in older cats, with predilection for the lumbar spine, although cervical disk displacements have been reported.

RISK FACTORS

In both dogs and cats, these disk displacements usually occur spontaneously and are not associated with external trauma.

CLINICAL PRESENTATION

HISTORY/CHIEF COMPLAINT

- Discomfort is produced chiefly by the attenuation of dorsal nerve roots as they pass to the spinal cord via the intervertebral foramina.
- Discomfort associated with thoracolumbar and lumbar disk disease may be severe (general stiffness) and may be misinterpreted by the client and/or veterinarian as evidence of intraabdominal pain.
- Reluctance to jump, climb, or engage in other forms of activity
- Paresis (weakness): caused by disruption of normal nerve transmission between the brain and nerves to the limbs. Ataxia (incoordination) and knuckling/tripping on digits (conscious proprioception deficits).

PHYSICAL EXAM FINDINGS

- Focal discomfort on palpation of the area
- Ataxia and/or proprioceptive deficits in limbs
- Paresis. The type of paresis seen in the affected limb(s) (i.e., upper motor neuron versus lower motor neuron) is determined by the longitudinal location of the spinal cord lesion produced by the displaced disk. The severity of paresis is linked to the amount of spinal cord compression.
- Segmental reflex alterations help with neuroanatomic (longitudinal) localization.
- Nociception. Alterations in perception of and response to noxious stimuli are of localizing and prognostic significance.

ETIOLOGY AND PATHOPHYSIOLOGY

- Hansen type I disk disease represents displacement of nucleus pulposus through a rent in the annulus fibrosis, producing a relatively focal mass effect within the vertebral canal and/or intervertebral foramen. It is typically associated with chondroid disk metaplasia as seen in chondrodystrophic breeds. This is usually associated with acute/ subacute clinical signs.
- Hansen type II disk disease represents a bulging of the annulus fibrosis and herniation of nucleus pulposus within the annulus to produce a somewhat more diffuse mass effect within the vertebral canal. It is more typically seen with fibroid metaplasia in non-chondrodystrophoid breeds. Clinical signs tend to develop more slowly and progressively.
- So-called Hansen type III disk disease, or “gunshot” disk/high velocity displacement of nucleus pulposus

DIAGNOSIS

OVERVIEW STATEMENT

Diagnosis is based on results of physical, neurologic, and imaging (myelography, CT, or MRI) examinations.

DIFFERENTIAL DIAGNOSIS

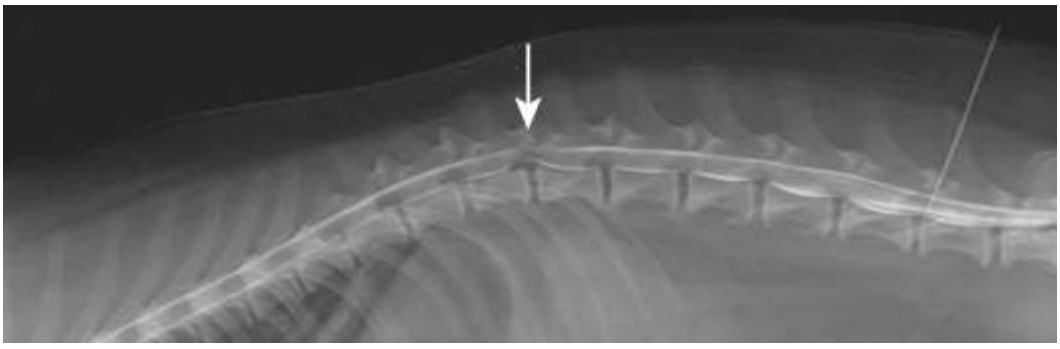
Spinal fracture/luxation; spinal cord, nerve root, epidural or vertebral neoplasia; fibrocartilaginous embolism; spinal cord inflammation (myelitis); diskospondylitis (intradiskal osteomyelitis); degenerative myelopathy; caudal occipital malformation syndrome with syringomyelia

INITIAL DATABASE

- Neurologic examination (see p. 1311):
  - Findings are consistent with a single focal spinal cord lesion (i.e., mentation and cranial nerve responses are within normal limits).
  - Deficits help to localize the lesion:
    - Upper motor neuron signs in fore-limbs and hind limbs: C1-C5 segments lesion
    - Lower motor neuron signs in fore-limbs, upper motor neuron signs in hind limbs: C6-T2 segments (cervical intumescence) lesion
    - Forelimbs normal, upper motor neuron signs in hind limbs: T3-L3 segments lesion
    - Forelimbs normal, lower motor neuron signs in hind limbs (femoral nerve distribution, diminishment of patellar reflex): L3-L6 segments lesion
    - Forelimbs normal, normal to increased patellar reflex (pseudohyperreflexia). Lower motor neuron signs in hind limbs (sciatic nerve distribution, diminishment of withdrawal and cranial tibial reflexes): L6-S1 segments lesion
    - Limbs normal (or mild LMN and CP deficits in pelvic limbs), decreased tail tone, decreased anal tone, decreased perineal reflexes: S2-coccygeal segments lesion
    - Cutaneous trunci (“panniculus”) reflex may help further localize in dogs with signs referable to a T3-L3 segment lesion, and might also help determine which side the lesion is preferentially affecting.
    - Palpation of epaxial muscles and vertebrae to determine if discomfort present and location of discomfort
    - Determination of a line of hypalgesia or analgesia (sensory level) if possible
  - Location of deficits helps determine the site of the lesion but does not confirm that intervertebral disk disease is the cause.
- CBC, serum biochemistry panel, urinalysis (possible dysuria/urine retention and infection), electrocardiogram (potential anesthesia for imaging studies and surgery).
- Survey radiography with orthogonal views of heavily sedated, properly positioned patient will rule out fractures/luxations, and severe bone neoplasia Calcified disks in situ are abnormal (degenerated) but may not be clinically significant.

ADVANCED OR CONFIRMATORY TESTING

- Myelography (see p. 1300, CT (see p. 1233), CT combined with myelography or MRI (see p. 1302) may reveal location of spinal cord compression due to disk displacement. Cerebrospinal fluid (CSF) analysis may be done in conjunction with myelography or after CT or MRI, especially if something other than a disk displacement is suspected to be the cause for myelopathy.
- Advanced imaging is usually done where surgery is contemplated as a possible treatment. If a client has ruled out surgical intervention, the results of any imaging study (including plain radiography) will only be of academic value and may have little to no influence on further treatment planning or prognostication.



INTERVERTEBRAL DISK DISEASE Myelogram in a dog with intervertebral disk disease, lateral view. Spinal needle used for injecting contrast agent is in the L5-L6 interspace *(right of image).* A dorsal deviation in the contrast column is seen at T13-L1, consistent with disk displacement *(arrow).* As an incidental finding, mineralization of the nucleus pulposus is seen in several intervertebral disks (T10-T11, T12-T13, L5-L6).

(Courtesy Dr. LeeAnn Pack.)

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to alleviate discomfort, reverse neurologic dysfunction, and prevent secondary complications such as those associated with urine retention and incontinence.

ACUTE GENERAL TREATMENT

- Based on severity and progression of neurologic dysfunction and discomfort
- Patients with discomfort alone and no neurologic deficits, or those with mild neurologic deficits that are not progressing rapidly: STRICT cage rest for 2–6 weeks (only activity = short walks to go to urinate/defecate) regardless of perceived improvement.
- Treatment with muscle relaxants and analgesics (nonsteroidal antiinflammatory drugs [NSAIDs], opiates).
    - Muscle relaxant (e.g., methocarbamol [Robaxin] 15–22 mg/kg PO or 44 mg/kg IV as needed up to q 4 h, not to exceed 330 mg/kg/day)
    - NSAIDs: meloxicam 0.1 mg/kg IV, SQ, or PO q 24 h; *or* carprofen 2 mg/kg PO q 24 h; *or* deracoxib 2–4 mg/kg PO q 24 h; *or* etodolac 10–15 mg/kg PO q 24 h. Do not use more than one NSAID at a time, or an NSAID concurrently with corticosteroids (risk of severe gastric ulceration).
- Patients with more severe neurologic signs and imaging evidence of cord compression: surgical decompression.
- Corticosteroids:
    - Time honored but increasingly unpopular with neurosurgeons due to frequent adverse effects and lack of proven efficacy
    - Corticosteroids do not eliminate the primary lesion and cannot be considered equivalent to surgical decompression.
    - Protocols advocated by other sources include methylprednisolone (Solu-Medrol) 30 mg/kg IV once, within 12 hours of onset of clinical signs; *or* dexamethasone 0.5-1 mg/ kg IV once within 6-8 hours of onset of clinical signs.
- If acutely paraplegic/tetraplegic: IV fluids to maintain hydration for optimal spinal cord perfusion

CHRONIC TREATMENT

- For animals that have lost motor function, the single most important aspect of treatment is bladder management to reduce the risk of urinary tract infection and bladder detrusor muscle damage from chronic overdistention. This may entail manual expression of the bladder every 4-6 hours or catheterization. In some cases, medication to help decrease urethral sphincter tone (e.g., phenoxybenzamine 0.25 mg/kg PO q 12 h; avoid if hypotension) may be helpful.
- Reducing antiinflammatory medications and analgesics after the acute phase, based on patient comfort
- Confined, padded rest areas, slings for assisted ambulation, hydrotherapy for cleanliness and to stimulate ambulation
- Control of body weight to avoid obesity
- Avoidance of climbing and jumping activities that stress the spine
- Physical rehabilitation including underwater treadmill use (see p. 1329) to strengthen axial and appendicular musculature and help retrain the nervous system
    - Acupuncture (see p. 1195): provides analgesia but does not alter the primary lesion; controversial.
    - Chiropractic maneuvers are highly controversial and may worsen neurologic status.

DRUG INTERACTIONS

Concurrent usage of corticosteroids and NSAIDs may lead to severe gastrointestinal ulceration and is contraindicated.

POSSIBLE COMPLICATIONS

- Urinary tract infection from incontinence/long dwell times or improper catheter use/care
- Detrusor atony from chronic overdistention of the bladder
- Urine scalding of skin from overflow incontinence
- Worsened neurologic status due to iatrogenic spinal cord trauma or vascular changes during decompressive surgery
- Ascending-descending myelomalacia: a devastating complication that occurs in <1% of acutely paraplegic dogs (mostly dachshunds). Focal lesion, commonly T3-L3, rapidly deteriorates to expanding cord necrosis, causing signs of ascending and descending cord dysfunction over a period of hours. There is no known treatment for this complication, and the key is early recognition so humane euthanasia can be performed.

RECOMMENDED MONITORING

Discomfort level, bladder/bowel evacuations, evidence of pressure sores, and neurologic status should be assessed frequently.

PROGNOSIS AND OUTCOME

- The most important prognostic indicator for paralyzed dogs (i.e., no voluntary motor function) is the presence or absence of nociception (deep pain), because the unmyelinated pain fibers in the spinal cord are the least vulnerable to ischemic injury. This assessment is always subjective, but apparent loss of sensation below the level of spinal cord injury suggests the possibility for permanent paralysis, regardless of treatment. Approximately 50% of dogs in this condition will recover if treated with decompressive surgery within 12 hours of the loss of nociception. Beyond 12 hours, the recovery rate decreases rapidly to between zero and 5%.
- For dogs with intact nociception, even if paraplegic (no motor function), approximately 80%–90% will recover fully or nearly fully with surgical decompression. However, the time frame for recovery is extremely variable (few days to many weeks or months).
- The recurrence rate (i.e., a new disk displacement at a different level) is almost nil in nonchondrodystrophic breeds, although some of these dogs (especially German shepherds) may have initial signs attributable to Hansen type II disease at multiple levels simultaneously.
- For chondrodystrophic breeds and Hansen type I displacements, the published recurrence rates vary widely, but the best estimates for a severe recurrence of signs that would require a second operation are in the 3%-5% range. A higher percentage of postdecompression dogs may suffer new signs that are less severe and can be managed medically.
- Patients treated without surgery may recover as well, regardless of severity of deficits. However, such recoveries usually take longer than in those dogs receiving surgery, and the recurrence rate for similar or worse clinical signs is much higher.
- Relapse of signs is seen in approximately 30%–50% of dogs managed nonoperatively and is likely due to more nucleus pulposus from the same disk displacing into the vertebral canal at a later time, rather than multiple disks displacing.
- Dogs with signs attributable to ascending-descending myelomalacia have a hopeless prognosis and should be humanely euthanized.

PEARLS & CONSIDERATIONS

COMMENTS

- Strict cage rest is critical for recovery in nonsurgical patients treated only with analgesics and antiinflammatory medications. Physical rehabilitation, weight control, and avoidance of jumping activities can reduce the risk of recurrence and future need for surgery.
- There is no direct correlation between severity of signs and amount of disk material displaced. It is a grievous mistake to assume that surgery is not indicated in dogs with pain as their only sign or those with only mild deficits (thinking that such mild signs imply only a small amount of displaced disk), since these patients may have huge amounts of displaced disk and marked spinal cord/nerve root compression. Conversely, some of the most severely affected dogs (e.g., acutely paraplegic/no deep pain) may have suffered a Hansen type III disk displacement (“gunshot disk”), and will not likely be improved by surgery, even if done on an emergency basis.
- Options for a patient with suspected disk disease include medical management, hospitalization versus home care, referral for 24-hour observation, or referral for possible surgery. Ongoing monitoring is essential to determine whether the current course should be continued or if failure to improve, relapse of signs, or worsening of signs make a new strategy advisable.

PREVENTION

- Avoidance of obesity and jumping activities for chondrodystrophic breeds may lessen the tendency for recurrence.
- Prophylactic disk fenestration or chemonucleolysis may reduce the risk for treated disk spaces to undergo later displacement, but risks and the true benefit are unproven at this time.

CLIENT EDUCATION

- See Prevention above
- For paralyzed patients, clients should be informed of bladder involvement in addition to the limb paralysis to understand this component of management.

1ST EDITION AUTHOR: JOSEPH HARARI

Interstitial Lung Diseases

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A heterogeneous group of uncommon lung diseases centered on the pulmonary interstitium, and that result from exaggerated inflammatory and/or reparative (fibrotic) responses to inhaled or hematogenous insults

SYNONYMS

Examples of interstitial lung diseases (ILDs) include:

- Bronchiolitis obliterans with organizing pneumonia (BOOP); recently renamed to cryptogenic organizing pneumonia (COP) in human medicine
- Endogenous lipid pneumonia
- Eosinophilic pneumonia (also called eosinophilic bronchopneumopathy *and* pulmonary infiltrates with eosinophilia [PIE]; see p. 350)
- Idiopathic pulmonary fibrosis
- Lymphocytic interstitial pneumonia
- Pulmonary alveolar proteinosis
- Silicosis and asbestosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs or cats; usually middle-aged to older; eosinophilic pneumonia often occurs in younger animals.
- No sex predisposition

GENETICS & BREED PREDISPOSITION

Some specific syndromes have a breed predisposition:

- Pulmonary fibrosis in West Highland white terriers and Staffordshire bull terriers
- Eosinophilic pneumonia in Siberian huskies, Alaskan malamutes and rottweilers (usually associated with hypereosinophilic syndrome in rottweilers).

RISK FACTORS

Generally unknown; exceptions may include:

- Pulmonary toxicant drugs (e.g., bleomycin)
- Inhaled chemical fumes (e.g., hydrocarbons)
- Mineral fibers
- Dusts
- Allergens

ASSOCIATED CONDITIONS & DISORDERS

- Eosinophilic pneumonia may occur alone or as part of the hypereosinophilic syndrome (e.g., rottweilers).
- Lymphocytic interstitial pneumonia has only been reported in cats with feline immunodeficiency virus infection.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Respiratory signs can include:
  - Cough

    - Tachypnea
    - Respiratory distress
    - Exercise intolerance
    - Hemoptysis
- Nonrespiratory signs can include:
    - Fever
    - Lethargy
    - Anorexia
    - Weight loss

PHYSICAL EXAM FINDINGS

- Spontaneous or elicited cough:
    - May be productive or nonproductive
- Audible pulmonary crackles on ausculation (inspiratory; with pulmonary fibrosis)
- Increased respiratory rate and/or effort
- Fever
- Poor body condition

ETIOLOGY AND PATHOPHYSIOLOGY

- Disease is believed to result from injury to the alveolar epithelial cells, leading to a cycle of inflammation and host reparative responses that proceed unchecked.
    - In humans, injury can be triggered by:
        - Inhalation of toxins, irritants, or allergens
        - Vascular damage from drugs
        - Collagen-related vascular diseases
        - Systemic immune-mediated diseases
        - Infection
        - Neoplasia
    - Many veterinary cases are idiopathic.
- Alveolar epithelial cell injury leads to:
    - Inflammatory cell influx
    - Release of proinflammatory and fibrogenic mediators
    - Deposition of extracellular matrix
    - Structural changes including fibrosis
- Idiopathic pulmonary fibrosis appears to be a fibroproliferative disorder that can originate independent of inflammation (i.e., inflammation is secondary).
    - Injured alveolar epithelial cells are still critical for triggering and sustaining fibrogenesis.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Diagnosis is suspected in patients with clinical signs and radiographic features consistent with ILD in which there is no evidence of infectious and neoplastic causes of respiratory disease; definitive confirmation requires lung biopsy for histopathologic examination.

DIFFERENTIAL DIAGNOSIS

- Physical examination (cough/respiratory distress):
    - Other airway diseases (e.g., chronic bronchitis, eosinophilic bronchitis)
    - Pneumonia (infectious, aspiration, foreign body)
    - Neoplasia
    - Pulmonary thromboembolism
    - Cardiogenic or noncardiogenic pulmonary edema
    - Pleural effusion or pneumothorax
- Radiographic:
    - Infectious pneumonia (bacterial, fungal, viral, protozoal, parasitic)
    - Noncardiogenic pulmonary edema
    - Neoplasia

INITIAL DATABASE

- CBC:
  - Inflammatory leukogram and eosinophilia possible
- Thoracic radiographs:
  - Interstitial, alveolar (especially in severe disease), or bronchointerstitial patterns
  - Interstitial nodules
  - Hypoinflation of the lungs
  - Hilar lymphadenopathy possible
  - Right-sided cardiomegaly from corpulmonale possible
- Arterial blood gas may show:
  - Hypoxemia
  - Hypocarbia
- Fecal flotation or sedimentation (Baermann): respiratory parasites
- Serologic titers: infectious agents endemic to the patient's area

ADVANCED OR CONFIRMATORY TESTING

- CT provides more specific information on the extent, pattern, and location of disease. High-resolution CT (HRCT) has become an important imaging modality for the diagnosis and staging of ILDs in humans, but key features of ILDs using HRCT have yet to be thoroughly characterized in small animals.
- Bronchoscopy, bronchoalveolar lavage, and fine-needle aspiration (all for cytologic evaluation and culture) can provide evidence of underlying infection or neoplasia only when microorganisms or neoplastic cells are identified:
  - Nonspecific inflammatory cells or poor cellularity is seen with ILDs.
  - Absence of microorganisms or neoplastic cells does not rule out these causes of respiratory disease.
- Lung biopsy is the only definitive means for diagnosis:
  - Can be performed by a keyhole technique, thoracoscopy, or thoracotomy
  - Special stains are indicated to rule out infectious agents.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of removing or addressing the inciting cause if it can be identified. If no underlying cause can be identified, treatment is focused on decreasing inflammation. No specific treatments have been found which will directly halt the progression of fibrosis.

ACUTE GENERAL TREATMENT

Oxygen supplementation is indicated for hypoxemic patients, particularly those in respiratory distress (see p. 1318). Many affected patients are comfortable with mild to moderate arterial hypoxemia.

CHRONIC TREATMENT

- Remove any potential inciting cause:
  - Consider discontinuation of any drug not immediately critical for the patient's health.
- For eosinophilic pneumonias, treat underlying etiology (e.g., heartworm, other parasites, or fungi) if identified. If none found, treat with immunosuppressive doses of glucocorticoids.
- For most other ILDs, immunosuppression has been advocated (provided infection is definitively ruled out), starting with glucocorticoids (e.g., prednisone, 2 mg/kg PO q 24 h).
  - Empirically (i.e., without scientific evidence of their efficacy), other immunosuppressive drugs have also been tried in refractory cases.
    - Azathioprine (dogs, 1–2 mg/kg PO q 24 h for 10–14 days, then q 48 h)
    - Cyclophosphamide (50 mg/m^2 PO q 24 h for 3–4 days/week)
    - Cyclosporine (3–5 mg/kg PO q 12 h; monitor serum concentrations; see p. 1471)

BEHAVIOR/EXERCISE

Minimize exposure to inhalant fumes, chemicals, or dusts.

POSSIBLE COMPLICATIONS

- Decompensation during and after bronchoscopy or lung biopsy, especially in patients with a significant degree of respiratory compromise at rest

- Immunosuppression can predispose to secondary infections.
    - After lung biopsy, allow the incision to heal before immunosuppressive medication administration.

RECOMMENDED MONITORING

- Clinical signs
- Physical examination
- Arterial blood gas (if significant respiratory compromise)
- Thoracic radiographs

PROGNOSIS AND OUTCOME

- For eosinophilic pneumonia (without hypereosinophilic syndrome), with appropriate treatment, prognosis is fair to excellent.
- For BOOP, if the insult is removed and the animal responds well clinically and radiographically to glucocorticoids, the prognosis is good.
    - Relapse is common if glucocorticoids are tapered too quickly.
    - For animals with BOOP that do not respond well to therapy, prognosis is guarded to poor.
- For other ILDs, including idiopathic pulmonary fibrosis, prognosis depends on stage of the disease and rapidity of progression.
    - In general, long-term outcome is guarded to poor.

PEARLS & CONSIDERATIONS

COMMENTS

- Lung biopsy is critical for appropriate diagnosis of interstitial lung diseases.
- Pulmonary crackles on auscultation are common with interstitial fibrosis and therefore are not exclusive to pulmonary edema.
- Advanced imaging (e.g., HRCT) may serve as a useful noninvasive diagnostic technique as ILDs gain further recognition in veterinary medicine.

TECHNICIAN TIPS

It is important to minimize stress and provide appropriate oxygen supplementation when handling patients. Serial evaluation of arterial blood gases may be useful as a means of assessing oxygenation and addressing the oxygen needs of each individual patient.

CLIENT EDUCATION

Over time, most interstitial lung diseases are associated with permanent architectural changes, and treatment cannot reverse fibrosis. The likelihood that clinical signs will resolve depends on the balance of “active” inflammatory and reparative events, which can be addressed, versus fibrosis, which cannot.

Insulinoma

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A functional pancreatic β-cell tumor that secretes excess insulin, causing clinical signs associated with hypoglycemia

SYNONYMS

β-cell tumor, hyperinsulinism, insulin-secreting tumor, islet cell adenocarcinoma, islet cell tumor

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: uncommon; middle-aged to older (mean 10 years, range 3–14 years); no sex predilection; most reports are of medium- to large-breed dogs.
- Cats: rare; older (mean 14.7 years, range 12–17 years); no sex predilection

GENETICS & BREED PREDISPOSITION

- Dogs: increased incidence suggested for Labrador retrievers, golden retrievers, Irish setters, boxers, German shepherds, standard poodles, fox terriers, and collies.
- Cats: 3 of 5 reported cases were Siamese cats.

ASSOCIATED CONDITIONS & DISORDERS

Obesity

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Dogs: seizures (48%–62%), weakness (40%), and collapse (30%–40%) are most common.
  - Ataxia, disorientation, mental dullness, tremors/muscle fasciculations, polyphagia, restlessness, and nervousness may also be seen. An associated peripheral polyneuropathy may lead to hyporeflexia or areflexia.
- Cats: seizures, weakness, ataxia, and muscle twitching

PHYSICAL EXAM FINDINGS

- Usually unremarkable
- Obesity/overweight is seen in some dogs.
- Signs listed under History, Chief Complaint above may be found if marked hypoglycemia is present at the time of presentation.

ETIOLOGY AND PATHOPHYSIOLOGY

- In normal animals, when blood glucose concentrations decrease below 60 mg/dL (<3.2 mmol/L), insulin secretion stops, and catecholamines and glucagon are released to help return the blood glucose concentration to normal.
  - Cortisol and growth hormone have more chronic antihypoglycemic effects.
- In animals with insulinoma, the neoplastic β cells do not respond appropriately but continue to secrete insulin despite hypoglycemia.
- The excess insulin causes increased glucose uptake and use and decreased hepatic glucose production.
- The clinical signs of insulinoma are the result of neuroglycopenia and/or hypoglycemia-induced release of catecholamines.
- In dogs, insulinoma develops within the right and left pancreatic lobes with equal frequency. Solitary nodules are most common, but multiple nodules and occult nodules can also occur.
- Insulinomas are notorious for masking their malignant tendencies in the dog. Virtually all β-cell tumors in dogs are malignant (95%), and up to 64% have metastatic lesions at the time of surgery. Metastasis to the liver, regional lymph nodes, and

omentum is most common.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Appropriate clinical signs, hypoglycemia and concurrent hyperinsulinemia, and the presence of a pancreatic tumor support the diagnosis. Immunocytochemical staining of the tumor during histopathologic analysis is confirmatory.

DIFFERENTIAL DIAGNOSIS

- Fasting hypoglycemia:
  - Neonatal and juvenile hypoglycemia
  - Insulin overdose
  - Sepsis
  - Xylitol toxicity
  - Extrapancreatic tumors (e.g., hepatocellular carcinoma, leiomyosarcoma, oral melanoma)
  - Endocrine (i.e., hypopituitarism, hypoadrenocorticism, glucagon deficiency)
  - Hepatic (i.e., vascular shunts, glycogen storage diseases, cirrhosis)
  - Pregnancy
  - Uremia
  - Severe polycythemia
- Seizures (see p. 1009)
- Collapse/weakness (see p. 230)
- Tremors/twitching (see p. 1116)

INITIAL DATABASE

- CBC, serum chemistry profile, and urinalysis may show hypoglycemia or may be normal.
  - A normal blood glucose concentration does not rule out insulinoma.
- Simultaneous measurement of serum glucose and insulin concentrations should be made when the blood glucose concentration is <60 mg/dL (<3.2 mmol/L).
  - At this blood glucose concentration, insulin secretion is normally suppressed.
- If insulinoma is suspected but the blood glucose concentration is normal, fast the patient and assess a blood glucose concentration every 1–2 hours, with collection of a sample for concurrent insulin measurement when hypoglycemia occurs.
- A low serum fructosamine concentration can also provide evidence of chronic/recurrent hypoglycemia.
- Hyperinsulinemia during hypoglycemia is supportive of the diagnosis of insulinoma.
  - An insulin concentration in the middle to upper-normal range (in the face of hypoglycemia) is also suggestive but not diagnostic of insulinoma.
- Amended and other insulin/glucose ratios (AIGR) do not improve diagnostic accuracy.
- Thoracic and abdominal radiographs are usually normal with insulinoma but may help identify other disorders causing hypoglycemia.
  - Insulinomas rarely metastasize to the lungs.
- Abdominal ultrasound may be helpful (tumor visible in 30%–50% of affected dogs) but should be used in conjunction with other diagnostic tests.

ADVANCED OR CONFIRMATORY TESTING

- Histologic evaluation and immunohistochemical staining of the tumor is confirmatory.
- Abdominal CT or MRI can identify the location of the tumor in up to 70% of cases.
- Scintigraphy and angiography have poor reliability in detecting insulinomas.
- Endoscopic ultrasonography used in humans has a reported sensitivity of 77%-93% but is not readily available in small animal medicine.

TREATMENT

TREATMENT OVERVIEW

Urgent management of hypoglycemia may be done during transport of the patient to the hospital if insulinoma was previously documented or is suspected. In-hospital correction of hypoglycemia should be sufficient to control clinical signs but not excessive (avoid stimulating insulin release). Definitive treatment consists of removal of the tumor.

ACUTE GENERAL TREATMENT

- Emergency therapy:
  - If signs are present but the patient is able to eat, feed a small meal (see Chronic Treatment below).
  - If seizure or severe collapse/weakness is present, administer intravenous dextrose bolus (1–2 mL/kg of 50% dextrose solution diluted with saline in the ratio 5 parts saline to 1 part 50% dextrose, IV). A rapid clinical improvement should be seen. Follow with an infusion of 2.5%–5% dextrose IV (1–2 mL/kg/h), or if the patient is able to eat, feed a small meal. Solutions with >5% dextrose should be sufficient to control clinical signs but only given via a central line to avoid thrombophlebitis.
  - Glucagon can be used in refractory hypoglycemic patients in an acute crisis. Initial infusion rate is 5–10 ng/ kg/min. Adjust as needed to maintain normoglycemia.
  - If seizures persist, also administer diazepam 0.5–1 mg/kg IV or another anticonvulsant medication (see p. 1009).
  - The goal is to abolish clinical signs; blood glucose levels may remain below normal, and acute treatment should not aim to fully normalize blood glucose levels because doing so may elicit greater insulin secretion from the tumor.
- Surgery:
  - Remove the tumor if possible.
  - Perform a partial pancreatectomy for multiple adenomas or if a nodule cannot be palpated.
    - Insulinomas have no predisposition for one lobe of the pancreas over the other.
- After surgery, treat for potential pancreatitis (see pp. 817 and 820).

CHRONIC TREATMENT

- Because metastasis is common, signs often continue or recur after surgery and require long-term management.
- Dietary therapy: feed 4-6 small meals/ day of a diet high in protein, fat, and complex carbohydrates. Simple sugars, often found in semimoist pet foods, should be avoided.
- Limit exercise.
- When frequent feedings no longer control the signs, prednisone (0.25 mg/ kg PO q 12 h) can be added. This dose can be increased up to 2 mg/kg q 12 h if needed.
- When frequent feedings and prednisone no longer control the signs, or signs of iatrogenic hyperadrenocorticism are causing problems, diazoxide (5 mg/kg PO q 12 h, with a gradual increase up to a maximum of 40 mg/ kg divided q 8-12 h) can be added to the treatment regimen. This drug inhibits insulin release, enhances glycogenolysis and gluconeogenesis, and decreases glucose tissue uptake. It is expensive and not readily available.
- When these treatments are no longer effective, the following treatments may be considered:
  - Octreotide (somatostatin analog): 10–50 mcg/dog SQ q 8–12 h; questionable efficacy reported.
  - Streptozotocin: selectively destroys β cells but is extremely nephrotoxic. If used, a 3-hour diuresis with 0.9% saline is done before drug administration (500 mg streptozotocin/ m^2 IV in 0.9% saline over 2 hours) and for 2 hours after the streptozotocin infusion. This may be repeated every 3 weeks until hypoglycemia resolves or adverse reactions occur.
  - Alloxan: also selectively destroys β cells but is nephrotoxic and may cause sudden acute respiratory distress syndrome. If used (65 mg/ kg IV), concurrent fluid therapy is needed.

POSSIBLE COMPLICATIONS

- The most common postoperative complication is pancreatitis in dogs.
- Recurrent or progressive episodes of hypoglycemia may occur postoperatively secondary to residual and/or metastatic disease.
- Iatrogenic hyperadrenocorticism may result from prednisone therapy.
- Anorexia, vomiting, and ptyalism are uncommon potential side effects of diazoxide therapy.
- Renal failure can occur with streptozotocin or alloxan therapy.

RECOMMENDED MONITORING

- At home: return or progression of clinical signs of hypoglycemia
- In hospital: serum glucose concentrations

PROGNOSIS AND OUTCOME

- Malignancy is common, and many patients have metastasis at time of surgery.
- Surgery improves survival time.
- Dogs: median survival time of 12 months after surgery. Younger dogs have shorter survival times. Only 20% of dogs with metastatic disease live longer than 1 year.
- Cats: median survival time of 6 months

PEARLS & CONSIDERATIONS

COMMENTS

- Insulinoma, although rare, is the most common islet cell tumor in small animals.
- Administration of new methylene blue 3 mg/kg diluted in 100–500 mL 0.9% saline and given IV over 30 minutes may make insulinomas more visible especially at the end of the infusion (insulinoma becomes reddish purple, versus blue-gray background of pancreas), but severe hemolysis is common 24–72 hours postoperatively and therefore this approach is controversial.
- Treatment of insulinoma is generally palliative and improves the quality of life for most patients.
- There is no predisposition for one lobe of the pancreas over the other.
- Recommend referral to a specialty center, as surgery and perioperative management can be complicated.

TECHNICIAN TIP

When treating severe hypoglycemia, remember to administer enough dextrose to abolish clinical signs but not more, as this stimulates the tumor to secrete more insulin.

CLIENT EDUCATION

The owner should be aware of the clinical signs of hypoglycemia and seek immediate veterinary attention if they occur.

EDITOR: SHERRI IHLE

Insect Growth Regulator Toxicosis

BASIC INFORMATION

DEFINITION

- Insect growth regulators (IGRs) are relatively safe insecticides in dogs and cats when used correctly and rarely cause concern for intoxication except under unusual circumstances.
- Oral ingestion of IGRs can cause mild stomach upset (hypersalivation, vomiting, and diarrhea), whereas sprays or spot-on formulations can result in dermal irritation, redness, itching, or rubbing.

SYNONYMS

Third-generation insecticides, growth inhibitors, juvenoids, juvenile hormone I, II, and III

EPIDEMIOLOGY

GEOGRAPHY AND SEASONALITY

Year-round in areas where target pests (usually fleas) are a nuisance

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Dogs and cats are typically presented for evaluation of signs caused by other flea and tick insecticides combined with the IGR (especially pyrethroid/ pyrethrin, organophosphate/carbamate insecticides).
    - Acute-onset gastrointestinal upset (presence of central nervous system [CNS] signs usually attributed to other pesticides present in the formulation)
- Dogs uncommonly access an IGR-containing livestock product, which typically involves the client noting the packaging disturbed and the dog showing signs of gastrointestinal upset.

PHYSICAL EXAM FINDINGS

- Patient vital signs should be within normal limits, as no direct systemic effect is expected following casual exposure to an IGR-only agent.
- Hypersalivation (common), mild vomiting
- Clinical signs from IGR-only products are typically due to other ingredients contained in the product.
- Dermal irritation, redness, itching, or rubbing could result from the carrier, the IGR, or other pesticides present in the formulation.

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- IGRs are used for controlling fleas, ants, mosquitoes, and roaches and are typically found in combination with other insecticides such as pyrethrins/ pyrethroids, organophosphates, carbamates (some of these are commonly encountered in clinical practice).
- They are available in sprays, foggers, monthly spot-on products, liquids, collars, or granules.
- IGRs are commonly added to flea control products sold for on-animal use and in the pet's environment (inside the home, yard, kennel areas, etc.).
- IGRs are subclassed, generally based by physiologic action or effect.
    - Chitin synthesis inhibitors: cyromazine, diflubenzuron, lufenuron, hexaflumaron, penflumaron, teflubenzuron, triflumaron
    - Juvenile hormone mimics: fenoxycarb, hydroprene, methoprene, pyriproxyfen
    - Molting hormone agonists: halofenozide, tebufenozide, methoxyfenozide
    - Others, like precocenes
- See online version of this chapter for a detailed table of IGRs, their toxic doses, and expected clinical signs.

Mechanism of Toxicosis:

- IGRs break the life cycle of the insect by disrupting normal activity of the endocrine or hormone system.
- IGRs have a much slower mode of action than “knock-down” insecticide (such as cholinesterase inhibitors and pyrethrins/pyrethroids that kill immediately).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Given the mild degree of signs and abnormalities associated with IGR intoxication, diagnostic testing is not necessary unless the patient was simultaneously coexposed to other toxic substances (in compound formulations). Therefore, the diagnosis rests on history of exposure, with or without supportive physical signs.

DIFFERENTIAL DIAGNOSIS

Toxicologic:

- Many household chemicals, cleaners, nontoxic plants that can cause acute hypersalivation and vomiting (see p. 880 and p. 217)

Spontaneous, Nontoxicologic:

- Dietary indiscretion, mild viral gastritis

INITIAL DATABASE

- If IGR is combined with other active ingredients, select diagnostic tests based on this information:
  - If product packaging is not available, begin with physical examination alone; if no abnormalities are present, consider conservative monitoring approach versus additional tests (below).
  - If presenting signs are not compatible with mild, IGR-only signs, consider baseline serum biochemistry profile, CBC, urinalysis, and abdominal and thoracic radiographs.

TREATMENT

TREATMENT OVERVIEW

IGR intoxication is typically very mild in degree and easily managed. It is important to know the ingredients for any product containing an IGR, as most are combined with insecticides that may be more toxic.

ACUTE GENERAL TREATMENT

- Antiemetic if significant vomiting (most IGR-only cases are self-limiting):
  - Metoclopramide, 0.1-0.2 mg/kg SQ; *or*
  - Maropitant, l mg/kg SQ; *or*
  - Dolasetron, 0.5–1 mg/kg IV
- Activated charcoal generally not indicated unless exceptionally large or complex (polytoxic) exposure
- Replacement fluids as needed
- Gastric protection, depending on severity of vomiting:
  - Famotidine (Pepcid), 0.5 mg/kg PO q 12 h × 3–4 treatments
  - Sucralfate (Carafate), optional, 0.5 mg/kg PO q 12 h × 48 hours

DRUG INTERACTIONS

IGRs do not interact to a negative degree with other insecticides or drugs.

PROGNOSIS AND OUTCOME

- Generally excellent (IGR-only agent exposures); unusual cases (e.g., ingesting large amounts of IGR-containing livestock feed) may require hospitalization for general supportive care.

PEARLS & CONSIDERATIONS 

COMMENTS

- Most IGR exposures result in very mild and transient clinical signs.
- Some clients ask about cyromazine (melamine precursor).
    - Should be no concern for systemic toxicosis following single exposure to any agent containing an IGR as the only active ingredient

PREVENTION

Keep any pesticide under lock when not being used, and avoid applying in an area where the pesticide could be accessible to a pet.

TECHNICIAN TIPS

- IGRs are not effective against adult insects; many clients are confused about this and mistakenly think the product “is not working” when adult fleas persist.
- IGRs may be sold as stand-alone products but typically are combined with a knock-down insecticide to kill fleas in later stages of maturity.

EDITOR: SAFDAR KHAN

Injection Site Sarcoma

BASIC INFORMATION

DEFINITION

Commonly occurring tumors that arise from mesenchymal tissue secondary to vaccine administration or other injection

SYNONYMS

Vaccine-site sarcoma, vaccine-associated fibrosarcoma, vaccine-associated sarcoma (all outdated terms)

EPIDEMIOLOGY

SPECIES, AGE, SEX

Almost exclusive to cats; rare reports involving dogs. Younger age (7–9 years) compared with cats that develop sarcomas at nonvaccine sites.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Many different tumor types have been identified at vaccination sites in cats, including fibrosarcoma, malignant fibrous histiocytoma, neurofibrosarcoma, nerve sheath tumor, hemangiopericytoma, schwannoma, leiomyosarcoma, rhabdomyosarcoma, undifferentiated sarcoma, osteosarcoma, chondrosarcoma, liposarcoma, and myofibroblastic sarcoma.

HISTORY, CHIEF COMPLAINT

- Cats are usually presented for veterinary attention because their owners have noticed a progressively enlarging mass.
- A vaccination history should be obtained. Often cats with vaccine-site sarcomas will have a known prior history of having been vaccinated in a site near the tumor.

PHYSICAL EXAM FINDINGS

Cats usually present with a palpable firm cutaneous mass. Typical locations include the interscapular area, dorsal lumbar area, flank, or lateral thorax. Less commonly they can be found on extremities. Often the mass is hairless and/or ulcerated.

ETIOLOGY AND PATHOPHYSIOLOGY

- Vaccine-site sarcomas have been clearly linked to vaccination with certain inactive vaccines, particularly vaccines that contain aluminum hydroxide adjuvants. It is believed that inflammation at injection sites causes local cell proliferation which may lead to tumor development.
- Small numbers of case reports and anecdotal reports suggest that these tumors may result from subcutaneous injection of medications or fluids.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis can only be confirmed histopathologically, although adjunctive tests such as diagnostic imaging are often helpful in defining the extent of the tumor. Since an aggressive first surgery is more likely to result in tumor control, an incisional biopsy should be used for confirming the tumor type prior to planning definitive treatment (rather than tumor removal with incomplete margins histologically, requiring reoperation).

DIFFERENTIAL DIAGNOSIS

- Local inflammatory vaccine reaction
- Other subcutaneous tumor
- Abscess

INITIAL DATABASE

- Fine-needle aspirate (FNA) and cytologic examination may help identify the tumor type prior to other tests.
- Thoracic radiographs to rule out pulmonary metastases
- Radiographs of the affected area may reveal involvement of underlying bone.
- Fine needle aspirate of draining lymph nodes to help rule out metastasis.

ADVANCED OR CONFIRMATORY TESTING

- Histopathologic examination of an incisional biopsy specimen. Markers that may link the tumor with vaccine administration include peripheral lymphocytic infiltrate or macrophages within the tumor that contain aluminum adjuvant. In the absence of these markers, the location of the tumor, vaccination history, and diagnosis of a sarcoma also can suggest that the tumor was caused by vaccination.
- Simple excisional biopsy is not recommended as a first step in obtaining a diagnosis for this tumor because such reaction is often inadequate. Reports suggest that aggressive surgical resection or multimodality therapy at the time of the first intervention is more likely to result in local disease control.
- Advanced imaging (i.e., CT scan or MRI) to delineate the local extent of the tumor. Many of these tumors have a peripheral region that is contrast enhancing, with a nonenhancing center. They also often have fingerlike projections that extend far into surrounding normal tissues, and identifying these helps with complete excision.

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to eradicate the local tumor and, in some cats, to prevent or delay metastasis.

ACUTE AND CHRONIC TREATMENT

- Radical surgical excision is the treatment of choice if physically possible.
  - Tumors on the distal limbs and tail may be successfully treated with amputation alone.
  - Tumors on the trunk are usually not amenable to radical excision. For these cases, a combination of radiation and surgery (excision with as wide a margin as possible based on physical examination and advanced imaging) is usually indicated for successful treatment of the local tumor.
  - Rarely, surgery with complete excision may be possible and result in adequate local control of the tumor; however, in one report, 31% of cats with complete excision of the tumor based on histopathologically clean margins developed a recurrence.
- Radiation therapy prior to surgery allows for adequate treatment of the microscopic tumor extensions with smaller radiation fields; however, therapy interferes with the histopathologic evaluation of the primary tumor mass and the margins, and it may slightly increase risk of wound complications after surgery.
- The role of chemotherapy in the treatment of vaccine-site sarcoma is not well defined. Studies have not shown a definite advantage to using chemotherapy if local therapy (surgery, radiation) is adequate. Nevertheless, many oncologists recommend chemotherapy (doxorubicin, cyclophosphamide, carboplatin, or ifosfamide).

POSSIBLE COMPLICATIONS

- Complications of surgery may include wound dehiscence or infection.
- Complications of radiation depend on the location of the tumor in relation to critical normal structures (e.g., spinal cord, kidneys) and the amount of radiation delivered to those structures.
- Chemotherapy complications: see p. 188

RECOMMENDED MONITORING

Owing to the aggressive local nature of these tumors and the low risk of metastasis, long-term monitoring should include:

- Routine examination by a veterinarian to monitor for local recurrence or side effects of treatment
- Routine thoracic radiographs to monitor for pulmonary metastases

PROGNOSIS AND OUTCOME

- Prognosis depends on the stage and location of the tumor.
  - Cats with tumors that can be resected with a wide margin of normal tissue (tumors on the tail or distal limbs, small localized tumors) may have an excellent prognosis.
  - Cats with larger tumors that can still be removed with an aggressive surgery and are treated with multimodality therapy (radiation, surgery, and chemotherapy) may still have an excellent prognosis for long-term tumor control; however, some of these cats will still develop metastases or recurrence of the primary tumor.
  - Cats with large nonresectable tumors or metastases at the time of diagnosis have a poor prognosis regardless of treatment.
- Another factor shown to affect recurrence of vaccine-site sarcoma is the extent of surgery performed at the first intervention after identification of the tumor. Cats that had the first excision of their tumor at a referral institution had a longer time to recurrence than cats that had surgery performed by their regular veterinarian. This is likely due to the relatively aggressive nature of surgery performed at the referral institutions.

PEARLS & CONSIDERATIONS

COMMENTS

- Treatment of cats with vaccine-site sarcoma is usually best performed using a team approach. Specialists, including a surgeon, oncologist, and radiation oncologist, should be consulted early in the course of diagnostic testing to determine the best multimodality approach.
- Many different types of sarcoma have been identified at vaccine sites.

TECHNICIAN TIP

For routine vaccination, it is helpful to record the location of administration (which site) of each vaccine to allow long-term monitoring and follow-up of local adverse reactions.

PREVENTION

- Early detection of these tumors may lead to more successful treatment.
  - Guidelines have been established by the American Veterinary Medical Association (AVMA) Vaccine Associated Sarcoma Task Force for approaching a cat that has a mass in an injection site after vaccination. According to these guidelines, the following masses should be investigated with an incisional biopsy to determine if further diagnostics or treatment are necessary:
    - A mass that is increasing in size after 1 month postinjection
    - A mass that is >2 cm in diameter
    - A mass that persists >3 months postinjection
- Vaccination of cats in areas of the body that may allow for an aggressive surgical removal if a tumor develops may prevent these tumors from requiring radiation or chemotherapy or from becoming life threatening.
- Critical evaluation of vaccination protocols for animals that have a low risk of contracting infectious disease may help decrease the risk of vaccine-associated sarcomas.

CLIENT EDUCATION

- Educate clients about the risks of tumor development following vaccination, as well as other risks of vaccination compared with the benefits of vaccination.
- Clients may also be educated on the importance of examining their cats regularly for new masses to allow for early detection and treatment of these tumors.

AUTHOR: JOHN FARRELLY

EDITOR: KENNETH M. RASSNICK

Inguinal Hernia

BASIC INFORMATION

DEFINITION

Protrusion of an organ or tissues through a weakened inguinal ring into the subcutaneous space at the level of the caudalmost portion of the ventral abdomen

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Middle-aged intact female dogs: acquired inguinal hernia
- Male and female puppies

GENETICS & BREED PREDISPOSITION

- Congenital:
  - Males: testicular descent may delay narrowing of inguinal ring.
  - Predisposed breeds may include basenji, Pekingese, poodle, basset hound, cairn terrier, Cavalier King Charles spaniel, Chihuahua, cocker spaniel, dachshund, Pomeranian, Maltese, West Highland white terrier.
- Heritability: may be polygenic in cocker spaniels and dachshunds
- No breed predilection for acquired (trauma-associated) inguinal hernia

RISK FACTORS

Obesity, trauma, pregnancy

ASSOCIATED CONDITIONS & DISORDERS

Umbilical hernia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Indirect inguinal hernia:
  - Abdominal viscera enter the cavity of the vaginal process. o Males: uncommonly, may progress to scrotal hernia
- Direct inguinal hernia:
  - More common form in small animals
  - Organs pass through inguinal rings adjacent to the normal evagination of the vaginal process.
  - Usually large
  - Usually not associated with incarceration/strangulation

HISTORY, CHIEF COMPLAINT

- Chief complaint generally involves one of two categories: either the owner has noticed an inguinal enlargement incidentally, or there are systemic signs of illness due to abdominal organ entrapment/strangulation within the hernia.
- Indirect inguinal hernia in male dogs; often causes organ dysfunction:
  - Vaginal process narrows considerably at the inguinal ring.
    - Potential organ incarceration/ strangulation
- Direct inguinal hernia usually larger
  - Less commonly associated with clinical problems
- If organ incarceration in hernia, small intestine, bladder, or uterine entrapment:
  - Abdominal pain, vomiting, dysuria, vaginal discharge/hemorrhage may be noted.
- Vomiting, abdominal pain, or depression:
  - Vomiting for several days' duration is predictive of strangulated, nonviable small intestine.
  - Overall, risk of strangulated intestines is <5% of cases of inguinal hernia.

PHYSICAL EXAM FINDINGS

Vary with size of the hernia and its contents:

- Uncomplicated inguinal hernia:
  - Soft, painless unilateral or bilateral mass
  - Mass reducible into abdomen
  - Enlarged inguinal ring palpable
  - May appear more caudally in the female
- Complicated inguinal hernia:
  - Firm, nonreducible inguinal mass
  - Painful on palpation
  - Bruising/erythema of overlying tissues

ETIOLOGY AND PATHOPHYSIOLOGY

- Nontraumatic inguinal hernia:
  - Anatomic: Females may be predisposed:
    - Entrance to the vaginal process remains open.
    - Inguinal canal is shorter and larger in diameter.
  - Hormonal:
    - Most inguinal hernias become clinically apparent during estrus or pregnancy.
    - Inguinal hernias occur less frequently in spayed females.
      - Estrogen may play a role in development of inguinal hernias (alters strength and character of connective tissue).
  - Nutritional/metabolic:
    - Weakening of abdominal wall
    - Obesity:
      - Increased intraabdominal pressure
      - Fat forced into the inguinal canals
        - Dilation of canal and vaginal process
- Blunt abdominal/pelvic trauma:
  - Disruption/weakening of caudal abdominal muscles
  - Enlargement of inguinal canal

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis usually is established on physical examination alone.

DIFFERENTIAL DIAGNOSIS

- Perineal hernia: hernia is adjacent to anus.
- Scrotal hernia (male): most dogs with inguinal hernias present with a fluctuant, painless, unilateral or bilateral mass, whereas scrotal hernias usually appear as a firm, cordlike mass that extends into the scrotum.
- Mammary neoplasia or mastitis: firm, enlarged, possibly painful mammary gland(s)
- Hematoma: ecchymosis; nonreducible (gentle pressure only)
- Abscess: may be inflamed; nonreducible (gentle pressure only)

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: if systemic clinical signs exist or as part of preoperative screening
- Avoid fine-needle aspiration unless performed with ultrasound guidance:
  - Risk of perforation of intestinal loop or gravid uterus

ADVANCED OR CONFIRMATORY TESTING

- Survey abdominal radiographs:
  - Displaced gravid uterus, small or large intestine, urinary bladder, or spleen
  - Loss of intraabdominal detail in the caudal abdominal and inguinal regions
- Contrast radiography:

- Cystogram to determine position of bladder
- Ultrasound examination:
  - Determine position of organs in abdomen and contents of hernia.

TREATMENT

TREATMENT OVERVIEW

- All inguinal hernias should be surgically corrected at the time of diagnosis, regardless of size. Delay may make surgery more difficult and increase the risk of complications (visceral strangulation, devitalization, and rupture).
- Inability to reduce strangulated organs (particularly bladder, intestines, or uterus), clinical signs of peritonitis, and pain are indications for immediate surgical intervention.

ACUTE GENERAL TREATMENT

- Treatment for inguinal hernia is herniorrhaphy, performed at the time of diagnosis to prevent complications and improve ease of surgical repair.
  - Tension-free apposition of tissue and ligation of the hernia sac
  - Generally performed via an external approach to the inguinal ring
  - In more complicated cases in the older female, herniorrhaphy via an abdominal approach (include ovariohysterectomy) may be most appropriate.

POSSIBLE COMPLICATIONS

- Hernia associated:
  - Incarceration/strangulation of abdominal organ(s): peritonitis, cellulitis
  - Edema, pain
- Associated with the surgical repair:
  - Hematoma/seroma: inadequate hemostasis, excessive tissue dissection, excessive activity after repair
  - Infection: herniorrhaphy site or peritonitis
  - Swelling or edema caused by incorporation of neurovascular bundle into repair
  - Overall postoperative complication rate for herniorrhaphy: 17%

RECOMMENDED MONITORING

- Postoperative exercise restriction for 10–14 days
- Surgical site should be monitored for swelling and discharge.

PROGNOSIS AND OUTCOME

- Excellent in uncomplicated inguinal hernia with successful repair
- Prognosis may be less favorable in complicated cases.
  - Intestinal incarceration/strangulation, peritonitis, pyometra
- There is no information in the literature to suggest that these hernias close spontaneously.

PEARLS & CONSIDERATIONS

COMMENTS

- Inguinal hernias are most commonly seen in middle-aged, intact female dogs.
- Prompt repair is recommended to minimize complications.
  - Surgical repair is easier with smaller hernias.
- Proper postoperative pain control and exercise restriction are necessary for good outcome.

PREVENTION

- Ovariohysterectomy may decrease risk.
- Obesity may increase risk.

- Dogs that have nontraumatic inguinal hernia should not be used for breeding purposes.

CLIENT EDUCATION

- Proper weight management is recommended.
- Nonbreeding female dogs should be neutered.

Influenza, Canine

BASIC INFORMATION

DEFINITION

An uncommon but highly contagious respiratory pathogen which is a mutation of the equine influenza A subtype H3N8

SYNONYMS

Dog flu, H3N8 influenza virus

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dog, no age or sex predilection. Since this is an emerging disease with no pre-exposure, all ages are susceptible.

RISK FACTORS

High-density canine populations (e.g., kennels, shelters, pet stores)

CONTAGION & ZOONOSIS

Dog-to-dog transmission, no known zoonotic transmission

GEOGRAPHY AND SEASONALITY

Confirmed diagnosis in 25 U.S. states and the District of Columbia. Several “hot spots” have been identified in New York, southern Florida, northern Colorado, and southern Wyoming.

ASSOCIATED CONDITIONS & DISORDERS

Bacterial pneumonia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Three forms exist:

- Mild subclinical form; no clinical signs.
- Mild upper respiratory disease that is similar to typical infectious tracheobronchitis/“kennel cough.”
- Severe form (occurs in 5%-20% of dogs) with life-threatening pneumonia.

HISTORY, CHIEF COMPLAINT

- Recent exposure to high-density dog populations
- Moist cough (productive or nonproductive), nasal discharge, lethargy, fever, and tachypnea/dyspnea

PHYSICAL EXAM FINDINGS

Soft, moist paroxysmal cough (can be a dry cough that is mistaken for kennel cough complex). Mucopurulent nasal discharge. Lethargy, fever, tachypnea and/or dyspnea. Harsh lung sounds/crackles and cyanosis can occur with pneumonia.

ETIOLOGY AND PATHOPHYSIOLOGY

- Incubation time is 2 to 5 days.
- Clinical infection generally lasting 2-4 weeks.

- Virus is typically shed in respiratory secretions for 4–10 days.
- Postexposure immunity may last up to 2 years.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The presence of clinical signs with a history of exposure to high-density dog populations, especially within the known hot spots, is suggestive of canine influenza. Confirmation requires positive canine influenza titer from serologic testing.

DIFFERENTIAL DIAGNOSIS

- *Bordetella bronchiseptica*
- Canine parainfluenza virus
- Canine distemper virus
- Canine adenovirus 2
- Bacterial pneumonia *(Pasteurella multocida, Klebsiella pneumonia, Escherichia coli, Streptococcus* spp., or *Mycoplasma* spp.)
- Canine reovirus

INITIAL DATABASE

- CBC: stress leukogram +/− immature neutrophils
- Serum biochemistry profile: nonspecific
- Urinalysis: nonspecific
- Thoracic radiographs: +/− interstitial to alveolar pattern
- Transtracheal wash or bronchoalveolar lavage (typically performed when suspecting other disorder, or to characterize secondary bacterial infection): neutrophilic infiltrate +/− bacteria

ADVANCED OR CONFIRMATORY TESTING

- Antibody titer: most commonly used method. Not detectable during first week. Positive titer confirms exposure in most cases, as most affected dogs develop a positive titer. Because vaccination has only recently become available, and its use is not widespread, a positive titer in the presence of clinical signs usually indicates disease. If a dog is vaccinated, titer will no longer be useful to confirm disease.
- PCR: nasal and pharyngeal swab samples; very sensitive and specific but can be variably rewarding depending on stage of disease
- Influenza A ELISA: less sensitive than PCR
- Virus isolation: taken from affected lung samples

TREATMENT

TREATMENT OVERVIEW

Canine influenza has a viral etiology, so treatment consists of supportive care and prevention/management of secondary bacterial infections.

ACUTE GENERAL TREATMENT

- Isolate from other dogs, and/or treat as outpatient if possible because of highly contagious nature.
- Maintain hydration (PO, SQ, or IV).
- Culture bronchoalveolar lavage fluid in dogs with pneumonia.
- Antibiotic therapy:
  - Doxycycline: 5–10 mg/kg PO q 12 h; *or*
  - Clindamycin: 5–11 mg/kg IM, SQ, or PO q 12 h; or 11 mg/kg IV q 12 h for sepsis; *or*
  - Ampicillin: 22 mg/kg IV or PO q 8 h; *or*
  - Chloramphenicol: 45–60 mg/kg PO, IM, SQ, or IV q 6–8 h; *or*
  - Enrofloxacin: 5–20 mg/kg IV q 24 h
- Nebulization and coupage q 6–8 h (can add gentamicin and/or albuterol to nebulizer)
- Oxygen supplementation if necessary

- Oseltamivir phosphate (Tamiflu): 1 mg/ kg PO q 24 h. Not approved for dogs; controversial because of concerns about creating resistant strains of influenza and using drugs on dogs that should be reserved for human outbreaks.
- Combinations of antimicrobials may be necessary for a broader spectrum of coverage while waiting for culture and susceptibility results.

CHRONIC TREATMENT

- Continue antibiotics for 2 weeks after resolution of clinical signs.
- Cough suppressants: case dependent and contraindicated with pneumonia or productive cough; useful for mild upper respiratory form

POSSIBLE COMPLICATIONS

Development of pneumonia +/− sepsis

RECOMMENDED MONITORING

- Auscultation of the patient multiple times daily to access lung sounds
- Repeat thoracic radiographs.
- Pulse oximetry (Spo2)
- Arterial blood gases, A: a gradient, Pao2/Fio2 ratio in dogs with pneumonia

PROGNOSIS AND OUTCOME

Good with supportive care and antibacterial therapy. Morbidity is estimated at 80% and mortality from l%–8%.

PEARLS & CONSIDERATIONS

COMMENTS

- Use proper isolation precautions, as with parvovirus.
- If possible, treat as an outpatient to prevent contamination of the veterinary clinic.
- Monitor the patient closely for signs of developing pneumonia.
- Maintain adequate hydration.
- Normal progression to pneumonia is 5-10 days.
- Continue medications for at least 2 weeks after the resolution of clinical signs.
- Coughing can continue for 10–30 days.

PREVENTION

- Restricted access to high-density dog populations
- If showing clinical signs, isolation from other dogs

TECHNICIAN TIPS

- Wear gloves, wash hands, strictly isolate patients to prevent spread to other hospitalized dogs.
- Clean nasal and ocular discharge with a warm moist disposable cloth.
- Warm food to enhance smell when offering food (nasal congestion) (see p. 80).

CLIENT EDUCATION

If treating at home, monitor for fever, loss of appetite, increased coughing and breathing effort.

Inflammatory Bowel Disease

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Common intestinal disease of dogs and cats. Characterized by chronic (>3 weeks) gastrointestinal signs of idiopathic origin, with inflammatory infiltration of small and/or large intestinal mucosa.

SYNONYMS

IBD. Depending on the infiltrating cell type: lymphocytic-plasmacytic, eosinophilic, suppurative, or granulomatous enteritis, colitis, or enterocolitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Most prevalent among middle-aged and old dogs and cats (median age 5–6 years) but can affect patients of all age categories

GENETICS & BREED PREDISPOSITION

Dog: chronic enteropathies are frequent in German shepherd dogs and shar-peis. IBD and protein-losing enteropathy occur frequently in soft-coated wheaten terriers and Lundehunds. Histiocytic ulcerative colitis is common in boxers.

ASSOCIATED CONDITIONS & DISORDERS

- Dog: soft-coated wheaten terriers often have concurrent protein-losing nephropathy.
- Cat: “triaditis” with concurrent IBD, cholangiohepatitis, and pancreatitis; relatively common

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Clinical signs vary depending on which segment of the intestine is involved. In cats, suspect concomitant small-intestinal involvement even in patients showing exclusively large-bowel signs.

HISTORY, CHIEF COMPLAINT

- Mild IBD may cause intermittent clinical signs, whereas severe IBD is characterized by progressive and severe clinical signs.
- Dogs are presented for evaluation of chronic diarrhea which can be of small- and/or large-bowel origin. Vomiting may also occur.
    - Small-intestinal disease may be associated with decreased appetite, weight loss, and lethargy.
    - Large-intestinal disease is often limited to typical diarrhea and occasional vomiting.
- Cats are usually presented for evaluation of chronic vomiting which may or may not be associated with diarrhea. Inappetence/anorexia, weight loss, and lethargy are common.

PHYSICAL EXAM FINDINGS

- Small-intestinal disease:
    - Poor body condition with poor hair coat is frequent with severe disease.
    - Dehydration is possible.
    - Thickened small intestinal loops may occasionally be palpated.
    - Animals may occasionally show pain or discomfort on abdominal palpation.
    - Ascites, hydrothorax and peripheral edema may occur in case of significant protein loss.
- Large-intestinal disease:
    - Often unremarkable; may be associated with abdominal discomfort in severe cases.
    - Mucoid and/or bloody stool during rectal exam

ETIOLOGY AND PATHOPHYSIOLOGY

- Abnormal interactions between intestinal microflora and innate/adaptive immune systems
- Penetration of luminal antigens into the lamina propria, with subsequent uncontrolled immune response
- Protein loss may reflect poor absorptive function or inflammatory exudation or ulceration.
- In some instances, associated with the presence of mucosa-adhesive bacteria such as *Escherichia coli* (feline IBD, canine histiocytic ulcerative colitis)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of IBD is reached by exclusion.

DIFFERENTIAL DIAGNOSIS

- General differentials
  - Chronic intestinal foreign body
  - Intestinal parasites: hookworms, whipworms, *Giardia* and *Tritrichomonas* (cat)
  - Chronic kidney disease
  - Chronic liver disease
  - Chronic pancreatitis
  - Endocrine diseases (hypoadrenocorticism [dog], hyperthyroidism [cat])
  - Cecal intussusception (dog, rare)
- Differentials that may result in GI signs and histologic evidence of GI inflammation:
  - Adverse reactions to food (food intolerance, food allergy)
  - Antibiotic-responsive diarrhea (dog)
  - Fungal enterocolitis (e.g., *Histoplasma)*
  - Colitis associated with *Pythium insidiosum* infection
  - Histiocytic ulcerative colitis (HUC) in boxer and other dogs
  - Bacterial enterocolitis (e.g., in dogs, *Campylobacter* spp., *C. perfringens, C. difficile)*
  - Infiltrative intestinal neoplasia (alimentary lymphoma, particularly cat)
- Differentials to consider for intestinal protein loss:
  - Intestinal lymphangiectasia (Yorkshire terrier, Lundehund), histoplasmosis, alimentary lymphoma
  - Liver, kidney or dermal origin

INITIAL DATABASE

- Fecal parasitology to rule out nematodes, protozoa
- Fecal *Giardia* antigen test to rule out giardiasis
- In endemic areas for fungal diseases: rectal scraping (see p. 1334)
- CBC, especially in dogs and cats with small-intestinal signs; useful to rule out differential diagnoses
- Serum biochemistry: panhypoproteinemia may be associated with severe disease, hypocalcemia reflects hypoalbuminemia and possibly malabsorption of fat-soluble vitamin D, concomitant liver disease (cat); useful to rule out differential diagnoses.
- Serum thyroxin concentration (cat)
- Consider ACTH stimulation test (dog)
- Abdominal radiographs to rule out intestinal obstruction (e.g. in vomiting cats)
- Abdominal ultrasound: may be normal or show focal or diffuse intestinal wall thickening, loss of layering, presence of mucosal striation or spicules, enlarged and/or hypoechoic mesenteric lymph nodes. Localization of lesions may help decide best approach for biopsies (endoscopy or celiotomy). Ultrasound-guided fine-needle aspiration of abnormal lymph nodes or intestinal wall can be useful.
- Serum trypsinlike immunoreactivity, cobalamin, and folate concentrations: recommended to identify concurrent pancreatic disease and cobalamin deficiency (especially in cats)

ADVANCED OR CONFIRMATORY TESTING

- Upper and/or lower gastrointestinal endoscopy: assess mucosa, sample eight deep (include upper submucosal layer) biopsies per anatomic site.
- Celiotomy if lesions are inaccessible by endoscopy or if full-thickness biopsies are desirable (e.g., to rule out lymphoma in cats)
- Histopathologic analysis: beware of differences between pathologists; objective is to confirm inflammatory mucosal infiltration and diagnosis of IBD.

TREATMENT

TREATMENT OVERVIEW

- Treatment of IBD most commonly centers on immune suppression with glucocorticoids. Other immune-suppressive drugs can be added as needed.
- The goal of therapy is to control the clinical signs, as a cure may be unattainable.

ACUTE GENERAL TREATMENT

- Supportive treatment as necessary if patient not stable (IV fluids, antiemetics, etc.)
- Ensure the following has been done before instituting immunosuppressive therapy for IBD:
  - Empirical deworming (e.g., with fenbendazole, 50 mg/kg PO q 24 h × 3 days
  - Elimination diet: novel protein or hydrolyzed peptide-based diet for 2 weeks or more
  - Modify intestinal microflora: especially in dogs, antimicrobial treatment with metronidazole (10–15 mg/ kg PO q 12 h), tylosin (25 mg/kg PO q 12 h), or tetracycline (20 mg/ kg PO q 8 h) for 2–6 weeks.
- In case of canine colitis (not HUC; see p. 228):
  - Sulfasalazine (10–30 mg/kg PO q 8 h) for 2 weeks, then taper to same dose q 12 h for 2 weeks, then half dose q 12 h for 2 weeks, and so on. Alternatively, olsalazine (10–20 mg/kg PO q 12 h). Monitor tear production (risk of keratoconjunctivitis sicca with sulfa drugs).
  - Consider adding soluble fiber (psyllium 1-2 teaspoons/10 kg per meal).
- In severe cases, in cases with protein-losing enteropathy, or in cases in which the above approach has failed, treatment with immune-suppressive doses of glucocorticoids is indicated:
  - Prednisone, 2 mg/kg PO initially q 12 h for a few days, then q 24 h for 2 weeks, then 1 mg/kg PO q 24 h, then 1 mg/kg q 48 h, then decrease dose by half every 2 weeks. Treatment and weaning period usually last for at least 8–12 weeks. Cats may respond better to prednisolone (up to 4 mg/kg PO q 24 h in the initial 10- to14-day phase).
  - Budesonide (dog, 3 mg/m^2 PO q 24 h; cat, 1 mg/cat PO q 24 h) can be substituted for prednisone. Budesonide undergoes some first-pass hepatic metabolism, and low systemic drug concentrations may cause fewer side effects.
- In steroid-refractory cases:
  - Cyclosporine A, 5 mg/kg PO q 24 h can be helpful (dog, cat); *or*
  - Dogs only: azathioprine, 2 mg/kg PO q 24 h for 2 weeks, then q 48 h (can be decreased to 1 mg/kg q 48 h) is another alternative; *or*
  - Cats: chlorambucil may be used as supplemental immune-suppressive therapy (2 mg/cat PO q 48 h).
- Supplement hypocobalaminemic patients with SQ vitamin B12 (see p. 220).
- Patients with PLE can be at increased risk for thromboembolism. Low-dose aspirin (0.5 mg/kg PO q 12 h in dogs; 5–81 mg/cat PO q 72 h in cats) is recommended if antithrombin levels are low. Gastroprotection with omeprazole (0.5–1 mg/kg PO q 24 h) or famotidine (0.5 mg/kg PO q 24 h) is recommended.

CHRONIC TREATMENT

The goal is to wean the patient off immune-suppressive therapy. If this is not feasible, the goal becomes finding the lowest-dose regimen that will allow reasonable control of clinical signs.

NUTRITION/DIET

- An elimination diet with novel proteins (requires good nutritional history) or hydrolyzed peptides is recommended in most dogs and cats with IBD.
- Alternatively, an easily digestible diet with low fat content is recommended in cases with IBD and severe PLE.

POSSIBLE COMPLICATIONS

- High doses of glucocorticoids may cause multiple systemic side effects (e.g., polyuria/polydipsia, iatrogenic hyperadrenocorticism)
- Side effects reported with cyclosporine use in dogs include decreased appetite and vomiting.
- Azathioprine may cause bone marrow suppression and has been associated with acute pancreatitis in dogs. Regular monitoring of CBC is advised. Avoid use in patients with previous history of pancreatitis.
- Immunosuppressive medications predispose animals to secondary infections.
- Metronidazole toxicosis may cause neurologic signs in cats.

RECOMMENDED MONITORING

Regular evaluation of the body weight and overall clinical condition are recommended. Consider rechecking serum albumin.

PROGNOSIS AND OUTCOME

- Short-term prognosis is usually good in mild to moderate cases of IBD.
- In dogs, negative prognostic factors include hypoalbuminemia and hypocobalaminemia, as well as severe mucosal lesions in the duodenum (noticed during endoscopy).
- Cases refractory to steroid treatment are not uncommon (l6%-55%) in dogs with non-food-responsive IBD. Cyclosporine therapy was successful in 25% of steroid-refractory patients.
- Treatment failures may be due to incorrect diagnosis, severe disease, presence of concurrent disease, or poor owner compliance. In cats, lack of response to treatment should motivate the clinician to reconsider the possibility of alimentary lymphoma.

PEARLS & CONSIDERATIONS

COMMENTS

IBD is a diagnosis of exclusion. It is essential to address possible intestinal parasites and initiate a dietary elimination trial in dogs and cats with chronic GI signs before making this diagnosis. Additionally, in dogs, consider antimicrobial treatment.

CLIENT EDUCATION

- A realistic goal for your pet's treatment is to manage the intestinal disease. As a definitive cure may not be attainable, our goal is to control the clinical signs while limiting the side effect of therapy.
- Your pet's diet is of central importance for the treatment. Please make every effort to adhere closely to our dietary recommendations.

Infertility, Male

BASIC INFORMATION

DEFINITION

- This chapter is limited to discussion of abnormalities of the spermiogram, which may be categorized as follows:
  - Asthenozoospermia: decreased numbers of progressively motile spermatozoa per ejaculate (<30%–50%)
  - Teratozoospermia: increased numbers of morphologically abnormal spermatozoa per ejaculate (>40%–50%)
  - Oligozoospermia: abnormally low numbers of spermatozoa per ejaculate <22 million spermatozoa/kg body weight in the dog; or <5 million total spermatozoa in the tom)
- Other causes of male infertility are listed on .

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dog or cat, intact males, any age

GENETICS & BREED PREDISPOSITION

Some etiologies may have a hereditary component.

RISK FACTORS

Age, systemic disease (especially those resulting in increased body temperature), endocrinopathy, testicular disease or trauma

CONTAGION & ZOONOSIS

Brucella canis possible (see p. 162)

GEOGRAPHY AND SEASONALITY

Lower total number of spermatozoa and lower percentage of morphologically normal spermatozoa in summer months are expected in North American dogs

ASSOCIATED CONDITIONS & DISORDERS

May be associated with poor libido

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Reversible versus irreversible
- Compensatory versus noncompensatory

HISTORY, CHIEF COMPLAINT

- Declining or consistently poor fertility
- Recent episode of malaise or fever is possible.
- Prior history of physical training (possibility of performance-enhancing drugs)
- History of bloody penile or preputial discharge or pain with ejaculation
- History of chronic respiratory disease (asthenozoospermia)

PHYSICAL EXAM FINDINGS

- ± Fever

- Libido may be normal or decreased.
- Testes may be small and soft or normal in size and consistency.
- Testes, epididymides, or spermatic cords may be enlarged (inflammation or neoplasia), and/or thickened.
- Scrotum may be enlarged or thickened (dermatitis, trauma, edema or fluid accumulation).
- Prostatomegaly possible (symmetric or asymmetric; painful or nonpainful)
- In dogs with asthenozoospermia due to primary ciliary dyskinesia/immotile cilia syndrome, additional signs may include recurrent nasal discharge and/ or cough, hydrocephalus (open fontanelle, domed calvaria), or situs inversus (spleen is palpated on the right side of the abdomen; heartbeat is strongest on right hemithorax).

ETIOLOGY AND PATHOPHYSIOLOGY

- Causes (all categories):
  - Infectious or inflammatory (orchitis, epididymitis, prostatitis including infection with *B. canis,* mycoplasmas or other aerobic bacteria, or feline infectious peritonitis [FIP])
  - Scrotal hyperthermia (due to fever, obesity with increased intrascrotal fat, hydrocele, hematocele, scrotal edema, or neoplasia)
  - Toxin exposure or exogenous drug administration (corticosteroids, anabolic steroids [human estrogen or testosterone patches or creams], other steroid hormones, chronic nonsteroidal antiinflammatory drug [NSAID] usage, gonadotropin-releasing hormone [GnRH] agonist/antagonists, chemotherapeutic agents)
  - Testicular degeneration (primary or secondary)
  - Immune mediated (lymphocytic thyroiditis or spermatozoal autoantibodies)
  - Unilateral or partial epididymal or tubular obstruction (granuloma, spermatocele)
  - Congenital
- Additional causes (specific to individual categories):
  - Primary ciliary dyskinesia with abnormal spermatozoal midpiece formation (asthenozoospermia)
  - Prostatic disease: benign prostatic hyperplasia, prostatitis, or squamous metaplasia (oligozoospermia, asthenozoospermia)
  - Neoplasia (oligozoospermia, teratozoospermia)
  - Hyperadrenocorticism (oligozoospermia)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on history (generally of suboptimal fertility), physical exam findings, semen evaluation, and cultures of semen or prostatic fluid in many cases. Remainder may require more advanced diagnostic testing.

DIFFERENTIAL DIAGNOSIS

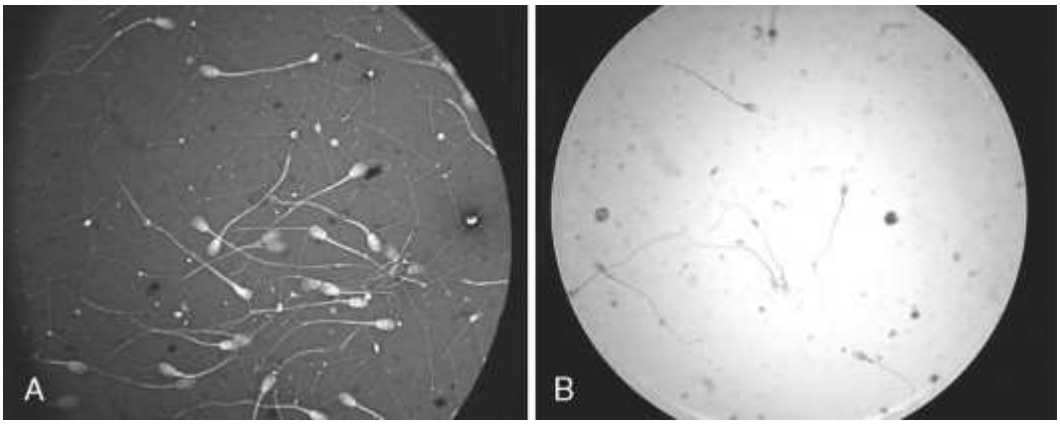
- Asthenozoospermia:
  - Contaminated or improperly washed ejaculate collection equipment (e.g., disinfectant residues)
  - Excessive use of lubricants
  - Prolonged exposure of ejaculate to latex, heat, or cold
  - Urine contamination of the ejaculate
  - Infrequent ejaculate collection, with accumulation of dead sperm in the epididymis and/or vas deferens
- Teratozoospermia:
  - Poor handling of semen after collection (especially if coiled tails or detached heads are present)
  - Improper microscopic interpretation
  - Prolonged sexual abstinence (increase in detached heads) or overuse, pubertal and geriatric patients (increases in cytoplasmic droplets)
- Oligozoospermia:
  - Retrograde ejaculation
  - Fear or apprehension of mating (i.e., presence of dominant female, timid male, first time breeding)
  - Overuse of males, resulting in depletion of epididymal sperm reserves

INITIAL DATABASE

- Physical examination, including palpation of the scrotal contents, spermatic cords, and prostate
- Semen collection and evaluation (including motility, morphology, concentration, volume) and libido evaluation
  - Seminal and prostatic fluid cytologic analysis and culture (see p. 1332)
  - CBC, serum biochemistry panel, urinalysis
  - Serology: *B. canis,* feline coronavirus/FIP

ADVANCED OR CONFIRMATORY TESTING

- All categories:
  - Scrotal and prostatic ultrasonography for structural lesions
  - Endocrine testing: baseline testosterone, estradiol, and follicle-stimulating hormone concentrations
  - Endocrine stimulation testing:
    - Administer 2.2-3.3 mcg/kg GnRH IM or 44 IU/kg human chorionic gonadotropin (hCG) IM in dogs with baseline testosterone and luteinizing hormone (LH) and then sample for LH (10 minutes post injection) and testosterone (1 hour post injection); *or* 250-500 IU hCG IM or IV; or 25 mcg GnRH IM in toms with baseline testosterone and poststimulation samples taken 2 and 4 hours later for hCG or 1 hour after GnRH
    - Normal response: a minimum of a twofold to fourfold increase in testosterone concentrations
    - Negligible or inappropriate response indicates either a primary testicular lesion or a lesion of the hypothalamic-pituitary axis, resulting in failed feedback loop mechanisms
  - Testicular biopsy or aspirate to be considered if noninvasive testing is unrewarding or if a structural lesion (e.g., mass) is present.
  - Advanced semen diagnostics: sperm chromatin structure assay, electron microscopy, in vitro functional assays
- Asthenozoospermia:
  - Radiography of the thorax, respiratory tract cultures, biopsy and electron microscopy of nasal or respiratory epithelium or spermatozoal midpieces for evaluation for primary ciliary dyskinesia (see p. 916)
  - Examination of ejaculate for pH and/or presence of urine crystals, indicating urine contamination
  - Collection directly into semen extender at body temperature, with fractionation of ejaculate
- Teratozoospermia:
  - Detailed morphologic examination using special staining and microscopic techniques such as Spermac, toluidine blue, or Coomassie blue stains, phase contrast, differential interference contrast or electron microscopy
- Oligozoospermia:
  - Urinalysis after ejaculation to assess for retrograde ejaculation. Sample may be obtained by cystocentesis or catheterization.
  - Seminal plasma alkaline phosphatase concentrations to confirm that ejaculation actually occurred with azoospermia



INFERTILITY, MALE Sperm morphology slides made with either an eosin-nigrosin (viability) stain **(A)** or Romanowsky stain (Diff-Quik) **(B)**. With the viability stain, sperm that have damaged cell membranes (dead) stain red (pink), whereas sperm with normal cell membranes (live) do not take up the eosin and therefore appear white. With the Romanowsky stain, increased incubation time (at least 5 minutes for each stain instead of the typical 10 dips within the stain jar) is required for the sperm cells to take up adequate amounts of stain to determine morphology.

TREATMENT

TREATMENT OVERVIEW

- Increase the number of total sperm, the number of total motile cells, and/ or the number of normal cells per ejaculate.
- Manage the use of the male to maximize fertility.

ACUTE GENERAL TREATMENT

- All:
  - Bacterial infections should be treated with appropriate antibiotics based on culture and sensitivity. Individuals positively confirmed to be infected with brucellosis should also be neutered and all kennelmates tested.

    - Hemicastration for unilateral inflammatory, obstructive, or neoplastic conditions
    - Cats that meet the clinical and laboratory criteria for FIP should be removed from catteries/multicat environments (see p. 383)
- Asthenozoospermia:
    - Careful cleaning, rinsing (at least twice with distilled water), and drying of artificial insemination equipment
    - Sparing use of nonspermicidal lubricants
    - Have males urinate immediately prior to collection to avoid urine contamination of ejaculate.
- Teratozoospermia:
    - With scrotal overheating, waiting a minimum of 65 days from onset of insult should result in return to normal spermatozoal morphology.
    - Weight reduction in obese males
    - Centrifugation with sperm gradients to remove abnormal sperm
- Oligozoospermia:
    - With scrotal overheating, waiting a minimum of 65 days from onset of insult should result in return to normal spermatozoal morphology.
    - For retrograde ejaculation: in dogs, phenylpropanolamine (1.1 mg/kg PO q 8–12 h) or pseudoephedrine (0.2–0.4 mg/kg PO q 8 h or 1 to 3 hours before breeding; in toms, phenylproponolamine 6.25–12.5 mg/cat PO q 8–12 h (contraindicated in systemic hypertension)
    - Administration of GnRH (Cystorelin) at 2.2 mcg/kg IM to increase libido, 20-30 minutes prior to collection; or dinoprost tromethamine (Lutalyse) at 0.025-0.05 mg/kg SQ 20 minutes prior to collection (results in sperm-rich ejaculate only +/− full erection)
    - Weight reduction in obese males
    - Positive reinforcement for behavioral issues

CHRONIC TREATMENT

- Asthenozoospermia:
    - Immediate centrifugation of the ejaculate in cases of urine contamination, followed by reextension with semen extender or centrifugation with sperm gradients
    - Depo-Testosterone enanthate (testosterone) plus pregnant mare serum gonadotropin (PMSG) every 2 weeks for 6 weeks has been advocated, but dosages, efficacy, and safety have not been established (50 mg/dog testosterone enanthate + 250 IU/dog PMSG have been used successfully in 15 kg dogs).
- Teratozoospermia, oligozoospermia + asthenozoospermia:
    - If testicular degeneration is present, long-term administration of GnRH (3.3 mcg/kg) IM once weekly or hCG (500-1000 IU IM) every 2 weeks in dogs; or hCG 250-500 IU IM every 2 weeks in toms has shown some positive effects

NUTRITION/DIET

- Administration of daily glucosamine, omega-3 fatty acid, and DHA supplement may be of benefit for asthenozoospermia.
- Administration of daily zinc sulfate and vitamin E supplement may be of benefit for all conditions.

BEHAVIOR/EXERCISE

Excessive exercise and stress may result in infertility from chronic stress or overheating.

DRUG INTERACTIONS

Ketoconazole, cimetidine, long-term NSAID therapy, sulfasalazine, amitriptyline

RECOMMENDED MONITORING

- Routine (monthly) microscopic reevaluation of the spermiogram and reassessment of endocrine function as indicated, beginning 2 to 3 months after initiation of treatment
- Monitor pregnancy rates and litter size.

PROGNOSIS AND OUTCOME

The prognosis for fertility is guarded if no response to treatment occurs within 3 months, poor if no response to treatment occurs within 6 months, and grave if no response to treatment occurs within a year.

PEARLS & CONSIDERATIONS

COMMENTS

- Optimize available sperm:
  - Accurate breeding management and ovulation timing
  - Reduce the number of matings per cycle.
  - Use of transcervical or surgical insemination (surgical insemination preferred)
  - Breeding to young, fertile females
- Avoid overuse:
  - Do not collect more than every other day.
  - Collection of males 7-10 days before anticipated matings in animals that have had prolonged abstinence, to flush the ejaculatory tract of dead sperm
  - Avoid strict raw-meat diets, as they may result in amino acid or vitamin/mineral deficiencies.
- Never diagnose sterility after a single exam.

PREVENTION

- Brucellosis screening biannually (dogs)
- Coronavirus/FIP screening of all new entries into catteries (see p. 383 and p. 258).

CLIENT EDUCATION

- Monitor semen quality regularly for breeding males.
- Freeze semen when dogs are young and fertile.

Infecundity, sterility

EPIDEMIOLOGY

SPECIES, AGE, SEX

Canine, anytime after puberty (6 months and older), female

GENETICS & BREED PREDISPOSITION

More prevalent in inbred families of purebred dogs. Anecdotal information indicating that some breeds of dogs have poor fertility (e.g., Norwich terriers, some sight hounds). Some have been bred to have conformations requiring assistance with breeding and parturition (e.g., bulldogs).

RISK FACTORS

- Advancing age can decrease fertility. Peak fertility is 2-4 years of age.
- Poor or incomplete breeding management is responsible for most apparent infertility in the bitch (see p. 155).
- Previous hormone therapy, abnormal hormone concentrations, and uterine disease also increase the risk of infertility.
- Anestrus, silent heat, persistent estrus, irregular estrus, abnormal sexual behavior, uterine disease, hypoluteoidism, structural abnormalities of the female reproductive tract, systemic illness, and inappropriate nutrition (excessive or inadequate caloric intake, raw diets contaminated with *Salmonella* spp. and/or *E. coli)* all may predispose to infertility.

CONTAGION & ZOONOSIS

Several bacterial and viral agents contributing to infertility are contagious and can be spread both by inhalation and venereally, including β-hemolytic *Streptococcus, Mycoplasma,* and *Ureaplasma* spp., and herpesvirus. The most significant canine venereal disease is *Brucella canis* (see p. 162).

GEOGRAPHY AND SEASONALITY

Female domestic dogs are nonseasonal, with the exception of the basenji that only enters proestrus in the late summer/ early fall.

ASSOCIATED CONDITIONS & DISORDERS

Pseudocyesis (see p. 929) occurs in many bitches whether they are pregnant or not and has not been linked to infertility. Vaginal hyperplasia (see p. 1156) may contribute to infertility by limiting or preventing natural service (does not interfere with artificial insemination).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Breeding management issues
- Abnormalities of the estrous cycle
- Uterine abnormalities

HISTORY, CHIEF COMPLAINT

Varies with the client; medical history is the most important tool in the approach to infertility. Important elements in the history include:

- General health history: vaccination status of the bitch; current medications; past medications, vitamins, and herbal supplements, including heartworm-preventative and topical medications
- Housing details: kennel, home, indoor, outdoor, and number of bitches in the household
- Bitch's age at first estrous cycle
- Length of each cycle from onset of vulvar swelling to diestrus cytology
- Intercycle interval? Details of cycle: onset of vulvar swelling and vulvar discharge, onset of estrous behavior (flagging), dates of mating.
- Method of mating: natural service or artificial insemination by bitch owner, stud owner, or veterinarian
- Artificial insemination: with fresh, chilled, or frozen semen? Was the semen deposited into the vagina or the uterus?
    - Stud dog status
- Dates of last *B. canis* serologic testing for both the bitch and the stud dog
- Method of pregnancy diagnosis: palpation, hormone assay, ultrasound, or radiographs
- Were hormone assays performed during the cycle? Was vaginal cytologic and/or progesterone testing performed to time the breedings? If progesterone testing was done, was it quantitative or qualitative?
- Was the bitch being campaigned or under any other stressful event such as a new home?
- History in infertility in the pedigree if any

PHYSICAL EXAM FINDINGS

Physical examination is usually within normal limits. Special attention should be paid to the external genitalia and mammary glands.

- Ambiguous genitalia may be an indicator of an intersex state (clitoral enlargement suggestive).
- Digital vaginal examination (see p. 1360): to assess patency and accessibility of the vulva and caudal vagina
- Vaginal examinations should be performed gently and atraumatically; may not be feasible in toy-breed bitches that are anestrous at the time of examination.
- Vaginal septae and circumferential strictures may interfere with natural service and with artificial insemination into the vagina as well.
- Visual inspection and palpation of the mammary glands

ETIOLOGY AND PATHOPHYSIOLOGY

- Mistimed breeding is by far the most common cause of infertility.
- Ovarian dysfunction: abnormalities in ovulation and maintenance of the corpus luteum, persistent estrus, and primary anestrus
- Uterine dysfunction: lesions of the uterus (cystic endometrial hyperplasia/ pyometra), subclinical uterine infection, shortened interestrus interval, resulting in implantation failure. The canine uterus requires 130 to 150 days following the onset of proestrus for endometrial repair to occur.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based on a compilation of history (most important), physical examination, and results of laboratory evaluation. Historical information provided by the client is the cornerstone of the diagnostic process and must be elicited comprehensively.

DIFFERENTIAL DIAGNOSIS

- Pregnancy loss
- Ovulation failure
- Silent heat
- Stud dog infertility

INITIAL DATABASE

- CBC, serum biochemistry profile, thyroid panel, *B. canis* serology, vaginal cytologic examination, vaginal culture if in estrus or if discharge present
- Hypoproteinemia and/or or renal dysfunction may contribute to infertility.

ADVANCED OR CONFIRMATORY TESTING

- Vaginoscopy
- Progesterone testing to document ovulation and assess luteal function. Progesterone testing is recommended monthly to assess cyclicity if the client has not observed cycles.
- Ultrasonography of the uterus and ovaries
- Herpesvirus titer
- Ovarian and/or uterine biopsy with histopathologic evaluation could be used in select cases.
- In cases of primary anestrus, it is wise to determine the karyotype of the bitch to assess her actual chromosomal makeup. Trisomy X, XO females and other abnormal chromosome combinations have been reported. Many normal sight hound bitches do not cycle until near 24 months old.

TREATMENT 

TREATMENT OVERVIEW

Targeted treatment is based on the underlying cause of the infertility. In most cases, it is improper breeding management, and client education is the critical issue.

ACUTE AND CHRONIC TREATMENT

- Shortened interestrus interval: mibolerone, 30–180 mcg (small to large dog) PO q 24 h (schedule IV controlled substance)
- Treatment for cystic endometrial hyperplasia/pyometra if present (see p. 954)
- Treatment for persistent estrus if present (see p. 916)
- There is no reliable therapy to induce fertile estrus in the bitch. There are many protocols in use with varying outcomes, but no controlled studies have been published. The most commonly attempted protocols include the use of Ovuplant (a deslorelin implant) or the oral antiprolactinic medication, cabergoline.

NUTRITION/DIET

- Diet with an Association of American Feed Control Officials statement that this diet is complete for all life stages, based on feeding trials.
- If feeding a puppy food during the second half of gestation, it should be a small-breed puppy food.
- No controlled studies to support any claims of over-the-counter supplements that purportedly increase litter size, regulate estrous cycles, promote normal delivery, and so on; some may result in infertility.
- Avoid calcium supplementation pre-partum.

BEHAVIOR/EXERCISE

- A bitch that is removed from her litter too early or a singleton puppy may never demonstrate normal breeding behavior because of her lack of appropriate interaction with littermates at an early age. These bitches may or may not demonstrate normal maternal behavior after whelping. A bitch that is the first canine within a household may not accept a male that is added to the household at a later date. Artificial insemination will overcome this difficulty.
- Performance bitches may be allowed to continue training in the venue in which they compete, provided consideration is allowed for temperature, confinement, stress, and the physical demands of the activity. Special consideration should be made for the potential for exposure to viral and bacterial pathogens for which there is no prophylaxis available. Show grounds, training fields, and training facilities are likely to be a source of many challenges to normal reproduction.

DRUG INTERACTIONS

Use care in the selection of any medication used in a breeding bitch. For example, topical corticosteroids can be absorbed systemically and are not recommended. Use reference list for appropriate drug selection in pregnancy.

POSSIBLE COMPLICATIONS

- Mibolerone causes clitoral hypertrophy, epiphora, and tear staining and may increase aggression towards other dogs. This drug can exacerbate existing liver enzyme elevation. Dogs with normal liver enzymes rarely have changes as a result of the drug.
- The progestational compounds may cause masculinization of female fetuses. Failure to withdraw progestational compounds at the appropriate time can unduly prolong gestation, resulting in fetal death. Progestational compounds can also cause mammary masses to increase in size.

RECOMMENDED MONITORING

Confirm pregnancy using ultrasonography at 30 days post breeding. One can measure progesterone concentrations at that time and weekly if there is any indication of variability in embryonic vesicle size or embryonic loss.

PROGNOSIS AND OUTCOME

Good to excellent for clients who will comply with breeding management recommendations. Guarded for bitches with uterine disease and/or ovarian dysfunction.

PEARLS & CONSIDERATIONS

COMMENTS

- Infertility of the stud dog is the second most common cause of female infertility after improper breeding management. The stud dog must also be evaluated and demonstrated to produce adequate numbers of motile and morphologically normal sperm, and the semen must be inseminated properly.
- Failure to cycle is often a failure to observe the bitch adequately for physical changes consistent with proestrus. The client should blot the vulva daily to detect vaginal discharge and change in vulvar size and shape +/— monthly progesterone assays to detect ovulation with unobserved estrus.

TECHNICIAN TIPS

Be prepared for many questions from clients whose dogs fail to produce puppies. Many clients think that all bitches should be bred on a particular (10th/12th/other) pair of days from the onset of proestrus or every day while she is receptive, and such preconceived notions need to be anticipated and addressed with medical fact, as described above.

CLIENT EDUCATION

- Suggest a reproductive workup before the next anticipated estrous cycle.
- Vaginal cytologic evaluation, vaginal culture, and serum progesterone testing
- Importance of good semen and proper insemination technique

Incontinence, Urinary

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Lack of voluntary control over the passage of urine

EPIDEMIOLOGY

SPECIES, AGE, SEX

- With young animals, congenital disorders are more likely.
- Female dogs: older, spayed females are prone to incontinence due to urethral incompetence.

GENETICS & BREED PREDISPOSITION

- Ectopic ureter: Siberian huskies, miniature and standard poodles, Labrador retrievers, Newfoundlands, fox terriers, West Highland white terriers, collies, and Welsh Corgis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Dribbling urine
- Incontinence while sleeping: a hallmark of urethral incompetence in spayed female dogs and ectopic ureter(s) in puppies

PHYSICAL EXAM FINDINGS

- Urine staining or scalding in perineum
- Neurologic deficits
- Bladder should be palpated before and after urination.
- Bladder expression:
  - Easy: decreased outflow resistance
  - Difficult: normal or increased outflow resistance
- Rectal examination
  - Urethral thickening (inflammation or infiltration)
  - Prostatomegaly (see p. 1420)
  - Bladder trigone abnormalities

ETIOLOGY AND PATHOPHYSIOLOGY

- Neurogenic:
  - Lower motor neuron (LMN; lesion at S1-S3 spinal cord segment, or peripheral nerve disorder)
  - Upper motor neuron (UMN; lesion cranial to sacral spinal cord segment S1)
- Non-neurogenic:
  - Anatomic
  - Functional

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Any patient with a chief complaint of urinary incontinence should have a complete medical history (notably to assess the possibility of behavioral causes and determine whether polyuria or pollakiuria is present); a physical examination including abdominal palpation, rectal palpation when feasible, neurologic examination, and examination of the genitalia and reproductive tract; a urinalysis; and a bacterial culture and sensitivity of urine. Additional tests are selected based on results of these evaluations and may include

monitoring response to treatment.

DIFFERENTIAL DIAGNOSIS

- Neurogenic:
  - LMN disorder (S1-S3 segment or peripheral nerve disorder):
    - Sacral fracture/malformation
    - Trauma to pelvic nerve
    - Lumbosacral disease
  - UMN disorder (cranial to S1); usually characterized by urine retention; overflow incontinence can occur:
    - Intervertebral disk disease
    - Spinal trauma
    - Fibrocartilaginous embolism
    - Spinal neoplasia
- Non-neurogenic:
  - Urethral sphincter mechanism incompetence:
    - Most common cause in adult female dogs
  - Urge incontinence/detrusor hyperspasticity:
    - Associated with lower urinary tract signs
  - Anatomic abnormalities:
    - Ectopic ureters
    - Patent urachus
    - Vaginal stricture

INITIAL DATABASE

- Neurologic examination:
  - UMN:
    - Firm, difficult to express bladder
  - LMN:
    - Flaccid, easily expressed bladder
    - Decreased/absent anal tone, bulbospongiosus reflex, perineal sensation
  - Pain on tail lift: associated with lumbosacral disease
  - Pain on spinal palpation; ataxia, proprioceptive deficits: associated with intervertebral disk disease
- Laboratory tests:
  - Urinalysis:
    - Cystocentesis preferred
    - Pyuria suggests infection of inflammation, leading to increased urge
    - Hematuria suggests inflammation or neoplasia
  - Urine culture and sensitivity
  - CBC/serum biochemistry panel

ADVANCED OR CONFIRMATORY TESTING

- Diagnostic imaging:
  - Abdominal radiographs/ultrasound: structural lesions
  - Cystourethrography/vaginography: radiolucent defects
  - Spinal radiography/myelogram/CT/MRI: spinal cord lesions
- Endoscopy:
  - Direct visualization of ectopic ureters and other anatomic defects
  - Evaluate, and if indicated, biopsy vaginal vault and mucosa of urethra and bladder.
- Urodynamic studies: urethral pressure profilometry
  - Measure pressure, volume, and flow in the urethra and bladder. Improves localization of anatomic site of dysfunction.
  - Generally only available at referral/ research facilities
  - Should be considered in patients refractory to treatment

TREATMENT

TREATMENT OVERVIEW

Some dogs may respond better to one medication than another. If there is no response to a medication, review the diagnosis and if unchanged, consider adding a second medication, changing to a medication in another class of action, and/or pursuing further

diagnostic testing. Goals of treatment are to correct any underlying anatomic defects, treat secondary conditions (e.g., infection), and palliate incontinence if persistent despite these measures.

CHRONIC TREATMENT

- When an underlying disorder is present (e.g., urinary tract infection, prostatic disease, urethral neoplasia), treatment is directed at improvement or resolution of this primary cause.
- If no underlying disorder is found and the patient is an adult female spayed dog with a history consistent with urethral incompetence, the following treatments may be considered.
- α-Agonists:
  - Phenylpropanolamine (PPA) used as first line treatment.
    - When given at 1.1–1.5 mg/kg PO q 8 h, effective in 85%–90% of female dogs with urethral sphincter mechanism incompetence
    - Much more effective when given q 8 h than q 12 h; if there is treatment failure, check dosing frequency with clients before changing medications.
  - Pseudoephedrine and ephedrine
    - Generally used when PPA is unavailable
    - Efficacy appears to be similar to PPA but not as well researched.
    - Incidence of side effects may be higher than with PPA.
- Reproductive hormones/estrogen:
  - Diethylstilbestrol (DES).
    - 0.1–0.2 mg/kg PO q 24 h for 5 days, then same dose PO reduced to 1–2 times per week
    - Efficacy 50%-65% in female dogs with urethral incompetence
    - Excessive doses associated with bone marrow suppression; monitor CBCs.
  - Estriol
    - Possible substitute to DES
    - Dosage for a medium-sized (20 kg) dog is 2 mg PO/day for 7 days, then reduced at weekly intervals to minimum effective dose.
    - Studies are limited, but bone marrow suppression has not been reported.
    - Efficacy and safety need to be further evaluated.
  - Estradiol cypionate (ECP) should not be used, owing to significant risk of bone marrow suppression.
- Surgical and endoscopic therapies:
  - Colposuspension/urethropexy:
    - Resolves incontinence in 50% of dogs
    - Remaining patients may respond to medication.
  - Bulking agents:
    - Endoscopic injection of collagen bulking agents into periurethral tissue
    - Repeat injections may be needed for satisfactory results.
    - Addition of PPA improves response rate.
    - Success rates of approximately 50% with mean duration of 17 months have been reported in preliminary studies.

PROGNOSIS AND OUTCOME

- Outcome for dogs and cats with correctable structural abnormalities is good to excellent.
- Treatment is generally successful with urethral incompetence, although dosage adjustment is often required and urinary tract infections must be identified and treated.
- Although not an inherently life-threatening disorder, urinary incontinence may lead to the consideration of euthanasia in refractory cases.

PEARLS & CONSIDERATIONS

COMMENTS

- Combination therapy of α-agonists and reproductive hormones is synergistic.
- Female dogs resistant to single-agent therapy should receive combination therapy.
- Treatment failure with PPA may result from inadequate dosing. Studies show three-times-daily therapy is effective, but owners may only administer twice a day.
- Multiple therapies may be needed to control refractory patients.

AUTHOR: CLAIRE WEIGAND

EDITOR: ETIENNE CÔTÉ

Incontinence, Fecal

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Inability to retain feces

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young animals: inappropriate house training, congenital disorders
- Old animals: senility/cognitive dysfunction, neoplasia

GENETICS & BREED PREDISPOSITION

- German shepherd: degenerative lumbosacral stenosis, perianal fistulas
- English bulldogs, Manx cats: congenital spinal malformations

RISK FACTORS

- Perineal surgery, radiation therapy
- Pelvic or lumbosacral trauma
- Perianal diseases
- Tail avulsion fractures

ASSOCIATED CONDITIONS & DISORDERS

Urinary incontinence

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Anal sphincter incontinence
  - Non-neurogenic
  - Neurogenic
- Reservoir incontinence
- Behavior
- Other

HISTORY, CHIEF COMPLAINT

- Sphincter incontinence:
  - Unaware of fecal elimination; unassociated with defecation behavior
  - Small amounts of normal or abnormal feces dribble out, especially when intraabdominal pressure increases suddenly (e.g. coughing).
  - Paraparesis
  - Urinary incontinence may be present.
  - Perineal soiling
  - Dogs with spinal lesions and episodic incontinence may be aware of the need to defecate but are unable to control the urge.
- Reservoir incontinence:
  - Animal aware of incontinence; defecation behavior present, but is unable to control the time and place of elimination.
  - Abnormal feces, suggestive of rectocolonic disease (diarrhea, mucoid, hematochezia)
  - Defecation associated with signs of rectocolonic disease (tenesmus, dyschezia)
- Behavior:
  - Housesoiling with normal feces and defecation

- Destructive behavior

PHYSICAL EXAM FINDINGS

- Sphincter incontinence:
  - Non-neurogenic:
    - Perineal/anal sphincter tumors, erosions, fistulas, trauma, anal sac disease, strictures, scarring
  - Neurogenic:
    - Spinal, lumbosacral pain
    - Hyperesthesia of hind limbs or perineum
    - Lower motor neuron signs: paresis/paralysis with decreased muscle tone, decreased spinal reflexes, decreased anal tone; abnormal bulbocavernosus, rectal inflation, or anal reflexes; + loss of tail tone and voluntary movement
    - Upper motor neuron signs: increased spinal reflexes, ataxia
    - Intracranial disease: abnormal behavior or mentation, abnormal cranial nerve examination
- Reservoir incontinence:
  - Abnormal feces: diarrhea, constipation
  - Rectal masses, mucosal changes, pain on digital rectal examination
  - Signs of gastrointestinal disease (weight loss, anorexia, vomiting)
- Behavior: normal physical exam

ETIOLOGY AND PATHOPHYSIOLOGY

- Sphincter incontinence: diseases of the anal sphincter or adjacent structures
  - Non-neurogenic: anatomic disruption of the anal sphincter preventing functional seal. Anal tone and reflexes normal.
  - Neurogenic:
    - Peripheral (either focal pathology or a polyneuropathy): sphincter dysfunction due to inadequate sensory or motor nerve supply, with normal sphincter anatomy (lower motor neuron deficits)
    - Central: loss of subconscious or conscious modification of reflex defecation (upper motor neuron deficits)
- Reservoir incontinence; diseases of the colon/rectum:
  - Diseases impairing colonic-rectal compliance, capacity, or causing irritation
  - Normal sphincter anatomy and neural supply
  - Altered fecal consistency or excessive volume: feces enter into rectum too rapidly for normal control to take place.
  - Urge incontinence
  - “Overflow incontinence”: liquid feces seeping around constipated fecal material

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Fecal incontinence is a sign, not a diagnosis. The underlying cause must be identified for optimal treatment and accurate prognostication. Neurologic exam, behavioral history, and rectal palpation are indicated in all cases.

DIFFERENTIAL DIAGNOSIS

- Sphincter incontinence:
  - Non-neurogenic:
    - Damage to the levator ani, coccygeal, internal and external anal sphincters
    - Perianal trauma, tumors, infections, fistulas; perineal surgery, hernias
  - Neurogenic sphincter incompetence:
    - Degenerative lumbosacral stenosis (“cauda equina syndrome”)
    - Spinal cord disease: trauma, neoplasia, compressive lesions, degenerative and inflammatory conditions
    - Autonomic dysfunction: dysautonomia
    - Peripheral neuropathies
    - Myopathies
    - Cerebral conditions
- Reservoir incontinence:
  - Inflammatory (colitis, proctitis) and noninflammatory (neoplasia) colorectal disease
  - Diets or diseases causing diarrhea, constipation (overflow incontinence)
- Behavior:
  - Inadequate or inappropriate housetraining
  - Cognitive dysfunction

- Conditions affecting locomotion: inability/unwillingness to walk to the elimination area (e.g., severe arthritic pain)
- Separation anxiety, litter box aversion, location preferences/aversions, inadequate privacy

- Other: rectovaginal fistulas

INITIAL DATABASE

- Physical examination including perineal and digital rectal examination
- Fecal analysis
- Complete neurologic examination, especially:
  - Bulbocavernosus, anal, and rectal inflation reflexes
  - Perineal and tail sensation
  - Anal sphincter and tail tone
- CBC
- Serum biochemistry panel
- Urinalysis ± culture and sensitivity

ADVANCED OR CONFIRMATORY TESTING

- Sphincter incontinence:
  - Electromyography
  - Nerve conduction velocity assessment
  - Muscle and nerve biopsies
  - Spinal radiographs + myelography, epidurography
  - Spinal CT, MRI
  - Cerebrospinal fluid analysis
- Reservoir incontinence:
  - Colonoscopy, proctoscopy
  - Rectal-colonic mucosal biopsy: cytologic, histopathologic analysis

TREATMENT

TREATMENT OVERVIEW

- Treat the primary cause.
- Supportive care

ACUTE GENERAL TREATMENT

Generally not required

CHRONIC TREATMENT

- Intestinal motility altering agents: loperamide, diphenoxylate
- Amitriptyline has been successful in an open-label trial in humans with idiopathic fecal incontinence.
- Maintain low intrarectal pressures:
  - Warm water enemas + laxatives (lactulose): may help decrease inappropriate fecal dribbling by keeping rectum empty in some cases.
  - Frequent opportunities to defecate if some control is present
  - Induction of reflex defecation: warm moist washcloth on anus/perineum
  - Avoid evening feedings.
- Prevent fecal scalding (clip and clean perineum, intermittent tail wrap if longhaired, barrier cream).
- Change in environment to make incontinence more acceptable, “doggy diapers”
- Surgical: consider referral to a board certified surgeon.
  - Anorectal reconstruction
  - Silicon elastomer sling
  - Neosphincter
  - Fecal diversion procedures: colonostomy
  - Semitendinous muscle transfer flap

NUTRITION/DIET

May respond to a therapeutic diet trial: either low-residue or high-fiber (soluble or insoluble) diets can be tried. Success is variable

and depends on the underlying etiology.

POSSIBLE COMPLICATIONS

- Fecal soiling predisposes to perineal dermatitis and urinary tract infections (females).
- Constipation possible with motility-modifying medication

RECOMMENDED MONITORING

Medical management must be regarded as a therapeutic trial; response guides subsequent treatment and diagnostic testing if necessary.

PROGNOSIS AND OUTCOME 

- Guarded to poor with:
  - Many neurogenic sphincter causes (degenerative neuropathies, dysautonomia, lumbosacral stenosis)
  - Severe anal sphincter lesions
  - Underlying cause not found
- Fair to good with:
  - Controlled rectocolonic disease
  - Behavioral causes
  - There have been some encouraging results with surgical correction of even long-standing focal UMN spinal lesions.

PEARLS & CONSIDERATIONS 

COMMENTS

- Fecal incontinence caused by UMN spinal cord lesions may develop prior to limb deficits.
- Fecal incontinence is a common reason for client-requested euthanasia.
- Response and client satisfaction are highly variable and based on client expectation and ability.

PREVENTION

Precise and atraumatic technique when performing perineal surgery

CLIENT EDUCATION

Discuss prognosis and complications early with clients to avoid unrealistic expectations.

AUTHOR: FRANK KETTNER

EDITOR: ETIENNE CÔTÉ

Inappropriate Elimination, Dog

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Urination or defecation in a location other than areas acceptable to the client
- Marking: urination (or less commonly defecation) for hierarchical purposes or as part of an anxiety disorder. Usually involves small amounts of urine deposited in several places, often vertical surfaces.
- Incontinence: inadvertent passage of urine or feces as a clinical manifestation of illness.

SYNONYMS

Housesoiling, incomplete housebreaking, incomplete housetraining, soiling, toileting issues

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Can affect dogs of any age and either sex
- Sexually intact dogs may have increased rates of urine marking.
- Puppies first develop physical abilities to inhibit elimination and cognitive abilities to make associations with a preferred substrate (i.e., surface onto which they eliminate) at 8.5 weeks of age. Therefore, between 7 and 9 weeks of age is the ideal age to housetrain a dog.
- Older dogs (particularly young neutered females) may experience urinary incontinence associated with age-related joint laxity and urethral sphincter mechanism incompetence. These problems are medical disorders, not behavioral abnormalities.

GENETICS & BREED PREDISPOSITION

Toy breed dogs eliminate small volumes and therefore may not be as strictly supervised or confined until fully housetrained as would be larger dogs, in which case treatment may be more protracted or difficult. Small bladder volume and greater metabolic rate also mean that smaller dogs need more frequent access to appropriate areas for elimination.

RISK FACTORS

- Sexually intact status
- Presence of intact animals, especially if in estrus (provokes urinary marking by neutered and intact animals)
- Re-homed street and kennel-raised dogs (may never have learned to inhibit their elimination behaviors and will have to learn inhibition and appropriate substrate and location preferences as adults).
- Urinary and fecal marking and increased urgency can be nonspecific signs associated with anxiety disorders. Many dogs with chronic generalized anxiety disorder, for example, have sporadic or chronic diarrhea. Any dog given a diagnosis of “inflammatory bowel disease” should be fully screened for behavioral problems.

CONTAGION & ZOONOSIS

If the inappropriate elimination is due to incomplete housetraining, marking by other dogs in the household may occur.

GEOGRAPHY AND SEASONALITY

- Harsh weather may inhibit a dog's willingness to eliminate outside. Snow and ice should be cleared in a way that allows access and traction.
- Dogs should be exposed to a variety of surfaces/substrates (e.g., grass, cement, sand, stones, sawdust) that will meet the seasonal and lifestyle requirements in which the dog is expected to live.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

House soiling may involve inappropriate urination, inappropriate defecation, marking with urine, marking with feces, or a combination.

Not all urinary marking is vertical. Both males and females can use a variety of positions to mark, and leg cocking is more associated with unfamiliar social stimuli than with sex-based behaviors.

HISTORY, CHIEF COMPLAINT

- Client finds urine or feces inside the home.
- Client may report that the dog was taken out and returned to eliminate in the house.
- Information on volume, frequency, appearance, and when the house soiling occurs is critical in determining underlying cause.

PHYSICAL EXAM FINDINGS

- Findings should be unremarkable in cases with a behavioral etiology (including rectal palpation).
- Abnormal physical exam findings should raise the possibility of medical disorders causing urinary or fecal incontinence (see pp. 599 and 598).

ETIOLOGY AND PATHOPHYSIOLOGY

- Inappropriate elimination is a nonspecific sign that may be “normal” (e.g., incomplete housetraining) or abnormal and associated either with medical or behavioral disturbances, specifically with anxiety disorders.
- Any condition that triggers a fight or flight response can lead to involuntary voiding that may be misinterpreted by the client as purposeful, malicious, or vengeful.
- Olfactory stimulation for normal elimination and marking behaviors is extremely important to dogs and poorly understood by humans.
- Meeting the individual dog's age- and size-specific needs is the key to understanding the root of house soiling and therefore to addressing it.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Inappropriate elimination in itself is a complaint, not a diagnosis, and not always a sign of abnormality, as when the problem is that the pet's choice of location for voiding is incompatible with the owner's wishes. The goal of diagnosis is, through careful behavioral history taking and after ruling out medical problems, to determine whether the behavior is normal but requires some modification to better fit living within a human household or if the elimination is a marker of an anxiety disorder.

DIFFERENTIAL DIAGNOSIS

- Behavioral differential diagnoses:
  - Incomplete housetraining: occurs regardless of client presence or absence, large volume of urine is voided. Normal stool is deposited. Certain areas of the house may be sought preferentially.
  - “Submissive” or excitement urination: occurs upon greeting a person or when the dog is excited. The dog often crouches down and starts to roll over when approached.
  - Marking behaviors: urine marking typically involves small quantities in several locations in the absence of another medical problem. Urine may be deposited in vertical (most common), horizontal, or a combination of surfaces. Fecal marking is less well understood, but small amounts of feces are deposited in response to the presence of unfamiliar animals. Texture and content of feces changes with frequency of marking.
  - Separation anxiety (see p. 1012)
  - Storm phobia (see p. 875)
  - Panic disorder
  - Generalized anxiety disorder
- Medical differential diagnoses:
  - Urinary and fecal incontinence (see pp. 599 and 598)

INITIAL DATABASE

CBC, serum chemistry panel, thyroid function evaluation (see and p. 562), urinalysis, and fecal flotation to assess possible etiologies for polyuria, pollakiuria, and abnormal stool consistency that may lead to inappropriate voiding

ADVANCED OR CONFIRMATORY TESTING

- Once any medical disorders are resolved, a behavioral diagnosis and treatment plan can be pursued if the inappropriate elimination persists, because the inciting causes may be medical, but the maintenance causes may be behavioral.

- Behavioral diagnosis may be achieved using detailed history; consultation with a veterinary behaviorist can be very rewarding.

TREATMENT

TREATMENT OVERVIEW

Treat underlying medical disorder(s). If inappropriate elimination persists, address behavioral sequelae to restore housetraining.

ACUTE AND CHRONIC TREATMENT

- Incomplete housetraining: fully confine or supervise when indoors, using a leash or crate. If the dog is “caught” eliminating, calmly take outside to the chosen elimination area, allow the dog to finish, and praise lavishly. Take to eliminate after eating, after play, after any slowing in play, and after awakening. Any yelling or punishment is likely to hasten the voiding process and is entirely counterproductive.
- Submissive or excitement urination: Owner should maintain an emotionally calm approach, especially when greeting the dog. It may be necessary to ignore the dog until it is very calm and then guide it outside to greet after elimination. Cornerstones of successful treatment are to keep the dog's bladder empty through frequent, well-timed walks outside to eliminate, and to use positive methods and rewards for teaching the dog to sit without leaking or cringing. Use rule structures that guide the pet to learn which behaviors are considered correct in the home and in social interactions. This approach lessens the dog's need to signal submission with urination. The owners should teach the dog that calm behaviors like sitting and lying down get praise, and attention will lessen overall reactivity and encourage the dog to react calmly.
- Clients should be advised against punishing after the fact. This makes no sense to the dog, may force it to housesoil out of sight, and eliminates the opportunity to praise for correct behavior.
- For small dogs with higher metabolic rates, or less agile or ill dogs, canine litter boxes may be a good solution, especially in urban areas. Accustoming the dog to the substrate to be used in the box at an early age may help. Commercially available boxes or homemade ones that accommodate the dog's size and mobility (low edges for arthritic dogs) can be filled with cat litter, especially made artificial turf or lined with paper. Owners' objections tend to dissipate when it is pointed out that litter boxes, even large ones, are easier to clean than carpets and rugs.
- For marking behaviors within the house, it is important to address the social interactions between the animals. Screening for overt and covert aggression (see p. 48) and other anxiety-related conditions in all of the household pets should be undertaken.
- For marking behaviors outside the house, exposure to other stimuli is the only feasible management approach. If feral and roaming animals are triggers, owners can contact local animal control and shelter organizations to arrange for humane trapping, neutering, and adoption.
- For intact male dogs who become distracted in the presence of female urine: a problem for many working (e.g., service, assistance, explosives detection) dogs, castration as early in the development of the marking behavior as is possible largely resolves the situation in most cases.
- Because of the learning component, veterinarians should screen all dogs at all visits for elimination complaints. Early intervention decreases the effect of the learning component.

BEHAVIOR/EXERCISE

- Taking a dog out twice daily often is insufficient. Encourage clients to think of how often they eliminate every day and to understand the dog's metabolism is just like theirs.

POSSIBLE COMPLICATIONS

Punishment will either be useless in resolving the problem or will make the problem worse, especially if anxiety is contributory.

PROGNOSIS AND OUTCOME

- Prognosis is excellent in cases of incomplete housetraining or “submissive” or excitement elimination, so long as proper identification of underlying cause and thorough behavior modification are carried out.
- Prognosis for problematic marking behaviors is excellent if the associated behavioral concerns of the household are competently addressed.
- Prognosis is guarded for an adult male dog that has urine marked for his entire life. The learning component is likely far more important at this stage than the hormonal component.

PEARLS & CONSIDERATIONS

COMMENTS

- Abuse of puppies and abuse of human children often starts with abusive behavior surrounding housetraining/ toilet training (see online chapter: Abuse). Veterinarians should be aware of the signs.
- Lack of attention to the dog's need is the most common reason for poor housetraining or other nonmarking elimination problems in dogs.
- Fecal marking and increased urgency (e.g., sporadic diarrhea) can be non-specific signs associated with anxiety disorders rather than primary gastrointestinal disease. Any dog given a diagnosis of inflammatory bowel disease should be fully screened for behavioral problems.

PREVENTION

- Ensure that dogs are not outside only for the purpose of elimination. If this is so, they may delay eliminating outside to have more opportunity to experience outdoor stimuli and may then eliminate indoors.
- Reward dogs for eliminating outside with play, freedom, exercise, praise, interaction with other dogs, and time to smell their canine world.

CLIENT EDUCATION

- Client education is key to preventing and fixing these problems. All veterinary practices should have handouts (see online version of this textbook for Client Education Sheets; also numerous specialized texts and sources) that explain how to housetrain dogs, and a designated staff member should be responsible for explaining and following up on such training with owners.
- Quick screening at each veterinary visit for elimination complaints and other behavioral concerns saves lives. Veterinarians need to know that clients are unlikely to share behavioral information and questions unless prompted to do so.

Inappropriate Elimination, Cat

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Situation characterized by the use of inappropriate or undesirable areas (locations or surfaces) for elimination of urine or feces. As used here, this is a diagnosis associated with an anxiety disorder. Otherwise, “inappropriate” elimination is often elimination that is normal for the species but undesirable to clients. Urinary incontinence: passage of urine without awareness, due to a medical problem. Comparatively rare in cats.
- Marking: passage of urine or feces involving social interaction. Very common in cats. Marking with urine may be in the form of spraying.

SYNONYMS

Toileting problems, litter box problems, undesirable litter box use

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Urine spraying: sexually intact animals > neutered animals. Possibly males > females.
- Marking behaviors—which need not involve spraying—may develop at sexual maturity (~6 months) if they pertain to sexual advertisement, or at social maturity (~24–48 months) if they pertain to social organization, relative roles in social relationships, or stress or distress.

GENETICS & BREED PREDISPOSITION

Long-haired cats possibly overrepresented with substrate (surface onto which a cat eliminates) aversions

RISK FACTORS

- Risk factors for elimination preferences and aversions include:
  - Dirty litter and/or litter boxes
  - Litter boxes that are too small and discourage active digging and exploration
  - Litter boxes that are too high for cats to enter readily
  - Styles (covered) and placement (in closets) that allow the cat using the litter box to be trapped by a child, another cat, a dog
  - Placement of boxes in locations cats cannot reach because of pain (arthritis), access (doors closed), or social factors (being chased by the new puppy)
  - Entrapment of odors by lids of covered boxes placed in areas without adequate ventilation
  - Illness of any cat in the household that causes changes in bladder and bowel function
- Risk factors for marking are based on social stress and distress. Stressors can include:
  - Addition of another pet
  - Loss of a pet
  - Change in the composition of the human household
  - Change in the “stress” level of the household (e.g., illness, changes in jobs)
  - Visitation by an outside cat
  - Illness or change of relationships between cats in the household (e.g., that concomitant with social maturity)
  - True intercat aggression

GEOGRAPHY AND SEASONALITY

Marking behaviors may intensify in spring, when more animals are let outside, visit indoor animals, and scents aerosolize. Marking increases in frequency (by both female and male, though males may be noticed more readily) when females enter estrus.

ASSOCIATED CONDITIONS & DISORDERS

Coexistent intercat aggression is common; identifying relative victims and aggressors is essential to resolving the social conflict and

fixing the toileting complaints.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Three classes of problems that can all be normal behaviors in free-ranging cats:

- Substrate (texture/surface) preferences or aversions. The amounts of urine or feces are small and distributed over areas associated with social stimuli.
- Location preferences or aversions; as for substrate
- In marking involving sprayed urine (spraying is part of a normal signaling repertoire in cats), the cat treads on its front feet, raises its tail, quivering the tip, and sprays urine vertically. If the cat is not backed against a vertical surface, sprayed urine makes a linear pattern on horizontal surfaces. Non-spraying marking involves elimination of small amounts of urine or feces in areas that have social, not tactile, significance.

HISTORY, CHIEF COMPLAINT

Clients find urine or feces in locations they consider unacceptable.

PHYSICAL EXAM FINDINGS

- Unremarkable
- Findings suggesting lower urinary tract disease, gastrointestinal problems, or other nonbehavioral disorder warrant a diagnostic medical evaluation.

ETIOLOGY AND PATHOPHYSIOLOGY

- Behavior is normal for the species but unacceptable to clients and/or coexists with intercat aggression or other behavioral disorder.
- Association between spraying and crystalluria, or inappropriate urination and defecation with impacted anal sacs, remains speculative.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Initially it is important to use history, physical exam, and routine lab tests to differentiate between inappropriate/ undesirable elimination and marking, which are behavioral, and urinary/fecal complaints that are primarily medical. Video recordings of the cat in the home environment can be helpful if the owner is unsure. If inappropriate/undesirable elimination of urine is confirmed, history and owner observation should be used for determining whether marking behaviors or substrate/location preferences/ aversions are involved. These different diagnoses have important management and treatment implications.

DIFFERENTIAL DIAGNOSIS

- Feline lower urinary tract signs/disease
- Bacterial cystitis
- Urethral obstruction
- Diabetes mellitus
- Cognitive dysfunction
- Hyperthyroidism
- Lower motor neuron disease
- Enteritis/colitis
- Parasitemia

INITIAL DATABASE

- Inappropriate urination and/or before initiating medications: CBC, serum biochemistry profile, urinalysis with culture, thyroid profile (if > 6 years old)
- Inappropriate defecation: fecal flotation and direct smear, thyroid profile (if >6 years old)

ADVANCED OR CONFIRMATORY TESTING

To identify the nature of inappropriate elimination and any concurrent issues (e.g., intercat aggression), client observations are essential. Videotaping interactions between cats in a multicat household may be extremely informative, especially if the client is unable to determine which cat is eliminating inappropriately and/or is unable to understand social interactions and dynamics between the cats.

TREATMENT

TREATMENT OVERVIEW

Treatment goals include:

- Appropriate and reliable use of intended substrates and locations for elimination, when the problem is substrate preference/aversion
- Identification and management of concurrent behavioral disorders (e.g., social factors such as intercat aggression) that can contribute to inappropriate elimination

ACUTE AND CHRONIC TREATMENT

- Identify previously preferred substrates and locations, and replicate these.
- Ensure there is at least one more litter box than the number of cats.
- Ensure the litter boxes are at least 1.5 cat body lengths long. This is larger than virtually all commercially available litter boxes for cats, but rigorous research has indicated that this is the size preferred by cats.
- Identify locations where the cat spends the most time, and place boxes accordingly.
- Ensure that clients are complying with an appropriate cleaning regimen:
    - Scoop litter multiple times daily.
    - Totally dump litter, including recyclable multicat litters, two to three times a week, depending on the number of cats using them.
    - Wash, rinse, and dry the litter box at least weekly.
    - Avoid liners and scented litters.
    - Ensure that covered litter boxes have good ventilation if they must be used.
- Use good odor eliminations (e.g., Anti-Icky-Poo [AIP]) on all substrates where urine or feces has been inappropriately deposited.
- Pheromonal analog products have been suggested for use to “calm” animals, but they may make some animals more reactive. Their efficacy is in doubt insofar as most studies are poor and show at best a weak contributory effect. No study on the use of pheromonal analogs shows efficacy to the extent seen when the underlying anxiety is treated with medication.
- Identify potential stressors or conflicts in the household (e.g., intercat aggression) and redress them. The most common of these may be relationships between cats in the household. Inter-cat aggression is a serious concern if:
    - One cat is avoiding one or more other cats.
    - One cat consistently leaves the room or a preferred resting spot when one or more other cats enter.
    - One cat cannot or does not eat or drink in the presence of the others.
    - One cat is always hiding.
    - One cat is hyperreactive to any noise or tactile stimuli.
- If any of the above conditions can be identified, ensure that clients separate afflicted cats when they are not supervised. The more timid cat should have free range; the more aggressive cat should be confined in a space that is not highly contested or desirable (e.g., not the client's bedroom or the kitchen).
- If anxiety and aggression are involved, benzodiazepines (BZDs), tricyclic anti-depressants (TCAs), or selective serotonin reuptake inhibitors (SSRIs) may be useful treatments for the anxious/ aggressive cat.
    - TCAs: amitriptyline or nortriptyline (0.5–1 mg/kg PO q 12–24 h × 30 days minimum); clomipramine (0.5 mg/kg PO q 24 h × minimum 60 days)
    - SSRIs: fluoxetine or paroxetine (0.5 mg/kg PO q 24 h × minimum 60 days)
    - BZDs: diazepam or oxazepam (0.2–0.4 mg/kg PO q 12–24 h × minimum 30 days); alprazolam (0.01–40.025 mg/ kg PO q 12–24 h or as needed q 4–5 h for panic)
    - BZDs are helpful primarily in behavior modification programs involving food reward (e.g., teaching cats that have problems with each other to tolerate each other).
    - TCAs and SSRIs can be extremely useful in helping overcome aversions and addressing anxiety involved in marking behaviors and intercat aggression.
- If the toileting issue is associated with intercat aggression and the victim needs to become more outgoing, the partial serotonin agonist, buspirone (0.5–1 mg/kg PO q 24 h × 60 days minimum) can be a good drug of choice, but it may act in part by rendering the afflicted cat sufficiently confident to engage in social interactions that could result in a true physical fight, which clients need to monitor and address if it occurs.
- If more animals are added to the household, clients should expect social upheaval and be prepared to restart analysis of

interaction and behavior.
- Attention should be paid to the victimized cat before the other cats.
- Litter box hygiene must be meticulous and lifelong.
- Outdoor or visitor cats should be kept to a minimum or excluded.
- Consider allowing the cat to be an indoor/outdoor cat if all else fails.

POSSIBLE COMPLICATIONS

- BZDs: hyperexcitability (rare), severe hepatotoxicity (rare), potential abuse by clients
- Cats treated with monoamine oxidase inhibitors (some flea and tick collars) should not be treated with TCAs or SSRIs.

RECOMMENDED MONITORING

Exam and laboratory tests at least every 6–12 months if taking medications

PROGNOSIS AND OUTCOME

- Without treatment, the prognosis is guarded. Inappropriate elimination is the single most common reason cats in North America are euthanized or relinquished.
- Clients maintain cats in their household for an average of 2 years after a complaint has been identified, but the more obvious inappropriate urination is to the client, the more likely he or she is to be intolerant of it.
- Prognosis is improved by early diagnosis, comprehensive treatment, attentive client monitoring, and open communication between clinician and client.

PEARLS & CONSIDERATIONS

COMMENTS

In the absence of meeting the cat's needs, attempts to constrain the cat to eliminate in places, on substrates, or in modes preferred by the client will likely result in a worsening of the problem.

PREVENTION

- Meeting the cat's needs, whether by providing sweater boxes or canine litter boxes, providing multiple boxes, or grouping cats by temperament, is the single best way to prevent elimination problems.
- Veterinarians should screen for elimination problems as a routine part of every appointment and should encourage clients to call at the first sign of any elimination “accident”. Because elimination is a complex behavior in cats, waiting to discuss the issue may result in the death or relinquishment of the cat.

CLIENT EDUCATION

- Treatment of behavioral conditions is an ongoing process, often for the life of the pet. Relapses may occur with treatment discontinuation or with added stressors.
- Physical illness is also a stressor and may promote a behavioral elimination problem where previously none existed.

AUTHOR & EDITOR: KAREN L. OVERALL

Immunodeficiency Syndromes, Dog

BASIC INFORMATION

DEFINITION

Primary immunodeficiency syndrome: an inherited defect involving either the humoral (B cell) or cell-mediated (T cell) immune system, a combination of the two, or the phagocytic system

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Signs first manifest around 8-12 weeks of age when the protective effects of maternal antibody are lost.
- No sex predilection except for sex-linked severe combined immunodeficiency syndrome (X-SCID)—males

GENETICS & BREED PREDISPOSITION

- Humoral (B-cell) immunodeficiency disorder:
  - Selective IgA deficiency: German shepherd dog, shar-pei, and beagle
  - Complement deficiency: Brittany spaniel
- Cell-mediated (T-cell) immunodeficiency disorder:
  - Thymic hypoplasia: dwarf weimaraner
- Combined (B-cell and T-cell) immunodeficiency disorder:
  - SCID: Jack Russell terrier
  - X-SCID: bassett hound, Cardigan Welsh corgi
- Functional phagocytic immunodeficiency disorder:
  - Canine leukocyte adhesion disorder (CLAD): Irish setter
  - Weimaraner immunodeficiency syndrome: weimaraner

CONTAGION & ZOONOSIS

Most opportunistic infections that affect immunocompromised individuals are overgrowths or infections with organisms that otherwise are not pathogenic to immunocompetent hosts. However, immunocompromised animals are also more susceptible than normal individuals to infection with organisms that are potentially zoonotic (e.g., dermatophytosis) or contagious to other dogs (e.g., respiratory tract pathogens).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Recurrent infections that may or may not respond to appropriate therapy. Type of infection may vary with defect in the immune system.

PHYSICAL EXAM FINDINGS

- Humoral (B-cell) immunodeficiency disorder: physical exam findings are largely unremarkable; however, some patients may present with signs associated with chronic/recurring infections; increased incidence of chronic respiratory, skin, and intestinal infections.
- Cell-mediated (T-cell) immunodeficiency disorder: absence of palpable lymph nodes, tonsils are not visible. Affected dogs typically have signs of growth retardation and unthriftiness as compared to the other puppies within the litter.
- Combined (B-cell and T-cell) immunodeficiency disorder: similar findings as for humoral and cell-mediated immunodeficiency disorder
- Functional phagocytic immunodeficiency disorder: fever, generalized lymphadenopathy, dermatitis, pododermatitis, gingivitis, osteomyelitis; striking absence of pus formation and poor wound healing

ETIOLOGY AND PATHOPHYSIOLOGY

- Humoral (B-cell) immunodeficiency: decreased concentrations or absence of certain immunoglobulins, with increased

susceptibility to bacterial infections
    - IgA deficiency: mode of inheritance is unknown. Epidemiologic studies show that puppies born to dams with IgA deficiency are at increased risk of developing upper respiratory infections as compared to puppies from dams with normal IgA concentrations.
    - Complement deficiency: autosomal recessive mode of inheritance; dogs that are homozygous for the trait have no detectable C3, required for opsonization of bacteria.
- Cell-mediated (T-cell) immunodeficiency: affected animals have either low numbers of or nonfunctional T cells. Findings include a small thymus and lack of lymph nodes, tonsils, and Peyer's patches on postmortem examination. Affected animals are at increased risk for infections with intracellular bacterial, fungal, protozoal, and viral organisms.
- Combined (B-cell and T-cell) immunodeficiency:
    - SCID: autosomal recessive: affected individuals are unable to mount an appropriate antigen-specific immune response, owing to a lack of DNA protein kinase (DNA-PK) activity; DNA-PK is required for lymphocyte precursors to mature.
    - X-SCID: sex-linked mutation in the g chain of the interleukin 2 (IL-2) receptor required for normal B-cell and T-cell function. Affected male puppies are able to synthesize IgM, but IgG concentrations are significantly reduced and IgA is not detectable.
- Functional phagocytic immunodeficiency: affected animals have an increased risk for systemic or superficial infections with pyogenic microorganisms.
    - Weimaraner immunodeficiency syndrome: inherited, exact mechanism unknown; neutrophil dysfunction at the site of the lesion. However, there also appears to be a failure to produce IgA and IgG.
    - CLAD: deficiency of leukocyte surface glycoprotein (B2 integrin) associated with leukocyte adherence and egress into affected tissues; failure to express B2 integrin CD18.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Affected puppies present with varying, often nonspecific clinical signs and commonly with recurrent infections. It is the recurrence of the infections and the poor response to therapy that warrant further investigation of a primary immunodeficiency syndrome.

DIFFERENTIAL DIAGNOSIS

- Humoral immunodeficiency: varies based on presenting complaint.
    - Upper respiratory infection: *Bordetella bronchiseptica*
    - Primary ciliary dyskinesia
    - Otitis
    - Stomatitis
    - Staphylococcal dermatitis
    - Atopic dermatitis
- Cell-mediated immunodeficiency:
    - Fungal (e.g., cryptococcosis, aspergillosis, blastomycosis, dermatophytosis)
    - Protozoal (e.g., toxoplasmosis, giardiasis)
    - Viral infections can be seen after vaccination with modified live virus vaccine
    - Intracellular bacteria (e.g., mycobacterial infections)
- Combined immunodeficiency: affected animals are susceptible to bacterial, viral, fungal, and protozoal agents.
- Functional phagocytic immunodeficiency:
    - Sepsis
    - Bacteremia
    - Pelger-Huët: hyposegmentation of nuclei in granulocytes and monocytes; persistent degenerative left shift without toxic change or any signs of illness (it is only an incidental finding).
    - Other infectious disease that would cause a neutrophilic leukocytosis with a left shift

INITIAL DATABASE

Appropriate diagnostic testing based on clinical presentation:

- Minimum database: CBC, serum biochemistry profile, urinalysis with culture and sensitivity, fecal examination, thoracic radiographs
- Humoral (B-cell) immunodeficiency disorder: minimum database within normal limits
- Cell-mediated (T-cell) immunodeficiency disorder: normal/decreased lymphocyte count
- Combined (B-cell and T-cell) immunodeficiency disorder: normal/decreased lymphocyte count (average 1000/mcL); possibly low total protein due to low globulin levels; agammaglobulinemia (protein electrophoresis)
- Functional phagocytic immunodeficiency disorder: persistent leukocytosis with regenerative left shift; neutrophil count >

200,000/mcL

ADVANCED OR CONFIRMATORY TESTING

- Specific tests performed should be geared toward the clinical presentation and tailored to the suspected immunodeficiency. Commonly considered tests include abdominal ultrasound, transtracheal wash with culture and sensitivity, bone marrow aspirate or core biopsy, lymph node biopsy, lesional biopsy. With CLAD, biopsy of lesion shows bacteria and possibly necrosis but no infiltration of neutrophils.
- Humoral immunodeficiency: serum protein electrophoresis to evaluate immunoglobulin concentrations, serum immunoglobulin quantitation, quantitation of serum C3 for C3 deficiency
- Cell-mediated immunodeficiency: lymphocyte transformation (blastogenesis) evaluates the ability of the T cell to proliferate after stimulation; measurement of growth hormone or insulin-like growth factor 1 if dwarfism is suspected (testing generally available only in research laboratories).
- Functional phagocytic immunodeficiency:
  - Bactericidal assays: measure the ability of neutrophils to kill bacteria.
  - PCR: to identify affected, normal, or carrier animals

TREATMENT

TREATMENT OVERVIEW

A substantial degree of variation in severity may exist for a given immunodeficiency syndrome. Therefore, treatment intensity, treatment success, and prognosis are individually variable and must be determined case by case. Some individuals require minimal or no treatment (e.g., intermittent antimicrobial treatment during clinical exacerbation), whereas in others, euthanasia is the most humane option. Control opportunistic infections with antimicrobials and supportive care; hospitalize when necessary.

ACUTE GENERAL TREATMENT

Supportive care to treat opportunistic infections:

- For example, antibiotics for confirmed bacterial infections. Empirical antibiotics may be used initially, pending culture and sensitivity results. Antibiotic type should be selected based on suspected bacterial population of involved site:
  - Skin: gram-positive bacteria most common; consider cephalosporins (e.g., cephalexin or cefadroxil, 22 mg/kg PO q 8-12 h) or penicillins (e.g., amoxicillin, 22 mg/kg PO q 8 h; or ampicillin, 22 mg/kg IV q 8 h).
  - Oral cavity and respiratory tract:
    - Gram positive cocci: consider cephalosporins, 22 mg/kg PO, IV q 8 h; or trimethoprim-sulfadiazine, 15 mg/kg SQ, IM, IV q 12 h
    - Gram negative rods: trimethoprim-sulfadiazine, 15 mg/kg SQ, IM, IV q 12 h; or enrofloxacin, 5-10 mg/kg IV q 24 h; or gentamicin, 8 mg/kg IV, IM, SQ q 24 h
    - *Bordetella* infection: gentamicin, 9 mg/kg IV, IM, SQ q 24 h; or doxycycline, 5 mg/kg IV, PO q 12 h; or chloramphenicol, 50 mg/kg IV, SQ, PO q 8 h
    - Mixed populations: consider fluoroquinolones (enrofloxacin, 5 mg/kg PO or slow IV q 12 h), or β-lactamase–resistant penicillins (e.g., amoxicillin-clavulanate, 10-20 mg/kg PO q 12 h), or macrolides (e.g., azithromycin, 5-10 mg/kg PO q 24 h × 1-5 days).
- Due to strong possibility of opportunistic fungal, viral, and protozoal infections, empirical antibiotic therapy may be inadequate or may select for resistant strains of bacteria; diagnostic samples for culture should be obtained before initiating antibiotic treatment, and judicious antibiotic use is warranted.
- Nebulization and coupage for bacterial pneumonia (see p. 887 and p. 1310)
- Disinfection of cutaneous wounds with diluted (0.05%) chlorhexidine solution
  - With standard 4% chlorhexidine solution, dilute 1 part chlorhexidine to 80 parts water to obtain 0.05% concentration.
  - The same concentration may be used as an ear wash in opportunistic otitis and as an oral antiseptic rinse in cases of stomatitis.

CHRONIC TREATMENT

- Humoral immunodeficiency:
  - Nonspecific supportive therapy tailored toward treating recurrent microbial infections
- Cell-mediated immunodeficiency:
  - Supportive care with frequent monitoring for opportunistic infections and then proceed with aggressive treatment when warranted.
  - Dwarf weimaraners respond to thymosin fraction 5 therapy (1 mg/kg SQ q 24 h for 7 days).
- Combined (B-cell and T-cell) immunodeficiency:

    - Bone marrow transplantation
- Phagocytic immunodeficiency:
    - Bone marrow transplantation

NUTRITION/DIET

- Caloric requirements of the critically ill patient may be less than those of healthy animal.
- Resting energy requirement: RER = 70 × body weight (kg)$^{0.75}$
- RER approximation - 30 × body weight (kg) + 70
- Parenteral nutrition versus enteral nutrition

DRUG INTERACTIONS AND CONTRAINDICATIONS

- When using chloramphenicol, consider human risks (myelosuppression, aplastic anemia; wear gloves).
- When using aminoglycosides, ensure that patient is well hydrated.

POSSIBLE COMPLICATIONS

- Sepsis
- Recurring and resistant infections

RECOMMENDED MONITORING

Monitoring of appetite, activity, temperature, and CBCs can aid in the early detection of infection.

PROGNOSIS AND OUTCOME

- Humoral immunodeficiency: fair to good
- Cell-mediated immunodeficiency: poor
- Combined (B-cell and T-cell) immunodeficiency: poor. Affected animals usually die between 2 and 4 months of age from systemic bacterial or viral infections.
- Phagocytic immunodeficiency: poor

PEARLS & CONSIDERATIONS

COMMENTS

The diseases listed here are rare but are severe and have a poor/guarded prognosis.

PREVENTION

The most important aspect of controlling the prevalence of the immunodeficiency syndromes that affect dogs of predisposed breeds is by client education and appropriate genetic screening of potential breeding pairs when molecular testing is possible.

TECHNICIAN TIPS

- Wear gloves when handling immunocompromised patients.
- Protect yourself from opportunistic zoonotic infections by wearing protective shielding.
- Use sterile saline when performing nebulization.
- Encourage patient appetite by warming foods (see p. 1377).

CLIENT EDUCATION

It is important to discuss with the client that affected dogs will not be cured, the disease is heritable, and other puppies of the same litter may be affected. Affected puppies are at an extremely high risk for secondary infections and should avoid other ill animals.

AUTHOR: TRACEY A. ROSSI

EDITOR: SUSAN M. COTTER

Immunodeficiency Syndromes, Cat

BASIC INFORMATION

DEFINITION

Conditions resulting from a defective immune response. They may be primary, from an inherited defect, or secondary to another disease process or infection. They may be specific, with a defect in either B or T lymphocyte function, or nonspecific, due to a defect in phagocytic cell function or skin or mucosal integrity.

SYNONYMS

Immune or immunologic deficiency

EPIDEMIOLOGY

SPECIES, AGE, SEX

- One rare nonspecific defect is seen in young Persian cats with Chédiak-Higashi disease syndrome.
- All other known specific immunologic defects in cats are acquired and secondary to retroviral (feline leukemia virus [FeLV; see 385], feline immunodeficiency virus [FIV; see 381]) infections. These infections can occur at any age and in either gender, although young cats are most susceptible to FeLV infection.

GENETICS & BREED PREDISPOSITION

Persian cats with a dilute smoke gray coat color and yellow irises may have Chédiak-Higashi syndrome.

RISK FACTORS

- Greater FeLV propagation in crowded multicat households or shelters
- FIV occurs primarily in adult, outdoor, intact male cats.
- Either virus can be spread easily through blood, as in transfusions.

CONTAGION & ZOONOSIS

- FeLV is spread through contact with saliva, respiratory secretions, and milk. Kittens < 4 months old are most at risk from queens or other cats.
- FIV is less contagious and is spread primarily through bite wounds.
- No known zoonotic risk

GEOGRAPHY AND SEASONALITY

Both viruses have worldwide distribution. FIV is more prevalent in countries where cats routinely roam outdoors. Over time, FeLV has decreased in prevalence in countries where testing and vaccination have been used.

ASSOCIATED CONDITIONS & DISORDERS

- Chédiak-Higashi syndrome: slight increased risk for bacterial infections. Bleeding tendencies are also more common with this disease.
- FeLV can cause hematologic neoplasia, myelosuppression, immune-mediated diseases.
- FIV is less pathogenic and more likely associated with stomatitis or neurologic disorders.
- Both FeLV and FIV cause immunodeficiency, which can result in opportunistic infections.
- Almost any infection can occur in cats infected with FeLV or FIV.
    - Examples: bacterial (stomatitis, pyoderma), fungal (dermatophytosis, cryptococcosis), protozoal (toxoplasmosis, cryptosporidiosis), other viral (feline infectious peritonitis, panleukopenia), and hemotropic mycoplasmosis (*Mycoplasma haemofelis* infection, formerly hemobartonellosis)
    - Some infections may be abnormally persistent or recurrent.
    - Some infections also may be secondary to neutropenia (more common with FeLV than FIV).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Signs may be vague, such as weight loss and lethargy, or may be referable to the specific infection that occurs. Common clinical signs are salivation or dysphagia from stomatitis, chronic nasal discharge from bacterial or viral rhinitis, or diarrhea from enteritis.

PHYSICAL EXAM FINDINGS

- Stomatitis (lymphocytic-plasmacytic proliferative type): more commonly associated with FIV than FeLV (FIV > FeLV; see 1051)
- Signs of neurologic disorders, especially dementia or twitching: FIV > FeLV
- Gingivitis: FeLV ≈ FIV
- Anemia: FeLV > FIV
- Lymphadenopathy (reactive; may be caused by bartonellosis): FeLV > FIV

ETIOLOGY AND PATHOPHYSIOLOGY

- FeLV/FIV (retroviral)-associated im-mune deficiency
  - The subset of lymphocytes most affected by retroviral infection is the CD4 helper T cell. The ratio of CD4 to CD8 cells is also decreased.
  - Also described with FeLV: secondary decreased ability of B cells to respond to new antigens
  - Thymic atrophy in neonatal kittens can cause “fading kitten syndrome.”
  - FIV is much less pathogenic than is FeLV. Many cats infected with FIV can live for many years without signs of illness (see p. 381 and p. 385).
  - Neither FeLV nor FIV causes cytopathic changes or inflammation in tissues. Thus if a fever is present, a second infectious agent is likely to be the cause.
- Chédiak-Higashi–associated immune deficiency (rare disorder)
  - Abnormal neutrophil granules with abnormal function and survival. Bleeding tendencies are a result of platelet function defects.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Proving that an immunodeficiency is present requires specialized testing, not readily available to clinicians (e.g., lymphocyte immunophenotyping, counting of CD4 cells).
- One may assume that cats with retroviral infections may be immunodeficient.

DIFFERENTIAL DIAGNOSIS

- Any unusual, persistent, or recurring infection in any cat might be secondary to a retroviral infection.
- Neutropenia can also be caused by other primary bone marrow disease, drugs, toxins, or may be secondary to an overwhelming infection.

INITIAL DATABASE

- CBC to evaluate for anemia, neutropenia, or thrombocytopenia
  - FeLV/FIV: anemia, neutropenia, or thrombocytopenia. Persistent lymphopenia may occur but is nonspecific.
  - Chédiak-Higashi syndrome produces characteristic large granules in neutrophils.
- Urinalysis to evaluate for proteinuria or infection
- Serum biochemistry profile: usually unremarkable but rarely will reflect visceral organ involvement with opportunistic infections (e.g., pyelonephritis, bacterial translocation via portal circulation). Serum globulin level may be normal or elevated.
- FeLV (antigen) and FIV (antibody) ELISA blood tests are excellent for initial screening.
  - Maternal antibody and vaccination interfere with FIV test but not FeLV.

ADVANCED OR CONFIRMATORY TESTING

- A positive ELISA for either FeLV (antigen) or FIV (antibody) in a cat with signs compatible with an immunodeficiency syndrome is likely to be accurate. A positive test in a healthy cat without known risk factors is more likely to be a false positive and should be confirmed by IFA testing (FeLV) or Western blot (WB; FIV).
- PCR testing for these retroviruses is somewhat variable between labs and is not needed in most situations.

- Specific testing for other infectious diseases as needed (e.g., serologic titers, bacterial culture and sensitivity for purulent/septic processes)
- Bone marrow aspirate and biopsy if cytopenias are present or abnormal cells are circulating
- Testing of CD4 counts not readily available nor prognostic, as not all cats with low counts develop infections.
- When compared to a normal cat, microscopic examination of the shaft of a hair plucked from a cat with Chédiak-Higashi syndrome reveals large, clumped melanin granules.

TREATMENT

TREATMENT OVERVIEW

- FeLV/FIV-associated immunodeficiency:
  - Maintain good nutrition and husbandry, including core vaccinations.
  - Keep infected cats indoors for their own protection as well as to protect other cats.
  - Treat any secondary infections early and aggressively.
- Chédiak-Higashi–associated immunodeficiency:
  - Treat secondary infections as they arise; prophylactic treatment if surgery or trauma (bleeding).

ACUTE GENERAL TREATMENT

- Find and treat any secondary infections as quickly and thoroughly as possible.
- Use supportive care and nutritional support as needed.
- No value in FeLV/FIV vaccines for infected cats

CHRONIC TREATMENT

- No drug has proven efficacy in eliminating feline retroviruses.
- Anecdotal benefit has been reported for oral human α-interferon (IFN), *Propionibacterium acnes*, acemannan, *Staph* protein A, and PIND-ORF, but so far none of these has been shown to be effective either in decreasing viral replication or prolonging survival in limited controlled clinical trials.
- Recently IFN-omega improved clinical signs and 1-year survival in some cats, but another study in FIV infection showed no benefit.
- Azidothymidine (AZT) at a dose of 5 mg/ kg q 12 h SQ caused improvement in clinical signs and immune function in some cats infected with FeLV or FIV. Anemia can result from long-term use of AZT.

BEHAVIOR/EXERCISE

Immunodeficient cats should be kept indoors, away from other cats.

DRUG INTERACTIONS

Avoid corticosteroids or other immunosuppressive drugs unless absolutely needed. They may increase the risk of infections.

POSSIBLE COMPLICATIONS

- Inability to eradicate some infections
- Bone marrow failure, myelodysplasia, or hematopoietic malignancy, especially from FeLV

RECOMMENDED MONITORING

Monitor weight, since weight loss is often an early sign of complications. Also monitor appetite and activity. Once or twice yearly, CBCs might identify a problem, but healthy FeLV-infected cats generally have normal counts except for lymphopenia.

PROGNOSIS AND OUTCOME

- Previous studies showing 50% mortality for FeLV infection in 2 years and 80% in 3 years were done with multicat households where risks of secondary infections were high. For a single indoor cat, the prognosis is guarded but much better than these figures indicate.
- Many FIV-positive cats will survive for many years without developing signs of illness if they are kept indoors.

PEARLS & CONSIDERATIONS

COMMENTS

- Although FeLV and FIV cause immunosuppression, most secondary infections can be treated successfully.
- Keeping these cats indoors and separated from ill or young cats (especially cats with signs of respiratory disease, skin disease, or diarrhea) will protect them from the majority of these infections.

PREVENTION

- FeLV: test kittens at 8 weeks. If negative and from a high-risk environment, repeat in 4 weeks. Isolate FeLV-negative kittens until they are >4 months old and have some natural resistance to FeLV.
- FIV test result can be positive from maternal antibody. Kittens testing positive should be retested after 5 months of age. Young kittens are rarely actually infected with FIV.
- FIV, FeLV: vaccinate only cats at risk (outdoor cats with exposure to other cats or those in multicat households). Neutered male cats are less likely to fight with other cats.

TECHNICIAN TIPS

- Be sure to wash hands thoroughly before and after handling cats carrying retroviruses.
- Most soaps and disinfectants will kill retroviruses, so infected cats may be housed in the same room as other cats so long as cages are cleaned well after they leave.

CLIENT EDUCATION

- Explain the benefits of keeping cats indoors. Never introduce new cats without testing. Indoor cats do not need to be vaccinated against retroviruses.
- For multicat households with endemic FeLV infection, isolate or remove positive cats, vaccinate the rest, and do not bring in new cats. Retest negative cats 3 months later. Repeat until all are negative.
- Spread of virus requires carrier cats, as the virus does not survive outside the cat.

AUTHOR & EDITOR: SUSAN M. COTTER

Idiopathic Tremor Syndrome

BASIC INFORMATION

DEFINITION

- A brain disorder of unknown etiology that causes spontaneous generalized tremors and is responsive to immunosuppressive doses of corticosteroids
- *Tremor* refers to a rhythmic oscillatory involuntary movement in the body.

SYNONYMS

Corticosteroid responsive tremor syndrome; white shaker dog syndrome (a poor term, as approximately half of the dogs with idiopathic tremor syndrome do not have a white coat)

EPIDEMIOLOGY

SPECIES, AGE, SEX

The majority of dogs affected with this syndrome are young (<5 years) and of small breeds (<15 kg).

GENETICS & BREED PREDISPOSITION

White dogs, including the West Highland white terrier and Maltese, are overrepresented, although any breed may be affected.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Owners typically notice an acute onset of a fine, whole-body tremor that often worsens with exercise, stress, and excitement and lessens with rest or sleep.
- The course of the disease is nonprogressive.

PHYSICAL EXAM FINDINGS

- The most notable finding is a fine, whole-body tremor.
- Additional findings may include poor menace responses, head tilt, nystagmus, paresis, tetraparesis, ataxia, seizure activity, and an elevated rectal temperature.

ETIOLOGY AND PATHOPHYSIOLOGY

The exact etiology is unknown but may be the result of an autoimmune-mediated disruption of neurotransmitter metabolism in the central nervous system (CNS), with a decreased conversion of tyrosine to dopamine. Dopamine is an important neurotransmitter for the regulation of movement.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A clinical diagnosis generally is reached based on signalment, history, and clinical signs. Advanced tools such as MRI and CSF analysis are helpful in ruling out other causes of tremors.

DIFFERENTIAL DIAGNOSIS

- Congenital abnormal myelin formation (e.g., hypomyelination, dysmyelination)
- Toxicosis (e.g., penitrem A produced by *Penicillium* in moldy foods, hexachlorophene, and organophosphates)
- Metabolic conditions (e.g., hepatic or uremic encephalopathies)

- Cerebellar disease

INITIAL DATABASE

Basic blood work (CBC, serum chemistry panel) is typically within normal limits.

ADVANCED OR CONFIRMATORY TESTING

- Cerebrospinal fluid analysis is helpful in differentiating idiopathic tremor syndrome from other inflammatory diseases:
  - Results may include minimal to moderate nonsuppurative pleocytosis (lymphocytic, with mean white blood cell count being approximately 16 cells/mcL).
  - This is in contrast to the polymorphonuclear pleocytosis associated with mycotic and bacterial encephalitis and the mixed-cell pleocytosis seen in granulomatous meningoencephalitis and protozoal diseases.
  - The protein concentration is often high in cases of idiopathic tremor syndrome.
- MRI of the brain is typically normal.
- Histopathologic evaluation:
  - Histopathologic lesions are not seen in all dogs with idiopathic tremor syndrome.
  - Abnormalities may include diffuse, mild meningoencephalitis with mild perivascular cuffing and lymphocytic infiltrates throughout the CNS, especially in the cerebellum.

TREATMENT

TREATMENT OVERVIEW

The goal of therapy is to eliminate tremors and is achieved mainly with corticosteroids, though diazepam can also be used. If tremors return when therapy is complete, they are typically mild and associated with excitement.

ACUTE GENERAL TREATMENT

Treatment consists of immunosuppressive doses of corticosteroids (i.e., prednisone, 1–2 mg/kg PO q 12 h). Clinical signs often decrease within the first few days of treatment.

CHRONIC TREATMENT

- Once tremors are fully controlled, the dose of prednisone should be gradually decreased over 1-3 months.
- Occasionally, dogs need to be kept on low doses or alternate-day therapy to control tremors.
- Additional tremor control can be achieved with oral diazepam (0.2 mg/ kg PO q 8 h).

PROGNOSIS AND OUTCOME

Excellent

PEARLS & CONSIDERATIONS

COMMENTS

The synonym *white shaker dog syndrome* is a poor term, as approximately half of the dogs with idiopathic tremor syndrome do not have a white coat.

AUTHOR: KERRY SMITH BAILEY

EDITOR: CURTIS W. DEWEY

Icterus

BASIC INFORMATION

DEFINITION

Yellow discoloration of the skin and mucous membranes

SYNONYM

Jaundice

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dependent on underlying cause (i.e., hepatobiliary disease, hemolytic anemia). Observed in both dogs and cats of any age.

GENETICS & BREED PREDISPOSITION

For primary liver disease:

- Dogs: Doberman pinschers (inflammatory liver disease), cocker spaniels, Labrador retrievers, Skye terriers
- Cats: Abyssinian (amyloidosis), Asian breeds (feline infectious peritonitis)

For hemolytic anemia: American cocker spaniel, English springer spaniel, Old English sheepdog, Irish setter, poodle

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Hepatobiliary disease:
  - Anorexia, lethargy/weight loss
  - Vomiting/diarrhea
  - Abdominal distension
  - Cranial abdominal pain
  - Polyuria, polydipsia
  - Orange discoloration to the urine
  - Encephalopathy
- Hemolytic anemia:
  - Pallor
  - Anorexia
  - Lethargy, weakness, exercise intolerance
  - Vomiting
  - Orange discoloration to urine
  - Pigmenturia (dark red/brown) if intravascular hemolysis
  - Syncope/collapse

PHYSICAL EXAM FINDINGS

- Yellow discoloration of skin, mucous membranes (gingival, nictitans, sclera, etc.)
- Hepatobiliary disease:
  - Abdominal distention
    - Cranial abdominal organomegaly
    - Ascites
  - Dehydration
  - Halitosis
- Hemolysis:
  - Pale mucous membranes

- Sinus tachycardia, ventricular arrhythmia
- Fever
- Respiratory difficulty if pulmonary thromboembolism (PTE)

ETIOLOGY AND PATHOPHYSIOLOGY

- Prehepatic icterus: increase in production of bilirubin due to presentation of excessive amount of heme (e.g., hemolysis)
- Hepatic icterus: abnormality in hepatic bilirubin uptake, conjugation, or excretion
- Posthepatic icterus: extrahepatic biliary system obstruction (bile duct system, gallbladder)

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Icterus is the result of either hemolysis or hepatobiliary disease. Therefore, in addition to history and physical exam, a hematocrit and assessment of biochemical liver values in serum are indicated in every icteric patient. Serum bile acid levels are not routinely measured in icteric patients unless a patient has both anemia and biochemical evidence of hepatobiliary disease (normal serum bile acid concentrations are consistent with hemolysis rather than cholestasis).

DIFFERENTIAL DIAGNOSIS

- Hepatobiliary disease:
  - Inflammatory/immune-mediated/ infectious:
    - Idiopathic chronic hepatitis (dogs)
    - Cholangiohepatitis of cats (suppurative/neutrophilic)
    - Cholangiohepatitis of cats (lymphocytic)
    - Secondary to bacterial translocation from the gastrointestinal system
    - Leptospirosis (dogs)
  - Hepatic lipidosis (cats)
  - Neoplastic:
    - Lymphoma, hepatocellular carcinoma, hemangiosarcoma, biliary carcinoma, other
  - Extrahepatic obstruction:
    - Pancreatitis
    - Cholelithiasis (rare in dogs and cats)
    - Bile duct neoplasia
    - Biliary mucocele
    - Inspissated bile syndrome (cats)
  - Cholestatic drug injury:
    - Acetaminophen, azathioprine, diazepam, phenobarbital, sulfonamide, many others
  - Extrahepatic sepsis: coliform septicemia most common resulting in cholestasis:
    - Endotoxin and acute phase reactants interfere with transport of bile acids into canaliculi.
  - Anoxia: can lead to cholestasis
- Hemolytic anemia:
  - Idiopathic immune-mediated hemolytic anemia
  - Associated with other immune disorders:
    - Inflammatory bowel disease
    - Systemic lupus erythematosus
  - Infectious:
    - Ehrlichiosis, Rocky Mountain spotted fever, leptospirosis, babesiosis, hemobartonellosis *(Mycoplasma haemofelis)*
    - Viral: feline leukemia virus
    - Bacterial: any chronic infection
  - Neoplasia: lymphoma, common association; any form of neoplasia
  - Microangiopathic hemolysis: commonly associated with hemangiosarcoma, heartworm, disseminated intravascular coagulation (DIC), vasculitis
  - Drug reaction: postvaccinal, sulfonamides, many others
  - Erythrocyte membrane fragility/oxidative damage:
    - Abyssinian, Somali cats (osmotic fragility)
    - Hypophosphatemia (phosphorus <1.5 mg/dL)
    - Oxidative damage (intoxications):
      - Onions (dogs)
      - Acetaminophen (cats)
      - Zinc

- Red blood cell (RBC) enzyme deficiencies: phosphofructokinase deficiency (English springer spaniel), pyruvate kinase deficiency (Basenji and others), stomatocytosis of malamutes

INITIAL DATABASE

- CBC:
  - Evaluation of plasma in PCV tube is more sensitive for icterus (seen at bilirubin = 1–1.5 mg/dL) than mucous membranes (icterus when bilirubin >2 mg/dL).
- Serum biochemical profile:
  - Alkaline phosphatase is always elevated in cholestatic disease causing icterus.
  - Liver enzymes may be elevated secondary to hypoxemia of severe anemia.
- Urinalysis and culture
- Abdominal radiographs
- Abdominal ultrasound
- Thoracic radiographs

ADVANCED OR CONFIRMATORY TESTING

- Hepatobiliary:
  - Prothrombin time (PT)/activated partial thromboplastin time (APTT)/ platelet count
  - Liver aspirate or biopsy for histopathologic evaluation and culture
  - Amylase/lipase/pancreatic lipase immunoreactivity
  - Infectious disease titers
  - Serial blood cultures, body fluid cultures if suspect sepsis
- Hemolysis:
  - Whole blood smear (spherocytes)
  - Reticulocyte count
  - PT/APTT platelet count to rule out bleeding disorder, disseminated intravascular coagulation (DIC)
  - Antinuclear antibody test
  - Direct Coombs' test (false-negative results common)
  - Slide agglutination test
  - Direct IFA for RBC isotype-specific antibodies (IMHA)
  - Infectious disease titers/PCR (see Etiology and Pathophysiology above).
  - PCR for RBC enzyme deficiencies
  - Arterial blood gas
  - D-dimer (to rule out PTE associated with hemolytic anemia; high sensitivity, low specificity)
  - Bone marrow aspirate (evaluate for erythrophagocytosis, differentiate from myelodysplasia, pure red cell aplasia, lymphoma).
  - Fecal occult blood to differentiate hemolysis from gastrointestinal blood loss

TREATMENT

TREATMENT OVERVIEW

- Hepatobiliary disease:
  - Suppress or eliminate the disease process.
  - Manage the metabolic condition.
- Hemolysis:
  - Treat inciting cause (e.g., drug withdrawal, toxin removal).
  - Suppress immune system if indicated.
  - Treat complications such as PTE, DIC.

GENERAL TREATMENT

Because icterus is a clinical sign, not a disease entity, appropriate management depends on identification and treatment of the underlying cause.

POSSIBLE COMPLICATIONS

- PTE: very common with immune-mediated hemolytic anemia
  - Oxygen/heparinization if PTE suspected
- Persistent/worsening anemia

- RBC transfusion reactions (cross-matching important)
- Hepatic encephalopathy (see p. 501)
- Gastric ulcer (see p. 440)

PROGNOSIS AND OUTCOME

- Varies with the cause of each disease
- Extrahepatic sepsis: mortality rate usually quite high
- Hemolytic anemia:
  - Prognosis good if inciting cause can be removed
  - Idiopathic immune-mediated hemolytic anemia: 40%–70% mortality rate: prognosis worse with intravascular hemolysis

PEARLS & CONSIDERATIONS

COMMENTS

- Bilirubin concentrations are usually above 2 mg/dL to result in clinical icterus.
- The purpose of measuring serum bile acids is to assess liver function. Therefore, bile acids are an unnecessary diagnostic test in an icteric patient with a normal PCV.
- PTE diagnosis is sometimes difficult: low PaO2 on an arterial blood gas that is drawn during oxygen therapy is suggestive. High-velocity tricuspid regurgitation also suggestive if a murmur is present. D-dimer for thrombolysis: high sensitivity but poor specificity (i.e., many false-positive results for unrelated conditions).
- Portosystemic shunts do not cause icterus unless a complicating factor (e.g., other concurrent hepatopathy) also is present.
- Subtle icterus may be difficult to detect (or “icterus” may incorrectly be detected in a normal patient) when the physical examination is performed in a room illuminated with fluorescent tube lighting.
- Ultra low-dose aspirin may become a new therapeutic to replace heparin in the prevention of PTE.
- Hemolytic anemia can be associated with immune-mediated thrombocytopenia (often referred to as Evans syndrome).
- Blood transfusions can suppress the reticulocyte response.

AUTHOR: MAUREEN CARROLL

EDITOR: ETIENNE CÔTÉ

Juvenile Polyarteritis

BASIC INFORMATION

DEFINITION

Systemic necrotizing vasculitis most often reported in young beagles. The neurologic aspects of this disorder are discussed in greater detail under Steroid-Responsive Meningitis-Arteritis, .

SYNONYMS

Beagle pain syndrome, canine juvenile polyarteritis syndrome, canine pain syndrome, juvenile polyarteritis, necrotizing vasculitis, steroid-responsive meningitis-arteritis (SRMA)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Seen most often in young (<12-month-old) beagles; also affects young (8-18 months) dogs of other breeds
- No sex predilection

GENETICS & BREED PREDISPOSITION

- Colonies of research beagles
- Beagle, Bernese mountain dog, boxer overrepresented; may be inherited in the beagle
- Reported in Nova Scotia Duck Toller retriever and occasionally other breeds

RISK FACTORS

Incidence may be higher in the spring.

CONTAGION & ZOONOSIS

Neither contagious nor zoonotic

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute form (typical)
- Atypical, protracted form

HISTORY, CHIEF COMPLAINT

- Acute to gradual onset of hunched posture, guarding of the neck, reluctance to move, cervical rigidity
- Paresis may occur.
- Signs may be episodic: persist for 2-7 days and then resolve.
- After several relapses without therapy, patients may develop the protracted form with progressive worsening of neurologic dysfunction.

PHYSICAL EXAM FINDINGS

- Signs of cervical pain and rigidity with an associated hunched posture and unwillingness to move
- Generalized hyperesthesia
- Fever
- Anorexia
- Weakness
- With the atypical/protracted form, patients may have proprioceptive deficits, ataxia, paraparesis, or tetraparesis.
- Cranial nerve deficits rarely reported

- Nonspecific signs such as lethargy, malaise, and depression common

ETIOLOGY AND PATHOPHYSIOLOGY

- Systemic necrotizing vasculitis with severe subarachnoid hemorrhages throughout spinal cord and brainstem
- Intimal thickening and fibrinoid necrosis of the tunica media of small to medium-sized arteries result in occlusion and thrombosis that may cause neural ischemia and pain.
- Vessels of the cervical spinal cord leptomeninges, cranial mediastinum, and coronary arteries may be involved.
- Mechanism is believed to be immune mediated; may be triggered by an environmental factor that has yet to be identified.
- Hereditary component suspected in beagles

DIAGNOSIS

DIAGNOSTIC OVERVIEW

There are many differential diagnoses for a dog presenting with these clinical signs. Initial lab work results are nonspecific; advanced imaging helps rule out other neurologic disorders, and arthrocentesis or a cerebrospinal fluid (CSF) tap confirms the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Bacterial meningitis: rule out with CSF analysis and culture
- Granulomatous and infectious menin-goencephalomyelitis
- Polyarthritis
- Polymyositis
- Discospondylitis: rule out with diagnostic imaging.
- Cervical disk disease, disk herniation: rule out with diagnostic imaging.
- Spinal cord trauma: rule out with diagnostic imaging, history.
- Protozoal infection: rule out with muscle biopsy, serology.

INITIAL DATABASE

- CBC: mild nonregenerative anemia, leukocytosis, neutrophilia
- Serum biochemistry profile: hypoalbuminemia possible
- Urinalysis: proteinuria possible
- Thoracic, abdominal, cervical radiographs: normal findings

ADVANCED OR CONFIRMATORY TESTING

- Synovial fluid analysis: neutrophilic inflammation typical; negative culture
- CSF analysis: characteristic findings include erythrophagocytosis, neutrophilic pleocytosis, increased protein; negative culture. In protracted cases, protein content is either slightly elevated or normal with a mild to moderate mixed pleocytosis.
- Brain MRI, CT: results usually normal
- Systemic and intrathecal immunoglobulin (Ig)A levels elevated in acute and atypical/protracted forms
- Histopathologic evaluation of tissues: severe necrotizing vasculitis, perivasculitis, and thrombosis of small to medium-sized vessels in the leptomeninges of the cervical spinal cord, cranial mediastinum, coronary arteries, and other affected organs

TREATMENT

TREATMENT OVERVIEW

Signs should resolve in 24-48 hours with corticosteroid therapy as remission is induced. To avoid relapse, treatment should not be abruptly stopped or tapered too quickly.

ACUTE GENERAL TREATMENT

- Fluid therapy may be needed if patient is anorexic.
- Restrict activity.
- Prednisone/prednisolone therapy: start at 1-2 mg/kg PO, IM, or SQ q 12 h

CHRONIC TREATMENT

- Taper corticosteroids to the minimum dose that controls clinical signs (usually 0.25-0.5 mg/kg q 48 h) over 6 months.
- Azathioprine (1.5-2 mg/kg PO q 48 h) for patients who do not respond to corticosteroids

POSSIBLE COMPLICATIONS

- Gastrointestinal (GI) upset and GI ulceration/bleeding, polyuria, polydipsia, polyphagia, Cushingoid syndrome as adverse effects of corticosteroid therapy
- Infections possible, secondary to chronic immunosuppression
- Myelotoxicity and hepatic failure are possible adverse effects of azathioprine therapy.

RECOMMENDED MONITORING

- CBC, serum chemistry profile, urinalysis every 4-6 weeks to monitor for inflammation and organ dysfunction.
- Monitor for neck pain (sign of possible recurrence) and GI bleeding.
- Repeat CSF tap every 4-6 weeks at the beginning of therapy to help guide corticosteroid therapy. Once CSF is normal and clinical signs remain absent, weaning can commence.

PROGNOSIS AND OUTCOME

- Good prognosis for acute cases if treated promptly and intensively
- Disease can spontaneously resolve when patient is 12 to 18 months old.
- Prognosis more guarded with protracted cases, owing to frequent relapses
- Some patients do not respond to further therapy after relapses.
- Some patients need continuous therapy to control clinical signs.

PEARLS & CONSIDERATIONS

COMMENTS

- Early diagnosis and aggressive treatment result in the best outcome.
- Adverse effects of corticosteroid therapy may be unacceptable to some clients. Azathioprine should be used for its steroid-sparing effects in these cases.

TECHNICIAN TIPS

- No neck leads
- These pets often are painful, so be cognizant of pain management.

CLIENT EDUCATION

Although patients usually respond to therapy for the acute form, relapses can be common, and some patients require long-term or indefinite treatment to control clinical signs.

AUTHOR: KIMBERLY B. WINTERS

EDITOR: SUSAN M. COTTER

Juvenile Cellulitis

BASIC INFORMATION

DEFINITION

An uncommon vesiculopustular to granulomatous skin disease primarily affecting dogs < 4 months old. The pinnae, face, and submandibular lymph nodes are typically involved.

SYNONYMS

Juvenile sterile pyogranulomatous dermatitis and lymphadenitis, puppy strangles, juvenile pyoderma

EPIDEMIOLOGY

SPECIES, AGE, SEX

Young puppies of either sex between 3 weeks and 4 months old are typically affected, although confirmed cases in young adults have been rarely reported. One or more puppies in the same litter may be affected.

GENETICS & BREED PREDISPOSITION

Many breeds, including mixed breeds, may develop this disease, but some breeds appear predisposed (e.g., golden retrievers, dachshunds). A hereditary component is proposed. The exact mode of inheritance has not been established.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Early in the course of the disease, an affected puppy develops an acutely swollen face, in particular the muzzle, lips, and eyelids. Marked submandibular lymphadenopathy is usually present even in the absence of cutaneous lesions.

PHYSICAL EXAM FINDINGS

- Acute swelling of face noted initially.
- Within 24-48 hours, vesicles and pustules appear around mouth, eyes, and muzzle. Lesions rapidly develop into a serous to purulent exudative dermatitis with or without fistulation.
- Serous to purulent bilateral otitis externa with edematous pinnae is common.
- Marked regional (submandibular and prescapular) to diffuse lymphadenopathy is common. Submandibular lymphadenopathy may occur as only clinical abnormality.
- Fistulation of affected lymph nodes is variable.
- Affected skin is frequently painful but rarely pruritic.
- Rarely, sterile subcutaneous nodules with or without fistulation develop on the trunk, preputial, or perineal regions.
- Approximately 50% of puppies are lethargic. Anorexia, pyrexia, and lameness (sterile suppurative arthritis) are inconsistent findings.

JUVENILE CELLULITIS Typical lesions in a 9-week-old rottweiler with edematous eyelids and papules, pustules, and swelling of the muzzle.

(Courtesy Dr. J. Wellington.)

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology and pathogenesis of juvenile cellulitis are unproven; immune dysfunction is suspected.
- Bacterial invasion is not considered to be the primary cause. Any evidence of infection usually reflects secondary pyoderma.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based almost entirely on signalment, history, and physical exam, with cytologic examination of smears for support and skin scrapings to rule out demodicosis. Juvenile cellulitis should be suspected when a puppy presents with an acutely swollen face, especially the eyelids, lips, and muzzle, edematous pinnae, and submandibular lymphadenopathy. The rapid development of papules, pustules, and serous crusts on the facial and pinnal lesions further supports the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Angioedema: vaccine reaction or insect bite reaction
- Deep pyoderma/muzzle folliculitis
- Demodicosis
- Drug eruption (cutaneous drug reaction)

INITIAL DATABASE

- Impression cytologic analysis of pustule: numerous neutrophils and macrophages (pyogranulomatous inflammation) without bacteria
- Skin scrapings: negative for *Demodex* mites

ADVANCED OR CONFIRMATORY TESTING

These additional diagnostic tests may be performed but are rarely required:

- Anaerobic or aerobic bacterial culture and sensitivity: usually sterile
- Skin biopsy: multiple discrete or confluent granulomas and pyogranulomas composed of nodular clusters of large epithelioid

macrophages with variably sized neutrophilic centers
- Lymph node aspirate: pyogranulomatous lymphadenitis

TREATMENT

TREATMENT OVERVIEW

Early and intensive immunosuppressive systemic therapy with predniso(lo)ne or dexamethasone is indicated to prevent secondary scarring. Concurrent systemic antibiotics are recommended if secondary pyoderma is found cytologically or marked fistulation is present.

ACUTE GENERAL TREATMENT

- Prednisone or prednisolone (2 mg/kg PO q 24 h, or total dose can be divided q 12 h) until lesions resolve (approximately 1-4 weeks), then reduce to 2 mg/kg PO q 48 h for 2 weeks, then taper off prednisone over the next 2-3 weeks.
- Some dogs respond better to dexamethasone (0.2 mg/kg PO q 24 h). Gradually taper dosage (similar to prednisone).
- Bactericidal antibiotics for 3-4 weeks required if cytologic or clinical evidence of secondary pyoderma present.
- Warm water soaks to remove crusts and exudates; topical astringents (e.g., 2% aluminum acetate [Burow's solution] q 12 h) can be attempted.

PROGNOSIS AND OUTCOME

Prognosis is good. Scarring may be extensive in severe cases.

PEARLS & CONSIDERATIONS

COMMENTS

- Taper corticosteroids gradually (over a few weeks) to reduce the risk of relapse.
- Adult dogs and dogs with panniculitis (subcutaneous nodules) require a longer treatment interval.
- If relapse occurs, restart immunosuppressive dosage of corticosteroid immediately.
- Avoid routine vaccinations during therapy.

EDITOR: MANON PARADIS

Keratoconjunctivitis Sicca

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A common inflammatory condition of the cornea and conjunctiva secondary to a deficiency in the aqueous portion of the tear film

SYNONYMS

KCS, dry eye, quantitative tear film abnormality, xerophthalmia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Common in dogs; rare in cats
- Age of onset variable depending on underlying cause
- Increased predisposition reported for both castrated male and spayed female dogs and female West Highland white terrier

GENETICS & BREED PREDISPOSITION

Predisposed breeds (dogs): English bulldog, West Highland white terrier, Lhasa Apso, pug, American cocker spaniel, Pekingese, Yorkshire terrier, shih tzu, miniature schnauzer, Boston terrier, dachshund, Chihuahua, German shepherd, Doberman pinscher

RISK FACTORS

- Medications, metabolic disorders, and infectious diseases (see Etiology and Pathophysiology below)
- Removal of gland of the third eyelid
- Systemic immune-mediated disease (e.g., systemic lupus erythematosus [see p. 1070])

CONTAGION & ZOONOSIS

Infectious causes (e.g., canine distemper; feline herpesvirus 1 [FHV-1]) are contagious.

ASSOCIATED CONDITIONS & DISORDERS

Conjunctivitis and ulcerative and nonulcerative keratitis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- “Red” eye (p. 967)
- Ocular pain
- Mucoid to mucopurulent ocular discharge

PHYSICAL EXAM FINDINGS

- Systemic: generally unremarkable
- Ophthalmic:
  - Mucoid to mucopurulent ocular discharge
  - Conjunctival hyperemia and chemosis
  - Blepharospasm
  - Protrusion of the third eyelid
  - Dry/lackluster corneal appearance
  - Signs of keratitis with chronicity:
    - Corneal vascularization (see p. 254)
    - Corneal pigmentation (see p. 246)

        - Corneal ulceration (see p. 250)
    - Blepharitis
    - Periocular dermatitis secondary to exudates and/or self-trauma
    - Vision impairment with chronic disease
- Cats often show fewer clinical signs than dogs.

ETIOLOGY AND PATHOPHYSIOLOGY

- Immune-mediated adenitis: most common (dogs)
- Congenital: lacrimal gland hypoplasia or aplasia
- Drug-induced: general or topical anesthesia and atropine (transient KCS)
- Drug toxicity: some systemic medications (e.g., sulfonamide therapy; phenazopyridine; 5-aminosalicylic acid; etodolac) may cause transient or permanent KCS.
- Iatrogenic: removal of the gland of the third eyelid increases risk of developing KCS, especially in predisposed breeds.
- Infectious disease (e.g., canine distemper [see p. 317], FHV-1 [see p. 524])
- Metabolic disease (e.g., hypothyroidism [see p. 588], hyperadrenocorticism [see p. 548], diabetes mellitus [see p. 297])
- Neurogenic: may occur with facial nerve paralysis and denervation of parasympathetic fibers innervating the gland, or following ocular proptosis (see p. 918)
- Chronic blepharoconjunctivitis due to obstruction of lacrimal ductules secondary to chemosis or ascending infection into lacrimal gland
- Chronic conjunctivitis (e.g., FHV-1; see p. 524)
- Irradiation: when primary beam near or on periocular region

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the presence of conjunctivitis or ulcerative and/or nonulcerative keratitis; the confirmatory test of choice is the Schirmer tear test (STT).

DIFFERENTIAL DIAGNOSIS

- Dogs, other causes of keratoconjunctivitis:
    - Conjunctivitis (see p. 239)
    - Corneal vascularization (see p. 254) or pigmentation (see p. 246)
    - Corneal exposure (e.g., lagophthalmos); common cause of misdiagnosis of “KCS”
    - Corneal ulceration (see p. 250)
    - Blepharitis
- Cats, other causes of keratoconjunctivitis:
    - FHV-1 conjunctivitis/keratitis
    - Proliferative (eosinophilic) keratoconjunctivitis

INITIAL DATABASE

Complete ophthalmic examination, including:

- Schirmer tear test (STT)
    - Normal: ≥15 mm/min in dogs; variable in cats
    - Early or subclinical KCS: 11-14 mm/ min
    - Mild to moderate KCS: 6-10 mm/ min
    - Severe KCS: ≤5 mm/min
- Fluorescein dye application: secondary corneal ulceration is common.
- Intraocular pressure (IOP): normal IOP values; normal IOPs range from 15-25 mm Hg (dogs and cats).

ADVANCED OR CONFIRMATORY TESTING

- Other quantitative test:
    - Phenol red-thread tear test:
        - Dogs: normal 34.15 ± 4.45 mm/15 sec
        - Cats: normal 23.04 ± 2.23 mm/15 sec

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to stimulate tear production, stabilize the tear film, and eliminate ocular pain by controlling ocular inflammation (conjunctivitis and nonulcerative keratitis), secondary bacterial infections, and corneal ulceration (see p. 250) if present.

ACUTE GENERAL TREATMENT

- Lacrimostimulants:
  - Cyclosporine-A (CsA) 0.2% ointment or 0.5%-2% solution q 8-12 h.
- Lacrimomimetics (tear substitutes and stabilizers) q 4-6 h (e.g., hyaluronic acid 0.4%)
- Antimicrobials if secondary bacterial conjunctivitis and/or corneal ulceration:
  - Topical broad-spectrum antibiotic (e.g., bacitracin-neomycin-polymyxin antibiotic solution q 6-8 h)
- Antiinflammatories if severe conjunctivitis and/or corneal vascularization/ pigmentation:
  - Dexamethasone, 0.1% solution q 6-8 h if corneal ulceration is absent

CHRONIC TREATMENT

Lacrimostimulants:

- CsA 0.2% ointment or 0.5%-2% solution q 8-24 h (typically q 12 h)
  - For STT values that remain 10 mm/ min after 3-4 weeks of treatment, CsA may be increased to q 8 h.
  - CsA should not be decreased until STT values are ≥20 mm/min.
  - CsA may be decreased to q 24 h if favorable response occurs.
- Tacrolimus 0.02%-0.03% ointment or aqueous suspension q 12 h
  - Used if no response to CsA after 3-6 weeks of treatment
  - Studies evaluating long-term safety have not been performed.
- Some ophthalmologists advocate increasing the concentration of the lacrimostimulant if there is no response (i.e., 0.2% CsA ointment to 2% CsA solution).
- Pilocarpine: 1 drop 2% pilocarpine/10 kg body weight on food q 12 h, gradually increasing by 1-drop increments until increased tearing or systemic side effects (e.g., vomiting, diarrhea, anorexia, salivation, bradycardia); primarily effective in neurogenic KCS
- Consider parotid duct transposition if no response to lacrimostimulants.

POSSIBLE COMPLICATIONS

- Corneal ulceration
- Vision impairment from progressive corneal vascularization/pigmentation (uncontrolled KCS)

RECOMMENDED MONITORING

- Variable depending on underlying cause
- Complete ophthalmic examination with STT and corneal fluorescein staining performed every 3-4 weeks initially
- Rechecks performed every 4-6 weeks until KCS controlled, then every 3-4 months

PROGNOSIS AND OUTCOME

Variable depending on underlying cause

PEARLS & CONSIDERATIONS

COMMENTS

- Immune-mediated KCS usually requires lifelong treatment.
- Some forms of KCS may require transient treatment until tear production returns (e.g., topical atropine, topical or general anesthesia).
- May take weeks to months of therapy before determining if favorable response to lacrimostimulants

PREVENTION

Breeds predisposed to KCS: avoid breeding affected or closely related dogs.

CLIENT EDUCATION

Immune-mediated KCS is a chronic disorder that is manageable but not curable; usually requires lifelong treatment.

AUTHOR: PHILLIP A. MOORE

EDITOR: CHERYL L. CULLEN

Lymphoma, Gastrointestinal

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Gastrointestinal (GI) lymphomas (LSA) are malignant tumors of lymphoid cell origin that can arise at any location within the gastrointestinal tract, including the stomach, small intestine, colon and rectum. Lesions may be of B-, T-, or large granular lymphocyte subtype, a distinction that is important prognostically.

SYNONYMS

Alimentary lymphoma, alimentary lymphosarcoma, gut-associated lymphoid tissue (GALT) lymphoma, large granular lymphocyte lymphoma, mucosal associated lymphoid tissue (MALT) lymphoma, neoplasm of globule leukocytes

EPIDEMIOLOGY

SPECIES, AGE, SEX: GI LSA is the second most common form of lymphoid malignancy in dogs (after multicentric lymphoma), accounting for 5%-7% of all LSA.

- Dogs with gastrointestinal lymphosarcoma are middle-aged to older (mean 7.7 years in one study).
- In the cat, the alimentary form of LSA is currently the most prevalent anatomic form, since feline leukemia virus (FeLV) infection as a cause of mediastinal and multicentric LSA in young cats has been largely curtailed by FeLV vaccination and management strategies.
    - Cats with GI LSA are typically older (7-10 years), although the disorder can occur in much older and also younger cats.
- No sex predisposition is noted in dogs or cats.

GENETICS & BREED PREDISPOSITION

- Dog breeds predisposed include boxers, shar-peis, golden retrievers, springer spaniels, Doberman pinschers, Labrador retrievers, and German shepherds.

RISK FACTORS: Etiology of most cases of alimentary LSA is unknown.

- Chronic inflammatory bowel disease is a predisposing factor.
- Epidemiologic studies implicate exposure to phenoxy herbicides (2,4-D) and environmental cigarette smoke in lymphoma genesis.
- *Helicobacter pylori* infection is implicated in human GI LSA, but that association has not been established in veterinary medicine.
- Underlying immune disorders may predispose.

CONTAGION AND ZOONOSIS: No infectious or zoonotic cause is known in dogs. In cats, retroviral infection with FeLV and/or FIV is rarely found associated with GI lymphoma genesis.

ASSOCIATED CONDITIONS & DISORDERS

- Anemia and panhypoproteinemia may occur secondary to chronic GI blood loss.
- Hypercalcemia may be associated with canine GI LSA but is rare in cats.
- LSA metastatic to the liver may be associated with elevated liver enzymes and biliary obstructive disorders.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Lymphoma of the gastrointestinal tract may be of B-, T-, or large granular lymphocyte (LGL) type. LGL lymphomas are typically of T-cell origin, although they can represent a null cell phenotype of natural killer (NK) cells.
- Lesions may be focal masses or diffusely infiltrative throughout the gut.
- Lesions may be submucosal, epitheliotropic, or transmural.

- GI LSA may be a low-grade disease of cellular accumulation due to impaired apoptosis, as in human MALT lymphoma, or may be high-grade with rapid cell replication.

HISTORY, CHIEF COMPLAINT: GI LSA is associated with gastrointestinal signs including:

- Evidence of malassimilation such as weight loss
- Anorexia
- Vomiting and diarrhea
- Melena, hematemesis, hematochezia

PHYSICAL EXAM FINDINGS

- On physical exam, these animals typically are thin and ill-kempt, especially cats.
- Signs of anemia (lethargy or weakness, hyperpnea, tachycardia) or hypercalcemia (muscle tremors) may be evident.
- Palpable abdominal masses and intraabdominal lymphadenomegaly may be noted.
- Hepatosplenomegaly may be present.
- In cases of diffuse intestinal infiltration, turgid, thickened intestinal walls may be palpated.
- Physical examination may be within normal limits.

ETIOLOGY AND PATHOPHYSIOLOGY

Most lymphomas are thought to arise secondary to abnormal somatic cell DNA recombination events, which may be random or may be induced by retroviral infection, environmental carcinogen exposure, or chronic infection/inflammation that increases lymphoid cell population expansion.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in a patient with persistent vomiting, diarrhea, systemic signs such as weight loss, or some combination thereof. Increased suspicion arises when abdominal ultrasound reveals thickening of the gastric or intestinal wall. Confirmation requires a biopsy; endoscopic samples are less invasive but may be insufficient; full-thickness samples are the gold standard but require laparoscopy or laparotomy. Interpretation of histologic features in some cases is difficult and may require advanced staining or other techniques, with some samples remaining permanently ambiguous.

DIFFERENTIAL DIAGNOSIS

Depending on the form and location of the LSA lesion(s):

- Inflammatory bowel disease
- Chronic endoparasitism
- GI foreign body or intussusception
- Chronic pancreatitis (especially cats)
- Other causes of liver disease such as hepatitis, cholangiohepatitis, toxic hepatopathy, or feline hepatic lipidosis
- Benign GI disease such as gastric ulcer, polyp, or adenoma
- Other GI tumors including mast cell disease, adenocarcinoma, and mesenchymal tumors
- Granulomatous bowel disease secondary to bacterial (i.e., mycobacterium) or fungal infection (i.e., histoplasmosis)

INITIAL DATABASE

- Minimum database: CBC, serum chemistry panel, urinalysis, fecal examination for parasites, *Giardia* antigen test, thyroid assay in cats, FeLV/feline immunodeficiency virus (FIV) testing in cats
- Evaluation for chronic pancreatic or GI disease (trypsinlike immunoreactivity [TLI], cobalamin/folate, or pancreatic lipase immunoreactivity [PLI])
- Three-view thoracic radiographs
- Abdominal ultrasonography with guided fine-needle aspiration cytologic analysis
    - Normal thickness (dog, cat) <5 mm
    - Any layer may be thickened, thickening may be focal or diffuse (diffuse more common), and mesenteric lymph node enlargement is common but not specific to lymphoma. Intestinal mural layering is commonly preserved.

ADVANCED OR CONFIRMATORY TESTING

- Endoscopy for biopsy of gastric, duodenal, or colorectal lesions
- Diagnosis is made histologically on endoscopic or full-thickness surgical biopsies of affected tissues (gut, lymph nodes, etc.).
- Tumor staging for extent of systemic involvement:
  - Radiographs and ultrasound as described previously
  - Bone marrow evaluation for staging and/or as indicated by cytopenias
  - Peripheral node aspiration or biopsy for staging and/or as indicated for lymphadenomegaly
- Immunohistochemical phenotyping for B-, T-, or LGL subtypes:
  - CD3 for T-cell subset
  - CD79a or CD20 for B-cell disease
  - CD3 and CD57 for LGL subtype
  - PCR for monoclonality by B-cell (IG gene rearrangement) or T-cell (T-cell receptor gene rearrangement) clonal expansion rather than polyclonal lesions seen in lymphoplasmacytic enteritis

TREATMENT

TREATMENT OVERVIEW

- Focal GI LSA lesions can be surgically cured by excision with complete margins, when neoplastic cells have not yet disseminated.
- It is extremely unlikely that dogs and cats with diffuse, nodal, or visceral organ involvement will be cured.
- For most cases, the goal is to prolong life with good quality while avoiding adverse effects to therapy.

ACUTE GENERAL TREATMENT

General supportive care includes:

- Rehydration and restoring electrolyte homeostasis
- Managing anemia with transfusions and hematinics as indicated by clinical condition
- Antibiotic and emergency management for peritonitis
- Analgesic management as indicated for pain in obstructive lesions or peritonitis
- Promotility agents are contraindicated in obstructive disease.
- Management of hypercalcemia of malignancy by IV fluid and furosemide (1-2 mg/kg IV or PO q 12-24 h) diuresis, possibly calcitonin (4-8 IU/kg IV, IM, or SQ q 12 h) acutely. Management of hypercalcemia by treating the underlying malignancy should be started (corticosteroids, chemotherapy) only *after* the cytologic or histopathologic diagnosis of GI LSA is established, as treatment with corticosteroids or other lympholytic agents can compromise detection of lymphoma lesions.

CHRONIC TREATMENT

- Curative therapy for focal GI LSA lesions is through complete surgical excision.
- Because of the high likelihood of systemic or local spread, these animals are followed with a course of lymphoma chemotherapy.
- Low-intensity radiation therapy may be palliative for refractory GI LSA.
- Chemotherapy is generally the treatment of choice for GI LSA.
- A number of chemotherapy protocols (see pp. 674 and 673) have been used to treat GI LSA, which include:
  - For high-grade disease, the University of Madison-Wisconsin protocol involves:
    - Rotating sequential treatment with vincristine, L-asparaginase, prednisone, cyclophosphamide, doxorubicin over 25 weeks
    - A concurrent combination form of this multidrug protocol called COPLA is less dose intense, and thus has lower adverse effects for metabolically compromised patients.
    - CHOP therapy (cyclophosphamide, doxorubicin, vincristine, prednisone) may also be effective.
    - Single-agent doxorubicin, mitoxantrone, ifosfamide, or CCNU and combination therapy with doxorubicin/dacarbazine have been used as rescue agents for refractory or relapsed disease, with limited success.
  - For low-grade disease, treatment with milder chemotherapy protocols may be helpful in prolonging life with good quality. Low-grade protocols include:
    - Chlorambucil and prednisolone
    - COP (cyclophosphamide, vincristine, and prednisone)

POSSIBLE COMPLICATIONS

- Surgical wound dehiscence with secondary peritonitis, pneumoperitoneum
- Chemotherapy-induced leukopenia might predispose to infection.

- Chemotherapy-induced thrombocytopenia might increase tumor hemorrhage.
- Chemotherapy might result in perforation of transmural lesions.

RECOMMENDED MONITORING

- Ultrasonography is most sensitive for detecting intraabdominal metastasis or recurrence and may identify small amounts of peritoneal fluid as the first manifestation of peritonitis in cases of bowel rupture.
- Periodic restaging (physical examination monthly, laboratory evaluation, thoracic radiographs, abdominal ultrasound examination every other month) for patients in complete remission after surgical excision or completion of dose-intense therapy with CHOP or University of Wisconsin, Madison protocol.

PROGNOSIS AND OUTCOME

- GI LSA is a serious, life-threatening illness, but because of the widely differing biological behaviors of various subtypes, predicting therapeutic response and duration of survival is difficult for individual cases.
- In general, low-grade disease is indolent and associated with longer survival than high-grade disease, depending on extent of disease at the time of diagnosis.
- T-cell phenotype is generally less responsive and associated with shorter survival duration than B-cell disease. Historically, median survivals for extra-nodal T-cell lymphomas were typically 6 months or less.
- Treatment efficacy remains variable, with reports of median remission times of 3 months or 12 months, depending on the study. Failure to achieve remission, and diarrhea at presentation, appear to be negative prognostic indicators.
- Anatomic location may have prognostic significance in dogs: colonic lymphoma is associated with a better prognosis than gastric or jejunal lymphoma.
- Cats with low-grade GI LSA requiring minimal therapy may survive for years.

PEARLS & CONSIDERATIONS

COMMENTS

- Full-thickness surgical biopsies may be necessary to establish a diagnosis of small-intestinal LSA, as endoscopic access is limited to the duodenum or ileum. Fine-needle aspiration cytology of intestinal wall is possible, but low-grade LSA is difficult to differentiate from reactive lymphocyte expansion.
- In general, the underlying cause of refractory diarrhea should be pursued aggressively, as GI LSA is an important differential diagnosis.
- Treatment with corticosteroids may impede the accurate diagnosis of LSA, as lymphoblasts will be rapidly lysed.

PREVENTION

- Aggressive management of lymphoplasmacytic enteritis is recommended, as some of these inflammatory bowel disease patients will progress to develop GI LSA.
- Managing endoparasitism and food allergies is theoretically important, but proof of benefit has not been established.
- Limiting exposure to lawn and agricultural chemicals and second-hand smoke is likely beneficial, but beyond these theoretical benefits, no specific preventive measures are known.

AUTHOR: BARBARA E. KITCHELL

EDITOR: DEBRA L. ZORAN

Lymphoma, Dog (Multicentric)

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Well-recognized systemic malignant neoplasm of lymphoid origin

SYNONYMS

Lymphosarcoma, malignant lymphoma. non-Hodgkin's lymphoma (human)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Lymphoma is the most common hematopoietic malignancy in dogs, with a reported incidence of 24-114 cases per 100,000 dogs.
- Affected dogs are typically middle-aged to older, although lymphoma may develop at any age.
- No gender predisposition

GENETICS & BREED PREDISPOSITION

- Several breeds are reported to be at increased risk, including golden retrievers, boxers, Rottweilers, Scottish terriers, basset hounds, cocker spaniels, German shepherds, Airedales, bulldogs, and poodles, and certain breeds (e.g., boxers) may be more likely to develop T-cell lymphoma.
- Genetic predisposition reported for a pedigree of bull mastiffs and for a family of rottweilers and otter hounds

RISK FACTORS

- Reported association between herbicide use, particularly 2,4-D, and lymphoma, although a subsequent study failed to confirm this relationship.
- Reported positive association with electromagnetic radiation exposure
- Residing in industrial areas and use of chemicals by the owners, specifically paints or solvents, are reported to increase risk of lymphoma in dogs by 8.5- and 4.6-fold, respectively.

ASSOCIATED CONDITIONS & DISORDERS: Hypercalcemia secondary to elaboration of parathormonerelated protein (PTH-rP) by tumor cells.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Histologic grade:
  - High-grade, or lymphoblastic, lymphoma: most common; rapid onset and progression; affected cells are large and blastic in appearance.
  - Low-grade, or lymphocytic, lymphoma: rare; chronic insidious onset; affected cells are well differentiated and similar in appearance to small lymphocytes.
- Stage: see table

HISTORY, CHIEF COMPLAINT

- Most typical presentation is generalized lymphadenopathy
- Owners usually report rapid increases in lymph node size over days to a few short weeks.
- Lymph nodes are generally nonpainful and dogs usually appear otherwise healthy in the early stages of disease.
- Some patients present for evaluation of nonspecific signs such as anorexia, weight loss, vomiting, diarrhea, dyspnea, and fever.

PHYSICAL EXAM FINDINGS

- Marked generalized lymphadenopathy is the most common physical exam finding, although occasionally dogs will present with only single lymph node or regional lymph node enlargement or single organ (e.g., spleen, GI, thymus) involvement with or without regional lymph node enlargement.
- Hepatosplenomegaly may be noted in dogs with visceral involvement.
- Other physical exam findings, including dyspnea, fever, and neurologic signs, may be reflective of other organ involvement.

ETIOLOGY AND PATHOPHYSIOLOGY

- Rapid onset and disease progression
- If untreated, most dogs succumb to disease within 1 to 2 months.

Lymphoma Staging

Stage	Characteristics
I	Single lymph node
II	Multiple regional lymph nodes
III	Generalized lymphadenopathy
IV	Hepatic and/or splenic involvement (± stages I-III)
V	Involvement of bone marrow, blood, and/or any nonlymphoid organ (±stages I-IV)
Substage a	No overt clinical signs of disease
Substage b	Overt clinical signs of disease are present.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the presence of marked generalized lymphadenopathy with minimal to no associated clinical signs in an otherwise healthy middle-aged to older dog; confirmation begins with aspiration cytologic analysis of an affected lymph node.

DIFFERENTIAL DIAGNOSIS

- Infectious diseases (e.g., Rocky Mountain spotted fever, ehrlichiosis, leptospirosis, bartonellosis)
- Sepsis
- Pyoderma causing lymphadenopathy
- Other neoplasms (e.g., leukemia, disseminated histiocytocytic sarcoma)

INITIAL DATABASE

- CBC: to identify anemia, thrombocytopenia (due to lymphoblast infiltration in the marrow or secondary to immune-mediated destruction), neutropenia, or the presence of circulating lymphoblasts (= leukemia)
- Serum biochemistry panel: to identify paraneoplastic hypercalcemia; to identify liver or renal value abnormalities which suggest organ involvement and may alter ability to metabolize chemotherapeutic agents
- Urinalysis ± urine culture and sensitivity: to identify urinary tract infections as may be present secondary to immunocompromise; to identify isosthenuria which, if associated with azotemia, suggests kidney disease (e.g., hypercalcemia-induced)
- Lymph node (or affected organ) aspiration cytology: may provide a definitive diagnosis of lymphoma

ADVANCED OR CONFIRMATORY TESTING

- If lymphoma is identified cytologically, the following tests are indicated as part of routine staging in all cases of lymphoma, prior to initiation of chemotherapy:
  - Lymph node biopsy: for definitive diagnosis, histologic grading, and possibly for immunophenotyping
  - Thoracic radiographs: to identify lymphadenopathy, cranial mediastinal mass, pulmonary involvement
  - Abdominal ultrasound exam: to identify changes consistent with hepatic or splenic involvement, lymphadenopathy, or other sites of lymphoma
  - Bone marrow aspiration cytology: to identify marrow involvement and/or develop better understanding of etiology of

any cytopenias
    - Phenotyping (flow cytometry, immunocytochemistry, immunohistochemistry, PCR): to determine B-cell versus T-cell origin (prognosis worse with T-cell)
- If financial restrictions prohibit these tests, one may elect to omit certain tests (e.g., if CBC results are unremarkable, one may elect not to perform a bone marrow aspirate), as long as the client understands that sites of disease may be missed, and staging will be less certain.

TREATMENT 

TREATMENT OVERVIEW

Treatment involves the administration of chemotherapy to promote rapid and complete remission (CR) of the cancer while maintaining an excellent quality of life for the patient. Special drug-handling requirements and potentially severe or life-threatening adverse patient effects exist with many of chemotherapeutics; these concerns and rapid evolution of protocols warrant consultation with/ referral to an oncologist.

ACUTE AND CHRONIC TREATMENT

- Reports on single-agent chemotherapy including prednisone, L-asparaginase, cyclophosphamide, and doxorubicin describe response rates ranging from 20%-80%, with remission durations of approximately 1-6 months. While prednisone may be used as a single agent, its use prior to the initiation of other chemotherapy should be avoided, since this may decrease response rate and duration to other agents.
    - Prednisone: (30-40 mg/m^2 PO q 24 h, usually for 2 weeks, then continued at 20-40 mg/m^2 q24-48 h as long as a clinical response is seen); approximately 50% of dogs achieve a complete or partial remission for duration of 2-3 months
    - Doxorubicin: (30 mg/m^2 IV q 21 days as long as a clinical response is seen and to a recommended maximum cumulative dosage of 180 mg/ m^2) 50%-75% complete remission rate for 4-6 months
- Improved remission rates and duration are achieved with combination chemotherapy. Numerous protocols are reported with variations in scheduling, drug dosages, and dose intensity, although most utilize induction followed by maintenance chemotherapy. The most commonly used agents in these protocols include prednisone, L-asparaginase, vincristine, cyclophosphamide, and doxorubicin, although recent studies suggest that while associated with low risk of complications, the inclusion of L-asparaginase in the initial protocol does not significantly impact outcome. Complete response rates range from approximately 65%-90%, with remission durations of approximately 6-11 months (see p. 674). Options may include one of the following:
    - COP (see p. 674): 70%-75% complete remission rate for median duration of 3-6 months; *or*
    - CHOP (see pp. 673, 674): 80% complete remission rate for a median duration of 9-10 months; *or*
    - AMC protocol: 77% complete remission rate for median duration of 9 months; *or*
    - UMW protocol (see online chapter: Lymphoma Chemotherapy Treatment Tables, Dog): 84% complete remission rate for median duration of 8 months; *or*
    - ACOPA1: 76% complete remission rate for median duration of 11 months; *or*
    - ACOPA2: 65% complete remission rate for median duration of 9 months; *or*
    - VELCAP-L (see online chapter: Lymphoma Chemotherapy Treatment Tables, Dog): 69% complete remission rate for median duration of 13 months
- Recent studies suggest that discontinuous chemotherapy protocols provide remission duration that is comparable to more traditional protocols relying on induction followed by maintenance chemotherapy.
    - VELCAP-S (see online chapter: Lymphoma Chemotherapy Treatment Tables, Dog): 68% complete remission rate for median duration of 10 months
    - Modified UMW protocol: 92% complete remission rate for duration of 9 months
    - 12-week combination chemotherapy protocol: 76% complete remission rate for median duration of 8 months
    - Chemotherapy remains standard therapy; however, its use in combination with other treatment modalities, such as radiation therapy or bone marrow transplantation, may improve remission duration. Early results suggest that half-body radiation therapy (HBRT) after induction chemotherapy is well tolerated and may increase remission duration compared to conventional protocols utilizing chemotherapy alone, although a more recent study with a shorter induction chemotherapy phase failed to confirm this. Bone marrow transplantation (BMT) after induction chemotherapy may also improve outcome and approximately 25%-30% of treated dogs become long-term survivors with remission durations of 7-22 months.
    - NCACTP protocol (11-week combination chemotherapy followed by HBRT)): 78% complete remission rate for median duration of 16 months
    - 8-week combination chemotherapy followed by HBRT: *66%* complete remission rate for median duration of 8 months
- Low-grade lymphoma: given the chronic indolent course of low-grade lymphoma, oral chemotherapy consisting of chlorambucil (6-8 mg/m^2 PO q 48 h as long as clinical response is seen) and prednisone (20-40 mg/m^2 PO q 24-48 h as long as clinical response is seen) may be more appropriate than intensive injectable chemotherapy for this group of dogs.

- When a patient relapses and no longer responds to front-line chemotherapy, rescue chemotherapy can be considered. Complete response rates for relapsed lymphoma are generally lower, ranging from approximately 30%-50%, with remission durations of approximately 2-4 months (see p. 674). Options may include one of the following:
  - MOPP (Mustargen, vincristine, procarbazine, prednisone): 31% complete remission rate and 34% partial remission rate for median duration of 2 months; *or*
  - MPP (Mustargen, procarbazine, prednisone): 17% complete remission rate and 17% partial remission rate for median duration of 7.9 and 1.8 months, respectively; *or*
  - DMAC (dexamethasone, melphalan, actinomycin-D, cytosine arabinoside): 44% complete remission rate and 28% partial remission rate for median duration of 4 and 2 months, respectively; *or*
  - Doxorubicin/DTIC: 35%-80% complete remission rate for median duration of 3 months; *or*
  - L-asparaginase/CCNU/prednisone: 52% complete remission rate and 35% partial remission rate for 4 and 1.4 months, respectively; *or*
  - CCNU: 25% complete and partial remission rate for median duration of 3 months

NUTRITION/DIET

Dogs with lymphoma have alterations in carbohydrate, protein, and lipid metabolism and may benefit from a low-carbohydrate/moderate-quantity high-quality protein diet. Supplementation with poly-unsaturated fatty acids may also be of benefit.

Body Weight–to–Body Surface Area (BSA) Correlation for Dogs

Weight, kg *(lb)*	BSA (m^2)

POSSIBLE COMPLICATIONS OF TREATMENT

- Systemic chemotherapy targets rapidly dividing cells. Due to their rapid and often abnormal division and defective repair mechanisms, tumor cells can be destroyed by chemotherapy.
- Some normal tissues have a high rate of cell turnover (gastrointestinal mucosa, bone marrow, hair) and may be sensitive to chemotherapy, although unlike cancer cells, these normal tissues are able to repair chemotherapy-induced damage. Potential side effects of chemotherapy include gastrointestinal upset 2-4 days following treatment, myelosuppression 7-10 days after treatment, and hair loss in breeds with continuously growing haircoats (e.g., poodle, Lhasa apso, Old English sheepdog, many terrier breeds; see pp. 188 and p. 706).
- All chemotherapeutic agents are potentially toxic, most are mutagenic or teratogenic, and at least some are proven

carcinogens. Safe handling requires the use of a vertical flow hood and closed-system drug transfer device.

RECOMMENDED MONITORING

- Regular monitoring of remission status
  - CR: disappearance of all clinical evidence of cancer
  - PR: decrease in volume of cancer by ≥50% without decrease to completely normal size
  - Stable disease (SD): decrease in volume of cancer by <50% or increase in volume of cancer by <25%
  - Progressive disease (PD): increase in cancer volume by ≥25% or appearance of new lesions
- CBC (including differential) monitoring after administration of chemotherapy

PROGNOSIS AND OUTCOME

Several prognostic factors have been identified that may help predict an individual's response to treatment:

- Gender (females better than males)
- Weight (small dogs better than large dogs, although possibly influenced by dosing regimen)
- Histologic grade (high-grade lymphoma has a better complete remission rate than low-grade, although low-grade is often associated with comparable survival times with less intensive chemotherapy due to its chronic indolent nature).
- Stage and substage (I, II, or III better than IV or V; *a* better than *b)*
- Phenotype (B-cell better than T-cell)
- Hypercalcemia (a negative prognostic indicator, likely because of its association with T-cell phenotype)
- Presence of a mediastinal mass (a negative prognostic indicator, likely because of its association with T-cell phenotype)
- Administration of prior prednisone (negative prognostic indicator, possibly because of induction of multidrug resistance or masking of higher-stage disease)
- Other factors conferring a more negative prognosis: AgNOR staining, chromosomal aberrations, older age, anorexia, anemia, fever, dyspnea, thrombocytopenia, hypoalbuminemia, and chronic inflammatory disease

PEARLS & CONSIDERATIONS

COMMENTS

- Lymphoma is a common canine malignancy.
- The majority of dogs with lymphoma achieve complete remission when treated with chemotherapy, and treatment can be very rewarding for both the pet owner and veterinarian.
- A variety of prognostic factors have been identified that may help predict an individual's response to treatment and guide the decision whether or not to pursue treatment.
- An understanding of the relative efficacy and potential toxicoses of the various protocols aids in determining the best treatment protocol for an individual animal.
- Differentiation of cell type (phenotype) is mainly prognostic. B-cell lymphoma carries a more favorable prognosis than T-cell lymphoma (“B is better”), and B-cell lymphoma makes up the majority of cases of lymphoma in dogs.

Lymphoma, Central Nervous System

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Lymphoma is a systemic malignant neoplasm of lymphoid origin. Central nervous system (CNS) lymphoma can be primary, occurring only within the CNS; or secondary, as part of multicentric disease.

SYNONYMS

Lymphosarcoma, malignant lymphoma, non-Hodgkin's lymphoma (human)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- In dogs, lymphoma is the most common hematopoietic malignancy, but involvement of the CNS is uncommon. There is no breed, age, or gender predilection.
  - Lymphoma accounts for <5% of all primary CNS tumors and <10% of all CNS tumors (primary and secondary) in dogs.
- In cats, lymphoma is the most common hematopoietic malignancy, and CNS involvement is reported in 5%-10% of affected cats.
  - Lymphoma accounts for about 15% of all brain tumors and 50% of all nonosseous tumors affecting the spinal cord in cats.
  - There is no breed or gender predilection. Cats of any age can be affected; those infected with FeLV tend to be <5 years old.

RISK FACTORS

- Feline leukemia virus (FeLV)
  - The relative risk of lymphoma in FeLV-seropositive cats is 60 times that of FeLV-seronegative cats.
  - Initial studies indicated that 90% of cats with spinal lymphoma are FeLV seropositive, but as the overall incidence of FeLV-associated lymphoma has decreased (see p. 669) more recent studies report only 55% testing positive.
  - Less than 20% of cats with brain involvement are FeLV seropositive.
- Feline immunodeficiency virus (FIV)
  - The relative risk of lymphoma in cats infected with FIV is five times that of noninfected cats.
  - FIV has been reported in association with CNS lymphoma, but many cats are not tested, and the true contribution of FIV is not known.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- CNS lymphoma can be primary or secondary (see Definition).
  - In dogs, CNS lymphoma is primary in 20% of affected patients and secondary in 80%.
    - Common sites affected concurrently include lymph nodes, liver, spleen, and bone marrow.
    - Up to half of dogs with secondary CNS lymphoma do not have neurologic signs at initial diagnosis; neurologic signs instead develop when the cancer relapses.
  - In cats, up to 30% of brain lymphomas are primary, but only 15% of spinal lymphomas are primary.
    - When CNS lymphoma is secondary, common sites affected concurrently include the kidneys, bone marrow (with or without circulating lymphoblasts), liver, spleen, and mesenteric lymph nodes.
    - Most cats present with neurologic signs at initial diagnosis, but up to 50% of cats with renal lymphoma relapse with CNS involvement.
- CNS lymphoma can be categorized based on anatomic site.
  - Intracranial disease usually affects the forebrain (cerebrum and diencephalon), but cerebellar and brain-stem involvement has been reported as well. Lesions can be focal, multi-focal, or diffuse. Infiltration of the meninges can occur with or without parenchymal involvement.
  - Involvement of cranial nerves III-VIII has been reported, with V and VII being the most common. Tumors may extend along the floor of the cranial fossa to involve multiple nerves and compress the adjacent brain.

- Spinal involvement historically has been characterized by focal extradural masses, but more recent studies have shown most lesions to contain both extradural and intradural components. Additionally, up to half of affected cats will have lesions involving multiple sections of the spinal cord. Concurrent brain and spinal involvement also has been reported.
- Brachial plexus involvement may occur in both dogs and cats. Lesions may extend through the subarachnoid space and invade the spinal cord.

HISTORY, CHIEF COMPLAINT

- Most patients present with neurologic abnormalities that are acute in onset and rapidly progressive.
  - The specific neurologic abnormalities depend on the site(s) of involvement (see Physical Exam Findings below).
- Patients with secondary CNS lymphoma might have other clinical signs referable to the extraneural sites affected.

PHYSICAL EXAM FINDINGS

- Forebrain lesions are associated with seizures, mentation or behavior changes, blindness, conscious proprioceptive deficits with a normal gait, circling, and occasionally neck pain.
- Brainstem lesions are associated with gait and proprioceptive abnormalities, vestibular changes, and occasionally mentation changes (stupor or coma).
- The clinical signs associated with cranial nerve deficits depend on the specific nerve(s) affected.
- Depending on the segments involved, spinal cord lesions can result in upper motor neuron signs (stiff ataxic gait, proprioceptive deficits, spastic paresis/ paralysis, hyperreflexia) and/or lower motor neuron signs (short-strided gait, flaccid paresis/paralysis, hyporeflexia). Signs can be bilateral but usually are asymmetric.
- Brachial plexus tumors present with unilateral sensory and motor deficits based on the specific nerve roots affected.

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology is unknown.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on signalment, history, neurologic abnormalities, and MRI imaging. Definitive diagnosis occasionally can be obtained from CSF analysis but usually requires cytology or preferably histopathology of a CNS lesion or, in patients with secondary CNS lymphoma, an extraneural lesion.

DIFFERENTIAL DIAGNOSIS

- Intracranial lesions: other primary brain tumors (meningioma, glioma, ependymoma, choroid plexus tumor), toxoplasmosis, neosporosis, meningoencephalitis of unknown etiology (including granulomatous meningoencephalitis), ischemic encephalopathy, feline infectious peritonitis
- Spinal lesions: intervertebral disk disease, diskospondylitis, abscess, fibro-cartilaginous emboli, infarction, spinal tumors (meningioma, glioma, nephroblastoma), vertebral tumors (osteosarcoma, chondrosarcoma, myeloma), feline infectious peritonitis virus
- Peripheral nerve lesions: peripheral nerve sheath tumor, trauma, avulsion of the brachial plexus or lumbosacral plexus, trigeminal neuritis (dogs)

INITIAL DATABASE

- Complete neurologic examination
- CBC, serum chemistry panel, urinalysis
- FeLV/FIV serology (cats)
- Thoracic radiographs, abdominal ultrasound, bone marrow aspiration: screening for evidence of lymphoma in other organ systems might allow a diagnosis to be reached rapidly and less invasively.

ADVANCED OR CONFIRMATORY TESTING

- MRI is the imaging modality of choice for CNS lesions.
  - Intracranial lesions can be intraaxial or extraaxial. Spinal lesions can appear extradural, intradural but extramedullary, or occasionally intramedullary.
  - Lesions typically are hyperintense on T2-weighted images and hypointense to isointense on T1-weighted images.

Contrast enhancement is strong but often patchy.
- CT or CT/myelogram (for spinal lesions) can be considered if MRI is not available.
- Radiography:
  - Skull radiographs are not routinely recommended.
  - Plain vertebral radiographs usually are normal, but purely lytic lesions occasionally are seen. Additionally, radiographs can be helpful for ruling out osseous tumors.
  - Myelography accurately identifies mass lesions and can help determine extradural, intradural, or intramedullary involvement.
- Cerebrospinal fluid (CSF) analysis:
  - CSF consistently has an elevated protein count.
  - Nucleated cell count can be normal or increased. A mixed-cell pleocytosis is most common.
    - Neoplastic lymphoblasts are identified in <50% of affected patients.
- To reach a definitive diagnosis, histopathologic or cytologic analysis is required. For CNS lesions, this usually requires surgery or specialized equipment (fluoroscopy, stereotactic biopsy [see p. 1214]). Whenever possible, obtaining samples from other affected organs is preferable.

TREATMENT

TREATMENT OVERVIEW

Optimum treatment regimens are not yet known. Definitive treatment centers around systemic chemotherapy, but drug selection is controversial owing to concerns about the blood-brain barrier. Additionally, surgery and radiation therapy play more prominent roles to help rapidly resolve neurologic abnormalities.

ACUTE GENERAL TREATMENT

- The majority of CNS lymphomas are secondary, and systemic chemotherapy remains the mainstay of therapy.
  - The protocols most commonly used to treat lymphoma include the drugs L-asparaginase, vincristine, cyclophosphamide, doxorubicin, and prednisone. (Several protocols exist; see pp. 673 and 674 for dosages.)
  - For tumors infiltrating the brain or spinal cord parenchyma, the ability of drugs to penetrate the blood-brain barrier is of concern. Inclusion of CCNU, cytosine arabinoside, and/ or procarbazine—drugs that cross this barrier and achieve therapeutic levels within the CNS—is reasonable but controversial.
    - Tumor microvasculature likely has greater permeability than the normal blood-brain barrier.
    - These drugs only have modest activity against other more common forms of lymphoma.
  - Consultation with an oncologist for the most current treatment recommendations is indicated.
  - Single-agent prednisone may be used as a palliative treatment.
- Radiation therapy used in combination with chemotherapy may improve outcome by rapidly shrinking compressive tumors.
  - Radiation treatment fields may be focal but more commonly include the entire brain and spinal cord.
- Surgery is indicated only when a biopsy is needed to confirm the diagnosis of lymphoma, or when rapid decompression of the brain or spinal cord is needed and radiation therapy is unavailable.

PROGNOSIS AND OUTCOME

- There is little information regarding the prognosis for dogs with CNS lymphoma. Treatment outcomes have been reported for very few dogs, and the protocols used were less aggressive than those currently recommended.
  - When treated with systemic chemotherapy, with or without radiation therapy, dogs have had reported survival times ranging from 1-3 months.
  - In the author's experience, when dogs present with CNS signs at the time of initial diagnosis, survival times of up to 1 year or more are possible. In contrast, when dogs first present with CNS signs at the time of relapse, prognosis is very guarded, and survival times are almost uniformly <l-2 months.
- Several recent studies that included cats with various forms of lymphoma (including CNS involvement) have not shown anatomic location to be a prognostic factor (see p. 669).
  - Earlier studies looking specifically at cats with brain lymphoma reported survival times of up to 7 months. Cats treated with both radiation therapy and chemotherapy tended to have a better outcome.
  - Earlier studies looking specifically at cats with spinal lymphoma reported remission rates of only 50% and median response durations of only 3-5 months. However, treatment protocols were not as aggressive as those currently recommended. Additionally, a higher percentage of the cats in those studies were FeLV seropositive compared to what is seen today.

PEARLS & CONSIDERATIONS

COMMENTS

If a cat tests positive for FeLV or FIV, the owner should be educated about these diseases, and all other cats in the household should be tested.

AUTHOR: DENNIS B. BAILEY

EDITOR: KENNETH M. RASSNICK

Lymphoma, Cat (Multicentric)

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A systemic malignant neoplasm of lymphoid origin

SYNONYMS

Lymphosarcoma, malignant lymphoma, non-Hodgkin's lymphoma (human)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Lymphoma is the most common hematopoietic malignancy in the cat.
- Disease forms/anatomic presentation has changed over the past 25 years, coincident with decreases in feline leukemia virus (FeLV) infection rates and FeLV-associated types of lymphoma.
- May develop at any age
- Siamese cats may be at increased risk for developing certain forms of lymphoma.

RISK FACTORS

- FeLV, and possibly feline immunodeficiency virus, infection are risk factors for the development of lymphoma.
  - FeLV status influences age and anatomic location at which lymphoma develops.
- Household exposure to environmental tobacco smoke (i.e., “second-hand smoke”) increases the risk.
  - In one study, cats exposed to tobacco smoke had a 2.4-fold increased risk of lymphoma.
  - Risk increased with duration of exposure, years of exposure, and number of smokers in the house.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Histologic grade:
  - High-grade, or lymphoblastic, lymphoma: most common; rapid onset and progression; affected cells are large and similar in appearance to lymphoblasts.
  - Low-grade, or lymphocytic, lymphoma: most often reported with gastrointestinal (GI) lymphoma; chronic insidious onset; affected cells are well differentiated and similar in appearance to small lymphocytes.
- Anatomic distribution:
  - Multicentric: typically lymph node, spleen, or liver involvement; presenting signs and physical exam findings vary with organ(s) affected.
  - Alimentary (GI) (see p. 678): older cats; majority are FeLV negative; presenting signs include anorexia, weight loss, vomiting, diarrhea; physical examination may reveal palpable abdominal mass.
  - Mediastinal: young cats; most are FeLV infected; thymus, mediastinal and sternal lymph nodes may be involved; presenting signs include dyspnea, tachypnea; physical exam may reveal a noncompressible anterior mediastinum and also be suggestive of pleural effusion.
  - Renal: presenting sign is acute renal failure which may completely resolve with chemotherapy; physical exam reveals marked bilateral renomegaly; high rate of central nervous system relapse.
  - Spinal: affected cats are often FeLV infected; presenting sign is hind limb paraparesis; many will have malignant lymphoblasts concurrently in bone marrow (see pp. 671 and 1037).
  - Nasal: unique form of lymphoma, as it is often localized and may be treated best with radiation therapy.

HISTORY, CHIEF COMPLAINT

- Highly variable presentation (see Disease Forms/Subtypes above)
- Generalized peripheral lymphadenopathy, as is common in dogs with lymphoma, is rare in cats with lymphoma.

PHYSICAL EXAM FINDINGS: Physical exam findings vary and are reflective of organs involved (see Disease Forms/Subtypes

above).

ETIOLOGY AND PATHOPHYSIOLOGY

- Rapid onset and disease progression over days to weeks
- Low-grade lymphoma, as reported with alimentary disease, may have chronic history.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the detection of a mass lesion in an affected organ or site with associated clinical signs; confirmation generally begins with aspiration cytology of the mass or site.

DIFFERENTIAL DIAGNOSIS

- Other neoplasms (e.g., leukemia, mast cell tumor)
- Multicentric: other neoplasms (e.g., mast cell tumor), cholangitis-cholangiohepatitis and other hepatopathies, pancreatitis
- Mediastinal: other neoplasms (e.g., thymoma, mesothelioma), heart disease, pyothorax, feline infectious peritonitis, diaphragmatic hernia
- Renal: acute renal failure, other renal failure, poly cystic kidney disease
- Nasal: other neoplasms (e.g., adenocarcinoma), rhinitis, inflammatory polyps, cryptococcosis

INITIAL DATABASE

- CBC: to identify anemia, thrombocytopenia and/or neutropenia due to lymphoblast infiltration in the marrow or secondary to immune-mediated destruction; to identify the presence of circulating lymphoblasts
- Serum biochemistry panel: to identify liver or renal abnormalities that may develop secondary to organ involvement and may alter ability to metabolize or eliminate chemotherapeutic drugs
- Urinalysis ± urine culture: to further evaluate renal function and to identify any occult urinary tract infection before chemotherapy
- FeLV serology: FeLV antigenemia is associated with certain forms of lymphoma and may be prognostic (see Prognosis and Outcome below).
- Aspiration cytologic evaluation of affected organ(s) or site(s): to identify lymphoblasts

ADVANCED OR CONFIRMATORY TESTING

- If lymphoma is identified cytologically, the following tests are indicated as part of routing staging, prior to initiation of chemotherapy:
    - Biopsy of affected organ(s): for definitive diagnosis and histologic grading
    - Thoracic radiographs: to identify lymphadenopathy, mediastinal mass, pleural effusion, pulmonary involvement
    - Abdominal ultrasound examination: to identify changes consistent with hepatic, splenic, renal, or gastrointestinal involvement, lymphadenopathy, or other sites of lymphoma
    - Bone marrow aspiration cytology: to identify marrow involvement and/or develop better understanding of etiology of any cytopenias
    - Phenotyping (flow cytometry, immunocytochemistry, immunohistochemistry, PCR): to determine B- versus T-cell origin
- If financial restrictions prohibit these tests, one may elect to omit certain tests (e.g., if CBC results are unremarkable, one may elect not to perform a bone marrow aspirate), as long as the client understands that sites of disease may be missed, and staging and follow-up monitoring will be less certain.

TREATMENT

TREATMENT OVERVIEW

Treatment involves the administration of chemotherapy to achieve complete remission (CR) while maintaining a good quality of life for the patient. Special drug-handling requirements and potentially severe or life-threatening adverse patient effects exist with many chemotherapeutics; these concerns and rapid evolution of protocols warrant consultation with/referral to an oncologist.

Body Weight–to–Body Surface Area (BSA) Correlation for Cats

Weight, kg (*lb*)	BSA (m^2)
2 *(4.5)*	0.159
2.5 *(5.5)*	0.184
3 *(6.5)*	0.208
3.5 *(7.75)*	0.231
4 *(8.75)*	0.252
4.5 *(10)*	0.273
5 *(11)*	0.292
5.5 *(12.25)*	0.311
6 *(13.25)*	0.33
6.5 *(14.25)*	0.348
7 *(15.5)*	0.366
7.5 *(16.5)*	0.383
8 *(17.5)*	0.4
8.5 *(18.75)*	0.416
9 *(19.75)*	0.432
9.5 *(21)*	0.449
10 *(22)*	0.464

ACUTE AND CHRONIC TREATMENT

- Reports on single-agent chemotherapy, including prednisone, doxorubicin, and mitoxantrone describe response rates ranging from 9%-40% with remission durations ranging from 3-12 months. Prednisone may be used as a single agent, but its use before the initiation of other chemotherapy should be avoided, as this may decrease rate and duration of response to other agents.
  - Prednisone/prednisolone (20-40 mg/ m^2 PO q 24-48 h as long as a clinical response is seen): mean survival of 1 month with spinal lymphoma
  - Doxorubicin (25 mg/m^2 or 1 mg/kg IV q 21 days as long as a clinical response is seen, provided there is no evidence of renal toxicosis and to a recommended maximum cumulative dosage of 180-240 mg/m^2): 26% complete remission rate for median duration of 3 months
- Improved remission rates and duration are achieved with combination chemotherapy. Numerous protocols are reported with variations in scheduling, drug dosages, and dose intensity, although most utilize induction followed by maintenance chemotherapy. The most commonly used agents in these protocols include prednisone, L-asparaginase, vincristine, cyclophosphamide, and doxorubicin (see p. 673). Complete response rates range from approximately 50%-75%, with remission durations of approximately 5-9 months. Options may include one of the following:
  - Cyclophosphamide, vincristine (Oncovin), prednisone (COP; see p. 673): approximately 50% complete remission rate for median duration of 3-8 months; *or*
  - Combination (cyclophosphamide, vincristine, prednisone, L-asparaginase, doxorubicin; see p. 673): approximately 75% complete remission rate for median duration of 7-9 months; *or*
  - COP induction + doxorubicin maintenance: 47% complete remission rate for median duration of 9 months; *or*
  - Combination (cyclophosphamide, vincristine, prednisone, L-asparaginase, doxorubicin, methotrexate [see online chapter: Lymphoma Chemotherapy Treatment Tables, Cat]): 38%-74% complete remission rate for median duration of 9-22 months
- When a patient relapses and no longer responds to frontline chemotherapy, rescue chemotherapy can be considered, with protocols such as MOPP (rnechlorethamine, vincristine, procarbazine, and prednisolone) or CCNU (50-60 mg/m^2 PO every

3-6 weeks, with dosing interval based on weekly CBC monitoring and individual patient's neutrophil nadir)

- Chemotherapy remains standard therapy; however, its use in combination with other treatment modalities, such as radiation therapy, may improve outcome. Studies are underway to evaluate the normal tissue tolerance and potential benefit of radiation therapy after a short course of induction chemotherapy in cats with lymphoma.
- Given the chronic indolent course of low-grade lymphoma, oral chemotherapy consisting of chlorambucil and prednisone may be more appropriate than intensive injectable chemotherapy for this group of cats.
    - Chlorambucil (6-8 mg/m^2 PO q 48 h as long as a clinical response is seen) and prednisone (20-40 mg/m^2 PO q 24-48 h as long as a clinical response is seen): 56%-69% complete remission rate for median duration of 21-30 months in cats with low-grade alimentary lymphoma.
- Radiation therapy may be considered for nasal lymphoma.
    - Disease-free intervals of 6-69 months are reported after radiation therapy.
    - It has been suggested that radiation therapy, chemotherapy, or a combination of both modalities yield comparable survival times.

POSSIBLE COMPLICATIONS

- Systemic chemotherapy targets rapidly dividing cells. Due to their rapid and often abnormal division and defective repair mechanisms, tumor cells can be destroyed by chemotherapy.
- Some normal tissues have a high rate of cell turnover (gastrointestinal mucosa, bone marrow, hair) and may be sensitive to chemotherapy, although unlike cancer cells, these normal tissues are able to repair chemotherapy induced damage. Potential side effects of chemotherapy include gastrointestinal upset 2-4 days after treatment, myelosuppression 7-10 days after treatment, and loss of whiskers (see p. 188).
- All chemotherapeutic agents are potentially toxic, most are mutagenic or teratogenic, and at least some are proven carcinogens. Safe handling requires the use of a vertical flow hood and closed-system drug transfer device.

RECOMMENDED MONITORING

- Regular monitoring of remission status
    - Complete remission: disappearance of all clinical evidence of cancer
    - Partial remission: decrease in volume of cancer by ≥50% without decrease to completely normal size
    - Stable disease: decrease in volume of cancer by <50% or increase in volume of cancer by <25%.
    - Progressive disease: increase in cancer volume by ≥25% or appearance of new lesions
- CBC (including differential) monitoring if administration of chemotherapy

PROGNOSIS AND OUTCOME

Several prognostic factors may help predict an individual's response to treatment:

- Stage
- Substage (*a* is better than *b)*
- Anatomic site of disease (mediastinal lymphoma may have a higher complete remission rate than other anatomic sites; nasal lymphoma has among the longest survival times).
- Histologic grade (low-grade lymphoma is often associated with longer remission and survival times with less intensive chemotherapy due to its chronic indolent nature).
- FeLV status; FeLV status does not appear to influence rates of response to chemotherapy, but FeLV-positive cats have significantly shorter remission and survival times, possibly due in part to concurrent FeLV-related diseases.

PEARLS & CONSIDERATIONS

COMMENTS

- Lymphoma is a common feline malignancy.
- The majority of cats achieve complete or partial remission when treated with chemotherapy, and treatment can be rewarding for both the pet owner and veterinarian.
- A variety of prognostic factors have been identified that may help predict an individual's response to treatment and guide the decision whether or not to pursue treatment.
- An understanding of the relative efficacy and potential toxicoses of the various protocols aids in determining the best treatment protocol for an individual patient.

Lymphedema

BASIC INFORMATION

DEFINITION

Lymphedema is a swelling of protein-rich interstitial fluid caused by impaired lymphatic function. The condition can be localized, regional, or widespread. Lymphedema is classified as primary (developmental) or secondary in origin.

SYNONYMS

While not specific for lymphedema, other terms for edematous states include anasarca, pitting edema, subcutaneous edema (see p. 333), and ventral edema.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs or cats. Primary lymphedema: puppies and young dogs. Secondary lymphedema: any age.

GENETICS & BREED PREDISPOSITION: Has been observed in English bulldogs, Labrador retrievers, and others. Idiopathic lymphedema may be more common in giant breeds such as Irish wolfhounds.

RISK FACTORS: Primary lymphedema is developmental in origin; diseases that obstruct, invade, inflame, or destroy normal lymphatic drainage predispose to secondary lymphedema. Lymphatic filariasis associated with infection by *Brugia pahangi* could be a consideration for lymphedema in tropical environments.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Localized involving a limb, intermandibular space, or ventral thorax
- Bilateral pelvic or forelimb lymphedema
- Generalized lymphedema (that may include pleural or peritoneal effusions)

HISTORY, CHIEF COMPLAINT

- In developmental lymphedema, the typical presentation is nonpainful, bilateral, pitting edema of the pelvic limbs. Generalized fluid retention is rare.
- In secondary lymphedema, there is nonpainful or painful swelling of the limb(s), ventral thorax, or intermandibular space.
- In generalized cases, respiratory distress may be related to pleural effusion.

PHYSICAL EXAM FINDINGS

- Nonpainful or painful swelling(s). In primary lymphedema, pain typically indicates secondary infection.
- Regional lymph nodes may be underdeveloped or enlarged.
- Isolated swellings with pain or inflammation suggest associated cellulitis, trauma, or neoplasia.
- Intermandibular edema with normal jugular venous pressure is suggestive of lymphatic obstruction; with jugular venous distension, vena caval thrombosis or compression is more likely.
- Chronic lymphedema or that associated with lymphangitis may produce firm, nonpitting swellings, skin ulceration, or oozing of serum across the skin.
- Lymphedema related to lymphangiosarcoma can be associated with ecchymotic hemorrhage.

ETIOLOGY AND PATHOPHYSIOLOGY

- Lymph is produced by ultrafiltration of capillary blood and normally returns to the bloodstream across the venous end of capillaries and via lymphatic channels and lymph nodes. Lymph traverses the thoracic or lymphatic ducts to reach the systemic venous circulation.
- Malformation of the lymphatic system, lymphangitis, widespread obstruction to lymph drainage, or infiltration of regional lymph nodes can cause accumulation of high-molecular-weight protein and edema. Interstitial or subcutaneous protein and fluid accumulation can initiate an inflammatory reaction and fibrosis.
- Progressive accumulation of lymphatic fluid leads to palpable swelling and impairs oxygen delivery, wound healing, and local

resistance to infection.
- Gravitational forces and the tightness of the skin influence the accumulation of tissue lymph.
- Lymphedema may be variable, pitting, nonpitting, or fibrotic in character. These are well-recognized stages of lymphedema in human patients and also may be observed in dogs or cats with chronic lymphatic disease.
- Strictly speaking, lymphedema stems from impaired lymphatic drainage. Subcutaneous edema also can be caused by reduced capillary oncotic pressure (hypoalbuminemia), increased vascular permeability, or elevated capillary hydrostatic pressure from venous obstruction, arteriovenous (AV) fistula, or right-sided congestive heart failure.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on nonpainful regional pitting edema and exclusion of other potential causes.

DIFFERENTIAL DIAGNOSIS

Lymphedema must be distinguished from other causes of tissue swelling, including:

- Overinfusion of intravenous crystalloid fluids; migration of subcutaneous fluids
- AV fistula
- Venous obstruction or thrombophlebitis
- Hypoproteinemia
- Localized infection
- Vasculitis
- Insect bites
- Localized or generalized allergic reactions
- Postinfarction edema
- Right-sided congestive heart failure
- Cellulitis, abscess, or localized infection
- Infectious or immune-mediated skin disorders with secondary edema
- Chylous effusion
- Localized neoplasm
- Lymphatic tumors: lymphangioma and lymphangiosarcoma

INITIAL DATABASE

- Careful inspection of regional systemic veins
- Auscultation over swellings for the bruit (continuous murmur) of an AV fistula
- Rectal examination to identify caudal abdominal or pelvic mass lesions
- CBC, serum biochemical panel, and urinalysis
- Chest radiographs: evaluate for heart disease, mediastinal mass, and pleural effusion
- Abdominal radiographs or ultrasonography: identify iliac lymphadenopathy, or pelvic mass lesion, or hepatosplenomegaly
- Cytologic examination of regional lymph nodes or tissue fluid
- Biopsy of affected tissues to rule out lymphangiosarcoma

ADVANCED OR CONFIRMATORY TESTING

- Culture and sensitivity (in cases of lymphangitis)
- Duplex Doppler ultrasonography to identify venous obstruction or AV fistula
- Serologic tests or PCR for tickborne infections, including *Bartonella* spp.
- Fluid and serum triglyceride concentrations when there is pleural or peritoneal effusion; elevated fluid triglycerides suggest a diagnosis of chylous effusion.
- Lymphoscintigraphy or lymphangiography: these advanced radiologic methods may demonstrate normal or abnormal lymphatic drainage.
- The patent blue violet dye test has been used to diagnose congenital lymphedema in dogs and cats.
- Computed tomography to identify regional mass lesions

TREATMENT

TREATMENT OVERVIEW

- Correct the underlying disorder if possible; for example, treat a malignancy with chemotherapy.
- Prevent or treat infections.
- Protect swollen tissues from injury; consider lightly compressive bandages.
- Improve macrophage function to reduce protein-rich edema.
- Treat associated pain.

ACUTE GENERAL TREATMENT

- Antibiotic treatment of infections
- Pain management for tense lymphedema or infection

CHRONIC TREATMENT

- Soft compression bandages (may not be well tolerated; discontinue if uncomfortable)
- Controlled exercise to enhance venous return.
- Long-term use of benzopyrones, such as rutin, to enhance macrophage function and proteolysis
- Advanced surgical techniques are of uncertain value: consult with a surgical specialist.

POSSIBLE COMPLICATIONS

Recurrent infection is likely even in cases of resolved primary lymphedema.

RECOMMENDED MONITORING

- Limb size, firmness, and associated pain
- Use of affected limbs
- Changes in subcutaneous swellings

PROGNOSIS AND OUTCOME

- Spontaneous resolution or marked improvement in some dogs with primary lymphedema
- Death or euthanasia related to complications of lymphedema
- Spontaneous death in puppies with generalized anasarca

PEARLS & CONSIDERATIONS

COMMENTS

- In primary lymphedema, the swelling is typically caudal and bilateral; regional lymph nodes are smaller or absent (whereas in healthy puppies superficial lymph nodes are prominent).
- A subtle pleural effusion in a dog with limb edema is suggestive of a more generalized lymphatic disorder (or severe hypoalbuminemia).
- Lymphangioma and lymphangiosarcoma can results in severe lymphedema unresponsive to treatment.
- When pelvic limb edema is caused by right heart failure, also expect ascites.
- Consultation with a radiologist may be informative regarding advanced imaging methods.

CLIENT EDUCATION

- Observe the swelling for discharge, odor, or inability to use a limb.
- Constitutional signs (anorexia, lethargy, fever) should prompt reevaluation.

Lymphangiectasia/Protein-Losing Enteropathy

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Intestinal lymphangiectasia: abnormality of the intestinal lacteals (lymphatics); commonly results in protein-losing enteropathy
- Protein-losing enteropathy (PLE): gastrointestinal (GI) disease or dysfunction, causing loss of protein into the GI tract; results in hypoalbuminemia +/− hypoglobulinemia
    - Intestinal protein loss can occur with both acute and chronic GI diseases.
    - The term *PLE* is usually reserved for patients with chronic disorders.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs are affected more commonly than cats.
- Can occur at any age
    - Breed-associated disorders are usually reported in young or middle-aged dogs.

GENETICS & BREED PREDISPOSITION

- Basenji: predisposed to immunoproliferative enteropathy
- Norwegian Lundehund: predisposed to intestinal lymphangiectasia
- Soft-coated wheaten terrier: predisposed to PLE with protein-losing nephropathy
- Yorkshire terrier: predisposed to intestinal lymphangiectasia +/− concurrent inflammatory bowel disease
- German shepherd dog, rottweiler, Chinese shar-pei: all appear predisposed to PLE.

RISK FACTORS: Dependent on underlying cause of PLE

CONTAGION & ZOONOSIS: Infectious causes are uncommon in patients with chronic PLE, although salmonellosis should be considered in febrile or immunocompromised patients. Fungal infections of the GI tract (e.g., *Histoplasma capsulatum)* may result in PLE, but affected animals are not directly contagious.

ASSOCIATED CONDITIONS & DISORDERS

- Inflammatory bowel disease (IBD)
- Lymphatic compromise/dysfunction:
    - Confined to the GI tract (i.e., intestinal lymphangiectasia)
    - Generalized
- Adverse food reactions (e.g., gluten-sensitive enteropathy)
- GI infection (e.g., histoplasmosis, salmonellosis, hookworms)
- Intestinal neoplasia (e.g., lymphoma, adenocarcinoma)
- Mechanical enteropathy (e.g., chronic foreign body, chronic intussusception)
- GI ulceration (e.g., NSAID-induced, hookworm infection)
- Venous hypertension:
    - Portal vein thrombosis or hypertension
    - Severe right-sided cardiac compromise
- Patients with PLE may present with complications from hypoproteinemia rather than overt GI disease:
    - Ascites, pleural effusion, pitting edema
    - Thromboembolic disease

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Patients may show no overt clinical signs; hypoalbuminemia may be an incidental finding.
- Weight loss commonly occurs and may be the only clinical sign.
- Intermittent vomiting

- Chronic small bowel diarrhea may or may not be present.
- Abdominal distension may be noted if ascites is present.
- Respiratory distress may occur with pleural effusion or pulmonary thromboembolism.
- Thromboembolic complications may cause central neurologic signs or limb dysfunction.

PHYSICAL EXAM FINDINGS

- Weight loss, emaciation
- Thickened intestinal loops may be noted on abdominal palpation.
- Ascites (generally noted if serum albumin <1.5 g/dL)
- Peripheral edema (may be present if serum albumin <1.5 g/dL)
- Dyspnea or tachypnea with pleural effusion and/or pulmonary thromboembolism
- Soft stool may be noted on rectal examination.

ETIOLOGY AND PATHOPHYSIOLOGY

- Hypoalbuminemia occurs when the loss of protein from the GI tract exceeds albumin synthesis by the liver.
- Several mechanisms (either alone or in combination) contribute to intestinal protein loss:
  - Abnormalities of the intestinal lymphatics cause leakage of lymph across the intestinal mucosa.
  - Increased intestinal permeability permits protein loss across the mucosa.
  - Intestinal mucosal erosion and ulceration results in protein loss into the GI lumen.
  - Elevated venous pressures result in protein leakage into the intestine.
- Hypoalbuminemia results in decreased oncotic pressure and leakage of fluid into interstitial spaces, causing peripheral edema, ascites, and/or pleural effusion.
- Loss of anticoagulant proteins, including antithrombin III, results in a prothrombotic state and predisposes patients to thromboembolic disease.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Preliminary diagnostics are used for confirming intestinal protein loss in a hypoalbuminemic patient. More advanced diagnostic testing then defines the cause of GI dysfunction and provides a targeted treatment plan.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis for hypoalbuminemia:

- Protein-losing nephropathy (PLN):
  - Glomerulonephritis
  - Glomerular amyloidosis
- Liver disease resulting in decreased albumin synthesis
- Other causes of albumin loss from the vascular space:
  - Peritonitis, pleuritis, vasculitis
  - Severe dermal burns or exudative dermatitis
- Protein malnutrition

INITIAL DATABASE

- Serum biochemistry profile:
  - Hypoalbuminemia is the hallmark of all PLEs.
  - Globulins are often decreased, resulting in panhypoproteinemia, but this finding is variable
    - Inflammatory GI diseases may cause serum globulins to increase.
  - Hypocholesterolemia is commonly noted in patients with PLE.
  - Hypocalcemia (both ionized and total) and hypomagnesemia also are common findings in patients with lymphangiectasia.
  - Liver enzymes may be slightly elevated with various GI diseases:
    - Serum bile acids are required to rule out hepatic insufficiency as cause of hypoalbuminemia.
- CBC:
  - Lymphopenia is commonly noted in dogs with lymphangiectasia.
  - Anemia may be noted; may indicate:
    - GI hemorrhage (anemia may be regenerative with acute blood loss or microcytic with chronic blood loss).

        - Chronic inflammatory disease may result in a nonregenerative anemia.
- Urinalysis:
    - Required to rule out proteinuria as cause of hypoalbuminemia.
    - Urine protein/creatinine ratio will help determine significance of any proteinuria:
        - Hypoalbuminemia due to PLN is associated with protein/creatinine ratios >5.
- Abdominal radiographs:
- May be unremarkable or demonstrate loss of serosal detail secondary to ascites
    - Underlying cause, such as an abdominal mass or foreign body, may be apparent.
- Thoracic radiographs:
    - May be unremarkable or reveal pleural effusion due to hypoalbuminemia.
    - Changes related to underlying etiology, such as pericardial disease or fungal disease, may be seen.
- Abdominal ultrasound:
    - Ascites may be noted if serum albumin <1.5 g/dL.
    - Intestinal walls may be thickened, +/− loss of normal layering.
    - Focal intestinal lesions may be noted in areas inaccessible via endoscopy.
    - Lymphadenopathy is commonly detected; suggests inflammatory, fungal, or neoplastic disease.
- Fluid analysis of ascites or pleural effusion: consistent with pure transudate
- Fecal evaluation (centrifuged flotation and saline preparation): for parasite and pathogen detection

ADVANCED OR CONFIRMATORY TESTING

- Canine fecal (α1-proteinase inhibitor can be assayed to confirm the presence of PLE:
    - (α1-proteinase inhibitor is a protein similar in size to albumin.
    - It is resistant to digestion by endogenous and bacterial proteinases.
    - It can therefore be measured in the feces to confirm PLE.
    - Three voided fecal samples are collected into calibrated tubes (available from the GI Lab, Texas A&M University; http://www.cvm.tamu.edu/gilab/assays/index.shtml).
    - Primary use is confirming PLE in the presence of coexisting PLN or liver disease.
- Rectal scrapings can be examined cytologically for histoplasmosis or lymphoma (see p. 1334).
- Serum folate and cobalamin concentrations should be measured:
    - Low folate suggests proximal intestinal disease.
    - Low cobalamin suggests distal small-intestinal disease or changes in GI microflora.
- Intestinal biopsies are necessary to establish a specific diagnosis in patients with PLE:
    - Tissue specimens may be collected via endoscopy, laparoscopy, or laparotomy.
    - General anesthesia carries substantial risk in severely hypoalbuminemic patients:
        - Fluid and electrolyte imbalances should be addressed first.
    - Endoscopy is minimally invasive and allows evaluation of intestinal mucosa for ulceration or dilated lacteals:
        - Tissue samples may be collected from stomach, duodenum, ileum, and colon.
        - Samples are not full thickness, so deeper lesions may be missed.
        - Feeding a small amount of corn oil 2 hours prior to induction may increase the visibility of dilated lacteals.
    - Exploratory laparotomy allows visualization of the entire abdomen and serosal surface of intestine:
        - Full-thickness biopsies may be diagnostically superior.
        - Risk of infection or dehiscence, especially with hypoalbuminemic state

TREATMENT

TREATMENT OVERVIEW

The long-term therapeutic goal is to increase serum albumin concentrations. However, some patients need immediate intervention to:

- Remove or control third-space fluid accumulation
- Provide nutritional support
- Prevent thromboembolic complications
- Address electrolyte imbalances (e.g., hypocalcemia and hypomagnesemia)

ACUTE GENERAL TREATMENT

- Fluid therapy should be planned carefully, as PLE patients have challenging colloid issues and may have an increased total body fluid volume at presentation. Injudicious fluid therapy may cause acute decompensation.
    - Synthetic colloids (e.g., hetastarch, dextran), improve oncotic pressure and limit peripheral edema and ascites.
        - Starting doses should be low (e.g., 5 mL/kg/d), as acute volume overload and pulmonary edema have been noted in dogs with severe PLE due to depletion of colloids in the interstitial space.

  - Fresh frozen plasma provides modest colloidal support; also supplies natural anticoagulant proteins such as antithrombin III.
  - Crystalloid support is rarely necessary in dogs with chronic PLE unless persistent vomiting or profuse diarrhea are reported; must be given with colloid support to minimize extravascular fluid accumulation.
  - Electrolyte disorders such as low potassium, ionized calcium, and magnesium should be addressed; patients with severe hypocalcemia may not improve unless magnesium is also supplemented.
- Abdominocentesis/thoracocentesis:
  - Fluid removal is required for patients with respiratory distress due to cavity effusion(s).
- Total or partial parental nutrition provides interim nutritional support in patients unable to absorb nutrients (see p. 1322).

CHRONIC TREATMENT

- Effective treatment of PLE requires management of the underlying cause; this may not be possible in all patients, particularly those with intestinal lymphangiectasia.
- Immunosuppressive agents should be used in patients with IBD:
  - Corticosteroids are the mainstay of medical therapy (e.g., prednisone, 1-2 mg/kg PO q 12 h, tapering to lowest effective dose after 14 days or when clinical signs are controlled).
  - Additional immunosuppressive agents (e.g., azathioprine, cyclosporine, chlorambucil) may be necessary in refractory patients or when chronic therapy is required.
- Corticosteroids +/− other immunosuppressive agents may be helpful in patients with lymphangiectasia:
  - Are thought to decrease lipogranuloma formation and lymphangitis
  - Inflammation triggered by release of chylomicrons into adjacent tissue exacerbates lymphatic dilation, dysfunction and leakage.
- Antibiotic therapy using metronidazole (10-15 mg/kg PO q 12 h × 4 weeks) may help control secondary bacterial disturbances and provide some antiinflammatory effects.
- Thromboembolism prophylaxis is warranted (e.g., aspirin 0.5 mg/kg PO q 24 h).
- Diuretics are rarely immediately helpful in patients with edema or cavitary effusion, but spironolactone may delay return of fluid (1-2 mg/kg PO q 12 h).

NUTRITION/DIET

- Dietary therapy is essential in dogs with PLE due to IBD, adverse food reactions, or lymphangiectasia.
  - Ultra low-fat, easily digestible diets should be fed to patients with intestinal lymphangiectasia to minimize fat malabsorption and lymph accumulation. Suitable choices would include cottage cheese (1% fat) and cooked white rice or commercially available highly digestible diets containing <3 g/100 kcal metabolizable energy fat.
  - Hypoallergenic or novel antigen diets should be considered in patients with concurrent IBD to decrease the inflammatory response in the intestine.
    - Most prescription diets in this category are not adequately fat restricted for patients with lymphangiectasia; consider a home-cooked diet or one of the commercially available novel antigen diets that are ultra low in fat.
  - Gluten-free diets should be provided if gluten-sensitive enteropathy is suspected.
  - Supplementation with an elemental enteral feeding product may be helpful. Such diets contain free amino acids to facilitate nutrient uptake by a compromised GI tract. Low-fat formulations such as Vivonex T.E.N. are appropriate for dogs with lymphangiectasia.
- Cobalamin supplementation should be provided if serum concentrations are subnormal:
  - Cyanocobalamin must be given parenterally (i.e., by SQ administration).
  - Dose is 0.25-1 mL/patient q 7 d for 6 weeks, then q 4 wk
- Folate supplementation should be provided if serum concentrations are subnormal:
- Dose is 0.5 mg PO q 24 h.
- Vitamin and mineral supplementation may be necessary in dogs with lymphangiectasia, as uptake of fat soluble vitamins is substantially compromised.
  - Vitamins D, E, and K are most likely to be depleted.
  - Calcium and magnesium supplementation may be necessary.

DRUG INTERACTIONS AND CONTRAINDICATIONS

- Immunosuppressive therapy is contraindicated in patients with infectious diseases such as intestinal histoplasmosis.
- Glucocorticoids should be withheld until surgical sites have healed.

POSSIBLE COMPICATIONS

- Azathioprine:
  - May cause substantial compromise in cats and should be avoided in this species
  - May cause myelosuppression or acute hepatopathy in dogs
- Thromboembolic disease:

- Patients may present with lameness, neurologic signs, or respiratory distress secondary to thromboembolic disease.
- Antithrombin III levels may be monitored to assess risk.

- Respiratory distress:
  - Patients may exhibit respiratory distress from severe ascites or pleural effusion, necessitating abdominocentesis or thoracocentesis.
  - Pulmonary thromboembolism associated with the PLE may also result in respiratory distress.

RECOMMENDED MONITORING

- Monitor serum albumin levels.
  - Response to therapy can be monitored objectively if no other disease processes are contributing to hypoalbuminemia.
- Monitor calcium (preferably ionized) and magnesium concentrations.
- Monitor CBC if patients are receiving myelosuppressive agents.
- Monitor body weight and assess at-risk patients regularly for third-space fluid accumulation.

PROGNOSIS AND OUTCOME

Long-term prognosis depends on eventual diagnosis:

- Most patients with PLE secondary to IBD have a guarded to fair prognosis.
- Basenjis with immunoproliferative enteropathy have a guarded to poor prognosis.
- Yorkshire terriers also have a guarded prognosis, as their inflammatory bowel disease or lymphangiectasia is often difficult to control.
- Prognosis for patients with GI fungal infection or neoplasia is guarded to grave.

PEARLS & CONSIDERATIONS

COMMENTS

- Hypoalbuminemia should always be investigated, even if the patient appears otherwise healthy. Early recognition of PLE may improve outcome and prevent life-threatening complications.
- Dietary modifications are an essential part of therapy in many cases.
- Always consider the risk of thromboembolism in patients with PLE.

CLIENT EDUCATION

- Clients should be warned that intestinal lymphangiectasia and IBD are usually lifetime problems and that chronic therapy may be necessary.
- Dietary recommendations must be strictly followed to minimize the chances of relapse.

Lymphadenopathy

BASIC INFORMATION

DEFINITION

Enlargement of a solitary, a regional group of, or all lymph nodes

SYNONYM

Lymphadenomegaly

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats, any age, either sex

GENETICS & BREED PREDISPOSITION: Dogs; bullmastiff, rottweiler, retrievers, other breeds: lymphoma

RISK FACTORS: Exposure to ticks and other vectors: infectious diseases

CONTAGION & ZOONOSIS: Exercise caution when aspirating lymph nodes, especially in animals with fungal disease (zoonosis via needlestick injury).

GEOGRAPHY AND SEASONALITY: Tick vectors are more prevalent in summer in the tropics. Many infectious agents have specific geographic areas of prevalence.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Solitary/regional versus generalized

HISTORY, CHIEF COMPLAINT

- History: visits to geographic areas where certain infectious diseases are endemic
- Clinical signs generally reflect the underlying disorder and are not directly caused by the lymphadenopathy.
    - Exception: if lymph node enlargement is marked, mechanical obstruction may cause dysphagia, respiratory stridor, regurgitation, cranial vena cava syndrome, swollen limb(s), and dyschezia.

PHYSICAL EXAM FINDINGS

- Evaluate all accessible lymph nodes during physical examination; the following nodes are readily palpable in dogs and cats:
    - Mandibular, prescapular (superficial cervical), axillary, superficial inguinal, and popliteal
    - Node pain, erythema, heat, adherence of node to underlying tissue suggest lymphadenitis.
- Patients with lymphadenopathy may show signs of systemic illness from underlying disease.
    - Signs generally are vague and include general malaise, pyrexia, anorexia, weight loss, lethargy and polyuria/polydipsia; lacking diagnostic specificity.
- Patients with chronic leukemias, postvaccinal lymphadenopathies, and early lymphoma generally show subtle signs or no clinical signs at all.
- Evaluate for overtly apparent inciting causes:
    - Example, lesions of the foot (dermatosis, foreign body, neoplasm) if a single node proximal to a limb is enlarged
      *Nodes that are normally palpable in the healthy dog.

Selected Superficial Lymph Nodes of the Dog and Associated Anatomic Regions of Lymphatic Drainage

Lymph Node (and Alternative Name)	Location	Distribution of Lymphatics Contributing to the Node
Submandibular (mandibular)*	Ventral to the angle of the mandible; subcutaneous and mobile (versus mandibular salivary glands, which are deeper, fixed structures)	Most structures of the head, except for the external ear and some parts of the skin of the dorsal muzzle
Prescapular (superficial cervical)*	Medial and dorsal to the point of the shoulder	Skin of the head, neck, and forelimb
Axillary	Dorsal to deep pectoral muscle and at the dorsal-most aspect of medial forelimb	Thoracic wall, deep structures of the forelimb
Inguinal (superficial inguinal)	Caudoventral abdomen, immediately caudal to the fifth mammary gland	Mammary glands, prepuce, scrotum, vulva, ventral abdominal wall up to the umbilicus
Popliteal*	Caudal surface of stifle (femorotibial joint)	All parts of the hind limb distal to the node
Sublumbar (medial or external iliac)	Trifurcation of aorta (dorsal surface of pelvic canal/abdomen); may be palpable per rectum	Genital system, caudal part of the urinary and digestive systems, pelvis, hind limbs, and dorsal half of the abdomen.

Lymph Node (and Alternative Name)	Location	Distribution of Lymphatics Contributing to the Node

- Fat surrounding lymph nodes is a common impostor for lymphadenopathy; the animal's overall body condition needs to be considered when suspecting lymphadenopathy.

ETIOLOGY AND PATHOPHYSIOLOGY

- Lymph nodes enlarge as a result of proliferation of normal cells within them or to infiltration with either normal or abnormal cells.
- Reactive hyperplasia:
  - Proliferation of lymphocytes and plasma cells in response to antigens arriving through afferent lymphatics
  - Occurs mostly in response to inflammation in the tissues drained by the lymph node
  - After vaccination
  - Immune-mediated diseases
- Lymphadenitis:
  - Migration of inflammatory cells into the node, usually caused by infection (bacterial, rickettsial, fungal, parasitic, viral)
- Neoplasia:
  - Primary: lymphoma
  - Secondary: carcinomas, melanomas, sarcomas, mast cell tumors
- Extramedullary hematopoiesis (rare)
- Vascular changes: edema, congestion (rare)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Start with a fine-needle aspirate of the lymph node to classify the disease process, then perform a CBC, serum biochemistry profile, and urinalysis together with diagnostic imaging as needed to search for the underlying cause. Lymph node biopsy may be necessary if no etiology is found.

DIFFERENTIAL DIAGNOSIS

- Generalized:
  - Reactive: systemic inflammation (infectious or noninfectious)
  - Lymphoma (most common), systemic mastocytosis, leukemia, multiple myeloma
  - Nonspecific hyperplasia (mainly cats)
  - Rickettsial diseases
  - Parasitic diseases
  - Systemic fungal infections
- Solitary or regional:
  - Superficial:
- Abscessation (lymphadenitis)
- Wounds, tick bites, and other inflammatory causes in the drained region
- Metastatic neoplasia
  - Deep (visceral):
    - Systemic mycoses
    - Metastatic neoplasia

INITIAL DATABASE

- Review history for visits to areas where specific infectious diseases are prevalent.
- CBC:
  - Anemia:
    - Anemia of chronic disease: inflammatory, infectious, or neoplastic disorders
    - Hemolytic anemia: hemoparasitic lymphadenopathies
    - Nonregenerative anemia: chronic ehrlichiosis, feline leukemia (FeLV), feline immunodeficiency virus (FIV), bone marrow neoplasia
  - Circulating blasts: lymphoma, acute leukemia
  - Eosinophilia: allergic, parasitic

  - Neutrophilia: lymphadenitis, lymph node hyperplasia or neoplasia, depending on the degree of systemic involvement
  - Thrombocytopenia: ehrlichiosis, lymphoma
- Serum biochemistry profile:
  - Hypercalcemia: lymphoma, multiple myeloma, anal sac adenocarcinoma if sublumbar nodes are enlarged
  - Hyperglobulinemia: neoplasia, ehrlichiosis, chronic inflammatory diseases
- Imaging: radiographs, CT, and ultrasound to search for neoplasia and determine the extent of lymph node involvement

ADVANCED OR CONFIRMATORY TESTING

- Fine-needle aspiration of lymph nodes allows classification of the disease process and frequently yields etiologic agents in infectious etiologies.
- Excisional lymph node biopsy (usually popliteal node) and histopathologic evaluation sometimes is necessary to confirm the diagnosis, especially in neoplasia and to perform immunophenotyping in lymphoma for prognostication.
- Aspiration and cytologic evaluation of spleen, liver, bone marrow
- Test cats for FeLV, FIV.
- Antibody tests for agents such as *Blastomyces* or *Ehrlichia*

TREATMENT

TREATMENT OVERVIEW

- Generalized lymphadenopathy: treat the underlying condition.
- Single node involvement: treat the process in the area drained by the lymph node.

ACUTE GENERAL TREATMENT

Prompt therapy in cases where lymph nodes obstruct the airway or vessels

CHRONIC TREATMENT

Chemotherapy protocols for lymphoma (see pp. 675, 669, 674, and 673)

POSSIBLE COMPLICATIONS

Acute tumor lysis syndrome (see online chapter: Acute Tumor Lysis Syndrome)

RECOMMENDED MONITORING

Imaging to monitor response to therapy or detect recurrence of neoplasia

PROGNOSIS AND OUTCOME

Variable, determined by underlying cause

PEARLS & CONSIDERATIONS

COMMENTS

- Most dogs and cats with lymphadenopathy have lymph nodes that are firm, irregular, painless, nonadherent to underlying tissue and not warm to the touch.
- Nodes that are softer, warm, painful, and adherent to underlying tissue denote lymphadenitis.
- Metastatic lesions or lymphoma with extracapsular invasion of nodes are adherent to underlying tissue.
- Marked generalized lymphadenopathy (5 to 10 times enlarged) occurs almost exclusively in dogs with lymphoma or in cats with lymphoma or lymph node hyperplasia.
- Sublumbar lymph nodes can be palpated per rectum in small- and medium-breed dogs.

LYMPHADENOPATHY Caudal ventral abdomen of a female dog; cranial is toward top of image. Marked bilateral superficial inguinal lymph node enlargement is evident, with vulvar inflammation. Caudal fifth (inguinal) mammary glands are normal and not palpable in this dog.

PREVENTION

Tick and flea control

CLIENT EDUCATION

Parasite control and early presentation for veterinary care

AUTHOR: JOHAN P. SCHOEMAN

EDITOR: ETIENNE CÔTÉ

Lung Parasites

BASIC INFORMATION

DEFINITION

Infestation of major airways or pulmonary alveoli with parasites such as *Oslerus osleri, Paragonimus kellicotti, Eucoleus aerophilus, Filaroides hirthi, Crenosoma vulpis,* or *Aelurostrongylus abstrusus*

SYNONYMS

Lungworms; *O. osleri* formerly was *Filaroides osleri; Eucoleus aerophilus* formerly was *Capillaria aerophila.*

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats:
  - Parasites seen in dogs include O. *osleri, C. aerophila, P. kellicotti, C. vulpis,* and *F. hirthi*.
  - Parasites seen in cats include *P. kellicotti, C. aerophila,* and *A. abstrusus.*
- Clinical signs are most common in younger animals but can be seen in animals of any age.
- No sex predisposition

RISK FACTORS: Dogs clinically affected by *F. hirthi* often have concurrent immune system compromise.

GEOGRAPHY AND SEASONALITY: The fluke *P. kellicotti* is most often found in the southeast, Midwest, and Great Lakes regions, owing to the prevalence of the snail and crayfish intermediate hosts. *Crenosoma vulpis* is highly prevalent in Atlantic Canada (red fox reservoir).

ASSOCIATED CONDITIONS & DISORDERS

- Eosinophilic pneumonia
- Pneumothorax

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Infestation can be an incidental finding.
- Cough
- Wheezes
- Exercise intolerance
  - Respiratory distress may be noted if pneumothorax is present.

PHYSICAL EXAM FINDINGS

- Cough may be elicited on tracheal palpation. However, this sign is nonspecific, and tracheal palpation may also elicit coughing in patients with other tracheal disorders, bronchial disorders, or pulmonary parenchymal diseases.
- Thoracic auscultation is usually unremarkable.
  - Wheezes or crackles can be heard in severely affected animals.

ETIOLOGY AND PATHOPHYSIOLOGY

- *O. osleri:*
  - Obtained via direct transmission (ingestion) of larvae in regurgitated food, feces, or saliva
  - Adults live in carina and mainstem bronchi and cause local nodular inflammation and fibrosis.
- *P. kellicotti:*
  - Obtained via ingestion of crayfish intermediate host or paratenic host such as rodents
  - Adult flukes live in a subpleural cyst that communicates with a bronchus.

        - Rupture of cyst/bulla in patients with *P. kellicotti* can cause pneumothorax.
- *E. aerophilus:*
    - Obtained via direct transmission (ingestion) of eggs in respiratory secretions or feces or by ingestion of earthworm intermediate host
    - Adults live in bronchial mucosa.
- *F. hirthi:*
    - Obtained via ingestion of larvae in feces
    - Adult worms live in lung parenchyma (alveoli and terminal airways).
- *A. abstrusus:*
    - Obtained via ingestion of snail or slug intermediate host or paratenic host such as birds and rodents
    - Adults live in terminal bronchioles, alveolar ducts and alveoli.
- *C. vulpis:*
    - Obtained via ingestion of snail or slug intermediate host
    - Adults live in bronchi.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on age of patient (typically young animals), signs of respiratory disease, possible exposure to paratenic or intermediate host, and compatible radiographic findings; confirmation requires seeing parasite or egg in specialized fecal examination.

DIFFERENTIAL DIAGNOSIS

- Chronic sterile bronchitis
- Infectious tracheobronchitis
- Asthma
- Pulmonary edema
- Bacterial or fungal pneumonia
- Pulmonary metastatic disease
- Pneumothorax
- Eosinophilic bronchopneumopathy (pulmonary infiltrates with eosinophils)

INITIAL DATABASE

- Thoracic radiographic abnormalities reflect the causative organism:
    - *O. osleri:* tracheal and bronchial nodules
    - *P. kellicotti:*
        - Solid or cavitary mass lesion, most commonly in the right caudal lobe
        - Bulla may also be present.
        - Pneumothorax
        - A bronchial or interstitial lung pattern is possible.
    - *C. aerophila:* normal or bronchial to bronchointerstitial pattern
    - *A. abstrusus:* bronchial to diffuse miliary or nodular interstitial pattern most common early; generalized alveolar pattern may be seen in severely affected animals.
    - *F. hirthi:* nodular interstitial pattern or alveolar infiltrates
    - *C. vulpis:* normal to mild to moderate bronchial or interstitial pattern
- No specific changes may be seen on CBC, serum biochemistry panel, or urinalysis.
    - Occasionally, eosinophilia is present, representing nonspecific parasitic infection or inflammation from other

ADVANCED OR CONFIRMATORY TESTING

- Transtracheal or bronchial washes may demonstrate larvae or eggs.
- Bronchoscopy to identify nodules of *O. osleri*
- Fecal examination may show eggs or larvae:
    - Zinc sulfate flotation or Baermann technique is recommended for identification of ova or larvae, respectively, of *O. osleri, A. abstrusus, C. vulpis,* and *F. hirthi.*
    - Fecal flotations can identify *C. aerophila* ova.
    - High-density fecal flotation or fecal sedimentation is preferred for identification of *P. kellicotti* ova.
- Nested PCR has been studied and may prove helpful for diagnosis of *A. abstrusus* in cats.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of administration of parasiticidal drugs to eliminate the parasite infestation, with other medications used as necessary to decrease clinical signs secondary to inflammation.

ACUTE GENERAL TREATMENT

- With severe respiratory signs (rare), oxygen administration may be necessary.
  - Although secondary inflammation is often seen with infection, corticosteroid therapy (antiinflammatory doses) should be reserved for severe cases.
- Thoracocentesis for pneumothorax
- Parasiticidal drugs:
  - Fenbendazole, 50 mg/kg PO q 24 h for 10-14 days (14-21 days for O. *osleri)* can be used for all.
  - Other approaches include:
    - *A. abstrusus*
      - Ivermectin, 0.4 mg/kg SQ once
    - O. *osleri*
      - Ivermectin, 0.4 mg/kg PO, SQ once every 2 weeks for 3 treatments
    - *P. kellicotti*
      - Praziquantel, 25 mg/kg PO q 8 h for 3 days (dog)
      - Praziquantel, 10 mg/kg PO q 24 h for 10 days (cat)
    - *F. hirthi*
      - Albendazole, 25-50 mg/kg PO q 12 h for 5 days, repeat in 3 weeks
    - *C. vulpis*
      - Milbemycin oxime, 0.5 mg/kg PO once

POSSIBLE COMPLICATIONS

Certain breeds of dogs (such as collies) should not be treated with ivermectin without testing for MDR (multiple drug resistance) gene mutations (see p. 706). Albendazole may cause bone marrow toxicity.

RECOMMENDED MONITORING

- Clinical signs
- Thoracic radiographs
- Fecal examinations

PROGNOSIS AND OUTCOME

The prognosis depends on degree of clinical signs and extent of disease; generally good for recovery with appropriate treatment.

PEARLS & CONSIDERATIONS

COMMENTS

Lung parasites should be considered in any young animal presenting for coughing and with radiographic evidence of interstitial or bronchial lung disease.

PREVENTION

Limit exposure to intermediate or paratenic hosts.

TECHNICIAN TIPS

- False-negative results are considered common when examining stools for respiratory parasites.
- Fresh stool samples obtained per rectum are preferred for Baermann testing to limit contamination and confusion caused by soil nematodes.

- MDR testing is easily accomplished by submission of a cheek swab to the Veterinary Clinical Pharmacology Laboratory (for information see this link: http://www.vetmed.wsu.edu/depts-VCPL/).

CLIENT EDUCATION

Reinfection is possible unless pets are limited in opportunities to ingest known paratenic hosts.

EDITOR: RANCE K. SELLON

Lung Lobe Torsion

BASIC INFORMATION

DEFINITION

A rotation of a lung lobe along its long axis, with twisting of the bronchus and pulmonary vessels at the hilus

EPIDEMIOLOGY

SPECIES, AGE, SEX: Reported in dogs and cats, although rare in cats. Middle-aged dogs are more commonly affected. There is no gender predilection.

GENETICS & BREED PREDISPOSITION

- Dogs with deep, narrow chests have a higher incidence.
  - Afghan hounds are overrepresented.
- Has been reported in small-breed dogs.
  - Pugs are overrepresented in the veterinary literature.

RISK FACTORS: Preexisting conditions leading to atelectasis of lung lobes such as:

- Pleural effusion
- Pneumothorax
- Trauma
- Surgical manipulation

ASSOCIATED CONDITIONS & DISORDERS

- Usually associated with massive pleural effusion
- Associated with chronic respiratory disease, trauma, chylothorax, thoracic surgery, or neoplasia

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of pneumothorax, pneumonia, or trauma
- Dyspnea
- Coughing
- Hemoptysis
- Anorexia with weight loss
- Exercise intolerance

PHYSICAL EXAM FINDINGS

- Muffled heart and lung sounds
- Crackles
- Coughing
- Hemoptysis
- Dyspnea

ETIOLOGY AND PATHOPHYSIOLOGY

- Spontaneous lung lobe torsion can occur.
- Any mechanism that increases the mobility of a lung lobe can lead to the development of torsion.
- Torsion of a lung lobe leads to venous congestion from occlusion of twisted pulmonary veins of the affected lobe and lung consolidation.
  - Persistent venous congestion leads to pleural effusion.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis should be considered in any patient, especially canine, with pleural effusion. Suspicion is typically increased by the presence of pleural effusion in an at-risk breed or by abnormalities found on thoracic imaging (plain radiographs, ultrasonography, CT scans) or bronchoscopy.

DIFFERENTIAL DIAGNOSIS

- Other causes of pleural effusion:
  - Hydrothorax
  - Hemothorax
  - Chylothorax
  - Pyothorax
- Pneumonia
- Pulmonary thromboembolism
- Pulmonary contusion
- Pulmonary neoplasia
- Pulmonary atelectasis
- Diaphragmatic hernia

INITIAL DATABASE

- Results of CBC, biochemistry panel, and urinalysis are variable.
  - Stress or inflammatory leukogram is possible.
- Analysis of pleural fluid may reveal a sterile, inflammatory serosanguineous effusion or chyle.
- Thoracic radiographs show pleural effusion and lung consolidation.
  - Large-volume pleural effusions may obscure lung atelectasis. Therefore repeating radiographs after thoracocentesis is important.
- Thoracic ultrasound reveals “hepatization” of the torsed lung lobe, with fluid-filled bronchi having an appearance similar to hepatic vessels and fluid-filled pulmonary parenchyma resembling normal liver.

ADVANCED OR CONFIRMATORY TESTING

Rarely needed or used

- Bronchoscopy may demonstrate an obstructed orifice of the main bronchus supplying the affected lobe.
  - Bronchial mucosa may appear folded and edematous.
- Thoracic CT may demonstrate anatomic alterations of the affected bronchus that suggest lung lobe torsion.
- For some patients, the diagnosis is confirmed at thoracotomy.

TREATMENT

TREATMENT OVERVIEW

- Improve respiratory function and stabilize the patient.
- Lobectomy of the affected lobe

ACUTE GENERAL TREATMENT

- Thoracocentesis (see p. 1338)
- Oxygen by face mask, nasal cannula, or oxygen cage (see p. 1318)
- Fluid therapy as needed based on patient status, physical examination, and laboratory parameters

CHRONIC TREATMENT

- This is a surgical condition; spontaneous resolution is rare.
- Lobectomy of the affected lobe is the treatment of choice.

POSSIBLE COMPLICATIONS

- Torsion of another lung lobe is possible.
- Lung lobe torsion may lead to chylothorax.

RECOMMENDED MONITORING

- Vital signs
- Respiratory pattern
- Resolution of pleural effusion:
- Thoracic radiographs
    - Volume of fluid aspirated from chest tube in the postoperative period; 1 mL/kg/d of fluid production is expected from the presence of the chest tube alone.
- Postoperative pain

PROGNOSIS AND OUTCOME

The prognosis is good if lung lobectomy is performed.

PEARLS & CONSIDERATIONS

COMMENTS

- Any lobe can torse, but the right cranial and middle lung lobes are more frequently affected.
- Air bronchograms can be seen in affected lobes early in the process, but bronchial air is absorbed and replaced by fluid within 2-3 days.
- During lobectomy, clamp the affected pedicle with noncrushing forceps before derotation to help prevent release of toxins into the bloodstream.
- The use of automated stapling devices (TA-30 V3) simplifies the surgery and decreases surgery time.
- Submit excised lung for culture and histologic examination.

TECHNICIAN TIPS

Materials for thoracocentesis to evacuate pleural fluid just after anesthetic induction to better stabilize the patient while prepping for surgery include: 22-gauge over-the-needle catheter or butterfly needle, three-way stop cock, extension set, syringe, and collection bowl.

CLIENT EDUCATION

Animals with concurrent chylothorax may have a poorer prognosis.

Lumbosacral Stenosis, Degenerative

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- A variety of pathologic conditions (malformation, growth disturbance, degeneration, compressive myelopathy, inflammation, infection, subluxation, ischemia) of the lumbosacral vertebral segments and related soft tissues
- The most common clinical presentation involves degenerative lumbosacral stenosis.

SYNONYMS

Cauda equina syndrome, lumbosacral spondylopathy, spondylolisthesis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Middle-aged, medium- to large-breed, male dogs overrepresented

GENETICS & BREED PREDISPOSITION: German shepherds are predisposed.

RISK FACTORS: Working dogs at increased risk

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Some or all may be present:

- Lumbosacral pain
- Pelvic limb weakness/dragging
- Exercise intolerance/reluctance to exercise (especially jumping, rising, climbing stairs)
- Unilateral or bilateral pelvic limb lameness
- Paresthesia of the perineum and/or extremities (manifested by licking or chewing)
- Tail paresis/paralysis
- Urinary/fecal incontinence

PHYSICAL EXAM FINDINGS: Some or all may be present:

- Pain on hind limb or tail hyperextension
- Pain when digital pressure is applied to dorsal sacral/caudal lumbar vertebrae, with or without simultaneous lifting of the pubis
- Pain on rectal palpation of L7-S1 disk space
- Abnormal hind limb conscious proprioceptive response (monoparesis or paraparesis)
- Reduced hind limb flexor reflex (especially hock flexion)
- Exaggerated patellar reflex (pseudohyperreflexia)
- Unilateral or bilateral atrophy of sciatic-innervated muscles (hamstring, gastrocnemius, cranial tibial); reduced perineal reflex
- Poor anal and urethral sphincter tone
- Atonic bladder
- Decreased tail sensation

ETIOLOGY AND PATHOPHYSIOLOGY

- Large biomechanical forces are placed on the lumbosacral joint, which acts like a “hinge” between the stiff pelvis and the mobile spine. Presumably, the mechanical stress in the lumbosacral joint leads to early disk degeneration, destabilization of the disk space, and dorsal protrusion of the disk.
- Osteophytes may form adjacent to the unstable disk space and contribute to spinal canal stenosis along with the bulging disk, hyperplastic soft tissues, and sacral subluxation.

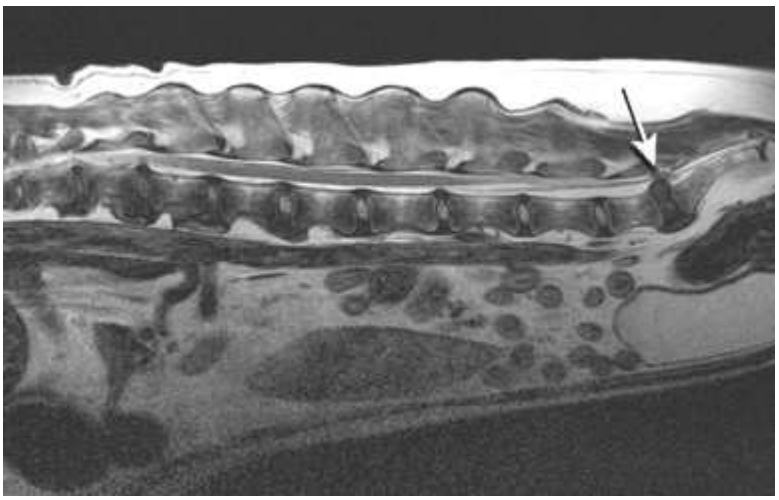
DIAGNOSIS

DIAGNOSTIC OVERVIEW

Lumbosacral stenosis is suspected in dogs with signalment, clinical signs, and radiographic findings consistent with this disease, especially if lower motor neuron signs (dysreflexia) to the hind limbs are noted. However, advanced imaging (MRI, CT, myelography/epidurography) is necessary to confirm diagnosis.

DIFFERENTIAL DIAGNOSIS

- Lumbosacral diskospondylitis
- Spinal cord, spinal nerve, or vertebral neoplasia
- Thoracolumbar disk disease
- Spinal trauma
- Degenerative myelopathy
- Coxofemoral arthritis/hip dysplasia
- Cranial cruciate disease
- Pelvic/sacral fracture(s)
- Fibrotic myopathy (semitendinosus, gracilis muscles)
- Prostatic disease



LUMBOSACRAL STENOSIS, DEGENERATIVE Sagittal T2-weighted MRI of the lumbosacral spine of a mature dog with degenerative lumbosacral stenosis; cranial is to the left. The disk at the LS junction *(arrow)* is protruding into the spinal canal and shows low signal intensity consistent with degeneration.

INITIAL DATABASE

- CBC, serum biochemistry panel, urinalysis (older dogs)
- Survey radiographs (heavy sedation/ general anesthesia) with evacuated colon, to rule out differential diagnoses (trauma, diskospondylitis). Radio-graphic changes associated with degenerative lumbosacral stenosis:
    - L7-S1 disk space narrowing
    - Lumbosacral end-plate sclerosis, spondylosis deformans
    - Ventral sacral subluxation
    - Lumbosacral disk mineralization
    - Note: These changes may also be identified in clinically unaffected dogs and do not predict the development of lumbosacral stenosis.

ADVANCED OR CONFIRMATORY TESTING

- MRI is extremely useful for evaluating disk degeneration or nerve root compression (soft tissue).
- CT gives excellent bone detail and can provide cross-sectional imaging. The soft-tissue imaging is inferior to MRI, however.
- Myelography: useful if the dural sac extends beyond the lumbosacral area. Contrast filling of the epidural space may be inconsistent and hard to interpret.
- Diskography: may demonstrate disk protrusion. Note: a normal disk can be injected with less than 0.2 mL contrast agent, and a degenerated disk can often easily receive 1 to 3 mL.
- Electromyography (EMG) may delineate denervation. Normal EMG does not rule out lumbosacral stenosis.

TREATMENT

TREATMENT OVERVIEW

Surgical treatment is recommended if pain is refractory to medical management and/or if neurologic signs are deteriorating. Goals of treatment are pain relief and return to function, although return to complete normalcy may not be possible.

ACUTE GENERAL TREATMENT

- Conservative management: strict rest (4-6 weeks), then gradually increased activity over 4-6 weeks. Antiinflammatory/analgesic medication to control pain as needed. Consider codeine, 1 mg/kg every 6-12 hours PO or tramadol (1 mg/kg q 4-6 h PO) in combination with a nonsteroidal anti-inflammatory drug.
- Dogs with continuous pain or neurologic dysfunction are surgical candidates. Surgical treatment most frequently consists of spinal canal/ nerve roots decompression through a dorsal laminectomy and (sometimes) foraminotomy.
- Distraction and stabilization of unstable LS space is possible with facet joint transarticular screws in combination with decompression. May decrease the risk of recurrence.

CHRONIC TREATMENT

- Strict confinement necessary for 8-12 weeks after surgery, followed by gradual return to function over 2 months. Early excessive exercise associated with less favorable outcome.
- Sling support may be necessary in the early postoperative period. Urinary bladder management is imperative until there is normal voluntary voiding.

NUTRITION/DIET

Dietary modification to avoid obesity is beneficial.

BEHAVIOR/EXERCISE

High-impact physical activity (jumping, frisbee catching, etc.) should be avoided, whereas consistent low-impact activity (walks, running on soft surfaces, swimming) should be provided.

POSSIBLE COMPLICATIONS

- Laminectomy scarring
- Implant failure

PROGNOSIS AND OUTCOME

- Decompressive surgery provides a good to excellent long-term outcome in 78%-97% of cases.
- Working dogs return to full function in 41%-78% of cases.
- Recurrence rates have been reported as 3% in a population of primarily pet dogs, whereas more active or working dogs show recurrence rates of 18%-54%. A second surgery can be beneficial in cases with recurrent clinical signs.
- Urinary or fecally incontinent dogs have less favorable outcomes.

PEARLS & CONSIDERATIONS

COMMENTS

- Transitional lumbosacral vertebrae and sacral osteochondrosis have been associated with lumbosacral stenosis but can also occur in normal dogs.
- Lumbosacral diskospondylitis can be difficult to distinguish from degenerative lumbosacral stenosis. In cases with osteolytic or severely proliferative changes, urine, blood, and, if surgery is performed, the removed disk should be submitted for bacterial and fungal culture.

SUGGESTED READING

Suwankong N, et al: Review and retrospective analysis of degenerative lumbosacral stenosis in 156 dogs treated by dorsal laminectomy. Vet Comp Orthop Traumatol 3:285, 2008.

AUTHOR: BOEL A. FRANSSON

EDITOR: JOSEPH HARARI

Liposarcoma

BASIC INFORMATION

DEFINITION

An uncommon primary malignant neoplasm of adipocytes. Can occur anywhere in the body but more commonly found in the skin and subcutaneous tissue.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Liposarcomas are uncommon in dogs and rare in cats. They are more common in older dogs (10 years of age average), but can occur at any age. They have been reported at injection sites in cats. No sex predilection has been reported.

GENETICS & BREED PREDISPOSITION: No breed predilection has been reported.

RISK FACTORS: Liposarcomas have been reported in previously irradiated tissues, at the site of a glass foreign body, and at the site of an injected microchip. The limited number of cases suggests that these factors may have a small impact on the risk of developing liposarcoma.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Liposarcomas have different pathologic subtypes, but these have not been shown to have prognostic significance. This tumor type has been reported at injection sites in cats (see 610).

HISTORY, CHIEF COMPLAINT

- Dogs and cats with liposarcoma in the skin and subcutaneous tissue usually present for evaluation of a progressively growing mass noticed by the owner.
- Dogs with abdominal liposarcoma often present for evaluation of signs related to an abdominal mass.

PHYSICAL EXAM FINDINGS

- Liposarcoma in the skin and subcutaneous tissue often presents as a firm, palpable mass.
- Regional lymphadenopathy may be present secondary to inflammation or (rarely) lymph node metastasis.
- Dogs with an abdominal liposarcoma may present with abdominal mass, pain, or enlargement.

ETIOLOGY AND PATHOPHYSIOLOGY

- Liposarcomas are thought to be spontaneously occurring in most cases in dogs. However, there are reports of tumors developing at the site of foreign bodies.
- Pathologic changes caused by liposarcomas depend on the location of the primary tumor and the invasion into and destruction of surrounding normal structures.
- Liposarcomas are not thought to be malignantly transformed lipomas.
- Liposarcomas may grow rapidly.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis can only be confirmed via histopathologic analysis, although additional testing such as diagnostic imaging is often helpful in defining the extent of the tumor.

DIFFERENTIAL DIAGNOSIS

- Other skin and subcutaneous tumors:
  - Soft-tissue sarcoma
  - Mast cell tumor

    - Lipoma
    - Others
- Other splenic tumors:
    - Hemangiosarcoma
    - Lymphoma
    - Others

INITIAL DATABASE

- Fine-needle aspirate cytologic analysis may help identify the tumor type before other diagnostics.
- Three-view thoracic radiographs to rule out pulmonary metastases
- Radiographs of the affected area may reveal involvement of underlying bone.
- Fine needle aspirate of draining lymph nodes to help rule out metastasis.

ADVANCED OR CONFIRMATORY TESTING

- CT or MRI may be necessary to delineate the local extent of the tumor and plan for surgery or radiation therapy.
- Biopsy: definitive diagnosis is based on histopathologic examination of tissue. Special stains may be necessary to differentiate liposarcoma from other soft-tissue sarcomas, especially poorly differentiated tumors.

TREATMENT

TREATMENT OVERVIEW

Definitive treatment is based on complete eradication of the primary tumor whenever possible. However, additional treatment such as chemotherapy may be indicated to prevent or delay metastases or in dogs with high-grade tumors or tumors that have already metastasized. Palliative treatment options, such as palliative radiation, may help control pain or discomfort in patients with advanced tumors or in patients where definitive treatment cannot be tolerated.

ACUTE GENERAL TREATMENT

- Aggressive surgical resection, radiation therapy, and/or chemotherapy may be used for treatment of liposarcoma (see 1034).
- Although response of liposarcomas to radiation and chemotherapy has not been determined, these treatments may be useful as adjuvant therapy.

POSSIBLE COMPLICATIONS

Complications of treatment for liposarcomas depend on the types of treatments and the location of the primary tumor.

RECOMMENDED MONITORING

After appropriate local treatment, follow-up examination should be done on a routine basis to monitor for recurrence (every 2-3 months) and metastasis (including thoracic radiographs at 6 months and 1 year). High-grade tumors may require more frequent monitoring for metastases during and after chemotherapy administration.

PROGNOSIS AND OUTCOME

- Early studies reported metastasis to multiple sites (liver, lung, bone). However, in a more recent retrospective study of 56 dogs, very few dogs died as a result of metastasis. Dogs in this study had a median survival of almost 2 years, and dogs that had wide excision of their tumor had a median survival >3 years.
- Surgical excision with a clean histopathologic margin may not be adequate for local tumor control in some dogs with liposarcoma, based on a recurrence rate of 31% for dogs with clean margins and a higher risk of recurrence following reexcision.

PEARLS & CONSIDERATIONS

COMMENTS

Fine-needle aspirates of skin and subcutaneous masses should always be evaluated microscopically. Aspirates of liposarcoma may

give “fatty” appearing fluid, which could falsely be interpreted as indicating lipoma or subcutaneous fat. However, liposarcoma can be readily differentiated from benign tumors of adipocytes such as lipoma or infiltrative lipoma with routine microscopic (cytologic) evaluation of smears.

PREVENTION

The individual case of liposarcoma developing at the site of an implanted microchip does not warrant concern about an increased risk of tumors caused by microchips.

CLIENT EDUCATION

Pet owners can be educated to monitor their pets for masses and have them evaluated in a timely fashion. Early detection may allow for easier treatment via surgery and may help avoid the need for radiation therapy.

Lily Toxicosis

BASIC INFORMATION

DEFINITION

Lilies are a family of flowering ornamental plants that are known to cause acute renal failure when ingested by cats. Lily poisoning is a well-recognized and potentially fatal plant toxicosis in cats. In dogs, only mild gastrointestinal upset is expected with lily ingestion.

SYNONYMS

Lilies toxic to cats include daylilies *(Hemerocallis* spp.), Easter lilies *(Lilium longiflorum),* Rubrum or Japanese showy lilies *(L. speciosum, L. landifolium),* Star-gazer lilies *(L. auratum),* and tiger lilies *(L. tigrinum).* There are many new *Lilium* varieties developed each year. All *Lilium* or *Hemerocallis* species should be considered toxic.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Lily toxicosis has only been reported in cats.

GENETICS & BREED PREDISPOSITION: All breeds, ages, and both sexes of cats are susceptible.

RISK FACTORS: Younger cats may be more likely to eat plant material.

GEOGRAPHY AND SEASONALITY

- Easter lilies are most commonly sold in March and April. Other lilies are found year round.
- Lilies grow naturally along the Pacific Coast of the United States. Lilies are frequently cultivated as garden plants or houseplants.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of plant ingestion and/or presence of lilies in owner's home. Cats typically present vomiting (plant material may be present in the vomitus), anorexic, and lethargic.
- Signs usually develop within 12 hours after exposure (range: 2 hours to 5 days).
- Polyuria, polydipsia, and acute renal failure develop within 36-72 hours post ingestion.

PHYSICAL EXAM FINDINGS

- Unremarkable if ingestion was recent. Initial signs of vomiting, anorexia, and lethargy may appear to resolve without treatment.
- Signs progressing to oliguria and anuria, dehydration, lethargy, and vomiting. Some cats also show vocalization, adipsia, drooling, tremors, ataxia, weakness, and seizures.
- Evidence of pancreatitis may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Lilies have large, showy, funnel-shaped flowers. The plants grow from bulbs and have erect stems 30-250 cm high. Lilies are frequently included in bouquets and floral arrangements. Daylilies are often grown in gardens.
- Peak incidence during Christmas and Easter holidays, as lilies are popular holiday ornamentals.

Mechanism of Toxicosis:

- Intoxication is via ingestion. A single bite, or even exposure to pollen only, can cause the clinical syndrome.
- Mechanism of action is unknown. Toxin is believed to be a water-soluble fraction. All parts of the plant are considered toxic, including pollen. Flowers contain the highest amount of toxin.

- Affected cats develop acute renal failure due to degeneration and necrosis of the proximal renal tubules. Sloughing of necrotic tubular epithelial cells results in tubular blockage and anuria.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on history of vomiting in a cat with either known exposure to lilies or unexplained/unexpected elevations in serum renal values (or both). In absence of history of exposure, other potential causes for acute renal failure must be ruled out, but empirical treatment should be initiated prophylactically during diagnostic testing because of the potentially severe consequences of unchecked toxicosis. There is no specific confirmatory test for in-clinic use.

DIFFERENTIAL DIAGNOSIS

Toxicologic:

- Ethylene glycol
- Nonsteroidal antiinflammatory drugs
- Cholecalciferol or calcipotriene
- Oxalic acid
- Nephrotoxic antibiotics

Nontoxicologic, spontaneous:

- Acute glomerulonephritis (e.g., feline infectious peritonitis, autoimmune disease related)
- Renal thromboembolism
- Acute-on-chronic renal failure (e.g., pyelonephritis, renal lymphoma, polycystic renal disease)

INITIAL DATABASE

- Serum biochemistry panel: azotemia (blood urea nitrogen [BUN] >34 mg/dL; creatinine is often disproportionately elevated), hyperkalemia, and hyperphosphatemia are common. Occasionally, hypercalcemia, elevated pancreatic enzymes.
- Urinalysis: isosthenuria, epithelial granular casts, and glucosuria in the absence of hyperglycemia are typical findings.

ADVANCED OR CONFIRMATORY TESTING

- There is no definitive confirmatory test for lily toxicosis.
- Histologically, the renal lesion generally includes acute necrosis of proximal convoluted tubules. Renal tubular mineralization may be present.
- Pancreatic acinar cells may show degeneration.
- Ultrasound can be used for measuring renal size and cortical thickness and to rule out other causes of acute renal failure.
- Renal biopsy may help determine extent of renal damage and prognosis (rarely done, since history and exclusion of other causes are usually sufficient).

TREATMENT

TREATMENT OVERVIEW

When cats are presented prior to the onset of clinical signs, the aim of treatment is early decontamination (induction of emesis, ideally within 2 hours, and administration of activated charcoal) and to prevent the development of acute renal failure. Such treatment, including therapy aimed at avoiding acute renal failure, is appropriate in all cases including exposures that are suspected but unconfirmed, because unchecked, toxicosis may have devastating and irreversible results

ACUTE GENERAL TREATMENT

- Decontamination of patient (no clinical signs):
  - Emesis: in cats with recent ingestion (within a few hours) and not showing clinical signs, induce vomiting (see p. 1364), and give activated charcoal 1-4 g/kg PO. Protect airway with cuffed endotracheal tube if patient is unconscious.
- Prevent/slow development of renal failure (if cat is suspected or known to have ingested lilies in the preceding 2 days).

Important: Treatment is implemented regardless of whether or not signs are present:
    - Intravenous fluids:
        - Intravenous fluid diuresis for a minimum of 48-72 hours at two to three times maintenance fluids plus volume deficit (adjust based on hydration, fluid volume tolerance, and response to treatment)
        - Cats with normal renal values throughout diuresis may be weaned off fluids after 48 hours.
        - In cats with elevations in renal values, IV fluids should be continued until azotemia resolves. In some cases, this may mean days to weeks of treatment.
    - Monitor urine output in azotemic patients. If oliguria is present (urine production < 0.25 mL/kg/h), furosemide (2.2-4.4 mg/kg IV q 8-12 h) may increase urine output.
    - Treat hyperkalemia if present (see p. 556).
- Supportive care:
    - Persistent nausea: if gastrointestinal obstruction has been ruled out, consider maropitant, 1 mg/kg SQ q 24 h; dolasetron mesylate, 0.6 mg/ kg IV q 24 h; or metoclopramide, 0.1-0.5 mg/kg SQ q 6-12 h.
    - Abdominal pain may be managed with opiates such as butorphanol, 0.1-0.2 mg/kg IV.
    - Peritoneal dialysis (see online chapter: Peritoneal Dialysis) or hemodialysis (see p. 1286) possibly oriented toward renal transplantation if response is positive; can be considered if anuric renal failure develops.
    - Control seizures with diazepam (0.5-2 mg/kg IV PRN).

RECOMMENDED MONITORING

- Serum biochemistry profile baseline, 24, 48, and 72 hours (especially electrolytes and renal values). Recheck BUN and creatinine daily during clinical syndrome or for 72 hours if no abnormalities are seen.
- Urinalysis (baseline, 24, 48, 72 hours): ensure isosthenuria/hyposthenuria as sign of adequate fluid diuresis.
- If azotemia develops, monitor urine output.
- Monitor for fluid overload: respiratory character, onset of gallop sound on cardiac auscultation, central venous pressure if possible.

PROGNOSIS AND OUTCOME

- If treatment is initiated within 18 hours of ingestion, before onset of renal failure, prognosis is good.
- Prognosis after renal failure has developed is guarded to poor.

PEARLS & CONSIDERATIONS

COMMENTS

- Even when vomiting is mild and self-limiting, the presence of plant material in vomitus makes it critical to initiate treatment, including intravenous fluids, to avoid subsequent renal failure.
- Lily toxicosis is high on the differential list for any cat with acute renal failure and an extremely high serum creatinine level.
- Neither lily-of-the-valley *(Convallaria majalis)* nor peace lily *(Spathiphyllum* spp.) belong to the *Lilium* or *Hemerocallis* genera. They are not true lilies and do not cause acute renal damage in cats.

TECHNICIAN TIP

Some florists believe that plucking the stamens out of lily flowers renders them nontoxic, which is wrong. Therefore, presence of any part of the lily plant in vomitus should be considered evidence of possible toxic exposure.

PREVENTION

Do not keep any *Lilium* or *Hemerocallis* species in the cat's environment

CLIENT EDUCATION

Clients should make sure plants are safe before bringing them into a cat's environment.

Licking and Barbering Behavioral Disorders

BASIC INFORMATION

DEFINITION

Self-directed, repetitive, apparently purposeless behaviors that may derive from otherwise normal processes such as grooming or eating but are abnormal in that they are excessive in duration, frequency, or intensity in the context in which they are performed.

SYNONYMS

Acral lick granuloma (ALG; see p. 22), feline hyperesthesia syndrome, obsessive-compulsive disorders (OCD; see p. 775).

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Age of onset may overlap with social maturity (dogs 12-36 months of age, cats 24-48 months of age).
- Excessive licking has been reported in all ages and sexes.

GENETICS & BREED DISPOSITION

- Some lines of some larger canine breeds may be more predisposed to acral lick granuloma (e.g., Doberman, dalmatian, Labrador retriever, golden retriever).
- Asian breeds of cats such as the Siamese appear to be more predisposed to OCDs such as wool eating.

RISK FACTORS: Pain, stress, or anxiety; injury to area that changes sensory function

GEOGRAPHY AND SEASONALITY: Hot humid weather has been associated with acute moist dermatitis, which in turn has been speculated to be associated with acral lick granulomas.

ASSOCIATED CONDITIONS & DISORDERS: Hypothyroidism in dogs, hyperthyroidism in cats, allergies, bacterial or fungal infections, nerve damage. Coexisting anxiety-related conditions are common.

CLINICAL PRESENTATION

DISEASES FORMS/SUBTYPES

- Feline: hyperesthesia, overgrooming, self-mutilation, and psychogenic alopecia
- Canine: acral lick dermatitis/granuloma (ALD/G)

HISTORY, CHIEF COMPLAINT: Persistent chewing, barbering, plucking, or licking of the skin and hair

PHYSICAL EXAM FINDINGS

- Hair loss and discoloration occur only on the parts of the body that can be reached by the teeth and tongue. In cats, it is especially evident around the sides and rump, back legs, and inguinal region; other areas may have normal hair coat (e.g., head and back of neck). Alopecia is usually patchy and asymmetric. Skin may look normal.
- Feline overgrooming may become true self-mutilation with cutaneous ulceration. Secondary bacterial infections may then occur.
- In dogs, ALG lesions appear as thickened oval plaques, often with secondary bacterial and/or fungal infection.

ETIOLOGY AND PATHOPHYSIOLOGY

- Normal adult cats spend about 30%-50% of their time awake grooming.
- Grooming behaviors such as licking and chewing serve many purposes, including cleaning, removal of parasites, thermoregulation, and potentially, alleviation of stress (e.g., after punishment, intercat aggression).
- Hair can be removed by plucking, barbering, or just by licking and excoriation. The plucked hair has evidence of shearing.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on a history of licking, chewing, or barbering excessively that has led to skin lesions that have no physical underlying cause. Trichography is an easy way to confirm that alopecia is due to hair plucking/removal, not hair spontaneously falling out.

DIFFERENTIAL DIAGNOSIS

Pruritic skin disease:

- External parasites
- Bacterial and/or yeast dermatitis
- Food allergy dermatitis
- Endocrine dermatopathies (hair loss symmetric)
- Pain associated with any condition including trauma, infection, anal sac disorders, or feline lower urinary tract signs/disease
- Behavioral response to environmental changes, such as moving, a new baby or spouse, separation from owner, too many cats in the household or area, presence of new cats in the area, changes in the social and physical environment, punishment from the owner, and lack of stimulation

INITIAL DATABASE

- Behavioral history
- CBC, serum biochemistry profile, urinalysis; serum thyroxine level in adults (hyper-/hypothyroidism): to rule out systemic disorders and prior to medication initiation
- Dermatologic examination, including scraping and culture (see p. 1248), to assess causes such as atopy, external parasites, food allergy
- Microscopic examination of plucked hair (trichogram) for evidence of shearing (broken hair shafts). Hair that is lost due to endocrine conditions may have visible telogen bulbs.

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to minimize or resolve the licking, chewing, or barbering of the hair and skin by removing or minimizing the underlying cause of the anxiety, and to treat any lesions and pruritus.

ACUTE GENERAL TREATMENT

- Treatment of any concurrent or underlying medical problem, such as elimination of fleas, or resolution of food allergy (see pp. 397 , p. 400, p. 402)
- Remove or minimize the cause of the anxiety if possible.
- Provide a regular predictable routine, such as feed and play at a set time each day.

CHRONIC TREATMENT

Treatment involves altering the neurochemical as well as the physical environment.

- Anxiolytic medication has also proved useful in some cases:
  - Tricyclic antidepressants (TCAs):
    - Cats:
      - Amitriptyline (0.5-1 mg kg PO q 12-24 h; average of 5-10 mg/cat PO q 24 h; start at the lowest dose and increase after 10 days if no response): *or*
      - Clomipramine (0.5 mg/kg PO q 24 h); *or*
      - Doxepin (0.5-1 mg/kg PO q 12-24 h)
    - Dogs:
      - Amitriptyline (1-2 mg/kg PO q 12 h); *or*
      - Clomipramine 1-2 mg/kg PO q 12 h for 2 weeks, then 3 mg/kg PO q 12 h; *or*
      - Doxepin 3-5 mg/kg PO q 12-24 h

- Selective serotonin reuptake inhibitors (SSRIs):
  - Cats:
    - Fluoxetine (0.5 mg/ kg PO q 24 h); *or*
    - Paroxetine (2.5 mg/cat PO q 24 h)
  - Dogs:
    - Fluoxetine (1 mg/kg PO q 12-24 h)
- Benzodiazepines such as diazepam (0.2-0.4 mg/kg PO q 12 h, average of 1-2 mg/cat PO q 12 h) or oxazepam (0.2-0.5 mg/kg PO q 12-24 h) are effective in some cats

- Medication may be necessary for a prolonged period (up to 6-12 months) and for some animals treatment may be lifelong.
- When long-term control of signs is successful, gradual withdrawal of medication may be attempted under veterinary supervision.

BEHAVIOR/EXERCISE

- Punishment is not effective in changing behavior. It serves to further increase the anxiety as well as impede learning of nonanxious behavior.
- Increasing physical and mental exercise may help decrease stress. Environmental enrichment may provide additional stimulation.

DRUG INTERACTIONS

TCAs and SSRIs should not be used concurrently with monoamine oxidase (MAO) inhibitors such as those present in medications or some flea and tick collars.

POSSIBLE COMPLICATIONS

May progress or coexist with other anxiety-related disorders such as panic disorders. Referral to a veterinary behaviorist should be considered.

RECOMMENDED MONITORING

- Serum biochemistry profile every 6-12 months or as needed based on clinical signs. Response to treatment should be monitored every 4-6 weeks.
- If long-term medication is needed, repeat blood work is recommended.

PROGNOSIS AND OUTCOME 

Prognosis is variable and depends on owner commitment, success in determining underlying cause, and management of the underlying problem. Early treatment leads to the best prognosis.

PEARLS & CONSIDERATIONS 

COMMENTS

Avoid punishing the behavior; doing so may increase the anxiety and arousal and exacerbate the undesirable behavior.

PREVENTION

Early intervention and redirection of concerning behaviors may be useful for cats and dogs without a genetic predisposition for the development of such conditions. Research has shown that even in cats with familial OCD, the specific behaviors involved do not substantially manifest until some social stressor (e.g., moving house) is involved. Clients who anticipate such stressors should be given guidance on prevention strategies.

TECHNICIAN TIPS

Educating clients about normal versus abnormal grooming behaviors in animals as well as early intervention can be very useful.

CLIENT EDUCATION

Clients should record the occurrence of these behaviors to assist in monitoring and managing triggers. Lifelong management and medication may be necessary.

EDITOR: KAREN OVERALL

Leukemias, Chronic

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Chronic leukemias are neoplastic diseases characterized by clonal proliferation of malignant mature hematopoietic cells in the bone marrow and blood. They are categorized as lymphoid or myeloid.
- Chronic lymphocytic leukemia (CLL) involves the proliferation of mature lymphocytes and is clinically indolent, similar to small lymphocytic lymphoma.
- Chronic myeloid (myelogenous) leukemias (CML) involve the proliferation of myeloid cells and include myeloid, monocytic, myelomonocytic, basophilic, mastocytic, megakaryocytic, and erythrocytic leukemias.

EPIDEMIOLOGY

Chronic leukemias are rare in dogs and cats. CMLs are extremely rare.

SPECIES, AGE, SEX: Typically older dogs and cats but can occur at any age

GENETICS & BREED PREDISPOSITION: Mast cell leukemia (MCL): associated with derangement of KIT receptor or its ligand (stem cell factor) in dogs and humans

RISK FACTORS: In contrast to acute lymphocytic leukemia, most cats with CLL are not infected with feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV).

ASSOCIATED CONDITIONS & DISORDERS

- CLL: monoclonal gammopathy, hyperviscosity syndrome
- CML: myelofibrosis
- Chronic basophilic leukemia (CBL) and MCL: hyperhistaminemia resulting in urticarial rashes and gastrointestinal (GI) signs/ulceration
- PV: hyperviscosity syndrome

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Chronic lymphocytic leukemia:
  - T-cell: 70%-90% canine CLL
  - B-Cell: 12%-30% canine CLL
  - Granular lymphocyte CLL (GL CLL; cytotoxic T cells or natural killer cells): 55%-80% of canine CLL; suspected to originate in the spleen
- CML: chronic myeloid leukemias
  - CNL: chronic neutrophilic leukemia
  - CMoL: chronic monocytic leukemia
  - CMML (or CMMoL): chronic myelomonocytic leukemia
  - CEL: chronic eosinophilic leukemia
  - CBL: chronic basophilic leukemia
  - MCL: mast cell leukemia
  - PV: primary erythrocytosis (polycythemia vera)
  - ET: megakaryocytic myelosis (essential thrombocythemia)

HISTORY, CHIEF COMPLAINT

- Insidious onset of increased peripheral blood count of affected cell line noted as incidental finding.
- Initially no clinical signs
- Later, nonspecific signs (lethargy, loss of appetite, weight loss) and signs associated with cytopenias (weakness, hemorrhage, infection)
- PV (rarely CLL) can cause neurologic signs (seizures, behavior changes, blindness, ataxia) due to hyperviscosity. Polyuria/polydipsia also possible.

- CEL in cats usually results in gastrointestinal (GI) signs due to infiltration.
- Some forms of CML frequently cause clinical signs due to production of cytokines or other factors (e.g., CBL, MCL: GI signs due to histamine).

PHYSICAL EXAM FINDINGS

- Initially, normal physical examination
- Hepatomegaly/splenomegaly common as disease progresses
- Lymphadenomegaly frequent in dogs with CLL
- Brick-red mucous membranes and neurologic signs possible with PV
- Palpable GI wall thickening possible with CEL and MCL
- Fundic examination: large, tortuous retinal vessels and retinal hemorrhages possible with PV

ETIOLOGY AND PATHOPHYSIOLOGY

- Chronic leukemias arise from neoplastic transformation of a pluripotent stem cell in the marrow or spleen.
- Progression is insidious, with gradual increases in marrow and peripheral blood cell counts of the leukemic cell type. Bone marrow infiltration may eventually result in myelophthisis (crowding of normal cells, changes in the marrow microenvironment, and secretion of suppressor factors) or myelofibrosis. These conditions result in anemia, neutropenia, and thrombocytopenia.
- Hepatic and splenic infiltration with leukemic cells is gradual, resulting in organomegaly, abdominal distension, and loss of appetite. Organ infiltration and dysfunction are possible in chronic stages or with transformation to acute leukemias.
- Transformation into a blast phase (acute leukemias) may occur in the terminal stages of chronic leukemias.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of chronic leukemias has traditionally been based on detection of a high count of a cell line on CBC and bone marrow cytologic findings. Recently, flow cytometric immunophenotyping of cells in blood or bone marrow has become readily available for diagnosing leukemias in veterinary patients. This technique is used in combination with cytologic exam and allows more accurate identification of cell type and count, primarily for CLL and acute leukemias.

DIFFERENTIAL DIAGNOSIS

- Based on the type of cell(s) with elevated counts on CBC and bone marrow cytology
- Lymphocytes:
  - CLL
  - Small cell or large granular cell lymphoma
  - Ehrlichiosis
  - Viral infection (feline leukemia virus, feline herpes virus type 1)
  - Chronic antigenic stimulation (e.g., inflammatory bowel disease, cholangiohepatitis)
  - Recent vaccination
  - Stress/epinephrine in cats (redistribution of lymphocytes, typically <20,000 cells/µL)
  - Pure red cell aplasia
  - Immune-mediated hemolytic anemia
  - Hypoadrenocorticism
  - Feline hyperthyroidism
  - Thymoma
- Neutrophils:
  - CML: CNL
  - Infection (bacterial, fungal, protozoal)
  - Inflammation (immune-mediated, tissue trauma, neoplasia)
  - Leukemoid reaction (regenerative bone marrow with IMHA or hemorrhage)
  - Rebound following myelosuppressive drugs or chemical or viral insult to the bone marrow
  - Paraneoplastic syndrome (lymphoma, others)
  - Demargination
- Monocytes:
  - CMoL
  - CMML
  - Chronic infection/inflammation
  - Granulomatous disease
- Eosinophils:

    - CEL
    - Hypereosinophilic syndrome (HES; difficult to distinguish from CEL; CEL may be associated with an increase in blast cells)
    - Parasites (gastrointestinal, dirofilariasis, other)
    - Eosinophilic granuloma complex
    - Mast cell neoplasia
    - Feline asthma
    - Eosinophilic enteritis
    - Allergic diseases
    - Paraneoplastic syndrome
    - Hypoadrenocorticism
- Basophils:
    - CBL
    - Mast cell neoplasia
    - Dirofilariasis
- Mast cells:
    - MCL
    - Systemic mast cell tumor
    - Allergies
    - Dermatitis
    - Parasites
    - Parvoviral infection (dogs)
    - Regenerative anemias
    - Trauma
- Platelets:
    - Essential thrombocytosis
    - Hyperadrenocorticism
    - Iron deficiency
    - Postsplenectomy
    - Chronic inflammatory disorders
    - Acute infection
- Erythrocytes:
    - Relative erythrocytosis:
        - Dehydration
        - Diuretics, cardiac medications
        - Breed variation (sight hounds)
    - Absolute erythrocytosis:
        - PV
        - Chronic hypoxemia (right-to-left cardiac shunts, chronic respiratory disease, high altitude)
        - Paraneoplastic production of erythropoietin (renal tumors, others)
        - Splenic contraction

INITIAL DATABASE

- Laboratory tests:
    - CBC and blood smear reveal a high count of the leukemic cell type. Cell counts can be very high (hundreds of thousands and higher); for PV, PCV typically ranges from 60% to ≥80%. Both mature and immature forms of affected cell line may be present. Cytopenias are not generally observed until leukemic cell counts are very high. Mild anemia is common with CLL and CML. CLL is associated with selective suppression of erythropoiesis.
    - Serum biochemistry profile and urinalysis to evaluate overall health and look for paraneoplastic syndromes
    - FeLV/FIV ELISA for cats; typically will be negative
    - Erythropoietin level should be low with erythrocytosis, if not, supports PV.
- Bone marrow cytology (see p. 1212; if unable to obtain diagnostic sample, core biopsy is indicated):
    - Infiltration of bone marrow with leukemic cell type and its precursors is diagnostic.
- Cytologic evaluation of enlarged peripheral lymph nodes may reveal leukemic cells.
- Imaging for staging and to evaluate overall health and identify concurrent abnormalities:
    - Thoracic radiography
    - Abdominal ultrasonography

ADVANCED OR CONFIRMATORY TESTING

- Chronic leukemias often can be diagnosed by cell morphology. Additional tests improve the accuracy of determining cell type in CLL (flow cytometric immunophenotyping and PCR for antigen receptor rearrangement [PARR]).
- For diagnosing CLL, fresh blood in EDTA should be submitted for flow cytometry or blood or bone marrow smears should be

submitted for PARR. Flow cytometry will provide cell counts and phenotype (B cell or T cell). PARR will confirm clonality and provide phenotype. Submission information: http://www.cvmbs.colostate.edu/mip/people/Faculty/clinimmuno-submit-form.pdf (Colorado State University) and http://www.cvm.ncsu.edu/dphp/labs/documents/ncsu_flow_cytometry_sub_form_052010.pdf (North Carolina State University). At this time, use of these tests for CML is not routine in veterinary medicine.

TREATMENT

TREATMENT OVERVIEW

Goals are to eradicate leukemic cells with chemotherapy and provide symptomatic care as needed.

ACUTE GENERAL TREATMENT

- Supportive care may or may not be necessary with chronic leukemias.
  - Broad-spectrum antibiotic therapy for treating/preventing secondary infections if severe neutropenia (see p. 188). This is uncommon in chronic leukemias. Cats generally do not require prophylactic antibiotic therapy for neutropenia.
  - Intravenous fluid therapy for patients with infection, fever, or decreased appetite
  - Situations that might result in hemorrhage (e.g., jugular vein venipuncture or catheterization) should be avoided if severe thrombocytopenia or hyperviscosity syndrome is present.
  - Transfusions if needed (see p. 1347); this is uncommon.
  - Phlebotomy for PV or plasmapheresis may be considered for hyperviscosity syndrome.
  - Nutritional support for patients with decreased appetite
- Chemotherapeutic agents are used for eradicating leukemia cells. Response is slower and more durable than for acute leukemias. Special handling requirements and potentially severe adverse effects exist for these drugs. Consultation with or referral to a veterinary oncologist is recommended to determine the best protocol.
  - CLL: Treatment recommended if patients have clinical signs, cytopenias, or lymphocyte counts > 60,000/mcL. Treat with prednisone (dogs: 30-40 mg/m^2 PO once daily for 7 days and then every other day; cats: prednisolone, 5-10 mg daily) and chlorambucil (6-8 mg/m^2 PO every other day; cats 2 mg PO every 2nd or 3rd day depending on size). Some protocols add vincristine (0.7 mg/m^2 IV for dogs) during the first 1-4 weeks. When these drugs fail, other drugs for lymphoma may be used.
  - CML: Treatment depends on diagnosis. Because these are exceptionally rare diseases, referral to/consultation with a veterinary oncologist is recommended.
    - PV, CML, and CEL: treated with hydroxyurea (dogs: 30 mg/kg PO once daily for 7-10 days, then 15 mg/kg PO once daily; cats: 125 mg PO q 3-4 days. Dosages are adjusted long term based on response and toxicity.). It is important to know the potential side effects of hydroxyurea before using this drug. PV may be able to be managed with phlebotomy and fluid replacement initially. Busulfan has also been used in the treatment of CML and ET, but a recommended dosage has not been established.
    - Imatinib mesylate is a tyrosine kinase inhibitor used in people with chronic myelogenous leukemia. Use in veterinary patients has been limited by cost and hepatotoxicity in dogs. A receptor tyrosine kinase inhibitor (toceranib) is currently FDA approved for dogs, but at this time it is unknown whether CML in dogs has the same genetic abnormality as the disease in humans, so the role of this drug is not known. Consultation with a veterinary oncologist is recommended.

CHRONIC TREATMENT

Patients responding to treatment typically receive chemotherapy for the rest of their lives or until they develop bone marrow toxicity.

POSSIBLE COMPLICATIONS

- Myelosuppression: neutropenia, thrombocytopenia
- Chronic bone marrow injury
- Hydroxyurea can cause methemoglobinemia in cats. It can also cause anemia and skin/hair/nail changes.
- Gastrointestinal toxicity
- Rare hepatic, renal, pulmonary, or neurologic toxicity

RECOMMENDED MONITORING

- Will depend on diagnosis and how severely patient is affected.
- Physical examinations: weekly or more frequently if needed in induction period. Monthly to every other month once on chronic maintenance therapy.
- CBC: to monitor myelosuppression and remission status. Performed weekly or more frequently if needed during the induction period. Monthly to every other month once on chronic maintenance therapy, must monitor for chronic bone marrow injury and

relapse.
- Serum biochemistry profile, urinalysis (free catch if risk of hemorrhage): 1 month after starting therapy and then q 3-4 months to monitor overall health, paraneoplastic syndromes, and toxicity; more frequently if indicated.

PROGNOSIS AND OUTCOME

In general, the prognosis for chronic leukemias is better than acute leukemias because of the indolent nature of chronic leukemias. Dogs and cats with CLL can enjoy long-term survival. There is less information for CML.

- CLL: progresses slowly; responsive to chemotherapy; survival times of 1-3 years expected for dogs and suspected to be similar for cats. If CLL transforms into lymphoma/acute leukemia (as indicated by recurrence of clinical signs and/or appearance of blast cells on a blood smear), the prognosis is poor.
- CML: depends on type. There is little or no information describing the prognosis for some of these conditions.
    - CML/CBL: some dogs may live 1 year or more with treatment.
    - PV: survival times of >1 to >6 years reported.
    - CEL: in cats, not very responsive to treatment. Survival times of a few months. Unclear if dogs develop CEL, but if they do, it may respond to prednisone.
    - ET: Early attempts at treatment did not yield responses. More recently a dog experienced long-term control (>500 days) with busulfan.

PEARLS & CONSIDERATIONS

COMMENTS

- Chronic leukemias have a slow onset and often progress slowly. Patients are initially clinically normal and then show nonspecific signs.
- Diagnosis is based on identifying proliferating mature hematopoietic cells in blood and bone marrow. Use of flow cytometry for immunophenotyping is becoming more routine.
- Patients with chronic leukemias can enjoy long survival times.

TECHNICIAN TIPS

- Patients with chronic leukemias often undergo chronic chemotherapy.
- Monitoring of CBCs for chronic bone marrow injury and relapse is important.
- Owners should be educated on how to monitor their pet and precautions to protect themselves from chronic exposure to chemotherapy.

Leukemias, Acute

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Acute leukemias are uncommon neoplastic diseases characterized by clonal proliferation of malignant immature progenitor cells in the bone marrow and blood and are broadly categorized as lymphoid or nonlymphoid (myeloid). The specific diagnosis depends on the cell of origin.
- Acute lymphoblastic leukemias (ALL) involve the proliferation of lymphoblasts and prolymphocytes.
- Acute myeloid leukemias (AML), involve the proliferation of myeloid cells and include myeloid, monocytic, megakaryocytic, and erythrocytic leukemias. Historically AML and myelodysplastic syndromes in veterinary patients have been classified according to the Animal Leukemia Study Group modified version of the French-American-British system used in humans.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young cats and dogs (median 4-5 years) are more commonly affected with acute leukemias. Recent studies indicate older median age at incidence (7-9 years) for dogs with ALL.
- ALL: uncommon. Because it is difficult to distinguish ALL from stage V lymphoma, the percentage of leukemic dogs with ALL is unclear but reported to be 25%-30%. When considering only acute leukemic dogs, 40%-60% have ALL. Golden retrievers are overrepresented in cases of T-cell lymphoproliferative disorders. Specifically considering ALL, purebred dogs, in particular large breeds, predominate; German shepherd dogs and retrievers.
- AML: rare. In studies of leukemic dogs, 15%-40% have AML. Considering acute leukemic dogs only, 40%-60% have AML. The reported frequencies of canine AML types vary; M1 has been cited as most common, but a new study of 33 dogs with AML described 10 cases of M0, 3 M1, 5 M2, 12 M4, 2 M5, and 1 M7 (no M3 or M6). In 99 cats, 21% had M1, M2 was most common at 32%, and M6 was seen in 29%. Less common AMLs were M4 in 5%, M5 in 7%, and AUL in 8%. There is a possible male predilection in dogs and cats but no known breed predispositions.

RISK FACTORS: FeLV infection: 60%-80% of cats with ALL are FeLV positive and ≥90% of cats with AML are FeLV positive. Some patients with myelodysplastic syndromes will progress to AML.

ASSOCIATED CONDITIONS & DISORDERS

- ALL in dogs: paraneoplastic hypercalcemia
- AML in cats: myelofibrosis, hypercalcemia, glomerulonephritis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute lymphoblastic leukemias:
  - B-cell origin: most common type in dogs
  - T-cell origin: most common type in cats
- Acute myeloid leukemias (classified based on bone marrow nucleated cell population):
  - Acute undifferentiated leukemia (AUL): ≥30% of bone marrow nucleated cells are blasts of uncertain lineage.
  - Myeloblastic leukemia without maturation (M1): ≥30% of marrow nucleated cells are myeloblasts; <10% of nonerythroid cells are maturing granulocytes.
  - Myeloblastic leukemia with maturation (M2): ≥30% of marrow nucleated cells are myeloblasts; >10% of nonerythroid cells are maturing granulocytes.
  - Promyelocytic leukemia (M3): ≥30% of marrow nucleated cells are myeloblasts; >10% of nonerythroid cells are maturing granulocytes, predominantly atypical promyelocytes. Has not been reported in animals.
  - Acute myelomonocytic leukemia (M4): ≥30% of marrow nucleated cells are myeloblasts and monoblasts; differentiated granulocytes and monocytes each represent >20% of nonerythroid cells.
  - Monoblastic/monocytic leukemia (M5): ≥30% of marrow nucleated cells are monoblasts or promonocytes.
  - Erythroleukemia (M6): ≥50% of marrow nucleated cells are erythroid precursors, and ≥30% of nonerythroid cells are myeloblasts and monoblasts, or ≥30% of bone marrow nucleated cells are rubriblasts, myeloblasts, and monoblasts.
  - Erythremic myelosis (M6-Er): ≥50% of marrow nucleated cells are erythroid precursors; ≥30% are erythroblasts.

- Megakaryoblastic leukemia (M7): ≥30% of marrow nucleated cells are megakaryoblasts.

HISTORY, CHIEF COMPLAINT

- Acute onset of nonspecific signs such as lethargy, weakness, loss of appetite, and weight loss
- Hemorrhage (e.g., epistaxis or petechiae) may be noted.
- Lameness due to bone pain is possible.

PHYSICAL EXAM FINDINGS

- Lethargy, weakness, pallor, weight loss, and dehydration are common.
- Fever due to secondary infection
- Tachypnea/dyspnea and tachycardia may be noted secondary to anemia.
- Hepatomegaly and splenomegaly are common.
- Lymphadenomegaly is often mild.
- Evidence of hemorrhage secondary to thrombocytopenia (petechiae, ecchymoses, epistaxis, intestinal bleeding)
- Ocular lesions (hyphema, uveitis, chorioretinitis, retinal detachment, chemosis, and conjunctivitis)

ETIOLOGY AND PATHOPHYSIOLOGY

- Acute leukemias are primary diseases of the bone marrow. As leukemic cells infiltrate the marrow, they crowd normal cells, change the marrow microenvironment, and secrete suppressor factors (myelophthisis). Consequently, normal hematopoiesis decreases, causing anemia, neutropenia, and thrombocytopenia. Cytopenias may result in weakness, secondary infections, and hemorrhage.
- Hepatic and splenic infiltration with leukemic cells is common, resulting in organomegaly, abdominal distention, and contributing to loss of appetite. Other sites may be involved, including lymph nodes, nervous system, kidneys, and gastrointestinal tract. Organ infiltration causes signs referable to failure of affected organs or nonspecific signs such as malaise and gastrointestinal disturbances.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is made by identification of abnormal numbers of blast cells on peripheral blood or bone marrow smears. Morphologic differentiation of acute leukemias and stage V lymphoma is limited. Recently, flow cytometric immunophenotyping (FCI) and PCR for antigen receptor rearrangements (PARR) have become routinely available for definitive diagnosis and classification of acute leukemias.

DIFFERENTIAL DIAGNOSIS

- Stage V lymphoma
- Ehrlichiosis

INITIAL DATABASE

- Laboratory tests:
  - CBC and peripheral blood smear may reveal a leukocytosis with circulating blasts and cytopenias of other cells. Nonregenerative anemia and thrombocytopenia are common (nearly 100% and 90% of canine patients, respectively) and may be severe. Neutropenia occurs in 60%-80% of dogs and neutrophilia in 10%-20%. Aleukemic or subleukemic patients have normal or low white blood cell counts with no or some circulating blasts, respectively.
  - Serum chemistry profile and urinalysis evaluate overall health and identify paraneoplastic syndromes.
  - FeLV/feline immunodeficiency virus ELISA test for all cats. Consider PCR test for FeLV using bone marrow (submit marrow sample in EDTA).
  - Rickettsial titers are indicated if in endemic area, history of tick exposure, or other compatible features.
- Bone marrow cytologic analysis (if unable to obtain a diagnostic sample, a core biopsy is indicated):
  - If the blast cell count is ≥30% of all nucleated cells in the bone marrow, a diagnosis of acute leukemia can be made.
  - Fine-needle aspiration and cytology of enlarged peripheral lymph nodes or organs frequently reveals infiltration with blasts.
- Imaging is performed to stage patients with leukemias and evaluate overall health:
  - Thoracic radiography
  - Abdominal ultrasonography

ADVANCED OR CONFIRMATORY TESTING

- Flow cytometric immunophenotyping is now routine for determining the cell lineage of acute leukemias. Morphologic appearance is not as accurate in distinguishing ALL from AML. Fresh blood in EDTA should be submitted for flow cytometry if there is a high number of circulating blasts; blood or bone marrow smears should be submitted for PARR in cases with rare abnormal cells. Flow cytometry provides cell counts, identification, and classification of leukemias. PARR identifies and confirms clonality of abnormal cells. Information for submission of samples for flow cytometry or PARR to the Colorado State University Veterinary Diagnostic Laboratory can be found at http://www.cvmbs.colostate.edu/mip/people/Faculty/clinimmuno-submit-form.pdf and for the North Carolina State University College of Veterinary Medicine Clinical Immunology Lab can be found at http://www.cvm.ncsu.edu/dphp/labs/documents/ncsu_flow_cytometry_sub_form_052010.pdf
- Cytochemical, immunocytochemical, or immunohistochemical staining are used by some centers to distinguish lymphoid from nonlymphoid leukemias and allow classification of AMLs.
- Acute leukemias are currently being examined for molecular abnormalities that might be prognostic or serve as targets for novel therapies. Mutations in RAS, FLT3, and C-KIT have been identified.

TREATMENT

TREATMENT OVERVIEW

Goals are to eradicate leukemic cells with chemotherapy and support the patient with transfusions and other measures until normal hematopoiesis resumes. Patients with ALL can respond to chemotherapy for short periods of time. AML are less responsive.

ACUTE GENERAL TREATMENT

- Intensive supportive care is important in patients with acute leukemias:
  - Broad-spectrum antibiotic therapy for treating/preventing secondary infections (see p. 188)
  - Intravenous fluid therapy for patients with infection, fever, or decreased appetite
  - Situations that might result in hemorrhage (e.g., jugular vein venipuncture or catheterization) should be avoided if severe thrombocytopenia is present.
  - Transfusions as needed (see p. 1347)
  - Nutritional support for patients with decreased appetite
- Chemotherapeutic agents are used for eradicating leukemia cells (induce remission). Clinically significant myelosuppression is expected because of myelophthisis. Hospitalization for supportive care during the induction period is indicated. Special handling requirements and potentially severe or life-threatening adverse patient effects exist with these chemotherapeutic drugs; these concerns and rapid evolution of protocols warrant consultation with/referral to an oncologist.
  - ALL: treatment is generally with standard chemotherapy protocols for lymphoma (see p. 674). Agents include prednisone, vincristine, cyclophosphamide, doxorubicin, and L-asparaginase.
  - AML: Chemotherapy protocols generally include cytosine arabinoside and doxorubicin. Agents such as 6-thioguanine, mitoxantrone, cyclophosphamide, busulfan, melphalan, vincristine, vinblastine, prednisone, and L-asparaginase have also been used. To date, results with chemotherapy have been disappointing.
  - Future treatments may include targeted therapies and bone marrow transplant.

CHRONIC TREATMENT

Patients responding to treatment will likely receive chemotherapy for the rest of their lives.

POSSIBLE COMPLICATIONS

- Myelosuppression:
  - Neutropenia: sepsis
  - Thrombocytopenia: hemorrhage
  - Anemia requiring transfusion
- Gastrointestinal toxicity: vomiting, diarrhea, lethargy, loss of appetite

RECOMMENDED MONITORING

- Physical examinations and CBC: weekly to every other week, more frequently if needed during the induction period; to monitor remission status and myelosuppression due to therapy
- Serum chemistry profile: every 2 months to monitor renal and liver status, electrolytes, and critical parameters; more frequently if indicated

PROGNOSIS AND OUTCOME

In general, the prognosis for acute leukemias is poor. Because many patients are euthanized at diagnosis and acute leukemias are relatively uncommon, there is limited information available regarding treatment outcomes. Most patients are clinically ill at presentation and if left untreated or given supportive care only, survival times are generally less than 2 to 4 weeks.

- CD34 expression: a stem cell marker; in dogs, expression of this antigen supports a diagnosis of acute leukemia and is associated with poor prognosis (median survival 16 days, range 3-128).
- ALL: for cats, a remission rate of 65% for a median of 7 months has been reported. Information about prognosis in dogs is confounded by the difficulty distinguishing ALL from stage V lymphoma; 30%-50% respond to chemotherapy for an average survival of 2-4 months. In dogs with CD8+ (cytotoxic T cell) lymphocytosis, higher cell counts are associated with poorer prognosis. The median survival for dogs with large cell CD21+ (B cell) lymphocytosis is 129 days. Note that this study of lymphocytosis included dogs with stage V lymphoma, CLL, and ALL. If chemotherapy is not an option, prednisone may be palliative.
- AML: A few cases surviving 3-4 months have been reported. Treatments attempted to date have done little to alter the course of AML, and prognosis is grave for cats and dogs.

PEARLS & CONSIDERATIONS

COMMENTS

- Cytologic examination of a blood smear is imperative for all patients with leukocytosis or significant cytopenias.
- Patients with acute leukemias present with an acute onset of nonspecific signs. Cytologic evaluation of peripheral blood and bone marrow smears will generally provide a diagnosis, but special diagnostics are needed to differentiate ALL, AML, and stage V lymphomas. Flow cytometry is recommended.
- Because acute leukemias progress rapidly, consultation with an oncologist should be pursued quickly, and emergency referral should be considered for sick patients.
- Owners should be advised of the poor prognosis and the potential for complications with treatment of acute leukemias. Supportive care may help reduce complications with treatment.
- Better characterization of acute leukemias and development of novel treatments targeting the molecular abnormalities that cause them will improve the treatment and prognosis of dogs and cats with acute leukemias in the future.

TECHNICIAN TIPS

- Patients with acute leukemias are often sick and pancytopenic. Hospitalization for supportive care and monitoring will be required at treatment induction. Precautions should be taken to avoid exposure to infectious diseases and hemorrhage during phlebotomy or treatment.
- Owners should be educated on how to monitor their pet and precautions to protect themselves from exposure to chemotherapy.

AUTHOR: NICOLE C. NORTHRUP

EDITOR: KENNETH M. RASSNICK

Lethargy

BASIC INFORMATION

DEFINITION

Inert or apathetic state; lack of interest and/or energy; morbid drowsiness

SYNONYM

Listlessness

EPIDEMIOLOGY

SPECIES, AGE, SEX: Any patient

ASSOCIATED CONDITIONS & DISORDERS: Any disease process affecting any organ system, if sufficiently severe (systemic and/or direct intracranial involvement), can cause lethargy.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- The owner presents the pet because of a period of decreased activity, depressed mentation, and/or associated loss of appetite.
- A detailed history includes information as to the pet's water intake, presence or absence of vomiting/diarrhea, and whether the pet is eating. Additional useful information includes the pet's exercise level in the preceding days, whether other pets are affected, current medication history, and vaccination and de worming status.

PHYSICAL EXAMINATION

- Temperature, pulse, and respiratory rate: comparison to normal to look for early signs of shock.
- Examination of the mouth for severe dental disease and mucous membrane color. Capillary refill time to assess peripheral perfusion.
- Palpation of all lymph nodes for enlargement, suggesting hyperplasia (e.g., inflammation) or infiltration (e.g., neoplastic).
- Chest auscultation must include listening to 3 to 5 breath sounds in each of a few quadrants of the chest as well as heart auscultation. Evaluate the pulse while auscultating the heart.
- Abdominal palpation must be methodical. It focuses on quadrants within the abdomen, involving specific palpation of individual organs. The examination includes palpating the small intestine a second time for a foreign body/mass or for fluid accumulation.
- Rectal examination: to check for perianal masses, to assess the prostate, and to collect feces for a fecal flotation.
- Manipulation of the neck for pain and palpation of the whole spine. Simultaneous palpation of the abdomen is important, as pressure on hyperpathic points in the spine always causes abdominal tensing.
- Manipulation of all joints

ETIOLOGY AND PATHOPHYSIOLOGY

- Direct central nervous system (CNS) insult (inflammatory, vascular, neoplastic, other)
- More commonly, lethargy is the result of systemic disturbances with CNS effects, such as:
    - Inflammation: cytokine effects
    - Vascular: decreased perfusion
    - Metabolic: hypoglycemia, electrolyte disturbance, acid-base imbalance
    - Environmental: hyperthermia/hypothermia
    - Many others

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Lethargy is one of the most common yet least specific chief complaints in small-animal practice. A useful approach to diagnosis is to use the history to differentiate between medical and social/ behavioral causes; to also use the history to identify other concurrent clinical signs with an onset that coincides more or less with that of the lethargy (guiding testing towards a particular body system); and to identify abnormalities on the physical exam that can focus diagnostic efforts. In most cases, routine blood tests and urinalysis are justified as screening tools.

DIFFERENTIAL DIAGNOSIS

Any disease process (metabolic, infectious, neoplastic, traumatic, vascular, degenerative)

INITIAL DATABASE

Minimum database on each case:

- Return to/repeat the physical exam (most important diagnostic test in these cases)
- Urinalysis
- Blood smear: evidence of infection versus inflammation; platelet count
- Fecal flotation

ADVANCED OR CONFIRMATORY TESTING

- CBC, serum biochemistry profile, urinalysis
- The minimum database and physical exam orient the selection of additional tests. The more tests are performed, however, the greater the likelihood of a false-positive result.
- Thoracic radiographs (two views)
- Abdominal ultrasound and/or radiographs

TREATMENT 

TREATMENT OVERVIEW

- Treatment for confirmed disease processes
- Antibiotics are reserved for confirmed or highly suspected bacterial disease.
- Withholding of glucocorticoids unless their need has been proven. Glucocorticoids complicate many further diagnostics and can cause clinical deterioration if used inappropriately.

ACUTE AND CHRONIC TREATMENT

- If no trigger is found after the history, physical exam, and initial database, and the pet is not very ill, outpatient empirical treatment can be acceptable (e.g., in patients with gastrointestinal signs, using intestinal formula diet and asking owner to watch and return if pet is no better).
- Antibiotics are only considered if the blood smear/CBC shows signs of infection or if there is fever *with a second sign of infection* (e.g., blood in the feces).
- Specific aspects of treatment are guided by results of the minimum database and advanced testing:
    - Fluids if dehydrated
    - Analgesics if needed

POSSIBLE COMPLICATIONS

Lack of communication. It is essential to explain to the owner that an underlying trigger exists and must be found to provide optimal treatment.

PROGNOSIS AND OUTCOME 

Highly variable, depending on the underlying cause of lethargy

PEARLS & CONSIDERATIONS 

COMMENTS

- First do no harm; treatment is centered on identified triggers and underlying causes.
- More than 35% of sick pets presented to veterinary clinics have acute gastrointestinal upsets.
- Confident presentation of information is essential. Otherwise, owners can mistakenly sense uncertainty rather than a logical stepwise approach to a biological system.

AUTHOR: DAVID MILLER

EDITOR: ETIENNE CÔTÉ

Leptospirosis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A bacterial disease affecting humans and animals, caused by pathogenic subtypes (serovars) of the aerobic gram-negative filamentous spirochetes, *Leptospira interrogans* and *L. kirschneri*

SYNONYMS

Weil's disease, Stuttgart disease, fall fever

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: 4-7-year-old males more commonly affected
- Younger dogs are more susceptible to severe disease
- Cats: not clinically affected nor renal carriers; do seroconvert with exposure

GENETICS & BREED PREDISPOSITION: More common in hounds, working dogs, and herding breeds (likely greater exposure risk)

RISK FACTORS

- Suburban or rural environment
- Outdoor exercise areas/activities
- Exposure to wildlife or livestock (maintenance hosts)
- Exposure to moist environments/ standing water or to raw sewage
- Flooding
- Human risk factors: direct contact with domestic animals, environmental exposure (e.g., fisheries, rice fields, water sports), exposure to wild rodents (urban areas of poor sanitation)

CONTAGION & ZOONOSIS

- Readily contagious and zoonotic, typically via exposure to infected urine. When handling patients suspected of having leptospirosis, veterinary personnel and laypersons must use gloves and personal protective equipment to avoid exposure to urine and fomites.
- Leptospirosis is the most widespread zoonosis worldwide, accounting for up to 30% of human cases of acute renal failure in developing countries. Most human infections are asymptomatic or associated with mild, self-limiting flulike symptoms.

GEOGRAPHY AND SEASONALITY

- Worldwide distribution but predominant serovar(s) responsible for disease vary by region. In North America, serovars grippotyphosa, pomona, and bratislava are most common (historically, serovars canicola and icterohaemorrhagiae prior to vaccines targeting them).
- Previously considered a rural disease, leptospirosis is now also urban (rodents) and suburban (wildlife).
- The organisms survive in warm, moist environments, especially water but also mud and soil.
- The incidence of disease is highest in warmer months.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- There are at least 8 serovars (*L. interrogans:* autumnalis, bataviae, bratislava, canicola, hardjo, icterohaemorrhagiae, pomona; *L. kirschneri:* grippotyphosa) infectious to dogs and cats, causing variable degrees of renal and liver disease in dogs.
- Most infections are asymptomatic.
- Clinical disease: peracute (rare; sudden death from massive leptospiremia), acute, subacute (common), or chronic (common)

forms
- Some reported variation in tissue tropism and disease severity depending on the infecting serovar and the age and immune status of the host

HISTORY, CHIEF COMPLAINT

- Acute form: younger animals; lethargy, anorexia, shivering, muscle tenderness, vomiting
- Subacute form: lethargy, anorexia, vomiting, polydipsia/polyuria, reluctance to move, lumbar pain, icterus, hemorrhage
- Chronic form: +/− polyuria/polydipsia, icterus, inappetence

PHYSICAL EXAM FINDINGS

- General:
  - Anorexia
  - Lethargy
  - Fever
  - Dehydration +/− progression to hypovolemic shock
  - Injected mucous membranes
  - Conjunctivitis, uveitis
  - Petechial and ecchymotic hemorrhages
  - Nasal discharge
  - Increased lung sounds
  - +/− Abdominal pain, myalgia
- Additional findings vary based on tissue tropism and severity of injury:
  - Most cases show hypovolemia.
  - Manifestations of renal disease are very common.
  - Liver involvement is common; overt signs of liver failure (icterus, hepatic encephalopathy) may be present.
  - Vomiting is common.
  - Diarrhea is very common in experimentally infected puppies, less common in naturally occurring infections (but more common than in other causes of renal failure).
  - Pulmonary disease (labored breathing, cough) is much less common.

ETIOLOGY AND PATHOPHYSIOLOGY

- Leptospires enter the body by penetrating intact mucous membranes or bruised, abraded, or water-softened skin.
- Leptospiremia (7-10 days) causes dissemination to kidney, liver, spleen, central nervous system, eyes, and genital tract.
- Leptospires can express hemolysin and other factors which cause endothelial damage and vasculitis.
- Renal tubular epithelial-cell colonization occurs in most infected dogs, causing shedding for months to years post infection if not appropriately treated.
- Hepatic disease may result from toxin-induced injury and may be severe; some cases present with acute hepatic dysfunction as the predominant feature. Leptospirosis has been implicated as a cause of chronic hepatitis (serovar grippotyphosa).

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Unexplained fever or signs of renal and/ or hepatic insufficiency should prompt consideration of leptospirosis. Diagnosis is multimodal: a serum titer alone is rarely sufficient, and a combination of history (exposure, clinical signs), physical examination, routine blood test results, serologic titers, and organism demonstration (via PCR) all contribute to confirming or refuting the clinical diagnosis.

DIFFERENTIAL DIAGNOSIS

- Other causes of acute renal failure (e.g., toxin, pyelonephritis, heat stroke, shock; see p. 31)
- Other causes of vasculitis (e.g., sepsis, rickettsial disease, pancreatitis)
- Other causes of hepatic injury (e.g., bacterial cholangiohepatitis, toxin, sepsis, idiopathic chronic hepatitis)

INITIAL DATABASE

- CBC:
  - Often inflammatory leukogram, with or without a left shift
  - +/− Variable degree of anemia

- +/− Thrombocytopenia; a third of cases, mild to moderate (90,000-150,000/mm^3), especially if vasculitis or disseminated intravascular coagulation (DIC)
- Serum biochemistry profile:
  - Azotemia and hyperphosphatemia are common.
  - Electrolyte disturbances: hyponatremia, hypochloremia, and hypokalemia
  - Metabolic acidosis
  - +/− Hypoalbuminemia in cases with vasculitis or severe liver dysfunction
  - Liver parameters: increased alanine aminotransferase (ALT), alkaline phosphatase (ALP), and bilirubin usually peak at 6-8 days after the onset of disease.
- Urinalysis:
  - Glucosuria, proteinuria, granular casts, pyuria, and hematuria may be present.
  - Variable specific gravity
- Thoracic radiographs: interstitial, nodular, or patchy alveolar infiltrates with pulmonary involvement or vasculitis
- Abdominal radiography and ultrasonography: +/— enlargement of liver, spleen, kidneys; renal “medullary rim sign” (hyperechoic concentric ring); perinephric effusion

ADVANCED OR CONFIRMATORY TESTING

- Microscopic agglutination test (MAT):
  - In animals with compatible clinical signs, the following results are considered diagnostic:
    - Titer > 1:800 in unvaccinated animal
    - Titer > 1:3200 in vaccinated (previous 3-4 months) animal
    - Paired titers 2-4 weeks apart with fourfold increase from first to second titer. Cross-reactivity among serovars is common, and highest serovar's titer often is not the causative serovar.
- ELISA: used as field tests for human infections
- PCR assays: sensitive and specific; may be positive in early infection before rise in specific antibody detected by MAT or ELISA is present. Current techniques distinguish pathogenic organisms but not serovars.
- Darkfield microscopy: examination of fresh urine for leptospires; low sensitivity (intermittent shedding means frequent false-negative results) and not routinely used
- Bacterial culture: leptospires are difficult to grow in culture; frequent false-negative results; does allow identification of infecting serovar (important epidemiologically)
- Fluorescent antibody techniques: fluid and tissue samples; not widely used
- Histopathologic assessment: lesions nonspecific (lymphoplasmacytic tubulointerstitial nephritis); organisms may be identified using special stains.

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to treat bacteremia/leptospiremia, maintain renal perfusion and urine output to minimize renal injury, eliminate bacteria to prevent disease progression and shedding to environment, and treat associated conditions (renal failure, hepatic insufficiency, DIC, uveitis).

ACUTE GENERAL TREATMENT

- Penicillins: antimicrobial of choice for bacteremic phase (crystalline [transparent] formulations for IV use)
  - Penicillin sodium, 20,000 IU/kg IV q 4 h; *or*
  - Ampicillin, 22 mg/kg IV or PO q 8 h; *or*
  - Amoxicillin, 22 mg/kg IV or PO q 8 h
- Intravenous fluid therapy to replace deficits (vomiting, polyuria, decreased intake) and initial management of renal injury: target is rapid rehydration without volume overload (see p. 31)
- Adjunctive management of organ dysfunction and other consequences of infection as indicated for individual case (see Acute Renal Failure, p. 31; Acute Liver Injury, ; Disseminated Intravascular Coagulation p. 315; Vasculitis ; Sepsis p. 1014)

CHRONIC TREATMENT

Doxycycline, 5 mg/kg PO q 12 h for 2 weeks to eliminate leptospires from tissues, eliminate renal shedding

RECOMMENDED MONITORING

- Serum electrolyte levels, renal and hepatic parameters: to assess response to treatment or disease progression and to tailor therapy

- Hypertension may occur, requiring modification of treatment (see p. 1068).
- Urine output monitoring is essential in patients with acute renal failure.
- Monitor for development of complications (DIC, respiratory failure).

PROGNOSIS AND OUTCOME

- Survival rates for patients with clinical leptospirosis: 70%-85%
- Patients with acute renal failure are frequently oliguric to anuric and may require dialysis.
- Survivors may have persisting/chronic kidney (common) or liver dysfunction.

PEARLS & CONSIDERATIONS

COMMENTS

- Leptospirosis should be considered as a differential in any case of acute renal failure, fever of unknown origin, vasculitis, and/or acute or chronic liver disease in a dog.
- Due to the zoonotic potential of *Leptospira* pathogens, extreme caution should be used when handling suspected leptospirosis cases (dogs with acute febrile disease, especially with evidence of acute renal or liver disease).
- Human physicians are often unfamiliar with leptospirosis and its zoonotic potential.
- Intensive early therapy is important both for the patient's benefit and to reduce the risk of transmission to humans and other animals (empirical penicillin therapy in leptospirosis suspects while awaiting confirmatory test results).
- Serovars icterohaemorrhagiae and pomona: liver disease > renal disease. Serovars canicola and grippotyphosa: renal disease > liver disease.
- Leptospirosis is a reportable disease in many U.S. states; contact regional authorities.

PREVENTION

- Vaccination: whole-cell killed bacterin and subunit vaccines exist; vary in duration of immunity (6-13 months) and which serovars are included; prevent clinical disease and development of carrier state; most protect against icterohaemorrhagiae and canicola, newer vaccines include pomona and grippotyphosa.
- Vaccine protection is serovar specific: no cross-protection against nonvaccine serovars.
- Adverse reactions have been reported with disproportionate frequency with whole-cell leptospirosis vaccines; patients with a history of intolerance should either not receive the vaccine or be premedicated with antihistamines (e.g., diphenhydramine, 2 mg/ kg IM) and glucocorticoids (e.g., dexamethasone, 0.2 mg/kg IM) 15-30 minutes before vaccination
- Rodent control, avoidance of contact with reservoir hosts, and proper sanitation/drainage are also important.

TECHNICIAN TIPS

- Leptospirosis can be transmitted from infected animals to humans. To prevent exposure of people and other animals to the disease, strict protective measures should be used in handling animals, their bedding, and all laboratory samples. Use of hoses to clean cages of infected animals may result in generation of aerosols that can spread the organisms to people and other animals, and seed building surfaces with bacteria. Goggles, masks, and gloves should be worn to prevent exposure via mucous membranes (eyes, nose, mouth) and skin.
- Leptospirosis patients or suspects should be isolated from other patients and their movement restricted (patient remains in assigned cage unless absolutely necessary). If moved, patients should be transported by gurney or portable carrier that can be thoroughly disinfected.

CLIENT EDUCATION

- Leptospirosis can be transmitted to people, principally through direct or indirect contact with urine.
- Owners should be advised to contact their family physician for recommendations following exposure to an infected pet.
- The Centers for Disease Control and Prevention (CDC) maintains an informational page for lay persons, “Leptospirosis and Your Pet” at: www.cdc.gov/ncidod/dbmd/diseaseinfo/leptospirosis_g_pet.htm.
- Dogs should be supervised to prevent direct exposure to wildlife and should not be allowed to play in/drink from pools of stagnant water.

AUTHOR: MARCELLA D. RIDGWAY

EDITOR: DOUGLASS K. MACINTIRE

Lens Luxation

BASIC INFORMATION

DEFINITION

Complete dislocation of the lens anteriorly (into the anterior chamber) or posteriorly (into the posterior segment/ vitreous) from its normal position. Occurs as a result of abnormal development or degeneration (*primary:* usually bilateral inherited condition in dogs) or rupture or degeneration (*secondary:* acquired) of the lens zonules (fibers from the ciliary body that hold the lens in place).

SYNONYM

Lens subluxation: partial dislocation of the lens

EPIDEMIOLOGY

SPECIES, AGE, SEX

- *Primary:* occurs most commonly in middle-aged dogs, especially terrier breeds
- *Secondary:* dogs and cats; any age

GENETICS & BREED PREDISPOSITION

- *Primary:* terrier breeds predisposed; typically between 3 and 7 years old
- German shepherd, border collie, and some spaniels may also be predisposed.

RISK FACTORS: See Etiology and Pathophysiology below.

ASSOCIATED CONDITIONS & DISORDERS

- Anterior uveitis
- Cataract
- Corneal endothelial-associated edema (anterior luxation)
- Glaucoma
- Vitreous degeneration
- Intraocular neoplasia
- Retinal detachment

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Signs of ocular pain in cases of anterior lens luxation including tearing, redness, and squinting/blepharospasm. The cornea may be cloudy from edema.
- Vision change noted by the owner, depending on the visual status of the contralateral eye.

PHYSICAL EXAM FINDINGS

- Systemic: generally unremarkable
- Ophthalmic:
  - Anterior chamber depth abnormal: shallow with anterior luxation; deep with posterior luxation
  - Iridodonesis (trembling of the iris)
  - Phacodonesis (trembling of the lens)
  - Aphakic crescent (portion of pupil no longer containing the lens)
  - Vitreous presentation in the anterior chamber (appears as fine white cotton strands)
  - Retina visualized without an ophthalmoscope (i.e., with penlight or transilluminator)
  - Focal or diffuse corneal edema from mechanical damage to corneal endothelium with anterior luxation.
  - Glaucoma (see p. 448) can result in secondary lens luxation by buphthalmos; conversely, primary lens luxation can also result in secondary glaucoma.

- Cataract: with chronic lens luxation
- Blindness from cataract, glaucoma, retinal detachment

ETIOLOGY AND PATHOPHYSIOLOGY

- *Primary* lens luxation occurs as a result of an autosomal recessive inherited, progressive defect in the lens zonules.
- *Secondary* lens luxation occurs as a result of degeneration and/or stretching of the lens zonules; causes include:
  - Chronic anterior uveitis (see p. 1151)
  - Glaucoma with associated buphthalmos (see p. 448)
  - Intraocular neoplasia (see p. 620)
  - Hypermature cataract (see p. 181)
  - Severe ocular trauma (results in other significant ocular damage; see p. 248)
  - Age-related (older dogs/cats)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Suspected on physical examination subsequent to owner presentation for reduced vision or observed ocular abnormality. A complete ophthalmic examination is indicated to confirm and characterize the luxation and identify predisposing causes that can be treated.

DIFFERENTIAL DIAGNOSIS

- Glaucoma (see p. 448)
- Anterior uveitis (see p. 1151)

INITIAL DATABASE

Ophthalmic examination (see p. 1313):

- Menace response and pupillary light reflexes
- Intraocular pressure (IOP); normal = 10-18 mm Hg with TonoPen
- Penlight or slit-beam examination to determine if the lens luxation is primary or secondary, evaluate depth of anterior chamber, and assess cornea, lens, and vitreous for opacities
- Direct or indirect ophthalmoscopy to evaluate the posterior segment for retinal detachment (see p. 985), and optic nerve and retinal degeneration (see p. 983)

ADVANCED OR CONFIRMATORY TESTING

Ocular ultrasound if opacities of the lens or transmitting media prevent complete examination

TREATMENT

TREATMENT OVERVIEW

Therapeutic goals are to remove anterior lens luxation or lens subluxation early to avoid secondary complications, and to remove posterior lens luxation *or* prevent lens from entering anterior chamber by constriction of the pupil.

ACUTE GENERAL TREATMENT

Primary:

- Acute anterior lens luxation is considered an emergency.
- Determine IOP; treat if pressure elevated (see p. 448).
- Prompt referral of acute anterior lens luxation to a veterinary ophthalmologist for surgical lens removal (lensectomy):
  - Intracapsular lens extraction (entire lens removed) ± intraocular lens sutured in place to restore emmetropia (normal vision, neither far- or near-sighted; without an intraocular lens implant, animals are 14 diopters hyperopic [far-sighted] with abnormal vision).
  - If lens only subluxated, phacoemulsification (ultrasonic fragmentation of the lens) may be attempted. A capsular tension ring may be placed to stabilize the subluxation and a foldable acrylic intraocular lens (IOL) placed.

- If referral is not possible and the lens is luxated anteriorly, consider pupil dilation and intravenous mannitol to shrink the vitreous and shift the lens into the vitreous (seep. 448).
- If lens luxation is posterior, consider use of a miotic (e.g., prostaglandin analog; see p. 448) to constrict the pupil and thus restrict lens movement; consider referral for surgery.

Secondary: treat underlying cause.

CHRONIC TREATMENT

See Cataracts, p. 181

POSSIBLE COMPLICATIONS

See Cataracts, p. 181

RECOMMENDED MONITORING

- See Cataracts, p. 181
- Contralateral eye should be monitored for lens position and anterior chamber vitreous presentation in predisposed breeds with unilateral lens luxation. If lens instability is noted, phacoemulsification should be considered prior to complete luxation.

PROGNOSIS AND OUTCOME 

- Variable depending on underlying cause, duration and extent of the lens displacement, and location of the lens (anterior versus posterior).
- Most common complications are glaucoma and retinal detachment; in some reports, complication rate may be as high as 50%.
- Early surgical intervention while the lens is subluxated will increase success. The use of a capsular tension ring and foldable acrylic IOL may allow restoration of normal vision, with reduced complications and risk of luxation.

PEARLS & CONSIDERATIONS 

COMMENTS

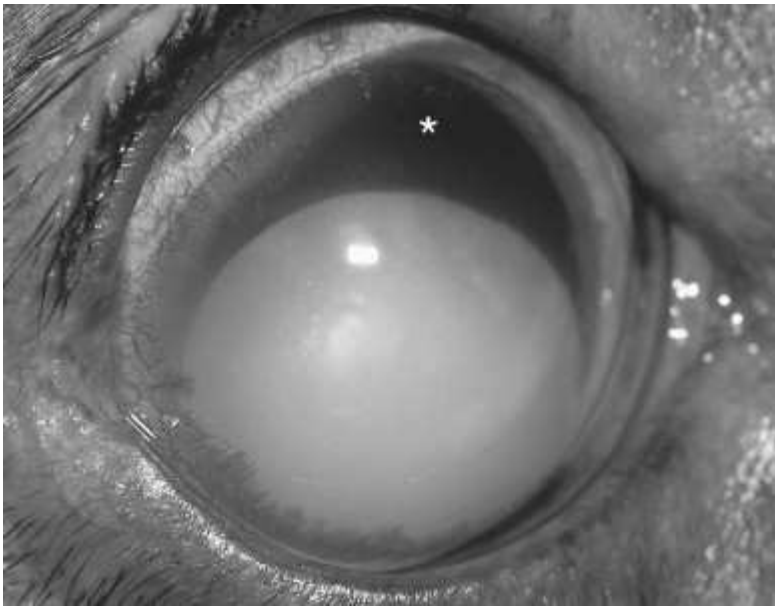
Terriers affected with lens luxation, regardless of severity, should not be used for breeding.

PREVENTION

- Dilated ophthalmic examination of all individuals of predisposed breeds, to detect early phacodonesis and anterior vitreous presentation (presence of vitreous rostral to the lens)
- Genetic testing of terriers to be used for breeding
- Complete dilated examination of the contralateral eye, especially in breeds with primary lens luxation
- Avoid head-shaking behaviors such as toys or rough playing in animals with phacodonesis or primary lens luxation in one eye.

CLIENT EDUCATION

- Breed predisposition and predilection for bilateral involvement in terriers
- With or without surgical intervention, affected eyes are at increased risk for retinal detachment and glaucoma.
- Genetic testing is available to distinguish affected, carrier and normal dogs. Homozygus affected dogs will luxate their lenses between 4-8 years of age.
- Animals that undergo surgical removal of the lens and do not receive an IOL implant have vision that, in human equivalence, is worse than 20/400 and corresponds to being “legally blind.”



LENS LUXATION Canine eye with anterior lens luxation. There is corneal edema, conjunctival hyperemia, deep corneal vascularization, an aphakic crescent (*), and the lens is cataractous.

Leishmaniasis

BASIC INFORMATION

DEFINITION

Leishmaniasis is a vector-borne zoonotic disease that is endemic in the Mediterranean region and South America (70 countries worldwide) and has recently been found in dogs in the United States.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs, cats, foxes, jackals, humans in endemic areas

GENETICS & BREED PREDISPOSITION: Boxers; most dogs with leishmaniasis in the United States have been foxhounds.

RISK FACTORS: Dogs that have travelled to endemic areas (Middle East, southern Europe, Central and South America), foxhounds, outdoor dogs living in areas where sandflies are endemic

CONTAGION & ZOONOSIS: Dogs are an important reservoir for human disease. In people, the disease occurs most commonly in infants, children, and immuno-suppressed or malnourished individuals.

GEOGRAPHY AND SEASONALITY: Disease is limited to temperate, warm, humid areas where vector sandflies are present. The sandfly vectors in the Old World (Middle East, southern Europe) are *Phlebotomus* spp. and in the New World (Central and South America), *Lutzomyia* spp.

ASSOCIATED CONDITIONS & DISORDERS

- Skin lesions: alopecia; exfoliative dermatitis, ulceration of face, pinnae, or limbs
- Glomerulonephritis
- Ocular lesions: keratoconjunctivitis, uveitis
- Lymphadenopathy
- Epistaxis
- Abnormal growth and elongation of nails (onychogryposis)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: One or more of the following: chronic weight loss, exercise intolerance, lymphadenopathy, skin lesions, eye lesions/vision loss, lameness, epistaxis

PHYSICAL EXAM FINDINGS

- Lymphadenopathy
- Splenomegaly
- Ulcerative skin lesions of pinnae, face, and limbs
- Ocular discharge
- Miosis, photophobia secondary to uveitis

ETIOLOGY AND PATHOPHYSIOLOGY

- *Leishmania infantum* is the cause of human and canine visceral leishmaniasis in Europe, the Middle East, Africa, Asia, China, and the Americas. It is synonymous with *L. chagasi* found in Latin America.
- The parasite's life cycle is diphasic (vector and host phases). Promastigotes develop in the gut of the sandfly and migrate to the proboscis. They are transmitted to the mammal host during a blood meal and are phagocytized by macrophages. Inside the macrophage, they become amastigotes and multiply by binary fission until the macrophage ruptures, and the amastigotes are then disseminated to other macrophages and throughout the body.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Highly sensitive and specific diagnostic serologic and molecular techniques to detect *Leishmania* infection are now widely available in commercial laboratories. Quantitative serologic and molecular (PCR) techniques are the assays of choice. These should be used wisely and take into consideration that in endemic areas, a large part of the canine population may be infected subclinically and could present for veterinary care for unrelated reasons. Diagnostic testing is usually performed to confirm disease in dogs with suspected clinical signs, to monitor response to treatment, or to evaluate possible infection in apparently healthy blood donors, imported dogs, or dogs who have traveled to endemic areas.

DIFFERENTIAL DIAGNOSIS

- Tickborne diseases: borreliosis, ehrlichiosis
- Leptospirosis
- Dirofilariasis
- Pyoderma
- Immune-mediated skin diseases, vasculitis, glomerulonephritis
- Demodicosis
- Lymphoma
- Malnutrition, poor husbandry

INITIAL DATABASE

- CBC: may show leukopenia or leukocytosis, nonregenerative anemia, thrombocytopenia
- Serum chemistry profile: hyperglobulinemia, hypoalbuminemia ± azotemia
- Cytologic evaluation of lymph node, skin, splenic, and bone marrow aspirates may reveal amastigote forms of *Leishmania.*
- Urinalysis: may reveal isosthenuria and proteinuria secondary to immunoproliferative glomerulonephritis
    - Urine protein/creatinine ratio may be elevated (>0.5).

ADVANCED OR CONFIRMATORY TESTING

- Histopathologic evaluation and immunohistochemical staining of skin biopsies may reveal organisms.
- Serologic tests: indirect immunofluorescent antibody test (IFAT) titers >1:32 indicate suspected exposure; titers >1:200 are consistent with active infection. Specific quantitative recombinant antigen rK39 ELISA or crude-antigen ELISA may also detect subclinical infection.
- PCR test: most sensitive test (confirmatory test of choice); will also detect subclinically infected dogs.

TREATMENT

TREATMENT OVERVIEW

Current drugs used for treating canine leishmaniasis, including newly developed therapies such as treatment with miltefosine or synergistic combinations of drugs, have limited efficacy and do not clear infection completely in most dogs. Treatment of dogs is usually followed by clinical improvement, but the parasite is rarely eliminated, and treated dogs remain latent carriers that may relapse and continue to harbor a zoonotic infection.

ACUTE GENERAL TREATMENT

- Sodium stibogluconate (Pentostam: available from the Centers for Disease Control and Prevention in Atlanta, GA) 30 mg/kg q 24 h IV or SQ for 3-4 weeks; *or*
- Meglumine antimonite (Glucantime): 100 mg/kg SQ or IV q 24 h for 3-4 weeks
- Allopurinol (20 mg/kg/d PO) for 6-12 months; can be administered in combination with meglumine antimonate at the same doses as above for both drugs
- Miltefosine (2 mg/kg/d PO) for 4 weeks with allopurinol (20 mg/kg/d PO) for 6-12 months

CHRONIC TREATMENT

- Dogs with renal insufficiency and protein-losing nephropathy do not respond well to therapy.
- Euthanasia should be considered in dogs with chronic poorly responsive disease or in households with immunosuppressed persons.

RECOMMENDED MONITORING

Negative PCR or declining titers post treatment. Periodic monitoring of renal parameters every 3 months in dogs with no initial azotemia and more frequently in dogs with azotemia at admission.

PROGNOSIS AND OUTCOME

Prognosis is guarded owing to inability to completely eradicate the organism.

PEARLS & CONSIDERATIONS

PREVENTION

- There is no vaccine available in the United States. A vaccine is marketed in Brazil, and there are progressive experiments on new commercial canine vaccines.
- Insecticidal collars and topical insect repellent may prevent vector transmission.
- If possible, keep pet dogs inside during dawn and dusk, the feeding times of sandflies.

CLIENT EDUCATION

- Leishmaniasis is a zoonotic disease that can be fatal in humans.
- Leishmaniasis does not respond very well to treatment.
- Leishmaniasis is often a chronic infection in dogs that may not manifest for years after the initial exposure.

AUTHOR: GAD BANETH

EDITOR: DOUGLASS K. MACINTIRE

Leiomyoma, Leiomyosarcoma

BASIC INFORMATION

DEFINITION

- Leiomyoma: uncommon benign tumor of smooth muscle origin
- Leiomyosarcoma: uncommon malignant tumor of smooth muscle origin
- Either can be found wherever smooth muscle is present. Most common sites: gastrointestinal (GI) tract, spleen, genital tract

SYNONYMS

Smooth muscle tumors

EPIDEMIOLOGY

SPECIES, AGE, SEX: Uncommon in dogs and rare in cats

- Leiomyoma: gastric: mean age 16 years (dogs)
- Leiomyoma: colonic: median age 12 years (dogs)
- Leiomyosarcoma: GI; median age 10.5-12 years (dogs)
- Leiomyo(sarco)ma: genital, urinary tract, or intestinal; female > male

GENETICS & BREED PREDISPOSITION: Leiomyosarcoma more common in large-breed dogs, notably in German shepherds (intestinal).

ASSOCIATED CONDITIONS & DISORDERS: Paraneoplastic syndromes:

- Hypoglycemia
- Nephrogenic diabetes insipidus (one dog with intestinal leiomyosarcoma)
- Polycythemia due to elevated plasma erythropoietin levels (one dog with cecal leiomyosarcoma)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- GI leiomyoma:
  - Incidental finding during endoscopy or necropsy. Occasionally, tenesmus or dyschezia if rectal; vomiting or regurgitation if gastroesophageal.
- GI leiomyosarcoma:
  - Signs referable to the GI tract, including chronic vomiting, weight loss, melena, hematemesis, gastric dilation, or regurgitation
- Peripheral leiomyosarcoma: progressively enlarging mass noticed by the owner
- Rarely, animals with leiomyosarcoma first present with signs related to paraneoplastic hypoglycemia.

PHYSICAL EXAM FINDINGS

- Abdominal mass possible with any visceral leiomyo(sarco)ma
- Signs of peritonitis possible as a result of intestinal rupture, especially with cecal leiomyosarcoma
- Abdominal pain, distended loops of bowel, and/or mass palpable per rectum in some cases
- Weakness or collapse due to gastric hemorrhage
- Subcutaneous mass with peripheral leiomyosarcoma
- Physical exam may be unremarkable, especially with leiomyoma.

ETIOLOGY AND PATHOPHYSIOLOGY

- Both leiomyomas and leiomyosarcomas have been associated with paraneoplastic hypoglycemia. Potential mechanisms: excessive glucose metabolism by the tumor, diminished hepatic gluconeogenic capacity due to hepatic damage by the tumor, associated peritonitis, or due to production of insulin-like growth factors by the tumor. Those tumors associated with

production of insulin-like growth factors have been associated with long-term disease-free intervals or cure as a result of resection of the tumor.
- Although not confirmed, leiomyosarcomas in the female urogenital organs are thought to develop secondary to hormonal stimulation.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on gastrointestinal signs in an older dog, typically with a mass visible on abdominal ultrasound; confirmation is obtained via histopathologic and immunohistochemical evaluation.

DIFFERENTIAL DIAGNOSIS

- GI: foreign body, enteritis causing ileus, other GI neoplasm, GI granuloma (fungal, other), GI inflammation/infiltration (inflammatory bowel disease), renal disease, hepatic disease
- Other sites: other neoplasms (benign or malignant), abscess, granuloma, hematoma

INITIAL DATABASE

- CBC: 63% of dogs are anemic.
- Serum biochemistry panel: 50% are hypoglycemic
- Three-view thoracic radiographs: usually within normal limits
- Abdominal radiographs: may reveal GI mass, evidence of lymphadenopathy, changes consistent with peritonitis, or no abnormalities
- Abdominal ultrasound: 66% have evidence of an abdominal mass. Lymphadenopathy may also be noted.
- Fine-needle aspirate cytologic evaluation, if possible, may help identify the tumor type before invasive diagnostic testing (biopsy).

ADVANCED OR CONFIRMATORY TESTING

- GI contrast radiography (e.g., barium series), endoscopy, or CT may confirm gastroesophageal or intestinal obstruction and/or mass.
- The gold standard for diagnosis is biopsy with histopathologic evaluation, preferably surgically (rather than endoscopically) to resect the entire neoplasm if possible. Histopathologic grade may be prognostic.
- Immunohistochemical staining is required to differentiate leiomyosarcomas from gastrointestinal stromal tumors.

TREATMENT

TREATMENT OVERVIEW

Treatment requires stabilizing the patient and attempting wide and complete surgical resection of the entire tumor (if possible).

ACUTE GENERAL TREATMENT

Stabilization of systemic effects: hypoglycemia, anemia (e.g., due to GI hemorrhage), electrolyte and acid-base disturbances (e.g., due to chronic vomiting).

CHRONIC TREATMENT

- Complete surgical resection:
  - Curative of leiomyoma, and leiomyosarcoma in the absence of metastases.
  - If small intestinal, removal of 5 cm of normal bowel on either side of the tumor and resection of the corresponding mesentery are recommended.
  - Even with gross metastatic disease, surgical resection of leiomyosarcomas can afford long-term survival.
  - Mesenteric lymph nodes, liver, and suspected metastatic lesions should be biopsied for staging purposes.
- Dogs with metastasis or a high likelihood of metastasis (based on tumor location; see Prognosis and Outcome below) can be considered candidates for chemotherapy, although no studies have shown promising efficacy of chemotherapy against these tumors.

POSSIBLE COMPLICATIONS

- Variable, depending on the types of treatments and the location of the primary tumor
- A 50% rate of localized peritonitis associated with tumor rupture has been reported.

RECOMMENDED MONITORING

- According to clinical signs
- Exam and three-view thoracic radiographs and abdominal ultrasound q 3 mon for postoperative GI leiomyosarcoma patients. Exact frequency based on clinical signs and tumor location (see Prognosis and Outcome below).

PROGNOSIS AND OUTCOME

Prognosis depends on the location of the tumor:

- Dogs with hepatic leiomyosarcoma frequently develop metastases and have a grave prognosis.
- Dogs with gastric or intestinal leiomyosarcomas may have metastatic rates >54%, but many can have a good prognosis, even with confirmed metastasis (e.g., median survival 21.7 months for those surviving the perioperative period, including dogs with metastatic disease); 1-year survival rate 75%, 2-year survival rate 66%, and 3-year survival rate 60%.
- Dogs with cecal leiomyosarcomas may have a lower metastatic rate (10%) and better overall prognosis. Most dogs with successful resection of the cecal tumor eventually die of causes unrelated to the tumor.
- Colorectal leiomyomas: mean survival 31.6 months

PEARLS & CONSIDERATIONS

COMMENTS

- Leiomyosarcomas most commonly occur in the cecum and jejunum. They are the second most common intestinal tumor in dogs.
- Even with metastatic disease, including gross hepatic and mesenteric involvement apparent at laparotomy, GI leiomyosarcoma is associated with a fair life expectancy (mean: 2 years) postoperatively.
- Some gastrointestinal leiomyosarcomas (GILMS) have been reclassified as gastrointestinal stromal tumors (GIST) via immunohistochemical techniques (they express c-kit, CD-117 positive; true GILMS do not). GIST are derived from interstitial cells of Cajal, which are the pacemaker cells of the gastrointestinal tract (regulate motility and peristalsis). One study indicated that in dogs, it may be that GILMS and GIST behave differently (GILMS more commonly located in the stomach and small intestine; GIST more commonly located in the cecum and large intestine). GIST were also thought to be more locally invasive and more likely to result in perioperative death as a result of gastrointestinal wall perforation and sepsis. Another study found no clinical importance of reclassification, but did note that future treatments may be dictated by this division.

CLIENT EDUCATION

If leiomyosarcoma: monitor for signs indicating recurrence or abdominal metastasis (e.g., vomiting, diarrhea, abdominal distention, and abdominal pain).

AUTHOR: M. RAQUEL BROWN

EDITOR: DEBRA L. ZORAN

Left Bundle Branch Block

BASIC INFORMATION

DEFINITION

An intracardiac conduction disturbance sometimes associated with left ventricular enlargement. There is failure of normal (rapid) conduction from the bundle of His through the left bundle branch to the Purkinje fibers in the left ventricle. Conduction to the left ventricle still occurs but is very slow because it must travel from muscle cell to muscle cell. This results in a marked delay in conduction to the left ventricle, and the QRS complex becomes wider on the electrocardiogram (ECG).

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of either sex and any age

RISK FACTORS: Left ventricular enlargement, particularly left ventricular dilation

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Intermittence: in some cases, left bundle branch block (LBBB) may occur only when the heart rate surpasses a certain individual threshold (heart rate dependent).
- Left anterior fascicular block:
  - Historically, it was believed the left bundle branched into anterior and posterior fascicles as it does in humans, and that left anterior fascicular block was implicated in causing a marked left axis deviation on the surface ECG, with only slight prolongation of left ventricular depolarization.
  - However, the left bundle does not branch into two distinct fascicles in dogs and cats, making this extrapolation inaccurate.
  - Still, a marked left axis deviation in cats, which has been called *left anterior fascicular block* by some, has often been observed both in cats with hypertrophic cardiac disease and in normal cats.
  - Thus, it is important to recognize this pattern of left axis deviation (tall R wave in leads I and aVL, S wave present in leads II, III, and aVF), although the name left anterior fascicular block is inappropriate.

HISTORY, CHIEF COMPLAINT: Reflective of the underlying structural heart disease. Chief complaints range in severity from none (uncommon; LBBB is an infrequent incidental finding on ECG) to decompensated states of heart disease, such as congestive heart failure (dyspnea, lethargy, abdominal distension possible) or syncope.

PHYSICAL EXAM FINDINGS

- Typically LBBB is clinically silent. However, in some individuals, split heart sounds may be present due to prolonged left ventricular ejection time and delayed closure of the mitral valve (causing a split first heart sound).
- LBBB does not alter the rhythm of the heartbeat or the pulse.
- Findings relating to underlying structural heart disease (heart murmur, arrhythmia, gallop sound, dyspnea) are common.

ETIOLOGY AND PATHOPHYSIOLOGY

LBBB usually indicates significant underlying cardiac disease such as:

- Cardiomyopathy
- Congenital heart disease, in particular subaortic stenosis
- Cardiac ischemia
- Certain drug toxicoses (doxorubicin)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is made entirely on the electrocardiogram: LBBB is suspected when QRS duration is longer than normal (canine: >0.07 sec; feline: >0.06 sec), wide and positive R waves are present in leads I, II, III, aVF and the left precordial leads, and the rhythm appears to be supraventricular in origin.

DIFFERENTIAL DIAGNOSIS

Wide QRS complex(es) on ECG:

- Left ventricular hypertrophy
- Ventricular ectopy (premature ventricular complexes, ventricular tachycardia)
- Ventricular escape rhythm
- ± Motion artifact

LEFT BUNDLE BRANCH BLOCK Lead II ECG from a dog showing normal sinus rhythm with left bundle branch block. The QRS duration is 0.1 sec (normal £0.07). The heart rate is 90 beats/min. 50 mm/sec, 1 cm =1 mV.

INITIAL DATABASE

Electrocardiography is the definitive diagnostic test. Electrocardiographic characteristics of LBBB:

- Prolonged QRS complex duration (canine >0.07 sec, feline >0.06 sec)
- Wide and positive QRS complexes in leads I, II, III, aVF, and left precordial leads (CV6LL [V2] and CV6LU [V4])
- Negative QRS complexes in leads aVR and CV5RL (rV2)

ADVANCED OR CONFIRMATORY TESTING

- Thoracic radiographs to evaluate for left ventricular enlargement
- Echocardiogram to assess heart structure and function

TREATMENT

TREATMENT OVERVIEW

No treatment is necessary for LBBB. LBBB does not result in any hemodynamic sequelae by itself and therefore does not require specific treatment. However, LBBB is often associated with underlying structural heart disease. Treatment of this underlying condition is indicated if present.

POSSIBLE COMPLICATIONS

Complete block of both the right and left bundle branches produces complete (third-degree) atrioventricular block

PEARLS & CONSIDERATIONS

COMMENTS

- The bizarre QRS morphology seen with bundle branch block can be confused with premature ventricular complexes or

ventricular tachycardia (ventricular ectopy).
    - If P waves are present and the PR interval is consistent for every heartbeat, the complex is likely coming from a supraventricular site (and the bizarre QRS morphology is due to bundle branch block rather than ventricular ectopy). However sometimes P waves are buried and not visible, although the rhythm is supraventricular in origin (particularly with tachycardias).
    - Because most dogs with heart rates <140 beats/min have sinus arrhythmia and some degree of irregularity to the heart rhythm, examining the regularity of rhythm can be a helpful clue. A regularly irregular (cyclically varying) rhythm with QRS complexes that are all wide, bizarre, but identical to each other, suggests respiratory sinus arrhythmia with bundle branch block. By contrast, when ventricular ectopy such as ventricular tachycardia produces wide, bizarre QRS complexes that are all of the same shape, the rhythm is often regular (same R-R interval).
- In human patients with heart failure, the presence of a LBBB indicates significant dyssynchrony of ventricular contraction. Cardiac resynchronization, by means of biventricular pacing, results in clinical benefits. This therapy may be used in veterinary patients in the future.

EDITOR: ETIENNE CÔTÉ

Lead Toxicosis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Syndrome secondary to exposure to injurious amounts of lead. Exposure is usually by ingestion, and clinical signs predominantly manifest as neurologic or (less commonly) acute gastrointestinal (GI) changes.

SYNONYMS

Plumbism; lead poisoning

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cats are at increased risk because of grooming habits in areas contaminated with lead-laden particles (e.g., during home remodeling with exposure to flakes of lead-based paint).
- Immature animals can absorb more lead from the GI tract than adults.
- Lead crosses the blood-brain barrier more readily in immature animals than in adults.
- Juvenile dogs are more likely to be involved, owing to their tendency to lick, mouth, and chew objects that may contain lead or be painted with lead-based paint.

RISK FACTORS

- Lead absorption can be greater in animals deficient in calcium, zinc, iron, or vitamin D.
- Animals living in homes containing paint formulated before 1977 may be at increased risk of exposure, especially during times of home remodeling/renovations.

CONTAGION & ZOONOSIS: Common source lead exposure can occur in animals and humans. The owners of animals with lead intoxication should be made aware of the possible risks of human lead toxicosis, especially to infants and young children who may chew on or swallow lead objects (e.g., curtain weights, fishing weights, older painted toys).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute toxicosis occurs after a single toxic dose of lead.
- Chronic toxicosis, which is more common, occurs after repeated exposures over time, leading to accumulation of lead in the body.

HISTORY, CHIEF COMPLAINT

- Observed or suspected exposure to lead-containing products
- Recent remodeling in older residences or agricultural outbuildings increases suspicion.
- Acute toxicosis: acute onset of anorexia and neurologic signs
- Chronic toxicosis: insidious onset of vomiting, diarrhea, anorexia, abdominal discomfort, regurgitation (uncommon; due to megaesophagus) in cats but not dogs, lethargy, weight loss, anemia, behavior changes and/or intermittent seizures

PHYSICAL EXAM FINDINGS

- Acute toxicosis:
  - Lethargy
  - Anorexia
  - Aberrant behavior
  - Ataxia
  - Tremors
  - Seizures

- Chronic toxicosis:
  - Weight loss
  - Anorexia
  - Lethargy
  - Vomiting
  - Diarrhea
  - Aberrant behavior
  - Intermittent seizures
  - Pallor (anemia)

ETIOLOGY AND PATHOPHYSIOLOGY

- Inhibition of enzymes associated with heme production results in microcytic, hypochromic, regenerative anemia with presence of nucleated red blood cells (RBCs) and possibly basophilic stippling.
- Competition with calcium ions results in storage of lead in bones, alteration of nerve and muscle transmission, and displacement of calcium from calcium-binding proteins.
- Inhibition of membrane-associated enzymes (e.g., sodium/potassium pumps) can result in increased RBC fragility and renal tubular epithelial injury.
- Lead may interfere with γ-aminobutyric acid (GABA) production or activity in the central nervous system (CNS) and lead to loss of inhibitory impulses, resulting in seizures.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

History and physical exam are often nonspecific (e.g., suggestive of gastroenteritis). Suspect lead toxicosis if there are concurrent GI and neurologic signs, if there is a history suggestive of lead in the pet's environment (old house, recent renovation remodeling), or with incidentally identified red blood cell abnormalities or metallic foreign bodies in the GI tract on radiographs. The confirmatory test of choice (indicated in all suspect cases) is lead concentration in whole blood.

DIFFERENTIAL DIAGNOSIS

- Sterile encephalitides (e.g., granulomatous encephalitis)
- Viral encephalitides (canine distemper, rabies)
- *Toxoplasma* encephalitis
- Hepatic encephalopathy
- Idiopathic epilepsy
- Brain neoplasm

INITIAL DATABASE

- CBC (hematologic abnormalities more common in chronic toxicosis):
  - Nucleated RBC (nRBC) counts of 5-40 nRBC/100 white blood cells (WBCs) consistent with lead toxicity:
    - If >40 nRBC/100 WBCs, rule out myeloproliferative disorders.
    - nRBCs present in approximately 54% of dogs with lead intoxication
  - Microcytic, hypochromic, regenerative anemias uncommon; anemia present in approximately 8% of dogs with lead intoxication
  - Basophilic stippling in dogs can be suggestive of lead toxicosis:
    - Differentiate from RBC parasites (e.g., *Babesia*).
    - Not a consistent finding; present in approximately 25% of dogs with lead intoxication
  - ±Anisocytosis, poikilocytosis, polychromasia, echinocytosis, target cells
  - ±Mature leukocytosis
- Serum bile acids (paired samples: after 12-hour fast [preprandial] and 2 hours postprandial) to help rule out hepatic encephalopathy due to portosystemic shunting unrelated to load toxicosis.
- Radiography:
  - Radiopaque material/objects in GI tract or joint space:
    - Absence does not rule out lead toxicosis.
    - Presence of metallic material in GI tract noted in approximately 20% of dogs with lead intoxication
  - “Lead lines” in epiphyses possible but not common
- Serum chemistry profile, urinalysis:
  - No specific abnormalities expected

ADVANCED OR CONFIRMATORY TESTING

- Neurologic examination (see p. 1311):
  - Mental dullness, depression are most common changes
  - Asymmetric (lateralizing) neurologic deficits are inconsistent with lead intoxication and should suggest other diagnoses.
- Blood lead level (BLL): whole blood (acceptable anticoagulants are heparin [green-top tube] or EDTA [purple-top tube]).
  - Levels >0.35-0.4 ppm (35-40 meg/ dL) are suggestive of lead toxicosis.
    - With appropriate clinical signs, BLL > 35 mcg/dL is diagnostic of lead toxicosis.
  - BLL between 0.1 and 0.35 ppm (10-35 mcg/dL) suggests significant exposure and with appropriate clinical signs is suggestive of lead toxicosis.
  - Normal background BLL usually <0.1 ppm (<10 mcg/dL)
  - BLL is not reflective of total body burden; may not correlate to severity of clinical signs.
  - In chronic toxicoses, BLL may not be appreciably high because of distribution of lead into body compartments (e.g., bone).

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to stabilize the patient and manage severe clinical signs (seizures) or blood abnormalities (anemia) if present, followed by removal of lead objects from the GI tract (if applicable) and chelation therapy for as long as needed to achieve nontoxic whole blood lead levels.

ACUTE GENERAL TREATMENT

- Manage seizures:
  - Diazepam, 0.5-2 mg/kg IV to effect
  - If seizures intractable with diazepam alone: phenobarbital, 2-10 mg/kg IV to effect
  - Consider IV diazepam constant rate infusion (0.1-0.5 mg/kg in 5% dextrose [D5W] at maintenance rate, titrated to effect) for acute, persistently refractory seizures.
  - Pentobarbital (3-15 mg/kg IV to effect), propofol (0.1-0.6 mg/kg/ min), or gas anesthesia are additional treatment considerations for persistently refractory seizures not responding to the treatments listed previously.
- Correct fluid and electrolyte abnormalities as needed.
- Remove macroscopic lead from GI tract. It is essential to accomplish this before chelation.
  - Chelators (except succimer) will enhance absorption of lead from the GI tract.
  - Emesis, gastrostomy, cathartics, enemas, whole bowel irrigation may be used for removing lead from GI tract.
    - Activated charcoal does not adsorb lead well and is not helpful.
    - Magnesium sulfate (125-250 mg/ kg PO) may precipitate lead in GI tract and thus reduce its systemic absorption as well as promote diarrhea (purgative).
- Chelation:
  - Most lead chelators are nephrotoxic.
    - Monitor serum renal values and maintain adequate hydration.
  - Monitor progress of chelation therapy by monitoring BLL; decline is first expected around 5 days after initiating chelation.
  - If signs persist and levels have not decreased after several days of chelation therapy, patient reassessment is necessary to be sure reexposure is not occurring (e.g., through environment, or GI lead foreign body).
  - Succimer (meso-2,3-dimercaptosuccinic acid [DMSA]): treatment of choice in most cases
    - Least nephrotoxic chelator
    - Can be administered orally or rectally
    - Less likely to bind essential minerals
    - Does not increase absorption of lead from GI tract
    - Dogs: 10 mg/kg PO or per rectum q 8 h for 10 days
  - Calcium disodium ethylenediaminetetraacetic acid (Ca EDTA): mostly replaced by succimer, except in patients with intractable vomiting or other situations in which parenteral treatment is preferred.
    - Dogs: 25 mg/kg SQ q 6 h, diluted in 5% dextrose, for 2 to 5 days
    - A 5-day rest is recommended if additional doses needed.
    - Cats: 27.5 mg/kg in 15 mL of 5% dextrose SQ q 6 h for 5 days
  - Dimercaprol (British anti-Lewisite [BAL]): mainly of historic interest; replaced by others (above)
    - Adsorbs lead from RBCs
    - Increases urinary and biliary excretion
    - Painful on injection
    - Nephrotoxic; also contraindicated in hepatic dysfunction

        - Administer 3-6 mg/kg IM q 6-8 h for 2 days.
    - Penicillamine: mainly of historic interest; replaced by others already listed
        - Nephrotoxic; maintain adequate hydration
        - Binds essential minerals (copper, iron zinc)
        - May cause vomiting (premedicate with maropitant 1 mg/kg q 24 h, SQ or 2 mg/kg PO q 24 h)
        - Dogs: 8-35 mg/kg PO q 6-8 h for 1-2 weeks
- Supportive care:
    - Maintain hydration and nutrition.
    - Manage GI signs.
- Prevent reexposure:
    - Identify and remove lead source from environment.

CHRONIC TREATMENT

- Management of CNS signs if persistent (e.g., seizures)
- Management of renal injury if present

NUTRITION/DIET

- NPO if there is excessive vomiting
- A bland diet may be indicated until resolution of signs if there is evidence of diarrhea.

BEHAVIOR/EXERCISE

Clients need to be informed of aberrant behavior some pets with high BLL show during toxicosis (and persistence during early stages of treatment).

POSSIBLE COMPLICATIONS

Severe neurologic injury may be permanent.

RECOMMENDED MONITORING

- CBC
- Packed cell volume
- Hydration
- Renal values
- BLL; generally, one round of chelation therapy is given, followed by reassessment:
    - If lead levels are still elevated *and* clinical signs are still present, consider second round of chelation therapy.
    - If lead levels are still elevated but patient is clinically normal, monitor without repeating chelation.

PROGNOSIS AND OUTCOME

- Animals with mild to moderate signs have favorable prognosis with treatment.
- BLL may rebound within 2 weeks of cessation of chelation owing to redistribution of lead from body stores (e.g., bone). If clinical signs recur at that time, then redosing with chelator is recommended; if no signs occur, monitoring lead levels q 14 days is acceptable to verify that levels are continuing to fall.

PEARLS & CONSIDERATIONS

COMMENTS

- Lead embedded in soft tissues is not a significant source of lead toxicosis.
- Lead in joint spaces or areas of active inflammation may undergo systemic absorption.
- Lead stored in bones may be mobilized during times of increased bone resorption (e.g., lactation, fractures) and can result in delayed toxicosis.
- If chelator therapy is not working, either the lead toxicosis is not being addressed or (more likely) the patient is continuing to be exposed to the source of lead.

PREVENTION

Remove lead objects and lead-based paint from pet's environment.

TECHNICIAN TIPS

If the patient is vomiting, note whether foreign material is in the vomitus (possibly eliminating the need for endoscopic/surgical removal of lead foreign body from the GI tract). All solid lead must be removed from the GI tract prior to chelation therapy or else chelation can extract lead from the foreign body, perpetuating toxicosis.

CLIENT EDUCATION

Keep pets out of areas where home renovation/remodeling is occurring.

Laryngeal Trauma

BASIC INFORMATION

DEFINITION

Trauma resulting in disruption of or damage to laryngeal structures (thyroid, cricoid, and arytenoid cartilages) and surrounding soft tissues

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats; no age or sex predilection. Cats may be more predisposed to iatrogenic laryngeal trauma from orotracheal intubation.

RISK FACTORS

- Animals that are outside unsupervised have increased risk for all types of trauma.
- Anesthesia with intubation
- Long-term intubation for positive pressure ventilation
- Bronchoscopy

ASSOCIATED CONDITIONS & DISORDERS

- Polytrauma: head trauma, respiratory compromise, cardiovascular shock
- Laryngeal laceration can result in subcutaneous emphysema, pneumomediastinum, and potentially, pneumothorax and pneumoretroperitoneum.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acute onset of dyspnea with upper airway stridor
- Possible: history of witnessed trauma (e.g., bite wounds, penetrating missile, choking), recent prolonged intubation, or difficult intubation or bronchoscopy
- The patient can have a change of voice and/or dysphagia

PHYSICAL EXAM FINDINGS

- Tachypnea, dyspnea
- Upper airway noise (stridor), usually more prominent on inspiration but can be both inspiratory and expiratory
- Mucous membranes: pallor or cyanosis possible
- Thoracic auscultation: referred upper airway noise; harsh lung sounds, crackles (with either noncardiogenic pulmonary edema or aspiration pneumonia)
- Subcutaneous emphysema may be present in cervical region with penetrating wounds such as bite, gunshot, or arrow wounds or with laryngeal fracture and laceration.
- Hyperthermia (dogs: inability to pant)

ETIOLOGY AND PATHOPHYSIOLOGY

- Rough or difficult intubation or prolonged intubation can cause trauma to the mucosa, arytenoids, and vocal folds, resulting in hyperemia or edema, ulceration, and granulation tissue formation.
- Bite wounds or projectile missiles can cause penetrating or crush injury to the cartilages or recurrent laryngeal nerves.
- Airway lumen diameter can be drastically reduced if cartilages are crushed (e.g., choke chains) or with swelling/ hemorrhage of surrounding soft tissues (e.g., stick foreign bodies).
- Decreased ventilation from airway compromise: hypoxemia ± hypercarbia.
- Worsened hypoxemia (from ventilation/perfusion mismatch) if blood is aspirated into lungs or with noncardiogenic pulmonary edema from airway obstruction.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on respiratory distress with upper airway noise in a patient with a history of recent trauma to the cervical region or anesthesia with intubation. Confirmation of the diagnosis is made with cervical radiographs, laryngoscopy, and/or tracheoscopy.

DIFFERENTIAL DIAGNOSIS

- Foreign body in airway
- Insect sting/bite or other allergic reaction
- Trauma to caudal pharynx or trachea
- Laryngeal paralysis
- Laryngeal/pharyngeal mass (neoplasm, granuloma)
- Pharyngeal mucocele

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: usually unremarkable
- Pulse oximetry/arterial blood gas analysis:
  - Hypoxemia is common.
  - Hypercarbia if severe airway obstruction is present
- Cervical radiographs:
  - Look for fractures, dislocations, or asymmetry in hyoid apparatus.
  - Subcutaneous emphysema
- Thoracic radiographs:
  - Pneumomediastinum, pneumothorax
  - Concurrent thoracic trauma (e.g., rib fractures)
  - Look for noncardiogenic pulmonary edema secondary to airway obstruction.
- Laryngoscopy under general anesthesia (can be performed after tracheostomy if patient does not have a patent airway, allowing for stabilization of patient first):
  - Evaluate symmetry and function of laryngeal structures.
  - Look for hematomas, exposed cartilage, foreign body, or flaps of laryngeal mucosa.

ADVANCED OR CONFIRMATORY TESTING

- Tracheoscopy/bronchoscopy (can be performed after tracheostomy, if needed):
  - Evaluate larynx beyond the arytenoids.
  - Examine lower airways for evidence of trauma or foreign body.
- Esophagoscopy: rule out concurrent esophageal injury.
- CT may be useful in evaluating the hyoid apparatus for fractures or dislocations.

TREATMENT

TREATMENT OVERVIEW

Treatment should first consist of ensuring a patent airway and providing oxygen supplementation as needed to stabilize the patient, followed by surgical repair if needed. Initial stabilization may require an emergency tracheostomy if the patient cannot be intubated with an orotracheal tube.

ACUTE GENERAL TREATMENT

- Oxygen supplementation (see p. 1318)
- Intubation if needed (see p. 1292)
- Emergency tracheostomy (see p. 1344) if unable to pass endotracheal tube
- Treat cardiovascular compromise (IV catheter, fluids) and other life-threatening injuries if present.
- Surgical exploration and repair or permanent tracheostomy if indicated. Approach: midline ventral thyrotomy or through thyroid cartilage fracture:
  - Mucosal flaps: trim, appose edges.

- Reduce and immobilize cartilage fractures to prevent stenosis.
- Intraluminal stents can be used for preventing adhesions, collapse, and other complications.
- Mitomycin C applied topically has been reported to reduce granulation tissue and stenosis after surgical repair of laryngeal trauma.
- Unilateral arytenoid lateralization (tieback) if traumatic laryngeal paralysis without fractures or if arytenoid avulsion

- Postoperative care:
  - Antibiotics after obtaining cultures from contaminated wounds; continue 3-4 weeks in the postoperative period. Empirical selections while awaiting culture results could include:
    - Ampicillin, 22 mg/kg IV q 8 h, and enrofloxacin 10 mg/kg slow IV or PO q 24 h in dogs (5 mg/ kg q 24 h in cats)
    - Clindamycin, 10 mg/kg IV or PO q 8 h, and either amoxicillin/clavulanic acid 15 mg/kg PO q 12 h or enrofloxacin, as listed above
  - Corticosteroids (dexamethasone sodium phosphate, 0.1-0.2 mg/kg IV) at time of surgery to reduce inflammation; may repeat at a dose of 0.05-0.1 mg/kg IV q 12-24 h for first 24-48 hours.

CHRONIC TREATMENT

- Intraluminal stents will require second surgery 3-4 weeks later to remove stent.
- Permanent tracheostomy may be required if severe damage to larynx has occurred.

POSSIBLE COMPLICATIONS

- Respiratory arrest if complete obstruction
- Stenosis or stricture over the ensuing 1-2 weeks, resulting in secondary airway compromise
- Obstruction of temporary or permanent tracheostomy site with mucus
- Laryngeal paralysis
- Infection

RECOMMENDED MONITORING

- Vital signs and frequent auscultation during initial admission and in the perioperative period
- Tracheostomy care
- Pulse oximetry and/or arterial blood gas analysis
- Respiratory rate and effort, respiratory noise, and exercise tolerance, during and after the recovery stage

PROGNOSIS AND OUTCOME

- Depends on severity of trauma, concurrent injuries, and time to diagnosis and treatment
- If severe laryngeal trauma is present and veterinary care can be quickly obtained, permanent tracheostomy can allow for fair to good prognosis (with the exception of cats and very small dogs, where stoma obstruction with mucus may be recurrent and severe).

PEARLS & CONSIDERATIONS

COMMENTS

- Early temporary tracheostomy: stabilizes patient and allows imaging including laryngoscopy, endoscopic examination, radiographs, and CT.
- Surgical exploration/repair must occur early, optimally within 24 hours after injury.
- Surgical exploration is necessary if:
  - Airway obstruction is severe enough to require temporary tracheostomy
  - There is emphysema in the cervical region and/or pneumomediastinum
  - There is exposed cartilage within the lumen of the larynx
  - The laryngeal cartilage is fractured

PREVENTION

- Selection of appropriate endotracheal tube size and endoscope size along with use of lubrication will prevent iatrogenic trauma.
- Direct visualization of the larynx for intubation can also reduce risk of iatrogenic trauma.
- Long-term intubation for positive pressure ventilation can be maintained by temporary tracheostomy to prevent laryngeal

damage.

TECHNICIAN TIPS

Careful monitoring of these patients is necessary; they can develop acute airway obstruction. Any increased respiratory rate/effort or increase/change in respiratory sounds may indicate impending crisis. If possible, these patients are better monitored when not in an oxygen cage so any airway noises caused by acute obstruction can be heard.

Laryngeal Paralysis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Lack of abduction of arytenoid cartilages and vocal folds secondary to dysfunction of either the cricoarytenoideus dorsalis muscle or the recurrent laryngeal nerve. Common in old, large-breed dogs but rare in cats.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Male dogs: affected 2 to 4 times more often than females; no gender predilection in cats
- Congenital form: animals <1 year old
- Acquired form: middle-aged/older dogs (mean: 9-10 years of age)

GENETICS & BREED PREDISPOSITION

- Commonly reported in Labrador retrievers, other large/giant breeds. No breed predilection in cats.
- Inherited (autosomal dominant): Bouviers des Flandres
- X-linked recessive inherited polyneuropathy: Leonberger dogs
- Congenital and most likely hereditary: bull terriers, dalmatians, rottweilers, Siberian huskies, white-coated German shepherd dogs, Pyrenean mountain dogs

RISK FACTORS

- Damage to the recurrent laryngeal nerve (blunt trauma, thoracic or cervical surgery)
- Any condition resulting in polyneuropathy or polymyopathy:
    - Myasthenia gravis
    - Immune mediated
    - Diabetes mellitus
    - Hypothyroidism
        - Cause/effect relationship not established

GEOGRAPHY AND SEASONALITY: Hot weather (panting) may increase severity of clinical signs.

ASSOCIATED CONDITIONS & DISORDERS

- An elongated soft palate may develop with chronic increased inspiratory effort.
- Weakness and muscle wasting may be present in chronically affected dogs.
- Dysphagia or megaesophagus possible in dogs with polymyopathy or polyneuropathy.
- Aspiration pneumonia can develop secondary to dysphagia or esophageal or laryngeal dysfunction.
- Noncardiogenic pulmonary edema/ acute respiratory distress syndrome with vigorous inspiration against upper airway obstruction

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Unilateral:
    - Clinical signs mild or absent except in performance animals
- Bilateral:
    - Clinical signs apparent in most animals

HISTORY, CHIEF COMPLAINT

- Early:
    - Inspiratory stridor; very common

- Exercise intolerance with associated respiratory noise and/or breathlessness; very common
- Coughing, gagging when eating
- Voice change

- With progression:
  - Dyspnea
  - Tachypnea
  - Signs exacerbated with exercise, stress, hot weather, obesity
  - +/− Regurgitation if associated esophageal dysmotility
- Severely affected animals may show:
  - Dyspnea at rest
  - Cyanosis
  - Collapse
  - Death

PHYSICAL EXAM FINDINGS

- Unremarkable in early stages
- With disease progression, one may see:
  - Increased inspiratory effort, inspiratory stridor
    - These hallmark signs often are characterized by open-mouth, gasping respirations (in contrast to reverse sneezing) and improvement or total resolution at rest compared to during exertion.
  - Increased upper airway sounds (referred on thoracic auscultation)
  - Coughing or gagging
    - Laryngeal compression may induce coughing/gagging or increased respiratory sounds.
  - Weakness
  - Muscle atrophy, neurologic deficits if peripheral neuropathy/myopathy is present
  - +/− Crackles from pneumonia or pulmonary edema
  - Severe hyperthermia +/− signs of heatstroke (petechial hemorrhages, mucous membrane hyperemia, abnormal mentation) in severely dyspneic animals

ETIOLOGY AND PATHOPHYSIOLOGY

- Causes:
  - Nucleus ambiguus or axonal degeneration (congenital forms)
  - Idiopathic: most common cause of acquired. Suspected to be a result of underlying generalized peripheral neuropathy.
  - Intrathoracic, peritracheal, or laryngeal masses or foreign bodies (rare)
  - Other acquired causes include trauma to recurrent laryngeal nerve, polymyopathy, polyneuropathy, myasthenia gravis.
- Whatever the cause, recurrent laryngeal nerve dysfunction results in loss of function to all intrinsic muscles of the larynx except the cricothyroideus, causing inability to abduct arytenoids during inspiration (loss of cricoarytenoideus dorsalis muscle function) or actively adduct arytenoids (close the rima glottidis) during swallowing.
  - With increased inspiratory pressure, arytenoids are drawn inward, collapsing the airway during inhalation (paradoxical movement).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis is usually based on lack of active laryngeal movement, +/− presence of paradoxical movement, on oral examination under light anesthesia. Intravenous doxapram will stimulate respiration in animals that have inhibition of respiration or reduced inspiratory motion because of sedative and anesthetic administration. Laboratory evaluations, thoracic radiographs, and complete neurologic exam should be performed to assess the animal for signs of concurrent disease (e.g., polyneuropathy/myopathy, pneumonia, hypothyroidism).

DIFFERENTIAL DIAGNOSIS

- Elongated soft palate
- Collapsing trachea
- Laryngeal collapse
- Reverse sneezing
- Laryngeal mass or other laryngeal or proximal tracheal obstruction

INITIAL DATABASE

- Results of a CBC, biochemistry panel, and urinalysis are usually unremarkable except when systemic disease, dehydration, or heat stroke is present.
- Thoracic radiographs:
  - Usually normal or age-related interstitial changes
  - +/− Aspiration pneumonia
  - +/− Megaesophagus in animals with polyneuropathy/polymyopathy
- Low total thyroxine (T4) or free T4 with normal/increased thyroid-stimulating hormone: hypothyroidism
- Pulse oximetry in dyspneic or cyanotic dogs; normal dogs have oxygen saturation ≥95%

ADVANCED OR CONFIRMATORY TESTING

- Definitive diagnosis with laryngoscopy (see p. 1295):
  - May be performed without sedation/anesthesia during dyspneic crisis
  - Otherwise, light anesthetic plane (propofol 2-6 mg/kg IV to effect] or acepromazine/butorphanol/isoflurane
  - If no motion, administer doxapram HCl (1 mg/kg IV):
    - If laryngeal paralysis is present, arytenoid and vocal fold motion will be absent or paradoxical (inward collapse on inhalation, blown open on exhalation).
- In patients with polymyopathy or polyneuropathy, electromyography or nerve conduction velocities may be abnormal (see online chapter: Electromyography and Nerve Conduction Velocity).
- Patients may have antibodies to acetylcholine receptors if myasthenia gravis is present.
- May visualize lack of arytenoid movement on cervical ultrasound or trans-nasal laryngoscopy
- Esophageal dilation or lack of peristalsis on fluoroscopic contrast esophagram if concurrent esophageal motility disorder. Esophagrams not routinely recommended because of risk of aspiration.
- Coagulation panels may be abnormal in animals with hyperthermia or signs of heatstroke.

TREATMENT

TREATMENT OVERVIEW

Mildly affected animals may respond to sedation and oxygen administration during acute exacerbations of clinical signs and may remain stable with limited exercise or stress. Severely affected animals are most commonly treated with unilateral arytenoid lateralization to maintain a patent airway; however, this procedure will increase the risk of aspiration pneumonia.

ACUTE GENERAL TREATMENT

- Oxygen
  - Provide flow by oxygen (mask or nasal catheter) if Spo2 < 95%.
    - Perform immediate tracheostomy (see p. 1344), intubation, and light anesthesia or unilateral arytenoid lateralization if Spo2 cannot be maintained ≥95% on oxygen.
- Reduce laryngeal edema (prednisolone, 0.5-1 mg/kg IV; dexamethasone, 0.1-0.2 mg/kg IV; or furosemide, 2.2-4.4 mg/kg IV)
- Sedation (acepromazine, 0.005-0.02 mg/kg with butorphanol, 0.2-0.4 mg/kg IV q 2-4 h as needed) in stressed animals
- Cool hyperthermic patients
- For dogs with prolonged prothrombin time (PT) and partial thromboplastin time (PTT) secondary to heat stroke, administer fresh frozen plasma

CHRONIC TREATMENT

- Nonsurgical: rarely sufficient long-term without surgery:
  - Weight loss
  - Exercise restriction
  - Stress reduction
  - Treatment of underlying diseases
- Surgical:
  - Unilateral arytenoid lateralization recommended because higher complication rates are seen with other surgical options (permanent tracheostomy, vocal fold excision, partial laryngectomy, castellated laryngofissure, muscle-nerve pedicle transposition)
    - Unilateral arytenoid lateralization is considered a referral procedure.
    - Lateralization should be accomplished with low tension sutures to prevent excessive abduction of arytenoid.
  - Palate resection in dogs with concurrent elongated soft palate
  - Dogs with laryngeal muscle fibrosis and arytenoid cartilage fusion from trauma may require permanent tracheostomy.

POSSIBLE COMPLICATIONS

- Aspiration pneumonia reported in 8% to 33% of dogs after unilateral arytenoid lateralization
- Coughing/gagging in 16% after unilateral arytenoid lateralization
- Dyspnea may recur if suture breaks after unilateral arytenoid lateralization.
- Respiratory distress requiring temporary tracheostomy; postoperative megaesophagus; concurrent respiratory tract, esophageal, neurologic, or neoplastic disease
- Bilateral arytenoid lateralization associated with increase risk of postoperative complications and death

RECOMMENDED MONITORING

- Monitor for respiratory distress 12-24 hours after surgery.
- Avoid morphine or heavy sedation postoperatively (may increase risk of aspiration during recovery)
- Restrict exercise and reduce barking for 1-2 months after surgery.
- Reevaluate laryngeal function and repeat chest films as needed if clinical signs recur.

PROGNOSIS AND OUTCOME 

- Reduction of respiratory signs and improved exercise tolerance in 90% of dogs after unilateral arytenoid lateralization
- Poor with progressive polyneuropathy (rottweiler, dalmatian, others)
- Poor in dogs <10 kg that have undergone unilateral arytenoid lateralization
- Mortality rate 14%; higher complications noted in older animals or those with concurrent respiratory, esophageal, or neurologic disease

PEARLS & CONSIDERATIONS 

COMMENTS

- Videoendoscopy improves visualization during laryngeal exam.
- Laryngeal function is inhibited in normal dogs with some anesthetic combinations (acepromazine/thiopental, acepromazine/propofol, ketamine/ diazepam).
- Nonsurgical management is recommended in mildly affected dogs because of high postoperative complication rates associated with surgical treatments.
- Metoclopramide at the time of surgery reduces the risk of perioperative aspiration pneumonia.

PREVENTION

There is no means of preventing the development of this disease. Affected animals, especially those reflecting predisposed breeds, should not be bred.

TECHNICIAN TIPS

- To assist during oral examination, position the dog in sternal recumbency and hold the upper jaw with a piece of rolled gauze.
- The examiner should pull the tongue down with a gauze sponge and use a videoendoscope or laryngoscope to visualize the larynx. Note each inhalation for the examiner so that normal opening of the cartilages during inspiration can be differentiated from abnormal, paradoxical movement (abnormal: inward motion on inhalation, passive outward motion on exhalation).

CLIENT EDUCATION

- Dogs with polyneuropathy/polymyopathy have increased risk of postoperative complications.
- Upper airway noise, change in/loss of bark, and coughing often persist after surgery.
- There is a lifelong risk of aspiration pneumonia after surgery.
- Some dogs do better when fed dry food from floor level; try different food consistencies, bowl positions, and feeding strategies to reduce postoperative coughing and gagging and slow down food intake.

AUTHOR: KAREN M. TOBIAS

EDITOR: RANCE K. SELLON

Laryngeal Masses

BASIC INFORMATION

DEFINITION

Proliferation of laryngeal tissues due to benign or malignant processes

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Laryngeal masses are rare in dogs and cats but occur most often in middle-aged to older animals.
- Benign lesions may be seen in younger animals.
- There is a higher incidence of laryngeal tumors in male dogs and cats.

ASSOCIATED CONDITIONS & DISORDERS: Laryngeal masses can lead to acute or chronic upper airway obstruction.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Benign or malignant masses

HISTORY, CHIEF COMPLAINT

- Acute or progressive history of inspiratory stridor
- Voice change
- Dyspnea
- Cough
- Exercise intolerance
- Gagging and/or dysphagia
- Ptyalism
- Cyanosis
- Collapse
- Mass in the neck

PHYSICAL EXAM FINDINGS

- May be normal, with mass as an incidental finding at time of endotracheal intubation
- Inspiratory dyspnea, with gasping if severe
- Inspiratory stridor
- Palpable mass in the ventral laryngeal area in some
- Coughing and/or gagging due to laryngeal compression
- Weakness

ETIOLOGY AND PATHOPHYSIOLOGY

- Laryngeal tumors cause luminal obstruction by external compression or internal obstruction.
- Primary:
  - Benign:
    - Oncocytoma
    - Laryngeal cyst
    - Laryngeal polyp
    - Rhabdomyoma
    - Lipoma
  - Malignant:
    - Squamous cell carcinoma (most common)
    - Mast cell tumor
    - Fibrosarcoma
    - Rhabdomyosarcoma

        - Lymphoma
        - Osteosarcoma
        - Melanoma
        - Mixed cell tumor
- Metastatic:
    - Lymphoma
    - Plasma cell tumor
    - Thyroid neoplasia

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis often hinges on direct observation of the larynx in an anesthetized or heavily sedated patient with stridor or voice changes.

DIFFERENTIAL DIAGNOSIS

- Laryngeal paralysis (dogs > cats)
- Laryngeal collapse
- Elongated soft palate (dogs, especially brachycephalic)
- Nasopharyngeal polyp (cats)
- Pharyngeal or laryngeal foreign body
- Granulomatous masses

INITIAL DATABASE

- Results of a CBC, biochemistry panel, and urinalysis are usually unremarkable.
- Cervical radiographs may show a soft-tissue opacity in the area of the larynx, leading to laryngeal distortion or decreased laryngeal luminal space. The normal larynx of dogs, especially if mineralized, should not be confused with an abnormality (foreign body or other on a lateral cervical radiograph).
- Ultrasonography may allow identification of laryngeal masses because of the distortion of normal structural/anatomic relationships. It may also allow for fine-needle aspirates to be taken.
- Thoracic radiographs may have evidence of metastasis or aspiration pneumonia.

ADVANCED OR CONFIRMATORY TESTING

- Note: Patients with large laryngeal masses may be at the cusp of respiratory collapse despite showing only moderate dyspnea (inspiratory).
    - These patients may be unable to recover from anesthesia without respiratory distress/suffocation. Therefore, *before* sedation/anesthesia for evaluation of the upper airway in patients suspected of having airway obstruction:
        - An appropriate-sized endotracheal tube must be available.
        - A tracheostomy kit should be available.
        - Hair should be clipped from the ventral neck (preparation for tracheostomy if needed).
        - A contingency plan should be discussed with the owner if the mass is nonresectable (e.g., recover with tracheostomy versus euthanize on the table).
- Laryngoscopy with animal under general anesthesia to directly visualize the mass
- Tissue biopsy specimen can be obtained by open surgical technique or endoscopically.
    - Masses may also be aspirated for cytologic analysis.
    - A misleading cytologic or histologic diagnosis of lymphoid hyperplasia may be initially obtained by needle cytology or pinch biopsies in patients with primary laryngeal neoplasia.
- Ultrasound may help visualize the mass and aid fine-needle aspiration.
- CT or MRI can better show the extent of the mass and possible involvement of other regional structures.

TREATMENT

TREATMENT OVERVIEW

- Remove/reduce laryngeal luminal obstruction.
- Treatment depends on the extent of the lesion and type of mass.

ACUTE GENERAL TREATMENT

Stabilize the patient:

- Oxygen by face mask, oxygen cage, or nasal cannula if needed (see p. 1319)
- Tracheostomy if in severe distress from near complete obstruction (see p. 1344)

CHRONIC TREATMENT

- Small, benign lesions may be surgically excised by submucosal resection or partial laryngectomy.
- Laryngeal lymphoma is amenable to treatment with chemotherapy.
- Large invasive lesions or malignant tumors are best removed surgically by total laryngectomy combined with a permanent tracheostomy.
    - Permanent tracheostomy can palliate signs of respiratory distress in nonresectable cases or cases managed conservatively. Rarely successful in small individuals (cats, small dogs), because tracheal lumen becomes recurrently obstructed with secretions.
- Certain tumors may be better treated with radiation therapy. Consultation with an oncologist can be beneficial.

POSSIBLE COMPLICATIONS

- Postoperative swelling
- Dysphagia and/or gagging
- Pharyngeal dehiscence
- Laryngeal stenosis/webbing
- Hypoparathyroidism/hypothyroidism (if removed during laryngectomy)
- Tumor recurrence or metastasis
- Obstruction or self-trauma of tracheostoma

RECOMMENDED MONITORING

- Monitor closely for upper airway obstruction secondary to postoperative pharyngeal swelling.
- Withhold water and food for at least 24-48 hours in the postoperative period.
- Exercise should be restricted for 2-4 weeks.
- Routine laryngoscopic reevaluation is recommended to identify tumor recurrence or laryngeal stenosis.
- Periodic physical and radiographic evaluation is recommended to check for recurrence or metastasis.

PROGNOSIS AND OUTCOME

- The prognosis is good for benign lesions if complete resection is possible.
- Prognosis for malignant laryngeal tumors is guarded:
    - Advanced disease is often present at the time of diagnosis.
    - May not be surgically resectable

PEARLS & CONSIDERATIONS

COMMENTS

- A CO2 laser works well for surgical dissection and results in less inflammation and hemorrhage.
    - When using a laser, make sure the endotracheal tube is protected from the laser beam.
- Some patients may benefit from placement of a feeding tube for postoperative nutritional support (see p. 1267 -1273).

PREVENTION

There is no means of preventing the development of laryngeal masses.

TECHNICIAN TIPS

When preparing for examinations of animals with laryngeal disease, handy items to have nearby include a laryngoscope, tongue depressor (to move the soft palate), an extra endotracheal tube (in case a first becomes occluded with blood and mucus), long cup biopsy forceps, formalin, 22- or 23-gauge needles of varying lengths (1-inch, l 1/2-inch, spinal needles) and 6- or 12-mL syringes and

microscope slides (for aspiration cytology), and cotton-tip swabs (or alternatively, gauze sponges and forceps or suction) for clearing mucus or blood.

CLIENT EDUCATION

Vocalization is lost after total laryngectomy.

AUTHOR: MICHAEL B. MISON

EDITOR: RANCE K. SELLON

Lameness

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Alteration of gait caused by structural or functional abnormality in one or more limbs

SYNONYMS

“Favoring leg,” limping

EPIDEMIOLOGY

RISK FACTORS

- Obesity
- Overnutrition during growth
- Trauma
- Genetics

ASSOCIATED CONDITIONS & DISORDERS

- Neurologic disorders
- Metabolic disorders
- Neoplasia
- Certain infectious diseases

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Lameness is most often secondary to pain. However, lameness also commonly occurs secondary to neurologic, mechanical, metabolic, or endocrine dysfunction.

HISTORY, CHIEF COMPLAINT: Thorough history is critical:

- Determine which limb is affected
- Abnormal gait or limping observed by owner
- Difficulty rising
- Improves or worsens with exercise
- Holding leg up (in contrast to neurologic deficit)
- Shifting leg lameness
- Acute or gradual onset
- Progression over time

PHYSICAL EXAM FINDINGS

- Complete general physical looking for any evidence of systemic abnormalities (e.g., fever)
- Complete orthopedic and neurologic examinations (see p. 1315and p. 1311).Orthopedic examination must include assessment of:
  - Abnormal posture
  - Joint effusion
  - Bone, joint pain, or muscle pain
  - Muscle atrophy
  - Thickening or bony prominences at or near joints
  - Crepitus
  - Abnormal range of motion in joints
- Observation at a walk and trot for gait abnormalities to help localize the limb that is affected:
  - Failing to bear full weight on limb
  - Short stride
  - Head bob (“down on sound”: head moves down when patient bears weight on normal limb then up with weightbearing

on affected limb to decrease weight on affected limb) with forelimb lameness
    - Toeing in or out
    - Dragging feet or scuffing nails
    - Bunny hopping (hindlimb weakness)
    - Stumbling
    - Ataxia
    - Hypermetria
- When both hind limbs are affected, weight may be shifted onto forelimbs, resulting in arched posture and abduction of the elbows.

ETIOLOGY AND PATHOPHYSIOLOGY

- Lameness secondary to pain from the musculoskeletal system: pain causes decreased weight bearing of the affected limb and shortness of stride. Severe acute pain may cause non-weight bearing on affected limb.
- Mechanical lameness: may be caused by abnormal length or angulation of bones, joints, ligaments, or tendons.
- Endocrine-related lameness: hyperadrenocorticism may cause myopathy, and diabetes mellitus may cause peripheral neuropathy.
- Neurologic disorders may cause ataxia, paresis, or pain manifesting as lameness.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Accurate diagnosis of lameness combines a thorough history, clinical exam, and consideration of signalment of the patient. An orthopedic exam (see p. 1315) is indicated in every case, and additional tests such as radiographs are selected based on abnormalities identified in the exam and medical history.

DIFFERENTIAL DIAGNOSIS

- Immature (<12 months) dogs and cats:
    - Forelimb:
        - Trauma (soft tissue, bone, joint)*
        - Osteochondritis dissecans (OCD) of the shoulder
        - OCD of the elbow
        - Ununited anconeal process (UAP; component of “elbow dysplasia”)
        - Fragmented medial coronoid process (FMCP; component of “elbow dysplasia”)
        - Elbow incongruity
        - Avulsion of flexor muscles
        - Premature growth plate closure
        - Retained cartilage core
        - Panosteitis
        - Hypertrophic osteodystrophy (HOD)
        - Infection (local or systemic)*
        - Nutritional imbalance*
        - Congenital abnormalities* (i.e., radial agenesis, congenital elbow luxation)
        - Atlantoaxial instability
    - Hind limb:
        - Trauma*
        - Hip dysplasia
        - OCD stifle
        - OCD hock
        - Patellar luxation*
        - Avulsion of long digital extensor
        - Aseptic necrosis of femoral head
        - Panosteitis
        - HOD
        - Infection (local or systemic)*
        - Nutritional imbalance resulting in overnutrition felt to be a factor in many developmental orthopedic diseases and dysplasias, or under-nutrition [nutritional secondary hyperparathyroidism/rickets] and development of pathologic fractures.*

        - Congenital abnormalities* (tibial agenesis in cats)
- Mature (>12 months) dogs and cats*:
    - Forelimb:
        - Trauma*
        - Elbow luxation
        - Shoulder luxation
        - Degenerative joint disease*
        - Bicipital tenosynovitis
        - Contracture of infraspinatus or supraspinatus
        - Mineralization of supraspinatus tendon
        - Elbow incongruity
        - Cervical disk disease*
        - Brachial plexus injury*
        - Inflammatory joint disease*
        - Polyneuritis
        - Polymyositis
        - Infection (local or systemic)*
        - Neoplasia of bone or soft tissue*
    - Hind limb:
        - Trauma*
        - Hip luxation*
        - Stifle luxation*
        - Patellar luxation*
        - Superficial digital flexor luxation
        - Hip dysplasia
        - Degenerative joint disease*
        - Cruciate ligament disease*
        - Avulsion of long digital extensor tendon
        - Panosteitis
        - Iliopsoas muscle injury
        - Thoracolumbar disk disease
        - Lumbosacral disease
        - Inflammatory joint disease*
        - Achilles tendon injury*
        - Polyneuritis
        - Polymyositis
        - Hypertrophic osteoarthropathy
        - Aortic thromboembolism*
        - Infection (local or systemic)*
        - Neoplasia of bone or soft tissue*

*Consider differential diagnosis in cats.

INITIAL DATABASE

- Complete orthopedic and neurologic examination
- Radiographs of affected limb(s)

ADVANCED OR CONFIRMATORY TESTING

- CBC
- Serum biochemistry panel
- Urinalysis
- Arthrocentesis (see p. 1199)
    - Can aid in distinguishing degenerative joint disease from infectious, inflammatory, or immune-mediated joint disease
    - Culture and sensitivity: joint fluid should be cultured in blood culture medium for highest yield
- Immunologic testing: rheumatoid factor, antinuclear antibody test
- Serologic evaluation for infectious disease (Lyme disease, Rocky Mountain spotted fever, ehrlichiosis)
- Ultrasound of tendons or muscles

- CT, MRI: CT is most useful for bones and joints, whereas MRI is most useful for soft tissue and spinal disease.
- Arthroscopy: can be used for both diagnostic and therapeutic purposes
- Arthrotomy
- Soft-tissue or bone biopsy
- Force plate and gait analysis
- Nuclear scintigraphy: used for localizing disease such as a difficult-to-diagnose lameness or metastatic tumors
- Electromyography (EMG) (see online chapter: Electromyography and Nerve Conduction Velocity): useful for evaluating neuromuscular conditions
- Muscle or nerve biopsy (see p. 1305)

TREATMENT

TREATMENT OVERVIEW

Treatment of lameness requires a multi-modal approach to alleviate pain and treat the underlying disorder causing the lameness.

ACUTE GENERAL TREATMENT

Lameness is a clinical sign, not a specific disease. Therefore treatment is based on determining the underlying cause.

CHRONIC TREATMENT

- Depends on underlying cause
- Adjunctive/supportive treatment:
  - Weight loss if indicated
  - Glycosaminoglycan administered intramuscularly or intraarticularly
  - Nonsteroidal antiinflammatory drugs (NSAIDs) such as meloxicam, deracoxib, firocoxib, etodolac, or carprofen
  - Amantadine as an *N*-methyl-d-aspartate (NMDA) receptor antagonist or other agents such as tramadol or gabapentin can be used as adjunctive medications for pain management.
  - Intraarticular corticosteroids can be administered for severe arthritis unresponsive to other therapies but carry risk of introducing infection and/or cartilage damage.
  - Stem cell therapy derived from autogenous adipose tissue has recently been described and become available.

NUTRITION/DIET

Nutritional and dietary therapeutics include eicosapentaenoic acid (EPA)-rich diets and nutraceuticals such as chondroitin and glucosamine.

BEHAVIOR/EXERCISE

Behavioral and physical activity recommendations include moderation of physical activity, physical rehabilitation (see p. 1329), stretching, and eliminating environmental risks such as slippery walking surfaces, stairs, and need for jumping.

DRUG INTERACTIONS

Glucocorticoids potentiate the gastrointestinal ulcerogenic effects of NSAIDs; this combination is contraindicated.

POSSIBLE COMPLICATIONS

NSAIDs may be associated with gastrointestinal irritation in some patients. They should also be used cautiously in animals with preexisting renal disease.

RECOMMENDED MONITORING

Repeat examination if response to therapy is not appropriate or if lameness progresses

PROGNOSIS AND OUTCOME

Highly variable, depending on underlying cause of lameness. For example, most cases of panosteitis in growing dogs resolve spontaneously over time (prognosis excellent), whereas lameness due to osteosarcoma of a long bone has a poor long-term prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

Attention to signalment, history, and thorough examination are essential for generating “short list” of differential diagnoses.

PREVENTION

Weight management has been proven to reduce the incidence and severity of osteoarthritis and clinical signs in patients with orthopedic disease.

AUTHOR: DAVID A. PUERTO

EDITOR: ETIENNE CÔTÉ

Lactation Disorders

BASIC INFORMATION

DEFINITION

Partial or complete failure to produce or secrete milk to meet puppies' demands. They include agalactia (complete failure to produce milk), hypogalactia (partial failure), and galactostasis (accumulation of milk within the mammary gland due to failure of ejection [let-down] from the gland). Primary agalactia is extremely rare, but a delay in milk let-down is more frequent.

SYNONYMS

Agalactia or agalactosis; hypogalactia or hypolactation

EPIDEMIOLOGY

SPECIES, AGE, SEX: Postpartum female dogs, young bitches seem more prone. These disorders have not been described in cats.

GENETICS & BREED PREDISPOSITION: Any breed potentially can be affected. A genetic component may be present with agalactia.

RISK FACTORS: Inadequate nutrition, stress, anxiety, premature delivery or caesarean section, progesterone therapy, and systemic illness may trigger hypogalactia or poor milk let-down with galactostasis.

ASSOCIATED CONDITIONS & DISORDERS: Lactation disorders can coexist with other puerperal diseases, such as mastitis, metritis, and endotoxemia.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: History reveals the previous occurrence of (premature) parturition or caesarean section. Inadequate neonate weight gain, and crying and restless puppies are frequent complaints due to insufficient lactation. Few puppies nursing or abrupt weaning may precede galactostasis.

PHYSICAL EXAM FINDINGS

- Hypogalactia and agalactia: mammary development and milk appearance at nipple squeezing are scarce or absent.
- Galactostasis: engorged, firm and painful mammary glands, which may be associated with nipple anatomic abnormalities.

ETIOLOGY AND PATHOPHYSIOLOGY

- Normal milk production is the consequence of an endocrine cascade of estrogens, progesterone, and prolactin as well as other ancillary hormones. Idiopathic primary agalactia may represent a disruption of the pituitary/ ovarian/mammary gland axis of unknown etiology.
- Failure of milk let-down (secondary agalactia) can be due to stress, anxiety, premature delivery, progesterone therapy, or systemic illness.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Crying puppies and a dam that is reluctant to nurse are suggestive of either primary or secondary agalactia. Consideration of environment where lactation is occurring and physical examination of the mammary glands help differentiate the two causes.

DIFFERENTIAL DIAGNOSIS

- Mastitis
- Mammary tumors
- Pseudocyesis

- Care should be taken, as mastitis and mammary tumors can coexist with lactation disorders.

INITIAL DATABASE

- History and physical findings (as already described)
- CBC is normal if no concurrent inflammatory illness is present.

ADVANCED OR CONFIRMATORY TESTING

- Diagnosis is confirmed by exclusion of other diseases. Occult primary illness may require serum biochemistry profile, vaginal discharge examination, and ultrasound of the uterus.
- Cytologic evaluation of milk reveals cell counts > 3000 cells/μL with macrophages and neutrophils when inflammation (see p. 254) is present.

TREATMENT

TREATMENT OVERVIEW

Agalactia treatment mainly consists of the administration of galactagogues (prolactin increasing drugs). Failure of milk letdown requires treatment of primary cause (see Mammary Disorders, Non-Neoplastic, p. 688; Pyometra, ; Sepsis,p. 954 .) Conversely, galactostasis could be treated with prolactin-decreasing drugs (dopamine agonists or antiserotonergics) if there are no puppies to nurse.

ACUTE GENERAL TREATMENT

Primary agalactia has no effective treatment, so puppies frequently need to be hand reared. Hypogalactia or secondary agalactia can be treated with:

- Metoclopramide, 0.1-0.2 mg/kg SQ q 6-8 h
- Domperidone, 2.2 mg/kg PO q 12 h for 4-6 days, is a safer choice than metoclopramide, as it does not cross the blood-brain barrier and therefore has no central side effects.
- Failure of milk let-down can be treated with nasal oxytocin spray 10 minutes before lactation q 8 h.
- Anxious bitches may benefit from mild tranquilization with phenothiazine compounds (e.g., acepromazine, 0.1-0.25 mg/kg PO or 0.05-0.1 mg/kg IM or SQ), which also increase prolactin release.
- In cases of galactostasis, reduction of milk production can be achieved by the administration of cabergoline, 5 mcg/kg PO q 24 h for 5-7 days. Diuretics and analgesics may also be beneficial when there are puppies to nurse and lactation cannot be interrupted.

NUTRITION/DIET

Diminishing food intake (half) and water for 2 or 3 days may contribute to resolving galactostasis.

BEHAVIOR/EXERCISE

- In hypo/agalactia cases, be sure puppies suckle vigorously so that a natural stimulation of the glands occurs.
- Galactostasis may benefit from wrapping mammary area with an elastic bandage to protect from trauma. Any stimulation on the mammary glands (e.g., padding, touching, or milking) should be avoided if lactation is going to be terminated.

DRUG INTERACTIONS

High metoclopramide doses (5 mg/kg) for more than 5 days usually cause behavioral side effects such as excitation and aggression. Domperidone provokes minimal (soft stools) to no side effects.

POSSIBLE COMPLICATIONS

When gross inflammatory changes of the mammary glands accompany the accumulation of milk, mastitis may be present.

PROGNOSIS AND OUTCOME

Primary agalactia has a poor prognosis for lactation, and neonates should be hand reared. Failure in milk let-down and galactostasis

typically respond to treatment or resolve spontaneously.

PEARLS & CONSIDERATIONS

COMMENTS

Lactation disorders do not pose a risk for the female's life, although they may cause considerable neonatal losses.

PREVENTION

- Provide gradual increase of food intake during the second half of pregnancy, and 125%-159% maintenance requirements after whelping.
- Be sure mammary development is adequate before caesarean section, and slowly and calmly introduce (preferably by the owner) the puppies to the dam after surgery.
- Gradual weaning prevents galactostasis.
- Considering the possible genetic component of primary agalactia, breeding affected bitches should be weighed against the potential of perpetuating the problem.

CLIENT EDUCATION

Teach clients to recognize lactation disorders early so puppies can be saved.

AUTHOR: CRISTINA GOBELLO

EDITOR: MICHELLE KUTZLER

Myocarditis

BASIC INFORMATION

DEFINITION

Inflammation of the heart muscle, typically associated with myocytolysis. Myocarditis is a poorly understood group of diseases that can result from a collection of diseases of infectious, chemical, or physical etiologies.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Myocarditis occurs rarely and is recognized more often in dogs than cats. No age predilection (exception: puppies—parvoviral myocarditis between 3 and 8 weeks of age).

RISK FACTORS: Myocarditis can result from an extension of infectious endocarditis; therefore preexisting heart disease, persistent bacteremia, or immune compromise can be considered risk factors. Dogs and cats that roam are at risk for traumatic myocarditis.

GEOGRAPHY AND SEASONALITY: Chagas myocarditis *(Trypanosoma cruzi):* southern United States, Latin America. Lyme myocarditis *(Borrelia burgdorferi):* more common in the northeastern United States.

ASSOCIATED CONDITIONS & DISORDERS: Myocarditis often results in or coexists with cardiac arrhythmias (especially ventricular tachyarrhythmias but occasionally atrial tachyarrhythmias or atrioventricular [AV] block). Myocarditis due to a chronic process, especially persistent infection, may lead to dilated cardiomyopathy.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Based on recent discoveries, viral myocarditis has three distinct phases of disease:

- Phase 1: acute myocarditis associated with acute viremia, myocyte necrosis, and macrophage activation
- Phase 2: subacute myocarditis associated with viral clearing and overzealous immune response by cell-mediated and humoral immunity and cytokine activation
- Phase 3: chronic myocarditis, or dilated cardiomyopathy, associated with fibrosis, cardiac dilation, and heart failure

HISTORY, CHIEF COMPLAINT: Presenting complaint can be vague or specific to the cardiovascular system and may include:

- Anorexia
- Lethargy/exercise intolerance
- Cough/dyspnea
- Syncope
- Sudden death
- With traumatic myocarditis, a history of the animal's having been hit by a car is common.

PHYSICAL EXAM FINDINGS: Possible findings include:

- Fever
- Murmur
- Lymphadenopathy
- Skeletal muscle weakness
- Signs of congestive heart failure (CHF; usually phase 3 myocarditis): cough, dyspnea, abnormal breath sounds, weak pulses, pale mucous membranes, ascites, weakness, hepatosplenomegaly, jugular venous distension
- Arrhythmias: bradyarrhythmia (e.g., AV block) and tachyarrhythmias (ventricular ectopy)
- With traumatic myocarditis, evidence of blunt chest trauma or generalized signs of trauma may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Bacterial:
  - *Bacillus piliformis, Citrobacter koseri;* streptococcal, staphylococcal, *Bartonella, Brucella, Leptospira,* and *Salmonella* spp.
- Spirochete:
  - *Borrelia burgdorferi*

- Protozoan:
  - *Trypanosoma cruzi, Toxoplasma gondii, Neospora caninum, Babesia* spp.
- Viral:
  - Parvovirus; panleukopenia (cats)
- Other:
  - Doxorubicin chemotherapy, catecholamines, lead, arsenic, stinging insect and snake venom, hyperthermia, radiation therapy, blunt or penetrating trauma

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is usually suspected based on the presence of complex arrhythmias in an atypical breed for heart disease; a recent history of febrile illness, trauma or toxin exposure further heightens suspicion. For suspected neonatal parvoviral myocarditis, a history of the dam having had parvoviral enteritis during gestation is suggestive. Definitive diagnosis requires histopathologic examination of a myocardial biopsy, which is not clinically practical; therefore, the clinical diagnosis is presumptive and treatment is initiated without biopsy confirmation in virtually all cases.

DIFFERENTIAL DIAGNOSIS

- Infectious endocarditis
- Idiopathic dilated cardiomyopathy
- Sepsis

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: inflammatory leukogram possible
- Blood cultures: for diagnosis of bacterial etiology
- Cardiac troponin I or other biomarker of cardiac necrosis: serum troponin levels usually are markedly elevated.
- Thoracic radiographs: may show signs of pulmonary edema and cardiomegaly (phase 3 myocarditis)
- Electrocardiogram (ECG): to identify bradyarrhythmias or tachyarrhythmias
- Echocardiogram: may show cardiac dilation and diminished myocardial function (phase 3 myocarditis)
- Infectious disease serologic tests: *Toxoplasma, Neospora, Bartonella;* based on geographic location, *Babesia,* Lyme, Chagas, and fungal titers may be indicated.

ADVANCED OR CONFIRMATORY TESTING

- Endomyocardial biopsy and histopathologic evaluation:
  - Considered the diagnostic gold standard
  - Rarely performed, owing to invasive nature
  - Classic findings include lymphocyte infiltrates with myocyte necrosis (Dallas criteria). Parvovirus inclusion bodies within cardiomyocytes are also possible.
- In acute viremia, parvovirus isolation may be attempted.
- MRI is an emerging modality, and early studies show high diagnostic accuracy for myocarditis.

TREATMENT

TREATMENT OVERVIEW

Treatment mainly consists of medications to control arrhythmias and CHF if present. If a bacterial or protozoal etiology is suspected, then antimicrobial treatment is recommended.

- Supportive care is the first line of therapy.
- Treatment of hemodynamically significant arrhythmias
- Pacemaker implantation for complete AV block
- Treatment of heart failure with diuretics and vasodilators. Support of cardiac output with positive inotropes may be necessary.
- Treatment with an antimicrobial agent if a bacterial or protozoan etiology is suspected

ACUTE AND CHRONIC TREATMENT

- If severe ventricular arrhythmias: see p. 1600 .
- If high-grade second-degree or third-degree AV block: see p. 117 .
- If CHF (e.g., pulmonary edema, pleural effusion, ascites): see p. 468 and p. 470.
- Antimicrobial therapy:
    - See specific infectious disease topics for recommendations.

POSSIBLE COMPLICATIONS

- Chronic CHF
- Dilated cardiomyopathy
- Complete AV block

RECOMMENDED MONITORING

- Acute monitoring:
    - Continuous ECG
    - Frequent blood pressure measurement: invasive or noninvasive
    - Dyspnea watch and respiratory rate
- Chronic monitoring:
    - Periodic ECG or Holter monitor
    - Echocardiogram
    - Thoracic radiograph
    - Renal and electrolyte parameters if receiving diuretics
    - Convalescent serologic titers for suspected infectious diseases

PROGNOSIS AND OUTCOME

Because myocarditis is an elusive diagnosis and uncommon disease, good information regarding prognosis and outcome is not known. The possibility of lethal arrhythmia and/or progression to dilated cardiomyopathy and CHF warrant an initial guarded prognosis. In humans, fulminant viral myocarditis is interestingly associated with better long-term prognosis than the more chronic clinical presentations if the initial phase is survived.

PEARLS & CONSIDERATIONS

COMMENTS

In the author's clinical experience, myocarditis is strongly suspected when a dog presents with clinical signs attributable to a sudden onset of complex ventricular arrhythmias or complete AV block with no clear underlying etiology.

Myiasis

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

An infestation of living animals with the *larvae* (maggots) of dipteran (two-winged) flies. They may cause cutaneous, nasal, or other tissue lesions.

SYNONYM

Maggot infestation

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats may be affected. Most of these larvae are relatively species specific. However, small animals may serve as aberrant hosts when housed near primary hosts. Overall, myiasis occurs without any predilections in age or sex.

RISK FACTORS: Wounded, soiled, debilitated, or weak animals living in temperate wet regions known to harbor flies causing myiasis may be predisposed. Some dipteran larvae can penetrate normal skin.

CONTAGION & ZOONOSIS

- Emerging adult flies are a potential public health risk, since they serve as fomites for bacteria found in animal waste.
- People with open wounds could be at risk for myiasis.
- Other implications: accidental reintroduction of screwworm *(Cochliomyia hominivorax),* which is currently eradicated from the United States, presents an ongoing threat because of the aggressiveness of infestations: superficial wounds are a point of entry for screwworm larvae, which voraciously feed on living flesh and have fatally infected or "have completely eaten away the facial bones" of unconscious human victims (Bowman). Veterinarians have played a key role in screwworm prevention through identification of larvae.

GEOGRAPHY AND SEASONALITY: Myiasis has a worldwide distribution; however, larvae-specific infestations do occur in some countries. In the Northern Hemisphere, myiasis occurs during the summer months in temperate moist areas.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: A foul, putrid-smelling animal may be the only reason an owner seeks veterinary care, although occasionally malodor may be absent or unnoticed. Other owners are well aware that maggots are taking residence in their animal's skin. Occasionally, owners will present an animal because of incontinence, debilitation, paresis, or skinfold dermatitis in which invading maggots are an incidental finding.

PHYSICAL EXAM FINDINGS

- Maggot infestation typically occurs in moist locations such as those around the eyes, nose, mouth, genitalia, anus, or adjacent to wounded skin. Irregularly ulcerated to crateriform lesions are characteristic.
- Several lesions may coalesce to form large soft-tissue defects.
- Tracts dissecting through nearby soft-tissue structures may cause fistulation.
- Parasitized skin may present as a focal fistulated subcutaneous nodule.
- Aberrant larval migration can cause signs specific to other tissues.
- Findings associated with incontinence or debilitation (e.g., musculoskeletal, neurologic, or internal disease) might be identified in select cases. Severely infested animals may be in shock.

ETIOLOGY AND PATHOPHYSIOLOGY

- Eggs are laid on the moist skin of debilitated or wounded animals. Emerging larvae (maggots) secrete proteolytic enzymes that liquefy cutaneous tissue, creating full-thickness skin defects within hours. Occasionally the initial larval infestation will favor the "strike" of other myiasis-causing flies, resulting in disease propagation.
- Many dipteran flies (e.g., house, stable, horn, and black flies) are capable of infesting the skin of animals with the above risk factors. These flies cause the typical myiases seen in routine small animal practice.
- Blowflies (common in large animals), screwworm flies (reportable in many parts of the world), and flesh flies rarely infest the

skin of small animals. However, their presence is alarming because of contagion implications.
- Although more common in rabbits and rodents, *Cuterebra* flies can cause myiasis in companion animals.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is confirmed based on the observation of maggots in the skin and surrounding soft tissue.

DIFFERENTIAL DIAGNOSIS

Direct visualization of maggots in representative cutaneous lesions excludes other differential diagnoses. Specific species identification is not usually required to treat most cases of myiasis.

INITIAL DATABASE

- Direct visualization of maggots
- Cytologic evaluation of wounded and infested skin to identify secondary bacterial infection

ADVANCED OR CONFIRMATORY TESTING

- Other diagnostic tests are at the discretion of the clinician, but in most patients a CBC, biochemistry profile, and urinalysis will be beneficial to exclude concurrent and predisposing conditions.
- Bacterial culture and susceptibility testing for lesions failing to heal rapidly or in septicemic animals
- Examination of the spiracle and stigmal plates on the maggot can aid in species identification (see online version of the present chapter).
- Larvae can be kept until developing adult flies emerge. Flies of severe concern include blowflies, characterized as having a metallic blue or green sheen on the body, and screwworm flies, which have orange-brown eyes and are bluish green with longitudinal stripes along their thorax. The economic importance of eradication of these flies warrants contacting a regional veterinary office for precautionary identification and confirmation if a suspicion of screwworm myiasis exists (see online version of the present chapter).

TREATMENT

TREATMENT OVERVIEW

The goals are to remove and kill maggots, manage the wound(s), and identify and treat underlying predisposing conditions.

ACUTE GENERAL TREATMENT

- Stabilize patient if needed (e.g., fluid therapy if hypotensive).
- Clip, clean, and surgically débride lesions (general anesthesia required).
- Mechanically remove larvae.
- Apply a non-alcohol-based pyrethrin or pyrethroid (dogs but not cats) spray on lesions to kill maggots.
- Systemically administered avermectins (ivermectin, 0.2-0.4 mg/kg PO or SQ, may repeat in 7-14 days) for nonherding dog breeds (negative for heart-worms) can be used for killing maggots. Caution: susceptible individuals or breeds (see p. 625 and 706).
- Although not approved for myiasis, topical spot-on application of selamectin (Revolution) or imidacloprid + moxidectin (Advantage Multi or Advocate) per label directions may help kill maggots. In the United States, these drugs are labeled U.S. Food and Drug Administration, not Environmental Protection Agency.
- Anecdotally, oral nitenpyram (Capstar) at routine doses may kill maggots.
- Wound care (e.g., wet-to-dry bandages to help débride wound)
- House animal in fly-free area (e.g., indoors, screened-in patio).
- Empirical antibiotic therapy for secondary bacterial infection (e.g., cephalexin, 22-30 mg/kg PO q 8-12 h; or clavulanic acid-potentiated amoxicillin, 12.5-20 mg/kg PO q 12 h for 21-30+ days)

PROGNOSIS AND OUTCOME

Guarded to good, based on the severity of the infestation and underlying predisposing conditions

PEARLS & CONSIDERATIONS

COMMENTS

- Myiasis is a disease of neglect.
- Depending on the country, some types of myiases are reportable.
- Avoid crushing or cutting maggots in vivo, as remaining body parts may cause allergic reactions.
- Some of the newer topical spot-on flea and tick preventatives, when used according to label directions, may also prevent or reduce the severity of myiasis.

TECHNICIAN TIPS

In warm weather, maggots are one of the reasons hygiene (avoidance of fecal staining or urinary scalding of the skin and haircoat) is so important, especially in recumbent patients.

CLIENT EDUCATION

Basic hygiene care and early intervention when a pet is debilitated for any reason are essential for preventing myiasis.

AUTHOR: ADAM P. PATTERSON

EDITOR: MANON PARADIS

Myelodysplasia

BASIC INFORMATION

DEFINITION

- Myelodysplasia (MDS) describes a group of bone marrow disorders characterized by peripheral blood cytopenias and a hypercellular to hypocellular bone marrow containing less than 30% blast cells. MDS is often considered a precursor of acute myeloid leukemia (AML) in which the bone marrow blast population exceeds 30%.
- Morphologic signs of abnormal maturation (dysplasia) are present in the erythroid, myeloid, and/or megakaryocytic cells.

SYNONYMS

Ineffective hematopoiesis, refractory cytopenias, preleukemia, smoldering acute leukemia

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats. MDS is becoming less common in cats as the incidence of feline leukemia virus (FeLV) infection decreases.

RISK FACTORS

- Feline leukemia infection
- Some drugs (chloramphenicol, cephalosporins, melphalan, cyclophosphamide, estrogen, and vincristine) have been associated with MDS in animals.
- Vitamin B^{12}/folate deficiency
- Lead toxicity
- Exposure to radiation
- Immune-mediated diseases targeting the bone marrow
- Chronic exposure to alkylating chemotherapy drugs

CONTAGION & ZOONOSIS: FeLV: contagious between cats

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Myelodysplasia may be primary or secondary. MDS is classified into three subtypes, based on cytologic examination of bone marrow. This classification system does not provide specific prognostic information at this time.

- MDS-ER (erythroid predominant): M: E ratio <1, blasts <30% of nucleated bone marrow cells
- MDS-RC (refractory cytopenia): M: E ratio >1, nonerythroid blasts <6% of nucleated bone marrow cells
- MDS-EB (excess blasts): M:E ratio >1, nonerythroid blasts 6%-29% of nucleated bone marrow cells

HISTORY, CHIEF COMPLAINT

- Rapid onset of nonspecific clinical signs related to anemia, including weakness, lethargy, tachypnea, and appetite changes (ranging from anorexia to pica)
- Recurrent/chronic infections if leukopenia or abnormal leukocyte function occur
- Bruising/bleeding secondary to thrombocytopenia or platelet function disorders
- It is important to determine the recent history of drugs administered to the patient.

PHYSICAL EXAM FINDINGS

- Weakness, tachycardia, heart murmurs, and pale mucous membranes may indicate anemia.
- Fever due to secondary infections
- Epistaxis or petechiae due to thrombocytopenia or abnormal platelet/megakaryocyte maturation
- Hepatomegaly and splenomegaly are common in cats and may be noted in dogs.
- Pleural effusion has been reported in cats, possibly leading to muffled heart and lung sounds.

ETIOLOGY AND PATHOPHYSIOLOGY

- MDS may be primary (presumably due to mutations in hematopoietic progenitor cells) or secondary (associated with FeLV infection, drug therapy, or disorders such as lymphoma, myelofibrosis, or immune-mediated anemia/thrombocytopenia).
- A variety of chromosomal abnormalities and mutations in oncogenes and tumor suppressor genes has been identified in humans with MDS, but it is not yet known whether these are present in veterinary patients.
- MDS-associated clonal proliferation, apoptosis, and ineffective hematopoiesis can result in lethal cytopenias, or MDS may progress to acute leukemia.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History and physical exam findings are nonspecific, but CBC usually reveals at least one abnormality that is repeatable. The diagnosis is obtained on bone marrow examination performed because of persistent peripheral blood cell abnormalities without identifiable cause. Additional tests for identifying underlying causes (e.g., titers for rickettsial diseases) are selected based on history, exam, and results of diagnostic tests to date.

DIFFERENTIAL DIAGNOSIS

- Acute leukemia
- Drug-induced bone marrow dyscrasia
- Hyperplasia of recovering bone marrow
- Nonregenerative anemia: anemia of chronic/inflammatory disease, anemia of renal disease, iron-deficiency anemia, aplastic anemia, drug- or toxin-induced anemia
- Neutropenia: tissue demand, endotoxemia/sepsis, immune-mediated destruction, inherited/genetic leukocyte maturation/function abnormalities
- Thrombocytopenia: drug therapy, immune-mediated destruction
- Rickettsial *(Ehrlichia* and *Anaplasma* spp., Rocky Mountain spotted fever) organism-induced bone marrow dyscrasias
- Congenital conditions associated with dysplastic features:
    - Miniature and toy poodles: familial nonanemic macrocytosis with dysplastic changes in erythroid precursors
    - English springer spaniels: congenital dyserythropoiesis, polymyopathy, and cardiac disease
    - Giant schnauzers: congenital malabsorption of vitamin B^{12} and myelodysplasia
    - Cavalier King Charles spaniels: idiopathic subclinical thrombocytopenia and dysplastic changes in megakaryocytes and platelets (macroplatelets)

INITIAL DATABASE

- CBC and blood smear review: cytopenias and dysplastic blood cell morphology. Blood smear must be reviewed by a clinical pathologist for accurate assessment.
    - Nonregenerative anemia: often with many nucleated red blood cells present. Thrombocytopenia and/or leukopenia also are often present.
    - Leukocyte abnormalities: ringed nuclei, micronuclei, nuclear fragments, abnormal cytoplasmic granulation, or maturation arrest
    - Giant platelets and dwarf megakaryocytes
- Bone marrow evaluation (biopsy may be preferred over aspirate in establishing most accurate detail of bone marrow cellularity and marrow architecture). See p. 1212.
    - Examination of bone marrow is necessary to confirm MDS and identify the subtype.
    - Diagnosis of MDS requires that fewer than 30% of the marrow nucleated cells are blast cells (if >30% blasts are present, the diagnosis is acute leukemia, and the associated prognosis is usually worse).
    - Asynchrony of nuclear and/or cytoplasmic maturation of affected cell lines
    - Bizarre nuclear morphologies resembling bowling pins, doughnuts, or abnormally small nuclei
- Serum biochemistry profile and urinalysis to evaluate overall health
- All cats with MDS should be tested for FeLV and feline immunodeficiency virus (FIV).

ADVANCED OR CONFIRMATORY TESTING

- Cytochemical stains, immunohistochemical stains, and/or flow cytometry may be useful to rule out myeloid and lymphoid malignancies.
- *Ehrlichia* and *Anaplasma* spp. titers may aid diagnosis of rickettsial disease.
- Serum iron, zinc, lead, and vitamin B^{12}/folate levels
- Coombs' test may be needed to rule out immune-mediated disease.

TREATMENT

TREATMENT OVERVIEW

Initial therapy consists of supporting the patient (if needed) until cytopenias resolve. Overall goals are to restore normal hematopoiesis, treat underlying cause (if appropriate), and eradicate dysplastic blast cells or neoplastic cells as possible.

ACUTE GENERAL TREATMENT

- Discontinue all drug therapies, especially agents known to be associated with MDS.
- Intensive supportive care may be warranted for patients with severe cytopenias.
  - Transfusions (see p. 1347)
  - Antibiotics as indicated for treating/preventing secondary infections:
    - For prophylaxis, a common choice is sulfadiazine-trimethoprim, 15 mg/kg PO q 12 h for dogs. Cats do not usually need prophylactic antibiotics.
    - If fever or overt infection is present, intravenous broad-spectrum antibiotics based on culture and sensitivity (preferred, if available) or empirical use of clinician's preferred combination are indicated. Example: a combination of either a cephalosporin (e.g., cefazolin, 22 mg/kg IV q 8 h slow bolus) or a penicillin (e.g., ampicillin, 22 mg/kg IV q 8 h slow bolus) together with either an aminoglycoside (e.g., amikacin, 20 mg/kg IV q 24 h [only in hydrated patient without renal dysfunction; can cause renal injury]) or a fluoroquinolone (e.g., enrofloxacin, 5 mg/kg diluted 1:1 in sterile water and given as a slow IV bolus q 12 h [dogs]; 5 mg/kg q 24 h in cats).
  - Intravenous fluids for patients with infection, fever, dehydration, or decreased appetite
  - Avoid jugular venipuncture or catheterization if severe thrombocytopenia is present.
  - Nutritional support
- Recombinant granulocyte colony stimulating factor (G-CSF; 5 mcg/kg SQ once daily), recombinant human erythropoietin (rh-Epo; Epogen [100 IU/kg SQ q 48-72 h until hematocrit rises, then q 7 days or as needed to maintain low-normal hematocrit; anecdotally, darbepoetin (Aranesp) 0.45 mcg/kg SQ once weekly at first, then q 2-3 weeks adjusted for maintenance, may be less antigenic]) and potentially granulocyte stimulating factor (G-CSF; filgrastim; Neupogen [5 mcg/kg SQ once daily until neutrophil count normalizes]) and/or thrombopoietin (currently experimental) may also have a role in treating refractory cytopenias. However, some recombinant human cytokines may cause dogs and cats to form cross-reactive neutralizing antibodies to the recombinant products and their own cytokines, especially with chronic or repeated use.
- Immunosuppressive doses of prednisone (2 mg/kg PO q 24 h) have been effective for some dogs and cats with refractory cytopenias.
- Low-dose cytosine arabinoside (LD-AraC, 0.7-1.4 mg/kg SQ q 24 h) has been attempted as a differentiation agent in the management of MDS in nine cats. One complete response was described. LD-AraC administered to a dog with MDS-Er at 10 mg/m^2 SQ q 12 h for 3 weeks was ineffective.

CHRONIC TREATMENT

- Patients responding to treatment will likely require lifelong therapy and chronic monitoring of disease progression to leukemic state.
  - Supportive therapy as indicated (antibiotic therapy, transfusions, hematopoietic cytokines as needed)
  - Hematopoietic cytokines should be reduced/discontinued once cell counts are improved, to reduce the risk of production of cross-reactive antibodies that could affect the patient's own erythropoietin, G-CSF, GM-CSF, or thrombopoietin.
- Patients with concurrent MDS secondary to drug administration should never receive that drug again.

POSSIBLE COMPLICATIONS

Chronic administration of rh-Epo can result in the production of antibodies that cross-react with feline or canine erythropoietin and cause severe nonregenerative anemia. Chronic or repeated administration of G-CSF can result in production of antibodies to innate leukocyte-stimulating cytokines and cause life-threatening leukopenias.

RECOMMENDED MONITORING

- Physical examinations and CBC: weekly to every 2 weeks, more frequently during initial therapy. Blood smear review to monitor cytopenias, blasts and other abnormal cell morphology, and possible adverse effects of treatment. If lasting response to therapy is noted, interval may be extended to monthly.
- Serum biochemistry profile: every 2 months to monitor overall health. More frequently if indicated.

PROGNOSIS AND OUTCOME

- In general, the prognosis for most animals with MDS is poor, with survival times ranging from a few days to a few months.
  - Primary MDS is considered to be a preneoplastic condition, progressing to acute leukemia in 40%-60% of cases. Animals may live a year or more but eventually succumb to acute leukemia or bone marrow failure.
  - The prognosis for animals with secondary MDS depends on successful resolution of the underlying disease condition or withdrawal of offending drugs.
- Cats with refractory anemia can enjoy long survival times; however, cats with other types of MDS are typically euthanized due to cytopenias or may develop AML within weeks to months.
- The prognosis for cats with concurrent MDS and FeLV infection is especially grave; most do not survive 1 week after diagnosis.
- Dogs with MDS-RC may have a better prognosis than those with MDS-EB. In one small study, dogs with refractory anemia lived longer (>6 months) than dogs with other MDS (mean, 2 weeks).
- In general, patients with high blast counts and/or poor clinical condition are likely to have a worse prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Management of MDS is focused on identifying and treating underlying diseases (especially immune-mediated hemolytic anemia and lymphoma in dogs) and supportive care of secondary cytopenias.
- Myelodysplastic syndromes are uncommon diseases, and it can be challenging to accurately diagnose them. When MDS is suspected based on clinical signs and evidence of hematologic abnormalities, bone marrow evaluation is required for definitive diagnosis.
- When considering these conditions, consultations with a veterinary clinical pathologist and a veterinary oncologist are highly recommended.
- Chemotherapy has not been shown to be beneficial for control of MDS or to prevent progression to leukemia.
- Although the overall prognosis for patients with MDS is poor, there is substantial interindividual variability; some patients can respond well to therapy and enjoy longer survival times.

PREVENTION

All cats should be tested for feline retro-viruses (FeLV; also FIV if >6 months old) as kittens.

CLIENT EDUCATION

- Retrovirus-negative cats should be kept inside to prevent them from becoming exposed to cats harboring FeLV or FIV.
- There is a high risk of progression of primary MDS to acute leukemia.

EDITOR: SUSAN M. COTTER

1ST EDITION AUTHORS: BRUCE E. LEROY, JENNIFER E. LOCKE, NICOLE C. NORTHRUP

Mycoplasma/Ureaplasma Infections

BASIC INFORMATION

DEFINITION

Relatively uncommon opportunistic infections with small microorganisms of the class Mollicutes, which live on respiratory and urogenital mucosal membranes in many species. Hemotropic feline mycoplasmosis (formerly hemobartonellosis) is discussed separately on p. 499)

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats each have a multitude of species, primarily *M. canis* and *M. felis/M. gatae*, respectively.

RISK FACTORS

- Immune suppression
- Underlying disease:
  - General: viral infection, neoplasia, diabetes mellitus
  - Urinary: uroliths, neoplasia, changes in urine concentration or content
  - Pulmonary: aspiration due to laryngeal or esophageal dysfunction; parenchymal disease (lung parasites, viral infection, neoplasia)

CONTAGION & ZOONOSIS: Considered part of the normal flora of upper respiratory, ocular, and urogenital mucosal membranes. There are extremely rare reports of immunocompromised humans with mycoplasmal infections acquired from domestic animals (anthroponosis).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Ocular: mucoid ocular discharge, excessive tearing, or squinting
- Respiratory: mucoid nasal discharge, sneezing, cough, tachypnea, lethargy, anorexia
- Urogenital: dysuria, stranguria, inappropriate elimination, infertility
- Subcutaneous abscesses: lethargy, anorexia, fluctuant subcutaneous swellings, or nonhealing open sores
- Joint disease (rare): intermittent lameness, unwillingness to move, lethargy, anorexia, swollen joints

PHYSICAL EXAM FINDINGS

- Mucoid to crusting ocular discharge, epiphora, blepharospasm, hyperemic conjunctiva, chemosis
- Tachypnea or dyspnea, increased airway sounds/wheezes upon auscultation, easily induced cough, nasal discharge, upper respiratory stertor
- Signs of pain on bladder palpation
- Subcutaneous abscesses
- Painful or swollen joints

ETIOLOGY AND PATHOPHYSIOLOGY

- *Mycoplasma*/*Ureaplasma* spp. are bacteria that live as normal flora in the upper respiratory tract and distal urethra and cause opportunistic infections in susceptible individuals.
  - Isolation of these bacteria alone is not evidence of infection; concurrent clinical signs and response to treatment must be observed to confirm the diagnosis.
- Pulmonary mycoplasmal infections are presumed to occur secondary to transfer of organisms from upper respiratory tract to the lungs. Often occurs as part of multiorganism pneumonia but can be sole causative agent.
- *Mycoplasma* or *Ureaplasma* spp. should not be found in the healthy urinary bladder. Urinary tract infections occur as a result of ascending opportunistic infections. Often found with mixed populations of bacteria.
- *Mycoplasma/Ureaplasma* spp. are not known to play a causative role in idiopathic feline lower urinary tract signs/disease.
- *M. felis* has been associated with conjunctivitis, rhinosinusitis, pneumonia, chronic bronchial disease, and arthritis in cats. Synovitis/arthritis is extremely rare and typically associated with immunosuppression.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis should be suspected in a patient in whom an infection (typically respiratory or urinary tract) persists despite appropriate sensitivity-based antibiotic treatment and control of known predisposing causes. Definitive diagnosis requires identification of *Mycoplasma/Ureaplasma* in diseased organ systems. Isolation of the organism without clinical signs of infection simply confirms its status as normal flora.

DIFFERENTIAL DIAGNOSIS

- Urinary tract: bacterial or fungal infection, uroliths, urinary tract neoplasia
- Respiratory: bacterial or viral pneumonia, asthma or allergic lung disease lung lobe torsion, foreign body, neoplasia
- Ocular infections in cats: feline herpesvirus 1, *Chlamydophila felis*, corneal ulcer, trauma, or foreign body

INITIAL DATABASE

- CBC: leukocytosis, neutrophilia, left shift possible
- Serum biochemistry profile: typically unremarkable
- Urinalysis:
  - Inflammatory sediment possible
  - *Mycoplasma/Ureaplasma* cannot be seen on sediment exam.
  - Cystocentesis essential, as voided or catheterized urine likely contains normal commensal *Mycoplasma/Ureaplasma* from the distal urethra.
- Urine culture: growth of *Mycoplasma* or *Ureaplasma* spp.
- Thoracic radiographs: alveolar pattern or areas of consolidation, consistent with pneumonia. Bronchial or interstitial pattern also possible, especially in cats.
- Arthrocentesis: thin, cloudy synov-ial fluid with many nondegenerate neutrophils

ADVANCED OR CONFIRMATORY TESTING

- Mycoplasmas cannot be seen with normal stains.
- Culture is the best method for identifying these organisms. Special handling and culture medium are required; contact laboratory prior to sample acquisition.
- Commercially available PCR testing for *M. felis* and *M. canis* is a useful adjunct to culture. Advantages include fast turnaround time, high sensitivity and specificity, and less stringent sample-handling requirements.
- Pulmonary infections should be identified via culture of bronchial wash, since finding *Mycoplasma* in orotracheal/transtracheal washes may be incidental. Pure *Mycoplasma* culture more likely indicates true pathogenicity; oropharyngeal contamination typically shows mixed infection with *Mycoplasma* and aerobic bacteria.

TREATMENT

TREATMENT OVERVIEW

Mycoplasmal/ureaplasmal organisms are very susceptible to appropriate antimicrobials, but opportunistic infection will recur if underlying predisposing factors are not addressed. Therefore, diagnosis and treatment of the causative disease is imperative.

ACUTE GENERAL TREATMENT

- Urogenital: fluid therapy for dehydrated animals, opioid or nonsteroidal antiinflammatories for pain, spasm
- Respiratory: oxygen therapy, nebulization, and coupage for severe pneumonia
- Ocular
  - Topical ophthalmic tetracycline
  - Topical ophthalmic pain medications
  - Systemic antibiotic therapy and pain control are often necessary in addition to topical treatment.

CHRONIC TREATMENT

Systemic antibiotic therapy: options include one of the following:

- Fluoroquinolones: enrofloxacin, 10-20 mg/kg (dogs), 5 mg/kg (cats) PO, SQ or slow IV q 24 h
- Doxycycline, 10 mg/kg PO q 12 h; or tetracycline, 20-30 mg/kg PO q 8 h (lower dose for cats)
- Macrolides: azithromycin, 5-10 mg/kg PO q 24 h; or erythromycin 10-20 mg/kg PO q 8 h
- Treatment duration may vary, typically 14-28 days. Treat for 1-2 weeks after resolution of radiographic pneumonia or negative culture.
- Because they lack cell walls, mycoplasmas are resistant to beta-lactam antibiotics (penicillins, cephalosporins). Failure to respond to these antibiotics should suggest possible mycoplasmal infection.

DRUG INTERACTIONS

- Macrolides and tetracyclines can cause gastrointestinal side effects such as vomiting, diarrhea, and anorexia; more common with erythromycin.
- Enrofloxacin and other fluoroquinolones can cause blindness in cats at high doses.
- Doxycycline has been reported to cause esophagitis and esophageal strictures in cats and possibly dogs. To prevent this complication, owners need to follow oral doxycycline administration with a small amount of butter, soft margarine, or water to ensure passage into the stomach.

RECOMMENDED MONITORING

- Pneumonia: serial radiographs, bronchial lavage cytologic examination, and culture
- Urinary: serial cystocentesis urinalysis and culture
- Ocular: recheck ocular exams and fluorescein staining

PROGNOSIS AND OUTCOME

Mycoplasma/Ureaplasma spp. are usually quite susceptible to appropriate antibiotic therapy. Prognosis is good with antibiotics and management of underlying disease or concurrent bacterial infection.

PEARLS & CONSIDERATIONS

COMMENTS

These organisms are often found in cultures of normal respiratory or urinary tracts and may be commensals that were inadvertently sampled. A search for other pathogens or underlying disease that have caused enhanced susceptibility to these organisms is essential.

TECHNICIAN TIPS

Gentle removal of oculonasal secretions with a warm moist cloth will improve patient comfort and prevent facial dermatitis. Keeping the nares clear and warming food to enhance smell can also keep patients eating better.

Mycobacterial Diseases

BASIC INFORMATION

DEFINITION

Infection by any species of *Mycobacterium*

SYNONYMS

Atypical mycobacteriosis, feline leprosy, leproid granuloma syndrome, rapidly growing mycobacterial (RGM) panniculitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Tuberculous and leproid forms are very rare.
- Opportunistic infections are uncommon in cats, rare in dogs.

GENETICS & BREED PREDISPOSITION: Miniature schnauzers, basset hounds, Siamese cats may be overrepresented with systemic forms.

RISK FACTORS: Traumatic injuries often precede opportunistic infection.

CONTAGION & ZOONOSIS

- Zoonotic risk is present with all mycobacterial infections, especially among immunosuppressed people.
- Tuberculous forms are a constant human health threat (especially exudates from cutaneous lesions). Gloves, mask, and eye protection are necessary during wound debridement and patient care.
- Anthroponosis (reverse zoonosis) is a common source of infection in animals.
- Common-source exposure is more likely than contagion in leproid and opportunistic forms; however, appropriate caution should be used in handling infected animals and their secretions, exudates, and tissues.
- Urine and feces do not pose a significant zoonotic risk to most immunocompetent people.
- *Mycobacterium tuberculosis* infection (tuberculosis) is a reportable disease from the time of clinical suspicion or diagnosis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Three clinical forms are commonly recognized:

- Tuberculous forms (very rare), characterized by skin and internal organ granulomata
- Leproid forms (very rare), consisting of regionalized cutaneous nodules
- Opportunistic forms (most prevalent), characterized by spreading, nonhealing subcutaneous lesions

HISTORY, CHIEF COMPLAINT

- Tuberculous forms often are subclinical, or cause skin lesions, weight loss, lethargy, coughing.
- Leproid forms are seen in young cats, with fleshy nodules on the face and forelimbs.
- Opportunistic infections produce nonhealing exudative wound(s). Often there is an associated history of partial response to prior antibiotic therapy but persistence of the lesions to some degree.

PHYSICAL EXAM FINDINGS

- Tuberculous: systemic signs reflecting the location of visceral granulomata, with/without cutaneous lesions. Involvement of the lungs, spleen, and/or liver is common. In the tuberculous form (very rare) in cats, the gastrointestinal tract may contain granulomata. Mediastinal or mesenteric lymphadenopathy may be noted on imaging.
- Leproid: multiple nonpainful, nonpruritic, fleshy cutaneous nodules, with/without ulceration. Usually, patients are otherwise well.
- Opportunistic: intermittent serous/serosanguineous discharge from spreading skin lesions at sites of prior trauma, especially the inguinal fat pad in cats.

ETIOLOGY AND PATHOPHYSIOLOGY

- Mycobacteria are a large group of acid-fast, aerobic bacilli, with widely varying pathogenicity.
- Tuberculous species (e.g., *M. tuberculosis, M. bovis)* are facultative intracellular parasites, and none has the dog or cat as the reservoir host.
- Leproid species *(M. leprae, M. lepraemurium)* are obligate intracellular parasites transmitted to cats from rodents.
- Opportunistic species (e.g., *M. avium* complex, *M. smegmatis, M. fortuitum,* etc.) are saprophytes, primarily acquired from water and wet soil across damaged or abraded skin.
- Immune response is insufficient to clear infection but may confine bacteria within granulomata.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The most common form encountered is the opportunistic skin infection, which is suspected when a ventral abdominal, inguinal, or other wound fails to respond to appropriate cleaning, débridement and antibiotic therapy. Cytologic examination of smears or biopsy obtained from a closed, intact portion of the involved skin is the most valuable diagnostic tool.

DIFFERENTIAL DIAGNOSIS

- Bacterial folliculitis
- Mycotic infections
- Sterile nodular panniculitis
- Cutaneous or pulmonary neoplasia
- Foreign-body reactions
- Drug eruption

INITIAL DATABASE

- CBC/serum biochemistry profile/urinalysis
  - Hypercalcemia of chronic granulomatous disease is possible, and it should not mislead the clinician into a diagnosis of neoplasia.
- Cytologic evaluation or biopsy of skin lesions reveals an acid-fast bacillus.
- Thoracic and abdominal radiographs reveal granulomata in systemic forms.

ADVANCED OR CONFIRMATORY TESTING

- Species identification, including antibiotic sensitivity testing, is essential.
- A specialized lab is required (e.g., the National Jewish Center for Immunology and Respiratory Medicine in Denver, Colorado [www.njc.org]).

TREATMENT

TREATMENT OVERVIEW

- Tuberculous: significant human health threat; treatment may not be recommended.
- Leproid: usually curable with aggressive surgical excision
- Opportunistic: often curable with long-term treatment
  - Treatment of opportunistic forms depends upon aggressive complete resection and guided antibiotic therapy for at least 3 months.

ACUTE GENERAL TREATMENT

- Surgical excision of leproid granulomata is the treatment of choice.
- Wide surgical debulking of large opportunistic lesions is the first step in long-term management.
- Submit surgical biopsies for species identification.

CHRONIC TREATMENT

- Consultation with an internist specializing in infectious diseases is advised for drug recommendations; antibiotic resistance is prevalent, and protocols are evolving rapidly.
- Treatment for tuberculous forms may not be recommended; if treatment is undertaken, combination antibiotic therapy must be administered for a minimum of 6-12 months.
- Medical therapy for leproid infections is only indicated if complete surgical excision is not possible.
- Treatment of opportunistic forms, guided by species identification (and sensitivity testing when possible), requires a minimum of 3 months.
- Enrofloxacin, with clarithromycin, gentamicin, or doxycycline, may be acceptable empirical therapy while definitive identification is pending.

POSSIBLE COMPLICATIONS

- Surgical sites prone to dehiscence and recurrence of infection
- Risks of drug resistance, toxicosis, or intolerance with long-term antibiotic use

RECOMMENDED MONITORING

- Reexamination every 2-3 weeks for continued effectiveness of therapy
- Monitor lab work for evidence of drug toxicosis.

PROGNOSIS AND OUTCOME 

- Recurrence or incomplete clearance is likely.
- Leproid forms have the best prognosis.
- With appropriate intensive management, outcome of opportunistic infections can be good.

PEARLS & CONSIDERATIONS 

COMMENTS

- Treatment of tuberculous forms may not be recommended (zoonotic risk).
- Significant commitment of owner time and resources is required for positive outcome.
- Accurate species identification and current antimicrobial therapy recommendations are essential.

PREVENTION

- Vaccination with human or large-animal products is not recommended.
- Limiting rodent exposure reduces risk of leproid forms.
- Opportunistic forms are ubiquitous.

AUTHOR: KATE E. CREEVY

EDITOR: DOUGLASS K. MACINTIRE

Myasthenia Gravis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Skeletal muscle weakness due to a decrease of acetylcholine receptors at neuromuscular junctions

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Congenital myasthenia gravis is uncommon, and signs occur by 8 weeks of age.
- Acquired myasthenia gravis is fairly common and occurs in adult dogs, with a bimodal age of onset with peaks at 3 and 10 years.
- Acquired myasthenia gravis is uncommon in adult cats.

GENETICS & BREED PREDISPOSITION

- Congenital myasthenia gravis is inherited as an autosomal recessive trait in Jack Russell terriers and smooth fox terriers, and occurs sporadically in other breeds of dog. It is rare in cats.
- Akitas, terriers, German short-haired pointers, and Chihuahuas have the highest relative risks. German shepherds and golden retrievers are also commonly affected.
- Abyssinians and Somalis are at increased risk of feline acquired myasthenia gravis.

RISK FACTORS: Methimazole may increase the risk of acquired myasthenia gravis in cats.

ASSOCIATED CONDITIONS & DISORDERS

- In dogs, associated conditions include hypothyroidism, thymoma and other tumors, hypoadrenocorticism, and thrombocytopenia.
- Thymoma is common in cats with acquired myasthenia gravis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acquired: an autoimmune disorder characterized by circulating antibodies against acetylcholine receptors. May occur in generalized, focal, or acute fulminating forms.
- Congenital: an inborn deficiency of muscle acetylcholine receptors

HISTORY, CHIEF COMPLAINT

- Congenital: generalized limb weakness with or without regurgitation/dysphagia, evident by about 8 weeks of age
- Generalized acquired: generalized limb weakness that may be precipitated by exercise, with or without regurgitation/dysphagia
- Focal acquired: dysphagia/regurgitation or facial weakness with no limb weakness
- Acute fulminating acquired: acute generalized limb weakness and dyspnea due to respiratory muscle weakness

PHYSICAL EXAM FINDINGS

- Generalized limb weakness characterized by stiffness, tremor, and short-strided gait that may progress to inability to walk. Weakness may be more severe in the pelvic limbs, is often precipitated by 1 to 2 minutes of exercise, and improves with rest.
- There is no ataxia, and proprioceptive positioning is usually normal when the patient's weight is supported. Muscle atrophy is absent, and tendon reflexes are usually preserved.
- Weak palpebral reflex, especially in cats
- Cats often have neck ventroflexion.
- Abnormal lung sounds and fever possible if concurrent aspiration pneumonia

ETIOLOGY AND PATHOPHYSIOLOGY

- Congenital myasthenia gravis is caused by mutations in genes coding for the acetylcholine receptor.
- Acquired myasthenia gravis is caused by circulating autoantibodies against the acetylcholine receptor. Factors that initiate the immune response are incompletely understood.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in one of four contexts (see History, above), all characterized by neuromuscular weakness that may (classically) or may not (often) resolve with rest. Measurement of serum antiacetylcholine-receptor antibody levels should be part of any diagnostic evaluation of such neuromuscular weakness in dogs and cats; it is the confirmatory clinical test of choice for myasthenia gravis.

DIFFERENTIAL DIAGNOSIS

- Myopathies: polymyositis, degenerative myopathies
- Tick paralysis
- Acute idiopathic polyradiculoneuritis
- Botulism
- Polyneuropathy
- Metabolic disorders: hypokalemia, hypoglycemia, hypoadrenocorticism, hyperthyroidism in cats
- Orthopedic diseases: polyarthritis

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis to rule out metabolic causes
- Thoracic radiographs to screen for megaesophagus, aspiration pneumonia
- Thyroid, adrenal function testing
- Edrophonium response test can help diagnose generalized myasthenia gravis. Administer edrophonium chloride (0.1-0.2 mg/kg IV) during weakness. A positive response is obvious improvement in strength within several minutes and suggests the diagnosis. False-negative results are common, and false-positive results are possible. Potential side effects include dyspnea due to bronchial constriction and secretions; treated with atropine.

ADVANCED OR CONFIRMATORY TESTING

- Acetylcholine receptor antibody test. Serologic evaluation to detect antibodies directed against acetylcholine receptors is the gold standard for diagnosis of acquired myasthenia gravis.
- Electrodiagnostic testing (single-fiber electromyography and repetitive nerve stimulation) is useful in the diagnosis and in excluding other causes (see onine chapter: Electromyography and Nerve Conduction Velocity).
- Definitive diagnosis of congenital myasthenia gravis requires quantification of acetylcholine receptors from muscle biopsy (see p. 1305).

TREATMENT

TREATMENT OVERVIEW

Treatment goals include improving neuromuscular transmission and administering supportive care and immunosuppression (acquired form only).

ACUTE GENERAL TREATMENT

- Anticholinesterase drugs. Pyridostigmine (0.5-3 mg/kg PO q 8-12 h in dogs; 0.25 mg/kg PO q 8-12 h in cats). Titrate dose based on weakness and side effects (hypersalivation, vomiting, diarrhea). If dysphagia/regurgitation precludes oral medication, neostigmine (0.04 mg/kg SQ q 6 h) is an alternative. Human intravenous immunoglobulin can be helpful for shortterm management of acute fulminating myasthenia.
- Aspiration pneumonia is treated with antibiotics, nebulization and coupage, and oxygen if necessary (see p. 1583).
- Endotracheal intubation and ventilatory support may be necessary for the acute fulminating form or for patients with severe aspiration pneumonia.

- Intravenous fluids as needed
- Nutritional support as needed: feedings with the head elevated, or placement of a gastrostomy, nasogastric, or esophagostomy feeding tube (see p. 1267, p. 1269, p. 1270,p. 1273).

CHRONIC TREATMENT

Immunosuppressive therapy (acquired form only) is indicated when there is an inadequate response to anticholinesterase medication. Prednisone is the initial drug of choice (start at 0.5 mg/kg PO q 24 h for 1-2 weeks, then increase to 2-4 mg/kg PO q 24 h if needed; gradual taper if possible based on clinical response). Azathioprine, cyclosporine, or mycophenolate mofetil can be added if there is an inadequate response to prednisone or to allow decreased dose of prednisone in patients with severe side effects caused by prednisone.

DRUG INTERACTIONS

- Avoid drugs that impair neuromuscular transmission, including ampicillin, aminoglycosides, and phenothiazines.
- Organophosphates may increase toxicity of anticholinesterase drugs.
- In cats that develop myasthenia gravis while taking methimazole, the methimazole should be discontinued if possible.

POSSIBLE COMPLICATIONS

Aspiration pneumonia is the most common and serious complication in patients with pharyngeal/esophageal weakness.

RECOMMENDED MONITORING

- Client monitors weakness and dysphagia/regurgitation at home daily.
- Monitor antiacetylcholinesterase receptor antibody titer every 8 weeks in patients with acquired myasthenia gravis, because the disease will spontaneously resolve in many patients, usually by 6 to 18 months.

PROGNOSIS AND OUTCOME

- Prognosis for the acquired form is good for patients without pharyngeal/esophageal weakness. Spontaneous remission occurs in almost 90% of affected dogs.
- Prognosis is guarded in patients with dysphagia/regurgitation, because aspiration pneumonia is a common complication and carries a ≈50% 1-year mortality rate. Spontaneous remission occurs in almost 90% of dogs that survive the acute disease.
- Relapse is rare but can be associated with stress (e.g., surgery) or vaccination.
- The prognosis for the acute fulminating form is poor; most affected dogs die from respiratory failure.

PEARLS & CONSIDERATIONS

COMMENTS

- Early diagnosis and treatment in an attempt to avoid aspiration pneumonia improves the outcome.
- Serologic testing for antibodies to acetylcholine receptors should be evaluated in any adult dog with unexplained megaesophagus or dysphagia.

SUGGESTED READING

AUTHOR: WILLIAM B. THOMAS

EDITOR: CURTIS W. DEWEY

Mushroom Toxicosis

BASIC INFORMATION

DEFINITION

Clinical condition resulting from ingestion of any of a variety of toxic mushrooms. Toxic syndrome produced depends on mushroom type and amount ingested:

- Gastrointestinal (GI) irritant mushrooms: large variety of species
- Isoxazole mushrooms: *Amanita gemmata, A. muscaria, A. smithiana, A. strobiliformis,* and *Tricholoma muscarium*
- Muscarinic mushrooms: *Inocybe* spp., *Clitocybe* spp.
- Gyromitrin mushrooms: *Gyromitra* spp., *Helvella crispa, H. lacuose*
- Hallucinogenic mushrooms: *Psilocybe* spp., *Panaeolus* spp.
- Hepatotoxic mushrooms: *Amanita* spp., *Galerina* spp., *Lepiota* spp.
- Nephrotoxic mushrooms: *Cortinarius* spp.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All mammalian species are susceptible; dogs more likely to ingest compared to cats.
- Cats are particularly sensitive to cardiovascular effects of muscarinic mushrooms.

GEOGRAPHY AND SEASONALITY

- GI irritant mushroom: wide distribution; large range of fruiting seasons
- Isoxazole mushroom: throughout eastern United States and Pacific Northwest; coniferous and deciduous forests; fruits in spring/early summer then again in fall
- Muscarinic mushroom: wide distribution; forests or fields; fruits in fall, early winter in temperate areas, year round in warm, moist climates
- Gyromitrin mushroom: grow throughout North America, primarily found in the spring
- Hallucinogenic mushroom: wide distribution; Pacific Northwest and Gulf Coast; lawns, gardens, roadsides, open woods; cultivated in homes for recreational use
- Hepatotoxic mushroom: wide distribution throughout United States; wide variation in habitats and fruiting seasons
- Nephrotoxic mushroom: abundant in North America, especially Canada. Grow in woods and forests. Uncommon in urban areas.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- GI: acute, self-limiting GI distress
- Isoxazole: acute inebriation followed by coma; generally self-limiting
- Muscarinic: acute muscarinic signs
- Gyromitrin: GI signs followed by neurologic, hepatorenal and/or hemolytic syndromes
- Hallucinogenic: acute central nervous system (CNS) signs; generally self-limiting
- Hepatotoxic: acute GI signs, then liver failure in 24-72 hours
- Nephrotoxic: renal tubular dysfunction

HISTORY, CHIEF COMPLAINT

- History of exposure to a mushroom; presence of mushroom in the vomitus
- GI: vomiting, diarrhea within 4 hours of ingestion
- Isoxazole: vomiting, ataxia, disorientation, sleep/coma within 4 hours of ingestion
- Muscarinic: muscarinic signs (salivation, vomiting, diarrhea, lacrimation, bradycardia) within 4 hours of ingestion
- Gyromitrin: GI signs within 6-8 hours, hepatorenal and hemolytic syndrome 36-48 hours post ingestion
- Hallucinogenic: dysphoria, vocalization within 30 minutes to 2 hours of ingestion
- Hepatotoxic: acute, severe vomiting ± diarrhea within 8-24 hours; apparent recovery then return of GI signs; evidence of

acute liver failure in 24-72 hours; renal failure possible in severe cases
- Nephrotoxic: renal insufficiency/renal azotemia 12 hours to 8 days post exposure

PHYSICAL EXAM FINDINGS

- GI: dehydration possible, but generally unremarkable
- Isoxazole: as described above
- Muscarinic: as described above; wet lung sounds
- Gyromitrin: vomiting, signs of abdominal pain, icterus, hepatomegaly, hemoglobinuria, anemia
- Hallucinogenic: vocalization, agitation
- Hepatotoxic: GI signs, signs of abdominal pain, icterus, hypotension, hepatomegaly, coma
- Nephrotoxic: polyuria, polydipsia, dehydration, vomiting

ETIOLOGY AND PATHOPHYSIOLOGY

- GI: several mechanisms; hypersensitivity, local irritation, induced enzyme deficiencies
- Isoxazole: muscimol mimics γ-amino-butyric acid, causing sedation; ibotenic acid acts on glutamate receptors triggering CNS stimulation; combined effects result in hyperesthesia, sedation, intermittent agitation
- Muscarinic: bind muscarinic acetylcholine receptors in parasympathetic nervous system; prolonged duration due to lack of degradation; does not inhibit acetylcholinesterase
- Gyromitrin: metabolized to monomethylhydrazine, leading to metabolic alterations
- Hallucinogenic: stimulate serotonin and possibly norepinephrine receptors in central and peripheral nervous systems
- Hepatotoxic: interfere with DNA synthesis, protein synthesis, resulting in cellular necrosis
- Nephrotoxic: cortinarin depletes nicotinamide adenine dinucleotide phosphate (NADPH), making cells more susceptible to free radicals and leading to lipid peroxidation (oxidative membrane injury).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History can be very helpful (observed ingestion of mushrooms, presence of mushrooms in pet's environment); otherwise, the diagnosis is reached when nonspecific disorders (e.g., gastroenteritis, hepatotoxicity, neurologic disturbance, etc.) are combined with direct evidence of exposure, such as mushrooms in vomitus. There is no practical clinical confirmatory test.

DIFFERENTIAL DIAGNOSIS

- GI, isoxazole, muscarinic, hallucinogenic: parvoviral enteritis, foreign body, garbage toxicosis, encephalitis, organophosphate and carbamate pesticide toxicosis, serotonergic drug toxicosis
- Hepatotoxic: other toxicoses (acetaminophen, iron, blue-green algae, *Cycas* spp.)
- Nephrotoxic: ethylene glycol, grapes, raisins, nonsteroidal antiinflammatory drug (NSAID) toxicity

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis, venous or arterial blood gas measurement: anemia (with hepatotoxic mushrooms); icterus, significant increase in liver enzymes ± bilirubin; hypoglycemia; acidosis
- Coagulation profile:
    - Coagulopathy possible with severe liver injury
    - Evidence of disseminated intravascular coagulation (hepatotoxic)

ADVANCED OR CONFIRMATORY TESTING

- Radiography: hepatomegaly may be present in cases of hepatotoxic mushroom toxicosis.
- Liver biopsy (hepatotoxic)
- Urine: muscimol can be detected in urine; turnaround time long, little value in acute cases.

TREATMENT

TREATMENT OVERVIEW

Initial treatment requires management of potentially life-threatening abnormalities if present (e.g., seizures, bleeding disorders). In the

absence of these acute abnormalities, treatment goals are centered on prevention and supportive care: induction of vomiting and administration of activated charcoal to minimize absorption, and treatment to prevent acute hepatic injury, excessive muscarinic effects, and complications as they arise.

ACUTE GENERAL TREATMENT

- Manage life-threatening conditions:
  - Control seizures (for isoxazole, hallucinogenic, hepatotoxic).
    - Diazepam (0.5-2 mg/kg IV) for seizures
    - Barbiturates, gas anesthetics if diazepam is ineffective (see p. 501)
  - Atropine for treating excessive bronchial secretions and bradycardia (muscarinic) 0.04 mg/kg (give ¼ of dose IV, remainder IM), titrate up as needed.
- Decontamination of patient (only animals showing no clinical signs):
  - Emesis induction (effective within a few hours; see p. 1364)
  - Gastric lavage (see p. 1281):
    - Consider where emesis is contraindicated (comatose, anesthetized, etc.) or if hepatotoxic mushroom ingestion is suspected.
  - Activated charcoal:
    - 1-4 g/kg or labeled dosage of commercial product given PO, or via stomach tube if patient is unconscious (see p. 1281). Repeat in 8 hours if animal is showing clinical signs of toxicosis, half original dose.
- Manage clinical signs:
  - Antiemetics (for GI irritant mushroom toxicosis):
    - Metoclopramide, 0.2-0.4 mg/kg q 6 h PO, SQ, or IM; or 1-2 mg/kg/d as constant rate IV infusion; *or*
    - Maropitant, 1 mg/kg SQ q 24 h; *or*
    - Dolasetron, 0.6-1 mg/kg IV q 12 h
  - Correct fluid/electrolyte/acid-base abnormalities (GI, hepatotoxic).
  - Blood replacement/clotting factors, vitamin K^1 for coagulopathy (hepatotoxic)
  - Cyproheptadine (for dysphoria or serotonin syndrome-like signs associated with hallucinogenic mushrooms):
    - 1.1 mg/kg PO or pre rectum q 6-8 h PRN
- Prevent/manage liver injury (hepatotoxic mushrooms):
  - *N*-acetylcysteine:
    - 200 mg/kg slow IV loading dose then 10 mg/kg/h IV constant rate infusion (CRI); *or*
    - 280 mg/kg PO loading dose, then 70 mg/kg PO q 6 h for at least 7 doses
  - Crystalline (sodium or potassium) penicillin G (interferes with enterohepatic recirculation of hepatotoxins):
    - 0.5-1 million U/kg/d × 3 days as IV CRI
    - Monitor serum electrolytes as appropriate based on formulation (e.g., sodium, potassium), and adjust therapy if necessary.
    - Do not use procaine penicillin G for intravenous administration (immediately fatal).
  - Silbinin and silymarin (extracts of milk thistle):
    - Veterinary formulation combines silybin and *S*-adenosylmethionine (SAMe) (Denamarin): 1 small/medium/large tablet PO q 24 h for dogs <5.5 kg/6-15.5 kg/16-29.5 kg, respectively.
- Supportive care:
  - Thermoregulation
  - Pain management (options include fentanyl, buprenorphine, tramadol)

CHRONIC TREATMENT

- SAMe:
  - For chronic management of liver injury
  - 18 mg/kg PO q 24 h for 2-3 months

NUTRITION/DIET

For management of chronic hepatopathy (hepatotoxic mushrooms)

- High-quality, low-residue protein, fiber diet (see p. 501)

POSSIBLE COMPLICATIONS

Hepatic insufficiency ± hepatic encephalopathy; chronic kidney disease

RECOMMENDED MONITORING

- Hydration, electrolytes if severe GI signs
- Hepatotoxic and gyromitrin mushrooms:
  - CBC
  - Blood glucose
  - Coagulation parameters
  - Liver enzymes
  - Renal values
- Nephrotoxic mushrooms:
  - Renal values

PROGNOSIS AND OUTCOME

- GI irritant, isoxazole, muscarinic, and hallucinogenic mushrooms: excellent with supportive care
- Hepatotoxic mushrooms: guarded to poor with hepatotoxicity
- Gyromitrin: guarded with hepatotoxicity and hemolysis
- Nephrotoxic: guarded

PEARLS & CONSIDERATIONS

COMMENTS

- Because of difficulty in differentiating between toxic and nontoxic mushrooms, any ingestion of unidentified mushrooms by pets should prompt decontamination procedures (emesis, activated charcoal, etc.).
- Identification of mushrooms is best done by a mycologist; local college biology departments or museums are potentially useful sources of expertise (mycologists). Internet can be used to help narrow down and match the picture of the mushroom involved.

TECHNICIAN TIP

Physical confinement can be important to prevent injury for dysphoric, disoriented animals.

EDITOR: SAFDAR A. KHAN

1ST EDITION AUTHOR: SAFDAR A. KHAN

Muscular Dystrophy

BASIC INFORMATION

DEFINITION

The muscular dystrophies (MDs) are a heterogeneous group of rare genetic disorders characterized by deficient or abnormal muscle cytoskeletal proteins. Progressive muscular weakness is the clinical feature MDs have in common.

SYNONYMS

There are many forms of muscular dystrophy; the most common terms used in veterinary medicine are Duchenne muscular dystrophy (DMD), or canine X-linked muscular dystrophy (CXMD), golden retriever muscular dystrophy (GRMD); Becker's muscular dystrophy (BMD); and autosomal recessive muscular dystrophy (ARMD) in Labrador retrievers (previously type 2 muscle fiber deficiency). This disorder has also been described as centronuclear-like myopathy.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- The disease is more prevalent in dogs but has been reported sporadically in cats.
- In dogs with DMD, clinical signs typically begin as early as 6 weeks of age and are progressive.
    - Cats frequently do not demonstrate overt clinical signs until they are ≥ years old.
    - The vast majority of affected animals are male.
- In Labradors with ARMD, clinical signs are generally apparent by 12-16 weeks of age. In this form of MD, both males and females may be affected.

GENETICS & BREED PREDISPOSITION

- DMD, an X-linked disorder, is best described in male golden retrievers but has been reported in the male rottweiler, Alaskan malamute, German shorthair pointer, Irish terrier, Samoyed, Groenendaeler shepherd, miniature schnauzer, Brittany spaniel, rat terrier, Pembroke Welsh corgi, Labrador retriever, and in domestic shorthair cats.
- A milder form (BMD) has been described in the Japanese spitz.
- In Labrador retrievers with ARMD, both yellow and black dogs of either sex can be affected.
- Sporadic cases of MD associated with dystrophin defects have been reported in female dogs.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- DMD: affects males mainly. Clinical signs often are severe.
- BMD: milder form
- ARMD: mainly Labrador dogs of either sex

HISTORY, CHIEF COMPLAINT

- Dogs affected with DMD are stunted.
- Dysphagia and difficulty prehending food can be seen as early as 6 weeks of age. Within weeks, muscle stiffness, “bunny-hopping,” exercise intolerance, and muscle atrophy may be observed. Clinical signs typically stabilize by 6-8 months of age. Regurgitation due to megaesophagus and diaphragmatic hypertrophy may lead to the development of cough, dyspnea, and respiratory distress due to aspiration pneumonia. Cardiomyopathy may lead to dyspnea, abdominal distension, and other signs of heart failure.
- ARMD: similar weakness, exercise intolerance, and atrophy may be seen, but dysphagia is rare, and clinical signs typically occur at a slightly later age.
- Cats with MD may show a predominance of muscle hypertrophy and stiffness. Occasionally dysphagia is evident.

PHYSICAL EXAM FINDINGS

- In DMD, no specific neurologic deficits are found. Affected animals have a characteristic gait, displaying elbow abduction,

hock adduction, and lordosis (ventroflexion of the spine). Hypertrophy of specific muscle groups is common, most notably the tongue.
- Dogs affected with ARMD, particularly if clinical signs are severe, will display limb-girdle muscle atrophy, kyphosis (extension/dorsiflexion of the spine), carpal hyperextension, and carpal valgus. In both disorders, myotactic reflexes such as the patellar reflex may be diminished or absent due to severe muscle atrophy.

ETIOLOGY AND PATHOPHYSIOLOGY

- Myofiber cytoskeletal proteins, usually dystrophin, are deficient or absent in DMD.
- Occasionally in DMD, dystrophin-associated or basement membrane proteins are dysfunctional.
- These proteins play a key role in maintaining structural integrity and contractile capability of myofibers. Dystrophin may also play a role in cellular homeostasis.
- The pathophysiologic mechanism of ARMD is unclear but likely related to an abnormally positive resting membrane potential in the myocyte.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on persistently elevated CK levels along with signs of neuromuscular weakness in young animals and a high index of suspicion in an at-risk breed.

DIFFERENTIAL DIAGNOSIS

- Polymyositis (autoimmune or infectious)
- Congenital myotonia
- Nemaline rod myopathy
- Polyneuropathy
- Spinal muscular atrophy
- Exercise-induced collapse of Labrador retrievers
- Progressive ossifying fibrodysplasia (cats)

INITIAL DATABASE

- Creatine kinase levels are markedly elevated in DMD as early as 1 week of age. Elevations peak at 6-8 weeks of age and then plateau at approximately 100× normal. Elevations are less dramatic in ARMD and in female dogs with DMD.
- Thoracic radiographs may reveal evidence of megaesophagus ± aspiration pneumonia.

ADVANCED OR CONFIRMATORY TESTING

- Electromyography (see online chapter: Electromyography and Nerve Conduction Velocity) reveals characteristic pseudomyotonic discharges and occasional fibrillation potentials and positive sharp waves. Abnormalities are evident by 10 weeks of age.
- Muscle biopsy in DMD (see p. 1305) typically shows areas of degeneration/mineralization along with areas of regeneration. ARMD is associated with type 2 fiber atrophy.
- Dystrophin deficiency can also be confirmed using immunocytochemistry on biopsy specimens.

TREATMENT

TREATMENT OVERVIEW

- Specific therapies for the muscular dystrophies are lacking. A new genetic technology called “exon-skipping” uses DNA-like molecules to patch the mutant dystrophin gene and has shown great promise for future clinical applications.
- Prevention of aspiration pneumonia

ACUTE AND CHRONIC TREATMENT

- Supportive (e.g., antibiotic therapy and nebulization/coupage for aspiration pneumonia)
- No definitive treatment at present

PROGNOSIS AND OUTCOME

- The prognosis with DMD is guarded to grave, depending on the severity of clinical signs and whether the animal has megaesophagus or congestive heart failure (both negative prognostic indicators).
- Because clinical signs tend to stabilize within the first year of life, some less severely affected animals may make acceptable house pets and may live for several years until they succumb.
- As with DMD, signs of ARMD tend to plateau between 6 and 12 months of age. Typically signs are mild compared with DMD, so affected Labradors may have a normal lifespan.

PEARLS & CONSIDERATIONS

COMMENTS

Breeders should be advised of the heritable nature of these disorders and remove carriers from the gene pool. Genetic counseling should be sought when an affected animal is identified.

Multiple Organ Dysfunction Syndrome

BASIC INFORMATION

DEFINITION

Failure of two or more organ systems, usually acutely and in association with a systemic illness; commonly represents the end-organ compromise caused by an unchecked systemic inflammatory response syndrome (SIRS)

EPIDEMIOLOGY

SPECIES, AGE, SEX: No predilection for age or sex; dogs appear more commonly affected than cats.

RISK FACTORS: Sepsis, polytrauma (e.g., hit by car), neoplasia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Multiple organ dysfunction syndrome (MODS) is a subset of critical illness; its expression varies according to the organ systems affected.

HISTORY, CHIEF COMPLAINT: Any critical illness and the associated chief complaint may be associated with the development of MODS.

PHYSICAL EXAM FINDINGS

- Physical exam findings are nonspecific and reflect the organs affected or the primary disease (such as abdominal sepsis).
- Animals are almost invariably collapsed, dull, tachycardic (or possibly bradycardic [cats]), tachypneic, and weak.

ETIOLOGY AND PATHOPHYSIOLOGY

- The organ systems that are commonly affected during MODS are the renal, cardiovascular, nervous, respiratory, gastrointestinal, hepatobiliary, and coagulation systems.
- Acute renal failure is a common feature of MODS in people and has been described in hospitalized dogs with critical illness. In this setting, acute renal failure is characterized by serum creatinine >2-3 mg/dL (>176-264 mmol/L), rising serum creatinine >0.5 mg/dL (>44 mmol/L) in 48 hours, or nonphysiologic oliguria.
- The lungs are a common site of organ dysfunction in MODS, manifesting as acute lung injury (ALI) or acute respiratory distress syndrome (ARDS; see p. 1369). ALI is characterized by a Pao^2:Fio^2 ratio between 300 and 200. ARDS is characterized by the presence of acute respiratory distress, bilateral radiographic pulmonary alveolar infiltrates, decreased pulmonary compliance, the absence of left-sided heart failure (pulmonary capillary wedge pressure <18 mm Hg), and a Pao^2:Fio^2 ratio of less than 200.
- Gastrointestinal (GI) dysfunction is common in dogs with MODS and can present as ileus, gastric ulceration, vomiting, and diarrhea. Secondary sepsis due to bacterial translocation from the GI tract to the circulation is common and potentially life-threatening.
- Neurologic dysfunction can present as peripheral or central disorders. Animals are usually weak, with decreased responsiveness that may progress to stupor or coma.
- Cardiovascular dysfunction may present as decreased cardiac output and hypotension (due to vasodilation, decreased cardiac contractility, etc.), or arrhythmias.
- Hematologic dysfunction produces prolonged coagulation times, decreased fibrinogen concentration, decreased antithrombin concentration, decreased platelet count, and/or clinical evidence of hemorrhage.
- Hepatic dysfunction manifests with progressive increases in alanine aminotransferase, serum alkaline phosphatase activity, and bilirubin concentration. Hepatic failure can lead to profound coagulopathy.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is reached by identifying overt and laboratory evidence of dysfunction of two or more organ systems in an ill patient. The implication of making a diagnosis of MODS is prognostic, since the presence of MODS conveys a worse prognosis.

DIFFERENTIAL DIAGNOSIS

Sepsis or SIRS may occur without the failure of multiple organ systems, in which case MODS is not present.

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis, coagulation profile: identification of abnormalities listed previously and abnormalities caused by underlying illness
- Thoracic radiography, pulse oximetry, and arterial blood gas measurement if respiratory dysfunction
- Blood pressure: identify hypotension.
- Electrocardiogram: identify cardiac arrhythmias.
- Neurologic exam: to rule out central and peripheral nerve involvement

TREATMENT

TREATMENT OVERVIEW

Treatment depends on the failing organ system. The overall goals are to stabilize blood pressure and ensure optimal perfusion of the involved organs (correction of dehydration, treatment of hemodynamically significant arrhythmias). This involves aggressive therapy for the underlying cause.

ACUTE GENERAL TREATMENT

- Respiratory failure:
  - Supplemental oxygen and/or positive pressure ventilation
- Cardiovascular dysfunction:
  - Positive inotropic drugs (dobutamine, 5-10 mcg/kg/min) and/or vasopressor drugs (dopamine, 10-20 mcg/kg/min) are used if critically ill, hydrated patients with MODS fail to produce a sufficient arterial blood pressure.
- Coagulopathy:
  - Disseminated intravascular coagulopathy (see p. 1387) is the most commonly seen coagulation dysfunction. Goals are to treat the underlying cause while maintaining an adequate hematocrit to ensure oxygen delivery to tissues (treatment with packed red blood cells) and to replace coagulation factors and endogenous anticoagulants (plasma transfusion).
- Renal dysfunction:
  - Goals are to ensure adequate volume status/hydration and blood pressure and to avoid nephrotoxic medications (see p. 1369).
- Gastrointestinal dysfunction:
  - Gastroprotectants (e.g., famotidine, 0.5-1 mg/kg IV q 12 h; or omeprazole, 0.7 mg/kg PO q 24 h) are administered routinely.
  - Prokinetic drugs (ranitidine, 1-2 mg/kg slow IV; or erythromycin, 0.5-1 mg/kg PO q 8 h; or cisapride, 0.1-1 mg/kg PO q 8-12 h) are considered if ileus is present without obstruction.
  - Start enteral feedings as soon as possible.

PROGNOSIS AND OUTCOME

The presence of MODS conveys a worse prognosis: mortality in dogs with abdominal sepsis is 70% if MODS is present and 25% if it is not.

PEARLS & CONSIDERATIONS

COMMENTS

- MODS should be suspected in any critically ill animal with evidence of organ dysfunction.
- The presence of MODS has prognostic importance (failure of four or more organs is associated with nearly 100% mortality in humans and, by extrapolation, in dogs and cats).
- The onset of MODS is a critical step back in any patient. Critically ill patients should be carefully monitored for the development of signs of failure in a previously unaffected organ, such as new azotemia, icterus, or coagulopathy.
- Rapid appreciation of new-onset abnormalities may permit reversal of organ failure before MODS and subsequently lead to a better prognosis. For example, development of azotemia may respond to a fluid challenge or therapy with mannitol or

dopamine. At the very least, discontinuation of a potentially nephrotoxic agent (e.g., amikacin) in a pet with azotemia is mandatory.

PREVENTION

Rapid identification and correction of sepsis or severe hypovolemia

TECHNICIAN TIPS

Careful monitoring is useful for early detection of MODS. Like many aspects of critical illness, MODS is best prevented rather than treated.

CLIENT EDUCATION

MODS is a severe complication of disease, with guarded to poor outcome.

Multiple Myeloma and Plasma Cell Tumors

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Multiple myeloma (MM) is a malignant disease of plasma cells derived from one clone in the bone marrow. It is a systemic disease, and multiple bone marrow sites are involved. This disease is characterized by the production of immunoglobulins (Ig) by malignant plasma cells; IgM or IgA in the dog, and IgG in the cat. *Waldenström's macroglobulinemia* refers to the disease in which IgM is the Ig type produced. Major extramedullary involvement (i.e., spleen, liver, skin) at initial presentation is common in cats.
- Plasma cell tumors (PCT) are solitary tumors composed of plasma cells, originating in sites other than the bone marrow (i.e., extramedullary). They can arise from skin, soft tissues, or bone. Serum globulin/Ig levels are often normal in this localized form of disease.

SYNONYM

Plasmacytoma, myeloma-related disorder (MRD)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Rare in dogs and cats
- Older animals (8-12 years)
- Male predominance in noncutaneous PCT, no sex predilection in MM

GENETICS & BREED PREDISPOSITION

- MM: German shepherd
- PCT: Airedales, cocker spaniels, Kerry blue terriers, Scottish terriers, standard poodles

ASSOCIATED CONDITIONS & DISORDERS: Multiple myeloma:

- Hyperviscosity syndrome
- Bence-Jones proteinuria
- Pathologic fracture
- Bleeding diathesis
- Increased susceptibility to infection; immunosuppression
- Heart failure
- Renal disease
- Visual/ocular disturbances
- Amyloidosis
- Cryoglobulinemia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Multiple myeloma
- Waldenström's (IgM) macroglobulinemia
- Cutaneous plasma cell tumor
- Extramedullary plasma cell tumor (EMP)
- Solitary osseous plasma cell tumor (SOP)

HISTORY, CHIEF COMPLAINT

- MM:
  - Dogs generally present with lameness or skeletal pain. Bleeding (epistaxis, ecchymoses, mucosal hemorrhage),

polyuria and polydipsia, central nervous system signs (seizures, dementia), and visual disturbances may also occur.
    - Cats tend to present with an insidious onset of nonspecific signs (anorexia, weight loss, lethargy). Other signs similar to those seen in dogs may rarely occur.
- Cutaneous PCT:
    - Raised nodule on the trunk, limbs, head, or in the oral cavity
- EMP:
    - Typically occur in the GI tract and cause signs such as weight loss, anorexia, nausea, vomiting, diarrhea.
- SOP:
    - Occur as a single lesion in bone and can cause bony swellings, lameness, or skeletal pain

PHYSICAL EXAM FINDINGS

- Skeletal pain, fractures
- Weight loss (MM, EMP)
- Lethargy (MM, EMP)
- Visual disturbances (MM)
- Depression, seizures, abnormal reflexes (MM)
- Epistaxis, gingival bleeding, ecchymoses
- Pallor, weak pulses, heart murmur, increased lung sounds (MM)
- Signs of congestive heart failure such as dyspnea (MM)
- Soft-tissue or bony masses
- Abdominal organomegaly

ETIOLOGY AND PATHOPHYSIOLOGY

- Malignant plasma cells produce large amounts of one type of Ig.
- Either the entire immunoglobulin can be produced or just a portion (e.g., light chain). The Ig or portion is referred to as the *M protein,* and the concentration is typically proportional to tumor burden in multiple myeloma. Low levels of M proteins are produced in PCT.
- Isolated lesions in bone or diffuse osteopenias are due to areas of proliferating malignant plasma cells. These areas are weakened, and pathologic fractures are common. Bone lesions are uncommon in cats.
- M protein in the blood increases serum viscosity, which causes hyperviscosity syndrome (HVS). HVS is due to sludging of blood in small vessels, and it causes ineffective oxygen and nutrient delivery. It is more common with IgM MM (Waldenström's), as the IgM molecule is large. HVS manifests as:
    - Bleeding disorder (due to protein coating of platelets, inhibition of platelet and coagulation factor release, and thrombocytopenia due to bone marrow infiltration)
    - Ocular changes
    - Congestive heart failure (due to hypertension, myocardial hypoxia, anemia, and increased workload)
    - Mentation changes and peripheral neuropathy (from M protein destruction of myelin)
- The light chain portion of the Ig is also called the *Bence-Jones protein,* and owing to its small size, it is filtered by the normal glomerulus. These can be detected in the urine of patients with MM with a specific test (but not on a urine dipstick).
- Renal disease develops secondary to Bence-Jones proteinuria, tumor infiltration into kidney, hypercalcemia, amyloidosis, and decreased renal perfusion.
- Hypercalcemia occurs secondary to the release of osteoclast activating factor by neoplastic cells.
- Cytopenias develop secondary to bone marrow infiltration and blood loss due to coagulopathies.
- An increased susceptibility to infection is seen because of the suppression of normal Ig levels, leukopenias, and impaired cell-mediated immunity. Urinary tract infections (UTIs) and pneumonia are the most common manifestations.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Differentials for monoclonal gammopathy: ehrlichiosis, leishmaniasis, feline infectious peritonitis, pyoderma, lymphoma, leukemia, idiopathic (monoclonal gammopathy of unknown significance)

INITIAL DATABASE

- Funduscopic exam: hemorrhage, retinal detachment, dilated/tortuous vessels
- CBC: cytopenias, thrombocytopenia
- Serum biochemistry panel may reveal hypercalcemia, elevated total protein, hyperglobulinemia, azotemia
- Urinalysis: infection possible (immunosuppression)

ADVANCED OR CONFIRMATORY TESTING

- MM:
  - For a diagnosis of MM in dogs, two of the following four criteria are needed: monoclonal gammopathy, lytic bone lesions, plasma cell infiltration of the bone marrow, and Bence-Jones proteinuria.
    - Serum protein electrophoresis: monoclonal gammopathy appears as a spike, typically in the β or γ region.
    - Survey radiographs: multiple areas of bony lysis or diffuse osteopenias are frequently found in the vertebrae, scapulae, and long bones in dogs with MM. Pathologic fractures may also be present. These signs are not typically found in cats. A solitary area of lysis is typically seen with SOPs.
    - Bone marrow aspiration: >10% plasma cells with atypia or >20% plasmacytosis are required for the diagnosis of multiple myeloma. Aspiration of multiple sites may be necessary.
    - Heat precipitation, or electrophoresis of urine: identifies Bence-Jones proteins. They are not detected on urine dipstick.
  - In cats, bony lysis and marked marrow infiltration are uncommon. Organ infiltration (e.g., liver, spleen) by neoplastic plasma cells may be useful in aiding the diagnosis of MM.
  - Serum or urine immunoelectrophoresis: identifies the class of immunoglobulin. (IgG, IgM, IgA). Dogs with multiple myeloma typically produce either IgG or IgM, and cats typically produce IgA.
  - Serum viscosity may be measured in some labs to verify HVS.
- Plasma cell tumor:
  - Tissue biopsy confirmation of cutaneous PCT, EMP, and SOP

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to reduce myeloma cell burden, relieve bone pain, allow for skeletal healing, and decrease serum viscosity and Ig levels.

ACUTE GENERAL TREATMENT

- Stabilize fractures.
- Surgical excision of plasma cell tumors if possible. Wide surgical margins generally are not necessary, but the margins should be free of both gross and microscopic evidence of neoplasia (i.e., “clean”).
- IV fluids for hydration and diuresis to decrease serum viscosity, azotemia, and hypercalcemia
- Analgesia for bone pain
- Plasmapheresis to decrease serum viscosity and remove Bence-Jones proteins may be available at some institutions. Therapeutic phlebotomy (with donor red cell transfusion) can possibly achieve a similar effect.
- Antibiotic therapy to treat infections (UTI, pneumonia); prophylactic broadspectrum antibiotics may be beneficial. Do not use nephrotoxic or bacteriostatic antibiotics.

CHRONIC TREATMENT

- Chemotherapy: melphalan with prednisone is the mainstay of treatment for MM. Cyclophosphamide can also be given initially in cases of widespread disease or severe hypercalcemia, but the benefit is unclear. Melphalan causes erratic myelosuppression in cats; substituting chlorambucil has been advocated. Chemotherapy can be attempted in cases of cutaneous PCT, EMP, or SOP that are nonresectable or if radiation therapy is not available. However, response information is limited. Other cytotoxic drugs (doxorubicin, vincristine) have been reported to have some activity in the rescue setting for some patients with MM. Consultation with an oncologist for the most current treatment options is recommended.
- Radiation therapy is the treatment of choice for SOP, some incompletely excised PCT, and localized MM bony lesions.
- Surgical excision is curative for most cutaneous PCT.

RECOMMENDED MONITORING

- Monitor CBCs frequently, owing to myelosuppressive effects of melphalan. Doses or schedule may require adjustment based on patient response.
- Monitor serum electrophoresis, as size of monoclonal spike is proportional to tumor burden. Plasma globulin level can also be used for monitoring remission status.
- Monitor for evidence of infection, and treat with antibiotics as needed, owing to immunosuppression.

PROGNOSIS AND OUTCOME

- MM:
  - Dogs: when treated with melphalan/prednisone, response rate is >90%. A good response is defined as 50% reduction of initial M protein level. Long-term prognosis is guarded, as recurrence is inevitable. Median survival time is 540 days with melphalan/prednisone, 220 days for prednisone alone. Negative prognostic factors in dogs include hypercalcemia, Bence-Jones proteinuria, and extensive bony lysis.
  - Cats: prognosis is poor; most responses are partial, and median survival time is 137 days. Degree of differentiation of predicts survival: cats with well-differentiated tumors have a median survival of 254 days, and cats with poorly differentiated tumors have a median survival of 14 days.
- Cutaneous PCT:
  - Benign biological behavior: surgical excision is generally curative.
- Extramedullary plasmacytoma (EMP):
  - EMP at sites other than the oral cavity frequently metastasize, but long-term survival is possible with surgical excision and chemotherapy and/or radiation. Oral plasmacytomas do not metastasize and local control provides long-term control. Median survival of dogs with complete resection was 474 days.
- SOP:
  - Eventually progress to MM, but there may be a long disease-free interval. Radiation therapy may provide control for 1 year or more.

PEARLS & CONSIDERATIONS

COMMENTS

- Perform serum protein electrophoresis on any animal in which MM is suspected, even if globulin and serum viscosity are normal.
- Use size of monoclonal gammopathy to monitor response to treatment.
- Extensive infiltration of plasma cells in sites outside the bone marrow is common during the initial presentation of cats.
- Cats experience more severe myelosuppression from melphalan than dogs.

AUTHOR: ANDREA B. FLORY

EDITOR: KENNETH M. RASSNICK

Mothball Toxicosis

BASIC INFORMATION

DEFINITION

Adverse reactions, mainly gastrointestinal/hemolytic or gastrointestinal/neurologic, that occur as a result of consuming naphthalene- or paradichlorobenzenecontaining mothballs, respectively

SYNONYMS

Common brand names of mothballs: Enoz Old Fashioned Moth Balls (naphthalene 99.9%), Enoz Para Moth Balls (paradichlorobenzene 99.6%), Garbage Can Deodorizer (paradichlorobenzene 99.75%)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs of all breeds, ages, and both sexes; dogs more commonly involved than cats
- Young animals may be more sensitive to naphthalene.
- Compared to dogs, cats are considered more sensitive to oxidative hemoglobin damage from naphthalene.

GENETICS & BREED PREDISPOSITION: Animals deficient in glucose-6-phosphate dehydrogenase (dog breeds such as Akitas, Shiba Inus, and Tosas) may be more susceptible to erythrocyte oxidative damage by naphthalene. **RISK FACTORS:** Use of mothballs as repellents

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Naphthalene mothballs
- Paradichlorobenzene mothballs

HISTORY, CHIEF COMPLAINT

- Availability of mothballs in pet's environment
- Acute onset of vomiting, diarrhea, lethargy

PHYSICAL EXAM FINDINGS

- Naphthalene:
  - Listlessness, abdominal pain, inappetence, vomiting, and diarrhea within a few hours after ingestion
  - Mothball scent on the breath
  - Evidence of hemolytic anemia (see p. 71 ; pale mucous membranes, poor capillary refill time, icterus) may not be present until 12-48 hours after ingestion with naphthalene mothballs.
- Paradichlorobenzene:
  - Vomiting, diarrhea, lethargy, tremors, and seizures within a few hours after ingestion

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Naphthalene is found in “old-fashioned” mothballs, and in some moth flakes/crystals. A naphthalene mothball weighs 3.6 g. Acute dose causing hemolysis in dogs = 1525 mg/kg, but a minimum lethal dose as low as 400 mg/kg is reported in dogs.
- Paradichlorobenzene mothballs are used as cake deodorizers in diaper and garbage pails and in bathrooms.
- A paradichlorobenzene mothball weighs 5 g. Paradichlorobenzene oral LD^{50} in mouse = 2950 mg/kg, rat = 500 mg/kg.
- Naphthalene-type mothballs are approximately two times more toxic compared to paradichlorobenzene type. Ingestion of one mothball for a medium-sized dog (30 lb [14 kg]) can be a potential toxic hazard.
- According to label claim on some brands, mothballs are occasionally used as animal repellents (rabbits, dogs, cats).

Mechanism of Toxicosis:

- Most cases occur acutely due to accidental ingestion of mothballs.
- Naphthalene:
  - Naphthalene itself does not cause hemolysis; its metabolites (alpha-and beta-naphthoquinones) are responsible for hemolysis. Hemolysis and methemoglobinemia occur secondary to the strong oxidant effect of naphthalene metabolites on red blood cells (RBCs) and the lack of RBC glutathione to prevent these oxidizing effects.
  - Nausea, vomiting, and diarrhea are due to the irritating properties of naphthalene.
- Paradichlorobenzene:
  - Paradichlorobenzene is an organochlorine insecticide. Other members of this class mainly affect the nervous system and cause tremors, salivation, ataxia, and seizures.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A functional diagnosis sufficient to initiate treatment can be made from a known history of exposure or suspected exposure with the presence of one of more of the following: mothball scent on the breath, signs of methemoglobinemia or hemolysis (naphthalene), or tremors and seizures (paradichlorobenzene).

DIFFERENTIAL DIAGNOSIS

- Naphthalene:
  - Other intoxications causing hemolysis (e.g., onions/garlic, zinc, acetaminophen; see p. 71 and p. 1374)
  - Immune-mediated hemolytic anemia
  - Erythrocytic parasites
- Paradichlorobenzene:
  - Other intoxications causing tremors/seizures (organophosphate/carbamate, garbage toxicosis, lead, arsenic)
  - Encephalitis (sterile, infectious)
  - Brain neoplasm
  - Idiopathic epilepsy

INITIAL DATABASE

- Naphthalene:
  - CBC: regenerative anemia due to hemolysis, hemoglobinemia, Heinz bodies (12-48 hours after exposure)
  - Serum biochemical changes: elevation in serum bilirubin, increased liver enzymes, increased blood urea nitrogen (BUN) and creatinine
  - Urinalysis: hemoglobinuria
- Paradichlorobenzene:
  - No significant CBC or serum biochemistry changes may be noted. Rarely, increases in BUN, serum creatinine, and liver enzymes are possible.

ADVANCED OR CONFIRMATORY TESTING

- Naphthalene or its metabolites (1-naphthol or mercapturic acid) can be found in urine, stool, or blood 8-24 hours after ingestion. Body fat or liver can also be used for detecting naphthalene.
- Abdominal radiographs may help differentiate between mothballs and other products which contain paradichlorobenzene (densely radiopaque) from those which contain naphthalene (radiolucent or faintly radiopaque).

TREATMENT

TREATMENT OVERVIEW

In patients with suspected or confirmed ingestion, induction of vomiting and activated charcoal administration are warranted even in the absence of clinical signs. Additional treatment (methemoglobinemia, anemia [naphthalene], control of seizure/tremor [paradichlorobenzene]) is implemented when the specific secondary effects occur.

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Induction of vomiting (): useful within 1-2 hours; do not induce if animal is already vomiting; feed the animal first; 3% hydrogen peroxide (0.5-2 mL/kgPO, maximum 45 mL in largest dogs; repeat once after 10-15 minutes if no vomiting); or apomorphine, 0.03 mg/kg IV or 0.04 mg/kg IM; or xylazine (dogs and cats) at 0.5-1 mg/kg IV or IM.
  - Activated charcoal: 2-4 g/kg; mix with 70% sorbitol 1-3 mL/kg and give PO.
- Treat methemoglobinemia:
  - *N*-acetylcysteine (NAC) acts as a precursor to glutathione; may provide some protection to liver and RBCs against oxidative damage; efficacy of NAC in naphthalene toxicosis is not proven; 140 mg/kg PO or slow IV. then 70 mg/kg/dose, q 6 h for up to 7 doses.
  - Similarly, *S*-adenosyl methionine (40 mg/kg PO, then 20 mg/kg PO q 24 h beginning 24 h later) has been used as a glutathione donor in a similar setting of Heinz body hemolytic anemia (acetaminophen toxicosis) in a dog.
  - Ascorbic acid (antioxidant effect) at 20-30 mg/kg PO, IM, or slow IV q 8 h for 2-3 days
- Supportive care:
  - Fluid diuresis
  - Control seizures with diazepam (0.5-2 mg/kg IV PRN) for intoxications involving paradichlorobenzene-type mothballs.
  - Blood transfusion if needed (see p. 1347)
  - 1-2 mEq/kg of sodium bicarbonate added to fluids may help reduce renal damage due to hemoglobinuria (assess and monitor acid-base status first).

POSSIBLE COMPLICATIONS

Rare liver or renal damage with paradichlorobenzene

RECOMMENDED MONITORING

- CBC (methemoglobinemia, Heinz body anemia)
- Serum biochemistry profile (serum bilirubin, renal values, and hepatic enzymes)
- Hematocrit
- Urinalysis

PROGNOSIS AND OUTCOME

- Naphthalene: good prognosis with supportive care; poor prognosis if evidence of severe hemolysis, renal or hepatic damage present
- Paradichlorobenzene: good prognosis with supportive care

PEARLS & CONSIDERATIONS

COMMENTS

- Differentiation of the two types of mothballs is difficult because both are white crystalline solids at room temperature, and both have a similar odor.
- Dissolving a mothball in turpentine for 60 minutes can help differentiate between the two types of mothballs. Paradichlorobenzene is more soluble in turpentine than naphthalene. A paradichlorobenzene mothball usually dissolves within 30-60 minutes compared to about ¼ of a naphthalene mothball.

1ST EDITION AUTHOR: SAFDAR A. KHAN

Mitral/Tricuspid Regurgitation Due to Myxomatous Valve Disease

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Pathologic degeneration of the atrioventricular (mitral and tricuspid) heart valves, characterized by accumulation of glycosaminoglycans (myxomatous proliferation) and fibrosis of the valve leaflets and tendinous cords. The valvular degeneration leads to valvular regurgitation and eventually to congestive heart failure (CHF). The condition most commonly involves the mitral valve, with or without changes of the tricuspid valve.

SYNONYMS

Acquired mitral or tricuspid regurgitation or insufficiency, chronic degenerative valvular disease, chronic valvular heart disease, chronic valvular fibrosis, endocardiosis, myxomatous degeneration

EPIDEMIOLOGY

SPECIES, AGE, SEX: The most common cardiac disease in dogs. Prevalence is strongly influenced by age; it is uncommon in young individuals but common in old dogs. Males develop the disease at a younger age than females.

GENETICS & BREED PREDISPOSITION: All breeds; most common in small to medium-sized breeds: papillons, poodles, Chihuahuas, dachshunds, and Cavalier King Charles spaniels. The age at which the disease develops is inherited as a poly genetic threshold trait (i.e., multiple genes influence the trait, and a certain threshold has to be reached before the disease develops). Males have a lower threshold than females, leading to a higher disease prevalence at a given age.

ASSOCIATED CONDITIONS & DISORDERS: Myxomatous degeneration of the semilunar valves (very uncommon in dogs and when present, seldom of clinical importance).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Incidental finding: no clinical signs of disease caused by the valvular regurgitation:
  - Cardiac auscultation (presence of systolic click [early stage] and/or systolic heart murmur)
  - Cardiomegaly on radiographs
  - Electrocardiographic changes: P mitrale and/or P pulmonale, increased R wave amplitude, increased QRS duration
- Valvular regurgitation causing clinical signs of CHF (most commonly left-sided)
- Sudden death may occur but is uncommon, especially in the absence of preceding clinical signs of CHF.

HISTORY, CHIEF COMPLAINT

- Cough (often worse in the morning or evening hours)
- Tachypnea/dyspnea/orthopnea
- Lethargy
- Reduced exercise tolerance
- Syncope
- Anorexia
- Weight loss
- Abdominal enlargement

PHYSICAL EXAM FINDINGS

- Patients without overt clinical signs:
  - Systolic click (early stage)
  - Systolic heart murmur; with progression, the murmur often increases in intensity.
- Patients showing overt clinical signs:
  - Loud heart murmur unless there is significant myocardial failure, which may develop because of concurrent myocardial disease or because of chronic ventricular volume overload
  - Tachycardia and loss of respiratory sinus arrhythmia

- Arrhythmia and pulse deficit may be present, most commonly atrial/supraventricular premature beats or atrial fibrillation.
- Weak femoral pulse
- Prolonged capillary refill time and pale mucous membranes
- Tachypnea/dyspnea/orthopnea
- Respiratory crackles/rales
- Expectation of pink froth: pulmonary edema may be evident in the nostrils and oropharynx in cases with severe CHF.
- Ascites possible with tricuspid valve disease

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary inciting factor for the valvular degeneration is unknown.
- Degeneration begins with subendothelial deposition of mucopolysaccharide and areas of fibrosis, which produces ballooning/thickening of the valve leaflet and tendinous cords.
- With progression, the valve lesions cause insufficient coaptation of the leaflets, leading to regurgitation of blood from the ventricle into the atrium.
- Severity and progression of atrioventricular (AV) valve regurgitation depends on the severity and progression of valve lesions (leaflets and/or tendinous cords).
- Slight to moderate AV valve regurgitation is often completely compensated for years and is not expected to cause clinical signs of disease.
- Compensatory mechanisms include cardiac dilatation and eccentric hypertrophy, increased force of contraction, increased heart rate, increased pulmonary lymphatic drainage (left-sided AV valve regurgitation), fluid retention, and neurohormonal modulation of cardiovascular function.
- With progression, the valvular regurgitation can no longer be compensated, leading to reduced cardiac output and increased venous pressures (leading to pulmonary edema if left-sided CHF and to ascites if right-sided).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the characteristic left apical location of a systolic heart murmur in an adult dog. Thoracic radiographs are indicated, particularly if cough or dyspnea is present, to differentiate between pulmonary edema and unrelated comorbid conditions such as collapsing trachea and chronic sterile bronchitis, which are common. Echocardiography is the diagnostic test of choice for demonstrating the valve lesion; a high index of suspicion usually exists prior to echocardiography, and it functions as a confirmatory test as well as to identify severity of secondary changes.

DIFFERENTIAL DIAGNOSIS

- Physical:
  - Other causes of heart murmurs:
    - Secondary mitral regurgitation due to dilated or hypertrophic cardiomyopathy
    - Congenital heart disease
    - Vegetative (bacterial) endocarditis
    - Anemia
    - Physiologic flow murmur
  - Other causes of respiratory distress:
    - Primary respiratory disease such as bronchitis, pneumonia, tracheal/bronchial collapse, and neoplasia
    - Pleural diseases with effusion
    - Anemia
    - Metabolic acidosis
    - Other causes of CHF
    - Other (noncardiac) causes of pulmonary edema
  - Other causes of reduced exercise capacity, lethargy, and wasting:
    - Primary diseases of locomotor system, such as chronic degenerative joint diseases, intervertebral disk disease
    - Other systemic or organ-related disease (i.e., renal or hepatic failure, neoplasia, and anemia)
- Radiographic:
  - Cardiac enlargement from other heart disease
  - Increased pulmonary interstitial or alveolar radiopacity due to primary respiratory disease (see Other causes of respiratory distress); expiratory radiographs
  - Normal variation
- Echocardiographic:
  - Valve abnormality: congenital (e.g., AV valve dysplasia) or infectious (endocarditis)

- Increased atrial and ventricular size and secondary regurgitation due to dilated cardiomyopathy or congenital heart disease

INITIAL DATABASE

- Diagnosis of AV valve myxomatous degeneration:
  - Echocardiography: detection of thickened/ballooning AV valve, identification of regurgitant jet (spectral or color-flow Doppler)
- Assessment of disease severity and complications:
  - Auscultation: a low-intensity murmur with or without a systolic click in an otherwise healthy dog usually indicates low disease severity.
  - Echocardiography: atrial and ventricular size, size and velocity of regurgitant jet (reduced velocity indicates high left atrial pressure and severe disease); ventricular motion (fractional shortening) is usually exaggerated in advanced stages, but a normal or reduced motion in the presence of severe regurgitation is indicative of myocardial failure and evidence of complication.
  - Electrocardiogram: presence of tachyarrhythmia such as atrial fibrillation or ventricular ectopy (usually indicates severe disease, presence of complication, or other cardiac disease).
  - Radiography: cardiac size, presence of pulmonary congestion and edema, exclusion of other (noncardiac) causes for clinical signs of disease
  - CBC, serum biochemistry panel, urinalysis: usually unremarkable in less severe cases; cases with CHF may have slightly increased liver enzymes and evidence of prerenal azotemia.

ADVANCED OR CONFIRMATORY TESTING

- Serum cardiac troponin I level: unremarkable in less severe cases, moderate to severe disease is associated with slightly to moderately increased levels, but significant increases indicate complication or presence of other cardiac disease.
- Serum natriuretic peptides (atrial natriuretic peptide [ANP], *N*-terminal pro-brain natriuretic peptide [NT-proBNP]): levels are often unremarkable in less severe cases. Moderate to severe disease is always associated with increased levels, and NT-proBNP levels can help differentiate dyspnea of cardiac origin from noncardiac causes; lack of a cage-side test is limiting.
- Blood culture in case of suspicion of vegetative endocarditis

TREATMENT

TREATMENT OVERVIEW

Goals of treatment:

- Treatment is not indicated in less severe disease without overt clinical signs.
- To alleviate clinical signs and improve quality of life and life expectancy in cases with signs of CHF by evacuating pulmonary edema/ascites and abolishing congestion; improving the hemodynamic situation by controlling heart rate, reducing aortic impedance and with inotropic support; and protecting from detrimental exposure to neurohormones.

ACUTE GENERAL TREATMENT

- For congestive heart failure (see p. 468)
- Provide optimal nursing care, including maintenance of appropriate environmental temperature and humidity, elevation of the head on a pillow and placement of sedated dogs in sternal posture

CHRONIC TREATMENT

- See Heart Failure, Chronic, p. 470
- Exact composition of medical therapy depends on disease severity and clinical signs. Most dogs with CHF require furosemide, which is usually combined with an angiotensin-converting enzyme inhibitor (ACEI) and pimobendan. However, spironolactone has also emerged as adjunct therapy to other heart failure therapy, owing to results from recent clinical trials.
- Furosemide PO. Dose depends on severity of heart failure (CHF) but should be kept as low as possible:
  - Mild to moderate CHF: 1 mg/kg q 1-2 days to 3-4 mg/kg q 8 h
  - Moderate to severe CHF: 2-3 mg/kg q 12 h or higher
- Pimobendan 0.5 mg/kg q 12 h PO
- ACEI (i.e., enalapril, benazepril, ramipril). Dosage and dosage interval dependent on particular ACEI used.
- Spironolactone 2 mg/kg q 12-24 h PO and/or hydrochlorothiazide 2-4 mg/kg q 12 h PO
- Digoxin 0.22 mg/m^2 q 12 h PO, or lower. See p. 675 for body surface area-body weight conversion table.
- Negative inotrope such as betareceptor antagonists or calciumchannel blockers may be required to control ventricular rate in

case of atrial fibrillation, but they should be used with caution because excessive suppression of heart rate is easily achieved, rapidly worsening heart failure. Begin with low dosage (only once CHF is controlled) and titrate up.

NUTRITION/DIET

Maintain adequate calorie intake (approximately 60 kcal/kg body weight) to minimize muscle wasting. Modestly restrict sodium intake, avoid food with high sodium content.

BEHAVIOR/EXERCISE

Allow walks, but avoid strenuous exercise.

DRUG INTERACTIONS

- Furosemide potentiates the effects of an ACEI, spironolactone, or a thiazide.
- Nonsteroidal antiinflammatory drugs should be used with caution in patients receiving furosemide and ACEI.
- The combination of pimobendan and a calcium-channel blocker or a β-receptor antagonist should be avoided.

POSSIBLE COMPLICATIONS

- Dogs initially not showing clinical signs may develop CHF.
- Dogs stabilized by medical therapy may suffer recurrent CHF.
- Dogs with initially left-sided HF may develop biventricular CHF, often due to pulmonary hypertension.
- Development of arrhythmia, most commonly atrial fibrillation
- Rupture of first-order tendinous cord(s), leading to a flail valve leaflet
- Atrial tear leading to acquired atrial septal defect or cardiac tamponade
- Formation of intracardiac thrombus and/or myocardial infarction

RECOMMENDED MONITORING

- Encourage owner to participate in a structured care program to facilitate body weight, appetite, respiratory and heart rate monitoring; provide client support to ensure good medication compliance and dosage adjustments.
- Frequency of reexaminations depends on severity of valvular insufficiency and severity of HF (if present).
- Dogs without signs of CHF:
  - Slight to moderate valvular regurgitation: once every 6 months to once a year
  - Moderate to severe valvular regurgitation may require more frequent monitoring.
- Dogs with signs of CHF:
  - Once acute CHF has been successfully treated, dogs may often be treated at home.
    - Reexamination after 1-2 weeks of therapy (check for signs of CHF, dehydration, electrolyte balance, renal function and presence of any complications)
    - Thereafter once every 3 to 6 months
    - More severe cases may require more frequent monitoring.

PROGNOSIS AND OUTCOME

- Dogs without signs of CHF:
  - Chronic disease progression. Dogs with low disease severity may sustain this compensated state for several years before signs of CHF develop.
  - Risk factors for progression from mild to severe: severity of valve lesions, age, and gender
  - Risk factors for CHF: regurgitant status, left atrial size, natriuretic peptides
- Dogs with CHF (acute or stabilized):
  - Prognosis depends on age, severity of heart failure, presence of complications or other disease (such as kidney disease).
  - Clinical trials indicate a mean survival time from onset of CHF of 8-10 months but may vary from days to years in different dogs.

PEARLS & CONSIDERATIONS

COMMENTS

- If presence of mitral valve regurgitation is equivocal, the murmur or regurgitant jet may become obvious after stressing the dog slightly.
- Loud musical murmurs are unusual. The intensity of this type of murmur is not related to disease severity.
- Dogs with syncope related to intermittent atrial arrhythmia may sometimes be managed by a low dose of digoxin (approximately half recommended dose).
- Syncopal dogs with MR but without clinical signs of CHF should be examined for the presence of pulmonary hypertension.
- Mild pleural and/or pericardial effusion may develop because of CHF. More pronounced accumulation of fluid in these locations raises the suspicion of other causes.

PREVENTION

- Because the susceptibility to myxomatous atrioventricular valve degeneration in dogs is inherited, the disease prevalence in affected breeds should be reduced by breeding measures.
- Currently, no medication or management are known to prevent the disease or stop or slow disease progression.

CLIENT EDUCATION

- The disease and expected progression: low disease severity indicates long period without clinical signs; moderate to severe indicates a shorter period.
- If the client is a breeder, inform him/her about the genetics of the disease and impact of the finding on future breeding.
- Appropriate level of exercise (no restrictions for low disease severity, avoid strenuous exercise in moderate to severe cases).
- Signs of CHF
- How to medicate (if indicated)
- How to monitor resting heart and respiratory rates at home (if indicated)
- Diet (if indicated)

Mitral Valve Stenosis

BASIC INFORMATION

DEFINITION

Rare congenital or acquired cardiac disorder characterized by narrowing of the mitral valve orifice. The narrowing is a result of an abnormal mitral valve apparatus; it leads to obstruction of diastolic transmitral inflow and (potentially) left-sided congestive heart failure (CHF).

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats. No reported age or sex predilection.

GENETICS & BREED PREDISPOSITION

- Dogs: bull terrier, Newfoundland (may be predisposed)
- Cats: two Siamese cats reported, but no evidence of breed predisposition

RISK FACTORS

- Predisposed breeds of dogs
- Cardiac valve neoplasia (very rare)

ASSOCIATED CONDITIONS & DISORDERS

- Dogs (concurrent conditions):
  - Mitral valve dysplasia
  - Subaortic stenosis (SAS)
  - Patent ductus arteriosus (PDA)
  - Pulmonic stenosis
- Dogs and cats (associated conditions):
  - Congestive heart failure
  - Pulmonary hypertension
- Cats (concurrent and associated condition): feline aortic thromboembolism

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Valvular mitral stenosis: involves the mitral valve leaflets (dog and cat)
- Supravalvular mitral stenosis: left atrium is divided by a membrane just above the mitral annulus (see online chapter: Cor Triatriatum Sinister and Supravalvular Mitral Stenosis)

HISTORY, CHIEF COMPLAINT

- Exercise intolerance/episodic weakness
- Lethargy
- Cough
- Dyspnea (most common sign in cats)
- Syncope

PHYSICAL EXAM FINDINGS

- Soft (I-III/VI) left apical diastolic murmur (inconsistent)
- Left apical systolic murmur (if mitral regurgitation is present)
- With CHF:
  - Tachycardia
  - Tachypnea

- Pulmonary crackles and wheezes

ETIOLOGY AND PATHOPHYSIOLOGY

- Congenital (possibly heritable in predisposed breeds)
- Acquired:
  - Bacterial endocarditis (controversial)
  - Intracardiac neoplasia (mitral valve chondrosarcoma reported in a dog).
- Pathophysiology:
  - Obstruction of the transmitral diastolic flow (increase in resistance to blood flow between the left atrium and ventricle)
  - Increase in left atrial, pulmonary vein, and pulmonary capillary pressures
  - Pulmonary edema formation
  - Exercise increases left atrial pressure; exercise induced dyspnea/syncope may occur.
  - Pulmonary hypertension may develop due to increased pulmonary capillary pressure.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in a young patient presenting with left apical diastolic murmur (often very subtle, difficult to hear). Cough, tachypnea, and dyspnea may be present. Left heart enlargement is usually evident on thoracic radiographs, and an echocardiogram is required for confirmation.

DIFFERENTIAL DIAGNOSIS

- Radiographic/electrocardiographic:
  - Left atrial enlargement: other types of cardiac disease (myxomatous mitral valve disease/endocardiosis, mitral valve dysplasia, dilated cardiomyopathy, subaortic stenosis, patent ductus arteriosus, and [in cats] hypertrophic cardiomyopathy)
- Echocardiographic:
  - Myxomatous mitral valve disease/endocardiosis
  - Mitral valve dysplasia
  - Bacterial endocarditis
  - Dilated cardiomyopathy

INITIAL DATABASE

- Thoracic radiographs: left atrial enlargement very common. Signs of pulmonary edema if CHF.
- Electrocardiogram: wide P waves in lead II, supraventricular premature complexes, atrial/supraventricular tachycardia, atrial fibrillation. Increased R wave amplitude in lead II if SAS or PDA is also present.
- Echocardiogram:
  - Two-dimensional mode: left atrial dilation (often severe), thickened mitral valve leaflets or supravalvular membrane (cat), decreased mitral valve leaflet excursion, diastolic doming of the leaflets
  - M-mode: thickened mitral valve leaflets, parallel motion of the leaflets, incomplete leaflet separation in diastole, reduced E-F slope; increased LA: Ao ratio
  - Color-flow Doppler: diastolic aliased or turbulent flow across the mitral valve. Systolic turbulent flow if mitral regurgitation is present.
  - Spectral Doppler: increased early diastolic filling (velocity E wave <1.1 m/s), prolonged pressure half-time (<50 ms), reduced mitral valve area (MVA)

ADVANCED OR CONFIRMATORY TESTING

- Cardiac catheterization: rarely necessary for confirming diagnosis, replaced by echocardiography
  - Angiogram: thickened and restricted MV leaflets, enlarged left atrium, ± mitral regurgitation
  - Pressure measurements: increase in left atrial pressure and pulmonary artery pressure, if pulmonary hypertension or CHF is present
- Transesophageal echocardiography: better visualization of the mitral valve apparatus

TREATMENT

TREATMENT OVERVIEW

Initial control of CHF signs, with therapy to reduce venous congestion (diuretics), inhibit sodium/water retention, counteract vasoconstriction (angiotensin-converting enzyme [ACE] inhibitors, vasodilators), and control supraventricular arrhythmias (digoxin, calcium channel or beta-blockers). Balloon valvuloplasty or mitral valve repair/replacement may be indicated. Consider referral to cardiologist for diagnosis and advice on treatment plan.

ACUTE GENERAL TREATMENT

- Diuretics: indicated if the patient is in congestive heart failure (see p. 468)
- Oxygen therapy/supplementation: for dyspneic patients
- ACE inhibitors: reduce preload and afterload (see p. 470)
- Digoxin, calcium channel blocker or beta-blocker: management of supraventricular arrhythmias (see p. 111)

CHRONIC TREATMENT

- Medical therapy:
  - Diuretics, ACE inhibitors, and antiarrhythmics (see p. 470)
  - In cats, antiplatelet and/or anticoagulant therapy for prevention of atrial thrombus formation (see p. 88). Aspirin, warfarin, unfractionated heparin/low-molecular-weight heparins, clopidogrel.
- Surgical therapy:
  - Open mitral commissurotomy: requires cardiopulmonary bypass (CPB); one encouraging report in the literature.
  - Mitral valve replacement: requires CPB. Postoperative management complications are common.
  - Balloon valvuloplasty: inconsistent results in canine patients; possible damage to the mitral valve apparatus, with worsening of mitral regurgitation.

BEHAVIOR/EXERCISE

Restrict exercise and excitement in patients with collapsing or syncopal episodes.

DRUG INTERACTIONS

- Excessive use of diuretics is contraindicated owing to the decrease in preload, electrolyte disturbances, prerenal/renal azotemia, and increased risk of digitalis toxicity.
- ACE inhibitor: may reduce glomerular filtration rate and cause azotemia; hypotension may occur when used with diuretics; risk of hyperkalemia when K^+ is supplemented or K^+-sparing diuretics are used concurrently.

POSSIBLE COMPLICATIONS

- Recurrence of signs due to progression of CHF
- Systemic thromboembolism (cats)
- Postsurgery: restenosis, coagulation disturbances due to postsurgical management (mitral valve replacement)

RECOMMENDED MONITORING

Recheck examinations should include: thoracic radiographs, serum renal panel including electrolytes, systolic blood pressure measurement, digoxin levels (if applicable), and electrocardiogram.

PROGNOSIS AND OUTCOME

- Long-term prognosis depends on the severity of the stenosis: guarded to poor in severe cases.
- Surgical approach may offer a better outcome in the future.

PEARLS & CONSIDERATIONS

COMMENTS

- A disproportionate number of cases occur in the bull terrier breed.
- Medical management is relatively unrewarding.
- Surgical approach may offer a better long-term prognosis in the future.

PREVENTION

Do not breed affected animals.

TECHNICIAN TIPS

The diastolic murmur/rumble is subtle and requires a quiet environment for auscultation.

CLIENT EDUCATION

- Monitor respiratory rate at rest, exercise tolerance, and appetite.
- Advise client not to breed affected animals.

Mitral Valve Dysplasia

BASIC INFORMATION

DEFINITION

Common congenital malformation of any component of the mitral valve apparatus (papillary muscles, chordae tendineae, leaflets, annulus), that results in valvular dysfunction

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats. Usually identified early in life.

GENETICS & BREED PREDISPOSITION: Dogs: bull terrier, miniature bull terrier, English bulldog, Great Dane, German shepherd, Newfoundland, and Irish setter are predisposed. Cats: two Siamese cats reported (mitral valve stenosis), but no evidence of breed predisposition.

RISK FACTORS

- Predisposed breeds of dogs

ASSOCIATED CONDITIONS & DISORDERS

- Dogs (concurrent conditions):
  - Mitral valve stenosis (MVS; see online chapter: Mitral Valve Stenosis)
  - Systolic anterior motion of the mitral valve (SAM)
  - Subaortic stenosis (SAS)
  - Patent ductus arteriosus (PDA)
  - Pulmonic stenosis
- Dogs and cats (associated conditions):
  - Congestive heart failure
  - Pulmonary hypertension
- Cats (concurrent and associated condition): feline aortic thromboembolism

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Valvular mitral stenosis (MVS): involves the mitral valve leaflets (dog and cat). See online chapter: Mitral Valve Stenosis.

HISTORY, CHIEF COMPLAINT

- Exercise intolerance/episodic weakness
- Lethargy
- Cough
- Dyspnea (most common sign in cats)
- Syncope

PHYSICAL EXAM FINDINGS

- Left apical systolic murmur (if mitral regurgitation)
- Grade I-VI/VI left apical systolic murmur (inconsistent with MVS)
- With CHF:
  - Tachycardia
  - Tachypnea
  - Pulmonary crackles and wheezes

ETIOLOGY AND PATHOPHYSIOLOGY

- Congenital (possibly heritable in predisposed breeds). Presumed genetic, although specific mutations have not been identified.
- Pathophysiology:
  - Mitral regurgitation (from the left ventricle to the left atrium during systole)
  - Obstruction of the transmitral diastolic flow (increase in resistance to blood flow between the left atrium and ventricle) in MVS
  - Obstruction of the left ventricular outflow tract with systolic anterior motion of the mitral valve (SAM)
  - Increase in left atrial, pulmonary venous, and pulmonary capillary pressures
  - Pulmonary edema formation
  - Exercise increases left atrial pressure; exercise induced dyspnea/syncope may occur.
  - Pulmonary hypertension may develop secondary to increased pulmonary capillary pressure.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in a young patient presenting with left apical murmur. Cough, tachypnea, and dyspnea may be present. Left heart enlargement is usually evident on thoracic radiographs, and an echocardiogram is required for confirmation.

DIFFERENTIAL DIAGNOSIS

- Radiographic/electrocardiographic:
  - Left atrial enlargement: other types of cardiac disease (myxomatous mitral valve disease/endocardiosis, dilated cardiomyopathy, subaortic stenosis, patent ductus arteriosus, and [in cats] hypertrophic cardiomyopathy)
- Echocardiographic:
  - Myxomatous mitral valve disease/endocardiosis
  - Bacterial endocarditis
  - Intracardiac neoplasia

INITIAL DATABASE

- Thoracic radiographs: left atrial enlargement very common. Signs of pulmonary edema if CHF.
- Electrocardiogram: wide P waves in lead II, supra ventricular premature complexes, atrial/supraventricular tachycardia, atrial fibrillation. Increased R wave amplitude in lead II if SAS or PDA is also present.
- Echocardiogram:
  - Two-dimensional mode: abnormal mitral valve leaflets, abnormal valve motion, mitral regurgitation, left atrial dilation. Supravalvular membrane (cat), decreased mitral valve leaflet excursion and diastolic doming of the leaflets (MVS).
  - M mode: thickened mitral valve leaflets, increased LA: Ao ratio, incomplete leaflet separation in diastole and reduced E-F slope (MVS); SAM.
  - Color-flow Doppler: systolic turbulent flow in the left atrium if mitral regurgitation is present, and in the left ventricular outflow tract with SAM. Diastolic aliased or turbulent flow across the mitral valve (MVS).
  - Spectral Doppler: increased early diastolic filling (velocity E wave >1.1 m/s), prolonged pressure half-time (>50 ms), and reduced mitral valve area (MVS).

ADVANCED OR CONFIRMATORY TESTING

- Cardiac catheterization: rarely necessary for confirming diagnosis but may yield quantitative information and help characterize unusual lesions.
  - Angiogram: mitral regurgitation, thickened and/or restricted MV leaflets, enlarged left atrium
  - Pressure measurements: increase in left atrial pressure and pulmonary artery pressure if pulmonary hypertension or CHF is present
- Transesophageal echocardiography: better visualization of the mitral valve apparatus

TREATMENT

TREATMENT OVERVIEW

Initial control of CHF signs, with therapy to reduce venous congestion (diuretics), inhibit sodium/water retention, counteract vasoconstriction (ACE inhibitors, vasodilators), and control supra ventricular arrhythmias (digoxin, calcium channel or beta-blockers). Consider referral to cardiologist for diagnosis and advice on treatment plan.

ACUTE GENERAL TREATMENT

- Diuretics: indicated if the patient is in congestive heart failure (see p. 468)
- Oxygen therapy/supplementation: for dyspneic patients
- Angiotensin-converting enzyme (ACE) inhibitors: reduce preload and after-load (see p. 470)
- Digoxin, calcium channel blocker or beta-blocker: management of supraventricular arrhythmias (see p. 111)
- For myocardial failure (advanced/end-stage state characterized by left ventricular hypocontractility): inodilators (pimobendan)

CHRONIC TREATMENT

- Medical therapy:
  - Diuretics, ACE inhibitors, inodilators and antiarrhythmics following the acute treatment guidelines ()
  - In cats, antiplatelet and/or anticoagulant therapy for prevention of atrial thrombus formation (see p. 88). Aspirin, worfarin unfractionated heparin/low-molecular-weight heparins, clopidogrel.
- Surgical therapy:
  - Mitral valve replacement or open mitral commissurotomy (MVS): requires cardiopulmonary bypass. Postoperative management complications are common.
  - Balloon valvuloplasty (MVS): inconsistent results in canine patients; possible damage to the mitral valve apparatus with worsening of mitral regurgitation.

BEHAVIOR/EXERCISE

Restrict exercise and excitement in patients with collapsing or syncopal episodes.

DRUG INTERACTIONS

- Excessive use of diuretics is contraindicated owing to the decrease in preload, electrolyte disturbances, prerenal/renal azotemia, and increased risk of digitalis toxicity.
- ACE inhibitors: may reduce glomerular filtration rate and cause azotemia; hypotension may occur when used with diuretics; risk of hyperkalemia when K^+ is supplemented or K^+-sparing diuretics are used concurrently.

POSSIBLE COMPLICATIONS

- Recurrence of signs due to progression of CHF
- Systemic thromboembolism (cats)
- Left atrial rupture (dogs)
- Postsurgery: coagulation disturbances due to postsurgical management (mitral valve replacement), restenosis (MVS)

RECOMMENDED MONITORING

Recheck examinations should include: thoracic radiographs, serum renal panel including electrolytes, systolic blood pressure measurement, digoxin levels (if applicable), and ECG.

PROGNOSIS AND OUTCOME

- Long-term prognosis depends on the severity of the dysplasia: guarded in severe cases.
- Surgical approach may offer a better outcome in the future.

PEARLS & CONSIDERATIONS

COMMENTS

- A disproportionate number of cases occurs in the bull terrier breed.
- Surgical approach may offer a better long-term prognosis in the future.

PREVENTION

Do not breed affected animals.

CLIENT EDUCATION

- Monitor respiratory rate at rest, exercise tolerance, and appetite.
- Advise client not to breed affected animals.

EDITOR: ETIENNE CÔTÉ

Microvascular Dysplasia, Hepatic

BASIC INFORMATION

DEFINITION

A congenital disorder of dogs in which there are histologic hepatic vascular abnormalities presumably causing intrahepatic shunting with no demonstrable macroscopic portosystemic shunt (PSS)

SYNONYMS

Hepatoportal microvascular dysplasia (HMD), MD, MVD, microvascular portal dysplasia, portal vein hypoplasia (with no shunt)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Primarily dogs; poorly documented in cats
- Typically affects young adult dogs; clinical signs develop at average age 3 years (can be any age), though most dogs show no overt clinical signs. By contrast, dogs with PSS first develop signs at average age 6-18 months.
- Female sex predilection

GENETICS & BREED PREDISPOSITION

- Polygenic mode of inheritance suspected in Cairn terriers
- Cairn terriers and Yorkshire terriers predisposed
- Has been documented in multiple breeds (the vast majority are small dogs)

ASSOCIATED CONDITIONS & DISORDERS: Similar histologic hepatic changes are seen in dogs with PSS

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Most affected dogs show no clinical signs.
- Severely affected dogs present with signs similar to those of dogs with PSS. Signs often wax and wane.
- Clinical signs are typically referable to the central nervous system (CNS), gastrointestinal (GI) system, or urinary tract
- CNS (all secondary to hepatic encephalopathy): lethargy, ataxia, weakness, abnormal behavior, abnormal vocalization, ptyalism (more common in cats), head pressing, bumping into objects because of central blindness, incessant pacing or circling, stupor, seizures, or coma
    - Exacerbation of encephalopathic signs with: high-protein meals, GI bleeding, constipation, azotemia, hypokalemia, metabolic alkalosis, tranquilization, and methionine-containing supplements or medications
- GI: intermittent anorexia, vomiting, diarrhea
- Urinary tract: hematuria, pollakiuria, or dysuria from ammonium urate urolithiasis

PHYSICAL EXAM FINDINGS

- Usually unremarkable
- Small body stature
- Questionably small liver (inability to palpate liver margins)
- CNS signs (see CNS in History, Chief Complaint above)
- Poor haircoat

ETIOLOGY AND PATHOPHYSIOLOGY

- Shunting is hypothesized to occur through microscopic intrahepatic vessels, but this has not been proven.
- Hepatic encephalopathy (HE; see p. 501) and resultant CNS signs occur from toxins and nutrients absorbed from the intestines; thought to bypass metabolism by the liver through microscopic intrahepatic shunting.
- High urinary excretion from elevated blood levels of ammonia and uric acid can occasionally result in development of urate

urolithiasis (renal, ureteral, bladder).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Microvascular dysplasia should be considered when a fasting or postprandial bile acids level is elevated, often with no apparent clinical signs. Histologic characteristics (liver biopsy), together with advanced testing that rules out a macroscopic shunt, are confirmatory.

DIFFERENTIAL DIAGNOSIS

- CNS signs: infectious disease, toxin, other metabolic encephalopathy (hypoglycemia), idiopathic epilepsy, congenital malformations (e.g., hydrocephalus)
- GI signs: parasitism, foreign body, dietary indiscretion, dietary allergy, intestinal inflammation/infiltration
- Urinary tract signs: urinary tract infection, other calculi

INITIAL DATABASE

- CBC is typically normal. Microcytosis, commonly seen in dogs with PSS, rarely occurs in dogs with hepatic microvascular dysplasia. In vitro changes in blood stored in EDTA may mask microcytosis, especially if not analyzed quickly.
- Serum biochemical profile is often normal, but mild elevations in hepatic enzyme activities and mildly low blood urea nitrogen concentration have been noted, as have hyperglobulinemia and hypercholesterolemia.
- Coagulation profile: typically normal
- Urinalysis: usually normal, but ammonium biurate crystalluria, hematuria, or pyuria are possible.
- Abdominal radiographs: usually normal, but occasionally mild microhepatica may be noted.

ADVANCED OR CONFIRMATORY TESTING

- Serum bile acids: Essentially all animals with microvascular dysplasia have elevated postprandial serum bile acid concentrations; fasting/preprandial may be normal. Mean serum bile acid concentrations are lower than in dogs with PSS.
- Plasma protein C concentrations may aid in differentiating between PSS and MD. In one study, a protein C activity of <70% was much more likely to indicate PSS and >70% was more indicative of HMD (though some overlap).
- Liver biopsy:
    - Typically reveals hepatic arteriolar hyperplasia, small portal triads, increased smooth muscle thickness of hepatic venules, and an increase in small vascular structures in the periportal area
    - These findings in association with elevated serum bile acids, in the absence of PSS, are diagnostic for microvascular dysplasia.
    - Certain histologic abnormalities such as portal endothelial cell hyperplasia, Kupffer cell hyperplasia, and portal vein dilation are considered highly suggestive of hepatic microvascular dysplasia, but this theory is not universally accepted.
    - Many pathologists believe the histologic findings in dogs with hepatic microvascular dysplasia are indistinguishable from those of dogs with PSS.
- Abdominal ultrasound: the liver is typically normal in appearance but may be small, and there may be a decreased ease of visualization and number of hepatic vascular structures. No PSS is noted. A portal vein/aortic ratio of >0.8 is strongly indicative of the absence of a PSS.
- Transcolonic or transsplenic portal scintigraphy: distinguishes hepatic microvascular dysplasia from PSS. There is significant hepatic uptake of the radionuclide in the liver with micro vascular dysplasia (<15% shunt fraction).
- Mesenteric or transsplenic portography: negative for shunts in dogs with hepatic microvascular dysplasia where no evidence of extrahepatic shunting is noted. There may also be truncating of the distal hepatic vessels and slow clearance of contrast. This test is typically only available at referral institutions.
- Helical CT angiography: negative for shunting vessels
- Ideally portal scintigraphy or CT angiography could be performed first to rule out the need for the more invasive mesenteric portography.

TREATMENT

TREATMENT OVERVIEW

Reversal of hepatic encephalopathy through reduction in protein intake, prevention of absorption of toxins from the GI tract, and excretion from the kidneys and colon. No treatment is indicated in the absence of clinical signs.

ACUTE AND CHRONIC GENERAL TREATMENT

- As for hepatic encephalopathy (see p. 501) if indicated
- With status epilepticus or seizures: anticonvulsant medications such as IV propofol, low-dose phenobarbital, or oral potassium bromide (via stomach tube if necessary) may be needed in addition to the other medications and dietary therapy listed previously.

NUTRITION/DIET

Restricted protein diets or those formulated for use in hepatic disease should be considered to reduce the overall production of ammonia. Avoid methionine-containing supplements.

DRUG INTERACTIONS

Be careful with drugs requiring hepatic metabolism.

POSSIBLE COMPLICATIONS

Sedative and anesthetic agents should be used with caution.

RECOMMENDED MONITORING

- Due to the typical lack of significant clinicopathologic abnormalities, repeat testing is not indicated.
- Serum bile acid concentrations are typically unchanged with dietary and medical therapy and are not routinely repeated.

PROGNOSIS AND OUTCOME 

- Prognosis is good to excellent in patients that have not shown any signs.
- Prognosis is poor to fair in patients with clinical signs.
- Some patients presenting primarily with gastrointestinal signs may lack adequate response to treatment, although the signs do not typically worsen.
- Rarely, patients will develop noncirrhotic portal hypertension. The prognosis in these patients is poor.

PEARLS & CONSIDERATIONS 

COMMENTS

- Biopsy alone cannot confirm HMD. Macroscopic portosystemic shunts must be ruled out by either transcolonic or transsplenic portal scintigraphy, CT angiography, or mesenteric portography.
- Patients not showing any clinical signs and patients diagnosed at a later age with milder increases in serum bile acid concentrations are more likely to have HMD than PSS.
- Patients with normal CBC and serum biochemistry profiles may be more likely to have HMD than PSS.

PREVENTION

Avoid breeding affected dogs of predisposed breeds.

Metronidazole Toxicosis

BASIC INFORMATION

DEFINITION

Neurologic dysfunction due to administration of high doses of the antibiotic metronidazole

SYNONYM

Flagyl toxicosis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of any age and either sex can be affected. **RISK FACTORS:** Toxicosis is usually associated with doses of 60 mg/kg/d or higher for 1 week or longer.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Initial signs in dogs are anorexia and vomiting that progress rapidly to generalized ataxia. Seizures and head tilt are less common.
- Cats suffer a sudden onset of weakness and disorientation, often with seizures

PHYSICAL EXAM FINDINGS

- Affected dogs typically show severe generalized ataxia, depression, and vertical nystagmus that changes in frequency with head position. Postural reactions and spinal reflexes are usually normal.
- Affected cats often show ataxia with postural reaction deficits in all limbs, depression or stupor, seizures, and blindness with intact pupillary light reflexes.

ETIOLOGY AND PATHOPHYSIOLOGY

- The cumulative dose may be important in the mechanism of neurologic dysfunction, although there seems to be substantial individual susceptibility to signs of toxicity.
- Metronidazole is recommended for two different indications in many drug formularies: at an enteric dose for acute gastrointestinal infections and parasitoses (30-65 mg/kg, “divided q 12 h for 5-7 days”) or at doses for anaerobic bacterial infections (15 mg/kg PO q 12 h for days to weeks; lower to 7.5 mg/kg PO q 12 h if hepatic dysfunction).
- Common dosage errors (and therefore risk of toxicosis) appear to be:
  - Prescribing the high enteric dose for >1 week
  - Overlooking the “divided q 12 h” indication and prescribing the high enteric dose q 12 h
  - Failing to reduce the dose in patients with liver disease
  - Failing to accurately divide the 250-mg tablets in cats or very small dogs, where small differences in tablet fractions correspond to relatively large excesses in dose per kg body weight

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based entirely on medication history and physical signs.

DIFFERENTIAL DIAGNOSIS

- Encephalitis
- Neoplasia

INITIAL DATABASE

Routine laboratory tests are usually normal, but mild elevations in liver enzymes are possible.

ADVANCED OR CONFIRMATORY TESTING

Diagnosis is based on clinical features, history of metronidazole administration, and recovery on stopping the drug.

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is to stop metronidazole administration and provide supportive care until the signs resolve, usually within 3-5 days.

ACUTE GENERAL TREATMENT

- Discontinue the metronidazole.
- Parenteral hydration and nutrition if necessary
- Antiseizure medication such as diazepam as needed
- Oral diazepam administration (0.5 mg/kg q 8 h) may speed recovery from metronidazole toxicosis in dogs, including those that are not showing seizure activity.

RECOMMENDED MONITORING

Clinical response to discontinuation of metronidazole. Deterioration or worsening of clinical signs should prompt evaluation for another diagnosis.

PROGNOSIS AND OUTCOME

The prognosis is excellent with prompt withdrawal of the offending drug. Most patients show improvement within 48 hours, although it may take a week for complete resolution.

PEARLS & CONSIDERATIONS

COMMENTS

- Clinicians should consider metronidazole toxicosis in any patient developing neurologic signs while taking this antibiotic. With prompt recognition and withdrawal of the offending drug, complete recovery is expected.
- In many instances of intestinal parasitosis, metronidazole may not be the best choice of treatment. Alternative medications (e.g., fenbendazole) have shown greater efficacy and far fewer adverse effects in canine *Giardia* infection, for example.

PREVENTION

Avoid doses of metronidazole higher than 30 mg/kg/d. Some published doses are high enough to cause toxicity.

AUTHOR: WILLIAM B. THOMAS

EDITOR: CURTIS W. DEWEY

Metaldehyde Toxicosis

BASIC INFORMATION

DEFINITION

An acute toxicosis manifested by rapid onset of clinical signs such as vomiting, anxiety/restlessness, panting, hypersalivation, increasingly vigorous muscle tremors, hyperesthesia, hyperthermia, and seizures. This toxicosis can be rapidly fatal (hours from onset of signs, which begin 30 minutes to 5 hours after ingestion).

SYNONYMS

- Slug or snail bait poisoning
- Ortho Bug-Geta, Corry's Slug and Snail Pellets, Deadline Force II, Dragon Snail and Slug Killer Pellets, Last-Bite Snail and Slug Killer Pellets, Lilly Miller Slug and Snail Bait, Corry's Liquid Slug and Snail Control, Corry's Slug Snail, and Insect Killer are some metaldehyde-containing commercial products.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Toxic to all species
- Poisoning seen mostly in dogs. Bait is more attractive to dogs.
- All breeds, ages, and both sexes susceptible

RISK FACTORS: Animals with preexisting liver or kidney problems may be more sensitive to the toxic effects of metaldehyde.

GEOGRAPHY AND SEASONALITY: Toxicosis can occur anywhere; most common in areas with large populations of snails and slugs (e.g., the North American Pacific Northwest coast [especially California] and East Coast), Hawaii, Caribbean, Upper Midwest region. Less common in drier states.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Witnessed or suspected ingestion or recent use of bait in the pet's environment
- Rapid onset of vomiting, restlessness, muscle tremors and seizures

PHYSICAL EXAM FINDINGS

- Rapid, progressively more frequent (or sustained) muscle fasciculations/tremors are characteristic of metaldehyde intoxication and may progress to extensor rigidity/tetany.
- Secondary hyperthermia, which may be severe (104°F-108°F [40°-42.2°C]), is common. Hyperthermia is not a true fever but rather the result of muscle fasciculations.
- Seizures
- Concurrent nonspecific signs are common:
  - Tachycardia
  - Tachypnea
  - Hypersalivation
  - Vomiting
  - Diarrhea

ETIOLOGY AND PATHOPHYSIOLOGY

- Metaldehyde is a tetramer of acetaldehyde used as a molluscicide.
- Common sources include metaldehyde-containing baits formulated as liquid, granules, powder, or pellets.
- Most poisonings occur in dogs when they consume metaldehyde-containing baits.
- Oral LD^{50} of metaldehyde in dogs in various sources = 100-1000 mg/kg, and in cats = 207 mg/kg.
- Clinical signs of toxicosis can be seen within 30 minutes to 5 hours after ingestion.

- Metaldehyde is rapidly absorbed orally.
  - Acetaldehyde is produced upon exposure to gastric (low) pH.
  - Acetaldehyde is presumed to contribute to acidosis and other central nervous system signs such as seizures.
- Minimum toxic dose of metaldehyde in dogs is not known.
  - Consumption of 1 tablespoon (15 g) of 2% powder or granular bait will provide approximately 300 mg of metaldehyde; possibly a significant hazard for a 10-kg dog (30 mg/kg of metaldehyde). Standard 2% bait = 20 mg metaldehyde/g bait.
- Clinical signs could be due to decreased level of cerebral γ-aminobutyric acid, norepinephrine, and serotonin, which can cause seizures; and increased monoamine oxidase activity, which further decreases serotonin and norepinephrine levels.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based on some or all of the following elements: geographic location (presence of snails/slugs in region), history of observed or suspected ingestion, and characteristic physical examination findings. No definitive confirmatory clinical test exists. A presumptive diagnosis is generally sufficient to initiate treatment, given the severity of signs in most cases and negative consequences of leaving such signs untreated.

DIFFERENTIAL DIAGNOSIS

- Strychnine toxicosis (see p. 1055)
- Tremorgenic mycotoxins
- Caffeine, nicotine toxicosis
- Permethrin toxicosis in cats
- Organophosphate and carbamate insecticide toxicosis (see p. 792)
- Zinc phosphide intoxication (see p. 1186)
- Garbage toxicosis (see p. 434)
- Primary central nervous system disease (neoplasia, encephalitis, idiopathic epilepsy, tetanus, other)

INITIAL DATABASE

- Acid-base status (acidosis may be present)
- Baseline serum liver enzyme (levels usually normal)
- Creatine phosphokinase (may be elevated due to muscle tremors)
- Baseline body temperature (commonly 104○-108○F [40○-42.2○C])
- Kidney function (myoglobinuria possible due to tremors)

ADVANCED OR CONFIRMATORY TESTING

- Metaldehyde may be detected in stomach contents, vomitus, serum, liver, and urine.
- Acetaldehyde smell (similar to formal dehyde) in the stomach or gastrointestinal tract may help in diagnosis.

TREATMENT

TREATMENT OVERVIEW

Immediate treatment of tremors and seizures when present is a primary goal, in order to curtail the development of severe hyperthermia. Active cooling is also indicated when body temperature >105○F (40.6○C), especially if seizures/muscle tremors are persistent. In patients without clinical signs (mild exposures and/or early presentation), induction of emesis is indicated. Activated charcoal administration is appropriate in essentially all cases, via stomach tube (with airway protection) if the patient is unconscious. Overall goals of treatment are to decontaminate the patient (remove remaining toxin), control tremors and seizures, correct acid-base abnormalities, control hyperthermia, and offer supportive care.

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Induction of vomiting (see p. 1364) in patients not showing any clinical signs; useful within 30 minutes of exposure:
    - Hydrogen peroxide, 1 mL/kg PO, repeat once in 10-20 minutes if needed, maximum dose in largest dogs is 45 mL.

        - Apomorphine, 0.04 mg/kg IM or IV, or instill into conjunctival sac part of a crushed tablet dissolved in water.
    - Give activated charcoal after inducing emesis at 1-3 g/kg PO mixed with a cathartic such as magnesium or sodium sulfate, 250 mg/kg; or sorbitol 1-3 mL/kg. Use label dose for commercial preparations; multiple doses may be helpful with large ingestion (Caution: aspiration risk in vomiting patient).
    - Gastric lavage (see p. 1281) if large ingestion in animal showing clinical signs; follow with activated charcoal.
- Control tremors/seizures (see p. 1009):
    - Methocarbamol, 55-220 mg/kg IV; repeat as needed (maximum dose 330 mg/kg/d).
    - Diazepam, 1-2 mg/kg IV; repeat as needed (and/or consider diazepam constant rate infusion).
    - General anesthesia if no response to above measures:
        - Pentobarbital, 10-30 mg/kg IV to effect, repeat as needed; *or*
        - Propofol, up to 5-6 mg/kg slow IV to effect, then constant rate infusion 0.1-0.6 mg/kg/min titrated to effect; *and/or*
        - Isoflurane inhalant anesthesia
- Fluid diuresis for hydration, renal perfusion
- Control hyperthermia (cold bath, fans).
- Control acid-base balance with sodium bicarbonate.

POSSIBLE COMPLICATIONS

- Disseminated intravascular coagulation secondary to prolonged hyperthermia possible
- Acute hepatic failure (see p. 503) in some dogs 2-3 days after exposure can occur (uncommonly) when the patient seems to have recovered; monitor closely.
- Acute renal failure due to myoglobinuria (uncommon)

RECOMMENDED MONITORING

- Body temperature
- Liver enzymes for 3 days (baseline, 24, 48, 72 hours)
- Acid-base status

PROGNOSIS AND OUTCOME

- Good with prompt decontamination of patient and control of tremors and seizures
- Guarded with poorly controlled tremors or seizures or prolonged hyperthermia

PEARLS & CONSIDERATIONS

COMMENTS

- Most commercial baits contain 2%-5% metaldehyde.
- Some formulations may also contain 5% carbaryl (a carbamate insecticide) along with metaldehyde (see p. 792). Toxicity of carbaryl is much less than metaldehyde.
- Read the label carefully. Several recently introduced Slug and Snail Baits contain ferric phosphate 1% as the active ingredient. Ingestion of 1% ferric phosphate-containing slug bait in dogs mostly results in mild to moderate signs of stomach upset (vomiting, diarrhea, anorexia, lethargy).

TECHNICIAN TIPS

- If a client calls with a suspected ingestion of any “bait,” metaldehyde is the most immediately urgent of the common bait poisonings, and the animal should be brought to be examined promptly. The client also should be told to bring the container or product sheet to make it easier to confirm the active component of the ingested bait.

PREVENTION

- Placement of bait in areas inaccessible to animals
- Use of relatively less toxic baits (e.g., iron-based baits) to control slugs and snails

Mesothelioma

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A neoplasm of mesodermal origin that may arise from the pleural, pericardial, or peritoneal surfaces. Also reported from scrotum or tunica vaginalis.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs > cats, males are overrepresented. Generally older. GENETICS & BREED PREDISPOSITION: German shepherd dogs (particularly male) are overrepresented. Large-breed dogs are more commonly affected.

RISK FACTORS: Possibly asbestos exposure. The type of cancer caused by chronic asbestos exposure in human beings is mesothelioma, and the same histopathologic findings (ferruginous bodies) have been noted in both canine and human mesothelioma.

ASSOCIATED CONDITIONS & DISORDERS: Pleural, pericardial, and peritoneal effusion with attendant dyspnea, acute cardiac tamponade and right-sided heart failure, or abdominal distension, respectively, are common.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Mesenchymal form: multiple focal nodules of solid or papillary neoplastic growth; historically, more common
- Sclerosing form: characterized by an intense fibroblastic reaction and thick fibrous adhesions involving all abdominal organs but most markedly centered around the stomach and prostate; uncommon in dogs

HISTORY, CHIEF COMPLAINT: Patients most commonly are presented for dyspnea or cough; possibly abdominal distension. This disease should be suspected in any adult patient with a cough that does not respond to standard treatment for nonspecific respiratory problems, or evidence of chronic disease and effusion in any body cavity. Depending on the anatomic location of the malignancy and the subsequent effusion, the patient may present with dyspnea, cough, weight loss, acute cardiac tamponade and right-sided heart failure, or abdominal distension.

PHYSICAL EXAM FINDINGS

- Dyspnea due to pleural effusion in dogs and cats is usually identified by forceful inspiration and prolonged expiration (“holding its breath”).
- In cats, a noncompressible cranial thorax suggests other diagnoses: thymoma, mediastinal lymphoma.
- Tachypnea, open-mouth breathing, cyanosis, muffled heart and lung sounds ventrally with increased bronchovesicular sounds dorsally, poor peripheral pulses, jugular distension, and abdominal distension are possible.
- In a standing patient, thoracic percussion may reveal a “fluid line” (zone of hyporesonance) ventrally.

ETIOLOGY AND PATHOPHYSIOLOGY

Mesothelioma involves a malignant transformation of mesothelial cells that line body cavities. Pleural, pericardial, and peritoneal effusion from mesothelioma are most likely due to increased capillary permeability (parietal foci) secondary to vasculitis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on chronic recurrent body-cavity effusions with no identified infectious, inflammatory, or other neoplastic cause. This is often a diagnosis of exclusion. Definitive diagnosis requires a biopsy.

DIFFERENTIAL DIAGNOSIS

- Pleural effusion (see p. 882)

- Pericardial effusion (see p. 854)
- Ascites (see p. 93)

INITIAL DATABASE

- The effusion should be sampled and evaluated with fluid analysis and cytological assessment.
- CBC, serum biochemical analysis, and urinalysis: no specific changes
- These tests should be supplemented with fungal, viral, and parasitic (tick and heartworm) serologic evaluations and microbial (fungal and bacterial) culture as clinical suspicion and history warrant.
- Radiographs (especially after removal of as much fluid as possible)
- Ultrasonographic studies (abdomen, heart, and pleural space)

ADVANCED OR CONFIRMATORY TESTING

- Definitive diagnosis requires tissue for histopathology.
- A normal fibronectin level in the effusion could help rule out mesothelioma.

TREATMENT

TREATMENT OVERVIEW

The primary and immediate goal of treatment is the removal of body-cavity fluid that is causing clinical signs.

ACUTE GENERAL TREATMENT

- Stabilization of the patient by relieving the cardiovascular or respiratory embarrassment is paramount.
  - This generally revolves around removal of large-volume effusions and doing so without delay if clinical signs are severe.
- Oxygen therapy is often indicated before centesis or obtaining blood or urine samples if patients are extremely dyspneic or volatile in their behavior, in order to prevent life-threatening cardiovascular or respiratory decompensation (especially cats).

CHRONIC TREATMENT

- For dogs with pericardial mesothelioma, surgical or thoracoscopic pericardectomy (see p. 1340) can palliate clinical signs and reduce tumor burden (disease cytoreduction).
- Periodic thoracocentesis (see p. 1338) or pericardiocentesis (see p. 1325) can be performed when fluid accumulation or symptoms are slow to return (weeks or more).
- The placement of a Pleuralport may aid in treatment. Some clients may be willing to learn proper care and use of such a device for home care.
- Administration of chemotherapy via intracavitary infusion on an every-3-week schedule can be attempted for long-term control.
  - Cisplatin, 50-70 mg/m^2 body surface area, along with saline fluid diuresis; *or*
  - Carboplatin, 250-350 mg/m^2 (has limited penetration); *or*
  - Mitoxantrone, 5-6 mg/m^2
- Potential benefits (unproven on a large scale) must be weighed against the real drawbacks of possible adverse reactions to these agents.
- At this time, only small numbers of patients have been evaluated, so efficacy remains unproven.
- Intravenous chemotherapy with cisplatin, carboplatin, or doxorubicin may have a role in some patients.
- Consultation with an oncologist for the most current treatment recommendations is indicated, but because of the rarity of this disease, multicenter clinical trials will be required to test and develop effective treatments.

POSSIBLE COMPLICATIONS

Pneumothorax, cardiac puncture, hemopericardium, hemothorax, infection

RECOMMENDED MONITORING

- Hourly for critical (ICU) patients: respiratory rates, degree of dyspnea, blood gases
- Daily to weekly for outpatients: respiratory rates, quality of life assessments, repeat thoracic radiographs as warranted or required
- As required per protocol for chemotherapy patients (i.e., CBC), quality of life assessments, repeat thoracic radiographs as

warranted or required

PROGNOSIS AND OUTCOME

- Poor to fair. Survival is dependent on rate of accumulation of the fluid and degree of compensation, which are both variable from patient to patient.
- Many patients are euthanized at the time of diagnosis.
- For those that are treated, the reported survival time varies considerably from weeks to years.
- Some animals may have a dramatic improvement after pericardiocentesis or thoracocentesis and a prolonged (weeks to months) period without clinical signs, whereas others have a reaccumulation of fluid and return of tamponade or dyspnea within hours or days.
- A good quality of life for months to 1-2 years with pericardial or pleural mesothelioma is realistically possible if a good response to the first centesis occurs, and owners are willing to follow up regularly with centesis on an as-needed basis.
- In this author's experience, owners rarely agree to continue with repeat pericardiocentesis after more than 2 or 3 episodes of acute decompensation.

PEARLS & CONSIDERATIONS

COMMENTS

- Thoracocentesis should be considered before blood or urine sample acquisition or radiographic or ultrasonographic studies in patients that are unstable. The removal of even a small amount of fluid may dramatically relieve the respiratory embarrassment and stabilize the patient.
- Although it shares similarities with mesothelioma in terms of distribution (body cavity surfaces), *carcinomatosis* refers to seeding of pleural or peritoneal surfaces with malignant carcinoma cells.
    - Management of dogs and cats with carcinomatosis may include treatment with intracavitary chemo-therapeutics as described for mesothelioma.

TECHNICIAN TIP

The pericardial effusion caused by mesothelioma is usually thick and hemorrhagic (indistinguishable from blood). If blood clots form in the discarded effusion during the pericardiocentesis procedure, this important observation should be brought to the attention of the clinician performing the procedure (catheter may be in the heart).

CLIENT EDUCATION

- Teaching the client to monitor respiratory rate will give both the client and the clinician an objective measure of progression and acuity of decompensation in the patient.
- Pleuralport management for dedicated clients.

AUTHOR: CARLOS RODRIGUEZ

EDITOR: KENNETH M. RASSNICK

Mesocestoides Infection

BASIC INFORMATION

DEFINITION

Infection with an adult cestode (tapeworm) in the small intestine of mammals (frequently dogs) and birds. The larval or metacestode form of this tapeworm, the tetrathyridium, may infect serous cavities of many animals, particularly canines, causing ascites and pleural effusion.

SYNONYMS

Mesocestoides lineatus, Mesocestoides corti

EPIDEMIOLOGY

SPECIES, AGE, SEX: There is a wide range of intermediate hosts (reptile, avian, amphibian, and mammals), especially carnivores. Domestic and wild canids may serve as definitive hosts and harbor the adult stages of the tapeworm. Cats may also be infected.

RISK FACTORS: Hunting, scavenging carrion, and exposure to wildlife

CONTAGION & ZOONOSIS: Unknown; infections with adult tapeworms have been reported in humans.

GEOGRAPHY AND SEASONALITY: Many parts of the world, including Africa, Asia, and throughout the United States. There is no seasonal association for this cestode/metacestode.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Anorexia, respiratory distress, abdominal distension

PHYSICAL EXAM FINDINGS: Signs of abdominal or pleural effusion (see p. 93and p. 882)

ETIOLOGY AND PATHOPHYSIOLOGY

- Life cycle involves two intermediate hosts.
- First intermediate host unknown but may be a ground-dwelling coprophagous arthropod (oribatid mite, beetle)
- Second intermediate host (reptile, amphibian, bird, rodent, cat) becomes infected by ingestion of the larval forms (cysticercoids) within the first intermediate host. Within this second intermediate host, the cysticercoid develops into a tetrathyridium.
- The tetrathyridium is the second larval stage and often occurs in the peritoneal cavity and musculature of the second intermediate host.
- Dogs and cats (definitive hosts) are presumably infected by ingestion of the tetrathyridia within the second intermediate host (i.e., from capturing infected birds, snakes, and small mammals as prey).
- Dogs often serve as definitive hosts, harboring the adult tapeworms, but may also be infected by the larval stages of the parasite, the tetrathyridia.
- Tetrathyridia develop into adult tapeworms within the intestines and rarely produce clinical disease. Development into adults may take 16-20 days in dogs. In cats, development into adults may take longer.
- Some tetrathyridia migrate through the intestinal wall and continue as tetrathyridia within subcutaneous tissues, liver, lungs, retroperitoneal space, or abdominal and thoracic cavities. These tetrathyridia are capable of asexual multiplication by binary fission; one tetrathyridium splits into two tetrathyridia, two into four, and so on. The tetrathyridia multiply to the point that they completely fill and expand both the peritoneal and pleural cavities.
- Tetrathyridia may incite a nonpurulent granulomatous inflammatory response on serosal surfaces.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A patient with abdominal or pleural effusion whose centesed fluid is grossly milky white should be suspected of having *Mesocestoides* infection, especially if the patient appears less ill than would be expected if the fluid were chylous or septic.

Confirmation is through cytologic examination of aspirated fluid.

DIFFERENTIAL DIAGNOSIS

Abdominal and pleural effusions: congestive heart failure, portal hypertension, liver disease, hemorrhagic effusions, neoplastic effusions, hypoalbuminemia, septic effusions, chylous effusions. The latter two would be most likely to be confounded grossly with *Mesocestoides*-related effusions (color).

INITIAL DATABASE

- Abdominocentesis or thoracocentesis typically reveals a distinctive thick, opaque white fluid, which often contains hundreds to thousands of tetrathyridia.
- Cytologic evaluation of fluid may show a mixed inflammatory exudate ± hemorrhage and necrosis. Calcareous corpuscles (clear to yellow-gold round to oval structures that are remnant tissues of the cestodes) may be present.
- Tetrathyridia are often found on aspiration of cystic lesions.

ADVANCED OR CONFIRMATORY TESTING

Recovery of organism from peritoneal cavity, with identification of cestode DNA via PCR

TREATMENT 

TREATMENT OVERVIEW

The adult stage of this parasite within the canine small intestine can be easily treated. The larval tetrathyridium stage within serous cavities is almost impossible to eliminate, owing to its ability to undergo asexual multiplication, and the goal of ongoing treatment becomes palliation of the infection.

ACUTE AND CHRONIC TREATMENT

- Laparotomy and lavage of peritoneal cavity may be helpful to decrease larval tetrathyridia burdens.
- Anthelmintics:
    - Praziquantel for adult organisms: 5 mg/kg PO q 24 h
    - Fenbendazole for larvae: 100 mg/kg PO q 24 h for 28 days. Off-label use. Side effects (bone marrow, others) possible.

POSSIBLE COMPLICATIONS

Gastrointestinal signs may be seen with antiparasitics.

RECOMMENDED MONITORING

Regular fecal examinations

PROGNOSIS AND OUTCOME 

Guarded for infection with larval tetrathyridia, since infection generally persists

PEARLS & CONSIDERATIONS 

PREVENTION

- Prevent dogs and cats from roaming and ingesting second intermediate hosts such as birds, amphibians, reptiles, and rodents as live prey or carrion.
- Regular anthelminthic therapy

TECHNICIAN TIPS

During microscopic examinations, look for the characteristic ovum on fecal flotation. Following administration of anthelminthics, look

for the characteristic gravid proglottids expelled in the feces of infected dogs. Look for the unique tetrathyridia within serous cavities.

AUTHOR: CHARLES M. HENDRIX

EDITOR: DOUGLASS K. MACINTIRE

1ST EDITION AUTHOR: LISA M. TIEBER

Mesenteric Volvulus

BASIC INFORMATION

DEFINITION

An uncommon disorder characterized by a twisting of the intestine around the root of the mesentery, a process that potentially can be rapidly fatal

SYNONYMS

Intestinal volvulus, mesenteric torsion

EPIDEMIOLOGY

SPECIES, AGE, SEX: Young adult (>3 years old), male dogs predisposed. Also reported in cats.

GENETICS & BREED PREDISPOSITION: Large-breed dogs, German shepherds, and English pointers

ASSOCIATED CONDITIONS & DISORDERS: Conditions that have been associated with mesenteric volvulus include exocrine pancreatic insufficiency, recent gastrointestinal surgery, gastrointestinal foreign bodies, enteritis, intestinal neoplasia, blunt trauma, and gastric dilatation volvulus (GDV).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Acute-onset abdominal distension, pain, vomiting, and hematochezia

PHYSICAL EXAM FINDINGS

- Physical findings consistent with hypovolemic shock: tachycardia (or bradycardia in cats), weak pulses, pale mucous membranes, prolonged capillary refill time, weakness or collapse
- Abdominal distension, palpably gas-filled intestinal loops

ETIOLOGY AND PATHOPHYSIOLOGY

- Twisting of intestine occurs around mesenteric axis or root, causing vascular occlusion to the intestines.
- Thin-walled veins and lymphatics become obstructed, causing edema in the intestinal wall.
- Blood flow through cranial mesenteric artery and its branches is partially or completely occluded due to twisting.
- Ischemic necrosis of intestine occurs, and blood is lost into the intestinal lumen.
- Endotoxins and bacteria translocate into the abdomen through the damaged intestinal mucosa.
- Patients eventually die from circulatory shock and endotoxemia/sepsis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on physical exam and appearance of abdominal radiographs. Differential diagnoses must be ruled out to the extent possible (e.g., ileus due to parvoviral enteritis: testing as appropriate). Confirmation of the diagnosis is made at the time of surgery.

DIFFERENTIAL DIAGNOSIS

Any condition associated with acute abdominal pain or hematochezia and vomiting:

- Gastric dilatation/volvulus (GDV)
- Cecocolic volvulus
- Intussusception
- Splenic torsion

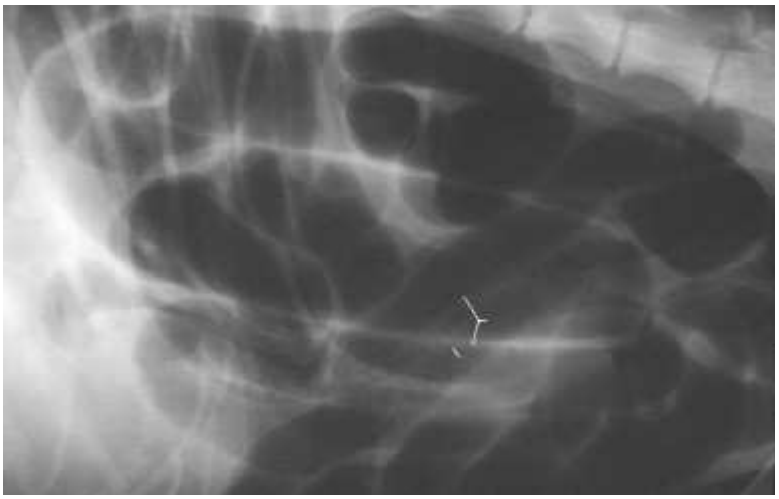
- Gastrointestinal obstruction or rupture
- Peritonitis
- Pancreatitis
- Hemorrhagic gastroenteritis
- Parvoviral enteritis

INITIAL DATABASE

- Abdominal radiography: multiple severely distended gas-filled intestinal loops; poor abdominal detail associated with peritoneal fluid; concurrent GDV
- CBC:
  - Packed cell volume usually normal
- Serum biochemistry profile:
  - Hypoproteinemia, hypokalemia
- Preoperative laboratory evaluation is often limited to on-site tests because of the potentially rapid deterioration of the patient's condition with mesenteric volvulus.
- Abdominocentesis (see p. 1193) with fluid evaluation: modified transudate (early) or septic exudate (eventually, with bacterial translocation or peritonitis). With bowel necrosis, the fluid may be dark and fetid.

ADVANCED OR CONFIRMATORY TESTING

Surgical confirmation of diagnosis



MESENTERIC VOLVULUS Lateral abdominal radiograph of dog with mesenteric volvulus; cranial is to the left. Marked gas distension of bowel present; a differential diagnosis would be severe enteritis.

(Courtesy Dr. Richard Walshaw.)

MESENTERIC VOLVULUS Same dog, gross appearance of bowel during exploratory laparotomy. Severe discoloration of much of small intestine and volvulus of mesenteric root are diagnostic.

(Courtesy Dr. Richard Walshaw.)

TREATMENT

TREATMENT OVERVIEW

Patients with mesenteric volvulus should be treated for circulatory shock as appropriate and have immediate surgical intervention to correct the volvulus and resect diseased bowel.

ACUTE GENERAL TREATMENT

- Crystalloids should be administered at shock doses (90 ml/kg/hr). Colloid boluses of 5 ml/kg can be administered simultaneously.
- Treat endotoxemia/sepsis with antibiotics:
  - Third-generation cephalosporin. 22 mg/kg IV q 2 h during perioperative period, then q 6 h postoperatively; *or*
  - Ampicillin, 22 mg/kg IV q 6 h combined with enrofloxacin, 5-10 mg/kg IV q 24 h (5 mg/kg maximum in cats)
- Correct hypokalemia and acid-base abnormalities with fluid therapy.
- If only parts of the intestine are devitalized, resect affected segment(s) before derotation, to reduce reperfusion effects.
- Perform derotation of intestines and monitor for perfusion.
- Perform thorough exploratory for associated conditions.
- Lavage abdomen, and consider postoperative drainage if peritonitis is present.

POSSIBLE COMPLICATIONS

- Septic peritonitis if diseased bowel not removed, contamination of abdomen not cleared, or resection and anastomosis site dehiscence
- Reperfusion injury
- Short bowel syndrome if >70% of small intestine resected

RECOMMENDED MONITORING

- Postoperative monitoring of hydration and electrolyte concentrations
- Blood pressure monitoring for hypotension
- Body temperature and blood glucose monitoring for sepsis

PROGNOSIS AND OUTCOME

- Grave prognosis unless volvulus recognized and treated immediately
- Most reports of mesenteric volvulus cite a 100% mortality rate unless the volvulus is found incidentally during exploratory celiotomy.
- One study reported a 58% mortality rate in patients with mesenteric volvulus presenting in shock and attributed increased survival to rapid initiation of treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- Surgery should not be delayed if an animal presents in shock with multiple gas-filled intestinal loops on radiographs, but parvoviral enteritis should be ruled out.
- Consideration should be given to the use of drugs that block the formation of, or scavenge, oxygen free radicals (i.e., corticosteroids).

EDITOR: RICHARD WALSHAW

Meningioma

BASIC INFORMATION

DEFINITION

A neoplasm of the meninges surrounding the brain or spinal cord

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Meningiomas occur in both dogs and cats and usually affect older patients.
- Dogs are usually older than 8 years, and females are affected slightly more than males.
- Cats are usually older than 10 years, and males are affected slightly more often than females.

GENETICS & BREED PREDISPOSITION

- **In** dogs, dolichocephalic breeds are more likely to develop meningiomas than other breeds.
- There is no breed predisposition in cats.

GEOGRAPHY AND SEASONALITY: Reported worldwide

ASSOCIATED CONDITIONS & DISORDERS: Meningiomas have been reported to occur in young cats with mucopolysaccharidosis type I.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Historic findings in general reflect neurologic compromise, but specific signs depend on lesion location.
- Clinical signs are often insidious and progressive; less commonly, acute onset of clinical signs is possible.
- The most common chief complaints for intracranial meningiomas include seizures, circling, behavior change (aggression), altered consciousness, and nonspecific signs such as inappetence and lethargy.
- The most common chief complaints for spinal meningiomas include acute to chronic onset of paresis, ataxia, and neck or back pain.

PHYSICAL EXAM FINDINGS

- Neurologic exam findings (see p. 1311) vary depending on lesion location.
- Cerebral meningioma: seizures, contralateral menace and postural reaction deficits, behavior change, contralateral hemiparesis
- Brainstem meningioma: ipsilateral cranial nerve deficits, hemiparesis or tetraparesis or hemiplegia or tetraplegia, or signs of central vestibular dysfunction
- Cerebellar meningioma: hypermetria, intention tremors, truncal sway, broad-based stance
- Spinal meningioma: paresis, ataxia, spinal pain

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology is unknown.
- Meningiomas usually occur as solitary masses, but multiple meningiomas are relatively common in cats.
- By definition, they originate on the periphery (neoplastic outgrowths of the meninges), adjacent to cranial or vertebral bone.
- Biological behavior and histopathologic characteristics are benign; clinical effects are due to space-occupying nature within confines of skull or vertebral canal.
- Most commonly reported in the supratentorial compartment (rostral to the tentorium cerebelli, including the cerebrum and diencephalon) in the brain
- Tumor tends to invade into the brain parenchyma in dogs but not in cats.
- Cervical portion of spinal cord is the most commonly affected segment in cases of spinal meningioma, but any location is possible.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in a middle-aged to older dog or cat with neurologic deficits suggesting a slowly growing intracranial or spinal lesion. Advanced imaging (preferably MRI) is the clinical confirmatory test of choice; the final diagnosis is obtained histologically.

DIFFERENTIAL DIAGNOSIS

- Other brain tumors (e.g., glioma, lymphoma, metastatic tumors)
- Infectious diseases (bacterial, viral, fungal, protozoal)
- Inflammatory diseases (e.g., granulomatous meningoencephalomyelitis)
- Intervertebral disk disease
- Diskospondylitis

INITIAL DATABASE

- CBC/serum biochemical profile/urinalysis: usually normal
- Survey thoracic and abdominal radiographs should be performed in older patients to rule out extracranial and/or concurrent diseases.

ADVANCED OR CONFIRMATORY TESTING

- CT (see p. 1233) or MRI (see p. 1302): intracranial mass located outside the brain or spinal cord parenchyma, with marked, often homogeneous, contrast enhancement. Compression of underlying brain or spinal cord is common.
- Cerebrospinal fluid analysis: used as an adjunct to advanced imaging, primarily to rule out encephalitis or myelitis. Results are generally nonspecific with meningioma and reveal normal to mildly elevated protein. Sterile neutrophilic pleocytosis is relatively common with meningioma but is not pathognomonic.
- Histopathologic evaluation is required for definitive diagnosis. Tissue samples can be obtained via surgical excision or stereotactic brain biopsy (see p. 1214).

TREATMENT

TREATMENT OVERVIEW

Definitive treatment involving surgical excision and/or radiation therapy

ACUTE GENERAL TREATMENT

- Cluster seizures or status epilepticus: see p. 1425
- Cerebral edema/brain herniation: mannitol, 0.5 g/kg IV slowly over 15 to 20 minutes; furosemide (2 mg/kg IV) has synergistic effects with mannitol and can be given if needed.

CHRONIC TREATMENT

- Surgical excision for histologic diagnosis and definitive treatment if tumor is accessible
  - In general, tumors located in superficial (dorsal or lateral) regions of the skull/vertebrae overlying cerebrum, cerebellum, and spinal cord are the best candidates for surgical excision.
- Radiation therapy: used as an adjunctive treatment to surgery or as a primary treatment
- Chemotherapy: generally less effective because the blood-brain barrier (BBB) prevents most chemotherapeutic agents from entering the brain and spinal cord.
  - There are special handling requirements and potentially life-threatening adverse patient effects associated with these drugs; consultation with an oncologist for appropriate usage and the most current treatment recommendations is indicated.
  - Hydroxyurea (20 mg/kg PO q 24 h) crosses the BBB and appears to be effective in dogs as it is in humans with intracranial meningioma. Possible adverse effects include bone marrow suppression (anemia, thrombocytopenia, leukopenia), pulmonary fibrosis, gastrointestinal upset, stomatitis, sloughing of nails, alopecia, and dysuria. Methemoglobinemia has been reported in cats at high dosages (>500 mg).
  - Anecdotally, nitrosourea agents such as lomustine (CCNU; 60-90 mg/m^2 PO q 6 weeks) or carmustine (BCNU 50

mg/m^2 IV q 6 weeks), which can cross the BBB, appear to have some effect; these agents are more specifically used for treating patients with gliomas. The most serious potential adverse effects are bone marrow suppression (anemia, thrombocytopenia, leukopenia) and hepatotoxicosis.

- Seizures: anticonvulsants should be used if more than one seizure occurs every 6 to 8 weeks (see p. 1009).
- Cerebral edema: prednisone, 0.5 mg/kg PO q 12 h initially, then taper to lowest dose that will control clinical signs.

DRUG INTERACTIONS

- Drug interactions or altered metabolism of medications have been reported between corticosteroids and amphotericin B, furosemide, thiazide diuretics, digitalis glycosides, cyclosporine, phenytoin, phenobarbital, and mitotane.
- Corticosteroids should not be given concurrently with nonsteroidal antiinflammatory drugs or other potentially gastrointestinally ulcerogenic medications.
- Phenobarbital: may cause excessive sedation in patients with intracranial tumors, even at low doses

POSSIBLE COMPLICATIONS

Progression of clinical signs, including status epilepticus, brain herniation, and sudden death

RECOMMENDED MONITORING

Serial neurologic exam every 4-6 weeks. Therapeutic drug monitoring of serum levels of anticonvulsants if relevant.

PROGNOSIS AND OUTCOME

- Dogs: prognosis is fair. Median survival time for cerebral meningioma is 5-9 months with surgery alone and 16-30 months with surgery and radiation therapy. Radiation therapy alone yields a survival time of approximately 6-12 months.
- Cats: prognosis is good after surgical excision, with a median survival time of approximately 2 years with surgical excision alone. Surgical excision can be curative in cats.
- Prognosis for meningiomas in other anatomic locations is fair to guarded.
- Many patients treated with supportive nonspecific treatments (e.g., anticonvulsants, corticosteroids) are euthanized within 3 months because of progression of clinical signs.
- Dogs with intracranial meningiomas treated with oral hydroxyurea have a mean survival time of approximately 7 months.

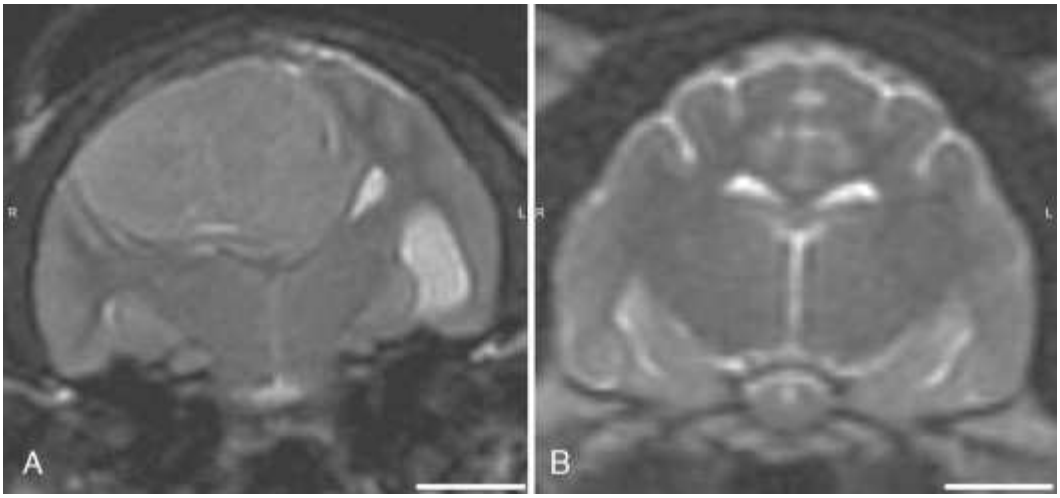
PEARLS & CONSIDERATIONS

COMMENTS

- Meningiomas are the most common primary brain tumor in dogs and cats.
- Surgical excision followed by radiation therapy provides the longest survival times for dogs.
- Surgical excision alone provides prolonged survival times for cats and may be curative in some cases.
- In canine intracranial meningioma cases with seizure activity, relatively nonsedative anticonvulsant drugs (e.g., felbamate, zonisamide, levetiracetam) should be considered, especially if surgical removal of the tumor is planned (see p. 1009and p. 353).

CLIENT EDUCATION

- With patients receiving corticosteroids, warn owner of expected side effects (e.g., polyuria, polydipsia, polyphagia, weight gain) and of effects warranting notification (obesity, signs of gastrointestinal ulceration, signs of iatrogenic hyperadrenocorticism).
- Phenobarbital (see p. 871): short-term side effects include sedation/lethargy and pelvic limb weakness and ataxia. Long-term side effects include polyuria, polydipsia, polyphagia, weight gain. Less common adverse effects warranting intervention include hepatotoxicity, blood dyscrasias.



MENINGIOMA A, Brain MRI of a patient with meningioma *(left panel).***B**, Normal patient for comparison *(right panel),* T2-weighted image. Patient's right is on the left of each image. Patient with meningioma has a large, sessile mass originating from the right dorsal calvarium; severe compression and displacement of right cerebral hemisphere and midline shift are seen. Bar = 1 cm.

Melena

BASIC INFORMATION

DEFINITION

Dark, tarlike, often foul-smelling stools, as a result of digested blood (specifically oxidized hemoglobin)

EPIDEMIOLOGY

SPECIES, AGE, SEX: Any age, breed, sex
RISK FACTORS: Anything that will cause hemorrhage into the proximal or mid-gastrointestinal (GI) tract (esophagus, stomach, small intestine) or the mouth, pharynx, nose, or lungs

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- The patient will normally present for signs associated with blood loss (i.e., weakness, pale mucous membranes, bleeding from other sites or due to the melena [foul-smelling flatulence or black tarry feces]).
- Medication history includes those known to have gastrointestinal ulcerogenic potential (e.g., glucocorticoids, nonsteroidal antiinflammatory drugs [NSAIDs]).
- Intoxication history: known exposure or accessibility of vitamin K antagonists (rodenticides, pharmaceutical) in the environment
- Specific questions related to potential specific sources of bleeding: coughing, sneezing, vomiting, diarrhea
- Some patients have a history of recent surgical skin lump removal (possibility of mast cell tumor).
- Overdiagnosis due to leading questions (e.g., “Are the stools dark and tarry?”) should be avoided; open-ended questions are preferred (e.g., “Have the color and consistency of the stools changed? How so?”) to avoid this error.
- Rule out false-positive results:
    - Animals eating meat-based diets
    - Diets high in iron
    - Drugs such as charcoal and bismuth
    - Normal variation

PHYSICAL EXAM FINDINGS

- Rectal exam to confirm the diagnosis
- Evaluation for petechial hemorrhages on the mucous membranes and for signs of bleeding on the skin
- Auscultation of the chest for signs of lung hemorrhage (bronchovesicular sounds that are either louder [interstitial or airway hemorrhage] or softer [pleural effusion])
- Thorough abdominal palpation: abnormal GI loops or masses
- Careful examination of the skin for suspect mast cell tumors
- Additionally, specific aspects of the physical exam will vary depending on the source of bleeding. The blood can originate from the mouth, nose, lungs, pharynx, esophagus, stomach, or small intestine.

ETIOLOGY AND PATHOPHYSIOLOGY

- Blood presented to proximal or mid-GI tract (via any route already mentioned).
- Slow GI transit time of longer than 8 hours (in humans) allows greater degree of oxidation of hemoglobin. Melena occurs based on the duration of the presence of blood in the GI tract, rather than the anatomic site of blood loss.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Gross inspection of feces should allow confirmation of melena. If uncertainty persists, a fecal occult blood test is indicated. Diagnosis of the source of melena begins with history and physical exam in an attempt to differentiate generalized bleeding disorders from primary gastrointestinal bleeding.

DIFFERENTIAL DIAGNOSIS

- GI bleeding (stomach, small intestine; or large intestine in anorexic animals with slow GI transit time). Examples: hemorrhagic gastroenteritis, foreign body, intussusception, volvulus, inflammatory bowel disease, helminthiasis, or neoplasia.
- Liver or renal failure (coagulopathy or gastric ulceration)
- Pulmonary or upper respiratory tract bleed with swallowing of blood
- Shock (shock gut)
- Pancreatitis
- Hypoadrenocorticism
- Mast cell tumor or (rarely) gastrinoma
- High meat-based diet or diet high in iron
- Drugs such as charcoal and bismuth darken the color of feces but do not signify digested blood.

INITIAL DATABASE

- Recheck history and repeat abdominal palpation
- CBC, serum biochemistry profile (including preprandial and postprandial bile acids if liver disease suspected), urinalysis. Thrombocytopenia may explain or be a result of hemorrhage. Microcytosis and hypochromia suggest chronic blood loss.
- Fecal flotation
- Imaging: survey radiographs of chest and abdomen; abdominal ultrasound
- Coagulation profile

ADVANCED OR CONFIRMATORY TESTING

- If still no diagnosis:
  - Repeat abdominal ultrasound exam
  - Thorough nasal and pharyngeal exam [with radiographs]; systemic blood pressure measurement if epistaxis is present
  - Endoscopy (see p. 1284)
  - Exploratory laparotomy:
    - Biopsy, aspiration, and/or resection of any lesions seen
    - Biopsies of liver, stomach, duodenum, ileum, and jejunum if no macroscopic lesion seen
- If still no diagnosis:
  - Scintigraphy (radiolabeled albumin)
  - Arteriography
  - Small-bowel radiographic contrast study

TREATMENT 

TREATMENT OVERVIEW

- Control hemorrhage and any secondary complications of hemorrhage
- Cure the trigger

ACUTE GENERAL TREATMENT

- Largely depends on underlying cause
- Identify shock early, and treat aggressively with IV fluids.
- Blood transfusion: if anemia with resultant clinical signs or for coagulopathy
- Plasma transfusion: for coagulopathy
- Antiemetics and antiulcer therapy as needed
- Stop the inciting medications

DRUG INTERACTIONS

Sucralfate inhibits the absorption of fluoroquinolone antibiotics for up to 8 hours, so patients receiving sucralfate and requiring quinolone antibiotics should receive the quinolones parenterally if feasible.

PROGNOSIS AND OUTCOME 

Dependent on the trigger

PEARLS & CONSIDERATIONS

COMMENTS

These cases generally are far more difficult to diagnose than hematochezia cases. A thorough and methodical approach is essential.

CLIENT EDUCATION

Advise all owners on the potential dangers of NSAIDs.

AUTHOR: DAVID MILLER

EDITOR: ETIENNE CÔTÉ

Melanoma

BASIC INFORMATION

DEFINITION

- Melanoma is a common neoplasm in the dog and is rare in the cat.
- Classification of melanomas by location generally has more clinical utility than by histologic subtype.
- Oral melanomas are uniformly malignant, locally invasive, and highly metastatic (>60%) tumors (see p. 708)
- Subungual (nail bed) melanomas are locally invasive tumors with a lower rate of metastasis (30%-60%)
- Cutaneous melanomas are generally (but not always) benign.
- Ocular melanomas are discussed elsewhere in this text (see p. 620).

SYNONYMS

Malignant melanoma, melanocytic tumor, melanocytoma

EPIDEMIOLOGY

SPECIES, AGE, SEX: Melanoma generally occurs in older patients (9-12 years).

GENETICS & BREED PREDISPOSITION

- Predisposed dog breeds include chow chow, Doberman pinscher, golden retriever, Gordon setter, Irish setter, giant schnauzer, miniature schnauzer, Scottish terrier.
- Breed predisposition suggests an underlying genetic mechanism for melanoma in veterinary patients.
- Black dogs may be predisposed, but any color dog may be affected.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Oral melanoma:
  - Detection of an oral mass by a veterinarian during routine examination or dental prophylaxis (common)
  - Identification of an oral mass by the owner
  - Recent onset of halitosis and ptyalism
- Cutaneous or subungual (nail bed) melanomas:
  - Identification of a mass by the owner

PHYSICAL EXAM FINDINGS

- Examination typically reveals a mass lesion.
- Oral examination should be thorough; some tumors are located at the base of the tongue or in the tonsils.
- Cutaneous and subungual tumors may become ulcerated.
- Melanomas may be pigmented or amelanotic.
- Thorough examination of draining lymph nodes is always indicated, but cytologic evaluation should be performed regardless of physical exam findings.

ETIOLOGY AND PATHOPHYSIOLOGY

- Underlying genetic mutations and ultraviolet light exposure are known etiologic agents in humans.
- Melanomas do not have to arise from pigmented skin.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Biopsy of an identified mass is the test of choice to establish a diagnosis of melanoma.

DIFFERENTIAL DIAGNOSIS

- Oral: squamous cell carcinoma, soft tissue sarcoma, epulides
- Cutaneous: any mass lesion of skin (neoplastic or non-neoplastic)
- Subungual: squamous cell carcinoma, nail bed infection

INITIAL DATABASE

CBC, serum biochemistry profile, urinalysis, lymph node aspiration, thoracic radiographs, abdominal ultrasound (in patients with hind limb or caudally located masses)

ADVANCED OR CONFIRMATORY TESTING

- Biopsy and histopathologic examination of tissue
- Immunohistochemical staining with S-100 or Melan-A may confirm the diagnosis of melanoma in undifferentiated and amelanotic tumors.
- Determination of mitotic index may be used for distinguishing benign and malignant canine cutaneous melanomas.
    - Determination of mitotic index requires histopathologic evaluation of tissue and cannot be reliably assessed on fine-needle aspiration/cytology.
    - Tumors with a mitotic index of <3 are typically benign; those ≥3 are generally malignant.

TREATMENT

TREATMENT OVERVIEW

Determination of an appropriate treatment plan for a patient with melanoma requires a thorough understanding of the patient's underlying prognosis. Evaluation of the patient to establish both local and metastatic disease status is essential. Goals of treatment are long-term disease control in patients amenable to definitive therapy and palliation of clinical signs in patients not treated definitively or those with metastatic disease. A general treatment overview is available on .

ACUTE GENERAL TREATMENT

- Oral melanoma:
    - Radical excision of mass indicated if:
        - Wide surgical margins (>2 cm, including underlying bone) can be obtained, and
        - Patient has no regional lymph node or distant metastasis
    - Removal of macroscopic (measurable) tumor followed by definitive course of radiation therapy to primary tumor site and regional lymph nodes indicated if:
        - Radical excision is not possible or regional lymph node metastasis is identified; and
        - Patient has no distant metastatic disease
        - Radiotherapy dosing; see Pearls & Considerations below.
    - Definitive course of radiation therapy alone to primary tumor and regional lymph nodes is indicated if:
        - Removal of macroscopic tumor burden is not possible; and
        - Patient has no distant metastatic disease
    - Palliative course of radiation therapy to tumor could be considered if:
        - The patient has distant metastatic disease; and/or
        - Financial or other restrictions preclude definitive therapy with surgery, radiotherapy, or both.
    - Chemotherapy indicated for all patients treated definitively with surgery and/or radiotherapy, owing to high rate of metastatic disease
        - Systemic therapy with platinum (carboplatin or cisplatin) chemotherapeutic agents, given reported activity of carboplatin in dogs with melanoma
        - Chemotherapy may benefit patients treated with palliative radiotherapy and those with evidence of distant metastasis.
    - DNA-based melanoma vaccine indicated for all patients where local/regional control has been attained.
- Subungual (nail bed) melanoma:
    - Radical excision of mass indicated if:
        - Wide surgical margins (>2 cm, to include underlying bone) are possible; and
        - Patient has no distant metastatic disease.
    - Limb amputation should be performed if wide surgical margins cannot be obtained with local resection (i.e., digital amputation)

- Limb amputation including removal of lymph nodes should be performed in patients with regional lymph node metastasis.
- Removal of macroscopic (measurable) tumor followed by definitive course of radiotherapy to primary tumor site and regional lymph nodes is indicated if:
  - Digital amputation not possible or clients decline amputation
  - Regional lymph node metastasis is identified
  - Patient has no distant metastatic disease
- Palliative course of radiotherapy could be considered if:
  - Patient has distant metastatic disease and clinical signs associated with local disease result in decreased quality of life for patient
- DNA-based vaccine and chemotherapy are indicated for all patients treated definitively with surgery and/or radiotherapy, owing to the high rate of metastatic disease in patients with subungual melanoma.

- Cutaneous melanoma
  - Surgical resection is the treatment of choice for benign melanomas (<3 mitoses/10 hpf)
  - Radical excision of malignant cutaneous melanoma (≥3 mitoses/10 hpf) is indicated if:
    - Wide surgical margins (<2 cm) can be obtained; and
    - Patient has no regional lymph node or distant metastatic disease
  - Removal of macroscopic (measurable) tumor followed by definitive course of radiation therapy to primary tumor site and regional lymph nodes are indicated if:
    - Radical excision is not possible or if regional lymph node metastasis is identified
    - Patient has no distant metastatic disease
  - Palliative course of radiation therapy could be considered if:
    - Patient has distant metastatic disease and clinical signs associated with local disease result in decreased quality of life for the patient
  - DNA-based vaccine and chemotherapy indicated for all patients with malignant cutaneous melanomas treated definitively with surgery and/or radiation therapy
    - Refer to oral melanoma section for comments regarding chemotherapy.

POSSIBLE COMPLICATIONS

Potential complications or therapy for patients with melanoma are those typically encountered after treatment with surgery, radiation, and chemotherapy.

RECOMMENDED MONITORING

After treatment, patients should be monitored with routine examination (determination of local disease status) and thoracic radiographs (identify metastatic disease).

PROGNOSIS AND OUTCOME

- Oral melanoma:
  - Prognosis:
    - Conservative surgery alone: median survival 3-4 months; local recurrence rate >70%
    - Radical surgery alone: median survival 9 to 10 months; local recurrence rate 20%-50%
    - Radiation therapy for microscopic tumors: median survival 15 months; local recurrence rate 26%
    - Radiation therapy for macroscopic tumors: response rate 82%; median survival 5 months; local progression/recurrence 45%
    - Chemotherapy for macroscopic tumors: response rate 28%; efficacy in adjuvant setting unknown
    - Prognosis for definitively treated feline oral melanoma is not known.
  - Prognostic factors:
    - Most apply to patients treated with radiotherapy.
    - Reported negative prognostic factors include macroscopic tumor burden, caudal tumor location, bone lysis; all oral melanomas should be considered malignant regardless of mitotic index.
    - In one study, median survival correlated with the number of negative prognostic factors present: 0 = 21 months, 1 = 11 months; 2 = 5 months; 3 = 3 months.
- Subungual melanoma:
  - Prognosis:
    - Surgical excision (local or limb amputation): median survival 12 months; local recurrence rate 30% (local resection only)
    - Role of radiotherapy and chemotherapy undetermined for this location
    - Prognostic factors: none identified
    - Prognosis is unknown for feline subungual melanoma.
- Cutaneous melanoma:

- Prognosis:
  - Surgical excision: median survival 24 months (benign); 7-11 months (malignant)
  - Efficacy of radiotherapy and chemotherapy is undetermined for this location.
  - Median survival for feline cutaneous melanoma treated with surgery alone is 12 months.
  - Mitotic index is not uniformly predictive of biological behavior.
- Prognostic factors:
  - Mitotic index is the most important prognostic factor: ≥3 indicates malignant tumor.
  - Breed: Doberman pinschers and miniature schnauzers more likely have benign melanoma (75%); miniature poodles more likely have malignant melanomas (85%).

PEARLS & CONSIDERATIONS

COMMENTS

- Radiotherapy treatment:
  - Melanoma has a greater capacity for sublethal damage repair and therefore is best treated with a hypofractionated (larger doses per fraction) treatment protocol instead of a conventional protocol such as 3-Gy doses given in 16 to 19 fractions.
  - Four reported veterinary protocols for melanoma are: 10 Gy × 3; 9 Gy × 4; 8 Gy × 3; 4 Gy × 12. The optimal protocol remains to be determined.
  - Because late-responding normal tissues (bone, muscle, central nervous system) are more susceptible to toxicosis with larger doses of radiation, large doses (8-10 Gy) should be avoided in patients in which long-term survival (<12 months) is expected.
    - In patients with probable long-term survival (e.g., dog with no negative prognostic factors), a protocol utilizing smaller doses per fraction (4-6 Gy) may be advisable.
    - In patients treated definitively but in which long-term survival is unlikely (e.g., with caudally located, macroscopic tumor) or in patients treated palliatively, a protocol utilizing larger doses per fraction is reasonable, since long-term survival and therefore late-responding tissue toxicity are unlikely.
- Chemotherapy:
  - In patients failing platinum chemotherapy, there is little information regarding rescue chemotherapy agents for melanoma.
  - Information from the veterinary and human literature may support the use of dacarbazine, melphalan, CCNU, piroxicam, and interferon.
- DNA-based vaccine:
  - Early studies indicate that patients with locally/regionally controlled disease experience a longer survival when the tyrosinase DNA vaccine is administered.
  - The utility of tyrosinase DNA vaccination in patients with advanced disease is unclear.

AUTHOR: DAVID PROULX

EDITOR: KENNETH RASSNICK

Megaesophagus

BASIC INFORMATION

DEFINITION

Dilatation of the esophagus due to weakness of the esophageal musculature from any cause. This is to be distinguished from dilatation of the esophagus orad to an obstruction.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of any age or sex. Acquired megaesophagus usually occurs after 2-3 years of age. Cats are less commonly affected.

GENETICS & BREED PREDISPOSITION

- For congenital megaesophagus:
  - Cats: Siamese
  - Dogs: German shepherds, Great Danes, Labrador retrievers, miniature schnauzers, Irish setters, sharpeis, fox terriers, Newfoundlands (but any dog can be affected).
- For acquired megaesophagus in dogs: black standard poodles (secondary to hypoadrenocorticism), but any dog can be affected.

RISK FACTORS: Any neuromuscular disease can cause acquired megaesophagus; localized myasthenia gravis is the most commonly identified cause.

ASSOCIATED CONDITIONS & DISORDERS

- Coughing due to tracheobronchitis or pneumonia secondary to aspiration
- Aspiration pneumonia is the most common cause of death.
- Weakness due to myopathy, neuropathy, or junctionopathy in the case of acquired megaesophagus

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Congenital megaesophagus
- Acquired megaesophagus

HISTORY, CHIEF COMPLAINT

- Regurgitation (must distinguish from vomiting) is the most common complaint.
- Cough (due to aspiration): this is sometimes seen before regurgitation is reported.
- Drooling (due to difficulty swallowing)

PHYSICAL EXAM FINDINGS

- Weight loss or failure to gain weight (if patient is losing excessive calories or has chronic pulmonary infection)
- Pulmonary crackles/easily elicited cough (due to aspiration pneumonia)
- Fever and signs of systemic illness (e.g., anorexia, lethargy) when sepsis from aspiration is present
- Bellows-like action at thoracic inlet, associated with breathing (due to filling and emptying of distended esophagus with air, associated with respirations)
- Nasal discharge (if pneumonia or rhinitis secondary to regurgitation is present)

ETIOLOGY AND PATHOPHYSIOLOGY

- Congenital or idiopathic megaesophagus:
  - Considered to involve the loss of peristaltic function
  - This defect can occur in any part of the neural reflex that controls the pharyngeal and esophageal phases of

swallowing, including the sensory receptors, the afferent nerves (glossopharyngeal and vagus), the tractus solitarius (leading to the nucleus solitarius), the swallowing center (near the lateral reticular formation), the lower motor neurons of the nucleus ambiguus, the efferent somatic and parasympathetic nerve fibers in the vagus, the myoneural junction in the esophagus itself, the esophageal striated muscle, and potentially the esophageal smooth muscle in the cat.
    - Most evidence suggests that the problem resides in the afferent limb of the reflex arc. This is supported by the fact that dogs with megaesophagus are prone to aspiration pneumonia, which is increased in dogs with loss of the afferent arc (abnormal respiratory reflexes also occur).
- Secondary megaesophagus; etiopathogenesis relates to primary cause:
    - Neurologic (polyradiculoneuritis, dysautonomia, demyelinating neuropathies, lead, etc.)
    - Neuromuscular (botulism, tetanus, myasthenia gravis)
    - Muscular (e.g., toxoplasmosis, polymyositis, systemic lupus erythematosus)
- Other causes of megaesophagus include certain metabolic conditions (hypoadrenocorticism).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected immediately in any patient that regurgitates. An essential diagnostic point is determining through simple questioning whether “vomiting” observed by the owner is in fact regurgitation. Thoracic radiographs confirm the diagnosis in most cases. Additional diagnostic tests are generally appropriate for evaluating possible underlying causes which present therapeutic opportunities.

DIFFERENTIAL DIAGNOSIS

Acquired megaesophagus in the dog:

- Myasthenia gravis (either generalized or localized)
- Hypoadrenocorticism
- Dysautonomia
- Polymyopathies/polyneuropathies of various causes
- Lead intoxication
- Organophosphate intoxication
- Botulism or tetanus
- Esophagitis
- Systemic lupus erythematosus
- Dermatomyositis
- Idiopathic

Acquired megaesophagus in the cat:

- Dysautonomia
- Myasthenia gravis
- Idiopathic (43% of feline cases)

INITIAL DATABASE

- CBC: look for evidence of inflammation consistent with aspiration pneumonia.
- Plain thoracic radiographs: look for megaesophagus (usually seen but is not always obvious) and for pneumonia (especially in right middle lung lobe; need ventrodorsal or dorsoventral projection to reliably see this lesion).
- Contrast esophagram using radiographs: if needed
    - Not always needed, as plain films can be confirmatory in many cases
    - Indicated if clinical signs suggest esophageal disease, but plain films are equivocal or interpreted as normal.
    - Can reveal unsuspected esophageal obstruction or segmental weakness
- Contrast esophagram using fluoroscopy (if needed): will detect megaesophagus missed by radiography, especially if only a segment of the esophagus is affected (especially cervical esophagus) or if there is only partial loss of muscular tone (see p. 1205).

ADVANCED OR CONFIRMATORY TESTING

- Antibodies against acetylcholine receptors (in dogs): when looking for cause of acquired megaesophagus (see p. 736)
- Resting serum cortisol concentration ± ACTH stimulation test (in dogs): when looking for cause of acquired megaesophagus (see p. 573)

- Serum creatine kinase determination: various myopathies
- Electromyography/motor nerve conduction velocity (see online chapter: Electromyography and Nerve Conduction Velocity): polymyopathy/polyneuropathy

TREATMENT

TREATMENT OVERVIEW

Treat acquired megaesophagus by finding and resolving the underlying cause (accomplished in approximately 15%-20% of dogs); treat aspiration pneumonia if present. If an underlying cause cannot be found, then treat as idiopathic megaesophagus. For idiopathic megaesophagus, try to minimize regurgitation by modifying feeding practices, and treat aspiration pneumonia when present.

ACUTE GENERAL TREATMENT

- Treat pneumonia if present (see p. 1583).
- Treat underling cause if found (see pp. 736 and p. 573).
- Feeding modification:
  - Feed from an elevated platform such that the patient's esophagus is as close to being perpendicular to the floor as possible so gravity aids in food/water emptying from the esophagus into the stomach. Probably beneficial to maintain this position for several minutes after eating to enhance food emptying into the stomach.
  - Feed different consistencies of food to find which is best tolerated: feeding a gruel is usually the best choice, but some animals fare better if fed canned or solid food or meatballs.
  - Feed several small meals per day (or free choice in the case of dry kibble) to minimize retention of large amounts in esophagus.
- Prokinetic drugs may be tried.
  - Only indicated when gastroesophageal reflux is suspected or confirmed, to increase normograde gastric emptying and reduce the volume of acid reflux. Prokinetic drugs are often useful for treating gastric motility disorders, but they do not increase esophageal motility to any clinically appreciable degree. Options include:
    - Cisapride (0.1-0.5 mg/kg PO q 8-12 h). Cisapride increases lower-esophageal tone (most effective prokinetic).
    - Metoclopramide (0.2-0.4 mg/kg PO, IM, or SQ q 8-12 h). The increase in lower-esophageal sphincter tone described for metoclopramide is not thought to be clinically significant and does not contraindicate usage in megaesophagus.
    - Erythromycin (2 mg/kg PO q 12-24 h). This drug stimulates motilin receptors, thereby enhancing gastric peristalsis.
    - Ranitidine (2.2 mg/kg PO, q 8-12 h). This H2 receptor antagonist has prokinetic activity.
- Gastric acid-reducing therapy: recommended if gastroesophageal reflux is documented or likely.
  - Omeprazole (1 mg/kg PO q 24 h); most effective drug

CHRONIC TREATMENT

- Ongoing implementation of measures described in acute treatment
- Treat specific conditions identified as indicated (e.g., hypoadrenocorticism, myasthenia gravis).
- Can place gastrostomy tube (see p. 1270) to minimize regurgitation of food (especially if waiting for treatment of underlying cause to succeed)
  - Dog can still swallow, regurgitate, and aspirate saliva, despite gastrostomy tube.

POSSIBLE COMPLICATIONS

- Aspiration pneumonia
- Infected stoma (gastrostomy tube)

PROGNOSIS AND OUTCOME

- If the underlying cause can be found and cured, the outlook is usually good, assuming that the patient does not die first from aspiration pneumonia.
- If the underlying cause cannot be found and treated, the outlook is guarded to poor. Many such patients die of aspiration pneumonia.
- The esophageal function of some dogs with congenital megaesophagus will spontaneously improve over time; however, one cannot predict which patients will improve.

PEARLS & CONSIDERATIONS

COMMENTS

- Certain drugs used for restraint (e.g., ketamine, xylazine) cause temporary megaesophagus.
- Some dogs with apparent megaesophagus on plain radiographs have normal function during barium-contrast esophagram, and the radiographic megaesophagus will spontaneously resolve.
- Radiography is the preferred way to diagnose megaesophagus; endoscopy is often the preferred way to diagnose esophagitis or the cause of esophageal obstruction, as well as other morphologic changes (e.g., hiatal hernia).
- The severity of radiographic dilation of esophagus is not always proportional to the severity of regurgitation or aspiration.
- Mild aspiration pneumonia is often missed on lateral radiographs; dorsoventral radiographs are more sensitive for finding this lesion.
- Any unexplained bacterial pneumonia in a dog could be caused by occult esophageal dysfunction; it is often reasonable to perform contrast radiographs looking for esophageal weakness in dogs with pneumonia that do not have esophageal dilation on plain radiographs.
- If a dog with megaesophagus vomits, esophagitis typically occurs due to gastric acid entering and not exiting the esophageal lumen.
- Surgery (cardiomyotomy) is not helpful or indicated in dogs with megaesophagus; true achalasia (which is helped by such surgery) is exceptionally rare in dogs.

PREVENTION

Do not breed animals with known history of producing litters with megaesophagus.

CLIENT EDUCATION

Aspiration pneumonia can occur at any time, even in dogs with mild radiographic signs of megaesophagus.

Mediastinal Disease

BASIC INFORMATION

DEFINITION

Disorders of the mediastinum, the potential space between the right and left lungs

EPIDEMIOLOGY

SPECIES, AGE, SEX: Mediastinal lymphosarcoma: young cats overrepresented. Other mediastinal masses more commonly affect middle-aged or older animals.

GENETICS & BREED PREDISPOSITION: Mediastinal lymphoma: Oriental-breed cats

RISK FACTORS

- Mediastinal lymphoma: feline leukemia virus infection (FeLV; see p. 385)
- Pneumomediastinum: tracheal laceration/avulsion; traumatic or iatrogenic
- Mediastinitis: esophageal foreign body or rupture

CONTAGION & ZOONOSIS: FeLV infection

ASSOCIATED CONDITIONS & DISORDERS: Mediastinal masses:

- Acquired myasthenia gravis (thymoma)
- Polyuria and polydipsia (lymphoma)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Pneumomediastinum
- Mediastinitis
- Mediastinal masses
- Mediastinal hemorrhage

HISTORY, CHIEF COMPLAINT

- Pneumomediastinum:
  - History of trauma
  - Recent anesthesia: overinflated endotracheal tube cuff, with tracheal necrosis; turning patient without disconnection of endotracheal tube
  - Recent transtracheal wash
  - Recent jugular venipuncture
  - Subcutaneous emphysema
- Mediastinitis (acute):
  - Obtundation
  - Inappetence
  - Dysphagia
  - Regurgitation
- Mediastinal masses:
  - Inappetence
  - Lethargy
  - Polyuria/polydipsia
  - Dysphagia or regurgitation
  - Cough
  - Dyspnea
  - Facial, neck, and/or forelimb swelling
- Mediastinal hemorrhage:

- Lethargy
- Weakness
- Tachypnea

PHYSICAL EXAM FINDINGS

- Pneumomediastinum:
  - Can be an incidental finding
  - Subcutaneous emphysema (see online chapter: Subcutaneous Emphysema)
  - Respiratory signs if severe:
    - Dyspnea
    - Muffled breath sounds
    - Hyperresonant thoracic percussion from pneumothorax
  - Jugular venous distention
  - Shock
- Mediastinitis:
  - Fever
  - Dyspnea, tachypnea, cough
  - Edema of head, neck, forelimbs secondary to cranial vena cava syndrome (see p. 263)
  - Dysphagia
  - Regurgitation
  - Thoracic pain
  - Reduced thoracic compressibility
- Mediastinal masses:
  - Poor compressibility of cranial thorax (especially cats)
  - Cranial vena cava syndrome (see p. 263)
  - Respiratory or gastrointestinal signs as mentioned previously
  - Occasionally paraneoplastic signs:
    - Weakness
    - Stridor if secondary laryngeal paralysis
  - Horner's syndrome possible
- Mediastinal hemorrhage:
  - Pale mucous membranes
  - Tachycardia
  - Weakness

ETIOLOGY AND PATHOPHYSIOLOGY

- Pneumomediastinum:
  - Air enters from:
    - Penetrating neck wounds
    - Tracheal laceration
    - Occasionally from esophageal air leakage
    - Positive-pressure ventilation
- Mediastinitis:
  -
    - Hematogenous infection
    - Penetrating wounds and migrating foreign bodies
    - Extension from surrounding tissues (especially esophagus)
    - Acute mediastinitis *(Staphylococcus* spp., *Streptococcus* spp., *Escherichia coli, Corynebacterium* spp.)
    - Chronic bacterial *(Nocardia, Actinomyces, Staphylococcus* spp.) or fungal (histoplasmosis, blastomycosis, cryptococcosis) infection also possible
    - Clinical signs due to sepsis, pleural effusion, and compression of vascular or respiratory structures
- Mediastinal masses:
  - Lymphoma, thymoma, thyroid neoplasia, chemodectoma, thymic cysts, granulomas
  - Clinical signs reflect compression of respiratory, cardiovascular, gastrointestinal structures, possibly pleural effusion, or sometimes neurologic abnormalities (Horner's syndrome, laryngeal paralysis).
  - Occasionally, paraneoplastic syndromes:
    - Hypercalcemia
    - Myasthenia gravis
- Mediastinal hemorrhage:
  - Trauma
  - Coagulopathy
  - Spontaneous thymic hemorrhage possibly associated with thymic involution

- Neoplastic disease
- Thyroid carcinoma
- Clinical signs are often related to acute blood loss.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Thoracic radiographs are typically the initial step in a diagnostic evaluation. If there is a mass lesion, advanced imaging such as CT scanning is often indicated, but fine-needle aspiration and cytologic analysis, or needle or surgical biopsy and histopathology, are typically required to define the nature of the disease process.

DIFFERENTIAL DIAGNOSIS

- Pneumomediastinum:
  - Tracheal trauma
  - Pneumothorax
- Mediastinitis:
  - Other causes of sepsis
  - Mediastinal masses/fat/fluid
  - Pleural effusions
- Mediastinal masses:
  - Mediastinitis
  - Pleural space disease
  - Pulmonary masses
  - Thoracic wall masses
  - Mediastinal fat or fluid
  - Normal thymic enlargement (young animals)
- Mediastinal hemorrhage:
  - Mediastinitis
  - Mediastinal fat or fluid
  - Mediastinal mass
  - Normal thymic enlargement (young animals)
  - Thymic hemorrhage (rare)

INITIAL DATABASE

- Thoracic radiographs:
  - Pneumomediastinum:
    - Visualization of mediastinal vascular structures not normally seen (e.g., branches of aorta) is pathognomonic.
    - Subcutaneous emphysema
  - Mediastinitis and mediastinal masses:
    - Mediastinal widening on dorsoventral or ventrodorsal views
    - Dorsal displacement of trachea on lateral view possible
    - Acute mediastinitis may cause no changes.
    - Pleural fluid possible
    - Gas in fascial planes of neck
- Abdominal radiographs: pneumoretroperitoneum possible
- CBC:
  - Leukocytosis if inflammation
  - Rarely cytopenias or leukemia
  - Anemia if mediastinal hemorrhage
- Serum biochemistry panel: hypercalcemia possible
- FeLV test
- Thoracic ultrasonography may identify:
  - Presence/structure of masses
  - Pleural effusion
  - Lymphadenomegaly
  - Vascularity/vascular invasiveness of mass (impacts biopsy/excision possibilities)
  - Mediastinal fluid if hemorrhage
- Fine-needle aspiration cytologic analysis:
  - Risks include hemothorax, pneumothorax, or nondiagnostic sample
  - If inflammatory: culture (aerobic, anaerobic, *Nocardia, Actinomyces,* ± fungal) indicated

- Thoracocentesis for cytology and culture if fluid present

ADVANCED OR CONFIRMATORY TESTING

- Tracheoscopy/bronchoscopy if pneumomediastinum (and patient stable)
- Contrast (water-soluble) esophagram if suspect rupture. See p. 1205.
- Esophagoscopy if suspect esophageal disease
- Cytologic evaluation of respiratory wash samples if underlying pulmonary disease
- Echocardiography if heart base mass
- Arterial blood gas to assess respiratory function
- Coagulation testing (prothrombin time, partial thromboplastin time [PT, PTT]) if hemorrhage
- CT or MRI will better delineate nature and extent of space-occupying disease and address possible metastatic disease (CT).
- Fungal serologic evaluation if possible fungal mediastinitis
- Biopsy for histopathologic evaluation can be obtained transthoracically (Trucut) or via thoracoscopy or thoracotomy.
- Flow cytometry can be helpful in distinguishing thymoma from thymic lymphoma.

TREATMENT

TREATMENT OVERVIEW

Many cases of pneumomediastinum will resolve over time with conservative management. Nonlymphoid cranial mediastinal masses typically require surgical intervention, whereas lymphoid neoplasia is treated nonsurgically.

ACUTE GENERAL TREATMENT

- Pneumomediastinum:
  - If mild signs, cage rest is sufficient; subcutaneous emphysema typically resolves in approximately 2 weeks.
  - If signs more marked, provide supplemental oxygen.
  - Drain subcutaneous emphysema only if causing discomfort (see p. 1060).
  - If tracheal tear/laceration, consider surgical repair (see p. 1108).
  - Thoracocentesis if pneumothorax
- Mediastinitis:
  - Broad-spectrum empirical antimicrobial therapy while culture/sensitivity results are pending
  - Severe systemic signs may require intravenous fluids and/or additional supportive therapy.
  - Esophageal laceration/rupture may require surgery.
- Mediastinal masses:
  - Surgery, chemotherapy, radiation therapy, or a combination based on type of mass
  - Mediastinal cysts are either drained transthoracically or excised.
- Mediastinal hemorrhage:
  - Volume support: crystalloid or colloids
  - Blood transfusion if severe o If coagulopathy, treat with vitamin K, 2.5 mg/kg SQ in multiple sites initially, and possibly a fresh frozen plasma transfusion.

CHRONIC TREATMENT

- Pneumomediastinum: cage rest as above
- Mediastinitis: long-term (minimum 4-6 weeks) antimicrobial therapy based on culture and sensitivity results
  - Fungal mediastinitis may require months of therapy.
  - Large granulomas causing cranial vena cava syndrome may require surgical excision/debulking.
- Mediastinal masses:
  - Chemotherapy or radiation therapy for lymphoma
  - Radiation therapy for incompletely resected thymoma

POSSIBLE COMPLICATIONS

- Pneumothorax, pleural effusion, pyothorax from thoracostomy tubes
- Gastrointestinal and/or myelotoxicity for many chemotherapeutics
- Individual toxicities for particular drugs:
  - Renal: aminoglycosides, amphotericin B
  - Hepatic: azole antifungals
- Surgery entails risks of anesthesia, hemorrhage, infection.

RECOMMENDED MONITORING

- Clinical signs
- Pulse oximetry, arterial blood gases
- Thoracic radiographs
- Pleural fluid volume if thoracostomy tube
- CBC (chemotherapy)
- Serum chemistries for renal and hepatic function, depending on antimicrobials or other drugs administered

PROGNOSIS AND OUTCOME

- Pneumomediastinum: good if underlying disease resolves or can be corrected
- Mediastinitis: variable depending on severity; chronic cases may be hard to resolve.
- Mediastinal masses:
  - Lymphoma: chemotherapy usually palliative
  - Others: surgery for cure or palliation. The prognosis for dogs and cats with surgical excision of thymoma is generally good.
- Mediastinal hemorrhage: prognosis variable, depending on cause and severity

PEARLS & CONSIDERATIONS

COMMENTS

- Advanced imaging helps define internal structure and extent of mediastinal masses and detect pulmonary metastases.
- In patients at risk of foreign body inhalation (hunting or field trial dogs), consider *Nocardia, Actinomyces* as causes of mediastinitis.

PREVENTION

Avoid iatrogenic tracheal injury associated with:

- Intubating with a stylet
- Overinflation of endotracheal tube cuffs
- Rotating a patient while attached to anesthetic circuit
- Traumatic jugular venipuncture

TECHNICIAN TIPS

- The complications of a fine-needle aspirate of a mediastinal mass include pneumothorax and hemothorax. If your patient suddenly develops a high respiratory rate or effort after the procedure, alert the attending clinician as soon as possible.
- Dogs that present with swollen front legs, neck, and face often have disease in the mediastinum.
- Cats with mediastinal masses can be very fragile (unstable respiratory/cardiovascular status). Minimize handling and avoid ventrodorsal projection for thoracic radiographs.

MDR1 Mutation

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

The MDR (multidrug resistance) 1 mutation causes enhanced sensitivity to a number of drugs such that affected dogs are extremely susceptible to adverse drug reactions at doses of drugs otherwise well tolerated by normal dogs.

SYNONYMS

Ivermectin or avermectin sensitivity; ABCB1, ABCB1-1 delta, or MDR1-1Δ gene mutation

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs **GENETICS** & **BREED PREDISPOSITION:** Herding breeds (collie, Australian shepherd, Shetland sheepdog, Old English sheepdog, English shepherd, border collie, German shepherd, McNab), sight hound breeds (long-haired whippet, silken windhound)

RISK FACTORS: Breed is a risk factor, based on the percentage of animals known to harbor the MDR1 mutation:

- Australian shepherd: 50%
- Border collie: 5%
- Collie: 75%
- English shepherd: 15%
- German shepherd: 5%
- Longhaired whippet: 65%
- McNab: 30%
- Old English sheepdog: 35%
- Shetland sheepdog: 15%
- Silken windhound: 35%
- Mixed breed dogs (presumed to be herding breed crosses): 10%

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Depends on the particular drug to which the animal is exposed:
  - Exposure to macrocyclic lactones (i.e., ivermectin, milbemycin, selamectin, moxidectin, etc.) may result in neurologic toxicosis. Note: Use of these drugs as labeled for heart-worm prevention is safe even for dogs with the MDR1 mutation. Neurologic toxicosis occurs only with higher doses (e.g., for treatment of mange, or accidental overdose).
  - Exposure to loperamide may result in neurologic toxicosis.
  - Exposure to some chemotherapeutic drugs (vinca alkaloids, anthracyclines such as doxorubicin) can result in severe gastrointestinal signs and/or severe myelosuppression.
  - Exposure to some antiemetics (ondansetron, possibly maropitant) may result in neurologic toxicosis.
  - Exposure to some preanesthetic agents (acepromazine, butorphanol) may result in more profound and prolonged sedation than expected for the dose administered.
- Onset of signs occurs within hours to days after drug exposure.
- Of note, exposure to macrocyclic lactones can occur through ingestion of feces of animals, particularly livestock, recently treated with these agents. Additionally, several pesticides contain avermectins and have caused neurologic toxicosis in dogs that were inadvertently exposed.

PHYSICAL EXAM FINDINGS: Determined by drug to which the dog has been exposed (see above):

- Macrocyclic lactones: mydriasis, hyper-salivation, ataxia, blindness, paresis, stupor, muscle tremors; may progress to coma
- Loperamide: paresis, ataxia, stupor
- Chemotherapeutic agents: anorexia; vomiting, diarrhea; signs of opportunistic infections or hemorrhage possible if neutropenia orthrombocytopenia, respectively
- Antiemetics: signs of mild to moderate central nervous system (CNS) dysfunction (usually depression)
- Preanesthetic agents: prolonged and more profound CNS depression

ETIOLOGY AND PATHOPHYSIOLOGY

- The MDR1 mutation is inherited in a simple Mendelian fashion.
- The MDR1 mutation itself is a 4-base-pair deletion mutation that results in dysfunction of P-glycoprotein, the product of the MDR1 gene.
- P-glycoprotein protects individuals from a number of drugs by restricting their access to the brain and enhancing their export from the body.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Screening for the MDR1 mutation can be performed preemptively in a dog of a high-prevalence breed. Otherwise, the mutation is suspected when signs of drug toxicosis have occurred despite the use of normal drug dosages. In either situation, confirmation is via genotyping.

DIFFERENTIAL DIAGNOSIS

- Idiopathic drug sensitivity
- Overdose

INITIAL DATABASE

Initial diagnostic tests are those that would be performed in any suspected case of toxicosis for the particular agent (e.g., CBC for chemotherapeutic drugs with myelosuppressive potential).

ADVANCED OR CONFIRMATORY TESTING

Definitive diagnosis consists of genotyping the dog. A DNA sample (cheek swab, using purpose-made kit) can be submitted to the Veterinary Clinical Pharmacology Laboratory at Washington State University. A DNA swab kit can be obtained at: www.vetmed.wsu.edu/vcpl.

TREATMENT 

TREATMENT OVERVIEW

- While there is no treatment that can alter the dog's MDR1 genotype, treatment of clinical signs resulting from drug exposure should be aimed at the particular drug involved.

ACUTE AND CHRONIC TREATMENT

- For macrocyclic lactones, supportive care is indicated (see p. 625). Administration of CNS depressants such as diazepam should be avoided. Recently the use of intravenous lipid emulsion for reversal of macrocyclic lactone toxicity has been discussed, but there are no clinical studies in dogs at this time.
- For loperamide, an opioid antagonist such as naloxone can reverse CNS depression.
- Chemotherapeutic agents, antiemetic agents, preanesthetic agents: supportive care (see p. 188)

PROGNOSIS AND OUTCOME 

- Clinical signs tend to be milder, and clinical outcome better, in dogs heterozygous for the MDR1 mutation (MDR1 mutant/normal).
- For dogs homozygous for the MDR1 mutation (MDR1 mutant/mutant), the prognosis is guarded for dogs exposed to doses of ivermectin used for treating mange (300-600 mcg/kg or higher) and customary doses of vincristine (0.5-0.7 mg/m^2) and doxorubicin (30 mg/m^2)

PEARLS & CONSIDERATIONS 

COMMENTS

- The MDR1 mutation (and exposure to a macrocyclic lactone or loperamide) should be considered in any herding-breed dog that develops unexplained signs of neurologic toxicosis.
- Prior to treatment with chemotherapeutic agents and/or off-label (i.e., anti-mange) doses of macrocyclic lactones, mixed-breed dogs or breeds listed above should be tested for the MDR1 mutation.
- The MDR1 mutation may explain the intolerance to stress and illness anecdotally observed in some breeds. In collies, the MDR1 mutation is associated with lower plasma cortisol concentrations at baseline and after ACTH stimulation. Since P-glycoprotein limits glucocorticoid passage into the brain, MDR1 mutation could favor such passage, increasing feedback inhibition and creating a state of relative adrenal insufficiency.

PREVENTION

- Treatment planning in dogs identified as having the MDR1 mutation (hetero-or homozygous): depending on the drug involved, patients requiring treatment with such drugs as those listed above may need to receive either a decreased drug dosage or an alternative drug. Studies to determine appropriate dosage adjustments have not yet been conducted.

CLIENT EDUCATION

Owners should be aware of drug sensitivities if their dog has the MDR1 mutation. Breeders should consider the MDR1 mutation as part of a comprehensive genetic assessment of their breeding program.

AUTHOR: KATRINA MEALEY

EDITOR: ETIENNE CÔTÉ

Masticatory Myositis

BASIC INFORMATION

DEFINITION

Masticatory myositis (MM) is an autoimmune disease affecting the muscles of mastication in dogs.

SYNONYMS

Masticatory muscle myositis (redundant because myositis by definition is muscle inflammation); eosinophilic myositis, atrophic myositis: incomplete (likely represent acute and chronic stages of a single disease)

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs of any age or breed, either sex.

GENETICS & BREED PREDISPOSITION

- Large-breed, young-adult to middle-aged dogs most commonly affected
- Overrepresentation in German shepherds
- Especially severe inflammation and myofiber destruction in rottweiler, Samoyed, and Doberman
- Reported in Cavalier King Charles spaniel littermates, with clinical signs beginning before 12 weeks of age

GEOGRAPHY AND SEASONALITY: Higher incidence reported to occur in the summer and fall

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Acute versus chronic

- An acute stage (painful muscle swelling/inflammation) may be followed by a latent stage (apparently healthy animal) which is then either followed by a chronic stage (muscle atrophy) or a recurrent acute stage.
- Untreated acute episodes last 2-3 weeks, and relapses in weeks or months frequently occur.
- The chronic form may develop without the client having observed acute signs.

HISTORY, CHIEF COMPLAINT:

Acute:

- Decreased activity, lethargy
- Fever, regional lymphadenopathy
- Dysphagia, reluctance to eat, weight loss
- Drooling of saliva, change in bark (more high-pitched)
- Pain on yawning or when grabbing toys

Chronic:

- Dogs usually bright, alert, and otherwise normal, but progressive atrophy of masticatory muscles

PHYSICAL EXAM FINDINGS: Acute:

- Visible or palpable swelling of the masticatory muscles
- Exophthalmos due to swelling of temporal and pterygoid muscles; inability to blink properly, ocular discharge, conjunctivitis, and keratitis; occasionally blindness due to optic nerve compression
- Pain on palpation of masticatory muscles and regional lymph nodes
- Resistance or inability to open the mouth (trismus)

Chronic:

- Moderate to severe atrophy of masticatory muscles
- Enophthalmos due to atrophy of temporal and pterygoid muscles (globes sinking into their orbits)
- Inability to fully open the mouth (trismus)
- In rare cases, open bite presentation due to inability to completely close the mouth

ETIOLOGY AND PATHOPHYSIOLOGY

- Masticatory myositis (MM) is an autoimmune disease affecting the muscles of mastication in dogs.
- Temporal, masseter, and (medial and lateral) pterygoid muscles (but not digastricus muscles) possess 2M fibers that differ from the common type 2C fibers of limb muscles.
- In dogs with MM, autoantibodies target the unique myosin component of type 2M fibers, resulting in inflammation, necrosis, and phagocytosis of muscle tissue.
- It has been speculated that autoantibodies are generated in response to an infectious agent cross-reacting with endogenous antigens.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

A diagnosis of MM can be made if clinical and histopathologic signs of myositis are limited to masticatory muscles, and antibodies against type 2M fibers are identified in serum or immune complexes found in biopsied muscle samples.

DIFFERENTIAL DIAGNOSIS

Masticatory myositis must be differentiated from a variety of disorders of the head and neck that can make a dog unwilling or unable to open its mouth.

- Maxillofacial trauma
- Temporomandibular joint disease
- Bone and soft-tissue neoplasia
- Foreign-body penetration (caudal to last maxillary molar, tonsillar region, pharyngeal wall, sublingual tissues)
- Ocular disease and space-occupying orbital/retrobulbar lesions
- Ear disease (e.g., otitis externa, neoplasia in ear canal)
- Other inflammatory muscle disorders (polymyositis, extraocular myositis, dermatomyositis, laryngeal myositis)
- Tetanus
- Chronic exposure to glucocorticosteroids (catabolic to muscle)
- Craniomandibular osteopathy (excessive bone deposition along caudal mandible and temporal bone region).

INITIAL DATABASE

- CBC (occasionally leukocytosis with eosinophilia)
- Serum biochemistry profile (occasionally increased serum globulin, total protein, and hepatic enzyme activities)
- Serum creatine kinase (normal or slightly elevated)
- Urinalysis (generally unremarkable; proteinuria uncommon)
- Orofacial examination: check for facial asymmetry, look for masticatory muscle swelling or atrophy, evaluate presence of pain on palpation or jaw manipulation, measure range of mandibular motion with a ruler as the distance between the incisal edges of the maxillary and mandibular first incisors.

ADVANCED OR CONFIRMATORY TESTING

- Serum type 2M fiber antibody titer (<1:100 = negative; 1:100 = borderline; >1:100 = positive; circulating antibodies against type 2M fibers detected in serum from 81% of dogs with MM)
- General anesthesia allows assessment of jaw tone without conscious resistance from the patient (occasionally requiring temporary tracheostomy for intubation).
- Skull radiographs: to rule out skeletal abnormalities in dogs that cannot open their mouths
- CT: for ruling out most differentials of MM, allowing CT-guided fine-needle aspiration, showing changes in size (larger due to edema or inflammation; smaller due to atrophy, necrosis or fibrosis), pre-contrast tissue attenuation (hypoattenuated due to edema) and contrast enhancement (heterogeneously enhanced due to inflammation) of affected masticatory muscles and lymphadenopathy
- MRI:

    - Advantages compared with CT: superb characterization of soft tissues and very sensitive in detecting early signs of muscle edema
    - Disadvantages compared with CT: more time-consuming and costly; less readily available; does not record signals from cortical or lamellar bone; not useable for fine-needle aspiration
- Electromyography (less useful in dogs with chronic MM): to demonstrate spontaneous electrical activity (i.e., increased insertional activity, fibrillation potentials, positive sharp waves, and bizarre high-frequency discharges), differentiate MM from neuropathy (denervation atrophy) or polymyositis, and facilitate selection of sites for muscle biopsy (though less helpful than CT)
- Muscle biopsy: (see p. 1305)

TREATMENT

TREATMENT OVERVIEW

The goal of therapy is to alleviate pain, blunt the inflammatory response, prevent muscle fibrosis, and restore normal opening and closing of the mouth.

ACUTE GENERAL TREATMENT

Glucocorticosteroid therapy should not be started prior to blood collection and muscle sampling:

- Dexamethasone, 0.4 mg/kg IV (once after blood collection and muscle biopsy): initially helpful in reducing the degree of inflammation in dogs with acute MM that can barely open the mouth.
- Prednisone, 1-2 mg/kg PO q 12 h (upon patient discharge): usually results in rapid (within days) improvement of clinical signs; after approximately 2-3 weeks, dosage can be decreased to 1 mg/kg q 24 h, and then slowly tapered to the lowest possible alternate-day effective dosage over a period of 8-12 months.

CHRONIC TREATMENT

- It is usually necessary to maintain dogs on a low-dose, alternate-day oral prednisone therapy to prevent relapses.
- Dogs unable to receive corticosteroids, unresponsive to corticosteroids alone, or showing unacceptable side effects in response to corticosteroids may instead benefit from administration of azathioprine (1-2 mg/kg PO q 24 h).

NUTRITION/DIET

Feeding tube placement (see p. 1270 and p. 1267), temporarily (treatment response) or permanent (lifelong)

POSSIBLE COMPLICATIONS

- Corticosteroids: typical effects
- Azathioprine: myelotoxicity (leukopenia, anemia, thrombocytopenia), acute pancreatitis, and hepatotoxicity
- Progressive inability to open the mouth (leading to starvation from inability to prehend)

RECOMMENDED MONITORING

- Physical examination (focus on body weight, muscle atrophy, pain on head palpation/jaw manipulation, and range of mandibular motion measured with a ruler) at 2 weeks, 1, 2, 6, 9, and 12 months after initiation of prednisone therapy and once every 6-12 months thereafter
- Serum type 2M fiber antibody titer at 2, 6, 9, and 12 months after initiation of prednisone therapy and once every 6-12 months thereafter (determining antibody titer is particularly important prior to decreasing prednisone doses when they are already very low [i.e., below 0.1-0.2 mg/kg q 24-48 h])
- CBC and serum biochemistry profile at 6 and 12 months after initiation of prednisone therapy (sooner and shorter interval if receiving azathioprine) and once every 12 months thereafter

PROGNOSIS AND OUTCOME

- Good prognosis for acute MM when initiation of treatment is prompt and therapy is long term. Inadequate dosing or treatment for an insufficient period of time is associated with a high rate of relapse. Dogs with relapses when the dose is lowered should be reinstituted at the maximum prednisone dose.
- Fair to guarded prognosis for chronic MM when extensive atrophy and fibrosis of masticatory muscles led to progressive

inability to open the mouth.

PEARLS & CONSIDERATIONS

COMMENTS

- MM is a leading differential diagnosis in a dog with difficulty, unwillingness, or inability to fully open the mouth; masticatory muscle swelling or atrophy; and pain upon palpation of the head (muscles, jaws, etc.).
- Clinical signs of MM are usually bilateral, but because they are not always equal in severity or time of onset, muscle swelling and atrophy may sometimes appear unilaterally.
- Treatment with corticosteroids prior to blood collection can result in false-negative serum type 2M fiber antibody titer results. Destruction of type 2M fibers and replacement with scar tissue may also lead to a decreased antigenic stimulus for autoantibody production in dogs with chronic MM.
- Serum creatine kinase is more likely to be high in dogs with acute than chronic MM but is generally lower than in dogs with polymyositis, owing to less muscle mass affected.
- Myotomy of affected muscles and slow traction to force open the mouth are considered to be experimental procedures that have not been evaluated in controlled studies and may be associated with increased morbidity and high rate of complications (iatrogenic jaw fracture).

TECHNICIAN TIPS

Technicians caring for these patients should be familiar with assisted feeding techniques, including the use and care of feeding tubes.

Mast Cell Tumors, Dog

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Canine mast cell tumors (MCTs) are neoplastic accumulations of cells that can degranulate, a process resulting in the release of bioactive substances that can produce cutaneous or systemic clinical signs.

SYNONYMS

Mastocytoma, systemic mastocytosis (metastatic MCT)

EPIDEMIOLOGY

SPECIES, AGE, SEX: Can occur in any age dog; the median age in dogs is 8 years.

GENETICS & BREED PREDISPOSITION: Breeds predisposed to MCT include boxer, Boston terrier, golden retriever, Labrador retriever, Pug, sharpei, Staffordshire bull terrier, Jack Russell terrier

ASSOCIATED CONDITIONS & DISORDERS: Caused by mast cell degranulation: gastrointestinal ulceration, pruritus, hypotension, delayed wound healing

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Most dogs show no clinical signs and are evaluated for an incidentally discovered cutaneous or subcutaneous mass. Some lesions are pruritic. MCTs often remain unchanged in size for months to years before presentation.
- Occasionally, dogs are evaluated because of signs related to gastric ulceration (vomiting, diarrhea, weight loss, melena) secondary to histamine-induced gastric acid secretion.

PHYSICAL EXAM FINDINGS

- Mast cell tumors have a highly variable appearance and may be mistaken for lipomas, skin tags, or insect bites. For this reason, skin and subcutaneous masses should always be aspirated and examined cytologically to obtain a diagnosis.
- Some dogs have multiple cutaneous MCTs, so a thorough examination of the entire skin surface is indicated.
- Because of the presence of histamine in mast cell granules, MCTs sometimes shrink and swell intermittently as degranulation (release of granules from the mast cell cytoplasm) occurs. Degranulation can result from manipulation of the tumor or can be spontaneous.
- Because of the presence of heparin in mast cell granules, MCT may bleed excessively when aspirated, but this is rarely clinically significant.
- Peritumoral bruising and edema (termed *Darier's sign)* and hyperemia (see p. 555) are uncommon but are associated with aggressive-behaving MCTs.

ETIOLOGY AND PATHOPHYSIOLOGY

- Mast cells participate in allergic and inflammatory responses. They contain preformed granules consisting of histamine, heparin, and other cytokines that are released on activation of the cells (degranulation). Cytokine release causes clinical signs.
- Mast cell tumors are accumulations of mast cells with malignant potential.
- Mast cell tumors occur primarily in the skin and subcutaneous tissues, and rarely in extracutaneous sites (GI tract, spinal cord, lung, nasal cavity) in dogs.
- MCTs most commonly metastasize to regional lymph nodes followed by spleen, liver, mesenteric lymph nodes, other cutaneous sites, and bone marrow.
- Chronic inflammatory skin diseases or mutations in a protooncogene, c-KIT, may predispose dogs to mast cell neoplasia; c-KIT encodes the receptor tyrosine kinase KIT, which promotes mast cell growth and differentiation. Mutations in c-KIT (present in about 20%-30% of canine MCT) allow abnormal continuous activation of the receptor and predispose dogs to aggressive MCT that are more likely to recur and metastasize. Inhibition of receptor tyrosine kinases through targeted therapies (see treatment below) holds promise in the treatment of advanced local or metastatic MCT.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of MCT is generally straightforward: microscopic examination of cytologic preparations or tissue samples reveals characteristic intracytoplasmic granules. Regional lymph nodes should be aspirated whenever possible, and additional staging tests should be considered if signs of aggressive tumoral behavior are present, including peritumoral edema, swelling, or bruising, or if tumors are recurrent.

DIFFERENTIAL DIAGNOSIS

- Gross appearance and palpation:
  - Hemangiosarcoma or hemangioma, cutaneous
  - Plasma cell tumor, histiocytoma, transmissible venereal tumor, lymphoma, amelanotic melanoma, squamous cell carcinoma
  - Lipoma
  - Phlebectasia
  - Granuloma
  - Abscess
- Cytologically, other round cell tumors (histiocytoma, lymphoma) may have a similar appearance.

INITIAL DATABASE

- MCTs are readily diagnosed cytologically by their characteristic blue-or-purple-staining intracytoplasmic granules. In poorly differentiated MCTs, these granules may not be visible, especially with Diff-Quik stain (in-clinic stain). Wright's stain (used in most university and commercial clinical pathology laboratories) is more sensitive to detect granules.
- Before surgical excision, a CBC, serum chemistry panel, urinalysis, and regional lymph node aspirate (regardless of size of the lymph node) should be obtained.
  - CBC abnormalities associated with MCT can include eosinophilia, basophilia, and regenerative or nonregenerative anemia.
- Complete staging for systemic mast cell disease is indicated before surgery in the following patients:
  - Lymph node metastasis is present.
  - Peritumoral edema or bruising is present.
  - Tumors are recurrent.
  - Tumors are located on the prepuce, scrotum, muzzle, digit, pinna or ear canal, or oral mucosa (locations associated with a high rate of metastasis). Tumors located on mucous membranes have a worse prognosis when compared to MCT of haired skin.
- Complete systemic staging to examine for evidence of MCT metastasis includes a CBC, serum chemistry panel, urinalysis, abdominal ultrasound, bone marrow aspiration cytologic study, regional lymph node aspirate or biopsy, and biopsy of the primary tumor.
- Splenic/liver aspirates are indicated if these organs are enlarged or have an abnormal echotexture ultrasonographically.
- The buffy coat smear can be part of complete staging for dogs with MCT, but it has a high rate of false-positive results and must be interpreted along with other staging tests to confirm metastasis.

ADVANCED OR CONFIRMATORY TESTING

- MCTs are categorized into grades based on their histologic appearance (Patnaik grading system):
  - Grade I = well-differentiated tumors
  - Grade II = intermediately differentiated tumors
  - Grade III = poorly differentiated tumors
- This grading system is the most consistent prognostic indicator for metastasis, disease-free interval, and survival for dogs with MCT. The metastatic rate for grade I and II tumors is <10%, and for grade III tumors it is >50%.
- The mitotic index ([MI]; # mitotic figures/high-power field) correlates with grade and prognosis. Dogs having cutaneous MCT with a MI < 5 had a median survival time (MST) of 70 months, compared to 5 months if the MI > 5.
- Mast cell granules may not be present or visible in highly anaplastic MCT; CD-117 (c-KIT) immunohistochemistry can be used to confirm a diagnosis of MCT.
- Normal lymph nodes may contain scattered mast cells; increased numbers or clusters of mast cells in a lymph node draining a MCT suggest metastasis.
- The liver, spleen, and bone marrow normally contain a few mast cells, but increased numbers or clusters of mast cells suggest MCT metastasis.
- Thoracic radiographs are of limited usefulness in dogs with MCT. Uncommonly, malignant pleural effusion containing mast cells occurs.

- Abdominal ultrasound:
  - Affected lymph nodes may be enlarged, hypo- or hyperechoic, or irregular.
  - Splenic/hepatic infiltration: hypoechoic lesions throughout the parenchyma, rarely a solitary mass

TREATMENT

TREATMENT OVERVIEW

Mast cell tumors have a wide variety of biological behaviors and outcomes, and treatment may include surgery, radiation therapy, chemotherapy, or a combination of these modalities. Newer targeted therapies are now available and may be indicated in patients with nonresectable or recurrent tumors. Consultation with an oncologist for current treatment options is warranted in these cases.

ACUTE GENERAL TREATMENT

- Surgery is the primary treatment modality for MCT.
  - For most MCT, tumors should be surgically excised with 2 cm or greater lateral margins and 1 fascial plane deep to the tumor.
  - All tissue should be submitted for histologic evaluation of grade and margins. Margins should be inked with a marking system before placement in formalin.
  - Histamine blockers are indicated in dogs with MCT before surgical excision (begin therapy a few days before and premedicate patient immediately prior to surgery) or in cases of nonresectable or metastatic disease:
    - H2 blocker: diphenhydramine (1-2 mg/kg PO or SQ q 12 h)
    - H2 blockers: ranitidine (1-2 mg/ kg PO or SQ q 12 h); or famotidine (0.5-1 mg/kg PO or SQ q 12 h).
  - Proton pump inhibitors (omeprazole, 0.5-1 mg/kg PO once daily) are indicated in dogs with MCT and suspected or confirmed gastric ulceration.
  - Perioperative complications may include hypotension and hemorrhage. Postoperative complications can include poor wound healing after resection of large or infiltrative MCT.
- For tumors that are not surgically resectable, owing to size, invasiveness, or metastasis, chemotherapy or radiation therapy (RT) before or instead of surgery may be indicated.
- Mast cell tumors are responsive to RT:
  - Treating MCT in a microscopic disease setting (i.e., postsurgical resection) yields better results than if treatment is performed in a setting of macroscopic (measurable) disease.
  - Potential indications for RT for mast cell tumors include incompletely excised grade I and II MCT where wider surgical excision is not possible; as an adjunct to surgery and chemotherapy in dogs with grade III MCT; and to attempt cytoreduction of nonresectable MCT.
  - Regional (draining) lymph nodes should be irradiated prophylactically, since one study demonstrated improved survival times versus patients whose nodes were not irradiated.
- The goal of chemotherapy is to delay or prevent metastasis and possibly local recurrence or to attempt to cytoreduce or slow progression of nonresectable tumors or metastatic lesions. Potential indications for chemotherapy in dogs with MCT include:
  - Dogs with grade III MCT (because at least 50% will develop metastasis) or tumors with MI > 5
  - Dogs with metastasis at diagnosis or with recurrent tumors
  - Dogs with tumors in locations associated with aggressive behavior (see above)
  - Before attempting surgical excision in large, fixed tumors or tumors with peritumoral edema or bruising
- Chemotherapy drugs considered to be effective in the treatment of MCT include CCNU (lomustine), prednisone, vinblastine, vinorelbine, chlorambucil, cyclophosphamide, and others. Special handling requirements and potentially severe or life-threatening adverse patient effects exist with these chemotherapeutic drugs; these concerns and rapid evolution of protocols warrant consultation with/referral to an oncologist.
- Targeted therapy: receptor tyrosine kinase inhibitors such as toceranib (Palladia; 2.2-3.25 mg/kg PO q 48 h; intolerance may warrant decrease to Mon-Wed-Fri dosage schedule) and mastinib inhibit normal and mutated KIT (see pathogenesis). They are indicated for use in dogs with metastatic, recurrent, or nonresectable grade II and III MCT. Consultation with an oncologist is recommended.

PROGNOSIS AND OUTCOME

- The most significant prognostic indicator for MCT is tumor grade. For dogs with completely excised grade I and II MCT, the prognosis is excellent; approximately 5% of these tumors will recur locally or metastasize.
- For dogs with incompletely excised grade I and II tumors, RT provides excellent long-term tumor control, with 80%-90% of dogs free of tumor 2-5 years after treatment. In one study, <25% of incompletely excised grade II MCT recurred following incomplete excision.
- For dogs with grade III MCT, survival times are unpredictable because of the possibility of metastasis and tumor recurrence. A recent study suggests that with effective local control, 70% of dogs with grade III MCT were alive 1 year after treatment. In

another study, dogs with grade III MCT treated with prednisone and vinblastine had a median survival time > 1300 days.
- Mitotic index correlates with grade, and MI > 5 (see above) warrants a guarded prognosis.
- Approximately 10%-40% of dogs develop additional cutaneous MCT in their lifetime.

PEARLS & CONSIDERATIONS

COMMENTS

- It is recommended to schedule patients for rechecks including thorough physical examinations every 4-6 months (or more often if indicated) to try to detect new MCT as soon as possible.
- Grossly, fine-needle aspirates of mast cell tumors can look transparent and watery and are indistinguishable from fat. All fine-needle aspirations must be examined cytologically to differentiate fat from MCT.
- Buffy coat exams frequently are falsely positive and are inferior to bone marrow aspiration and cytologic evaluation for assessing hematologic involvement.
- Because of interpathologist variation when assigning histologic grades to MCT in dogs, the clinician must consider factors including tumor grade, MI, location and size of the tumor, presence of regional and systemic metastasis, and completeness of surgical excision to determine an appropriate treatment plan and prognosis.
- Intralesional therapies such as deionized water or corticosteroids may provide temporary shrinkage of MCT but are rarely effective for long-term tumor control and are not recommended.

CLIENT EDUCATION

Any new masses on the skin should be evaluated as soon as possible.

Mast Cell Tumors, Cat

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Feline mast cell tumors are neoplastic accumulations of mast cells in cats. Mast cell tumors (MCTs) produce deleterious effects when the mast cells degranulate, a process resulting in the release of bioactive substances that can produce cutaneous or systemic clinical signs depending on tumor location. Cutaneous MCTs are common, splenic MCT is uncommon, and visceral MCTs are rare.

SYNONYMS

Mastocytoma, splenic or visceral mastocytosis

EPIDEMIOLOGY

SPECIES, AGE, SEX: MCT is primarily a disease of older cats, although all ages can be affected. Males may be predisposed.

GENETICS & BREED PREDISPOSITION: Siamese (possibly)

ASSOCIATED CONDITIONS & DISORDERS: Related to mast cell degranulation:

- Gastrointestinal ulceration
- Pruritus
- Hypotension
- Delayed wound healing

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: In cats, there are two distinct presentations:

- Cutaneous MCTs
- Splenic or visceral MCTs

HISTORY, CHIEF COMPLAINT

- Most cats with cutaneous MCT show no clinical signs, although some lesions are pruritic. MCTs often remain unchanged in size for months or years prior to presentation.
- Cats with splenic or visceral MCTs display nonspecific signs of illness (weakness, lethargy, anorexia) or gastric ulceration-associated bruxism, vomiting, diarrhea, weight loss, and melena. Abdominal distension secondary to ascites and splenomegaly may also occur.

PHYSICAL EXAM FINDINGS

- Although most cutaneous MCTs are found on the head, a thorough examination of the skin is indicated. Tumors are usually alopecic, small (<5 mm), round, and pink or white. Some MCTs are plaquelike. Regional lymph nodes may be normal in size even if metastasis is present.
- Approximately 15% of cats with cutaneous MCTs have concurrent splenic or visceral MCTs.
- Physical exam findings in cats with splenic or visceral MCTs include splenomegaly, ascites, abdominal mass, bowel wall thickening, abdominal pain, and mucous membrane pallor secondary to anemia (induced by gastrointestinal ulceration and bleeding, or rarely myelophthisis).

ETIOLOGY AND PATHOPHYSIOLOGY

- Mast cells participate in allergic and inflammatory responses.
- Mast cells contain preformed granules consisting of histamine, heparin, and other cytokines that are released upon activation of the cells (degranulation). Cytokine release causes clinical signs.
- Mast cell tumors are accumulations of mast cells with malignant potential.
- Mast cell tumors have a variable potential for metastasis (visceral MCT > cutaneous MCT); when it occurs, regional lymph nodes, spleen, liver, bone marrow, mesenteric lymph nodes, and other cutaneous sites can be affected.

- The etiology of feline MCTs is unknown.
- Feline leukemia virus (FeLV), feline immunodeficiency virus (FIV) infection: not associated with the development of feline MCT.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Cutaneous MCT should be suspected in cats with small pimple-like lesions of the head and neck; fine-needle aspirate is usually diagnostic. Any cat with splenomegaly or ascites should be suspected to have splenic MCT, and fine-needle aspiration of the spleen should be performed.

DIFFERENTIAL DIAGNOSIS

- Cutaneous form: histiocytoma, lymphoma, eosinophilic granuloma complex, and lipoma
- Splenic and visceral forms: splenomegaly: infectious splenitis, lymphoma, myeloproliferative disease, and hemangiosarcoma
- Visceral lesions: inflammatory bowel disease, lymphoma, intestinal adenocarcinoma or sarcoma, and granulomas

INITIAL DATABASE

Cutaneous form:

- The diagnosis of MCTs is frequently obtained by fine-needle aspiration of the lesion for cytologic examination.
- Prior to treatment, CBC, serum biochemistry panel, serum thyroxine (T4), urinalysis, FeLV/FIV test, and a regional lymph node aspirate should be obtained.
- Staging for systemic mast cell disease is indicated prior to surgery in patients with the following:
    - Lymph node metastasis is present.
    - Peritumoral edema or bruising is present.
    - Tumors are recurrent or multiple.
    - There is any suspicion of splenic or visceral MCTs (e.g., splenomegaly).
- Complete staging for metastasis includes CBC, serum biochemistry panel, urinalysis, serum T4 level, FeLV/ FIV tests, buffy coat smear, thoracic and abdominal radiographs, abdominal ultrasound, bone marrow aspirate, regional lymph node aspirate or biopsy, and aspirate or biopsy of the primary tumor. Splenic/liver aspirates are indicated if these organs are enlarged or have an abnormal echotexture.

Visceral and splenic forms:

- All cats with the splenic or visceral form of MCTs should have complete staging prior to definitive therapy.

ADVANCED OR CONFIRMATORY TESTING

- Cytologically, mast cells have a round nucleus and intracytoplasmic granules are almost always present.
- The histologic grading system used for canine cutaneous MCTs is not clinically significant in cats. Some feline dermal MCT have histologic characteristics that would suggest aggressive behavior (anisokaryosis/ -cytosis, nuclear atypia, multiple nucleoli), but in one study 14/15 cats whose tumors fit this description did not develop tumor recurrence or metastasis. A high mitotic index (≥1-2 mitoses/high power field) is likely related to a malignant phenotype.
- CBC abnormalities associated with MCTs can include eosinophilia, basophilia, and regenerative or nonregenerative anemia.
- Normal lymph nodes may contain scattered mast cells; metastasis to regional lymph nodes is documented by the presence of increased numbers or clusters of mast cells in a lymph node draining an MCT.
- The buffy coat smear is more specific in cats than dogs. A positive test supports a diagnosis of mast cell metastasis in cats with MCT.
- The liver, spleen, and bone marrow normally contain a few mast cells; increased numbers or clusters of mast cells are supportive of MCT metastasis.
- Thoracic radiographs: limited usefulness. Uncommonly, pleural effusion containing mast cells occurs with MCTs, and mediastinal MCTs have been reported.
- Abdominal ultrasound:
    - Affected lymph nodes may be enlarged or irregular.
    - Splenic/hepatic infiltration: hypoechoic lesions throughout the parenchyma, rarely a solitary mass
    - Gastrointestinal tract lesions may be solitary or diffuse throughout the bowel.

TREATMENT

TREATMENT OVERVIEW

In most cases, the goal of therapy is to control the local disease to prevent recurrence and metastasis. In cases presenting with metastasis or nonresectable local disease, the goals are to minimize tumor volume and secondary GI signs and to maintain quality of life.

ACUTE AND CHRONIC TREATMENT

Cutaneous form:

- Treatment options include surgery and radiation therapy.
- Spontaneous resolution is rare.
- Chemotherapy may play a role in some cats with cutaneous MCTs.
- Surgery is the primary treatment for cutaneous MCTs.
    - Wide surgical margins are not as important in cats as in dogs, since recurrence following incomplete excision is uncommon in the cat.
    - All tissue should be submitted for histologic evaluation; margins should be inked prior to placement in formalin.
    - Treatment with antihistamines for at least 48 hours prior to surgery is recommended (to reduce effects of mast cell degranulation induced by surgical manipulation of the tumor).
    - Postoperative complications are uncommon; wound healing should be monitored following resection of large, infiltrative MCTs.
- Mast cell tumors in locations that preclude complete excision (i.e., periocular, pinna) are common; radiation therapy may be effective as a primary or adjunct (postoperative) treatment. External beam radiation therapy (via linear accelerator) is uncommonly used to treat cats with MCT, but strontium-90 plesiotherapy (radiation source applied directly to the tumor) is a very useful treatment to prevent recurrence of superficial (<4 mm deep) feline cutaneous MCT.
- Nonresectable (large/highly invasive/ metastatic) tumors may require chemotherapy or radiation therapy prior to or instead of surgery.

Visceral form:

- Surgery is the primary treatment modality for visceral MCTs.
- Exploratory laparotomy is indicated, with incisional liver and mesenteric lymph node biopsies even if the tissue appears normal. Bowel-wall masses should be resected if possible.
- Splenectomy is the treatment of choice in cats with splenic MCTs, even if metastasis or cutaneous MCT is present. Following splenectomy, disseminated disease often resolves or improves significantly.
- Take care not to excessively manipulate known tumor tissue, since degranulation can result in anaphylaxis and hypotension during surgery.

Chemotherapy for feline MCT:

- The goal of chemotherapy is to delay or prevent metastasis or to attempt cytoreduction for nonresectable tumors or metastases. A single study evaluating the use of lomustine (50-60 mg/m^2 PO q 3-6 wk, based on neutrophil count) in cats with measurable MCT revealed a response rate of 50% with a median duration of response of 168 days. Other drugs that may be effective in the treatment of MCTs include prednisone and vinblastine. Special handling requirements and potentially severe or life-threatening adverse patient effects exist with these chemotherapeutic drugs; these concerns and rapid evolution of protocols warrant consultation with/referral to an oncologist.
- Potential indications for chemotherapy in cats with MCTs include: multiple or recurrent cutaneous MCTs, presence of metastasis at the time of diagnosis, or prior to attempting surgical excision in large, infiltrative tumors.

Adjunctive therapies:

- Antihistamines are indicated in cats with MCTs prior to surgical excision or in cases of nonresectable or metastatic disease.
- H2 blockers: cyproheptadine (2 mg/ cat PO q 12-24 h) or diphenhydramine (1-2 mg/kg PO or SQ q 12 h); cyproheptadine is recommended for feline MCT due to its antiserotonin properties and ease of administration as compared to diphenhydramine.
- H2 blockers: ranitidine (1-2 mg/kg PO or SQ q 12 h) or famotidine (0.5 mg/ kg PO or SQ q 12-24 h)
- Proton pump inhibitors (omeprazole, 0.7 mg/kg PO q 24 h) are indicated in cats at risk for or that have developed gastric ulceration.
- Supportive care including nutritional and blood-product support and analgesia are indicated perioperatively as needed.

PROGNOSIS AND OUTCOME

- The prognosis for cats with cutaneous MCTs is good, and recurrence after excision or strontium irradiation is uncommon.

Some cats will develop multiple cutaneous MCTs, regional lymph node metastasis, or splenic or visceral MCTs, and currently there is no reliable way to predict in which cases this type of progression will occur; client education and frequent rechecks are recommended.

- In one study, cats with solitary dermal MCT with or without regional lymph node involvement had longer median survival times (MST) (MST was not reached in cats with solitary tumors +/− lymph node involvement) as compared to cats with multiple cutaneous MCT or cats with cutaneous tumors + distant metastasis (MST 582 days in this group of cats). Survival times were longer in cats with cutaneous tumors as compared to those with splenic or visceral tumors.
- The prognosis for cats with solitary splenic MCT is good (MST following splenectomy: 19 months).
- For cats with splenic MCT with other sites involved, the prognosis can be good, and the remaining mast cell disease may resolve following splenectomy. There is no reliable way to predict tumor behavior, so chemotherapy can be considered if metastatic sites do not resolve within 2 months of splenectomy or if clinical signs persist despite splenectomy.
- Primary gastrointestinal MCTs have the poorest prognosis, which may improve if the lesions are surgically resectable. The role of adjuvant chemotherapy is unclear but should be considered.

PEARLS & CONSIDERATIONS

COMMENTS

Many cats with mast cell disease will develop additional MCTs during their lifetime, including cutaneous, splenic, or visceral forms. It is wise to schedule patients for rechecks at least every 4-6 months (or more often if indicated) for physical examinations and possibly restaging.

CLIENT EDUCATION

Any new skin masses or signs of illness should be evaluated as soon as possible.

AUTHOR: TRACY GIEGER

EDITOR: KENNETH M. RASSNICK

Mass: Cutaneous, Subcutaneous

BASIC INFORMATION

DEFINITION

A lump made up of cohering cells in the skin (cutaneous) or soft tissue between the skin and underlying fascia, muscle, or bone (subcutaneous). A very common condition in dogs, and common in cats.

SYNONYMS

Bump, growth, lump, nodule, tumor

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Older animals more commonly develop benign and malignant neoplasms.
- Eosinophilic lesions and plasma-cell pododermatitis or stomatitis (cats)
- Canine juvenile cellulitis (puppies)
- Histiocytomas and viral papillomas (young dogs)
- Intact male cats are prone to abscesses because of fighting behavior.
- Mammary tumors (intact female dogs)
- Perianal gland tumors (intact male dogs)

GENETICS & BREED PREDISPOSITION

- Malignant tumors are more common in purebred dogs versus crossbred dogs.
- Boxers are prone to a variety of benign and malignant neoplasms.
- Cutaneous histiocytoma (flat-coated retrievers)
- Keratinous cysts and nodular dermato-fibrosis syndrome (German shepherds)
- Idiopathic focal mucinosis (Doberman pinschers)
- Dermatophyte pseudomycetoma (Persian cats)

RISK FACTORS: Long-term exposure to sunlight increases the risk of cutaneous hemangioma and hemangiosarcoma (dogs) and squamous cell carcinoma (dogs and cats).

CONTAGION & ZOONOSIS: Transmissible venereal tumors and viral papilomas are contagious between dogs.

GEOGRAPHY AND SEASONALITY: Transmissible venereal tumor is more prevalent in temperate climates.

ASSOCIATED CONDITIONS & DISORDERS: Nodular dermatofibrosis syndrome in German shepherds may be associated with renal adenocarcinoma and uterine leiomyoma.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Most commonly, the pet owner visualizes or feels the mass, but it may be found incidentally by the veterinarian on physical examination.
- Historic information obtained should include:
  - Presence of similar lesions
  - Rapidity of onset (malignant tumors tend to grow rapidly)
  - Evidence of pruritus or pain
  - Presence of other animals in the household
  - Possibility of exposure to anticoagulant rodenticides (hematomas)
  - Known trauma
  - In cats, indoor/outdoor status should be known (increased risk of bite or scratch wounds, foreign bodies, other trauma).

PHYSICAL EXAM FINDINGS

- Characterize the mass in terms of size, shape, location, consistency, depth, ulceration, and whether it is freely movable. Malignant tumors are more likely to be ulcerated, fixed to underlying structures, and have poorly defined margins.
- Examine local lymph nodes and possible sites of metastasis (e.g., lungs, abdomen). Local lymph nodes may be enlarged due to inflammation (i.e., reactive lymph node) or metastasis.
- A complete physical exam is essential to identify any associated abnormalities.

ETIOLOGY AND PATHOPHYSIOLOGY

- A neoplasm is caused by progressive, uncontrolled growth of cells. Unlike benign neoplasms, malignant neoplasia shows a greater degree of anaplasia and exhibits invasive and metastatic properties. Most have an unknown cause, but some may be induced by irritation, trauma, viruses, vaccinations, ultraviolet radiation exposure, thermal injury, immunologic or genetic influences, or hormones.
- Cysts are accumulation of material (keratin, serum, glandular product) within a membrane. May arise from idiopathic, traumatic, congenital, follicular, or pilar causes.
- A granuloma is a focal accumulation of mononuclear inflammatory cells due to bacteria, mycoses, mycobacteria, dermatophytes, parasites, endogenous or exogenous foreign objects, allergic, or idiopathic causes. Pyogranulomas also include neutrophilic inflammation.
- Keratoses are solid circumscribed lesions caused by overproduction of keratin.
- A hamartoma is a benign, disorganized overgrowth of normal cells within a tissue, whereas a nevus is a hamartoma arising from any skin component.
- A hematoma is local extravasation of blood due to trauma and/or bleeding disorder.
- Abscesses result from a local accumulation of neutrophils and necrotic tissue cells, usually secondary to a bacterial or fungal infectious agent.
- Urticaria is a group of wheals in the dermis caused by a hypersensitivity reaction to insect bites, food, irritants, drugs, allergens, or physical stimuli. Angioedema is a hypersensitivity reaction that occurs below the dermis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Cytologic analysis of a fine-needle aspirate, impression smear, scrape, or swab sample from a mass may provide a tentative or sometimes a definitive diagnosis; histopathologic evaluation of an incisional or excisional biopsy may be necessary for final diagnosis.

DIFFERENTIAL DIAGNOSIS

- Neoplasm:
  - Benign
  - Malignant:
    - Epithelial
    - Glandular
    - Mesenchymal
    - Round cell
- Pseudoneoplasm:
  - Cyst
  - (Pyo)granuloma
  - Keratoses
  - Hamartoma/nevus
  - Acral lick dermatitis
  - Feline plasma cell pododermatitis or stomatitis
  - Calcinosis cutis
  - Calcinosis circumscripta
  - Canine juvenile cellulitis
  - Nodular sterile panniculitis
  - Idiopathic lichenoid dermatitis (coalescent plaques)
  - Idiopathic focal mucinosis (Doberman pinschers)
  - Eosinophilic lesions:
    - Eosinophilic plaque
    - Indolent ulcer
    - Collagenolytic granuloma
- Hematoma

- Abscess
- Urticaria
- Angioedema
- Normal structures:
  - Lymph node
  - Salivary gland
  - Bulbus glandis (transient preputial “mass” in male dogs)

INITIAL DATABASE

- Confirm that the mass is not a normal structure (anatomic location).
- Cytologic examination of samples obtained from a mass via fine-needle aspiration, impression smear, scrape, or swab may provide a diagnosis.
- Fine-needle aspiration cytologic evaluation of a local lymph node may help discern an inflammatory reaction from metastasis.
- Examination for evidence of distant metastasis via three-view thoracic radiographs and/or abdominal ultrasound
- Preoperative blood work (e.g., CBC, serum biochemical profile, urinalysis, depending on the age of the patient) if a biopsy is planned

ADVANCED OR CONFIRMATORY TESTING

Histopathologic evaluation +/− bacterial and fungal culture of an incisional or excisional biopsy sample generally is necessary for a definitive diagnosis.

TREATMENT 

TREATMENT OVERVIEW

Eliminating the mass via surgery and/or medical management is ideal if possible; however, known benign neoplasms or pseudoneoplasms may not require treatment if they are not causing harm to the patient.

ACUTE AND CHRONIC TREATMENT

- Many cutaneous or subcutaneous masses can be successfully removed surgically and possibly cured if not malignant.
- Drainage and antibacterial therapy based on culture and sensitivity information is recommended for most abscesses.
- Medical therapy without surgical removal may be appropriate in cases of eosinophilic lesions, urticaria and angioedema, dermatophytic pseudomycetoma, hematomas, and some round cell tumors.

PROGNOSIS AND OUTCOME 

- Depends on the diagnosis
- Many benign growths can be cured with complete surgical removal or appropriate medical therapy.
- Therapy for malignant neoplasms rarely results in a cure, but long remissions can be obtained in many cases.

PEARLS & CONSIDERATIONS 

COMMENTS

- Cytologic examination of a sample obtained by fine-needle aspiration from a cutaneous or subcutaneous mass is a simple and inexpensive diagnostic aid that should be recommended in most cases.
- Establishing a diagnosis via physical examination alone and treating with clinical neglect can lead to inappropriate patient outcomes.

Mass, Splenic

BASIC INFORMATION

DEFINITION

Diffuse nodular or focal enlargement of the spleen

EPIDEMIOLOGY

GENETICS & BREED PREDISPOSITION

- Large- to giant-breed, geriatric dogs: German shepherds, great Danes, retrievers
- Cats: splenic lesions are less common and when present usually consist of diffuse splenomegaly (see p. 1428).

ASSOCIATED CONDITIONS & DISORDERS

- Anemia
- Hemoabdomen
- Disseminated intravascular coagulation (DIC)
- Metastasis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Diffuse, nodular splenic enlargement (multiple masses)
- Focal splenic enlargement (single mass)

HISTORY, CHIEF COMPLAINT

- Incidental finding (no clinical signs)
- Nonspecific signs: inappetence, lethargy, weight loss, vomiting, diarrhea, discolored urine (hemoglobinuria due to hemolysis)
- Abdominal enlargement
- Weakness, collapse

PHYSICAL EXAM FINDINGS: Variable, depending on etiology of splenic mass:

- Abdominal distension:
  - Fluid (palpable fluid wave possible)
  - Mass
- Pale mucous membranes, poor or nonpalpable pulses, weakness, tachycardia and tachypnea:
  - Acute blood loss despite normal coagulation (e.g., mass rupture)
  - Bleeding/coagulation disorder
- Nonspecific findings:
  - Fever, dehydration
- Associated findings depending on etiology
  - Peripheral lymphadenopathy
  - Neoplasia elsewhere

ETIOLOGY AND PATHOPHYSIOLOGY

- Diffuse, nodular splenic enlargement (multiple masses):
  - Diffuse neoplasia (e.g., lymphoma, mast cell neoplasia)
  - Metastatic neoplasia (hemangiosarcoma, mast cell neoplasia)
- Focal splenic enlargement (single mass): hematoma, neoplasia (benign [e.g., hemangioma] or malignant [e.g., hemangiosarcoma, soft-tissue sarcoma])

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis may be suspected from signalment, history, and physical examination findings alone. Confirmation requires further diagnostic testing, notably diagnostic imaging, to determine that the mass is splenic in origin and define the underlying etiology.

DIFFERENTIAL DIAGNOSIS

Mass arising from/involving another abdominal organ:

- Liver (diffuse hepatomegaly, neoplasia [benign [e.g., hepatocellular adenoma] or malignant [e.g., hepatocellular carcinoma, hemangiosarcoma])
- Kidney
  - Neoplasia (renal adenocarcinoma, lymphoma, hemangiosarcoma)
  - Hydronephrosis
  - Cyst/polycystic renal disease
  - Perirenal pseudocyst
- Stomach: gastric dilatation/volvulus
- Abdominal cavity: omental mass
- Paraprostatic cyst

INITIAL DATABASE

Some, all, or none of these abnormalities may be present, depending on the case:

- CBC, serum biochemistry profile, urinalysis:
  - Hemorrhage (regenerative anemia, mild panhypoproteinemia)
  - Mass-associated hemolysis (schistocytosis)
  - Paraneoplastic immune-mediated hemolytic anemia (anemia, spherocytosis)
  - Involvement of other organ systems
- Survey abdominal radiographs:
  - Determine if mass appears to be arising from spleen
  - Evidence of other intraabdominal disease
  - Lymphadenopathy
- Survey thoracic radiographs:
  - Metastatic disease
  - Lymphadenopathy

ADVANCED OR CONFIRMATORY TESTING

- Ultrasound examination:
  - Confirmation of origin of mass
  - Involvement of other organs
  - Metastatic disease
  - Identification of free abdominal fluid for centesis
- Coagulation profile:
  - Hemangiosarcoma potentially can be associated with coagulation dis-orders
  - Prothrombin time, partial thromboplastin time, platelet count, antithrombin lll, fibrin degradation products, D-dimer
- Electrocardiogram (ECG):
  - Ventricular arrhythmias possible; other arrhythmias occasionally:
    - Common in dogs with splenic hemangiosarcoma
- Fine-needle aspiration cytologic analysis/needle biopsy (ultrasound guided); often contraindicated if splenic mass is highly vascular (poor diagnostic yield, and risk of rupture):
  - Benign versus malignant disease
  - Type of malignancy:
    - Primary versus metastatic
  - May be a low-yield procedure with certain malignancies (hemangiosarcoma):
    - May only obtain blood
    - Miss focus of neoplastic cells
  - Concern about seeding tumor cells throughout abdominal cavity
- Echocardiography:
  - Rule out presence of cardiac hemangiosarcoma

TREATMENT

TREATMENT OVERVIEW

Treatment of a splenic mass depends upon the etiology of the mass (surgical or nonsurgical) and whether the mass has ruptured and is causing potentially fatal intraabdominal hemorrhage (splenic hemangiosarcoma, others), requiring intensive care and immediate intervention.

ACUTE GENERAL TREATMENT

Dependent upon etiology of splenic mass:

- Nonsurgically treated splenic masses:
  - Neoplasia; lymphoma, mast cell neoplasia (dog ± cat): chemotherapy
  - Diffuse metastatic disease; hemangiosarcoma: palliative, nonsurgical treatment
- Surgically treated splenic masses (splenectomy with histopathologic examination of excised spleen):
  - Benign disease (hematoma, hemangioma)
  - Malignant disease without widespread metastasis (hemangioma, soft-tissue sarcoma)
  - Malignant disease with evidence of metastasis, as part of multimodality treatment plan: mast cell neoplasia (cat)
- Prior to splenectomy, if acute intraabdominal hemorrhage has occurred:
  - Support cardiovascular system by replacing intravascular volume and reestablishing peripheral tissue perfusion, replacing blood loss if significant, and maintaining a perfusing cardiac rhythm.
  - Definitive surgical therapy is recommended as soon after stabilization as possible.
  - Abdominal wrap/gentle abdominal pressure bandage to reduce rate of bleeding if surgery is delayed; ensure ventilation is not compromised.
- Treat any coagulation disorder:
  - Fresh frozen plasma
  - Fresh whole blood
- Correct or control cardiac arrhythmias such as premature ventricular complexes and ventricular tachycardia (see p. 1165):
  - In an anemic or hypokalemic patient, correction of these problems often resolves the ventricular arrhythmia without antiarrhythmic drugs.
  - Lidocaine:
    - 2-4 mg/kg, intravenous bolus
    - 50 mcg/kg/min continuous rate IV infusion

CHRONIC TREATMENT

- Continued supportive care in the postoperative period:
  - Intravenous fluid therapy
  - Transfusion therapy (see p. 1347)
  - Treatment of cardiac arrhythmias
- Long-term treatment dependent upon etiology of splenic mass:
  - Chemotherapy for certain types of neoplasia (lymphoma, mast cell neoplasia, hemangiosarcoma without gross metastatic disease)

DRUG INTERACTIONS

- Avoid thiobarbiturates as part of anesthetic protocol:
  - Cause relaxation of smooth muscle of the splenic capsule (red blood cell sequestration causing splenic congestions +/- increasing difficulty of removal of spleen, quantity of blood removed from patient [in spleen])
  - Potentially contraindicated if preexisting ventricular arrhythmias exist. Thiopental causes arrhythmias in approximately 40% of dogs.
- Avoid acepromazine or other phenothiazine tranquilizers as part of anesthetic protocol:
  - Cause hypotension via central mechanisms and through alpha-adrenergic actions
  - May cause cardiovascular collapse secondary to bradycardia and hypotension

POSSIBLE COMPLICATIONS

- Associated with preoperative rupture of the splenic mass:
  - Hypotension
  - Hemorrhagic/hypovolemic shock
  - Cardiovascular collapse and death

- Associated with splenectomy:
  - Hemorrhage
  - Coagulation disorders
  - Sepsis:
    - Loss of white blood cell reservoir
    - Loss of phagocytic function of spleen
- Anemia:
  - Loss of RBC reservoir
  - Decreased hematopoiesis
  - Altered iron metabolism
- Diminished immune function
- Portal vein thrombosis
  - Uncommon
- Acute onset of shock often fatal due to intestinal ischemia
- Pancreatitis:
  - Inadvertent ligation of pancreatic branch of splenic artery and vein
  - Traumatic handling or retraction of pancreas during splenectomy

RECOMMENDED MONITORING

- Postoperative patient monitoring
- Detection of ongoing hemorrhage:
  - Packed cell volume (PCV), CBC
- Maintenance of normovolemia and tissue perfusion:
  - PCV, total solids
  - Urine output
  - Blood pressure
- Continuation/development of cardiac arrhythmias (ventricular premature complexes):
  - ECG monitoring
  - Appropriate treatment, if indicated
  - See Acute General Treatment above.
- Long-term monitoring dependent upon etiology of splenic mass; may include:
  - Repeat radiographs and ultrasound examination to detect recurrence of malignancy/development of metastasis
  - Monitoring associated with adjuvant chemotherapy:
    - Periodic blood tests
    - Echocardiogram

PROGNOSIS AND OUTCOME

Dependent upon etiology of splenic mass:

- Hemangiosarcoma in dogs:
  - Most common malignant splenic neoplasm
  - Median survival time post splenectomy ranges from 10-23 weeks.
- Postsplenectomy survival times:
  - 2-month survival times: 83% if non-neoplastic disease, 31% if hemangiosarcoma
  - 12-month survival times: 64% if non-neoplastic disease, 7% if neoplastic
  - Cats with systemic mastocytosis that undergo splenectomy often have extended survival times and may be cured.
- Preoperatively, dogs with anemia, nucleated RBC, abnormal RBC morphology, or splenic rupture are more likely to have malignant splenic neoplasia. NOTE: These findings should not lead to the definitive conclusion that the splenic mass is due to malignant neoplasia.

PEARLS & CONSIDERATIONS

COMMENTS

- In the dog, a splenic mass may be a non-neoplastic (hematoma) or benign (hemangioma) or malignant (hemangiosarcoma) neoplasm. A single biopsy may result in a false-negative diagnosis. Therefore, the *entire* spleen should always be submitted for histopathologic examination.
- It can be difficult to differentiate splenic masses by their gross appearance. Therefore, a diagnosis is always based on histopathologic examination, not on gross appearance.

    - Over 50% of dogs have malignant disease, and over 40% have benign disease.
- An echocardiogram is recommended prior to splenectomy to rule out presence of primary cardiac hemangiosarcoma. The splenic hemangiosarcoma may represent metastatic disease.

CLIENT EDUCATION

- Splenic masses may rupture and cause lethal intraabdominal hemorrhage.
- Over 50% of splenic masses in the dog are malignant neoplasms.
    - Splenectomy does not extend survival time with regard to the malignancy.
    - Splenectomy prevents exsanguinations.
    - Splenectomy improves the quality of life for the patient.

Mass, Pancreatic

BASIC INFORMATION

DEFINITION

Mass visualized in the pancreas via ultrasonography or during exploratory celiotomy; very rarely identified as an incidental finding on abdominal palpation

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs:

- Masses associated with pancreatitis: older intact or spayed females are overrepresented.
- Endocrine pancreatic neoplasia: middle-aged to older dogs are overrepresented.

Cats:

- Exocrine pancreatic neoplasia: middle-aged to older cats

RISK FACTORS: Dogs: pancreatitis-associated masses from a high-fat diet

ASSOCIATED CONDITIONS & DISORDERS: Dogs:

- Pancreatitis-associated masses:
  - Hyperadrenocorticism
  - Diabetes mellitus
  - Hyperlipidemia
  - Biliary obstruction secondary to the mass
- Exocrine pancreatic neoplasia:
  - Biliary obstruction
  - Paraneoplastic alopecia or pan-niculitis
- Endocrine pancreatic mass:
  - Insulinoma: hypoglycemia: weakness, collapse, possibly seizures
  - Gastrinoma: gastric ulceration, vomiting, melena, anemia

Cats:

- Exocrine pancreatic neoplasia:
  - Biliary obstruction
  - Paraneoplastic alopecia
- Endocrine pancreatic mass
  - Gastrinoma (rare): gastric ulceration, vomiting, melena, anemia, lethargy

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Dogs:

- Associated with pancreatitis:
  - Inflammatory/necrotic mass
  - Abscess
  - Pseudocyst
- Nodular hyperplasia
- Neoplasia (primary pancreatic): exocrine (adenocarcinoma) or endocrine (e.g., insulinoma, rarely gastrinoma)
- Metastatic or local extension of another primary neoplasm
- Icterus secondary to biliary obstruction

Cats:

- Associated with pancreatitis

- Exocrine neoplasia
- Icterus secondary to biliary obstruction
- Endocrine neoplasia (i.e., insulinoma, gastrinoma): extremely rare

HISTORY, CHIEF COMPLAINT

- Pancreatitis: vomiting, anorexia, lethargy, inappetence, diarrhea
- Exocrine neoplasia: similar but may include weight loss
- Secondary biliary obstruction: similar; some owners may also note icterus
- Endocrine neoplasia:
  - Insulinoma: weakness, lethargy, altered neurologic state
  - Gastrinoma (rare): vomiting, melena, anemia, lethargy

PHYSICAL EXAM FINDINGS

- Mass may be palpable.
- Otherwise, variable depending on etiology of pancreatic mass:
  - Pancreatitis, exocrine pancreatic neoplasia
    - Abdominal pain, dehydration, icterus, palpable abdominal mass, pyrexia
  - Endocrine pancreatic neoplasia
    - Neurologic findings associated with hypoglycemia

ETIOLOGY AND PATHOPHYSIOLOGY

- Pancreatitis (see p. 817 and 820)
- Exocrine pancreatic neoplasia: etiology unknown
- Secondary biliary obstruction: lack of bile secretion into the intestine results in a lack of digestion and absorption of fat and fat-soluble vitamins, most importantly vitamin K; development of significant coagulopathy.
- Endocrine pancreatic neoplasia: inappropriate, excessive insulin secretion leads to persistent, profound hypoglycemia (see p. 613and online chapter: Gastrointestinal Endocrine Disease).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Presenting history and physical examination findings are often nonspecific, so diagnosis is based on results from the initial database and particularly on diagnostic imaging.

DIFFERENTIAL DIAGNOSIS

- Pancreatitis: inflammation, necrosis, abscess, pseudocyst, fibrosis
- Exocrine neoplasm: adenocarcinoma
- Metastasis of another primary neoplasm to the pancreas: gastric or duodenal adenocarcinoma, leiomyosarcoma, lymphoma

INITIAL DATABASE

- CBC: inflammatory leukogram with or without evidence of inflammation (e.g., with pancreatitis): left shift, toxic neutrophil changes
- Serum biochemistry profile, urinalysis: reflect underlying disorder
  - Elevated amylase, lipase, ± bilirubin, ± liver enzyme concentrations: pancreatitis
  - Hypoglycemia: insulinoma
  - Hyperbilirubinemia, bilirubinuria: secondary biliary obstruction
- Survey abdominal radiographs:
  - Mass effect in region of pancreas: may displace duodenum laterally, pylorus cranially
  - Possible increased radiopacity in area of pancreas (pancreatitis)
  - Diffuse granular appearance to abdomen: carcinomatosis
- Survey thoracic radiographs: help rule out metastatic disease if neoplasia suspected

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound examination:
  - Pancreas, morphology/echogenicity of mass:

        - Generalized inflammation of pancreas and surrounding structures: pancreatitis
        - Fluid-filled mass: pancreatic abscess (mixed echogenicity common), cyst (contents generally anechoic)
        - Solid mass (head of pancreas): exocrine neoplasia
        - Small, isolated, well-defined mass: insulinoma (hepatic metastases commonly present at time of diagnosis)
    - Evaluation of adjacent organs:
        - Extension of pancreatic disease into duodenum:
            - Inflammation
            - Neoplasia
        - Extension of duodenal disease into pancreas:
            - Neoplasia
        - Evidence of metastatic disease:
            - Regional lymph nodes
            - Liver
            - Carcinomatosis (ascites usually is also present)
    - Evidence of secondary biliary obstruction; any mass when sufficiently large:
        - Common bile duct dilation
    - Possible ultrasound-guided fine-needle aspiration (cytologic examination) or needle biopsy of pan-creatic mass:
        - Possible metastatic sites:
            - Regional lymph nodes
            - Liver
    - Suspected insulinoma:
        - Simultaneous measurement of fasting blood glucose and serum insulin concentrations, (see p. 613and p. 444).

TREATMENT

TREATMENT OVERVIEW

Treatment of this problem depends on the etiology of the pancreatic mass and typically includes intensive supportive care, surgical correction and/or nutritional support.

ACUTE GENERAL TREATMENT

Dependent on etiology of pancreatic mass but may include:

- Rehydration by IV administration of balanced electrolyte solution and possibly colloid solutions:
    - Correction of fluid deficits
    - Normalization of serum electrolyte concentrations
- Possible administration of fresh frozen plasma (see p. 1347):
    - Hypoproteinemia
    - Possible coagulopathy
- Treat hypoglycemia if present:
    - Addition of dextrose (5%) to IV fluids
    - Change of diet and feeding schedule
    - Corticosteroids
- Vitamin K administration if biliary obstruction (vitamin K1 2.5-5 mg/kg SQ or IM q 12 h for 3 days, then once weekly until obstruction relieved)
- Exploratory laparotomy:
    - Identifying pancreatic mass and extent of intraabdominal disease
    - Removing mass or performing biopsy
    - Draining and omentalizing pancreatic abscess if present
    - Performing biopsy of possible metastatic lesions
    - Correcting biliary obstruction
    - Placing feeding tube for nutritional support

NUTRITION/DIET

Animal that has pancreatitis: in patients that have undergone extensive pancreatic/duodenal resections, parenteral and enteral nutritional support should be provided postoperatively (see p. 1322and p. 1273).

POSSIBLE COMPLICATIONS

- Ongoing or recurrent pancreatitis

- latrogenically induced pancreatitis
- Persistent hypoglycemia: incomplete removal of primary tumor or functioning metastatic lesions

RECOMMENDED MONITORING

- Dependent on etiology of pancreatic mass but may include:
  - CBC and serum biochemistry profile
  - Blood glucose concentrations
  - Serum amylase and lipase concentrations
- Repeat abdominal ultrasound examination for chronological assessment:
  - Resolution or progression of pancreatic disease
  - Regrowth of pancreatic neoplasm
  - Development of metastatic disease

PROGNOSIS AND OUTCOME 

- Fair to guarded in animals with pancreatitis with or without secondary development of abscesses
- Poor in animals with malignant exocrine pancreatic neoplasia (adenocarcinoma)
- Insulinoma:
  - Persistent hypoglycemia or inability to completely resect all neoplastic disease indicates a poor prognosis.
  - Resolution of hypoglycemia or complete resection of neoplastic disease indicates a good prognosis.

EDITOR: RICHARD WALSHAW

Mass, Abdominal

BASIC INFORMATION

DEFINITION

An abnormal confluence or collection of inflammatory cells, infectious organisms, or neoplastic cells within the abdominal cavity

EPIDEMIOLOGY

SPECIES, AGE, SEX: Any; based on the origin of the mass

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Variable, from overt illness to incidental discovery on routine exam
- Dependent on organ system affected and systemic involvement

PHYSICAL EXAM FINDINGS

- Specific abdominal findings may include distension, pain, palpable mass, free fluid/ballotable (fluid-wave) ascites.
- All dogs with abdominal masses require a digital rectal examination (see p. 1333).

ETIOLOGY AND PATHOPHYSIOLOGY

Variable, depending on organ system affected and systemic involvement

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on physical examination findings. Due to the extensive list of rule-outs for this problem, confirmation of the underlying etiology of the mass requires diagnostic imaging and diagnostic sampling of specimens in virtually all cases.

DIFFERENTIAL DIAGNOSIS

Common differential diagnoses for abdominal masses include:

- Spleen: malignant neoplasia (hemangiosarcoma, fibrosarcoma, chondrosarcoma, lymphoma, mastocytosis), benign neoplasia (hemangioma, lipoma), splenic abscess, splenic torsion, hematoma, splenic congestion secondary to drug administration or other toxins, mastocytosis, autoimmune disease, systemic infection/ inflammation, normal folded spleen
- Liver: malignant neoplasia (hepatocellular carcinoma, lymphoma, hemangiosarcoma, mastocytosis, etc.), benign neoplasia (biliary [cyst]adenoma, lipoma, etc.), abscess, hematoma (trauma), chronic passive congestion, regenerative nodular hyperplasia
- Lymphadenopathy: reactive versus infiltrated
- Gastrointestinal tract: malignant neoplasia (leiomyosarcoma, adenocarcinoma, etc.), benign neoplasia (adenoma, leiomyoma, etc.), foreign body, intestinal volvulus, trichobezoar, ileus, gastric dilation-volvulus, fecal material
- Granuloma: secondary to foreign body reaction (retained suture material or gauze), infectious organisms such as protozoa or fungi
- Pancreas: abscess, hemorrhagic pancreatitis, phlegmon
- Uterus: uterine torsion, pyometra, mucometra/hydrometra, pregnancy.
- Ovary: cyst, neoplasia (papillary adenoma/adenocarcinoma, granulosa cell tumor, etc.)
- Prostate: benign prostatic hypertrophy, prostatitis, prostatic abscess, prostatic cyst, paraprostatic cyst
- Testicles: neoplasm of cryptorchid testicle, torsion of cryptorchid testicle
- Urinary bladder: malignant neoplasia (transitional cell carcinoma, others), cystitis, urolith
- Kidney: malignant neoplasia (renal cell carcinoma, lymphoma, hemangiosarcoma, etc.), benign neoplasia, polycystic renal

disease, toxin ingestion (ethylene glycol), pyelonephritis, hydronephrosis, perirenal pseudocysts
- Adrenal glands: malignant or benign neoplasia (adenocarcinoma, lymphoma; adenoma)
- Peritoneal cavity and mesentery: cyst, malignant neoplasia (carcinomatosis, mesothelioma), benign neoplasia (lipoma, other)

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: results depend on underlying cause.
  - Avoid cystocentesis if ascites, caudal abdominal mass, or evidence of bleeding disorder.
- Urine culture and sensitivity: if involvement of urinary tract
- Survey abdominal radiographs:
  - Complementary to ultrasound; may be superior if mass is extremely large or if vertebral involvement is possible
- Abdominal ultrasound helps determine:
  - Origin of the mass
  - Texture and vascularity of the mass (fine-needle aspirate/core biopsy possible?)
  - Invasiveness of the mass/amenability to surgical removal
  - Presence of free fluid for aspiration and cytologic analysis
  - Presence of visible lesions consistent with metastasis

ADVANCED OR CONFIRMATORY TESTING

- Contrast radiographic studies of urogenital tract
- Nuclear scintigraphy (liver, renal)
- CT, MRI
- Abdominal exploratory celiotomy and tissue sampling for histopathologic examination

TREATMENT

TREATMENT OVERVIEW

Remove mass if possible.

- Rationale: pathologic discrete abdominal masses often produce one or more of the following sequelae:
  - Localized or systemic infection
  - Signs of pain or organ dysfunction (mechanical compression; see p. 4)
  - Ongoing growth and potential for metastasis or local invasion
  - Death from hemorrhage, metastasis, infection/sepsis, shock, or organ failure

ACUTE GENERAL TREATMENT

- Variable, depending on the origin of the mass
- The usual treatment of choice for pathologic discrete abdominal masses is medical stabilization of the patient (if necessary) followed by surgical removal.

CHRONIC TREATMENT

- Variable, depending on the origin of the mass
- Adjunct therapy including intravenous fluid therapy, blood products (see p. 1347), nutritional supplementation, chemotherapy, or antimicrobial medication administration may be indicated, depending on origin of mass and final histopathologic diagnosis.

POSSIBLE COMPLICATIONS

- Recurrence of infection or neoplasia
- Metastasis
- Hemorrhage
- Shock
- Weight loss, anorexia
- Peritonitis

RECOMMENDED MONITORING

Variable, depending on source of abdominal mass

PROGNOSIS AND OUTCOME

Variable, depending on source of abdominal mass

PEARLS & CONSIDERATIONS

COMMENTS

- Some normal processes (folded spleen, pregnancy) cause an abdominal mass effect and must be ruled out before proceeding to treatment.
- Some masses (including very large ones) are benign (e.g., intraabdominal lipoma), and therefore the presence of a mass does not by itself confer any particular prognosis.
- Abdominal masses may be suspected as being pathologic via careful abdominal palpation and abdominal ultrasound and, if so, are definitively diagnosed by surgical exploration and histopathologic examination.
- Nonresectable discrete masses may be treated with alternative therapies depending on the diagnosis; however, prognosis is generally poorer for a patient with a nonresectable mass.

PREVENTION

Variable, depending on the origin of the mass

CLIENT EDUCATION

- Tests including laboratory evaluation, imaging, and biopsy are necessary in most cases for definitive assessment of an abdominal mass.
- Definitive treatment and outcome for a patient with an abdominal mass are dependent on the origin of the mass, whether the mass is resectable, and if the mass is causing any systemic effects.

Marijuana Toxicosis

BASIC INFORMATION

DEFINITION

Common toxicosis resulting from ingestion of *Cannabis sativa* and characterized by any of the following signs: central nervous system (CNS) depression, ataxia, vomiting, hypothermia, urinary incontinence, bradycardia, hyperreflexia, possibly coma and seizures.

SYNONYMS

Common street names: *Cannabis sativa,* grass, hashish, hemp (not to be confused with textile hemp, which is THC-deficient), marijuana, Mary Jane, pot, reefer, THC

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most commonly exposed animals: dogs (96%), cats (3%), other species (1%)
- Dogs exposed are commonly under the age of 5 years.

ASSOCIATED CONDITIONS AND DISORDERS: In humans with a history of seizures, use of marijuana has been associated with lowering the seizure threshold.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of exposure to marijuana
- Ataxia, CNS depression, tremors, vomiting within 15 to 30 minutes of ingestion
- Specific history of exposure may be withheld by owner, owing to illicit nature of marijuana.

PHYSICAL EXAM FINDINGS

- Common:
  - Bradycardia
  - Hypothermia (body temperature: 98○F-99○F [36.7○C-37.2○C])
  - Mydriasis
  - Vomiting
  - Urinary incontinence/dribbling
  - Weakness, ataxia
- Possible:
  - Hyperesthesia
  - Hypersalivation
  - Recumbency
  - Tachycardia
  - Tremors
  - Coma

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- *Marijuana* refers to a mixture of cut and dried flowers, leaves, and stems of the leafy green hemp plant, *Cannabis sativa.* It grows in warm, moist climates or is grown artificially indoors (greenhouses) and can be rolled into cigarettes or in some cases baked into food, especially brownies.
- Exposure to marijuana in pet animals is mostly accidental, but occasionally is intentional or malicious. Sometimes drug-detection dogs ingest large amounts of marijuana accidentally.

- Marijuana is a Schedule I controlled substance commonly used as an illicit recreational drug.
- It is also used for treating nausea for chemotherapy patients and to decrease intraocular pressure in glaucoma patients. A synthetic THC is available under the trade names Marinol and Cesamet for treatment of these conditions.

Mechanism of toxicosis:

- The predominant psychoactive portion of marijuana is Δ-9-tetrahydrocannabinol (THC). THC is believed to act on a unique receptor in the brain that is selective for cannabinoids and is primarily responsible for CNS effects (ataxia and depression).
- Cannabinoids also enhance CNS formation of norepinephrine, dopamine, and serotonin and stimulate release of dopamine and enhance γ-aminobutyric acid (GABA) turnover.
- When taken orally, THC goes through substantial initial hepatic metabolism (first-pass effect). It is highly lipophilic and distributes to brain and other fatty tissues after absorption.
- Clinical signs in dogs may last 24-96 hours.
- Oral LD^{50} of THC in rats = 666 mg/kg, mice = 482 mg/kg. Clinical effects of marijuana are seen at much lower doses than this.
- Concentration of THC in marijuana varies between 1% and 8%.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Intoxication is typically suspected in one of two contexts: history of known or suspected ingestion provided by the owner or presence of typical clinical signs without such a history, as some clients may be reluctant to admit exposure or may not be aware that the agent is in their house. Exposure can be confirmed with a more thorough medical history or via a positive result when the pet's urine is evaluated with an over-the-counter illicit drug test kit. A low rate of life-threatening intoxications means a test kit may be obtained at some point during the first few hours of treatment/observation if definitive confirmation is needed (e.g., uncertain history).

DIFFERENTIAL DIAGNOSIS

Toxicologic:

- Ethylene glycol toxicosis
- Macadamia nut toxicosis
- Ivermectin toxicosis
- Other CNS depressants such as benzodiazepines, barbiturates

Spontaneous, Nontoxicologic:

Overall, the onset of clinical signs can mimic metabolic or toxic CNS disorders, but acute decompensation of primary CNS diseases (e.g., granulomatous meningoencephalitis, neoplasia, others) is possible, especially in an animal that is not closely observed by its owner. A sudden onset of signs, with near-complete resolution and no recurrence all within 24 hours, makes intoxication much more likely than these nontoxicologic diagnoses.

INITIAL DATABASE

- Arterial blood pressure (normal or below normal; normal [systolic] >120 mm Hg in clinical setting)
- CBC, serum biochemistry panel, urinalysis (to assess for preexisting conditions): no significant changes expected

ADVANCED OR CONFIRMATORY TESTING

- Over-the-counter illicit drug test kits (urine) may help confirm exposure during the early course of exposure. Caution: such kits have not been validated in dogs, and some do not appear to be accurate; a negative result does not preclude exposure.
- Rapid analysis at human hospital labs is also an option for confirmation.

TREATMENT

TREATMENT OVERVIEW

Treatment goals are early decontamination (induction of emesis and administration of activated charcoal) of the patient, correcting hypothermia, and providing supportive care. In a patient showing no clinical signs and presenting more than 1 hour after possible

ingestion, treating with activated charcoal only and monitoring for onset of signs, without further treatment if no signs emerge, is acceptable.

ACUTE GENERAL TREATMENT

- Decontamination of the patient:
  - Emesis: can be induced within 15-30 minutes of exposure as long as no overt clinical signs of toxicosis are present. Use hydrogen peroxide at 2.2 mL/kg PO; max 45 mL. Repeat once if emesis does not occur first time.
  - Apomorphine: not likely to work as an emetic because of the strong central antiemetic effect of marijuana
  - Activated charcoal: very beneficial. Indicated when emesis is absent in patients with or without clinical signs. In patients with clinical signs or large ingestions, multiple doses can be used every 8 hours to reduce enterohepatic recirculation; 1-3 g/kg or labeled dosage of commercial products. Caution: risk of hypernatremia when using repeated doses of charcoal products containing a purgative (e.g., Toxiban)
- Supportive care:
  - IV fluids as needed for dehydration, hypovolemia
  - Thermoregulation (heating pads for hypothermia)
  - Monitor cardiovascular function. Atropine, 0.022-0.044 mg/kg IM or SQ can be given for bradycardia in normotensive patients.
  - Control tremors with diazepam at a low dose of 0.25 mg/kg IV.
  - Monitor for signs of aspiration pneumonia in recumbent animals. Pass cuffed endotracheal tube if needed, ensuring a mouth gag/speculum is also used in order to avoid the patient biting and transecting the tube when recovering.
  - Control severe vomiting with metoclopramide, 0.2-0.4 mg/kg q 6 h PO, SQ, or IM; or maropitant, 1 mg/kg SQ or 2 mg/kg PO q 24 h, once ingested material has been expelled.

DRUG INTERACTIONS

Other CNS depressants (barbiturates, benzodiazepines) may exacerbate signs.

RECOMMENDED MONITORING

- Heart rate
- Blood pressure
- Body temperature

PROGNOSIS AND OUTCOME

- Excellent with treatment
- Fatalities are extremely rare.

PEARLS & CONSIDERATIONS

COMMENTS

- Until proven otherwise, a dog presenting with acute-onset ataxia, CNS depression, and urinary incontinence that improves with stimulation and then gets worse again with decreased stimulation should be considered suspect of marijuana ingestion.
- Marijuana may be mixed with other substances for smoking (e.g., phencyclidine [PCP]) which may alter the patient's signs.

TECHNICIAN TIP

Some owners may mention the possibility of this type of drug exposure in the veterinarian's absence (due to embarrassment, oversight, or fear of consequences). If the client raises the possibility with any member of the technical staff, this valuable piece of information could determine the course of treatment and the patient's outcome and therefore should be mentioned to the attending veterinarian.

Mammary Gland Neoplasia, Dog

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Mammary gland tumors are benign or malignant neoplasms arising from mammary tissue.

SYNONYMS

Mammary cancer, breast cancer Benign mammary tumors:

- Adenoma/cystadenoma (very common)
- Benign mixed mammary tumor (very common)
- Fibroadenoma (uncommon)

Malignant mammary tumors:

- Adenocarcinoma/cystadenocarcinoma (common)
- Carcinoma (common)
- Inflammatory carcinoma (uncommon)
- Malignant mixed mammary tumor (uncommon)
- Carcinosarcoma (rare)
- Sarcoma (uncommon)

Note: Different pathologic classification schemes exist.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Mammary gland tumors are the most common tumor in female dogs, according to some surveys.
  - Incidence ~ 2:1000.
  - Due to the common practice of early-age ovariohysterectomy (OHE), the incidence has decreased in the United States. In European countries, mammary tumors represent 40%-50% of all tumors in female dogs.
- Greater prevalence with older age; median age 10-11 years
- Mammary gland tumors in male dogs are uncommon (approximately 1% of mammary tumors occur in males).

GENETICS & BREED PREDISPOSITION

- Breeds at increased risk include:
  - Spaniel breeds
  - Pointer breeds
  - Poodles
  - Dachshunds
  - German shepherds
  - Yorkshire terriers
- A genetic factor in the development of mammary tumors seems to be present; however, a specific, common mutation has not been identified. The following genes have been found to be mutated in select canine mammary gland tumors:
  - p53
  - c-erb-2 (Her-2/neu)
  - BCRA 1, 2

RISK FACTORS

- Timing of OHE: the relative risk for developing mammary gland tumors:
  - 0.5% if OHE is performed before the first estrus
  - 8% if OHE is performed between the first and second estrus
  - 26% if OHE performed between the second and third estrus

- Intact females and females neutered after 2 years of age have a sevenfold greater risk of mammary neoplasia compared to those neutered before age 6 months.
- Body condition/diet: reduced risk in dogs with lean body condition at age 9-12 months
- Progesterone treatment: increases the risk for the development of benign and malignant mammary tumors.
- Pregnancy, lactation, pseudopregnancy:
  - Unlike people, pregnancy does not afford a protective effect against the development of mammary tumors in dogs.
  - Lactation and pseudopregnancy also do not seem to have an influence.

ASSOCIATED CONDITIONS & DISORDERS: Ovarian cysts, cystic endometrial hyperplasia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Clinical staging:
  - Tumor: T1, <3 cm; T2, 3-5 cm; T3, >5 cm
  - Regional lymph node: N0, no metastasis; N1, metastasis detected
  - Distant metastasis: M0, no metastasis; M1, metastasis detected
- Histologic staging:
  - 0 Without stromal invasion
  - I With stromal invasion
  - II With neoplastic emboli in vessels

Stage Grouping	T	N	M
I	T1	N0	M0
II	T2	N0	M0
III	T3	N0	M0
IV	T1-3	N1	M0
V	T1-3	N0, N1	M1

HISTORY, CHIEF COMPLAINT

- Owners may note a swelling, “lump,” or ulceration in their dog's mammary chain, or these may be incidental findings on routine physical examination.
- Duration of clinical signs is highly variable, ranging from days to months.
- In cases of metastasis or inflammatory carcinoma, dogs may be presented due to general signs of illness or specific complaints attributable to a certain site of metastasis (e.g., lameness in cases of bone metastasis).

PHYSICAL EXAM FINDINGS

- Variable depending on extent and stage of the disease
- Single or multiple nodules may be present. Multiple tumors are common in dogs, and both mammary chains may be affected. Multiple tumor types are common.
- Signs of malignancy include fixation to skin or underlying structures, rapid increase in size, ill-defined borders, ulceration, pain, inflammation or edema.
  - Absence of these signs does not exclude malignancy.
- Inflammatory carcinomas present with diffuse, firm, and painful swelling of the affected gland or chain. The adjacent extremity may be affected. Cutaneous involvement in form of small beadlike nodules may also be found.
- Regional lymph nodes (inguinal and axillary) may be enlarged (due to metastasis or reactive hyperplasia) or normal on palpation. The internal iliac, popliteal, and prescapular nodes may also be affected.

ETIOLOGY AND PATHOPHYSIOLOGY

- Estimates of malignancy rates range from 30%-50%.
- Metastasis most common to the regional lymph nodes and lungs
- Tumors are classified according to their tissue of origin into epithelial, mesenchymal, and mixed tumors.
  - Inflammatory carcinoma is not a specific histologic subtype but an aggressive high-grade carcinoma with invasion into the dermis and dermal lymphatics. The inflammatory cell infiltrate is moderate in most cases and consists of lymphocytes, plasma cells, and macro-phages.

- Primary mesenchymal mammary tumors (e.g., fibrosarcoma, osteosarcoma) are infrequent. Malignant mesenchymal mammary tumors often behave aggressively, with frequent metastasis and a short survival.
- Mixed mammary tumors consist of epithelial, myoepithelial, and mesenchymal tissue. Most mixed mammary tumors are benign. Malignant mixed mammary tumors and carcinosarcomas are rare exceptions.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the presence of a mass in the mammary chain. Histologic evaluation is required for definitive diagnosis which is usually obtained from an excisional biopsy.

DIFFERENTIAL DIAGNOSIS

- Mastitis
- Other cutaneous and subcutaneous tumors
- Inguinal/axillary lymphadenopathy (reactive, neoplastic)
- Inguinal hernia

INITIAL DATABASE

- Physical examination:
  - Measure primary tumor (T)
  - Describe possible signs of invasiveness (ulceration, fixation)
  - Evaluation of regional lymph nodes (N): palpation and cytologic study
- Thoracic radiographs (three views)
- Abdominal ultrasound in case of suspected metastasis to abdominal organs or lymph nodes
- CBC, serum biochemistry profile, urinalysis
- Coagulation profile in cases of suspected inflammatory carcinoma (risk of disseminated intravascular coagulation)

ADVANCED OR CONFIRMATORY TESTING

- Excisional biopsy of the tumor and thorough histologic examination are necessary to obtain a definitive diagnosis.
- Fine-needle aspiration cytology is *not* recommended:
  - Poor differentiation between malignant and benign mammary tumors, owing to their heterogeneous composition
- Incisional biopsy also may not represent the whole tumor and is not recommended.
- Lymph node metastasis: fine-needle aspiration and cytologic evaluation of lymph nodes has been shown to increase diagnostic accuracy of mammary tumor metastasis. Metastases may be present in palpably normal nodes.
- Advanced imaging (CT, MRI) may be more sensitive to detect metastatic lesions in the thoracic and abdominal cavities and should be considered in cases in which metastasis is strongly suspected but cannot be detected on radiographs or ultrasound.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of complete surgical removal of the mammary tumor(s). The role of chemotherapeutics to delay the onset of metastatic disease has not been well defined in dogs. For dogs with inoperable tumors or inflammatory carcinomas, palliation with piroxicam or other antiinflarnmatory medications may improve quality of life.

ACUTE GENERAL TREATMENT

- Mainstay of treatment is surgical excision of the mammary tumor(s) with wide margins (at least 2 cm in all planes if possible).
- Type of surgery (nodulectomy, regional or radical mastectomy) depends on the size, location, and number of tumors present.
  - Type of surgery does not influence survival so long as the entire tumor is removed with histologically clean margins.
- Lumpectomy possible for freely move-able tumors <5 mm but increases risk of local recunence of carcinoma.
- Simple or radical (block or unilateral chain resection) mastectomy: both increase disease-free interval.
- Unilateral radical chain mastectomy will decrease the chances of tumor development in the remaining mammary tissue. In one study, 58% of dogs that underwent a regional mastectomy for a solitary mammary tumor developed a new tumor in the ipsilateral mammary chain after the first surgery.

- Removal of inguinal lymph node with caudal gland tumors; excise axillary nodes only if metastasis is suspected.
- Inflammatory carcinoma is nonresectable; palliative surgery may be possible in select cases.

CHRONIC TREATMENT

- Chemotherapy: limited information available
  - Antitumor activity has been demonstrated in vitro, in select patients with gross metastatic disease, and as adjuvant treatment in a small group of dogs with advanced-stage disease. High-risk patients may therefore benefit from adjuvant chemotherapy.
  - Chemotherapeutics studied for monotherapy include doxorubicin (30 mg/m^2 IV), 5-fluorouracil (150 mg/m^2 IV), cyclophosphamide (200 mg/m^2 IV), and platinum compounds (cisplatin, 50-70 mg/m^2 IV plus saline diuresis; carboplatin, 250-350 mg/m^2 IV). Special handling requirements and potentially severe, life-threatening adverse patient effects exist for these drugs.
  - Consultation with an oncologist for the most current treatment recommendations is indicated.
- OHE at time of mammary tumor surgery: benefit is controversial, with some studies reporting increased survival and others showing no difference.
- Radiation therapy: limited information available. May be of use in the palliative setting or to improve local control in inoperable cases.
- Antiestrogen therapy (tamoxifen): not recommended. Most anaplastic mammary tumors lack estrogen receptors, so antiestrogen therapy may not be beneficial for most cases in which systemic therapy is indicated. In addition, estrogen-like side effects including vulvar swelling, vaginal discharge, stump pyometra, signs of estrus, and urinary tract infection may occur in dogs treated with antiestrogen drugs.
- Pain medication: analgesics should be considered in the palliative treatment of advanced stage disease or inflammatory carcinoma. Options include nonsteroidal antiinflammatories (including carprofen, 2 mg/kg PO q 12 h; or etodolac, 10-15 mg/kg PO q 24 h; or deracoxib, 1-2 mg/kg PO q 24 h; or meloxicam, 0.1 mg/kg PO q 24 h; or piroxicam, 0.3 mg/kg q 24 h).

POSSIBLE COMPLICATIONS

See Chemotherapy: Adverse Reactions, p. 188.

RECOMMENDED MONITORING

Regular examination of surgical site and local lymph nodes: radiology or other imaging techniques if indicated (e.g., diagnosis of malignancy, respiratory signs, other signs suggestive of internal metastasis)

PROGNOSIS AND OUTCOME

- Dogs with benign mammary tumors are cured by surgical excision so long as histologically clean margins are achieved.
- Prognosis for dogs with malignant mammary gland tumors is extremely variable and ranges from a cure with surgery (especially low-grade malignancy) to rapid recurrence and metastasis within the first year after surgical excision. Prognostic factors include:
  - Tumor size: tumors <3 cm have a better prognosis than tumors >3 cm.
  - Tumor histologic characteristics
    - Epithelial tumors (adenocarcinomas, cystadenocarcinomas. carcinomas) may have a better prognosis than sarcomas, malignant mixed tumors, and carcinosarcoma. Median survival = 6.5 months (solid carcinoma), 12 months (invasive tumor), 29 months (noninvasive tumor), 10 months (sarcoma), 18 months (carcinosarcoma).
    - Inflammatory carcinomas have a grave prognosis.
    - Anaplastic and high-grade, invasive tumors with stromal or lymphatic or vascular infiltration carry a worse prognosis than well-differentiated low-grade or noninvasive lesions.
  - Clinical stage: a worse prognosis is associated with:
    - Large tumors (stages II-V)
    - Lymph node involvement (stages IV-V)
    - Distant metastasis (stage V)
- Disease-free interval of 24 months for malignant tumors = 27%-55%.

PEARLS & CONSIDERATIONS

COMMENTS

- Canine mammary tumors represent a heterogeneous group of tumors with different prognoses.

- Multicentric mammary tumors occur in >50% of affected dogs; multiple tumor types occurring concunently or sequentially are common.
- Highest-risk patients that will benefit most from postoperative adjuvant chemotherapy still need to be identified. These may include patients with advanced clinical stages (II-V), histologic evidence of vascular/lymphatic invasion, and/or high degree of anaplasia on histopathologic evaluation.
- The benefit of OHE at the time of mammary tumor surgery remains controversial, but a subset of dogs with differentiated estrogen receptor-positive tumors may indeed benefit from concurrent OHE.

PREVENTION

OHE at age <6 months is not preventive but will significantly reduce risk.

CLIENT EDUCATION

- Early age OHE of bitches not intended for breeding
- Regular examination of the mammary chain
- Prompt presentation for veterinary examination if abnormalities are found

1ST EDITION AUTHORS: DANIELA SIMON, BETH A. VALENTINE

Mammary Gland Neoplasia, Cat

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Mammary gland tumors are benign or malignant neoplasms arising from mammary tissue.

SYNONYM

Mammary cancer, mammary tumor Specific mammary neoplasms:

- Adenocarcinoma
- Adenoma/cystadenoma
- Carcinoma
- Duct papilloma
- Fibroadenoma
- Inflammatory carcinoma

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Mammary gland tumors represent less than 20% of all tumors in female cats.
- Incidence ≅0.25:1000.
- Mean age is 10-12 years. Males may be slightly older, with a mean age of 12.8 years.
- Most common: malignant epithelial carcinoma/adenocarcinoma (female), mammary carcinoma (male)
- Mixed mammary tumors and sarcomas are extremely rare to nonexistent.
- Siamese cats may develop mammary tumors at an earlier age than other cats.
- Mammary tumors are rare in male cats (1%-2% of feline mammary carcinomas).

GENETICS & BREED PREDISPOSITION

- Siamese cats have a twofold risk of developing mammary gland tumors and have a higher incidence of malignant tumors with lymphatic invasion.
- Persian cats may have a higher incidence of benign mammary tumors.
- A genetic factor in the development of mammary tumors has not been identified. The following oncogenes have shown abnormal expression in select feline mammary gland tumors:
    - p53
    - Her-2 (neu/c-erb-2)

RISK FACTORS: Hormonal factors:

- Ovariohysterectomy (OHE) reduces the risk of developing mammary tumors.
    - OHE < 6 months: 91% risk reduction compared with intact cats
    - OHE 7-12 months: 86% risk reduction compared with intact cats
    - OHE 13-24 months: 11% risk reduction compared with intact cats
    - OHE > 2 years: no benefit
- Treatment with progesterone and estrogen/progesterone combinations is associated with a threefold increased risk of development of benign and malignant mammary tumors in cats (progesterone treatment: 36% of male cats with mammary carcinoma).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Clinical staging:

- Tumor: T1: <2 cm; T2: 2-3 cm; T3: >3 cm
- Regional lymph node: N0, no metastasis; N1, metastasis detected
- Distant metastasis: M0, no metastasis; M1, metastasis detected

Stage Grouping	T	N	M
I	T1	N0	M0
II	T2	N0	M0
III	T1, T2	N1	M0
	T3	N0, N1	M0
IV	T1-3	N0, N1	M1

HISTORY, CHIEF COMPLAINT

- A swelling, “lump,” or often ulcerated tissue may be noted in a cat's mammary chain.
- In cases of metastasis or inflammatory carcinoma, cats may be presented for general signs of illness or specific complaints attributable to a certain site of metastasis (e.g., dyspnea due to pulmonary metastases or pleural effusion).
- Duration of clinical signs is variable, ranging from a few days to several months.

PHYSICAL EXAM FINDINGS

- Clinical signs vary depending on extent and stage of disease.
- More than 50% of cats will have more than one mammary tumor present, and both mammary chains may be affected simultaneously.
- Tumors may be firm on palpation and occasionally fixed to underlying structures.
- Discrete to infiltrative, soft to firm swelling within mammary gland or overlying skin is most common.
- Ulceration is frequently present.
- Can have associated discharge from nipple.
- Regional lymph nodes (inguinal and axillary) may be enlarged or normal on palpation.
- Lymph node enlargement can indicate metastasis or reactive change secondary to inflammation.
- Inflammatory carcinomas occur rarely in cats after mastectomy for mammary carcinoma. These cats present with local erythema, edema, pain, and involvement of the extremities.

ETIOLOGY AND PATHOPHYSIOLOGY

- The vast majority (85%-93%) of feline mammary tumors are malignant, with more than 80% of feline mammary tumors classified as adenocarcinoma.
    - Metastasis is common (61%). Preferred sites of metastasis include the lungs (76%), pleura (40%), and lymph nodes (27% or more).
- Inflammatory carcinomas occur rarely in cats after mastectomy for mammary carcinoma.
    - These are aggressive anaplastic carcinomas with considerable inflammatory cell infiltrate, intradermal and dermal lymphatic invasion that leads to edema, pain, and rapid metastasis.
- Benign tumors including adenomas, fibroadenomas, and duct papillomas occur uncommonly in cats.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the presence of a mass in the mammary chain. Histologic evaluation is required for definitive diagnosis which is usually obtained from an excisional biopsy.

DIFFERENTIAL DIAGNOSIS

- Fibroepithelial hyperplasia: involves multiple glands, most often in young intact females and spayed females given progesterone compounds
- Mastitis
- Other cutaneous and subcutaneous tumors
- Inguinal/axillary lymphadenopathy (reactive, neoplastic)
- Inguinal hernia
- Enlarged inguinal fat pad

INITIAL DATABASE

- Physical examination:
  - Measure primary tumor (T)
  - Describe possible signs of invasiveness (ulceration, fixation)
  - Evaluate regional lymph nodes (N): palpation and cytologic analysis
- Thoracic radiographs (three views) for pulmonary metastasis
- Abdominal ultrasound in case of suspected metastasis to abdominal organs or lymph nodes
- Fine-needle aspiration and cytologic evaluation are of limited utility and generally not recommended. Although seemingly more accurate than in dogs, feline mammary mass aspirates often are not representative of the entire mass, and cytologic criteria of malignancy are not correlated to histologic findings nor clearly defined.
- CBC, serum biochemistry profile, urinalysis, coagulation profile in cases of suspected inflammatory carcinoma

ADVANCED OR CONFIRMATORY TESTING

- Definitive diagnosis is via biopsy and histopathologic evaluation of mammary masses
  - Histologic grading scheme is based primarily on mitotic activity, areas of necrosis, and degree of infiltration into soft tissue and vasculature.
  - Because >85% of feline mammary tumors are malignant, histopathologic examination most often is performed on tumor tissue obtained from a radical mastectomy.
  - When fibroepithelial hyperplasia (see Differential Diagnosis above) or other nonmammary tumors are suspected, incisional (wedge) biopsies may be done.
- Lymph node evaluation:
  - In general, the ipsilateral inguinal lymph node should be removed during radical mastectomy and assessed histopathologically.
  - Axillary lymph nodes may be difficult to isolate, but fine-needle aspiration or biopsies can be done if they are enlarged.
- Distant metastasis:
  - Cytologic evaluation of pleural effusion can aid in the diagnosis of thoracic metastatic disease.
  - Advanced imaging (CT, MRI) may increase diagnostic accuracy of metastatic lesions in the thoracic and abdominal cavities.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of complete surgical removal of the mammary tumor(s). The recommended surgical approach for cats is radical mastectomy. Adjuvant chemotherapy is advised for cats with poor prognostic factors, although the true survival benefit is not known.

ACUTE GENERAL TREATMENT

- Surgery:
  - Radical mastectomy of the affected mammary chain(s) is recommended.
  - In contrast to individual mastectomies or lumpectomies, radical mastectomy significantly reduces the risk for local tumor recurrence.
  - Affected lymph node(s) should be removed along with mammary chain.
  - Fixation of the tumor to underlying muscle or fascia necessitates en bloc removal of these structures.
  - In cats with advanced metastatic disease, local mastectomy to remove ulcerated or infected mammary tumors may be palliative.
  - Inflammatory carcinoma is nonresectable.

CHRONIC TREATMENT

- Chemotherapy:
  - Single-agent doxorubicin, doxorubicin in combination with cyclophosphamide or single-agent carboplatin may lead to complete and partial responses in cats with metastatic disease or nonresectable mammary gland tumors.
  - Adjuvant chemotherapy using the previously mentioned drugs as single agents or in combination is recommended in cats after radical mastectomy. However, a true survival benefit has yet to be proven.
  - Consultation with an oncologist for the most current treatment recommendations is indicated.
- Radiation therapy:
  - Radiation to palliate nonresectable disease may be an option in some cats.
- Immunotherapy:
  - Treatment with levamisole, bacterial vaccines, and other immunomodulators has not led to any improvement in local tumor control or survival.
- Analgesics:

- Analgesics should be used in cats that present with advanced disease.

POSSIBLE COMPLICATIONS

Inflammatory carcinoma after mastectomy for mammary carcinoma: rare

RECOMMENDED MONITORING

Regular examination of surgical site, local lymph nodes, lung fields

PROGNOSIS AND OUTCOME

- Local recurrence rate: 51%-66% (female), 45% (male)
- Prognostic factors for cats with mammary gland carcinomas:
  - Tumor size:
    - >3 cm: median survival of 4-6 months (female), 1.6 months (male)
    - 2-3 cm: median survival of 1-2 years (female), 5.2 months (male)
    - <2 cm: median survival of >3 years after mastectomy (female), 14 months (male)
  - Type of surgery:
    - Radical mastectomy significantly reduces the risk for local tumor recurrence compared with conservative surgery but does not appear to improve survival time. o Degree of histologic differentiation: high grade is associated with a shorter survival time.
  - Other unfavorable prognostic factors include old age of the cat and incomplete surgical excision.
- Benign tumors and low-grade malignant tumors may be cured by wide excision.

PEARLS & CONSIDERATIONS

COMMENTS

- Mammary carcinoma in the cat is a highly malignant neoplastic disease that warrants early diagnosis and an aggressive treatment approach.
- Adjuvant chemotherapy should be considered in cats with resectable mammary carcinoma after radical mastectomy.
- In cats with advanced disease, palliative measures including surgery, chemotherapy, radiation, and analgesics may be considered.

PREVENTION

- Ovariohysterectomy before age 6 months reduces the risk but will not prevent mammary carcinoma in female cats.
- Castration does not prevent mammary carcinoma in male cats.

CLIENT EDUCATION

- Early ovariohysterectomy of queens not intended for breeding
- Regular examination of the mammary chain
- Prompt presentation for veterinary examination when abnormalities are found

1ST EDITION AUTHORS: DANIELA SIMON, BETH A. VALENTINE

Mammary Disorders, Non-Neoplastic

BASIC INFORMATION

DEFINITION

- Mastitis: inflammation of the mammary gland, usually septic; blood-milk barrier not intact
- Mammary hyperplasia: aseptic noninflammatory enlargement of mammary glands

SYNONYMS

Mammary hyperplasia, fibroadenomatous mammary hyperplasia, benign feline mammary hyperplasia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Mastitis: more common in the postpartum bitch than the bitch with overt false pregnancy or the postpartum queen. Occasionally occurs in spayed bitches. Older bitches may be at greater risk (unverified).
- Mammary hyperplasia: usually young intact cats or pregnant queens

GENETICS & BREED PREDISPOSITION: Mastitis: short-legged breeds and dogs with pendulous mammary glands have greater risk of trauma.

RISK FACTORS

- Mastitis: poor hygiene, trauma (environmental or secondarily to puppies nursing), infections from other sites in the body
- Mammary hyperplasia: young intact cats, pregnant queens or cats with false pregnancy. Cats of either sex with recent gonadectomy. Cats of either sex receiving exogenous progestogen treatment.

GEOGRAPHY AND SEASONALITY: Mammary hyperplasia: spring when queens cycle; incidence is 40%-50% post ovulation in cats with false pregnancy.

ASSOCIATED CONDITIONS & DISORDERS

- Mastitis:
  - Bitches and queens with secondary septicemia from other infections may have hematogenous spread to mammary tissue.
  - Galactostasis following weaning or overt pseudopregnancy
  - Benign mammary hyperplasia in queens
  - May be associated with mammary neoplasia
- Mammary hyperplasia:
  - Secondary mastitis and/or necrosis
  - Conditions which may result in treatment with exogenous progestogens

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Mastitis: acute, fulminate or chronic, near subclinical
- Mammary hyperplasia: acute

HISTORY, CHIEF COMPLAINT

- Mastitis:
  - Lactating bitch or queen
    - Uncomfortable dam may or may not want to nurse puppies; neonates do not nurse (crying puppies or kittens)
  - Rarely, pseudopregnant bitch
- Mammary hyperplasia: acute enlargement of mammary glands

PHYSICAL EXAM FINDINGS

- Mastitis:
  - Firm, warm, swollen, often painful mammary gland (one or more)
  - Lethargy
  - Dehydration
  - May be possible to express purulent or discolored milk from gland
  - Gland may abscess, become gangrenous, and rupture.
  - +/− Fever
  - May progress to septic shock
- Mammary hyperplasia
  - Enlarged mammary glands
  - All glands usually involved
  - Can be painful
  - Can develop necrosis

ETIOLOGY AND PATHOPHYSIOLOGY

- Mastitis
  - Possible ascending infection from poor environmental hygiene or traumatic injury from nursing offspring
  - Incidence highest in stimulated mammary glands; may be due to presence of abundant substrate (milk), open ducts, trauma from nursing, and increased trauma because glands are enlarged
- Mammary hyperplasia
  - Hormonally induced condition
    - Hormones include progesterone, growth hormone, and prolactin.
    - Key: high progestogen concentrations, either endogenous or exogenous

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History and physical examination are generally sufficient to formulate a diagnosis: enlarged, painful mammary glands (usually during lactation) in mastitis patients, or rapidly enlarged nonseptic mammary glands in cats with mammary hyperplasia.

DIFFERENTIAL DIAGNOSIS

- Mammary adenocarcinoma (inflamed or septic) usually in older females with no concurrent lactation (see pp. 690 and 692)
- Galactostasis: dam not ill, nonseptic

INITIAL DATABASE

- CBC in mastitis unremarkable or leukocytosis with left shift; if acute sepsis, leukopenia is possible. CBC in mammary hyperplasia normal.
- Cytologic examination of mammary secretions: in mastitis, many toxic neutrophils; in mammary hyperplasia, normal
- Mastitis: pH of mammary secretions will help determine which antibiotic to use.

ADVANCED OR CONFIRMATORY TESTING

- Bacterial culture and sensitivity of mammary secretions
- Biopsy of mammary tissue (to rule out neoplasia and benign mammary hyperplasia)

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are returning the patient to normal mammary function and preventing septicemia. For mammary hyperplasia: prevention of mastitis.

ACUTE GENERAL TREATMENT

- Mastitis:
  - If mammary necrosis is present or milk is too contaminated for puppies and kittens, offspring should be removed and the necrotic tissue surgically drained and débrided.
    - Signs include milk that is grossly purulent, malodorous, or markedly discolored, or hungry neonates that are not nursing on their own or are developing diarrhea, vomiting, or losing weight.
  - Antiprolactin therapy may be administered to stop lactation (cabergoline, 5 mcg/kg PO q 24 h; response usually seen within 3-4 days; over 80% response by day 7).
  - Systemic antibiotic treatment of the dam is required. General guidelines are initially based on Gram stain and on whether neonates are still nursing; subsequently use culture and sensitivity results for definitive treatment. The therapeutic goal is to achieve significant antibiotic concentrations in the milk.
  - While awaiting culture results, the choice of antibiotic for initial empirical treatment is limited (e.g., cefadroxil, 22 mg/kg PO q 8 h or amoxicillin-clavulanic acid 12.75 mg/ kg PO q 12 h) if the dam's offspring continue to nurse.
  - Nursing puppies and kittens can be negatively affected by antibiotic concentrations in the dam's milk.
    - Recommendations for nursing dam:
      - Aerobic bacteria:
        - Gram-negative: cefoxitin, 30 mg/kg IV q 6 h; or chloramphenicol, 40 mg/kg PO q 8h
        - Gram-positive: first-generation cephalosporins (e.g., cefadroxil, 22 mg/kg PO q 8 h; or erythromycin, 10-20 mg/ kg PO q 8 h)
      - Anaerobic bacteria: erythromycin, cefoxitin, chloramphenicol
        - *Mycoplasma:* erythromycin, chloramphenicol
    - Recommendations for dam not nursing neonates:
      - Aerobic bacteria:
        - Gram-negative: quinolones (e.g., enrofloxacin, 5 mg/kg PO q 12 h [5 mg/kg PO q 24 h in cats]), or second- or third-generation cephalosporins (e.g., cefoxitin)
        - Gram-positive: first-generation cephalosporins, amoxicillin/clavulanic acid, or erythromycin
      - Anaerobic bacteria:
        - Penicillin (e.g., procaine penicillin G, 20,000 IU/kg IM or SQ q 12-24 h); metronidazole (15 mg/kg PO q 12 h); clindamycin (5-11 mg/kg PO q 12 h); erythromycin or cefoxitin
        - *Mycoplasma:* tetracyclines (e.g., doxycycline, 5 mg/kg PO q 12 h), erythromycin, or quinolones.
  - Warm packing and ongoing nursing. Unless the gland is necrotic, continued nursing by the offspring and warm packing the affected glands will prevent galactostasis and promote drainage.
- Mammary hyperplasia:
  - Progesterone withdrawal
  - Usually self-limiting in 2-3 weeks
  - If sexually intact, ovariectomy or ovariohysterectomy recommended
  - Pain control
  - Medical therapy
    - Progesterone receptor blocker: aglepristone (15 mg/kg SQ q 24 h × 2 days or 20 mg/kg SQ once). Note: not approved for use in cats in the United States; will abort pregnant cats.
    - Prolactin inhibitor: bromocriptine mesylate (0.25 mg per cat PO q 24 h × 5-7 days. Note: not approved for use in cats in the United States; will abort pregnant cats.
    - Androgens: testosterone enanthate or testosterone cypionate (2 mg/ kg IM once). Note: not approved for use in cats in the United States.

CHRONIC TREATMENT

Mastectomy

BEHAVIOR/EXERCISE

Limit activity which might induce mammary trauma. This may include weaning puppies and kittens.

DRUG INTERACTIONS

Antiprolactinics will stop lactation. Some antibiotics are contraindicated in lactating bitches. Aglepristone is abortifacient in the cat.

POSSIBLE COMPLICATIONS

Systemic antibiotic therapy in lactating dams may interfere with normal bacterial colonization of gastrointestinal flora in nursing neonates, resulting in diarrhea.

RECOMMENDED MONITORING

- Temperature, respiration and heart rate

- Physical signs of septicemia
- Offspring that are nursing: weigh daily to determine adequate milk intake.

PROGNOSIS AND OUTCOME

Prognosis is generally good unless sepsis occurs.

PEARLS & CONSIDERATIONS

COMMENTS

- Neonates 4½ to 5 weeks old should be allowed access to dam's food, and the bitch or queen should have an area where she can remove herself from the neonates (e.g., top of crate, raised platform).
- Neonates will then start eating solid food for a portion of their caloric intake, decreasing the amount of time they are nursing on the mother. Additionally benefits the dam by greatly reducing her metabolic requirements.
- Older neonates with teeth nurse more aggressively and can induce both bite and nail trauma to the mammary gland, greatly increasing the risk of inflammation and infection.
- Frequently, chronic mastitis has been suspected when neonates fail to thrive. However, subclinical mastitis has not been demonstrated in dogs and cats.

PREVENTION

- Adequate husbandry, particularly clean bedding for mother and offspring
- Keep mammary glands clean, monitor glands for trauma from neonate's claws or teeth.
- Clipping neonates' toenails
- Mammary hyperplasia: limit the clinical use of exogenous progestogens.

CLIENT EDUCATION

Primarily husbandry issues of proper hygiene and weaning instructions.

Malocclusion

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

An abnormal position of the teeth. In dental malocclusion, one or several teeth is/are in an abnormal position, whereas in skeletal malocclusion there is an upper/lower jaw discrepancy.

SYNONYM

Malalignment of teeth

EPIDEMIOLOGY

SPECIES, AGE, SEX: Malocclusion can be seen in all species, all age groups, and is usually present from the time of eruption of the deciduous or permanent dentition.

GENETICS & BREED PREDISPOSITION: Occlusal development is determined by genetic and environmental factors. Most brachycephalic cats and dogs show malocclusion due to a shortened upper jaw.

RISK FACTORS

- Persistent deciduous teeth
- Facial trauma during tooth and jaw development
- Selective breeding for exaggerated head types

ASSOCIATED CONDITIONS & DISORDERS

- Discomfort and pain can result from maloccluding teeth.
- Linguoverted mandibular canines may lead to oronasal fistula formation.
- Crowded teeth are at risk for early periodontitis from plaque retention.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Dental malocclusion:
  - Neutroclusion (class 1 malocclusion; a normal rostrocaudal relationship of the maxillary and mandibular dental arches, with malposition of one or more individual teeth)
    - Distoversion/mesioversion/lin-guoversion/labioversion/bucco-version: tooth in its anatomically correct position in the dental arch is abnormally angled in a distal/mesial/lingual/labial/buccal direction, respectively.
    - Crossbite: malocclusion in which a mandibular tooth or teeth have a more buccal or labial position than the antagonist maxillary tooth
      - Rostral crossbite: one or more of the mandibular incisor teeth is labial to the opposing maxillary incisor teeth when the mouth is closed
      - Caudal crossbite: one or more of the mandibular cheek teeth is buccal to the opposing maxillary cheek teeth when the mouth is closed
- Symmetric skeletal malocclusion:
  - Mandibular distoclusion (class 2 malocclusion; an abnormal rostrocaudal relationship between the dental arches in which the mandibular arch occludes caudal to its normal position relative to the maxillary arch)
  - Mandibular mesioclusion (class 3 malocclusion; an abnormal rostrocaudal relationship between the dental arches in which the mandibular arch occludes rostral to its normal position relative to the maxillary arch)
- Asymmetric skeletal malocclusion:
  - Maxillary-mandibular asymmetry describes skeletal malocclusions that can occur in a rostrocaudal, side-to-side, or dorsoventral direction.
    - Rostrocaudal: mandibular mesioclusion or distoclusion is present on one side of the face, but the contralateral side retains normal dental alignment.
    - Side-to-side: there is loss of the midline alignment of the maxilla and mandible.
    - Dorsoventral: results in an *open bite,* defined as an abnormal vertical space between opposing dental arches

when the mouth is closed

HISTORY, CHIEF COMPLAINT

- Abnormal incisor occlusion (show and breeding dogs)
- Abnormal tooth position
- Obvious length difference between upper and lower jaws or between left and right

MALOCCLUSION Clinical photograph of a cat with mesioversion of the right maxillary canine tooth *(asterisk).* There is no diastema between the right maxillary canine and third incisor, which the right mandibular canine tooth could occlude into when the mouth is closed (compare with normal left side). Mesioversion of the right maxillary canine tooth resulted in mild labioversion of the right mandibular canine tooth and an open bite (incomplete closure of the mouth).

PHYSICAL EXAM FINDINGS

- Normal occlusion (in the dog):
  - Maxillary incisor teeth are positioned rostral to mandibular incisor teeth. Crown cusps of mandibular incisor teeth contact the cingulum of maxillary incisor teeth.
  - Mandibular canine tooth inclined labially and bisecting the interdental space between the maxillary third incisor tooth and canine tooth
  - Maxillary premolar teeth do not contact mandibular premolar teeth. Crown cusps of mandibular premolar teeth positioned lingual to the arch of maxillary premolar teeth. Crown cusps of mandibular premolar teeth bisect the interdental spaces rostral to corresponding maxillary premolar teeth.
  - Mesial crown cusp of the maxillary fourth premolar tooth positioned lateral to the space between the mandibular fourth premolar and first molar teeth
- Dental malocclusion:
  - Abnormal positioning of one or more teeth
  - No jaw discrepancy
  - Trauma to soft tissue or other teeth
- Skeletal malocclusion:
  - Abnormal maxillary-mandibular incisor relationship
  - Loss of premolar interdigitation
  - Incorrect mandibular canine occlusion
  - Jaw length discrepancy (symmetric or asymmetric)
  - Trauma to soft tissue or other teeth

ETIOLOGY AND PATHOPHYSIOLOGY

- Jaw length, tooth bud position, and tooth size are independently inherited. Unharmonious development of upper and lower jaw and teeth results in malocclusion.
- Persistent deciduous teeth are associated with malpositioned permanent teeth.
- Significant facial trauma at a young age may lead to abnormal development and malocclusion.

- Significant facial trauma at any age may cause changes in jaw relationship.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based entirely on physical examination to identify malpositioned teeth.

DIFFERENTIAL DIAGNOSIS

- Skeletal malocclusion versus dental malocclusion
- Functional (mal)occlusion versus clinically relevant malocclusion (causing discomfort or pain)

INITIAL DATABASE

Physical examination:

- Look for persistent deciduous teeth.
- Differentiate between dental and skeletal malocclusion.

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is to have a pain-free, comfortable patient with a functional bite. Cosmetic considerations should not play a role.

ACUTE AND CHRONIC TREATMENT

- Extract maloccluding deciduous teeth as early as possible (6-10 weeks of age) if they appear to cause discomfort or interfere with jaw growth.
- Treatment options for maloccluding permanent teeth causing trauma to soft tissue or other teeth:
    - Extraction
    - Surgical crown reduction and vital pulp therapy
    - Orthodontic movement (passive or active)
- Linguoversion of mandibular canines: “Verhaert's rubber ball technique” is useful for young dogs (below 7 months of age) with normal jaw relationships and sufficiently wide diastema between maxillary third incisor and canine teeth. The dog is stimulated to actively play with a smooth-surfaced hard rubber ball for at least 15 minutes 3 times daily.

POSSIBLE COMPLICATIONS

- Inappropriate extraction technique of deciduous teeth may cause trauma to developing permanent teeth.
- Surgical crown reduction may lead to pulpitis and pulp necrosis.
- Orthodontic treatment usually requires several corrective procedures under general anesthesia and may cause soft-tissue trauma from the appliance, tooth ankylosis and root resorption, displacement of anchor tooth, overcorrection of target tooth, avulsion of anchor or target tooth, discomfort, and pain.

RECOMMENDED MONITORING

- Teeth treated by surgical crown reduction should be monitored radiographically after 4-6 months and then on a yearly basis.
- During orthodontic treatment, regular monitoring is necessary to assess tooth movement and to recognize possible complications at an early stage.

PROGNOSIS AND OUTCOME

Prognosis is good once a functional bite has been accomplished.

PEARLS & CONSIDERATIONS

COMMENTS

- Dental malocclusions are not considered inherited unless a familial predisposition exists.
- Skeletal malocclusion is considered inherited unless a developmental cause (e.g., significant facial trauma) can be identified.
- Inherited malocclusion should only be corrected by orthodontic movement if the animal is neutered.

PREVENTION

- Selective breeding
- Remove persistent deciduous teeth

CLIENT EDUCATION

Neuter animals with skeletal malocclusion (if not “normal” for the breed).

AUTHOR: LEEN VERHAERT

EDITOR: ALEXANDER M. REITER

Malnutrition

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Malnutrition is the inappropriate intake of nutrients, resulting in nutritional deficiencies or excesses.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Malnutrition can affect animals of any species, age, life stage, or lifestyle.

GENETICS & BREED PREDISPOSITION: No specific genetic link or breed disposition is known for malnutrition associated with nutritional deficiencies. An increased prevalence of obesity resulting from excessive caloric intake has been associated with basset hounds, beagles, Cairn terriers, Cavalier King Charles spaniels, cocker spaniels, long-haired dachshunds, Labrador retrievers, and Shetland sheepdogs.

RISK FACTORS

- Animals fed vegetarian, homemade, or single-food diets may be at risk for nutrient deficiencies (see p. 686).
- Animals with a history of chronic vomiting or diarrhea could have altered digestion or absorption, resulting in decreased nutrient assimilation.
- Drugs such as corticosteroids, cancer chemotherapeutic agents, antibiotics, or diuretics may adversely affect nutritional homeostasis.
- Neutering, decreased physical activity, age or calorie-dense foods may predispose dogs or cats to obesity.

GEOGRAPHY AND SEASONALITY: Inadequate food or water intake during severe weather conditions may result in nutrient deprivation.

ASSOCIATED CONDITIONS & DISORDERS

- Decreased protein/calorie intake negatively effects immune function.
- Increased risk of orthopedic problems or diabetes mellitus (cats) with prolonged excessive food intake

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Weight loss, emaciation, low body condition score (1 or 2 on a scale of 1-5 or 1-9). Weight gain, obesity, high body condition score (4 or 5 on a scale of 1-5 or 8 or 9 on a 1-9 scale)

HISTORY, CHIEF COMPLAINT

- Nutrient-deprived animals present with a history of failure to thrive and inappetence or anorexia.
- Overnourished or obese animals often present with clinical signs associated with lameness or endocrinopathy.

PHYSICAL EXAM FINDINGS: Nutrient-deprived animals are often in poor physical appearance: thin body condition; dry, coarse haircoat; flaky skin; hyperkeratosis; muscle wasting; broken or missing teeth; skeletal abnormalities; pressure sores; poor wound healing. Obese animals are also in poor physical condition with fat deposition over the ribs, hips, tail head, and throughout the abdomen. Some are unable to adequately groom themselves, which can result in an unkempt hair coat, dry skin, skinfold dermatitis, and the inability to walk, run, or jump.

ETIOLOGY AND PATHOPHYSIOLOGY

- Inadequate or excessive nutrient intake results in malnutrition.
- Decreased nutrient intake diminishes immune cell response and production, as well as protein turnover, tissue synthesis, and wound healing.
- Altered drug metabolism results from protein/calorie malnutrition and may increase or decrease both drug efficacy and drug toxicity.

- Although not well documented in hospitalized veterinary patients, malnutrition is thought to increase morbidity and mortality.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of malnutrition is made on the basis of a thorough diet history and the physical examination findings.

DIFFERENTIAL DIAGNOSIS

Gastrointestinal disease: protein-losing enteropathy, lymphocytic-plasmacytic enteritis, inflammatory bowel disease

INITIAL DATABASE

- A thorough diet history should include sufficient information to purchase all food items necessary to feed the patient exactly as the owner does at home.
- The physical examination should include a body weight, body condition score (1-5 or 1-9 scale), and muscle mass score (1-3 scale).
- Laboratory evaluation plays a limited role in diagnosing nutrition-related problems.

TREATMENT

TREATMENT OVERVIEW

The goals of treatment are to correct nutrient deficiencies or excesses and return patient to a normal plane of nutrition and a more appropriate body weight and body condition.

ACUTE GENERAL TREATMENT

- Stabilize patient: rehydrate, correct electrolyte imbalances, hemodynamic abnormalities, and hypothermia before initiating nutritional support.
- Determine whether the gastrointestinal tract is functional and how nutrition support is to be delivered (enteral or parenteral).
- For patients unable or unwilling to prehend, choose the type of feeding tube for enteral delivery that fits your patient (e.g., gastrotomy tube for patients with persistent regurgitation or vomiting, esophagostomy tube for facial trauma). See p. 1267 and p. 1273 .
- Estimate an initial daily caloric goal for resting energy needs based upon animal's current weight (rather than an ideal weight), using the equation: $70 \times BWkg^{0.75}$
- For patients weighing between 15 and 30 kilograms, use the equation: 30 × BWkg + 70. This provides a reasonably accurate assessment of resting energy needs.
- Select a diet or food type that meets the nutritional needs of the patient.
- Determine a feeding regimen (continuous or intermittent feedings) that will deliver the estimated caloric goals over a 24-hour period.
- Administer nutrition to patients by assisted feeding until patient is eating at least 50% resting energy needs.
- Plan to get the animal eating its own food in its own environment as soon as possible.

CHRONIC TREATMENT

- Identify dietary, animal-related, owner-related or environmental issue(s) that caused or contributed to the nutritional deficiency or excess.
- Educate owner(s) about nutritional needs of their animal, given the species, age, life stage, and lifestyle.
- Provide information about, or resources for, complete and balanced homemade diets (website formulation services, laboratory analyses, and continuous monitoring).
- Provide information and support for owners considering a weight management program for their animal.

DRUG INTERACTIONS

Medical therapies instituted for primary conditions will be altered without adequate nutrition support.

RECOMMENDED MONITORING

Client education and repeated follow-up is critical for animals enrolled in weight management programs, or those who are fed homemade or raw meat diets.

PROGNOSIS AND OUTCOME

- Prognosis is good to excellent with immediate identification and correction of nutrient deficiencies or excesses.
- Prognosis is poor to good with prolonged identification and correction of nutrient deficiencies or excesses.

PEARLS & CONSIDERATIONS

COMMENTS

- Obesity prevention is much easier than obesity management. Client education campaigns should focus on prevention at every well-pet visit.
- Obesity management programs should be directed by veterinarians and delivered by trained, licensed veterinary technicians who are excellent communicators.
- Pet owners interested in feeding homemade or raw meat diets should consult with a veterinarian, identify a balanced recipe to use, and plan on regular monitoring of both their pet and the diet (see online chapter: Malnutrition: Home-Prepared Diets).

PREVENTION

- Complete nutritional assessments should be performed daily on hospitalized patients to identify patients at risk of malnutrition before it occurs.
- Clients should be educated on the basic nutrient needs of animals, considering species, age, life stage, and environmental conditions.

TECHNICIAN TIPS

- Technicians can be instrumental in providing client education about the proper diet and feeding management of dogs and cats and in overseeing patients enrolled in weight management programs.
- In the outpatient setting, technicians should ensure that every patient is weighed, body condition scored, and has a diet history taken.
- In the inpatient setting, technicians can aid in identifying patients at risk of malnutrition.

CLIENT EDUCATION

- Consultation for customized homemade diet formulations is available through the American College of Veterinary Nutrition (ACVN.org), or diets can be purchased at www.balanceit.com or www.petdiets.com.
- Homemade diet recipes can be analyzed through the Nutrition Laboratory in the Diagnostic Center for Population and Animal Health at Michigan State University: 517-353-9312.

EDITOR: KATHRYN E. MICHEL

Malnutrition, Home-Prepared Diets

DEFINITION

Feeding of an unbalanced diet of uncooked and cooked foods as a sole source of nutrition; this practice is becoming more common among pet owners.

SYNONYMS

Home-cooked diet, homemade diet

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs more likely to be fed home-prepared diets than cats. Young and reproductive animals at increased risk for deficiencies and excess. All animals at risk of illness from foodborne pathogens.

GENETICS & BREED PREDISPOSITION: Dogs and cats: all breeds affected. Dogs: large and giant breeds at increased risk of developmental orthopedic disease. Cats: taurine-deficient cardiomyopathy and/or central retinal degeneration.
CONTAGION & ZOONOSIS: Dogs and cats: *Salmonella, Escherichia coli, Campylobacter, Toxoplasma, Cryptosporidium*

ASSOCIATED CONDITIONS & DISORDERS: Poor skin and coat, obesity, vomiting, diarrhea, pathologic fractures, seizures, pancreatitis (high-fat diet), oral trauma, intestinal obstruction/perforation

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Incidental: no clinical signs
- Overt illness: varies with dietary imbalance/excess or ingredients

HISTORY, CHIEF COMPLAINT: Vomiting, diarrhea, lethargy, decreased activity, poor skin and coat, reproductive failure, fetal resorption, dystocia, failure to gain weight (young), weight loss (adult). May be an incidental finding during routine history-taking.

PHYSICAL EXAMINATION: Varied: dull coarse coat, coat color change, dental fractures, skeletal abnormalities, fractures, heart murmur, loss of vision (cats), abdominal pain, dehydration, poor body condition (obese or cachectic)

ETIOLOGY AND PATHOPHYSIOLOGY

- Essential nutrient deficiency
  - Lethargy, anorexia, reproductive failure: any
  - Poor skin and coat: zinc, iron, iodine, phenylalanine-tyrosine, niacin, biotin, linoleic acid, linolenic acid and/or total protein
  - Osteopenia/osteomalacia: calcium and/or vitamin D
  - Anemia: iron, copper, folate and/or total protein
  - Hypoalbuminemia: individual amino acids, total protein and/or total calories
  - Heart murmur (cats, large-breed dogs, cocker spaniels): taurine
  - Central retinal degeneration (cats): taurine
- Essential nutrient excess
  - Anorexia: vitamin A, vitamin D, iron, calcium, iodine
  - Hypercalcemia: vitamin D
  - Vomiting and/or diarrhea: sodium and/or selenium; total fat (pancreatitis or fat malabsorption)
- Dietary contamination
  - Vomiting and/or diarrhea: foodborne pathogen, bone ingestion
  - Seizures: *Neospora, Toxoplasma*

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis is suspected when an unusual dietary history is revealed, suggestive physical abnormalities are noted, or both.

DIFFERENTIAL DIAGNOSIS

Allergic dermatitis, underlying end-organ disease (hepatic, renal, intestinal, central nervous system)

INITIAL DATABASE

- Diet history: consider adequate energy content, type and amount of protein, source of essential fatty acids, source of calcium, and source of trace minerals and vitamins.
- Serum biochemistry, CBC, urinalysis, may be unremarkable or show nonspecific changes (e.g., hypoalbuminemia, hypocalcemia, hypokalemia, hypomagnesemia, increased alkaline phosphatase, and anemia).

TREATMENT 

TREATMENT OVERVIEW

Manage sequelae of imbalance and correct underlying deficiency.

ACUTE GENERAL TREATMENT

- Varies with imbalance
- Vomiting and/or diarrhea: correct dehydration with intravenous (IV) fluids
- Supplemental calcium gluconate, magnesium sulfate, or balanced B-vitamin solution (IV if needed)
- Foodborne pathogens respond to supportive and antimicrobial therapy unless sustained end-organ damage
- If no clinical signs of disease: dietary deficiencies and/or excesses are corrected with feeding a complete and balanced diet.

POSSIBLE COMPLICATIONS

None known if home-prepared diet complete and balanced

RECOMMENDED MONITORING

- Diet recipes evaluated and balanced by trained veterinary nutritionist
- Physical examination, biochemistry, CBC and urinalysis every 6-12 months
- Diet and supplement review at each visit
- Diet reformulation may be necessary if health status changes.

PROGNOSIS AND OUTCOME 

Good if dietary imbalance corrected

PEARLS & CONSIDERATIONS 

COMMENTS

- Home-prepared diets are becoming more common among dog and cat owners as all or part of the daily diet.
- Normal test results do not rule out deficiency or suboptimal nutrient intake.

PREVENTION

- Client education important to help prevent foodborne illness and dietary imbalances
- Review diet history at each visit; owner substitution of ingredients and omissions of essential nutrients is common.

CLIENT EDUCATION

- Important to understand motivations for feeding home-prepared diets to help direct client education and prevent diet-induced disease.
- Feeding raw meat increases risk of pathogenic bacteria exposure for people and other animals in household; especially at risk are young, old, and immune-compromised adults. Proper food sanitation and hygiene are essential if home-prepared diet

is fed.

Malignant Fibrous Histiocytoma

BASIC INFORMATION

DEFINITION

An uncommon primary tumor made up of fibrous and inflammatory cells thought to arise from a primitive mesenchymal cell. It is not to be confused with malignant histiocytosis (histiocytic sarcoma), a disease of localized or multisystemic histiocytic infiltration (see p. 535).

SYNONYMS

Epithelioid sarcoma, giant cell fascial sarcoma, giant cell tumor, reticulum cell sarcoma

EPIDEMIOLOGY

SPECIES, AGE, SEX: Malignant fibrous histiocytoma is an uncommon tumor of the skin and subcutaneous tissue of dogs and cats, and can also occur in the spleen in dogs. This tumor type has been reported at injection sites in cats (see p. 610).

GENETICS & BREED PREDISPOSITION: Golden retrievers and rottweilers may be overrepresented.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Different pathologic types include storiform-pleomorphic, inflammatory, and a giant cell variant. The giant cell variant, which occurs in dogs but is very rare in cats, is associated with metastasis and a poor prognosis.
- Malignant fibrous histiocytoma has been reported at injection sites in cats (see p. 610).

HISTORY, CHIEF COMPLAINT

- Pets with malignant fibrous histiocytomas in the skin and subcutaneous tissue usually present for a progressively enlarging mass noticed by the owner.
- Dogs with malignant fibrous histiocytomas of the spleen usually present for signs related to an abdominal mass or abdominal hemorrhage.

PHYSICAL EXAM FINDINGS

- Malignant fibrous histiocytomas in the skin and subcutaneous tissue often present as firm, palpable masses. Occasionally they are hairless or ulcerated.
- Regional lymphadenomegaly may be present secondary to inflammation or (rarely) lymph node metastasis.
- Dogs with splenic tumors may present with abdominal mass, pain, or abdominal enlargement.

ETIOLOGY AND PATHOPHYSIOLOGY

- Malignant fibrous histiocytomas are typically firm, slow-growing tumors that commonly infiltrate into surrounding soft tissues and along fascial planes. Overall they have a moderate metastatic potential, but some variants or grades may be more likely to metastasize (see prognosis).
- Lesions caused by malignant fibrous histiocytoma depend on the location of the primary tumor.
- These tumors are considered a separate entity from the other histiocytic diseases. Peripheral tumors can metastasize, but usually to the lungs.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis can only be confirmed via histopathologic analysis, although additional testing such as diagnostic imaging is often helpful in defining the extent of the tumor.

DIFFERENTIAL DIAGNOSIS

- Other skin and subcutaneous tumors:
  - Soft-tissue sarcoma
  - Mast cell tumor
  - Others
- Other splenic tumors:
  - Hemangiosarcoma
  - Lymphoma
  - Others

INITIAL DATABASE

- Fine-needle aspirate cytologic analysis may help identify the tumor type before other diagnostics.
- Three-view thoracic radiographs to rule out pulmonary metastases
- Radiographs of the affected area may reveal involvement of underlying bone.
- Abdominal ultrasound to identify splenic tumors and rule out metastasis. However, abdominal ultrasound cannot be relied on to differentiate malignant fibrous histiocytoma from other splenic tumors.
- Fine needle aspirate of draining lymph nodes to help rule out metastasis

ADVANCED OR CONFIRMATORY TESTING

- CT or MRI may be necessary to delineate the local extent of the tumor and plan for surgery or radiation therapy.
- Biopsy: diagnosis of malignant fibrous histiocytoma is based on histopathologic evaluation of tissue.
  - Special stains may be necessary to differentiate malignant fibrous histiocytoma from other soft-tissue sarcomas, especially poorly differentiated tumors.
  - Care should be taken to differentiate these tumors from other histiocytic tumors, including histiocytic sarcoma and malignant histiocytosis (see p. 535). These other tumors usually have a different prognosis and recommended course of treatment.
  - Histopathologic grade of the tumor is necessary for determining the prognosis and treatment of most soft tissue sarcomas (see p. 610).
    - Histopathologic grading typically involves using the general grading system for soft-tissue sarcomas based on mitotic rate, percent necrosis, and degree of differentiation.
    - Tumors are graded as low, intermediate, or high grade.
    - In most cases, high-grade tumors are larger and more invasive, but gross size and invasiveness cannot be used as a substitute for histopathologic grading.

TREATMENT

TREATMENT OVERVIEW

Definitive treatment is based on complete eradication of the primary tumor whenever possible. However, additional treatment such as chemotherapy may be indicated to prevent or delay metastases or in dogs with high-grade tumors, the giant-cell variant of this tumor or tumors that have already metastasized. Palliative treatment options, such as palliative radiation, may help control pain or discomfort in patients with advanced tumors or in patients where definitive treatment cannot be tolerated.

ACUTE AND CHRONIC TREATMENT

- Aggressive surgical resection, radiation therapy, and/or chemotherapy may be used for treatment (see p. 610).
- Chemotherapy may be indicated to delay or prevent metastasis for malignant fibrous histiocytoma affecting the spleen, high-grade tumors, or giant-cell variants of malignant fibrous histiocytoma.

POSSIBLE COMPLICATIONS

Complications of treatment depend on types of treatments and location of the primary tumor.

RECOMMENDED MONITORING

After appropriate local treatment, follow-up examination should be done routinely to monitor for recurrence (every 2-3 months) and metastasis (thoracic radiographs at 6 months and 1 year). High-grade tumors may require more frequent monitoring (at least every 2-3 months) for metastases during and after chemotherapy administration.

PROGNOSIS AND OUTCOME

- Prognosis is excellent for histologically low- to intermediate-grade tumors with appropriate treatment. This includes either surgical resection with clean histopathologic margins or incomplete resection combined with radiation therapy.
- Dogs with the giant-cell variant of this tumor often have metastases at the time of diagnosis or soon afterward, and prognosis is usually poor despite treatment. Few cats with this variant develop metastases.
- Dogs with splenic tumors are more likely to develop metastases and therefore have a poor prognosis.
- High-grade malignant fibrous histiocytoma: like other soft-tissue sarcomas, prognosis is considered guarded based on the increased likelihood for metastases.

PEARLS & CONSIDERATIONS

COMMENTS

Aside from the giant-cell variant, malignant fibrous histiocytoma should be considered like other soft tissue sarcomas (see p. 1034) in treatment and prognosis. Tumors at injection sites in cats should be treated like injection-site sarcomas (see p. 610).

CLIENT EDUCATION

Pet owners can be educated to monitor their pets for palpable or visible masses and have them evaluated in a timely fashion. Early detection may allow for easier treatment via surgery and may help avoid the need for radiation therapy.

EDITOR: KENNETH M. RASSNICK

Malassezia Dermatitis

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

An extremely common pruritic dermatosis caused by the overgrowth of *Malassezia* spp. yeast. Most infections are caused by the lipophilic unicellular organism *Malassezia pachydermatis.*

SYNONYMS

Malasseziasis, yeast dermatitis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Very common in dogs of all ages; uncommon in cats of any age; either sex

GENETICS & BREED PREDISPOSITION: May occur in any breed of dog or cat. Terriers, shih tzus, dachshunds, shar-peis, spaniels, hounds, and German shepherd dogs seem predisposed, likely to underlying conditions favorable to yeast overgrowth. Devon Rex cats are more susceptible.

RISK FACTORS

- Excessive sebum production, poor sebum quality, cutaneous moisture accumulation (particularly in skin folds), a disrupted epidermal surface, and altered host immune defenses. These alterations are often the result of primary underlying diseases (e.g., allergy, endocrinopathy).
- Specific disorders that predispose to cutaneous yeast overgrowth include allergic skin disease (e.g., atopic dermatitis, food allergy, flea allergy, contact allergy), endocrinopathies (e.g., iatrogenic or spontaneous hyper-adrenocorticism, hypothyroidism, hyperthyroidism, diabetes mellitus), primary or secondary cornification disorders, folliculitis (e.g., pyoderma, demodicosis, dermatophytosis), ectoparasitism (e.g., demodicosis, sarcoptic mange, notoedric mange), metabolic diseases (e.g., superficial necrolytic dermatitis, zinc-responsive dermatosis), nutritional deficiencies, cutaneous or internal neoplasia, and in cats, retroviral infections.

CONTAGION & ZOONOSIS: *Malassezia* yeasts have been transmitted from the contaminated hands of dog-owning health care workers to infants in an intensive care nursery, causing mycotic sepsis. Therefore *Malassezia* yeast should be considered a potential zoonotic agent, especially in immunoincompetent individuals.

GEOGRAPHY AND SEASONALITY: *Malassezia* dermatitis may occur more frequently in humid geographic regions, and/or with underlying causes that worsen seasonally (e.g., atopic dermatitis).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Localized dermatitis: involving the face (perioral, muzzle, ears), ventral aspect of the trunk (neck, axillae, inguinal area), perineal region (ventral tail, perianal area), and paw (interdigital web and nail fold)
- Generalized dermatitis: involving several regions as noted above

HISTORY, CHIEF COMPLAINT: Intense pruritus: most common chief complaint. Rancid offensive odor; an oily coat; hair loss (alopecia); redness (erythroderma); thickened, elephant-like skin (lichenification); scaling (dander); and/or relapsing and remitting dermatitis unresponsive to antibiotics or glucocorticoids are also frequently noted.

PHYSICAL EXAM FINDINGS

- Skin lesions reflect existing pruritus and seborrhea and are not specific to *Malassezia* dermatitis.
- Lesional skin may be erythematous, hyperpigmented, hyperkeratotic, lichenified, scaly, greasy or dry, alopecic, saliva-stained, and excoriated. Hyperpigmented lichenification implies chronicity.
- Intertriginous areas (skin folds) are typically affected. Occasionally, yellow/orange to slate gray seborrheic plaques are present in body folds.
- A brown waxy discharge may be evident in the nail folds, signifying paronychia.

- A brown discoloration around the base of white nails may be seen in dogs with *Malassezia* pododermatitis.
- Follicular casts (keratosebaceous material adhered to the proximal hair shaft) might be suggestive of an underlying keratinization disorder.
- Cats, particularly Devon Rex, may present with alopecia, erythema, and greasy exudation of the axillae, groin, and paws.

MALASSEZIA* DERMATITISMalassezia* dermatitis in a miniature poodle. Alopecia, erythema, and lichenification on the ventral neck.

ETIOLOGY AND PATHOPHYSIOLOGY

Malassezia spp. yeasts are part of the normal skin microflora. They become opportunistic invaders when changes occur in the cutaneous microclimate (e.g., lipid composition, relative humidity) or defense mechanisms (e.g., epidermal barrier dysfunction, immunosuppression). Once colonization takes place, yeasts may release proteases and lipases that alter cutaneous homeostasis, allowing for continued yeast overgrowth. In some atopic dogs with cytologic demonstration of yeasts, *Malassezia* may elicit a type-1 cutaneous hypersensitivity reaction.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Malassezia dermatitis should be considered in any pruritic dog or cat. Confirmation requires typical clinical signs, cytological demonstration of yeast, and most importantly, response to antifungal therapy. Underlying primary conditions must be identified and corrected. Importantly, Devon Rex cats may not have an identifiable predisposing disease.

DIFFERENTIAL DIAGNOSIS

Since *Malassezia* dermatitis is a secondary complication of underlying disorders in most cases, the chief differential diagnosis consists of identifying whether the underlying disorder (see Risk Factors, above) exists in an uncomplicated state or if secondary *Malassezia* dermatitis is present.

INITIAL DATABASE

- Skin cytologic analysis is performed on every case with compatible historical/physical findings.
    - Cytologic examination specimens can be obtained by direct impressions, acetate tape preparations, or dry or wet swabs.

- *Malassezia* are ovoid, monopolar budding yeasts that resemble the shape of footprints or peanuts. They are 3-8 mcm in diameter (the same size as, or slightly smaller than, a red blood cell).
- Yeasts are best visualized using high power (40x) or oil immersion (100x).

- Multiple skin scrapings to exclude superficial and deep ectoparasites
- Especially with cats: dermatophyte culture to exclude ringworm

ADVANCED OR CONFIRMATORY TESTING

- Biopsy and histopathologic analysis: rarely necessary
  - Suggestive but nonspecific findings include parakeratotic hyperkeratosis, epidermal hyperplasia, superficial perivascular dermatitis, and possibly eosinophilic microabscesses.
  - Occasionally, yeast may be found in the superficial keratin layer and/or in hair follicles.
  - Other histopathologic findings may represent changes associated with the underlying dermatosis.
  - Loss of surface scale during processing may decrease the chance of finding yeast organisms.
- Elimination diet trial to exclude food allergy
- Intradermal and/or immunoglobulin (Ig)E serologic testing if history and clinical findings are supportive of atopic dermatitis
- CBC, serum chemistry panel, and urinalysis to screen for internal diseases
- Hormonal testing (e.g., screening tests for hyperadrenocorticism, hypothyroidism, and diabetes mellitus)
- Feline retroviral testing

TREATMENT

TREATMENT OVERVIEW

The main goal your job is to reduce pruritus and remove seborrhea. This is accomplished by killing yeast and controlling for underlying primary diseases and risk factors.

ACUTE GENERAL TREATMENT

- Keratomodulating (antiseborrheic) and antiyeast topical therapies (e.g., sulfur/salicylic acid, phytosphingosine, benzoyl peroxide, selenium sulfide, boric/acetic acid, miconazole, clotrimazole, ketoconazole, terbinafine, enilconazole, lime sulfur, or chlorhexidine) can be applied daily to weekly depending on the formulation used (e.g., shampoo, solution, lotion, spray, wipe, powder).
- Systemic antifungal therapy may be warranted for severe infections or those not responding to sole topical therapy. Duration of systemic therapy should persist beyond (e.g., 1-2 weeks) clinical and cytologic improvement (usually a minimum of 3-4 weeks). Griseofulvin has no effect against *Malassezia* species.
  - Ketoconazole, 5-10 mg/kg PO q 24 h with food; other azoles better suited for cats, *or*
  - Itraconazole, 5-10 mg/kg PO q 24 h with (capsules) or without (suspension) food, *or*
  - Fluconazole, 2.5-5 mg/kg PO q 24 h (generic available in some countries), *or*
  - Terbinafine, 30 mg/kg PO q 24 h with food
- Because dogs with *Malassezia* dermatitis frequently have concurrent staphylococcal pyoderma, treating any secondary bacterial infection with oral antibiotics at an appropriate dose and duration (minimum 21 days) will help improve cutaneous signs.

CHRONIC TREATMENT

- Therapy for underlying predisposing diseases
- Topical keratomodulating and/or antiyeast therapy at reduced frequencies of application if possible
- Azole pulse therapy can be used for remitting and relapsing episodes of *Malassezia* dermatitis, as these drugs concentrate in the skin. Typically, the same initial dose is prescribed for 2 consecutive days per week or given daily for 1-week-on/1-to-4-weeks-off cycles after the initial induction dose described in Acute Treatment above.

DRUG INTERACTIONS

Azole therapy may alter the metabolism or distribution of other prescribed medication by inhibiting cytochrome P450 metabolizing enzymes and P-glycoprotein transporting pumps. Terbinafine does not inhibit these enzymes. Specifically, azoles cannot be given with macrocyclic lactones (e.g., avermectins); if so, dosage reduction and close monitoring is required (see p. 706).

POSSIBLE COMPLICATIONS

- Idiosyncratic cutaneous adverse reactions to topical therapies (e.g., pruritus, erythroderma, papular rash, pustulation, vesiculation, necrosis, ulceration) may occur on the patient or person applying therapy and must be considered along with

reassessment of possible underlying causes in “refractory” cases of *Malassezia* dermatitis.
- The patient may have adverse reactions to systemic azoles (e.g., vomiting, diarrhea, hepatotoxicity, vasculitis, lightening of haircoat, pruritus). Ketoconazole may inhibit cortisol synthesis at doses greater than 10 mg/kg/d.

RECOMMENDED MONITORING

- Clinical signs and skin cytology every 2-4 weeks during therapy
- Other monitoring recommendations are at the discretion of the clinician, based on underlying predisposing diseases.

PROGNOSIS AND OUTCOME

- Failure to detect and treat underlying problems will result in partial treatment success, treatment failure, or relapse.
- For incurable diseases (e.g., primary cornification disorders), therapy for *Malassezia* dermatitis may need to be lifelong.

PEARLS & CONSIDERATIONS

COMMENTS

- *Malassezia* dermatitis is one of the most overlooked causes of pruritus in the dog.
- *Malassezia* dermatitis tends to occur in body areas rich in sebaceous glands and high in relative humidity, and is commonly associated with allergic dermatitis.
- How many yeast are cytologically significant? Finding any yeast from typical clinical lesions is significant.
- Dogs with atopic dermatitis may be hypersensitive to *Malassezia,* resulting in yeast numbers disproportionate to the level of pruritus experienced by the animal.
- Skin culture for *Malassezia* yeast is not recommended in clinical practice, as these organisms are residents on the skin.
- Biopsy with histopathologic evaluation is not considered superior to cytologic evaluation for the diagnosis of *Malassezia* dermatitis (most of the surface scale is lost during biopsy processing) but may be useful in the diagnosis of primary skin disorders in addition to which *Malassezia* dermatitis is a secondary phenomenon.
- Do not use selenium sulfide on cats; it is too irritating to their skin.
- Enilconazole is not approved for small-animal use in some countries.
- Griseofulvin has no effect against *Malassezia* species.
- Cats tend to have gastrointestinal upset with oral ketoconazole, so other systemic antifungals are preferred.
- When given in tablet or capsule form, the azole drugs, ketoconazole and itraconazole, are best absorbed systemically if administered with food; failure to do so may reduce bioavailability of these drugs by up to 40%.

PREVENTION

Correctly identifying and treating for all underlying predisposing factors favorable to yeast overgrowth

TECHNICIAN TIPS

Technicians managing patients with *Malassezia* dermatitis should be proficient in collection and examination of cytologic skin samples, and capable of instructing owners on appropriate use of topical therapy.

AUTHOR: ADAM P. PATTERSON

EDITOR: MANON PARADIS

Macadamia Nut Toxicosis

BASIC INFORMATION

DEFINITION

Acute and often self-limiting toxicosis of dogs resulting from ingestion of macadamia nuts. It is characterized by paresis, depression, vomiting, ataxia, tremors, hyperthermia, abdominal pain, lameness, and/or stiffness. Toxicosis can occur after ingestion of commercially available macadamia nuts or macadamia nut-containing cookies or candies.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Currently, the syndrome has been described in dogs only.
- All breeds, ages, and both sexes are susceptible.

RISK FACTORS

- Dogs develop signs of toxicity after ingesting 2.2-62.4 g/kg macadamia nuts.
- Dogs will readily eat large amounts of chocolate-coated macadamia nuts.

GEOGRAPHY AND SEASONALITY

- Macadamia nuts are obtained from *Macadamia integrifolia* and *Macadamia tetraphylla* trees, mostly cultivated in Hawaii in the United States.
- Toxicosis can occur year round, although it is more likely to occur during holiday seasons.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Severity and onset of signs will depend on amount of macadamia nuts ingested.
- Majority of dogs show clinical signs within 12 hours after ingestion.
- Clinical signs usually resolve within 24-48 hours.

HISTORY, CHIEF COMPLAINT

- History of exposure to macadamia nuts
- Evidence of macadamia nuts in the vomitus or in the stool
- Hind limb weakness, depression, vomiting

PHYSICAL EXAM FINDINGS

- Hind limb weakness with no evidence of central nervous system involvement, musculoskeletal pain, or trauma
  - Rarely, generalized weakness is possible.
  - Forelimb weakness without hind limb weakness is inconsistent with macadamia nut toxicosis.
  - Respiratory muscle paralysis likewise has not been a feature of macadamia nut toxicosis in dogs.
- Mild tremor of hind limbs
- Depression
- Vomiting
- Ataxia
- Hyperthermia (due to tremor; not true fever)

ETIOLOGY AND PATHOPHYSIOLOGY

- Exact cause and mechanism of macadamia nut toxicosis are not clear.
- Evidence suggests that the syndrome is dog specific.
- Toxic principle in macadamia nuts is not known at this time.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based entirely on history and physical signs: observed or suspected ingestion of macadamia nuts, especially if concurrent signs (paresis, ataxia, stiffness, hyperthermia, and/or vomiting within 12 hours of exposure) are present, is sufficient to warrant treatment.

DIFFERENTIAL DIAGNOSIS

- Rule out other toxicoses that can cause hind limb weakness, ataxia, and vomiting:
  - Ethylene glycol
  - Cholinesterase inhibitor pesticides: organophosphates and carbamates
  - Marijuana (dogs)
  - Phenoxy herbicide (2,4 D)
  - Coral snake bite
  - Bromethalin (dogs)
- Rule out nontoxic causes for hindlimb weakness and ataxia (see p. 837):
  - Systemic disturbances (e.g., anemia, acid-base or electrolyte abnormalities, cardiac arrhythmias)
  - Neuromuscular disorders (polyradiculoneuritis, myasthenia gravis, tick paralysis, botulism)
  - Orthopedic disorders
  - Trauma
  - Right-to-left shunting patent ductus arteriosus (weakness confined to hind limbs)

INITIAL DATABASE

- Abdominal radiographs (may show a large amount of ingesta in the gastrointestinal tract)
- Examination of stomach contents for presence of macadamia nuts (if vomiting occurs)
- Rectal palpation may show presence of macadamia nuts in feces.
- Body temperature
- A complete medical examination is needed if concurrent ingestion of other harmful compound is suspected and to rule out any preexisting condition.

ADVANCED OR CONFIRMATORY TESTING

Serum biochemistry profile: mild elevation in serum triglycerides and serum alkaline phosphatase may be noted but is nonspecific.

TREATMENT

TREATMENT OVERVIEW

Treatment is general and supportive: induction of emesis and administration of activated charcoal if ingestion is suspected or confirmed and patient is stable. Management of complications of severe intoxications (e.g., nursing care if recumbent; treatment of hyperthermia) is applied as needed. Most clinical signs resolve within 24-48 hours with or without treatment.

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Emesis (within 2-4 hours after ingestion in dogs not showing overt clinical signs; see p. 1364); *or*
    - Apomorphine (0.03-0.04 mg/kg IV or IM, or crush tablet portion with water and instill into conjunctival sac, rinse after emesis); *or*
    - Hydrogen peroxide 3% (2 mL/kg, max 45 mL PO, repeat in 10-15 minutes if no vomiting)
  - Activated charcoal:
    - Give after inducing emesis or if a few hours have elapsed after exposure; administer activated charcoal (1-4 g/kg) with a cathartic such as 70% sorbitol (3 mL/kg) orally.
  - Warm tap water enema (5-10 mL/ kg) with large ingestion may help move the macadamia nuts more quickly through the gastrointestinal tract.
  - Supportive care:
    - Administer IV fluids as needed.
    - Thermoregulation (cold bath, cooling fans if needed)

RECOMMENDED MONITORING

Serum electrolytes, biochemistry profile, and triglycerides in severely affected dogs

PROGNOSIS AND OUTCOME

- Generally, excellent prognosis
- Dogs recover with or without treatment within 24-48 hours

PEARLS & CONSIDERATIONS

COMMENTS

- Consider concurrent methylxanthine (chocolate) toxicosis if macadamia nuts were covered with chocolate and large amounts of macadamia have been ingested.
- Mild uncomplicated cases may resolve with home observation for 12 hours.

PREVENTION

Keep macadamia nuts out of reach of dogs

EDITOR: SAFDAR A. KHAN

1ST EDITION AUTHOR: MOAZZAM KHAN

Nystagmus

BASIC INFORMATION

DEFINITION

Repetitive, rapid, and involuntary movement of the globe of the eye in a horizontal, rotary, or vertical manner

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Any age or breed, either sex
- Idiopathic vestibular disease is more common in older dogs (>8 years) but affects cats of all ages.

GENETICS & BREED PREDISPOSITION

- Cats: pendular nystagmus occurs in otherwise normal Siamese cats. Vestibular nystagmus is a congenital abnormality in Siamese, Tonkinese, and Burmese breeds.
- Dogs: vestibular nystagmus is a congenital abnormality in the Doberman pinscher, cocker spaniel, German shepherd, and other breeds.

GEOGRAPHY AND SEASONALITY: Idiopathic vestibular disease in cats may predominate in late summer/early fall.

ASSOCIATED CONDITIONS & DISORDERS: Frequently associated with head tilt, ataxia, circling, vomiting, and anorexia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Types of nystagmus:

- Vestibular nystagmus: eye movements are faster in one direction than in the other (fast phase and slow phase for each cycle of the nystagmus); also called *jerk nystagmus*.
- Pendular nystagmus: no fast or slow phase. Pendular nystagmus is uncommon, is a congenital anomaly, and is not associated with vestibular disease or progression of signs.

HISTORY, CHIEF COMPLAINT

- Vestibular nystagmus usually is acute in onset (e.g., idiopathic vestibular disease):
  - The animal may initially exhibit vomiting, followed by vestibular ataxia, circling, or even whole-body rolling.
  - The owners may not notice the nystagmus.
- Much less common are pendular nystagmus or congenital vestibular nystagmus that are present from birth and not associated with deteriorating vestibular function; chief complaint is limited to eye movements.

PHYSICAL EXAM FINDINGS

- Nystagmus due to peripheral vestibular disease (not all signs may be present):
  - Jerk nystagmus (horizontal or rotary) with fast phase away from the side of the vestibular lesion and away from the side of the head tilt
  - The nystagmus may be difficult to observe, especially in the cat, and may be observed only when the animal's head is changed in position (especially dorsal extension of the neck) or when the animal is placed on its back.
  - Head tilt
  - Circling
  - Ataxia with falling to the side of the lesion and to the side of the head tilt
- Nystagmus due to central vestibular disease (not all signs may be present):
  - Jerk nystagmus (horizontal, rotary, or vertical) with fast phase away from the side of the vestibular lesion and away from the side of the head tilt
  - Head tilt toward the side of the lesion
  - Circling
  - Ataxia

- Proprioceptive deficits, motor weakness on the side of the lesion
- Central vestibular disease may (rarely) cause paradoxical signs (the nystagmus fast phase is away from the side of the lesion). Proprioceptive deficits indicate the true side of the lesion (ipsilateral).
- Other cranial nerve deficits (V, VI, VII)

ETIOLOGY AND PATHOPHYSIOLOGY

- The vestibular system allows the body to know its position in space (proprioception) relative to head position, gravity, and linear or rotary acceleration.
- Sensory fibers in the peripheral vestibular system send impulses to the nuclei of cranial nerves III, IV, and VI, coordinating eye movements and allowing the eyes to remain centered on an object until it is beyond the visual field; then, the eyes are able to jerk back to again center on an object ("watching railroad cars go by").
- Damage to the vestibular system can stimulate these eye movements inappropriately, producing nystagmus.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Nystagmus is specific to vestibular dysfunction. Therefore, the diagnostic process identifies whether the brain (central) or inner/middle ear (peripheral) is the site of the lesion, which can usually be determined with a clinical neurologic exam. Further testing is selected based on a differential diagnosis list elaborated from history, physical exam, and neurologic exam findings.

DIFFERENTIAL DIAGNOSIS

- Nystagmus from peripheral vestibular disease:
  - Idiopathic
  - Bacterial infection (otitis media/interna)
  - Neoplasia
  - Hypothyroidism (rare)
  - Post surgery on the middle ear (ear ablation in the dog, removal of polyps in the cat)
  - Congenital or hereditary
- Central vestibular nystagmus:
  - Infection
  - Neoplasia
  - Trauma
- Pendular nystagmus: congenital disease affecting the visual pathway

INITIAL DATABASE

- Neurologic examination (see p. 1311)
- CBC, serum biochemistry profile, urinalysis: usually unremarkable
- Otoscopic exam
  - Otitis externa, polyp, blood (head trauma) possible
  - Careful examination may reveal fluid in the middle ear for cases with infectious causes
- Radiographs of the tympanic bullae

ADVANCED OR CONFIRMATORY TESTING

- MRI or CT of the middle ear and posterior fossa of the brain (see p. 1302 and p. 1233)
- Cerebrospinal fluid (CSF) analysis if signs of central vestibular disease are present (see p. 1228)
- For cases in which there is no nystagmus but other clinical signs suggest vestibular disease, a postrotary nystagmus evaluation may be performed:
  - The animal is rotated in a circle first in one direction for 10 rotations, and the duration of nystagmus is noted.
  - The animal is then rotated in the opposite direction, and the duration of the postrotary nystagmus is again noted.
  - Postrotary nystagmus is usually less or absent when the animal is spun away from the side of the lesion.

TREATMENT

TREATMENT OVERVIEW

Treatment goals are improvement in the clinical condition by decreasing nausea and anorexia, and treatment of the primary cause when possible.

ACUTE GENERAL TREATMENT

- Nystagmus is a clinical sign associated with various underlying causes. Therefore, treatment is aimed at the primary disorder.
- Since it may be difficult for the animal to walk or stand, good nursing care is very important: The animal should be able to get to food and water and should be cleaned after urinating or defecating so urine or fecal scalding is avoided.

POSSIBLE COMPLICATIONS

Treatment of otitis with products that contain aminoglycoside antibiotics may be detrimental (ototoxic), particularly if the tympanum is not intact.

PROGNOSIS AND OUTCOME 

- The prognosis for idiopathic vestibular disease and nystagmus caused by otitis media/interna are good to excellent for both dogs and cats, but recurrence is possible.
- A head tilt may remain after resolution of all other signs.
- The prognosis for neoplasia and virtually all causes of central vestibular nystagmus is guarded to poor.

PEARLS & CONSIDERATIONS 

COMMENTS

- Idiopathic peripheral vestibular disease causes nystagmus in the majority of cases (for cats and dogs); the condition should resolve spontaneously in 1-2 weeks.
- Idiopathic vestibular disease is a diagnosis of exclusion.
- Nearly all patients with nystagmus caused by central vestibular disease will have other central nervous system (CNS) signs (proprioceptive defects, weakness, other cranial nerve involvement).

CLIENT EDUCATION

When idiopathic vestibular disease is the primary consideration, the owners need to know that the problem will usually resolve with time.

Nutritional Secondary Hyperparathyroidism

BASIC INFORMATION

DEFINITION

Chronic elevation of circulating parathyroid hormone (PTH) resulting from low serum ionized calcium concentrations (iCa) due to deficiency of absorbed calcium or vitamin D or due to a calcium/phosphorus (Ca:P) imbalance

SYNONYMS

NSHP, nutritional osteodystrophy. The term *rickets* describes bony changes consistent with a vitamin D deficiency.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Nutritional secondary hyperparathyroidism (NSHP) is seen in young, growing animals of any sex or species that have been fed an improperly formulated diet. The condition is occasionally seen in older animals, especially those with malabsorptive disorders.

GENETICS & BREED PREDISPOSITION: Young, large-breed dogs may be at increased risk because of rapid growth rate.

RISK FACTORS

- Animals fed improperly formulated homemade (especially all-meat) diets, particularly during growth. Such diets typically contain decreased calcium and/or increased phosphorus, with a Ca:P ratio of =1:16 (1:1-2:1 for dogs and 1:1-1.5:1 for cats is recommended) and inadequate vitamin D.
- Exotic pets, since dietary requirements for calcium, phosphorus, and vitamin D are not always known
- Animals with severe gastrointestinal disease that limits calcium or vitamin D absorption

GEOGRAPHY AND SEASONALITY: Condition may be more common in winter months in some indoor-housed exotic pets, owing to decreased exposure to sunlight.

ASSOCIATED CONDITIONS & DISORDERS: Animals may have decreased bone density or fractures related to increased circulating PTH.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Inadequate dietary calcium or vitamin D concentration or altered dietary Ca:P ratio
- Inadequate absorption of dietary calcium and vitamin D due to intestinal disease

HISTORY, CHIEF COMPLAINT

- History of a poorly formulated homemade diet
- Excessive use of supplements such as meats, vitamins, and minerals
- History of malabsorption due to intestinal disease
- Reluctance to walk, stiff gait, bone pain, lameness, or limb deformities (pathologic bone fractures); tooth loss; ± neurologic signs if the axial skeleton is involved
- Signs of hypocalcemia: twitching, tremors, stiffness, or seizures (rare)

PHYSICAL EXAM FINDINGS

- Bone palpation may elicit pain; fractures may be noted.
- Swelling of costochondral junctions or metaphyses may be evident.

ETIOLOGY AND PATHOPHYSIOLOGY

- Inadequate calcium absorption decreases iCa, increasing PTH production.

- Inadequate absorbed vitamin D decreases calcitriol production, decreasing iCa and increasing PTH production.
- PTH stimulates renal 1,25-dihydroxyvitamin D (calcitriol, the active metabolite of vitamin D) synthesis and bone resorption and increases renal calcium resorption and phosphorus excretion.
- Calcitriol also stimulates bone resorption to raise iCa into the normal range and decreases PTH production.
- Excessive PTH production reduces bone density, and pathologic fractures may occur.
- Excess circulating phosphorus also inhibits calcitriol synthesis and can lower iCa by the mass law effect.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is strongly suspected in young animals with a history of an inadequate diet, radiographic evidence of diffuse bone loss, and pathologic fractures.

DIFFERENTIAL DIAGNOSIS

- Other causes of lameness, bone pain, loss of bone density, or fractures, including congenital problems in young animals
- Renal secondary hyperparathyroidism (ruled out based on serum biochemistry profile and urinalysis)
- Hyperadrenocorticism associated secondary hyperparathyroidism in older dogs (ruled out based on adrenal function testing and clinical signs)
- Genetic defects in calcitriol production or utilization (rare). Clinical signs are the same in the absence of compatible diet history or malabsorptive disorder.

INITIAL DATABASE

- CBC and serum biochemical profile: serum total calcium concentration normal to low. NOTE: Serum phosphorus and alkaline phosphatase may be elevated in normal animals, especially in those who are young and growing.
- Radiography of the skull, axial skeleton, and limbs: diffusely decreased cortical bone density; fractures possible.
- Dietary history

ADVANCED OR CONFIRMATORY TESTING

- Measure PTH (increased), iCa (low to normal), and 25-hydroxyvitamin D (25-OH-D; typically low) concentrations to confirm the diagnosis.
- Serum calcitriol determination, although helpful, currently is not readily available.
- Vitamin/mineral analysis of homemade diets may be useful.

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to increase intestinal absorption of calcium and vitamin D and decrease PTH production.

ACUTE GENERAL TREATMENT

- Feed a properly formulated diet.
- Stop the feeding of all supplements.
- Supportive therapy for pain or fractures (cage rest or limited activity as indicated)
- Treatment of malabsorption when present
- Dietary supplementation with oral calcium (25-50 mg/kg elemental Ca [e.g., 62.5-125 mg/kg calcium carbonate] daily) if clinical signs of hypocalcemia are present, discontinuing when signs resolve (see p. 576)

CHRONIC TREATMENT

- Ensure that a properly formulated diet is fed.
- If a homemade diet is fed, a sample of the diet may be sent for vitamin D and mineral analysis.
- Supplemental oral calcium may be indicated in cases of chronic malabsorption.

RECOMMENDED MONITORING

- Clinicians should repeat tests of PTH, iCa, and 25-OH-D concentrations 3-4 weeks after initiating treatment. PTH should be decreased and 25-OH-D increased compared to pretreatment values. Clinicians should monitor the animals monthly until levels are normal.
- Clinicians can measure PTH, iCa, and 25-OH-D concentrations every 3-4 months, even if secondary hyperparathyroidism has resolved and if intestinal malabsorption is present.
- Clinicians should order repeat radiography tests to assess bone density and fracture healing.

PROGNOSIS AND OUTCOME

- Depends on presence of pathologic fractures, which worsen the prognosis because of pain and a potentially long convalescent period.
- Incidentally discovered NSHP that is due to inappropriate diet typically carries a good prognosis.
- For animals with malabsorption, the prognosis depends on the underlying cause and effectiveness of therapy.

PEARLS & CONSIDERATIONS

PREVENTION

Clinicians should inform owners to:

- Feed their pets nutritionally complete and balanced pet foods rather than improperly formulated homemade diets.
- Avoid supplementing balanced diets with meats, vitamins, or minerals.

CLIENT EDUCATION

- Clinicians should explain skeletal problems associated with deficiencies of calcium or vitamin D or with the excess of phosphorus to clients feeding homemade diets to their pets, especially to young, growing animals.
- Clinicians should have the adequacy of homemade diets verified by a veterinary nutritionist.
- Clinicians should suggest periodic nutrient analysis of homemade diets, especially for vitamin D and mineral content.

Nonsteroidal Antiinflammatory Drug Toxicosis

BASIC INFORMATION

DEFINITION

A common toxicosis secondary to acute overdose or chronic administration of a nonsteroidal antiinflammatory drug (NSAID), most commonly affecting the gastrointestinal (GI) tract or kidneys. Hepatopathy is also possible.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cats generally more sensitive than dogs because of deficiency in enzymes which metabolize these drugs.
- Most cases are reported in dogs. All breeds and both sexes are susceptible.
- Elderly and very young animals are at higher risk.

GENETICS & BREED PREDISPOSITION: Labrador retrievers are not considered at greater risk for developing hepatic adverse effects from carprofen administration, despite the fact that one third of the initially reported cases of hepatic syndrome were in Labradors.

RISK FACTORS

- Preexisting renal, cardiovascular, or hepatic disease may increase severity of signs.
- Dehydration, hypotension, and concurrent use of other potentially nephrotoxic drugs can potentiate signs.
- Concurrent use of other NSAIDs or corticosteroids may lead to severe complications.
- Hypoproteinemia or concurrent use of other highly protein-bound drugs can result in higher active drug levels.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute toxicosis: after a single large ingestion (usually 5-10 times the recommended dose)
- Chronic toxicosis: in sensitive animals after NSAID use for days, weeks, or months at recommended doses

HISTORY, CHIEF COMPLAINT

- History of exposure (acute or chronic) to an NSAID
- Clinical signs typically begin within hours after acute exposure (exception: days or weeks with chronic therapeutic use or when hepatopathy develops).
- Vomiting (±hematemesis), anorexia, lethargy, diarrhea (melena)
- Polyuria and polydipsia (PU/PD; due to kidney disease/renal failure)

PHYSICAL EXAM FINDINGS

- Variable, from minor GI upset to life-threatening effects of GI perforation
- Minor to moderate toxicosis: signs of abdominal pain, vomiting, diarrhea, lethargy, anorexia
- Severe toxicosis: dehydration, pallor, tachycardia, icterus, bruising (aspirin), hyperthermia (aspirin), ataxia, seizures, sudden death
- Hematemesis or melena is not reliably linked to GI perforation, and absence of hematemesis is not an indicator of absence of perforation.

ETIOLOGY AND PATHOPHYSIOLOGY

- Examples of commonly-implicated NSAIDs:
  - Acetic acid derivatives: diclofenac, etodolac (EtoGesic)*, indomethacin, nabumetone
  - Cyclooxygenase (COX)-2 inhibitors: celecoxib, deracoxib (Deramaxx)*
  - Fenamic acids: meclofenamic acid

- Oxicams: meloxicam (Metacam)*, piroxicam
- Propionic acids: carprofen (Rimadyl)*, flurbiprofen, ibuprofen, ketoprofen, naproxen
- Pyrazolones: phenylbutazone
- Salicylic acid derivatives: aspirin, flunixin meglumine

- NSAIDs inhibit COX enzymes, blocking prostaglandin (PG) production. PGs formed by COX-1 are important for normal physiologic function (GI protection, renal medullary blood flow). PGs formed by COX-2 mediate inflammation. Therefore adverse effects are generally fewer when COX-2 is selectively inhibited.
- NSAID hepatopathy is due to the formation of antigenic proteins that trigger an immune-mediated attack against the liver.

*Approved for use in dogs in the United States

DIAGNOSIS

DIAGNOSTIC OVERVIEW

In most cases, exposure is known (whether acute overdose or ongoing therapeutic administration). In acute overdoses, history and clinical signs may be sufficient to make the diagnosis. In chronic treatment-associated toxicosis, detailed diagnostic testing and/or drug discontinuation to monitor for regression of signs (if mild toxicosis) is often required to distinguish between NSAID toxicosis and naturally occurring disorders mimicking NSAID toxicosis.

DIFFERENTIAL DIAGNOSIS

Any disease process that can cause GI, renal, or hepatic adverse effects.

INITIAL DATABASE

- CBC: anemia from GI hemorrhage (regenerative), leukocytosis (stress or peritonitis) possible
- Serum chemistry profile: azotemia (prerenal or primary renal insult [usually within 24-48 hours after exposure in acute toxicosis]) or elevated liver enzymes and bilirubin (hepatopathy)
- Urinalysis: hematuria, glycosuria, pyuria, proteinuria, casts, and isosthenuria possible with renal injury
- Abdominal radiographs: free air in peritoneal cavity strongly suggests GI tract perforation.

ADVANCED OR CONFIRMATORY TESTING

- Usually, serum/plasma drug levels are not useful clinically.
- Endoscopy (with persistent nonspecific GI signs, especially when NSAID therapy is not discontinued): GI ulceration/irritation /perforation
- Histopathologic evaluation:
  - Stomach (endoscopic or surgical): irritation/duodenal ulceration/hemorrhage; peritonitis if gastric perforation
  - Kidneys (postmortem): renal tubular or papillary necrosis or interstitial nephritis
  - Liver (if persistent enzyme elevation; rarely performed): multifocal to bridging hepatocellular degeneration and necrosis (apoptosis), with mild to moderate periportal inflammation (neutrophils and lymphocytes)

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are decontamination of the patient (induce vomiting and give repeated doses of activated charcoal), preventing/managing/monitoring GI, renal, and hepatic effects, and providing supportive care.

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Induction of vomiting (see p. 1364): indicated in any acute overdose patient not showing clinical signs
  - Activated charcoal: 1-3 g/kg PO (or as labeled) with a cathartic, repeated (half dose) q 6-8 h to reduce enterohepatic recirculation of NSAID
- Prevent and/or manage GI effects with combination therapy (sucralfate + H^2 receptor antagonist or proton pump inhibitor + misoprostol):
  - Misoprostol for dogs: 1-3 mcg/kg PO q 8 h. Prostaglandin analog, helps replace NSAID-induced PG depletion.
  - H^2 receptor antagonist: famotidine: 0.5 mg/kg PO, SQ, IM, IV q 12-24 h (dogs, cats)

- Proton pump inhibitor: omeprazole 0.5-1 mg/kg PO q 24 h (dogs, cats)
- Sucralfate: 0.25-1 g PO q 8-12 h (dogs, cats)

- Prevent and/or manage renal effects:
  - Fluid diuresis (2-3 times maintenance rate, barring cardiovascular disease) to enhance NSAID excretion and maintain renal perfusion. For at least 48 h if potential renal toxicity dose has been ingested.
- Prevent and/or manage hepatic effects:
  - Discontinue use of NSAID.
  - Begin IV fluids.
  - Administer vitamin K^1 (1-2 mg/kg PO) if evidence of coagulation disruption.
  - *S*-adenosyl-L-methionine (SAMe), 18 mg/kg PO q 24 h for 1-3 months
- Supportive care:
  - Control vomiting with metoclopramide (0.2-0.4 mg/kg q 6 h PO, SQ, or IM or 1-2 mg/kg/d IV as constant rate infusion) or maropitant, 1 mg/kg SQ q 24 h for up to 5 consecutive days.
  - Correct fluid losses and electrolyte changes.
  - Control seizures with diazepam 1-2 mg/kg IV.
  - Administer a blood transfusion if needed.
  - Treat GI tract perforation (laparotomy, antibiotics) if suspected.

CHRONIC TREATMENT

Some animals may need long-term therapy for renal or hepatic insufficiency.

NUTRITION/DIET

Use appropriate prescription diets in patients with kidney or liver dysfunction.

DRUG INTERACTIONS

- Concurrent use of corticosteroids or other NSAIDs may dramatically increase the risk for adverse effects.
- Increased serum drug levels: phenytoin, valproic acid, oral anticoagulants, sulfonamides, sulfonylurea hypoglycemic agents, ketoconazole, methotrexate, and fluconazole
- Increased risk of nephrotoxicity: aminoglycosides, angiotensin-converting enzyme (ACE) inhibitors, and diuretics

POSSIBLE COMPLICATIONS

- Chronic kidney disease
- Hepatopathy
- GI perforation and peritonitis

RECOMMENDED MONITORING

- Blood urea nitrogen, serum creatinine, electrolytes, urinalysis (baseline, 24, 48, 72 hours in acute cases)
- Serum liver enzymes and bilirubin (for hepatopathy)

PROGNOSIS AND OUTCOME

- Excellent from mild to moderate gastric irritation/ulceration with appropriate treatment
- Guarded to poor with GI tract perforation
- Renal effects of NSAIDs are reversible if discovered early and treated intensively.
- Recovery from idiosyncratic hepatic toxicity is good when NSAID is discontinued and with supportive care.

PEARLS & CONSIDERATIONS

COMMENTS

For most NSAIDs, the minimum toxic/lethal dose is unknown. Generally, a single acute ingestion of 5-10 times more than the recommended dose could cause potentially severe GI irritation/ulceration in dogs.

- Some NSAIDs (naproxen and meclofenamic acid) have a much longer half-life in the dog, owing to extensive enterohepatic recirculation (naproxen: 92 hours).

- Check baseline CBC and serum biochemistry profile in all patients before long-term use of NSAIDs.

PREVENTION

- Clinicians should inform owners to keep all NSAIDs, especially chewables, out of the reach of pets.

TECHNICIAN TIPS

Clients may ask casually about using over-the-counter NSAIDs like ibuprofen in their dog or cat. Ibuprofen is not recommended in small animals; it is the most commonly reported NSAID toxicity.

CLIENT EDUCATION

Discuss common adverse effects associated with NSAIDs. Owners should not give any medications to their pets without first consulting a veterinarian.

Nodular Skin Disorders

BASIC INFORMATION

DEFINITION

A large group of diseases that manifest as solid elevated lesions of the skin of >1 cm in diameter, usually as a result of infiltration of inflammatory or neoplastic cells into the dermis or subcutis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Seen in cats and dogs
- Neoplastic conditions are more common in mature individuals.

GENETICS & BREED PREDISPOSITION

- Familial vasculopathy and nodular dermatofibrosis of German shepherd
- Histiocytic sarcoma complex in Bernese mountain dog, Rottweiler, golden retriever (see p. 535)
- Sterile nodular panniculitis in dachshunds (see p. 824)
- Mucinosis in the shar-pei

RISK FACTORS

- Any disease or medication that causes immune compromise (e.g., feline leukemia virus [FeLV] infection, feline immunodeficiency virus [FIV] infection, hyperadrenocorticism, hypothyroidism, diabetes mellitus) predisposes animals to infections, which in turn may cause nodular dermatoses.
- Foreign-body penetration, bite wound: increased risk of infectious nodular dermatitis
- Mineralizing fat necrosis/panniculitis in dogs with pancreatitis or pancreatic carcinomas

CONTAGION & ZOONOSIS

- Dermatophytic granuloma: *Microsporum canis* and *Trichophyton mentagrophytes* are potentially contagious to human and other animals.
- Sporotrichosis: Cat-to-human transmission is extremely high. Dog-to-human transmission has not yet been described.
- Blastomycosis, coccidioidomycosis, histoplasmosis: risk of zoonosis by aerosol from culture plates; in-house culture is always contraindicated.

GEOGRAPHY AND SEASONALITY: Straelensiosis: France, Spain, Portugal; Sporotrichosis: outbreak in Brazil; See Blastomycosis, p. 138; Histoplasmosis, p. 538; Coccidioidomycosis, p. 222; Pythiosis and Lagenidiosis, p. 960; Protothecosis, p. 926.

ASSOCIATED CONDITIONS & DISORDERS: Renal cystadenocarcinoma is typically a concurrent finding with nodular dermatofibrosis.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Animals present with acute to chronic onset of single or multiple subcutaneous nodules, with or without draining tracts, and potentially accompanying systemic signs such as fever, cough, rhinitis, anorexia lethargy.

PHYSICAL EXAM FINDINGS: Lesions are elevations above the epidermal surface of 1 cm or greater in diameter. They can be solitary to multiple, localized to generalized, firm to fluctuant, draining or intact, and pruritic to nonpruritic, all depending on the underlying etiology. Depending on etiology, systemic signs such as fever and/or coughing may be noted.

ETIOLOGY AND PATHOPHYSIOLOGY

Nodules, which are larger than papules (<1 cm diameter), are usually the result of a massive infiltration of inflammatory and/or neoplastic cells into the dermis or subcutis. The inflammatory cells are in response to an infectious, antigenic, or neoplastic etiology.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Nodular skin disorders are caused by a variety of different etiologies. Biopsies for histopathologic examination and/or bacterial and fungal cultures are often required in order to obtain a diagnosis.

DIFFERENTIAL DIAGNOSIS

- Noninfectious granuloma/pyogranuloma:
  - Idiopathic sterile pyogranuloma/granuloma; sterile nodular panniculitis
  - Juvenile cellulitis (see p. 627)
  - Foreign-body reaction
  - Acral lick granuloma (see p. 22)
  - Sarcoidosis
  - Histiocytic diseases (see p. 535; histiocytoma, cutaneous or systemic histiocytosis)
  - Cutaneous xanthomatosis
- Infectious granuloma/pyogranuloma:
  - Bacterial/botryomycosis, methicillinresistant bacteria, actinomycotic
  - Systemic and subcutaneous/intermediate fungal, dermatophytic pseudomycetomas
  - Feline leprosy, atypical mycobacterial infection (see p. 737), canine leproid granuloma
  - *Rhodococcus equi* infection
  - Toxoplasmosis (see p. 1105), leishmaniasis (see p. 643)
- Lymphocytic/plasmacytic:
  - Lupus profundus (panniculitis associated with systemic lupus erythematosus [SLE]; see p. 1070)
  - Vaccine reaction, drug eruption (see p. 323), erythema nodosum
  - Plasma cell pododermatitis (see p. 891)
  - Lymphomatoid granulomatosis
  - Pseudolymphoma
  - Epitheliotropic lymphoma
  - Plasmacytoma
- Neutrophilic:
  - Deep pyoderma *(Pseudomonas. Staphylococcus;* see p. 951)
  - Familial vasculopathy of German shepherds
  - Abscess
- Eosinophilic:
  - Eosinophilic granulomas, insect-bite granulomas, straelensiosis
  - Dracunculiasis, dirofilariasis
  - Pythiosis (see p. 960)
  - Ruptured hair follicle
- Other fibrosing, dysplastic, or neoplastic cells:
  - Dermoid cyst/pilonidal cyst (see online chapter: Pilonidal Cyst)
  - Acral pruritic nodule/fibropruritic nodule
  - Calcinosis circumscripta
  - Nodular dermatofibrosis (see p. 834)
  - Mucinosis
  - Hemangioma, sebaceous gland hyperplasia/adenoma
  - Mast cell tumors (see pp. 669 and 701), cutaneous lymphoma (T-cell, B-cell; see p. 671), melanoma (see p. 711), transmissible venereal tumour (see p. 1114)

INITIAL DATABASE

- Dermatologic exam to rule out *Cuterebra* infestation, protruding foreign bodies, and any other grossly visible etiologies
- Skin scrapings to identify possible *Demodex* mites or *Dirofilaria*
- Impression smears from draining material for cytologic examination
- Fine-needle aspirate to acquire cells for cytologic examination or discover *Dracunculus* parasite
- Cytologic examination of an impression smear or fine-needle aspirate to help identify any evidence of:
  - Infectious organisms:
    - Coccal *(Staphylococcus* spp.) or rod-shaped *(Pseudomonas* spp.) bacteria
    - Gram-positive branching filamentous organisms: *Actinomyces* spp. (non-acid-fast); *Nocardia* (partially acid-fast)
    - Diff-Quik: yeast or fungal elements of systemic mycoses sometimes detectable

        - Acid-fast bacilli: atypical mycobacteria, feline lepraemurium
        - Spindle- to crescent-shaped protozoal organisms (*Toxoplasma gondii* or *Neospora caninum)*
        - Amastigotes in Giemsa-stained smears (leishmaniasis)
        - Nematodes (dracunculiasis) or microfilaria (dirofilariasis)
        - Organisms in foamy macrophages (may be noted)
    - Noninfectious findings:
        - Foamy macrophages without evidence of infectious agents often detected with sterile nodular panniculitis.
        - Eosinophils noted with eosinophilic granulomas, foreign body, or insect bite reactions.
        - Neoplastic cells: round cell tumors (e.g., histiocytes, mast cells, plasmacytoma)
- Surgical biopsies to obtain a sufficiently deep sample to incorporate the panniculus. If using a punch biopsy, clinicians should be certain to double-punch to obtain the subcutaneous fatty tissue.
- Dermatohistopathologic evaluation required to:
    - Differentiate the cellular infiltrate (neutrophils, histiocytes, plasma cells, lymphocytes, eosinophils, multinucleated giant cells, neoplastic cells)
    - Identify the presence of infectious organisms with the aid of special stains (GMS, PAS, Fite's acid-fast)
    - Help direct advanced diagnostics

ADVANCED OR CONFIRMATORY TESTING

- Clinicians should submit part of a biopsy specimen aseptically for tissue maceration and culture.
- Clinicians should also be certain to notify the laboratory of suspected organisms (adjustments to culture media selection and incubation times; precautions).
    - Bacterial culture and sensitivity testing:
        - Aerobic: *Staphylococcus* spp., *Rhodococcus equi, Nocardiosis*
        - Anaerobic: *Actinomycosis*
    - Rapid-growing atypical mycobacterial culture
    - Fungal culture (many are biohazards; clinicians should notify the laboratory and not culture these in-house): protothecosis, blastomycosis, histoplasmosis, coccidioidomycosis, cryptococcosis, pythiosis, sporotrichosis, zygomycosis, and phaeohyphomycosis, as well as dermatophytic granulomas.
    - Negative cultures support a diagnosis of sterile nodular panniculitis, lupus profundus, sterile pyogranuloma/granuloma syndrome, immune-mediated conditions and neoplasia.
- For the detection of antibody deposition (lupus) and identification of infectious agents that are at times difficult to culture or typically found low in numbers (canine sporotrichosis with direct immunofluorescence [DIF], leishmaniasis with PCR):
    - DIF
    - Fluorescent antibody testing
    - Immunoperoxidase staining
    - Immunohistochemistry
    - Immunostaining with polyclonal BCG antibody (promising method)
    - PCR
- Serologic testing:
    - *Coccidioides, Blastomyces, Cryptococcus, Histoplasma, Leishmaniasis*
- Additional laboratory tests:
    - FeLV/FIV
    - Antinuclear antibody (lupus profundus, SLE) testing
    - CBC/serum biochemistry/thyroid profile/urinalysis:
        - Rule out any metabolic disturbances resulting in immunosuppression.
        - Evidence of concurrent immune-mediated process (e.g., SLE)
        - Baseline prior to commencing any long-term medications
- Diagnostic imaging:
    - Radiographs: metastasis or infection dissemination
    - Abdominal ultrasound: clinicians should evaluate concurrent factors (pancreatitis, hyperadrenocorticism) and invasion of neoplasms (mast cell tumor, histiocytic sarcoma) into abdominal organs.

TREATMENT 

TREATMENT OVERVIEW

Because the group of nodular skin disorders encompasses such a variety of etiologies, treatment is dependent on identification of the specific cause.

PROGNOSIS AND OUTCOME 

Variable: good to poor depending on the ability to identify and specifically treat the underlying etiology

PEARLS & CONSIDERATIONS

COMMENTS

A thorough and methodical diagnostic protocol is often necessary to confirm a specific cause.

CLIENT EDUCATION

It is better to invest in a diagnostic workup to identify and treat the specific etiology rather than pursue countless therapeutic trials that often result in minimal response and maximal frustration.

EDITOR: MANON PARADIS

Nicotine Toxicosis

BASIC INFORMATION

DEFINITION

Intoxication in pets generally due to ingestion of tobacco or related products and manifesting with acute onset of gastrointestinal (GI) signs followed by transient, potentially severe, neurologic dysfunction.

EPIDEMIOLOGY

SPECIES, AGE, SEX: All animals of all ages and both sexes are susceptible; dogs are more likely to be involved compared to cats.

RISK FACTORS

- Availability of nicotine-containing products in pet's environment
- Dogs may be particularly attracted to chewing tobacco containing flavoring agents such as honey, molasses, licorice, syrups, or sugars.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Observation or indirect evidence of exposure to nicotine-containing products
- Clinical signs occur >1 hour after ingestion; spontaneous vomiting, salivation, and diarrhea.
- Initial central nervous system (CNS) excitation and tachypnea

PHYSICAL EXAM FINDINGS

- Hypersalivation
- Nausea
- Tenesmus
- Bradycardia (sinus); may be followed by tachycardia.
- Shallow, slow respiration, eventually leading to cyanosis, respiratory paralysis
- Neuromuscular weakness, tremors, collapse

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Sources include cigarettes, cigars, chewing tobacco, Bidi cigarettes, nicotine gum, nicotine skin patches (Nicorette, Nicotrol), inhalers, nasal sprays, nicotinic insecticides (nicotine sulfate is available at a concentration of 0.05%-4% as insecticide dust or sprays and as a concentrated 40% solution [Black Leaf 40]; banned in the United States since 2001).
- Nicotine is a water-soluble alkaloid found primarily in cultivated tobacco *(Nicotiana tabacum)* but also in wild tobacco (*N. attenuata* and *N. trigonophylla*). Tree tobacco *(N. glauca)* contains mostly anabasine (a teratogen) but does contain some nicotine. Indian tobacco (*Lobelia inflata*) contains mostly lobeline (curare-like paralytic) and some nicotine.

Mechanism of Toxicosis:

- Nicotine mimics acetylcholine at sympathetic and parasympathetic ganglia, neuromuscular junctions of skeletal muscle, and at some synapses in the CNS. Low doses cause depolarization and stimulation of receptors similar to acetylcholine. Higher doses cause stimulation followed by blockade of autonomic ganglia and neuromuscular junctions of skeletal muscle.
- Stimulation of sympathetic cardiovascular ganglia and adrenal medulla can lead to release of catecholamines.
- GI effects: parasympathetic stimulation can lead to increased tone and motility.
- Death can result from respiratory paralysis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A tentative diagnosis is made based on nicotine in the animal's environment and appropriate clinical signs. Confirmation with nicotine in-clinic tests is possible, especially if history of exposure is uncertain, but it is not essential.

DIFFERENTIAL DIAGNOSIS

- Other intoxications: strychnine, methylxanthines, tremorgenic mycotoxins/garbage toxicosis, organophosphates/carbamates
- The initial stages of nicotine poisoning produce physical signs that are similar to those of anticholinesterase insecticide poisoning. The latter stages produce signs that are similar to intoxication with depressants (ethanol, barbiturates, marijuana, etc.).

INITIAL DATABASE

- Serum chemistry profile: electrolyte abnormalities, azotemia (vomiting, dehydration)
- Blood gas analysis
- Electrocardiogram (ECG): sinus bradycardia or sinus tachycardia most common, ventricular arrhythmias possible

ADVANCED OR CONFIRMATORY TESTING

- Nicotine can be detected in urine, blood, GI contents, vomitus, or lavage washings. Clinicians can contact a veterinary diagnostic laboratory or a human hospital for analysis, but such confirmation should not delay initiation of treatment if nicotine toxicosis is known or suspected.
- Necropsy samples: nicotine in liver and kidney

TREATMENT

TREATMENT OVERVIEW

Treatment consists of management of severe signs first (e.g., seizures) if present, followed by decontamination of the patient (induce vomiting and give activated charcoal) in all cases not showing overt clinical signs, and enhancement of excretion of nicotine in all likely or confirmed cases.

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Decontamination of dermal exposure consists of bathing the patient with liquid dishwashing detergent solution (wear thick rubber gloves).
  - Induction of emesis (see p. 1364) is indicated only if the patient is not showing any clinical signs (<1 hour after exposure).
  - Gastric lavage (see p. 1281) is necessary only if very large doses have been ingested and emesis cannot be induced (comatose animal).
  - Activated charcoal 1-4 g/kg PO (repeated doses may be necessary). Airway protection with a cuffed endotracheal tube is indicated if the animal is unconscious. Obtain a baseline serum sodium because some animals develop hypernatremia after activated charcoal administration.
  - Antacids are contraindicated because they will enhance absorption.
- Enhance excretion:
  - Fluid diuresis
  - Urine acidification may promote excretion of nicotine, but this should only be done if the acid-base status is monitored. Ammonium chloride (50 mg/kg PO q 6 h) or vitamin C (20-30 mg/kg IM or IV q 8 h) can be used.
- Treat sinus bradycardia with atropine, 0.04 mg/kg SQ, IM, or IV as needed.
- Supportive care:
  - Oxygen and/or artificial respiration for respiratory difficulty or paralysis
  - Diazepam for seizures (0.5-2 mg/kg IV in dogs and 0.5-1 mg/kg in cats, PRN)

RECOMMENDED MONITORING

- ECG
- Blood pressure
- Acid-base status
- CNS physical signs
- Respiratory system

PROGNOSIS AND OUTCOME

- Poor prognosis with large doses or if artificial ventilation is required
- Prognosis good if patient survives first 4 hours after ingestion

PEARLS & CONSIDERATIONS

COMMENTS

- In dogs, 10 mg/kg nicotine PO is potentially lethal. Ingestion of approximately 1 mg/kg or more should be considered serious.
- Clinically significant toxicosis has been reported in dogs at 4 mg (one cigarette in a small- to medium-sized dog).
- Most dogs vomit spontaneously after ingestion, reducing the severity of toxicosis.
- Nicotine is absorbed more in alkaline pH. In humans, the half-life is 2 hours; excretion occurs via kidneys and is pH dependent.
- Nicotine from gum has comparatively low bioavailability at about 15%.
- Nicotine content in various products:
    - Cigar: 15-40 mg/cigar
    - Cigarettes: 13-30 mg/cigarette
    - Low-yield cigarette: 3-8 mg
    - Cigarette butt: 5-7 mg
    - Snuff: 4.6-32 mg/g moist; 12.4-15.6 mg/g dry
    - Nicorette gum: 2 or 4 mg per piece (effectively 0.3-0.6 mg at bioavailability 15%)
    - Nicotrol nasal spray: 10 mg/mL
    - Transdermal patches: 8.3-114 mg/patch
    - Nicotine inhaler: 10 mg/cartridge

PREVENTION

Pet owners should keep nicotine-containing products out of their pets' reach.

Neutropenia, Immune-Mediated

BASIC INFORMATION

DEFINITION

Antibody-mediated destruction of neutrophils and/or their precursors in the marrow, resulting in an absolute decrease in the number of circulating neutrophils.

SYNONYM

Steroid-responsive neutropenia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Any age or gender, but female dogs <4 years old may be at increased risk.

GENETICS & BREED PREDISPOSITION

- One report involved three female giant schnauzers.
- Cats and Belgian Tervuren dogs may have physiologic neutropenia causing no clinical signs.

RISK FACTORS: None known. Drugs (phenylbutazone, griseofulvin [cats]) or infectious agents (viruses, rickettsiae) sometimes implicated.

ASSOCIATED CONDITIONS & DISORDERS: May be seen with anemia, thrombocytopenia, or pancytopenia (see p. 68)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Lethargy or anorexia may be reported by owners.
- Signs may arise from infections, usually bacterial from invasion of normal flora.
- Clinical signs are nonspecific and usually are not helpful in localizing the infection.

PHYSICAL EXAM FINDINGS: Fever and weakness may be the only findings. Sometimes signs of opportunistic infections (e.g., diarrhea or gingivitis) may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Idiopathic; not well studied
- Drugs or infections occasionally cause immune-mediated destruction of neutrophils.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Neutropenia may be the primary problem, or it may occur secondary to overwhelming infection, and determining which situation exists in a given patient is of paramount importance. A combination of physical examination, CBCs, and often diagnostic imaging and bone marrow evaluation are usually necessary to make this determination and provide appropriate treatment and an accurate prognosis.

DIFFERENTIAL DIAGNOSIS

- Immune-mediated neutropenia is more often associated with thrombocytopenia or anemia and clinical signs of variable severity.
- Secondary neutropenia is usually associated with severe clinical illness, and the count may improve within days of appropriate antibiotic treatment; conversely, primary neutropenia persists after an infection is treated.
- Primary but nonimmune-mediated neutropenia:
    - Bone marrow abnormality such as aplasia, fibrosis, dysplasia, or neoplasia. Neutropenia occurs first, then thrombocytopenia and anemia.
    - Infections such as parvovirus or ehrlichiosis in dogs, and retroviruses (feline leukemia, feline immunodeficiency) or panleukopenia virus in cats
    - Hyperestrogenism from testicular or ovarian tumors, or iatrogenic estrogen administration
- Some normal cats may have neutrophil counts between 1800 and 2500/mcL.
- Immune-mediated neutropenia is a diagnosis of exclusion. Neutrophil counts are usually <500/mcL at presentation.
- Response to treatment with corticosteroids may allow for retrospective diagnosis of immune-mediated neutropenia.

INITIAL DATABASE

- CBC: if the neutropenia is associated with other cytopenias, or if it persists for more than 2–3 days (if <1000/mcL neutrophils) or 1 week (if 1000–2000/ mcL), a bone marrow aspirate and biopsy are indicated.
- Serum biochemistry profile and possibly thoracic and abdominal radiographs can help clinicians assess for underlying disorders causing secondary (transient) neutropenia, such as neoplasia or infections.
    - Serum chemistry profile usually unremarkable, although hyperglobulinemia may be present.
    - Possible thoracic radiographic lesions (e.g., mediastinal or pulmonary disease)
- Urinalysis with bacterial culture and sensitivity (C&S) test to evaluate for urinary tract infection

ADVANCED OR CONFIRMATORY TESTING

- If relevant, abdominal ultrasonography to evaluate for evidence of neoplasia or infection
- Serologic testing for relevant infectious diseases
- No available commercial test for antineutrophil antibodies, but they have been demonstrated by flow cytometric immunofluorescence.
- Any concurrent drug therapy should be stopped if possible to rule out immune-mediated neutropenia due to adverse drug reaction.

TREATMENT

TREATMENT OVERVIEW

Assume that sepsis is present whenever fever and neutropenia are present concurrently, regardless of the cause of the neutropenia. Intensive treatment with IV bactericidal antibiotics is indicated, since sepsis may be rapidly fatal. Corticosteroids can be added later if primary immune-mediated disease remains the most likely diagnosis by exclusion.

ACUTE GENERAL TREATMENT

- It is important to weigh risks and benefits and rule out other causes of neutropenia before starting corticosteroid therapy.
- Appropriate antibiotics based on a C&S if fever is present. Empirical antibiotic treatment may be necessary initially (first few days) while bacterial cultures are underway.
    - In severely ill patients, intravenous antibiotics should be used. Options include cefoxitin, 30 mg/kg IV q 6-8 h; or ampicillin, 20 mg/kg IV q 8 h, plus enrofloxacin, 5 mg/kg (diluted 1:1 with sterile saline and given slowly IV) q 12 h (5 mg/kg q 24 h in cats).
    - In severe sepsis, consider temporary use of human G-CSF 5 mcg/kg SQ q 12 h. Development of antibodies will prevent long-term benefits.
    - In stable cases, oral trimethoprimsulfa (15 mg/kg PO q 12 h) is often suitable because it preserves normal intestinal anaerobes. Trimethoprimsulfa has rarely been implicated as a cause of neutropenia.
- Prophylactic antibiotic treatment may be warranted even for afebrile animals with severe neutropenia.
- Prevent infection by paying special attention to sterile technique with IV catheters and other invasive procedures.
- Start prednisone at 2 mg/kg PO q 24 h, which may be given after infectious causes have been ruled out or treated. Continue until neutrophil count is normal.
- If risk of ehrlichiosis (see p. 334), consider doxycycline (5 mg/kg PO q 12 h) while awaiting serologic results.

CHRONIC TREATMENT

- Neutrophil count should increase within 2 weeks of prednisone therapy.

- If there is no response, reassessment of the diagnosis is indicated. If the diagnosis is unchanged, consider human intravenous immunoglobulin (0.5 g/kg slow IV once, and a second dose may be administered after 24-48 hours if necessary; risk of anaphylaxis at either time) or cyclosporine (e.g., Neoral, Atopica: 2-5 mg/kg PO q 12 h); monitoring of serum cyclosporine levels is recommended (target: 200-500 ng/mL). It is generally best to avoid administering myelosuppressive drugs such as azathioprine or cyclophosphamide.

POSSIBLE COMPLICATIONS

Sepsis

RECOMMENDED MONITORING

Frequent assessment of body temperature and periodic reevaluation of neutrophil count

PROGNOSIS AND OUTCOME

Most dogs affected with primary immune-mediated neutropenia that are under 4 years of age recover. Older dogs or those with pancytopenia are more likely to develop complications, and their prognosis is guarded.

PEARLS & CONSIDERATIONS

COMMENTS

- The combination of fever and neutropenia should be considered to be a life-threatening emergency that warrants obtaining specimens for culture and starting IV antibiotics immediately.
- Cats tolerate neutropenia better than dogs.

TECHNICIAN TIPS

- Pay special attention to aseptic technique when placing catheters or performing any other invasive techniques in neutropenic patients.

CLIENT EDUCATION

- Clients can monitor temperature at home. If a fever develops, they must contact their veterinarian immediately for further tests and treatment.

AUTHOR & EDITOR: SUSAN M. COTTER

Nerve Sheath Tumors

BASIC INFORMATION

DEFINITION

A benign or malignant tumor of peripheral nerve cell origin. Nerve sheath tumors may affect peripheral nerves, spinal nerve roots, or cranial nerves. Approximately 80% of nerve sheath tumors occur in the brachial plexus region. The remaining 20% involve cranial nerves or other spinal nerve roots. The trigeminal nerve is the most common cranial nerve affected.

SYNONYMS

Peripheral nerve sheath tumor (PNST), malignant nerve sheath tumor (MNST)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Common in dogs, less common in cats
- Reported age range is 3-13 years in dogs and 8-19 years in cats.
- Usually seen in medium- to large-breed dogs

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Nerve sheath tumors include:

- Ganglioneuroma
- Peripheral neuroblastoma
- Paraganglioma
- Peripheral nerve sheath tumors
    - Benign peripheral nerve sheath tumors
        - Schwannoma
        - Neurofibroma
    - Malignant peripheral nerve sheath tumors
        - Malignant schwannoma
        - Neurofibrosarcoma

HISTORY, CHIEF COMPLAINT

- Chronic, progressive lameness or pain
- Muscle atrophy
- Weakness
- Ataxia

PHYSICAL EXAM FINDINGS

- Varies with respect to tumor location and nerve root(s) affected
- Abnormalities *may* include:
    - Localized muscle atrophy
    - Chronic, progressive lameness (commonly in the unilateral forelimb)
    - Asymmetric paresis
    - Proprioceptive deficits
    - Hyporeflexia
    - Sensory deficits
    - Pain on palpation of tumor site (e.g., axilla)
    - Ipsilateral loss of cutaneous trunci reflex (may occur with C8-T1 spinal segments)
    - Ipsilateral Horner's syndrome (may occur with cervical or brachial plexus nerve sheath tumors)

ETIOLOGY AND PATHOPHYSIOLOGY

Undetermined; recent research suggests a point mutation in the *neu* oncogene; however, there is insufficient evidence to determine the consistency of this finding.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A presumptive diagnosis can be made with history, clinical signs, and diagnostic imaging; however, cytologic or histopathologic evaluation is required for definitive diagnosis.

DIFFERENTIAL DIAGNOSIS

- Other soft-tissue tumors may invade or compress nerves and result in similar neurologic deficits and imaging appearance (e.g., fibrosarcoma, chondrosarcoma, lymphoma).
- Abscess, granuloma
- Orthopedic abnormalities (e.g., osteoarthritis, osteochondrosis desiccans [OCD], biceps tenosynovitis)
- Other cranial neuropathies (e.g., tumors of the brainstem or cavernous sinus)
- Other neuropathies (e.g., lateralized disk herniation)
- Traumatic brachial plexus injury

INITIAL DATABASE

- Neurologic examination
- Radiographs of the affected limb may rule out orthopedic conditions.
  - Clinicians should not overinterpret presence of osteoarthritis; osteoarthritis may be a concurrent condition and not the primary cause for presentation.
- Spinal radiographs may show subtle osteolysis at the vertebral foramen.

ADVANCED OR CONFIRMATORY TESTING

- Electrophysiologic studies (see online chapter: Electromyography and Nerve Conduction Velocity):
  - Differentiate neurologic from orthopedic conditions
  - Determine specific nerve roots involved; aid in surgical planning
- Cerebrospinal fluid (CSF) evaluation (see p. 1228):
  - Occasionally, albuminocytologic dissociation (disproportionate elevation in CSF albumin concentration compared to cellularity)
- Myelography (see p. 1306):
  - May indicate local invasion into spinal canal
  - May rule out lateralized disk herniation
- Advanced imaging:
  - MRI (see p. 1302) is the preferred modality for identifying soft-tissue and intracranial lesions. However, a normal MRI does not completely rule out the presence of a small or diffuse nerve sheath tumor.
  - CT (see p. 1233) may be particularly useful in evaluating compressive spinal lesions post myelogram
- Fine-needle aspiration for cytologic examination
- Biopsy (percutaneous or surgical excision)
- Tumor staging:
  - Thoracic radiographs
  - Abdominal ultrasound
  - Lymph node aspirates

TREATMENT

TREATMENT OVERVIEW

Complete tumor excision if possible and pain relief are the desired goals; radiation therapy may be used for attempting palliation.

ACUTE GENERAL TREATMENT

- Surgical exploratory/excision:
  - Radical excision (i.e., limb amputation, ± hemilaminectomy) provides the optimal chance of complete excision and is

recommended in most cases.
- Radiation therapy:
  - Adjunctive to surgical excision
  - May be used as monotherapy in nonresectable cases
- Adjunctive chemotherapy:
  - Rarely used as monotherapy
  - Doxorubicin (dogs, cats), mitoxantrone (dogs, cats), or ifosfamide (dogs)

CHRONIC TREATMENT

- Analgesics
- Corticosteroids may help alleviate some discomfort and may reduce peritumoral inflammation; however, there is insufficient research to support or refute their use for treating this condition.

DRUG INTERACTIONS

- Concurrent administration of nonsteroidal antiinflammatory drugs (NSAIDs) and corticosteroids is *not* recommended.
- Other potential drug interactions depend on the specific therapeutic modalities chosen; clinicians should consult appropriate references.

POSSIBLE COMPLICATIONS

- Local invasion into adjacent tissues (e.g., brainstem or spinal cord)
- Metastasis:
  - Metastatic rates for nerve sheath tumors have not been established although appear to be low.

RECOMMENDED MONITORING

Clinicians should monitor for progressive/recurrent neurologic deficits and/or pain.

PROGNOSIS AND OUTCOME

- Variable; histopathologic grade, tumor location (e.g., surgical accessibility), and stage are prognostic.
- Although complete excision can be curative, often local invasion into the spinal cord or brainstem has already occurred by the time of diagnosis, making cure unlikely.
  - Median postoperative survival time is 5-6 months, with a disease-free interval of about 1 month.

PEARLS & CONSIDERATIONS

COMMENTS

- Early diagnosis increases the potential for complete excision.
- Orthopedic conditions typically do not produce neurologic deficits; if proprioceptive deficit or localized muscle atrophy is present, a nerve sheath tumor may be the cause.
- Even advanced imaging may fail to identify the tumor if it is small or diffuse.

CLIENT EDUCATION

- Clients should understand the potential for progression/recurrence.
- Clients should be counseled regarding quality-of-life issues that pertain to their pets.

EDITOR: CURTIS W. DEWEY

1ST EDITION AUTHOR: REBECCA A. PACKER

Nephrotic Syndrome

BASIC INFORMATION

DEFINITION

The presence of pathologic proteinuria, hypoalbuminemia, hypercholesterolemia, and edema. This combination is an uncommon but important complication of protein-losing nephropathy.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- More common in dogs than in cats
- More common in middle-aged to older dogs (average is about 8.5 years of age).
- For most causes, no sex predilection

GENETICS & BREED PREDISPOSITION

- Labrador and golden retrievers may be overrepresented.
- Hereditary nephritis: bull terrier, dalmatian, English cocker spaniel, Samoyed, American Eskimo, beagle, mixed breed dog (see p. 926).
- Amyloidosis: Chinese shar-pei (see pp. 926, p. 1372, and online chapter: Shar Pei Fever).

RISK FACTORS: Diseases that can cause substantial glomerular protein loss (e.g., membranous glomerulonephritis, amyloidosis) are invariably the underlying cause of nephrotic syndrome. In turn, neoplasia, infectious, and noninfectious inflammatory diseases predispose an animal to some of these glomerular diseases (see p. 450).

CONTAGION & ZOONOSIS: Some causes are zoonotic (see p. 450).

GEOGRAPHY AND SEASONALITY: Some causes are geographically and/or seasonally restricted (see p. 450).

ASSOCIATED CONDITIONS & DISORDERS

- Thromboembolic disease
- Chronic kidney disease
- Systemic hypertension
- Dyspnea from pulmonary thromboembolism or, less commonly, pleural effusion
- Ascites
- Reduced renal perfusion and possibly acute renal failure from decreased plasma oncotic pressure

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Incomplete nephrotic syndrome (edema absent): the most common form

HISTORY, CHIEF COMPLAINT: Patients may not show overt clinical signs. When present, signs may be nonspecific (e.g., weight loss, lethargy) or caused by:

- Fluid retention (e.g., edema, abdominal distension)
- Renal failure/uremia (e.g., polyuria and polydipsia [PU/PD], vomiting, halitosis)
- Thromboembolism (e.g., dyspnea, collapse)
- Systemic hypertension (e.g., blindness)
- Related to predisposing disease

PHYSICAL EXAM FINDINGS: May be unremarkable. Abnormalities may include:

- Subcutaneous edema, ascites, pleural effusion
- Evidence of thromboembolism (e.g., dyspnea, decreased peripheral pulse)
- Evidence of hypertension (e.g., choroidopathy, CNS signs, new cardiac murmur)
- Evidence of predisposing disease

- Variably sized kidneys

ETIOLOGY AND PATHOPHYSIOLOGY

- Proteinuria is due to altered glomerular capillary wall permselectivity and abnormal (inadequate) filtration of plasma proteins, primarily albumin.
- Hypoalbuminemia develops when the renal loss of plasma proteins exceeds hepatic regenerative capacity.
- The pathogenesis of hypercholesterolemia is complex and incompletely understood. Hypoalbuminemia or decreased oncotic pressure stimulates hepatic protein synthesis, including lipoprotein synthesis, leading to hypercholesterolemia. Altered lipid catabolism may contribute to the condition.
- Sodium retention and decreased plasma oncotic pressure contribute to edema formation.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis of partial nephrotic syndrome is based on the combination of proteinuria, hypoalbuminuria and hypercholesterolemia; complete nephrotic syndrome includes the presence of fluid retention. Finding partial or complete nephrotic syndrome prompts further evaluation of the patient.

DIFFERENTIAL DIAGNOSIS

- The combination of proteinuria, hypoalbuminemia, hypercholesterolemia, and edema/effusion is pathognomonic for nephrotic syndrome.
- Most likely glomerular diseases that cause severe proteinuria: amyloidosis, membranous nephropathy/glomerulonephritis, membranoproliferative glomerulonephritis, hereditary nephritis, minimal change disease

INITIAL DATABASE

- CBC, biochemical profile, urinalysis: clinician should assess glomerular filtration (creatinine, blood urea nitrogen [BUN]), renal tubular function (urine specific gravity), identify evidence of predisposing disease, and rule out other causes of proteinuria (see pp. 450, p. 61, and p. 926).
- Urine protein/creatinine (UPC) ratio: confirm nephrotic range proteinuria (UPC > 2), and establish pretreatment baseline. UPC only accurate when urine sediment is inactive.
- Urine culture and susceptibility testing (C&S) to rule out infection
- Blood pressure measurement: hypertension is common. High-risk of end-organ damage if systolic >180 mm Hg.

ADVANCED OR CONFIRMATORY TESTING

- Identify predisposing diseases with abdominal ultrasound, thoracic radiographs, infectious disease testing (e.g., heartworm, ehrlichiosis), and anti-nuclear antibody (ANA) serologic analysis.
- Renal biopsy: allows definitive diagnosis of glomerular lesion; should include light, electron, and immunofluorescent microscopic evaluation. May provide prognostic information.

TREATMENT 

TREATMENT OVERVIEW

The goals of treatment are to reduce the magnitude of proteinuria, manage uremia, control systemic hypertension, and reduce patient discomfort (e.g., relief from edema, effusion).

ACUTE GENERAL TREATMENT

- Clinician should initiate angiotensinconverting enzyme (ACE) inhibitor therapy: enalapril, 0.5 mg/kg PO q 24 h to q 12 h; or benazepril, 0.25 mg/kg PO q 24 h.
- Address edema and effusion:
  - Abdominocentesis (see p. 1192) if ascites impinging on ventilation: thoracocentesis rarely required
  - Appropriate diuretic use:
    - If plasma volume is reduced (e.g., dehydration), diuretics may be ineffective and dangerous, increasing risk of renal failure or thromboembolism.

        - If plasma volume is normal, spironolactone may help delay return of third-spaced fluid and provide benefit of inhibiting aldosterone.
    - Low-level exercise may help mobilize edema.
- Address components of uremia if present (see p. 205).
- Initiate aspirin therapy as anticoagulant (0.5 mg/kg PO q 12 h) if serum albumin is <2–2.5 g/dL to reduce risk of thromboembolism.
- Add additional medications as needed to control systemic hypertension (see p. 1068).
- Address concurrent/underlying disease when possible.
- Uremic crisis may require colloid support for appropriate diuresis.

CHRONIC TREATMENT

- Disease-specific treatment indicated on basis of renal biopsy and other test results
- If proteinuria is not reduced by >50% with an ACE inhibitor, another inhibitor of the renin-angiotensin-aldosterone system (RAAS) should be added (e.g., angiotensin receptor blocker [losartan])

NUTRITION/DIET

Diet formulated for renal disease

BEHAVIOR/EXERCISE

Moderate, comfortable physical activity is encouraged; inactivity may worsen peripheral edema.

DRUG INTERACTIONS

- Hypoalbuminemia will increase the unbound (often active) fraction of highly protein-bound drugs; dosages may need to be adjusted accordingly.
- Warfarin is avoided in the face of hypoalbuminemia.
- Heparin is an ineffective anticoagulant when antithrombin is depleted.

POSSIBLE COMPLICATIONS

- Hypotension from ACE inhibitor and Ca channel blocker or severe reduction in plasma oncotic pressure
- Hyperkalemia from ACE inhibitor
- Bleeding tendency from aspirin (very rare at recommended dose)
- Worsening azotemia as a result of ACE inhibitor administration; rare
- Worsening of ascites/edema following parenteral fluid administration

RECOMMENDED MONITORING

The UPC, urinalysis, blood pressure, serum albumin and creatinine, body weight and condition score should be monitored regularly —weekly to monthly initially. Once stable, reevaluate every 3-6 months unless changes in therapy are initiated or changes are noted in clinical condition.

PROGNOSIS AND OUTCOME

- Variable but usually guarded. Prognosis improves if underlying disease causing proteinuria can be identified and corrected.
- Azotemia, systemic hypertension, and marked tubulointerstitial lesions on biopsy may be negative prognostic indicators.

PEARLS & CONSIDERATIONS

COMMENTS

- Nephrotic syndrome is a complication that can develop in animals with specific types of glomerular diseases. Nephrotic syndrome is pathognomonic for glomerular disease.
- The clinical condition can deteriorate rapidly; prompt intervention is warranted.
- Nephrotic syndrome is a predisposing factor for thromboembolic disease.

PREVENTION

- Urinalyses screening during routine health evaluations may allow early detection.
- Early intervention might prevent the development of nephrotic syndrome.

TECHNICIAN TIP

Affected dogs need frequent evaluation because they can destabilize rapidly.

CLIENT EDUCATION

Rapid deterioration is possible; frequent rechecks are necessary.

AUTHOR: SHELLY VADEN

EDITOR: LEAH A. COHN

Nephrolithiasis

BASIC INFORMATION

DEFINITION

Deposition of crystallized minerals within the kidney is less common than urolithiasis in the lower urinary tract, but incidence (or recognition) is increasing.

SYNONYMS

Kidney stones, renal urolithiasis, renolithiasis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Feline: prevalence increases with age. Up to 47% of cats with chronic kidney disease may have upper urinary tract uroliths.
- Canine: middle-aged to older dogs

GENETICS & BREED PREDISPOSITION: (Data extrapolated from general uroliths)

- Cat: domestic short hair (DSH), domestic long hair (DLH), domestic medium-haired (DMH), Siamese, Persian, Himalayan, Manx, Maine coon
- Dog:
  - Oxalate: miniature schnauzer, Lhasa apso, Yorkshire terrier, bichon frise, Pomeranian, shih tzu, miniature poodle (see p. 1141)
  - Struvite: miniature schnauzer, shih tzu, bichon frise, miniature poodle, cocker spaniel, and Lhasa apso (see p. 1143)
  - Urate: dalmatian, English bulldog, miniature schnauzer, shih tzu, Yorkshire terrier (urate/biurate; see p. 1145)

RISK FACTORS

- Struvite: pyelonephritis
- Calcium oxalate: hyperadrenocorticism, hypercalcemia (any cause), diet
- Urate: portosystemic shunt, breed-related risk

ASSOCIATED CONDITIONS & DISORDERS

- Hydronephrosis/hydroureter
- Ureteral obstruction
- Pyelonephritis
- Renal failure

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Unilateral or bilateral
- Unobstructed or obstructed (partial or complete)
- Urolith type: calcium oxalate, struvite, urate and other purities, xanthine, silica, cystine, compound/mixed

HISTORY, CHIEF COMPLAINT: Clinical signs may be absent or may include:

- Abdominal pain
- Anorexia
- Depression
- Hematuria
- Pollakiuria
- Polyuria and polydipsia (PU/PD)

- Stranguria
- Vomiting
- Weight loss

PHYSICAL EXAM FINDINGS: Physical examination may be unremarkable or may reveal:

- Abdominal pain
- Dehydration
- Halitosis/oral ulcers (uremia)
- Renomegaly or small kidneys

ETIOLOGY AND PATHOPHYSIOLOGY

- Nephroliths are less common than cystouroliths, representing approximately l%-4% of analyzed uroliths. The actual prevalence is likely higher, since nephroliths are less frequently removed for analysis.
- The most common nephrolith types in dogs are calcium oxalate (about 40%), struvite (about 33%), and urate (about 12%). The most common nephroliths in cats are calcium oxalate.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Nephrolithiasis may be an incidental finding on abdominal imaging studies or may be associated with urinary obstruction, renal failure, or recurrent urinary infections.

DIFFERENTIAL DIAGNOSIS

- Radiodense renal opacities:
  - Nephrocalcinosis
  - Radiodense intestinal content
  - Calcified lymph nodes
  - Calcified adrenal glands
  - Neoplastic mineralization
  - Other ectopic calcification
- Clinical signs:
  - Urolithiasis (ureters, bladder, urethra)
  - Feline lower urinary tract signs/disease (FLUTS/D)
  - Pyelonephritis or cystitis
  - Renal failure
  - Urinary tract neoplasia
  - Prostatic disease
  - Causes of hematuria (see p. 1394)

INITIAL DATABASE

- CBC: often unremarkable
  - Normocytic, normochromic, nonregenerative anemia (if chronic kidney disease)
  - Leukocytosis ± left shift (if pyelonephritis)
- Serum biochemical profile: often unremarkable. Depending on degree of renal dysfunction and/or urinary obstruction, may reveal:
  - Azotemia
  - Hyperphosphatemia
  - Hypokalemia/hyperkalemia
  - Metabolic acidosis
- Urinalysis: may be unremarkable, or may reveal:
  - Hematuria
  - Proteinuria
  - Pyuria
  - Bacteruria
  - Crystalluria
  - Isosthenuric urine
- Urine culture and sensitivity (C&S) to rule out infection

- Blood pressure to rule out hypertension associated with chronic kidney disease
- Abdominal radiography:
  - Depending on urolith composition, radiopaque density within one or both renal pelvises
    - Radiopaque: calcium phosphate, calcium oxalate, struvite; small uroliths are difficult to detect radiographically.
    - Radiolucent: urate, cystine
  - Concunent ureteral, cystic, or urethral calculi are sometimes present.
  - Enlarged or atrophied kidneys
- Ultrasound is a sensitive means of detection but may overestimate nephrolith size:
  - Acoustic shadowing in renal pelvis
  - Concunent pyelectasia or hydronephrosis

ADVANCED OR CONFIRMATORY TESTING

- If nephroliths are recovered, quantitative urolith analysis and culture
- If definitive therapy is anticipated:
  - Nuclear scintigraphic or CT glomerular filtration rate (GFR) to determine contribution of each kidney to global GFR
  - Intravenous pyelography (IVP) or CT to confirm urolith location in kidney

TREATMENT

TREATMENT OVERVIEW

Incidentally discovered nephroliths may not require therapeutic intervention. Nephroliths may remain stationary, pass into the bladder, or become lodged in the ureter, resulting in renal dysfunction. When present, urinary obstruction (rare) should be relieved and uremia addressed directly. Whenever possible, measures to dissolve or prevent urolith growth are undertaken.

ACUTE GENERAL TREATMENT

- Complete urinary obstruction is rare, but when present, it requires interventional (surgical, endoscopic) treatment.
- Address renal failure, including electrolyte and acid-base disorders (see pp. 205, p. 207 , and p. 31).
- Address pyelonephritis (see p. 947).

CHRONIC TREATMENT

- Medical dissolution possible for some types of nephrolithiasis (see pp. 1143, p. 1145, and p. 1138).
- Invasive intervention not routinely required, and benefit must be carefully weighed against risk.
  - Indications for surgery (nephrotomy, pyelolithotomy, or nephrectomy):
    - Complete obstruction to urine flow
    - Recurrent infection (nephrolith may be nidus)
    - Marked, persistent renal hematuria
    - Progressive nephrolith enlargement (despite medical management) accompanied by reduction in renal function or in a solitary functional kidney
- Lithotripsy (extracorporeal shock wave, laser, or electrohydraulic):
  - Results in fragmentation or crushing of calculi; may require multiple treatments, depending on calculi shape, size, location, and type.
    - Indications similar to those for surgical intervention.
  - Shock wave availability limited (e.g., University of Tennessee, Pennsylvania, Purdue, Tufts, Animal Medical Center in New York City). Can cause renal damage.
  - Laser lithotripsy more readily available (several large referral centers) but technique best suited to larger animals. (see p.1297)

POSSIBLE COMPLICATIONS

- Nephrolith may lodge in ureter, causing obstructive nephropathy; particularly likely when calculi shrink (e.g., medical dissolution, lithotripsy).
- Surgical trauma of incision and transection of intrarenal vessels may further damage renal parenchyma.
- Some medical conditions may be worsened by calculolytic diets (see pp. 1143 and p. 1145).
- Recurrence rates are high, especially for calcium oxalate nephroliths.

RECOMMENDED MONITORING

- Monitoring should include imaging, urinalysis and culture, and serum biochemistry as described for urolithiasis.

- Repeated abdominal ultrasound or excretory urography (contrast is potentially nephrotoxic) should be considered in patients with radiolucent stones.

PROGNOSIS AND OUTCOME

- Dependent on urolith composition, degree of obstruction, remaining renal function, concurrent infection, and ability to identify and treat underlying cause
- Surgical intervention does not address causation; recurrence rates are high.

PEARLS & CONSIDERATIONS

COMMENTS

- Small nephroliths can be incidental findings requiring no therapy.
- Medical management of nephroliths mirrors medical management of cystoliths of identical composition.
- Nephrolithiasis does not worsen prognosis for cats with stage 2 or 3 chronic kidney disease.

PREVENTION

- Promote water consumption.
- Identify and address risk factors.

CLIENT EDUCATION

Strict adherence to dietary recommendations is crucial.

Neonatal Losses

BASIC INFORMATION

DEFINITION

Life-threatening illness occurring between birth and 4 weeks of age

SYNONYMS

Fading kittens, fading puppies, stillbirth

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Canine, feline: both sexes.
- Neonatal mortality rates: 5%-30%. Greatest incidence occurs within the first week of birth.

GENETICS & BREED PREDISPOSITION

- Purebred puppies and kittens are more prone to congenital and hereditary defects.
- Cats: British shorthair, Scottish fold, Devon rex, Abyssinian, Birman, Himalayan, Persian, Somali.

RISK FACTORS

- Dam condition
- Premature labor
- Dystocia, causing fetal distress
- Prolonged labor, over 6-12 hours
- Low birth weight or failure to grow
- Lack of colostrum ingestion, immunodeficiency
- Endometritis in the dam
- Congenital anomalies (hereditary, developmental, or teratogenic)
- Malnutrition or nutritional diseases
- Assisted feeding (bottle or tube feeding, causing potential aspiration pneumonia)
- Poor environment, stress
- Parasitism
- Infectious diseases
- Inbreeding
- Tom with blood type A having mated with queen with blood type B (see p. 757)

CONTAGION & ZOONOSIS

- *Brucella cants* infection
- Herpesvirus infection
- *Bartonella* infection
- Toxoplasmosis
- Feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) infections

GEOGRAPHY AND SEASONALITY: Colder climates may negatively affect neonatal survival.

ASSOCIATED CONDITIONS & DISORDERS: Failure to thrive (weight loss), vomiting, diarrhea, respiratory distress

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Low birth weight, low weight gain, and/or failure to gain weight

- Separation from the dam or other littermates
- Sudden onset of illness characterized by depression, anorexia, hypothermia, persistent crying, abdominal distension/pain, and failure to suckle. Death can occur in 18-24 h depending on the cause.
- Primarily respiratory and gastrointestinal signs in puppies. Hemolytic or respiratory signs in kittens. With infectious causes, clinical signs vary according to the route and time of infection.
- Severity of presenting signs influences survival.

PHYSICAL EXAM FINDINGS

- General: weakness, diarrhea, gasping/panting/labored breathing/respiratory distress
- Decreased activity, decreased muscle tone, pale mucous membranes, decreased gastrointestinal sounds, dehydration, hypothermia
- Characteristics of neonatal isoerythrolysis in cats: pallor, icterus, tail tip necrosis, tachypnea, discolored urine (hemoglobinuria)

ETIOLOGY AND PATHOPHYSIOLOGY

- Mechanisms:
  - Hypoglycemia, dehydration, hypoxemia, and hypothermia are the main mechanisms for neonatal losses in both dogs and cats.
  - Hypothermia causes failure to suckle and intestinal ileus at temperatures <96°F (<35.6°C). The most common route of entry for bacterial organisms is through the umbilicus, but the oronasal route and contact with infectious vaginal fluids/discharge are also recognized portals for infection.
  - Meconium aspiration may cause pneumonia and systemic bacterial infection.
  - Neonatal isoerythrolysis (see p. 757)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the presence of persistent crying, anorexia, hypothermia, and abdominal pain or a combination of these in puppies and kittens under 2-3 weeks of age. Specific cause of illness can sometimes be determined by performing additional diagnostic tests.

DIFFERENTIAL DIAGNOSIS

See Etiology and Pathophysiology above.

INITIAL DATABASE

- CBC, serum chemistry profile, urinalysis:
  - Volume of blood withdrawn should be conservative owing to small body size. Do not take more than 1 mL per 100 grams of body weight. In very small patients, minimal database should consist of hematocrit, total protein, glucose, blood urea nitrogen, and urinanalysis.
  - Neonates normally have mild serum alkaline phosphatase and phosphorus elevations as well as mild blood urea nitrogen, albumin, globulin, cholesterol, and hematocrit reductions, compared to adult normal ranges.
- Compare serum gamma-glutamyl transferase (GGT) and alkaline phosphatase (ALKP) levels to assess transfer of colostrum.
  - Adequate colostral transfer should produce neonatal serum levels of these enzymes that are 30 (GGT) to 100 (ALKP) times higher during the first 1-3 days of life than normal adult values.
- FeLV/FIV test
- Fecal flotation
- Thoracic and abdominal radiographs

ADVANCED OR CONFIRMATORY TESTING

- Urine culture
- Serologic titers: *Brucella canis,* canine herpesvirus, *Toxoplasma, Neospora;* PCR test is confirmatory for herpesvirus.
- Blood typing (purebred cats)
- Virus isolation
- Pleural/abdominal fluid analysis
- Necropsy (e.g., canine herpesvirus: characteristic lesions of petechial hemorrhage in kidneys, liver, and intestinal mucosa)

TREATMENT

TREATMENT OVERVIEW

Treatment is generally supportive, based on the test results and affected body systems. Not all treatments need to be instituted at once, as it is very easy to overstress puppies and kittens of such young age. Assess organ involvement and institute/revise treatments as clinical signs dictate.

ACUTE GENERAL TREATMENT

- Management of isoerythrolysis in kittens if present (see p. 757)
- Hypothermia needs to be corrected gradually over 30 minutes to 2 hours.
- If immune compromised due to insufficient colostrum ingestion, frozen colostrum, or serum administration: serum can be given SQ at a dose of 5 mL per 100–150 grams of body weight SQ q 8 h × 24–36 h, or 15 mL/100 gram PO over 12–24 h.
- Start administering broad-spectrum bactericidal antibiotics (e.g., ceftiofur [Naxcel], 2.5 mg/kg SQ q 12 h for 5 days), which is very safe and has minimal effects on intestinal flora.
- Correct dehydration with warmed, balanced crystalloid fluids (lactated Ringer's solution or Normosol-R and 5% dextrose; 1 mL/30 g body weight IP or IO initially, then as needed based on response). See p. 1291 for Intraosseous Catheter placement.
- Correct hypoxemia by administration of oxygen at 30%–40%.
- Administer vitamin K1 once SQ (0.01–0.1 mg), as puppies <2 days old have reduced thrombin levels.
- Correct hypoglycemia if present (see p. 1571).
- Correct hypokalemia if present (see p. 377).
- Once the patient is stable, provide supportive nursing. In weaker patients with an inadequate suckle reflex, tube feeding is better than bottle feeding because it is a more reliable method to minimize possibility of aspiration. During the first week of life, feeding guidelines for kittens are 100-175 kcal/lb (220–380 kcal/kg); for puppies, requirements are 105–120 kcal/lb (230–260 kcal/kg) divided equally into 6–8 feedings daily.
- Viral replication might be inhibited by maintaining body temperature above 101°F–102°F (38.3○–38.8°C). Clinician should monitor the animal closely to avoid overheating. Incubator should be at a temperature of 85°F-95°F (29.4○–35°C) and relative humidity of 55%–65%. Acyclovir suspension can be attempted at a dose of 20 mg/kg PO every 6 hours for 7 days.

CHRONIC TREATMENT

- Supportive care
- Commercial milk replacement if mother's milk is not available. During the first week of life, neonatal caloric requirements are 133 kcal/kg/d; the requirements thereafter are 155 kcal/kg/d for week 2, 175–198 kcal/kg/d for week 3, and 220 kcal/kg/d for week 4.

NUTRITION/DIET

Supplemental feedings with milk replacer

DRUG INTERACTIONS

- Avoid drugs contraindicated for neonates (e.g., glucocorticoids, immunosuppressive agents, NSAIDs, fluoroquinolones, tetracyclines, aminoglycosides, trimethoprim-sulfa, and chloramphenicol).
- Drug absorption, metabolism, and excretion in dog or cat neonates differ from those of adult neonates and vary according to the drug; detailed drug information should be obtained prior to use in neonates.

POSSIBLE COMPLICATIONS

- Possible short-term damage to the affected organ systems (e.g., gastrointestinal, cardiovascular, respiratory) from the disease process
- Due to patient's small size, clinician needs to be careful with the amount of the administered fluid therapy so as not to create volume overload.
- Tube feeding or oral medication administration could potentially cause aspiration pneumonia.

RECOMMENDED MONITORING

Daily weighing is very important. Puppies and kittens should gain weight daily at a rate of 2–7 g per day for each kilogram of anticipated adult weight and should double their birth weight by 10 days of age.

PROGNOSIS AND OUTCOME

Supportive care is the cornerstone of successful treatment.

PEARLS & CONSIDERATIONS

COMMENTS

Instituting intensive early treatment is the key, as neonates deteriorate rapidly.

PREVENTION

Incidence of neonatal problems is reduced when clinicians:

- Avoid administering modified live vaccines during pregnancy.
- Avoid administering teratogenic drugs and chemicals.
- Avoid incompatible matings in cats and check blood type before breeding.
- Ensure that neonates have ingested colostrum within the first 24 hours to acquire passive immunity. Administer serum if immunity status is questionable.
- Administer broad-spectrum anthelmintic therapy to the dam/queen 2 weeks prior to birthing, and then to neonates every 2-3 weeks starting at 3 weeks of age and continuing until 12 weeks old.
- Administer appropriate vaccination protocols.

TECHNICIAN TIPS

- Tube feeding guidelines:
  - Use a 5-Fr or 8-Fr red rubber catheter.
  - Measure from the nose to last rib, and mark 75% of that distance.
  - Preload 6-mL syringe with milk replacer, empty all air out of the catheter by squeezing the syringe until milk starts to drip from the edge of the catheter.
  - Advance catheter along the roof of the mouth along the path of least resistance until it reaches the mark.
  - Pull back on the syringe to make sure that you have negative pressure (no air in the syringe).
  - Feed appropriate amount of milk replacer over 5-10 seconds, kink the catheter, and pull it out.
  - This technique can also be used for serum administration if colostral ingestion is questionable.

Neonatal Isoerythrolysis

BASIC INFORMATION

DEFINITION

Neonatal isoerythrolysis (NI) is an immune-mediated hemolytic disease seen in newborn kittens and (rarely) puppies. NI is caused by ingestion of maternal colostrum containing antibodies to one of the neonate's blood-group antigens.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Occurs most commonly in cats

GENETICS & BREED PREDISPOSITION: Feline breeds with a high incidence of type B blood types are predisposed to NI (see p. 71)

RISK FACTORS: Any litter resulting from parents of opposite blood types is at risk of developing NI.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Patients that develop NI are normal at birth but begin to fade within 48-72 hours of birth.

ETIOLOGY AND PATHOPHYSIOLOGY

- Fetuses are not exposed to maternal antibodies in utero, as they do not cross the placenta.
- NI is caused by ingestion of maternal colostrum containing antibodies to one of the neonate's own blood-group antigens.
- Cats are unusual in that blood type B cats have naturally occurring anti-A antibodies without prior exposure: their kittens may be of blood type A, however, in which case they develop hemolysis after nursing.
- Similarly, cats with type A blood can develop anti-B antibodies, but these antibodies are weaker than anti-A antibodies in type B cats, and clinical anemia is less common.
- In dogs, the maternal antibodies may develop to a specific foreign blood group from previous transfusions.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of NI is generally based on compatible history and/or physical exam findings within hours/days of birth. Early clinical signs of the disease are pigmenturia (dark red-brown urine), pale mucous membranes, and icterus.

DIFFERENTIAL DIAGNOSIS

Heritable red blood cell (RBC) disorders, zinc toxicosis

INITIAL DATABASE

- Packed cell volume, cytological evaluation of RBCs for evidence of agglutination and/or spherocytosis consistent with NI
- Urine: pigmenturia in fading kittens is highly suggestive of NI.

ADVANCED OR CONFIRMATORY TESTING

Blood typing of both parents. Diagnosis is confirmed by screening maternal serum, plasma, or colostrum against the paternal or neonatal RBCs (see p. 1234).

TREATMENT

TREATMENT OVERVIEW

Treatment is primarily supportive, and success depends largely on early identification and intervention.

ACUTE GENERAL TREATMENT

Kittens should be removed from the queen to terminate nursing, and all kittens in the litter should be blood typed. Type B kittens can be returned to a Type B queen. Type A kittens may require transfusion and supportive care. They should not be returned to the queen for at least 72 hours. Kittens removed from the queen need attentive bottle feeding.

PROGNOSIS AND OUTCOME 

Prevention is the preferred “treatment” for NI. Affected kittens need supportive care and blood transfusions. The prognosis remains guarded even with treatment, emphasizing the importance of prevention.

PEARLS & CONSIDERATIONS 

PREVENTION

Affected or at-risk kittens (see Epidemiology, above) should not be permitted to nurse from their mother for the first 3 days. A blood type A queen can be substituted for nursing if the natural dam was of type B, or a milk replacer can be used for the first 3 days after birth. The kittens can be returned to the dam after 3 days, because antibody-rich colostrum is generally no longer present in clinically significant quantities at that point.

CLIENT EDUCATION

Proper client education is essential, since prevention of NI is so important. Feline breeders should be counseled about making proper breeding choices and strategies for prevention.

AUTHOR: SCOTT SHAW

EDITOR: SUSAN COTTER

Necrotizing Meningoencephalitis

BASIC INFORMATION

DEFINITION

A unique nonsuppurative meningoencephalitis resulting in brain parenchymal necrosis; lesions predominate within the cerebral hemispheres.

SYNONYMS

NME, Pug or Maltese meningoencephalitis, pug dog encephalitis, Yorkshire terrier leukoencephalitis, necrotizing leukoencephalitis (NLE). Because necrotizing meningoencephalitis (NME) is not limited to pugs, clinicians often refer to the condition as *NE* (necrotizing encephalitis) or *NME* instead of pug dog encephalitis.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs of either sex, ranging in age from 6 months to 13 years; young females may be over-represented.

GENETICS & BREED PREDISPOSITION

- Many authors propose a genetic predisposition in pugs, although the exact mode of inheritance is unknown.
- Maltese dogs and Yorkshire terriers are similarly affected, although the distribution of lesions in Yorkshire terriers is different than in pug and Maltese dogs.
- The disease has been seen sporadically in other small breeds of dogs, including Chihuahuas, shih tzus, Lhasa apsos, Pekingeses, and Papillons.

GEOGRAPHY/SEASONALITY: One report found that clinical signs of NME tended to become apparent between the months of May and September.

CONTAGION AND ZOONOSIS: This disease is not transmissible between animals and poses no known threat of zoonosis. To date, attempts to isolate infectious agents including herpesvirus, adenovirus, or canine parvovirus have been unsuccessful.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Forms include acute (<2 weeks) or chronic (4 to 6 months).

HISTORY, CHIEF COMPLAINT: The majority of cases present with generalized seizures, circling, visual deficits, and head pressing. Yorkshire terriers often show signs of vestibular disturbance (ataxia, head tilt) in addition to the aforementioned signs of prosencephalic (forebrain) dysfunction.

PHYSICAL EXAM FINDINGS

- General physical examination is unremarkable
- Neurologic examination (see p. 1311) reflects the distribution of lesions in the central nervous system (CNS):
  - Deficits are often asymmetric.
  - When forebrain signs predominate, menace deficits, postural deficits (with a normal gait), nasal hypalgesia, and abnormal mentation may be present.
  - Yorkshire terriers often have signs of central vestibular disease, including abnormal nystagmus, falling, head tilt, and postural deficits.
  - Neck pain is occasionally elicited, secondary to either meningitis or forebrain disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- An immune-mediated basis is strongly suspected. Autoantibodies against glial cells have been identified in the cerebrospinal fluid (CSF) and serum of affected pug dogs.
- Selective neuronal necrosis, perivascular mononuclear infiltrates, and foci of malacia and cavitation are seen in both gray and white matter.
- Many female dogs with recent pregnancy/pseudocyesis preceding clinical signs have been reported, but the role, if any, of hormonal factors in the pathogenesis of NME is poorly understood.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based on breed, history, clinical signs typical of forebrain disease (or vestibular signs in Yorkshire terriers), characteristic cavitary changes on MRI, CSF analysis, and exclusion of other disorders such as granulomatous meningoencephalitis (GME) or infectious encephalitis.

DIFFERENTIAL DIAGNOSIS

- GME
- Infectious meningoencephalitis (e.g., protozoal, fungal, rickettsial, viral)

INITIAL DATABASE

- CBC and serum chemistry panel results are generally unremarkable.
- Infectious disease titers *(Toxoplasma, Neospora,* Rocky Mountain spotted fever, *Ehrlichia, Cryptococcus)* can rule out other potential causes of encephalitis.

ADVANCED OR CONFIRMATORY TESTING

- MRI (see p. 1302): Findings may include asymmetric ventriculomegaly, cerebral edema, noncontrast-enhancing focal or multifocal cavitating lesions, and (rarely) tentorial herniation.
- In Maltese and pug dogs, the lesions are almost exclusively supratentorial; in Yorkshire terriers, lesions may also be found in the brainstem.
- CSF analysis (see p. 1228): mild to moderate lymphocytic pleocytosis and elevated protein

TREATMENT

TREATMENT OVERVIEW

Therapeutic goals are reduction of seizure activity if present and reduction of intracranial inflammation.

ACUTE GENERAL TREATMENT

- Mannitol (1 g/kg IV) in suspected cases of cerebral edema or rapidly deteriorating neurologic status
- Anticonvulsant therapy, such as with phenobarbital or potassium bromide, is often used. These drugs, however, may cause excessive sedation in patients with structural forebrain disease.
    - Zonisamide (5–10 mg/kg PO q 12 h), levetiracetam (20 mg/kg PO q 8 h), or felbamate (15 mg/kg PO q 8 h) may be preferable choices for controlling seizures without sedative effects.
- Antiinflammatory therapy, usually prednisone at a dose of 0.5–1 mg/kg PO q 12 h, may ameliorate clinical signs.

CHRONIC TREATMENT

- Anticonvulsant therapy (as above) is required for life.
- Antiinflammatory doses of glucocorti-costeroids (e.g., prednisone 0.5–1 mg/kg PO q 12 h initially, then tapered to q 24 h or preferably q 48 h for long-term use) are required for life.
- Immunosuppression with various agents such as cyclosporine, procarbazine, cytosine arabinoside, lefluno-mide, or mycophenolate mofetil is considered a mainstay of treatment. While these medications hold promise for future treatment options, more information and long-term studies are needed before predictions can be made regarding efficacy.

POSSIBLE COMPLICATIONS

With disease progression: seizures

RECOMMENDED MONITORING

Drug monitoring of serum levels (e.g., phenobarbital, KBr) if appropriate

PROGNOSIS AND OUTCOME

Prognosis for long-term survival is grave. Despite therapy, clinical signs progress, and seizures become intractable.

PEARLS & CONSIDERATIONS

COMMENTS

The majority of dogs with NME die or are euthanized within 6 months of the onset of clinical signs. Clinicians must inform clients of the extremely guarded prognosis of NME.

PREVENTION

Unknown prevention methods.

CLIENT EDUCATION

Due to the uncertainty regarding inherit-ability of this disorder, caution should be exercised when considering breeding relatives of affected dogs.

SUGGESTED READING

AUTHOR: GEORGINA BARONE

EDITOR: CURTIS W. DEWEY

Necrotizing Fasciitis

BASIC INFORMATION

DEFINITION

Acute onset of a fulminant, rapidly progressive infection of the skin, subcutis, and fascia, causing coagulation necrosis of affected tissues, most commonly caused by β-hemolytic group G *Streptococcus.* Septic shock may be seen, either at presentation or as a later sequel.

SYNONYMS

Flesh-eating bacteria, flesh-eating disease

EPIDEMIOLOGY

SPECIES, AGE, SEX: Both dogs and cats of all ages have been reported to present with necrotizing fasciitis.

CONTAGION & ZOONOSIS: Not known to be directly transmissible to humans, but the same clinical disease occurs in humans, involving the same organisms. Therefore, strict precautions of hygiene, especially involving exposure to broken skin or mucous membranes, are warranted. Possible risk in immunocompromised humans bitten or licked by animals.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Type II (single-organism) infections of β-hemolytic group G *Streptococcus* predominate in dogs.

HISTORY, CHIEF COMPLAINT: History of recent minor trauma (e.g., minor laceration, bite) is typical but not essential. The injury may be a nonpenetrating wound (e.g., bumping, falling).

- Swelling, pain, and lameness may be noted by the owner if the disease is concentrated on a limb.
- Concurrent sepsis results in typical systemic signs, including anorexia, depression, lethargy, weakness or collapse, and diarrhea.
- The onset of clinical signs is generally acute, and the disease progression is rapid (hours).

PHYSICAL EXAM FINDINGS

- Signs include local edematous swelling, erythema, heat, and often severe pain.
  - The intensity of pain is characteristically disproportionate to the appearance of the lesion and may be excruciating.
- Overlying skin can vary in presentation, appearing from normal to soft and exudative or as a hard eschar.
- Involved muscle bellies may be hard and severely painful on palpation.
- Systemic signs include pyrexia, tachycardia, and dehydration.
- Septic shock (see p. 1591)

ETIOLOGY AND PATHOPHYSIOLOGY

- Causative organism: Lancefield group G, β-hemolytic *Streptococcus* consistent with *S. canis* is cultured in most infections.
- Bacterial exotoxins and proteases appear to cause lesions and signs.
- An extremely rapid course of progression (line of tissue inflammation/edema visibly advances over minutes to hours) is a hallmark of necrotizing fasciitis, ultimately leading to sepsis and/or the systemic inflammatory response syndrome (SIRS) (see online chapter: Systemic Inflammatory Response Syndrome).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Generally, the diagnosis is suspected based on the clinical presentation of a patient with a vague history of mild trauma who presents with disproportionately severe soft-tissue pain.

DIFFERENTIAL DIAGNOSIS

Subcutaneous abscess, seroma, or hematoma (secondary to bleeding diathesis); soft-tissue or orthopedic trauma including fractures (suspected based on intense pain) or less compatibly, blunt trauma, bites, and other such inflictions; and envenomation (insect, venomous snake)

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis:
  - Nonspecific abnormalities consistent with severe inflammation
  - Results often not available before important treatment decisions (e.g., amputation) need to be made
- Radiographs of affected area to rule out fractures and other lesions as cause of pain
- Advanced or septic cases have clinical pathologic abnormalities of sepsis and/or disseminated intravascular coagulation (DIC).

ADVANCED OR CONFIRMATORY TESTING

- The fulminant progression of infection requires rapid intervention, which generally precludes extensive diagnostic testing.
- Presumptive diagnosis is based on history, physical exam, absence of other causative lesion (e.g., fractures), and surgical findings; subcutaneous tissue that offers little resistance to blunt (finger) dissection, and copious foul-smelling, thin, turbid subcutaneous fluid (± bacteria and degenerate neutrophils cytologically) intraoperatively offer support for the diagnosis.
- Definitive diagnosis: histopathologic confirmation of necrotizing fasciitis and bacteriologic isolation of the causative organism.

TREATMENT

TREATMENT OVERVIEW

Prompt, intensive treatment consists of wide surgical excision of affected tissue, antimicrobial therapy, aggressive pain management, and medical therapy for shock and sepsis if present.

ACUTE GENERAL TREATMENT

- Immediate aggressive treatment for SIRS and for septic shock if present (see p. 1591).
- Early aggressive surgical débridement.
  - Immediate owner consent for amputation is essential when infection is on a limb; guarded prognosis and risk of reoperation are also important consent issues.
  - Débridement of all affected and questionable tissues, followed by copious lavage with warm isotonic fluids; the addition of chlorhexidine 0.05% may be beneficial (unconfirmed).
  - Wet-to-dry bandaging until infection is controlled; the bandage should contain a thick absorptive layer and be changed daily (at least).
- Intravenous antibiotics: β-lactamase-resistant antibiotics are generally effective against *S. canis;* a broader-spectrum regime may be superior initially, because polymicrobial infections may be present.
  - Cefoxitin, 30 mg/kg IV q 6 h; *or*
  - Cefazolin or ampicillin, 22 mg/kg IV q 6 h, plus enrofloxacin, 20 mg/kg IV q 24 h (dogs) or 5 mg/kg q 24 h (cats); alternatively, cefazolin or ampicillin as above, plus amikacin, 20 mg/kg IV q 24 h (dogs and cats)
  - Aggressive analgesia (condition is usually very painful and likely refractory to analgesics).
    - Opioids (examples: morphine sulfate, 0.05-0.15 mg/kg/h IV constant rate infusion; or buprenorphine, 0.02 mg/kg IV q 6 h) combined with a nonsteroidal antiinflammatory drug (NSAID) such as carprofen, 2.2-mg/kg SQ or PO q 12 h
    - The concern that NSAIDs caused poorer outcomes in humans was unconfirmed in prospective studies.

NUTRITION/DIET

- Enteral feeding is preferred over parenteral unless contraindicated. Feed twice basal requirements.
- Placement of an esophagostomy (see p. 1267) or gastrostomy (see p. 1270) tube during surgery, using separate instrumentation and draping.

DRUG INTERACTIONS

- NSAIDs: avoid in septic shock

POSSIBLE COMPLICATIONS

Diagnostic delays allow progression of local necrosis. Further delay or inadequately aggressive early treatment increases risk of sepsis or SIRS.

RECOMMENDED MONITORING

- Monitoring of patients for septic shock and DIC and for the progression of the infection, which would indicate the need for further débridement
- Monitoring of the bandage for amount and character of exudate

PROGNOSIS AND OUTCOME

Negative prognostic factors: delay of surgery, incomplete débridement, and concurrent sepsis. Reported mortality is 17%-60% for humans and approximately 8% for dogs to date.

PEARLS & CONSIDERATIONS

CLIENT EDUCATION

Owners should be aware that treatment of these cases is drastic and should be pursued as soon as clinical suspicion arises.

Neck Ventroflexion

BASIC INFORMATION

DEFINITION

A syndrome in which the neck is continuously or intermittently maintained in a flexed position, owing to an inability or unwillingness to extend the neck dorsally or involuntary muscular flexion of the neck

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cats are predominantly affected, but dogs may also show neck ventroflexion.
- Age and sex both vary depending on the underlying cause for the syndrome.
- Cats: hypokalemic polymyopathy, hyperthyroidism
- Young animals: inherited myopathies
- Old animals: chronic renal failure

GENETICS & BREED PREDISPOSITION

- Burmese cat: hereditary hypokalemic periodic paralysis
- Devon rex cat: hereditary myopathy
- Labrador retriever dog: hereditary myopathy

RISK FACTORS: Hypokalemia, thiamine deficiency, organophosphate toxicity, hyperthyroidism

ASSOCIATED CONDITIONS & DISORDERS: Megaesophagus, aspiration pneumonia, generalized neuromuscular weakness

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: The syndrome can be divided into three general categories:

- Neuromuscular weakness; most common in cats
- Neck guarding; more common in dogs than cats
- Active flexion; rare

HISTORY, CHIEF COMPLAINT

- Neuromuscular weakness
  - The clinician may or may not notice ventroflexion, and it may be associated with generalized weakness, reluctance or inability to walk, stiff stilted gait, and other signs of systemic illness. Signs may be transient or persistent.
- Neck guarding
  - Clinician may notice mental depression and ataxia. The neck may be held in a fixed position, with decreased movement of the head.
- Active flexion
  - The animal may experience seizure-like activity (thiamine deficiency).
  - Dietary history: Raw fish diets are high in thiaminase, causing thiamine deficiency.

PHYSICAL EXAM FINDINGS

- Neuromuscular weakness:
  - Generalized or localized neck muscle weakness is possible. Ventroflexion may be episodic or continuous. Exercise or stress may induce weakness or collapse. Muscle pain may be present.
- Neck guarding:
  - Pain on neck manipulation can occur with or without neurologic abnormalities such as ataxia, limb reflex and proprioception abnormalities, and mental depression (cervical orthopedic/neurologic disease). The animal shows resentment or resistance to neck manipulation.
- Active flexion:
  - The animal experiences seizure-like activity, and the neck is actively tucked in under sternum; the clinician may notice

increased muscle tone and encephalopathic signs (thiamine deficiency).

ETIOLOGY AND PATHOPHYSIOLOGY

- Weakness: muscle weakness is such that the neck muscles are unable to lift the head. Ventroflexion of the neck is a hallmark of weakness in cats.
- Neck guarding: cervical pain may cause an animal to hold the neck in a fixed flexed position (guarding) so unnecessary head and neck movement is minimized.
- The clinician may notice active contraction of the neck flexor muscles.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Neck ventroflexion is a sign, not a diagnosis. The underlying cause must be identified by a systematic diagnostic approach. Since the list of potential causes is fairly short, history, physical exam, and basic clinical blood tests are generally sufficient.

NECK VENTROFLEXION Seven-year-old female spayed domestic shorthair cat with flaccid ventroflexion of the neck due to severe hypokalemia (serum K^+ = 2.8 mEq/L).

(Courtesy Dr. Etienne Côté.)

DIFFERENTIAL DIAGNOSIS

- Neck or generalized weakness:
  - Metabolic: hypokalemia (i.e., hypokalemic polymyopathy), hypernatremic myopathy (rare), hypomagnesemia, hypoglycemia
  - Toxic (organophosphate toxicosis, botulism, tick paralysis *[Ixodes, Dermacentor],* snake bite)
  - Endocrinopathies: hyperthyroidism, hyperaldosteronism, and diabetes mellitus (hypokalemic polymyopathy)
  - Myopathies: Burmese hereditary episodic paralysis/hypokalemic periodic paralysis, Labrador retriever hereditary myopathy, Devon rex myopathy, polymyositis, myasthenia gravis, hyperkalemic periodic paralysis
  - Polyneuropathies: chronic inflammatory demyelinating polyneuropathy
- Neck pain:
  - Polyarthritis
  - Meningitis/meningoencephalitis
  - Cervical-orthopedic diseases: disk herniation, caudal cervical spondylomyelopathy, spondylitis, spinal ankylosis (hypervitaminosis A, mucopolysaccharidosis), vertebral fractures, tumors, or infections
- Active neck flexion:
  - Thiamine deficiency

INITIAL DATABASE

- Complete neurologic examination
- CBC, serum biochemistry panel (biochemistry profile to include blood glucose, creatinine, creatine kinase, sodium, potassium, calcium), urinalysis

ADVANCED OR CONFIRMATORY TESTING

- Organophosphate poisoning: serum acetylcholinesterase levels
- Myasthenia gravis: repetitive nerve stimulation, serum acetylcholine receptor antibody titer, edrophonium test
- Hyperthyroidism: serum thyroxine levels
- Other metabolic causes of weakness: serum magnesium concentration (hypomagnesemia), blood gas analysis (acid base disturbances)
- Neck pain with or without neurologic lesions localized to the neck or intracranial region: spinal survey radiographs, cerebrospinal fluid (CSF) analysis, myelogram, cervical CT, and/or MRI

Uncommon or rare:

- Polymyopathies/neuropathies: electromyography, nerve conduction velocities, nerve and muscle biopsies, preexercise and postexercise electrolyte measurements (see p. 1305 and online chapter: Electromyography and Nerve Conduction Velocity)
- Urinary fractional excretion of potassium
- Arthrocentesis (see p. 1199)

TREATMENT

TREATMENT OVERVIEW

Treatment consists of correcting the underlying problem (e.g., treat hypokalemia by potassium administration).

ACUTE AND CHRONIC TREATMENT

Depends on the underlying mechanism

POSSIBLE COMPLICATIONS

- Complications are usually associated with the underlying primary disease and not with neck ventroflexion per se.
- Megaesophagus with secondary aspiration pneumonia: myasthenia gravis, organophosphate poisoning
- Generalized weakness: decubital ulcers
- Respiratory failure: hypokalemic polymyopathy
- Dysphagia with food accumulation in larynx/pharynx, with laryngospasm and asphyxiation: Devon rex

PROGNOSIS AND OUTCOME

Depends on the underlying disease and varies from poor to good

PEARLS & CONSIDERATIONS

COMMENTS

Hypokalemic polymyopathy is probably the most common cause of ventroflexion in cats and hypokalemia must be excluded before an extensive workup is undertaken.

PREVENTION

- Appropriate amounts of potassium in food and intravenous maintenance fluids
- Appropriate thiamine levels in the diet and correct storage of food to prevent thiamine breakdown
- Correct dosage and application of organophosphate products

AUTHOR: FRANK KETTNER

EDITOR: ETIENNE CÔTÉ

Neck Pain

BASIC INFORMATION

DEFINITION

Sensation of discomfort or distress associated with the cervical spine or surrounding tissues

SYNONYMS

Cervical hyperesthesia or hyperpathia

EPIDEMIOLOGY

GENETICS & BREED PREDISPOSITION

- Atlantoaxial instability:
  - Toy breeds: Chihuahua, toy poodle, Pomeranian, Pekingese
- Intervertebral disk disease (IVDD): chondrodystrophoid breeds: dachshund, beagle, basset hound, Pekingese, shih tzu, other breeds
- Cervical spondylomyelopathy (CSM, Wobbler's syndrome): Great Dane, Doberman pinscher, many other breeds
- Corticosteroid responsive meningitis/arteritis: Bernese mountain dog, boxer, Nova Scotia duck tolling retriever

CONTAGION & ZOONOSIS

- Distemper viral myelitis: dog to dog
- *Brucella* canis-associated diskospondylitis: dog to dog

ASSOCIATED CONDITIONS & DISORDERS

- Horner's syndrome may be present with caudal cervical spinal lesions.
- Nerve root signature: holding up of a forelimb may be sign of nerve root pain.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Spinal disease:
  - Congenital: CSM in young Great Danes, atlantoaxial instability
  - Acquired/degenerative: IVDD, CSM in Doberman pinschers
  - Traumatic
- Infectious disease: canine distemper myelitis, systemic fungal myelitis, diskospondylitis
- Inflammatory: cranial cervical pain sometimes found with meningitis
- Traumatic: cervical fractures, instability, penetrating pharyngeal or neck wounds
- Neoplastic: spinal tumors, axial skeletal osteosarcoma, nerve sheath tumor, and other such growths

HISTORY, CHIEF COMPLAINT

- Reluctance to rise
- Reluctance to walk on stairs
- Reluctance to jump
- Crying out when changing positions, getting up, or lying down
- Shaking

PHYSICAL EXAM FINDINGS

- Abnormal head posture: holding head down, reluctant to turn head
- Arched neck or back
- Pain on manipulation of the neck

- Pain on palpation of the cervical musculature
- Reluctance to walk
- Abnormal gait if animal is neurologically impaired
- Heat and swelling in cervical tissues
- Hypersalivation, which is possible with pharyngeal injuries
- Fever associated with infections or meningitis
- Root signature (see online chapter: Root Signature [Nerve])

ETIOLOGY AND PATHOPHYSIOLOGY

- Various tissues may be the source of neck pain:
  - Epaxial musculature:
    - Traumatic muscle injury
    - Exertional rhabdomyolysis
    - Myositis from penetrating injury or foreign body (stick or grass awn migration)
    - Inflammatory myositis: immune mediated, parasitic, bacterial, or protozoal
  - Spinal column:
    - IVDD: progressive degeneration of intervertebral disk, resulting in protrusion or herniation of disk material into the spinal canal. The annulus fibrosus is the portion of the disk that contains pain receptors. Typically affects dogs 3–8 years of age but can also occur in cats.
    - Diskospondylitis: bacterial infection of vertebral body end plates; the caudal cervical region is one of the predilection sites.
    - Malformation: CSM in Great Danes, hemivertebrae, spinal canal stenosis
    - Instability: atlantoaxial instability, CSM, vertebral subluxation, traumatic fracture or luxation
    - Neoplasia: osteosarcoma, hemangiosarcoma, fibrosarcoma, chondrosarcoma, or metastatic tumors involving the vertebrae
  - Meninges:
    - Inflammatory, parasitic, protozoal, bacterial, and neoplastic lesions
  - Spinal nerves:
    - Nerve root compression, ischemia
    - Inflammation: immune mediated, infectious (protozoal, viral, parasitic)
    - Neoplasia

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of neck pain is made by observation of the patient and physical examination. Determining the underlying cause of neck pain begins with orthopedic and neurologic examinations and a review of the history to identify duration and severity of signs and response to treatment if any (shortening the differential diagnosis list).

DIFFERENTIAL DIAGNOSIS

Neck pain is a nonspecific clinical sign. Differential diagnosis includes orthopedic, neurologic, and soft-tissue problems (see Etiology and Pathophysiology above).

INITIAL DATABASE

- Neurologic examination (see p. 1311)
- CBC
- Serum biochemistry panel
- Urinalysis
- Neck radiographs

ADVANCED OR CONFIRMATORY TESTING

- Myelogram (see p. 1306), CT (see p. 1233), or MRI (see p. 1302)
  - Very useful for spinal imaging
  - Myelogram with dynamic views may be useful for diagnosis of CSM.
  - Myelogram is also useful for IVDD and some spinal tumors.
  - MRI is best for spinal cord and nerve lesions and is becoming more widely used for IVDD.
  - MRI is more sensitive and specific than myelography or CT for identifying the location and potential cause of many

spinal lesions.
    - CT is best for evaluating bony lesions: tumors and fractures of the spine.
    - CT can be used as an adjunct to myelography.
- Cerebrospinal fluid (CSF) tap if meningitis or neoplasia is suspected (see p. 1461)
- Aspiration or biopsy of abnormal tissues
- Ultrasound of soft tissues to locate an abscess, foreign body, neoplasm, or other such abnormalities
- Surgical exploration
    - Histopathologic evaluation of tissue samples
    - Bacterial culture and sensitivity (C&S)
- Urine culture and possibly blood culture if there is a concern for diskospondylitis

TREATMENT

TREATMENT OVERVIEW

In most cases, therapeutic tenets are relief of pain, immobilization if movement is detrimental or painful, and treatment of underlying disease process.

ACUTE GENERAL TREATMENT

- Animals with acute severe neck pain are often treated with cage rest and medications such as analgesics (hydromorphone, 0.1-0.2 mg/kg SQ, IM, or IV as needed up to q 4 h; or buprenorphine, 10–15 mcg/kg IV q 6–8 h; or butorphanol, 0.1–0.2 mg/kg IV as needed up to q 4 h); and/or muscle relaxants (methocarbamol, 20–50 mg/kg PO q 8 h). Empirical glucocorticoids given prior to ruling out infectious causes can exacerbate infectious diseases.
- If spinal instability is suspected, a neck brace for immobilizing the neck can provide pain relief and prevent further tissue damage. Cage rest and exercise restriction are also important for the same purpose.

CHRONIC TREATMENT

- Nonsteroidal antiinflammatory drugs (NSAIDs; e.g., carprofen, 2 mg/kg PO q 12 h; or etodolac, 10-15 mg/kg PO q 24 h; or deracoxib, 1-2 mg/kg PO q 24 h; or firocoxib, 4-5 mg/kg PO q 24 h; or meloxicam, 0.1 mg/kg PO q 24 h)
- Low-dose corticosteroids: clinician should taper the medication during periods of improvement.
- Amantidine, 3–5 mg/kg PO q 24 h; or other agents such as tramadol, 1–4 mg/kg PO q 8–12 h; or gabapentin, 10 mg/kg PO q 8 h, can be used as adjunctive medications for pain management.
- Acupuncture
- Surgery if indicated by imaging and lack of response to conservative therapy

BEHAVIOR/EXERCISE

- Exercise restriction
- Use of a harness instead of a collar for walks
- Elevation of food and water bowls

DRUG INTERACTIONS

The clinician should never coadminister NSAIDs with corticosteroids, owing to risk of serious or life-threatening gastroenteritis and gastrointestinal ulceration.

POSSIBLE COMPLICATIONS

- Adverse reactions to the medication, especially gastrointestinal ulceration caused by taking corticosteroids and NSAIDs simultaneously, may occur.
- Pneumonia is a common complication in dogs that have tetraparesis and are recumbent.
- Respiratory obstruction is possible with a neck brace; it is important to adjust the brace so it fits properly, and the owner and clinician should monitor the animal.
- Paralysis or death is possible with acute spinal injury.

RECOMMENDED MONITORING

Any dog with signs of neck pain should be closely monitored for the development of neurologic conditions such as ataxia, paresis, paralysis, and respiratory impairment. These conditions suggest a neurologic cause and possibly warrant intensive care and further intervention.

PROGNOSIS AND OUTCOME

Highly variable depending on underlying disease process

PEARLS & CONSIDERATIONS

COMMENTS

- Neck pain in certain dog breeds is a very common problem in clinical practice.
- All dogs being considered for nonspecific supportive treatment should have cervical spinal radiographs prior to treatment.
- Cage rest, typically for at least 4 weeks is a critical component of conservative treatment.
- If a dog does not respond appropriately to nonspecific supportive therapy, the clinician should perform further diagnostic testing.

PREVENTION

- Owners should use a harness for walking their dogs.
- The clinician should inform the owner of exercise restrictions.

AUTHOR: DAVID A. PUERTO

EDITOR: ETIENNE CÔTÉ

Nasopharyngeal Stenosis

BASIC INFORMATION

DEFINITION

Narrowing or obliteration of the communication between the nasopharynx and oropharynx, usually involving the rostral nasopharynx

EPIDEMIOLOGY

SPECIES, AGE, SEX: Nasopharyngeal stenosis can be seen in cats and dogs of any age or gender.

GENETICS & BREED PREDISPOSITION: Smooth-haired dachshunds have been described with anomalous development of pharyngeal musculature, contributing to caudal nasopharyngeal stenosis.

RISK FACTORS: Recurrent/chronic rhinitis, nasopharyngeal surgery, reflux of gastric contents into the nasopharynx during anesthesia

ASSOCIATED CONDITIONS & DISORDERS: Chronic rhinitis and sinusitis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Congenital stenosis of the internal nasal meatus has been described in the literature. Most cases, however, are acquired.

HISTORY, CHIEF COMPLAINT: Some or all of the following may be present:

- Upper respiratory tract disease:
  - Nasal discharge
  - Nasal stertor
  - Sneezing
  - Intermittent respiratory distress, especially cats since they are reluctant to open-mouth breathe
- Worsening of the respiratory signs during sleeping, eating or swallowing
- Poor response to empirical therapy

PHYSICAL EXAM FINDINGS

- Nasal discharge
- Nasal stridor

ETIOLOGY AND PATHOPHYSIOLOGY

- In cats, this condition is thought to result from scar formation across the rostral nasopharynx secondary to mucosal ulceration from chronic rhinitis and/or sinusitis. Therefore, the disease is usually associated with recurrent upper respiratory tract infections or allergic disease. Scar formation leads to complete or partial obstruction of the rostral nasopharynx, resulting in the accumulation of nasal secretions within the nasal cavity and consequent nasal stertor and discharge.
- Nasopharyngeal injury from surgery or contact with gastric contents or other caustic material can presumably provoke inflammation and scar tissue formation.
- Chronic inflammation from nasopharyngeal foreign bodies in dogs has also been anecdotally associated with the disease.
- Abnormal development of the muscles of the soft palate and pharynx, causing stenosis of the caudal nasopharynx, has been described in smooth-haired dachshunds.
- Nasopharyngeal tumors can also cause stenosis.
- There is a single report of choanal atresia with secondary rostral nasopharyngeal stenosis in a 20-month-old shih tzu dog.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Nasopharyngeal polyps

- Chronic rhinitis or sinusitis
- Foreign body
- Intranasal or nasopharyngeal neoplasia
- Mycotic rhinitis

INITIAL DATABASE

- CBC: usually normal
- Urinalysis: usually normal
- Serum biochemistry profile: usually normal

ADVANCED OR CONFIRMATORY TESTING

- Diagnostic imaging:
  - Nasal radiographs may be normal or show opacification of turbinate structures secondary to accumulation of nasal secretions or a mass in the nasopharynx.
  - CT scan can document the presence of a stenotic lesion or mass in the nasopharynx.
- Other diagnostic procedures:
  - Inability to pass a small catheter (3.5 Fr gauge) gently through the ventral nasal meatus into the pharynx
  - Visualization of the membrane by use of a retroflexed pediatric bronchoscope or a dental mirror
  - Histopathologic or cytologic examination of masses

TREATMENT

TREATMENT OVERVIEW

The primary aim of therapy is restoration of nasopharyngeal patency.

ACUTE GENERAL TREATMENT

Restoration of nasopharyngeal patency by:

- Surgical resection of a stenotic membrane or mass
- Dilation of the stenosis with a valvuloplasty balloon dilation catheter under endoscopic or fluoroscopic guidance
- Placement of a stent across the stenotic region:
  - Often requires CT scanning of the head, and endoscopic and fluoroscopic capabilities

CHRONIC TREATMENT

- Antiinflammatory doses of corticosteroids after surgery/dilation
- Other treatments (surgery, chemotherapy, radiation therapy) for neoplastic causes
- Stenting would be of potential palliative benefit for neoplastic stenosis not treatable by other means.

POSSIBLE COMPLICATIONS

Recurrence of the stenosis

RECOMMENDED MONITORING

Clinical signs

PROGNOSIS AND OUTCOME

Dependent on the ability to restore nasopharyngeal patency. Long-term resolution of clinical signs has been achieved with balloon dilation and stents in patients with non-neoplastic acquired stents.

PEARLS & CONSIDERATIONS

PREVENTION

Conditions that predispose to nasopharyngeal stenosis are difficult to predict, prevent, or treat, so prevention of stenosis is likewise difficult to prevent.

TECHNICIAN TIPS

- Be prepared for rapid endotracheal intubation of affected cats once anesthesia has been induced.
- Feed small frequent meals of a soft consistency, especially after surgery.

CLIENT EDUCATION

Recurrence is possible.

AUTHOR: REMO LOBETTI

EDITOR: RANCE K. SELLON

Nasopharyngeal Polyp

BASIC INFORMATION

DEFINITION

Non-neoplastic pedunculated mass originating from the middle ear or auditory tube epithelium. Well recognized in young adult cats; very rare in dogs.

SYNONYM

Inflammatory polyp

EPIDEMIOLOGY

SPECIES, AGE, SEX: Primarily in young adult cats

RISK FACTORS: Chronic inflammation of the upper respiratory tract or any process that obstructs middle ear drainage are proposed.

ASSOCIATED CONDITIONS & DISORDERS

- Otitis media, interna, or externa
- Horner's syndrome

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Ear (aural) polyp if mass grows into external ear canal instead of nasopharynx

HISTORY, CHIEF COMPLAINT

- Nasal discharge
- Sneezing
- Stertor
- Dyspnea
- Dysphagia
- Gagging
- Voice change
- +/− Headshaking or pawing at ears if concurrent otitis externa. Presence of concurrent nasopharyngeal and aural polyps is rare.
- +/− Vestibular signs if concurrent otitis externa progresses to otitis media/interna

PHYSICAL EXAM FINDINGS

- Increased inspiratory noise (often stertor)
- Mucoid to mucopurulent nasal discharge (unilateral or bilateral)
- Gagging
- Unilateral deafness in 35% of cats because of concurrent middle ear disease
- Uncommon signs include otitis externa, head tilt, ataxia, nystagmus, or facial nerve palsy.
- +/− Horner's syndrome: miosis, ptosis, enophthalmos, and third eyelid prolapse on affected side

ETIOLOGY AND PATHOPHYSIOLOGY

- Exact etiology is unknown, but proposed causes include inflammatory conditions and congenital persistence of branchial arches.
    - The significance of herpesvirus, calicivirus, bacteria, or fungi recovered from polyps is questionable.
- It is suspected that proliferation of the auditory (eustachian) tube or tympanic bulla mucosal epithelium obstructs drainage from the middle ear. The resulting fluid accumulation and inflammation (otitis media), which can extend into the inner ear (otitis interna) or drain through the tympanic membrane (otitis externa), provokes formation of a fibrous polyp.
- Enlarged mass fills the nasopharyngeal region, obstructing caudal nasal drainage and airflow, eventually impeding inspiration

and swallowing and causing nasal discharge.
- Alternatively, the tympanic membrane ruptures, and the mass extends into the horizontal ear canal.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The primary method of diagnosis is visualizing a firm, pink mass dorsal to the soft palate on oral examination under anesthesia. Confirmation is based on histologic analysis.

DIFFERENTIAL DIAGNOSIS

- Neoplasia (e.g., lymphoma, squamous cell carcinoma)
- Infectious rhinitis
- Nasal/nasopharyngeal foreign body
- Nasopharyngeal stenosis
- Laryngeal paralysis
- Granuloma (cryptococcosis)

INITIAL DATABASE

- Results of the CBC, biochemistry panel, and urinalysis are usually normal.
- Otoscopic examination:
  - If the patient has otitis media, bulging of tympanic membrane from fluid or mass is noted.
  - Masses extending through the tympanic membrane are visible in the external ear canal.
  - If the tympanic membrane has ruptured, the cat will have otitis externa.
- Skull radiographs:
  - Increased soft-tissue density in pharynx (lateral view)
  - Evidence of otitis media:
    - Enlarged or thickened bulla containing increased soft-tissue density

ADVANCED OR CONFIRMATORY TESTING

- Oral examination under anesthesia:
  - Palpable mass dorsal to soft palate or mass protruding into oropharynx
- CT:
  - Increased fluid and soft-tissue density in bulla
  - The bulla wall may be thickened or thin and distended.
- Histologic examination:
  - Well-vascularized fibrous tissue covered by stratified squamous or columnar epithelium
  - Inflammatory cells, primarily lymphocytes, plasma cells, and macro-phages, present within the stroma

TREATMENT

TREATMENT OVERVIEW

Nasopharyngeal polyp removal by gentle, steady traction and avulsion will cure many cats; recurrence rates are lower if removal is combined with bulla osteotomy or oral prednisolone therapy.

ACUTE GENERAL TREATMENT

- Oxygen supplementation (see p. 1318) if the patient is in respiratory distress.
- Induction of general anesthesia and removal of the polyp. Retract soft palate rostrally with spay hook, stay sutures, or Babcock forceps, and grasp the polyp gently at the base with Allis tissue forceps. Apply slow steady traction to avulse stalk of polyp from auditory tube or middle ear.
- Ventral bulla osteotomy with removal of the epithelial lining to reduce recurrence rate; culture from the bulla is also indicated at the time of surgery.

CHRONIC TREATMENT

Antibiotics if otitis media present (e.g., amoxicillin with clavulanic acid, 62.5 mg/cat PO q 12 h until culture results return).

POSSIBLE COMPLICATIONS

- Horner's syndrome is seen in approximately 80% of cases after a bulla osteotomy and can also occur with polyp traction avulsion alone; it usually resolves within 1 month.
- Otitis interna occurs in approximately 40% of cases following ventral bulla osteotomy; ataxia and head tilt can affect quality of life.

RECOMMENDED MONITORING

- Reevaluate nasopharynx, bulla, external ear canal if clinical signs recur.
- Repeat otoscopic examination and otic cytologic examination if otitis externa is present.

PROGNOSIS AND OUTCOME

- Polyp regrowth reported in 11%-50% of cats treated with traction avulsion without concurrent ventral bulla osteotomy. Recurrence lowest when postoperative prednisolone administered.
- Ventral bulla osteotomy prevents recurrence in most cats.
- Deafness in affected ear often persists after polyp removal.

PEARLS & CONSIDERATIONS

COMMENTS

- CT is more sensitive than survey skull radiographs for detecting otitis media.
- For a broad-based mass, fine-needle aspiration and cytologic evaluation are indicated to rule out lymphoma.
- The feline tympanic bulla has two chambers; the epithelial lining of both chambers should be removed during bulla osteotomy.
- Sympathetic fibers are superficial in the feline bulla; thus, development of Horner's syndrome is likely after bulla osteotomy.
- With traction alone, treatment with prednisolone (1–2 mg/kg PO q 24 h for 2 weeks after the procedure) reduces recurrence.

TECHNICIAN TIPS

- Cats with nasopharyngeal polyps can be difficult to intubate if the polyp is large. An intravenous catheter placed before induction permits administration of intravenous anesthetics.
- A laryngoscope and several sizes of cuffed endotracheal tubes should be available. Mucus and saliva may collect at the back of the throat; therefore, suction or swabs may be needed during intubation.
- The endotracheal tube may need to be tied to the lower jaw to allow soft palate retraction.
- The cuff of the endotracheal tube should be inflated, since hemorrhage is possible after polyp extraction.

CLIENT EDUCATION

Complications with bulla osteotomy are common but usually temporary.

AUTHOR: KAREN M. TOBIAS

EDITOR: RANCE K. SELLON

Nasal Neoplasia

BASIC INFORMATION

DEFINITION

Neoplastic growth, usually malignant, originating in the nasal passages

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Rare in cats (1% of all tumors). Older (mean age 8–10 years), neutered male cats most often affected. Has been reported as early as 2 years of age.
- In dogs, nasal tumors represent l%-2.4% of all tumors. Older dogs (mean 9-10 years; earliest reported age of 1 year) most often affected; possible male predilection.

GENETICS & BREED PREDISPOSITION: Airedale terrier, basset hound, collie, German shepherd, German short-haired pointer, keeshond, and Old English sheepdog thought to have an increased risk.

RISK FACTORS: Possible but not consistently proven risk factors include large breed, dolichocephalic breeds, urban environment, and exposure to secondhand smoke.

ASSOCIATED CONDITIONS & DISORDERS: Central nervous system signs (seizures or behavior changes) from direct tumor invasion into the brain are possible. Paraneoplastic syndromes are rare, but hypercalcemia and erythrocytosis have been reported.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Malignant tumors:
  - Epithelial:
    - Adenocarcinomas, squamous cell carcinomas, and other carcinomas account for two-thirds of nasal tumors.
  - Mesenchymal:
    - Chondrosarcoma is the most common.
    - Osteosarcoma and fibrosarcoma can occur.
    - Lymphoma is more common in cats.
  - Miscellaneous (usually rare):
    - Transmissible venereal tumors (likely to be more common where this tumor is common)
    - Olfactory neuroblastoma
    - Melanoma
- Benign tumors:
  - Epithelial or mesenchymal
  - Inflammatory polyps

HISTORY, CHIEF COMPLAINT: Average duration of clinical signs prior to diagnosis is 3–4 months:

- Epistaxis
- Bilateral or unilateral nasal discharge
- Airflow obstruction
- Sneezing or reverse sneezing
- Stertor
- Facial deformity: more common in cats
- Neurologic signs rare but may be the only clinical sign of nasal tumors

PHYSICAL EXAM FINDINGS: Same as chief complaints:

- Airflow obstruction may be detected via a mirror or glass held at the nares or from an occlusion of one nostril at a time while listening to airflow at the opening of the nares.
- Stertor

- Mandibular lymph node enlargement
- Diminished ocular retropulsion; pain with ocular retropulsion or opening mouth
- Facial deformity
- Altered mentation
- Physical exam may be unremarkable insofar as signs such as epistaxis and nasal discharge can be intermittent.

ETIOLOGY AND PATHOPHYSIOLOGY

Weak links to exposure to urban environmental pollution and secondhand smoke in the dog, and exposure to wood dust and employment in boot making and the flooring industry in people, leads to conjecture that pollutants filtered in the nasal passages initiate or promote neoplastic transformation. Upregulation of the cyclooxygenase-2 enzyme in canine nasal epithelial tumors has been recently described, but its role in tumorigenesis (if any) is unknown.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Nasal neoplasia is a common cause of nasal discharge, particularly in middle-aged to older dolichocephalic breeds of dogs. Be suspicious of nasal neoplasia in a dog with a history of chronic nasal discharge that is responsive to antibiotics but recurs.

DIFFERENTIAL DIAGNOSIS
